THE ALKALOIDS OF FUMARIACEOUS PLANTS

LI. CORYDALIS SOLIDA (L.) SWARTZ[1]

BY R. H. F. MANSKE

ABSTRACT

Only six alkaloids, namely protopine, allocryptopine, corydaline, *d*-stylopine, *dl*-tetrahydropalmatine, and aurotensine, could be isolated from this plant. The total yield of alkaloids was approximately 0.06%. Chemically, the plant is closely allied with *Corydalis ambigua* and both had been relegated to the same botanical section of the genus.

The section Pes-gallinaceous Irmish of the genus *Corydalis* Vent. includes those representatives in which the root is bulbous and does not become hollow. The best known representative is *C. solida* (L.) Swartz which is widespread throughout temperate Europe. Many minor variations have given rise to an extensive synonomy the most common of which is *C. bulbosa* DC.

It has been examined by Haars (1) who claimed the presence of bulbocapnine and by Heyl (2) who found protopine and two bases melting at 145° and 132° respectively, but has not been further characterized. In the writer's experience this plant is the least rewarding of any in the entire genus. Not only is the total alkaloid content very low (about 0.06%) but only six alkaloids could be definitely identified and these are all known ones, namely protopine, allocryptopine, corydaline, *dl*-tetrahydropalmatine, *d*-stylopine, and aurotensine. These constituents are much the same as those of *C. ambigua* Cham. and Schlecht. (4) and it is perhaps significant that the two plants under discussion belong to the same section.

EXPERIMENTAL

The material for the present investigation was grown in a local garden and the crops collected annually for several successive years. In all cases the aerial portion (7.9 kgm.) was collected at the time the seeds were just approaching maturity. The tubers (6.7 kgm.) were collected at various times of the year. The two portions were worked up separately but no quantitative or qualitative differences were evident.

The procedure for isolating the various alkaloids was the same as that repeatedly used by the writer (3).

Protopine and Allocryptopine

The fraction (BS) of nonphenolic alkaloids whose hydrochlorides are insoluble in chloroform was purified by dissolution in dilute acid and regenerating the free bases with ammonia in the presence of a large volume of ether. The residue from the ether extract crystallized readily in contact with methanol and when recrystallized once from chloroform–methanol the resultant protopine melted at 210°C.* either alone or in admixture with an authentic specimen. The small amount of protopine remaining in the methanolic filtrate was separated as its sparingly soluble nitrate and the base then remaining in solution regenerated again by the addition of ammonia in the presence of ether. The residue from the washed ether solution in contact with methanol crystallized at once when innoculated with a crystal of allocryptopine and when recrystallized once from methanol the base melted at 160° either alone or in admixture with authentic allocryptopine. The yield of protopine was *ca.* 0.014% and that of allocryptopine was *ca.* 0.005%. Neither cryptopine nor any further bases could be isolated from the fraction under discussion.

Corydaline

The fraction BC consists of nonphenolic alkaloids whose hydrochlorides are extractable from aqueous solution by means of chloroform. When it was purified by taking through dilute acid and regenerating with ammonia and extracting with ether there was obtained a pale yellow resin which readily crystallized in contact with methanol. The characteristic elongated hexagonal plates thus obtained were recrystallized once from hot methanol and then melted sharply at 135°C. Admixture with *d*-corydaline did not lower the melting point. The yield was *ca.* 0.02%. This is probably Heyl's alkaloid of m.p. 132°.

d-Stylopine

The filtrate from the crystallization of the corydaline deposited a very sparingly soluble base in the course of several days. When it was recrystallized from chloroform–methanol it consisted of colorless prisms which melted sharply at 202°C. either alone or in admixture with *d*-stylopine. The yield was less than 0.002%.

dl-Tetrahydropalmatine

When the mother liquors from the *d*-stylopine were freed of organic solvent and the residue dissolved in hot dilute hydrochloric acid there was formed a sparingly soluble hydrochloride. This was recrystallized from hot water and the base from it recrystallized from methanol. The almost colorless crystals then obtained melted at 150°C. and when they were admixed with *dl*-tetrahydropalmatine there was no alteration in melting point. The yield was about 0.01%. This may be Heyl's alkaloid of m.p. 145°.

Aurotensine

The phenolic fractions (BSE and EES) of the alkaloids whose hydrochlorides are not dissolved by chloroform were combined and converted to

**All melting points are corrected.*

hydrochloride in methanol. The base regenerated from the hydrochloride crystallized in contact with methanol and when recrystallized from the same solvent was obtained in almost colorless rectangular plates which, either alone or in admixture with aurotensine, melted at 128°C. The yield was less than 0.001%.

By reworking other fractions and the mother liquors it was possible to obtain roughly the above yields. It is more than likely that other bases are elaborated by the plant under scrutiny but since the total uncrystallized portion weighed less than one gram there can only be traces of other alkaloids. Bulbocapnine definitely seems to be absent.

THE POLAROGRAPHY OF THE MONOXIMES AND DIOXIMES OF BENZOQUINONE, NAPHTHOQUINONE, AND ANTHRAQUINONE[1]

By R. M. Elofson[2] and J. G. Atkinson[3]

ABSTRACT

The polarographic behavior of the monoximes and dioximes of 1,4-benzoquinone, 1,4-naphthoquinone, 1,2-naphthoquinone, and 9,10-anthraquinone has been investigated in the pH range 3 to 14. All of the compounds produce well-defined polarographic reduction waves which can be used for analytical purposes. Polarographic evidence indicates that the monoximes and the dioximes exhibit tautomerism.

INTRODUCTION

In this investigation the polarography of the monoximes and dioximes of 1,4-benzoquinone, 1,4-naphthoquinone, 1,2-naphthoquinone, and 9,10-anthraquinone over the pH range 3 to 14 has been studied. Because of the structural relationship of the monoximes with nitroso compounds, the polarography of nitrosobenzene has been reinvestigated.

The polarography of 9,10-anthraquinone monoxime (17), 1,4-benzoquinone monoxime (2), and 1,2-naphthoquinone-1-monoxime (8) has been determined previously and separately over different pH ranges. Recently, Souchay and Ser (15), and Calzolari (5) have reported systematic polarographic investigations of the oximes of aromatic ketones. The oxidation–reduction potential of nitrosobenzene has been previously determined by electromotive force measurements by Lutz and Lytton (10) and by polarographic methods by Holleck and Exner (6). No work has been reported on the polarography of the quinone dioximes.

EXPERIMENTAL

Apparatus

A Leeds and Northrup Electrochemograph Type E was used to record the polarograms. A minimum of damping was employed (position 1) to prevent distortion of the waves.

The capillaries that were used were made from marine barometer tubing obtained from the Corning Glass Works. For the data portrayed in Tables I, II, and IV, the value of h was 54.6 cm., t was 4.13 sec., and m was 2.36 mgm./sec. at zero applied voltage vs. saturated calomel electrode in pH 7 buffer and 50% ethanol at 25° C.

The electrolysis cells were of the usual type. A saturated calomel electrode was used as the anode, connected by means of a flexible saturated potassium chloride agar bridge to the electrolysis cell.

Media

Buffers were prepared according to Clark and Lubs; pH measurements of alcohol mixtures were recorded with a Beckman Model G pH meter and glass electrode.

Chemicals

1,4-Benzoquinone monoxime, m.p. 136–138° C. (decomp.), and 1,4-benzoquinone dioxime, m.p. 247–248° C. (decomp.), were prepared according to Beilstein.

9,10-Anthraquinone monoxime, m.p. 222–223° C. (decomp.), was prepared according to Julian (7).

9,10-Anthraquinone dioxime was prepared by treating 5 gm. 9,10-anthraquinone with 10 gm. hydroxylamine hydrochloride in 50 ml. of pyridine; the yield was quantitative. Upon recrystallization from methanol it melted at 259–260° C. (decomp.) (11).

1,2-Naphthoquinone-2-monoxime, m.p. 165–167° C. (decomp.), and 1,4-naphthoquinone monoxime, m.p. 190–192° C. (decomp.), were prepared according to Beilstein from α-naphthol.

1,2-Naphthoquinone dioxime, m.p. 150° C. (decomp.), and 1,4-naphthoquinone dioxime, m.p. 221° C. (decomp.), were prepared from the corresponding monoximes by treatment with hydroxylamine hydrochloride and pyridine in alcohol according to Beilstein.

Nitrosobenzene, m.p. 66.5–68° C., was purified by recrystallization from ether.

RESULTS

The Polarography of Nitrosobenzene

In Table I are tabulated the half-wave potentials of nitrosobenzene over the pH range 6 to 11.

TABLE I

HALF-WAVE POTENTIALS OF NITROSOBENZENE VS. S.C.E.
Concentration 0.9×10^{-4} *M* approx.

A. Water solution					
pH	6	7	9	10	
$-E_{\frac{1}{2}}$ volts	0.012	0.075	0.185	0.245	
B. Alcohol 52% by volume					
pH	6.3	8.3	10.4	11.4	0.1 *N* NaOH
$-E_{\frac{1}{2}}$ volts	0.072	0.190	0.320	0.380	0.480

The first series of measurements carried out in aqueous solution obey equation [I]:

$$E_{\frac{1}{2}} \text{ vs. S.C.E.} = +0.339 - 0.0584 \text{ pH}. \qquad [I]$$

This represents the reversible nitrosobenzene–phenylhydroxylamine system whence the normal electrode potential E_0 becomes $0.339+0.246 = 0.585$ v.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

which is in excellent agreement with the results of Lutz and Lytton (10) who obtained E_0 equal to 0.582 v. by potentiometric titration.

In alcohol solution the relationship between the half-wave potential and the pH as measured with the glass electrode is exactly linear but the equation is given by [II]:

$$E_{\frac{1}{2}} \text{ vs. S.C.E.} = +0.323 - 0.0603 \text{ pH}, \qquad [II]$$

whence E_0 becomes 0.569 volts. The discrepancy in the results, which amounts to about 50 mv. in the actual measurements, is presumably partly due to the errors of measuring pH with the glass electrode in nonaqueous solutions. Similar considerations would probably apply to the other measurements recorded in this paper.

Because of the high volatility of nitrosobenzene exact diffusion current measurements were not made, but the wave heights indicated quite clearly that two electrons were involved in the reduction. This was also evident from a plot of E_{de} vs. log $[i/(i_d - i)]$. Straight lines were obtained with a slope of 27 mv. at pH 7 and 31 mv. at pH 10, which agree well with the theoretical value of 29 mv. for a two-electron reduction.

The Polarography of the Quinone Dioximes

The half-wave potentials of the quinone dioximes in alcohol solution are presented in Table II. All the dioximes were reduced in acid solutions and in strongly alkaline solutions by a process involving six electrons. This was established by comparing the wave heights for anthraquinone dioxime and benzophenone in tetramethylammonium hydroxide solution. Under these

conditions a 2.7×10^{-4} M solution of benzophenone produced a wave of 1.31 μa. and a 0.9×10^{-4} M solution of anthraquinone dioxime produced a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

wave of 1.30 μa. Since the number of electrons required for the polarographic reduction of benzophenone in alkaline solution is known to be two, it follows that the number of electrons required in the reduction of anthraquinone dioxime must be six. The corresponding value for a 0.9×10^{-4} M solution of benzoquinone dioxime was 1.36 μa. under the same conditions. At a pH of 3.1 the diffusion currents of 0.9×10^{-4} M solutions of 1,4-benzoquinone dioxime and 9,10-anthraquinone dioxime in the same concentration of alcohol were respectively 1.32 and 1.26 μa. Therefore it follows that the number of electrons required at the low pH is likewise six. The height of the reduction wave of both of the naphthoquinone dioximes likewise corresponded to the assignment of six-electron reduction waves at low and high pH's.

The surprising equality of the diffusion currents for anthraquinone dioxime and benzoquinone dioxime, despite the fact that the molecular weight of the former was much larger than that of the latter, prompted a controlled potential analysis of anthraquinone dioxime. This was carried out with a 0.001 M solution in 50% ethyl alcohol and buffer of pH 4. A stirred mercury pool was used as cathode and a saturated calomel electrode as anode in order to prevent formation of oxygen. After electrolysis for 12 hr. no cathodic current remained on a test polarogram. Instead, an anodic wave was obtained at -0.20 v. The original cathodic current was 20 μa. The anodic current was 6.5 μa. or almost exactly one-third of the original cathodic wave. Anthrahydroquinone produced an anodic wave under these conditions at about -0.4 v. Since the diamine would have a higher oxidation potential than the anthrahydroquinone, that is, a more positive polarographic oxidation potential, the anodic wave corresponds to the wave of the expected diamine. Further confirmation of this hypothesis resulted when the alcohol was removed under vacuum and a reddish-brown powder was obtained which decomposed at 190° C.; reported m.p. for anthracenediamine 196° C. (14). The powder dissolved in hydrochloric acid and, upon heating, anthraquinone—identified by melting point 270–275° C. with sublimation—was precipitated out (18).

Variation of the height of mercury in the column showed that the height of the reduction waves varied with the square root of h (Table III). This indicates that the waves are diffusion-controlled in both acid and alkaline solutions.

At intermediate pH's the polarograms may show reduction in two steps and the total height of the waves does not correspond to an integral number of electrons. Detailed examination of these waves showed that the lower wave was rate-controlled, while the upper wave was diffusion-controlled, at least when it was the dominant wave. This was proved by the fact that the height of the lower wave was independent of the height of mercury in the reservoir while the height of the upper wave varied with the square root of the height of mercury in the reservoir as shown in Table III.

Kolthoff and Liberti (9) observed similar behavior in the polarographic reduction of N-nitrosophenylhydroxylamine. These authors attributed the kinetic current to the fact that the lower wave corresponded to the reduction of the neutral molecule and the higher wave to reduction of the anion. How-

*$\sqrt{(h_2/h_1)} = 1.25$.

ever, at the intermediate pH's the concentration of the neutral molecule was calculated to be much smaller than that which corresponded with the height of the reduction wave attributed to it. The height of this wave then corresponded with the rate of formation of the neutral molecule from the anion. Similar behavior has been observed with pyruvic acid and has been attributed by Brdicka (4) to slow formation of the undissociated acid from the anion at the electrode.

However, while the behavior of the quinone dioximes resembles that of these compounds, the kinetic waves cannot arise from the same reason since the dissociation constants are much smaller ($k = 10^{-10}$ to 10^{-12}) than for the compounds just discussed. This fact suggests that isomerization takes place at the electrode at intermediate pH's before reduction occurs. This will be discussed more fully in a subsequent section.

The diffusion currents vary directly with concentration in both acid and alkaline solutions over the concentration range studied of about 0.9 to 1.67×10^{-4} M. At intermediate pH's the waves may be indefinite enough to make quantitative measurement difficult.

The variation of the half-wave potentials with concentration has not been studied in detail. In acid solutions the half-wave potential of anthraquinone dioxime varies markedly with concentration. Changing the concentration from 0.9×10^{-4} M to 1.67×10^{-4} M changes the half-wave potential 0.22 v., whereas with benzoquinone dioxime the variation is much less than 0.01 v. for a similar change. In alkaline solutions the half-wave potentials are independent of concentration.

The Polarography of the Quinone Monoximes

The half-wave potentials of the quinone monoximes at various pH values in 55% ethanol are presented in Table IV. Inspection of the table shows that reduction involves four electrons at all pH values for the four compounds, with the exception of 1,4-benzoquinone monoxime at low pH values and 1,4-naphthoquinone monoxime at pH 10.4 and 11.4. In the latter cases the height of the waves is somewhat smaller than that corresponding to four-electron reductions. Previous workers have reported four-electron reduction for benzoquinone monoxime (2) and anthraquinone monoxime (17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

Number of electrons.

The fact that four electrons are involved in the reductions was established not only by comparison with the dioximes but by comparison with *p*-nitrophenol, the polarography of which has been elucidated by Astle and McConnell (2) and by Stocesova (16). In 0.1 N NaOH and 50% ethanol the current due to *p*-nitrophenol at a concentration of 0.9×10^{-4} M was 1.48 μa. and to benzoquinone monoxime at the same concentration was 1.0 μa. Since the reduction of *p*-nitrophenol in alkaline solutions involves six electrons, the reduction of the quinone monoxime involves four electrons.

The reduction of the quinone monoximes proceeds in single steps in acid solutions. In alkaline solutions one wave only is obtained except in the case of the monoxime of 1,2-naphthoquinone in which a stepwise reduction occurs. 9,10-Anthraquinone monoxime provides only one reduction wave at all pH's studied. The other compounds show double waves in the pH range 9 to 11.

TABLE V

EFFECT OF MERCURY HEIGHT ON REDUCTION WAVES OF QUINONE MONOXIMES
Concentration 0.9×10^{-4} M in 50% ethanol

Monoxime	pH		Current, μa.		Ratio* of current at h_2/h_1
			h_2 = 5.6 cm.	h_1 = 35.6 cm.	
1,4-Benzoquinone	4.3		1.4	1.3	1.07
1,4-Benzoquinone	9.4	Lower	0.48	0.48	1.00
		Upper	1.4	1.0	1.4
9,10-Anthraquinone	3.1		1.68	1.34	1.25
9,10-Anthraquinone	13.9		1.80	1.36	1.32

*$\sqrt{(h_2/h_1)} = 1.25$.

Since it was observed that only *p*-benzoquinone monoxime showed abnormally small diffusion currents at low pH's, these were investigated further by varying the height of the mercury reservoir as illustrated in Table V. These

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

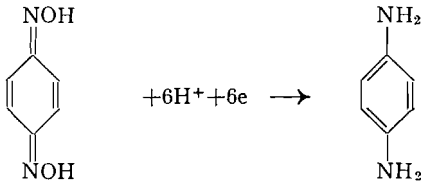
results indicate clearly that the wave at high pH's is diffusion-controlled for both 1,4-benzoquinone monoxime and 9,10-anthraquinone monoxime but only for 9,10-anthraquinone monoxime at low pH's. 1,4-Benzoquinone monoxime at low pH shows a reduction wave which is almost purely kinetic in nature, and this persists to the region where a double wave is observed. This proves that at low pH's the reduction of this compound must be preceded by a change at the surface of the electrode before reduction can take place. Since this reaction could not be the formation of the undissociated acids from the anion (pK for benzoquinone monoxime is about 6), it must involve tautomerization. This may involve the system p-nitrosophenol – benzoquinone monoxime or p-benzoquinone monoxime – p-benzoquinone nitrone.

The diffusion currents have been found to be directly proportional to concentration in the range studied of 0.9 to 1.67 $\times$ 10^{-4} M.

The half-wave potentials were subject to less variation with concentration than was the case with the dioximes. In the case of anthraquinone monoxime at pH 5.3 changing the concentration from 0.9 $\times$ 10^{-4} M to 1.67 $\times$ 10^{-4} M changed the half-wave potential by 0.01 v. In more acid solutions, and also in alkaline solutions, the half-wave potentials were much less dependent or not dependent at all on concentration.

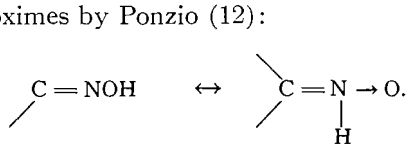
DISCUSSION

The polarographic reduction of the oximes of aromatic ketones (5, 15) has been shown to involve four electrons and results in the production of the corresponding amine. Since the polarographic reduction of the quinone dioximes requires six electrons, the products of the reduction of these substances must be the corresponding diamines, according to equation [III]:



[III]

In the preceding section it has been shown that reduction in neutral solutions is stepwise. Since the lower wave is a kinetic wave, isomerization at the electrode before reduction must be postulated. As it has been pointed out, this must involve tautomerization and not simply re-formation of the undissociated oxime from the anion. Presumably this must involve some form of the classical nitrone–oxime isomerization, equation [IV], postulated originally by Angeli (1) and applied to dioximes by Ponzio (12):



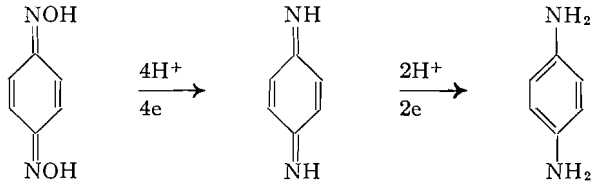
[IV]

It is not possible from the results of this study to state which form is actually reduced at the electrode, but it is hoped that a consideration of these results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

with infrared and ultraviolet spectra analyses currently in progress will elucidate this isomerism. In strongly alkaline solutions, the anion is stabilized by resonance and the molecule is reduced at a considerably higher potential.

The actual reduction probably proceeds according to equation [V]:



[V]

through the intermediate diimino compound. This mechanism is supported by the fact that the slope of the plot of $E_{\frac{1}{2}}$ vs. pH in acid solutions approximates 0.100, which corresponds to a critical step involving four H^+ and presumably four electrons. The results of catalytic and electrolytic reduction of various oximes has necessitated the hypothesis of a similar mechanism. These reductions result in the formation of mixtures of both primary and secondary amines. In order to explain this, von Braun (3) postulated similar imino intermediates which condense with the amine already produced. Elimination of ammonia and further hydrogenation results in the formation of the secondary amine according to equation [VI]:

$$R_1R_2C{=}NOH \xrightarrow[-H_2O]{H_2} R_1R_2C{=}NH \xrightarrow{H_2} R_1R_2CHNH_2 \qquad [VI]$$

$$\downarrow + R_1R_2CHNH_2$$

$$R_1R_2CH{-}NH{-}CHR_1R_2 \xrightarrow[+H_2]{-NH_3} (R_1R_2CH)_2NH.$$

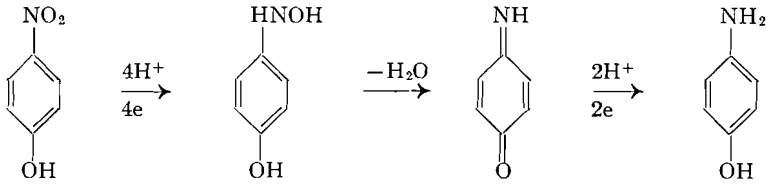
$$\quad NH_2$$

As illustrated in Table III, the polarographic reduction of benzoquinone dioxime at a pH of 7.3 results in a single wave of about one-half the normal height. Since this is a kinetic wave whose height depends on a rate of isomerization, no conclusion can be drawn, at this pH, about the formation of final reduction products corresponding to the dihydroxylamine or the diimino compound. That is, the small wave height may be due entirely to slow isomerization of the dioxime, and only the normal reduction product—the diamine—may be produced.

In all cases where diffusion-controlled waves were observed the reduction of quinone monoximes involves four electrons; hence the over-all reduction product must be the corresponding aminophenol over the entire pH range. On the other hand, the reduction of nitrosobenzene has been shown to stop at the phenylhydroxylamine stage in the pH range studied here. The polarographic reduction of nitrobenzene proceeds to phenylhydroxylamine in alkaline solution, and to aniline in acid solution. *p*-Nitrophenol is reduced stepwise at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

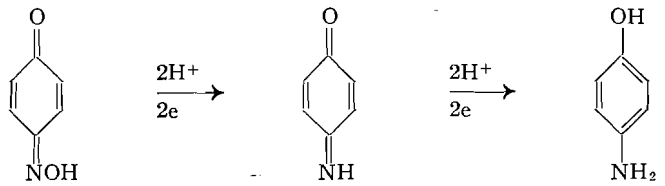
nearly all pH values to *p*-aminophenol. In the case of *p*-nitrophenol these observations have been explained by the hypothesis of quinoidation (16), according to equation [VII]:



[VII]

However, *p*-nitrosophenol (benzoquinone monoxime) is reduced in one step and at more positive potentials than *p*-nitrophenol. For *p*-nitrophenol, at pH 3, Astle and McConnell (2) report a stepwise reduction at $E_{\frac{1}{2}} = -0.41$ and -0.86 v. whereas this investigation has shown a single step reduction at pH 3.9 of $E_{\frac{1}{2}} = 0.04$ v. for benzoquinone monoxime. Furthermore, at pH 12, they found that $E_{\frac{1}{2}}$ was -0.93 v. and -1.57 v. for *p*-nitrophenol, whereas at pH 11.4 this investigation showed $E_{\frac{1}{2}} = -0.88$ v. for benzoquinone monoxime.

These results indicate that the reduction of the monoximes does not involve the intermediate formation of *p*-hydroxylphenylhydroxylamine which would be expected during the reduction of *p*-nitrosophenol, but rather the reduction of the oxime according to equation [VIII]:



[VIII]

This mechanism is supported by the results of the reduction of the quinone dioximes and by the results of the chemical reduction of oximes. The fact that the wave for 1,4-benzoquinone monoxime at low pH's is a kinetic wave indicates that the oxime or other species actually reduced must form slowly at the electrode before reduction can take place. The other monoximes either do not need to rearrange before reduction, or else rearrange very rapidly. As discussed in the section on the dioximes, the possibility of the existence of nitrone forms of the oximes must be considered. This point will require further investigation but the ultraviolet work of Ramart-Lucas (13) confirms the existence of three forms of benzoquinone monoxime in buffered solutions. These are probably nitrosophenol, benzoquinone monoxime, and the corresponding nitrone.

Whereas the reductions of the quinone oximes are irreversible and no particular significance should be placed on the slope of the waves, it is interesting to compare the values obtained by plotting E_{de} vs. log $[i/(i_d - i)]$. In alkaline solution no variation of the slope as a function of structure is obtained, but in acid solution the values obtained for the corresponding monoximes at pH 3.9 are: 1,4-benzoquinone 32 mv.; 1,2-naphthoquinone 52 mv.; 1,4-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

naphthoquinone 58 mv.; and 9,10-anthraquinone 73 mv. The corresponding figures for the dioximes at pH 3.1 are 36 mv., 35 mv., 47 mv., and 69 mv., respectively. The values correspond to actual slopes that are much too low for the number of electrons involved in the reduction. However, it is noteworthy that the derivatives of benzoquinone have much steeper waves than the derivatives of anthraquinone. The derivatives of the two naphthoquinones have waves of intermediate slope. This, of course, is the order of aromaticity of the parent hydrocarbons, the oxidation potentials of the corresponding quinones, and, particularly, the order of conjugation between the functional groups in the oximes themselves.

Since the reactions are highly irreversible, it is not feasible to attach much significance to the actual half-wave potentials of the monoximes and dioximes and their relationship to the reduction potentials of the quinones. However, the fact that the half-wave potentials of the anthraquinone derivatives are at the more negative potentials, and those of benzoquinone derivatives are at more positive potentials, indicates that conjugation is the controlling factor. Since 1,2-naphthoquinone derivatives have potentials very close to those of the benzoquinone oximes, this would indicate a very high degree of conjugation due to proximity of the functional groups.

THE METAL–SOLUTION SILVER ION EXCHANGE[1]

By I. I. Tingley,[2] I. H. S. Henderson,[3] and C. C. Coffin[4]

ABSTRACT

The exchange of silver ions between silver nitrate solutions and surfaces of metallic silver was studied, using radioactive silver (Ag^{110}, 270 day half-life) as a tracer. Marked differences in behavior of surfaces prepared in different ways were observed. Crystalline (annealed and etched) surfaces exchanged rapidly to a depth of a few atomic layers, and about 80% of the acquired radioactivity was removed as quickly by exchange with inactive silver nitrate solution. Highly polished surfaces exchanged up to ten times as great an extent as the etched annealed surfaces, but required 40 hours' immersion to attain their maximum activity. The deactivation of polished surfaces by inactive solutions was inversely proportional to the period of immersion in active solution, with surfaces immersed for 17 hr. or more retaining all but 30% of their acquired activity. Abraded surfaces exchanged quickly and retained most of their activity, the extent of the exchange depending upon the ratio of "worked" to "unworked" material on the surface. Some evidence of comparatively rapid diffusion in the polish layers was obtained. The interior of cold-worked silver when exposed to the nitrate solution behaved similarly to abraded surfaces. Mechanisms for the behavior of these different types of surface are offered, and the data of other workers discussed.

INTRODUCTION

Experiments on the exchange of silver ions between silver metal surfaces and dilute solutions of silver nitrate were carried out in the Chemistry Department of Dalhousie University between 1948 and 1950. Brief reports on the earlier part of this work have been published (5, 26). While further work is necessary before the exchange mechanisms can be fully elucidated, it was felt that a presentation of these results and suggested mechanisms might be of value to others working in the field.

Excellent reviews of the published work on metal–metal ion exchanges have been made by Haïssinsky (13) and Simnad (23). In order to indicate the development of ideas about the mechanisms, however, a brief summary of certain investigations is given here.

The first published reports of metal–solution ion exchanges are those of Hevesy and Biltz (15). Using lead marked with thorium B, they observed a rapid exchange, extending to 1000 atomic layers, considering the surface to be perfectly flat. They postulated local currents on the surface to account for this exchange, and pointed out that the exchange between a layer of lead dioxide and a lead nitrate solution was much slower. This latter exchange approached much more nearly the ideal case of a "kinetic" exchange, according to their view. A lead sol did not show the rapid exchange with the solution that the massive lead surface did, and the authors explained this as due to the formation of an electrical double layer around each colloidal particle of lead.

Erbacher was the first to study the effect of surface treatment upon the metal–solution exchange (8). Mechanical abrasion with emery or sandpaper caused on some metals multilayer exchange due to local electrolytic cells, he explained, but with other metals, or after passivation of the cells in certain conditions, only monolayer exchange took place. He also studied similar exchanges between metals and "nobler" metal ions, and used the metallic exchange to measure the actual area of metal surfaces. For silver he found that a polished surface had 1.72 times the area of the surface as measured ordinarily, while coarse- and fine-sandpapered surfaces had 2.49 and 2.53 times the measured areas, respectively.

With abraded silver surfaces (polished with crocus cloth) Rollin observed an exchange involving 150 atomic layers with silver nitrate solution (22). Gold and platinum surfaces also exchanged to a depth of 100 atomic layers with silver nitrate solution.

Cottin and Do Carma Anta carried out experiments with silver metal powder and 0.2 *M* silver nitrate solution. Some of the powder was prepared by chemical reduction of silver nitrate solution by NaH_2PO_2 and some by electrolytic deposition from a 15% silver nitrate solution. The exchange with the metal prepared by electrolysis was found to involve 30 atomic layers compared with 7500 atomic layers for the silver prepared by chemical reduction, in 20 hr. For short times (a few minutes) at 100° C., the exchange involved 20 layers with electrolytic and 1000 atomic layers with chemically reduced silver. The exchange increased with temperature, and decreased after pretreatment with inactive silver nitrate solution. After exchange of long duration, the structure of the powder of chemical origin was found to have modified; it recrystallized in contact with the solution (14).

Simnad and Ruder used radioactive cobalt in solution and surfaces of various metals in both oxygen-containing and oxygen-free solutions (24). They were the first to publish autoradiographs, showing that when an abraded surface was exposed, the radioactive cobalt was deposited on the cathodic (unworked) areas.

Gerischer and Vielstich found a rapid initial exchange which varied in extent with the surface treatment, but was to a depth of 20 atomic layers with crystalline silver. When specimens were immersed for long periods of time, they found a second slower increase in the radioactivity of the metal, and explained this as due to diffusion into the metal lattice. The process was considered to consist of three steps: (*a*) the diffusion through the solution to the surface, (*b*) the discharge of ions at the boundary and their entry into the "exchange-layer", and (*c*) the diffusion into the solid lattice (11).

Baerg and Winkler found that abraded foils, which had 15 times the planar area, as measured by the Bowden–Rideal method, exchanged in one hour to a depth of 30 atomic layers with a 3×10^{-4} *N* silver nitrate solution. When equilibrated with inactive silver nitrate solution of the same concentration for 300 hr. or more, they exchanged with the radioactive solution to a depth of 15 atomic layers. When foils of the same metal were etched with 7 *N* HNO_3, they gave Bowden–Rideal areas of 8 times planar, but exchanged to a depth

of only 2.5 atomic layers, and the exchange was unaffected by inactive equilibration. Fifty to sixty per cent of the acquired radioactivity on both types of surface was subsequently removable by exchange with inactive silver nitrate solution (1).

In kinetic studies on etched surfaces, Baerg and Winkler used the equation $-2.3 \log F = kt$, where $F = (x_3 - x)/x_3$ for the forward equation (inactive surface, radioactive solution) and $F = (x - x_3)/(x_0 - x_3)$ for the reverse reaction (radioactive surface, inactive solution). x is the radioactivity on the surface at time t, x_3 is the value of x at the end of three hours, and x_0 is the initial (zero time) activity for the reverse exchange; k is a proportionality constant. The lines obtained were segmented, with straight portions, except for the reverse exchange from electrodeposited adsorbed ions, which gave a definite curvature. In the earlier portions, the lines for forward and reverse exchanges coincided; after about 12 min., however, the reverse rate was lower, and the slope of its line less. According to the authors, the segmented appearance of the graphs indicates several different rates of reaction and disclosed the heterogeneous character of the metal surface. The curved plot indicated a surface structure of a completely heterogeneous character and suggested random, "out-of-lattice" deposition of the ions. They explained the heterogeneous character of the other surfaces to be due to crystal faces of different orientation, each of which exchanges at a separate rate.

EXPERIMENTAL

A. Apparatus

In the work described below, silver metal surfaces prepared in various ways, as indicated, were exposed to 0.1 N or 0.005 N silver nitrate solutions containing radioactive silver (Ag^{110}, 270-day half life) and to 0.1 N and 0.005 N inactive silver nitrate solutions, with a view to determining the effect of surface treatment upon the exchange taking place between silver metal and its ions in nitrate solution.

The solutions used were as follows:

(1) 0.1 N silver nitrate solution, containing Ag^{110} and giving 4×10^4 c.p.m. per ml. when evaporated on a 1-in. in diameter planchet.

(2) 0.005 N silver nitrate solution containing Ag^{110} and giving 1×10^5 c.p.m. per ml. This solution had a pH of 6.2.

(3) Inactive 0.1 N silver nitrate solution.

(4) Inactive 0.005 N silver nitrate solution, with a pH of 6.2.

The radioactive solutions were prepared by dissolving silver foil of high specific activity in nitric acid and evaporating the solution just to dryness. The resulting silver nitrate crystals were taken up in distilled water, the solution re-evaporated, the crystals redissolved in distilled water and made up to the required volumes. Inactive solution No. 3 was prepared in the same way, using inactive foil, while solution No. 4 was prepared by dissolving Merck

reagent grade silver nitrate. Isotopic dilution of the radioactive solutions, when necessary, was carried out by the addition of inactive silver nitrate of the same concentration.

The silver metal was obtained from Johnson, Matthey, and Mallory in the form of 0.12 mm. cold-rolled foil and $\frac{3}{4}$ in. in diameter rods. The specimens for the exchange experiments were prepared as $\frac{3}{4}$ in. disks or $\frac{3}{4}$ in. squares of the silver foil, or, in the later experiments, to obtain more reproducible surfaces, 3/16 in. slugs cut from the silver rods. The circular surfaces thus had areas of 2.8 cm.^{2}, and the square ones 3.63 cm.^{2}

Unless otherwise stated, the silver was annealed before each experiment for at least two hours in a muffle furnace at 850° to 950° C. in order to obtain a reproducible starting point for the preparation of each specimen. This annealing produced grains up to 3 mm. in diameter in silver which had been severely cold-worked previously. Surfaces described as "annealed, etched" were prepared by etching specimens of annealed silver with 35% nitric acid, and surfaces described as "emeried" were annealed specimens rubbed with 00 metallographic polishing paper.

Several silver slugs were electrolytically polished. The polishing cell consisted of a 150-ml. beaker containing phosphoric acid (specific gravity 1.7) and a cylindrical silver foil cathode held coaxially with the anode, the slug to be polished. Electrical contact and support for the anode was a 1/16 in. platinum rod threaded into the edge of the slug, and insulated from the solution by a coating of paraffin wax. With a current density of about 50 ma. per sq. cm., electrolytic polishing of the anode took place, producing a bright crystalline surface, with individual crystals well defined in specimens of large grain size.

Silver foil was polished as a strip 6 in. by $1\frac{1}{2}$ in. by hand polishing or on a low-speed polisher, before it was cut into disks or squares. Polishing was carried out by hand using a water suspension of levigated alumina and chamois skin, and on the polisher by affixing the silver strip to a smooth, curved block of wood which was held against a velvet lap continually moistened with a water suspension of levigated alumina. Silver metal slugs were polished by the procedure suggested by Desch (6), using three grades of metallographic polishing paper followed by a smoothing of the surface on a wax lap with levigated alumina. The final polishing was carried out on the low-speed polisher using Linde "B" (alumina) on a "Gamal" lap. The flow of material reported by Beilby (3) in final polishing was observed under a low-power microscope, polishing being discontinued when surface scratches were no longer visible. After polishing, the surfaces were rinsed with water and then with alcohol. In some instances a solution of potassium hydroxide in alcohol was used to remove grease film, followed by distilled water. This treatment had no observable effect on the surface of the metal or on its behavior when exposed to silver nitrate solution.

For exposure to the silver nitrate solution, silver foils were cemented to a picene wax block, and the block suspended in a stirred electrolytic beaker containing 100 ml. of solution. Silver slugs were individually mounted on the

flattened ends of 6 mm. glass rods by means of picene, with the edges of the slugs and the portion of the mounting rods in contact with the solution carefully painted with molten paraffin wax. Seven such specimens mounted on glass rods were exposed to the solution simultaneously, the upper ends of the rods being retained in fuse clips on a circular holder as shown in Fig. 1.

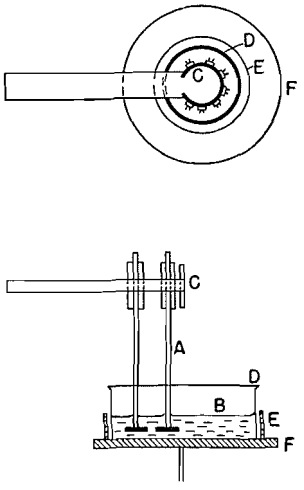

FIG. 1. Slug holder and stirrer assembly. A. Glass rod and silver slug. B. Silver nitrate solution. C. Slug holder with fuse clips. D. 10-cm. crystallizing dish. E. Steel guard ring. F. Phonograph turntable.

It was concluded after runs made both with and without nitrogen bubbling through the solution that the exchange phenomena discussed below were not dependent upon the presence or absence of oxygen. Stirring of the solution at a uniform rate was achieved by revolving the cells containing solution at 78 r.p.m. on a phonograph turntable, the silver specimens being held stationary.

The pH measurements on silver nitrate solutions were made with the system illustrated in Fig. 2, which consisted of a glass electrode, a calomel electrode,

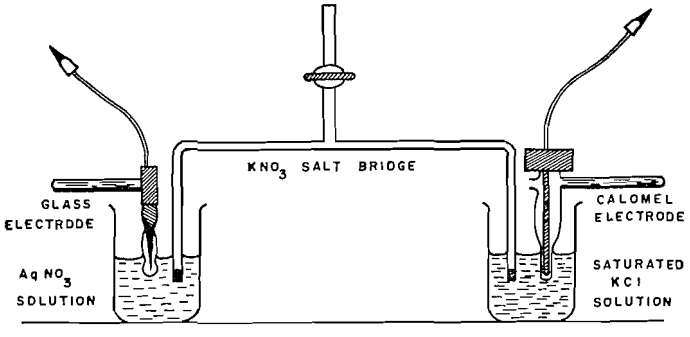

FIG. 2. Apparatus for pH measurement on $AgNO_3$ solutions.

a salt bridge containing 2 *N* potassium nitrate solution, and a Beckman Model G pH meter. The meter was standardized against buffer solution of pH 7.

After exposure to solution, specimens were rinsed in distilled water, cleaned with boiling benzene and then with detergent (Alconox), and the radioactivity was determined using an end-window β–γ counter in a conventional setup, with the counter tube shielded in a lead "castle". At least 1000 counts were taken from each sample, so the statistical error limit in the counts was 6%. The counts were corrected for day to day fluctuation of the counter efficiency, and for decay, by comparison with a standard Ag^{110} source.

B. Experimental Results

From their behavior toward silver nitrate solutions, the different silver surfaces were classified as crystalline, polished, and "mixed". A "mixed" surface is defined as a surface prepared by scratching, grinding, or partially polishing an annealed specimen, so that some unworked metal is left exposed along with the worked portions.

A number of runs established a marked difference between polished and crystalline (etched) surfaces in the uptake of radioactivity from the solution. Crystalline surfaces acquired very quickly an activity of 10 to 20 c.p.m. from solution No. 1, and this did not increase during immersion up to nearly 90 hr. in the solution, while polished disks acquired radioactivity in a regularly increasing amount until a maximum of about 200 c.p.m. was reached at about 40 hr. After 24 hr. in the solution about 85% of the maximum radioactivity was obtained. Values for a typical run are plotted in Fig. 3.

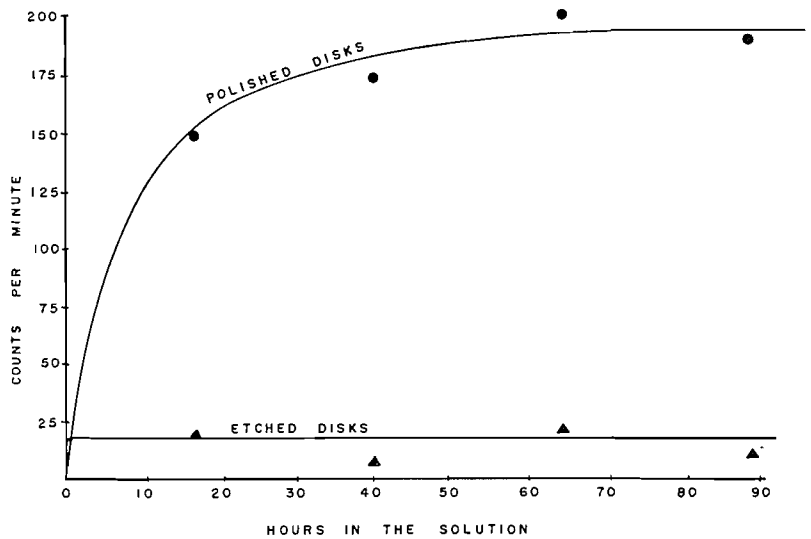

FIG. 3. Activity uptake of etched and polished disks.

Considering the surface of the disks to be perfectly flat, it was calculated that the maximum uptake of radioactivity by the etched and polished surfaces amounted to penetrations of 11 and 110 atomic layers, respectively, i.e., that the amount of silver which had transferred from the solution to the metal surfaces was sufficient to make up these numbers of layers. The value for the

polished surface compared well with the 100 to 150 atomic layers' penetration found by Rollin for silver surfaces, while that for the etched surfaces is comparable to the figures of 20 and 30 atomic layers found by Do Carmo Anta and Cottin for electrodeposited silver, which was certainly crystalline, and to the value of 20 atomic layers found by Gerischer and Vielstich for surfaces etched with nitric acid or electrodeposited from solution.

Using solution No. 2, with a higher specific activity and much lower concentration, a similar pair of curves was obtained, the maximum for the polished surfaces being only five times as high as that for the etched ones, however. There is some uncertainty regarding the number of layers penetrated, due to the fact that the solution radioactivity was determined by evaporating an aliquot on a 1-in.-in-diameter planchet, while the specimens used in the exchange were $\frac{3}{4}$ in. squares. The difference in counting efficiency might be as much as 30%. Neglecting this factor, the penetration with solution No. 2 amounted to only 3.5 atomic layers for etched surfaces and 17 atomic layers for polished surfaces. This value for crystalline surfaces agrees fairly well with those of Baerg and Winkler, who used a solution of 3×10^{-4} N concentration, and would seem to indicate that the depth of the exchange depends to some extent upon the concentration of the solution. Electropolished surfaces prepared from annealed metal without prior abrasion took up approximately the same amount of radioactivity as the etched surfaces, while if the surface was emeried before electropolishing the uptake was two or three times as great.

When the mixed surfaces produced by etching unannealed foil were exposed to the solution along with polished surfaces, the radioactivities acquired by both types of surface were almost identical, as shown by Fig. 4.

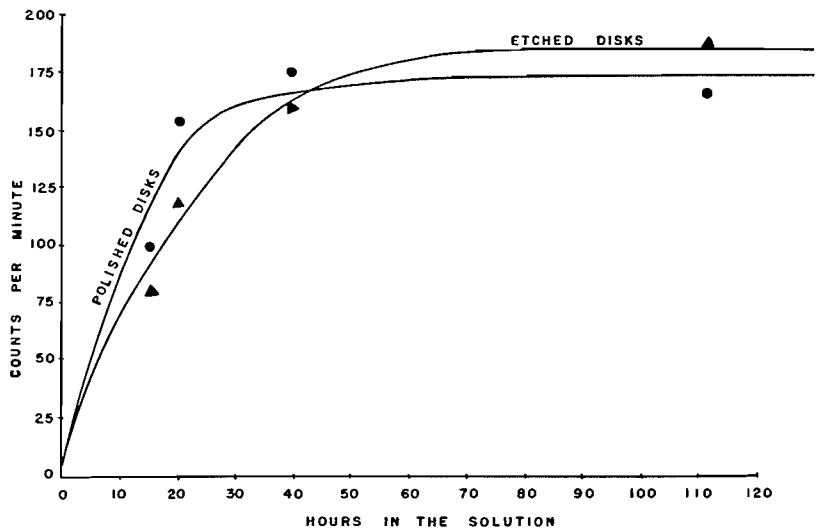

FIG. 4. Activity uptake of unannealed etched and polished disks.

To determine how quickly the radioactivity was acquired upon immersion of the disks in the solution, etched and polished disks were exposed to solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

No. 1 for instant dips, 10 sec., 1 min., 15 min., 30 min., and 60 min. The results are plotted in Fig. 5. Each count represents a different specimen and

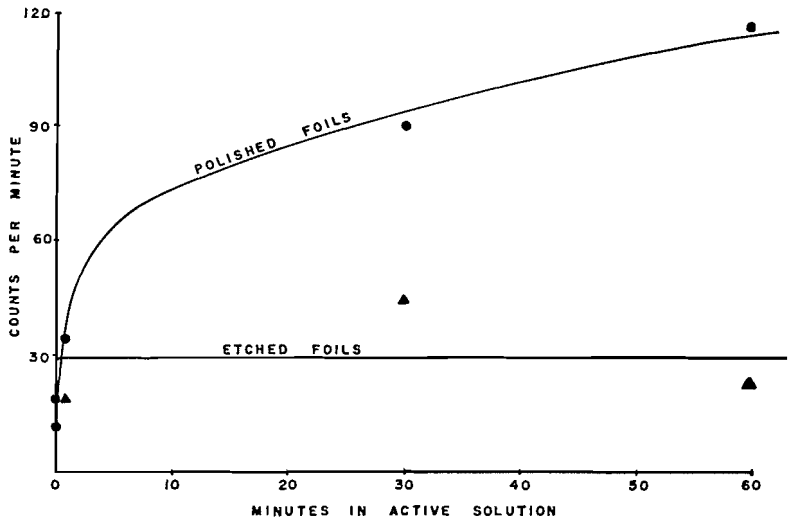

FIG. 5. Behavior of etched and polished surfaces immersed for short periods in silver nitrate solution.

with the etched ones the values were random with respect to time, with the instant dip giving 20 c.p.m. Polished surfaces, though apparently slower starting (13 c.p.m. after an instant dip), continually increased their radioactivity, but at an ever-slower rate, up to the end of the test period.

Experiments with solution No. 2 gave very similar results, to which reference will be made later.

In attempting to show that an electric potential difference existed between the amorphous polish material and the crystalline metal, experiments were carried out in which disks of the same size were connected by a strip of the same foil, the whole dumbbell piece being cut out from a polished strip at one time. One disk of the dumbbell was etched, the other left polished. The piece was placed on the wax block and the connection waxed over, so that the two disks were connected electrically outside the solution. It was thought that if a potential difference existed between the two disks, the polished one would go into solution to some extent, while an equivalent quantity of ions would plate out on the crystalline disk. Compared with unconnected disks in the same solution for the same time, the polished connected disk would acquire less radioactivity and the etched connected one more activity than the respective unconnected ones. The results of many such runs were inconclusive, however, as the effect seemed to be indicated sometimes and in other cases was definitely absent. Modifications on the experimental arrangement were tried, but always the results were inconclusive.

Other workers have observed that the exchange between silver metal and silver ions in solution was diminished by pretreatment of the silver surface

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

by exposing it to inactive silver nitrate solution (1, 8, 11, 14), although Haïssinsky and his collaborators found the opposite effect with some metals (14). Polished and etched disks were exposed to inactive solution No. 3 for 19 hr., and then put into radioactive solution No. 1, one pair for an instant, and two other pairs for 30 and 90 min., respectively. The counts obtained on the polished disks were 17, 132, and 168 c.p.m., respectively, while the results for the etched disks were 9, 26, and 36 c.p.m. Later experiments with both foils and slugs in radioactive solution No. 2, after pretreatment for times of 1 min., 5 min., 1 hr., and 17 hr. in inactive solution No. 4, showed that the uptake of activity by both crystalline and polished surfaces was unaffected by pretreatment with inactive solution of nearly neutral pH (6.2). However, using

TABLE I

EFFECT OF ACIDITY OF PRETREATING SOLUTION ON ACTIVITY UPTAKE

Surface	Activity (c.p.m.)	
No pretreatment	100	130 (two disks)
Pretreated with solution of pH 5.4	140	115
Pretreated with solution of pH 0.3	230	250

crystalline silver slugs and inactive 0.005 *N* silver nitrate solution with its pH adjusted, the results found in Table I were obtained after one minute each in the inactive solution and in radioactive solution No. 2. It thus appears that the increase in exchange found with solution No. 1 after pretreatment with solution No. 3 may have been a pH effect. It may also have been just the result of a different degree of polish.

Rollin found that the pretreatment of an inactive silver surface with sodium nitrate solution increased its radioactivity uptake by a factor of 10. When

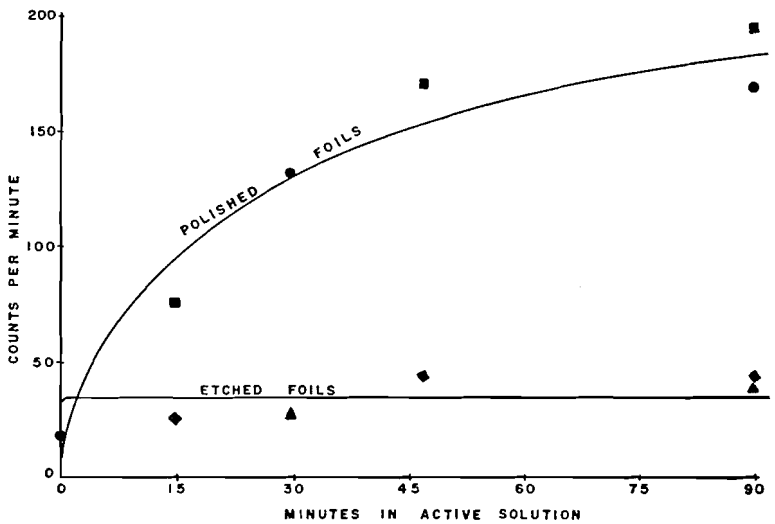

FIG. 6. Effect of pretreatment with inactive solutions upon exchange.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

this was tried by the authors, the results agreed very well with those obtained in the silver nitrate pretreatment, the increase in activity uptake being about 1.5 times for polished surfaces, rather than 10 times, and no change with etched surfaces. More careful experiments should be made to check the effect of pretreatment on the different surfaces. The results of these experiments are plotted in Fig. 6, which should be compared with Fig. 5.

Besides the observation that unannealed foil when etched gave a less obviously crystalline surface, which took up considerable activity from the solution, the effect of cold-working on the properties of the interior of the metal was shown by the following experiments: Two pieces of annealed foil, of the same size, were cut out, and one was pounded with a hammer on an anvil for some time. The two pieces were then set on the wax block, etched, and put into the radioactive solution No. 1. After five hours they were removed and counted. The results were: 98 c.p.m. for the pounded piece, and 17 c.p.m. for the unpounded one. Silver slugs, $\frac{1}{8}$ in. thick, were placed on a steel block and pounded out to a thickness of about 3/64 in. by a single 2000 p.s.i. blow from an electric hammer. After etching with nitric acid, some of these slugs were annealed, and then they were all exposed to the radioactive solution. The unannealed slugs took up three to five times as much radioactivity as the annealed ones.

In an attempt to get a more quantitative idea of the effect of cold working, three pieces of annealed foil, about 2 cm. square, were treated as follows: While it was held between two blocks of wood, the piece was bent through a right angle in each direction for a number of times, and then shifted and bent again at a different place. The pieces were bent in this way at four lines along one dimension, and at four lines along the other dimension, one piece for 4 times, a second for 8 times, and a third for 16 times. (Bending more than 18 times resulted in fracture of the metal.) These pieces were then put on the block along with an unworked piece of the same foil, all four pieces were etched and put into radioactive solution No. 1 for 22 hr. Upon counting, the results were: for the unworked piece, 44 c.p.m.; the one worked 4 times, 56 c.p.m.; 8 times, 53 c.p.m.; and 16 times, 60 c.p.m. Thus, although there was little difference between working the pieces 4 times or 16 times in this way, the difference between worked and unworked appears real. It must be remembered also that etching with the acid undoubtedly removes more of the worked material than the unworked, and so the difference in behavior is probably greater than was found.

To determine how the ratio of "vitreous" or worked metal to crystalline metal affected the uptake of radioactivity, the following experiments were performed.

From a sheet of annealed, etched foil, four disks were prepared, one being polished with wet, fine alumina for 6 sec., a second for 60 sec., a third for 600 sec., and the fourth left unpolished. After being held in the active solution No. 1 for one minute, the disks showed radioactivity as follows: No. 1, (polished 6 sec.) 36 c.p.m.; No. 2 (polished 60 sec.) 111 c.p.m.; No. 3 (polished 600 sec.) 32 c.p.m.; and No. 4 (unpolished) 23 c.p.m. After being in the solution a

For personal use only.

further nine minutes, the disks counted: No. 1, 47 c.p.m.; No. 2, 168 c.p.m.; No. 3, 73 c.p.m.; and No. 4, 28 c.p.m. When returned to the radioactive solution for further periods, the disks increased their radioactivities regularly, with the magnitudes of the increases being in the order No. 2, No. 3, No. 1, and No. 4, until at 17 hours' total exposure to the solution the counts were No. 1, 118 c.p.m.; No. 2, 392 c.p.m.; No. 3, 214 c.p.m.; and No. 4, 67 c.p.m.

When the disks were put into inactive solution No. 3 for the same periods of time, their radioactivities were lost in a similar manner, except that the most highly polished disk retained its radioactivity through the one minute period, while all the others lost considerably. After 17 hr. in the inactive solution the counts were No. 1, 72 c.p.m.; No. 2, 248 c.p.m.; No. 3, 175 c.p.m.; and No. 4, 37 c.p.m.

These results are plotted in Fig. 7.

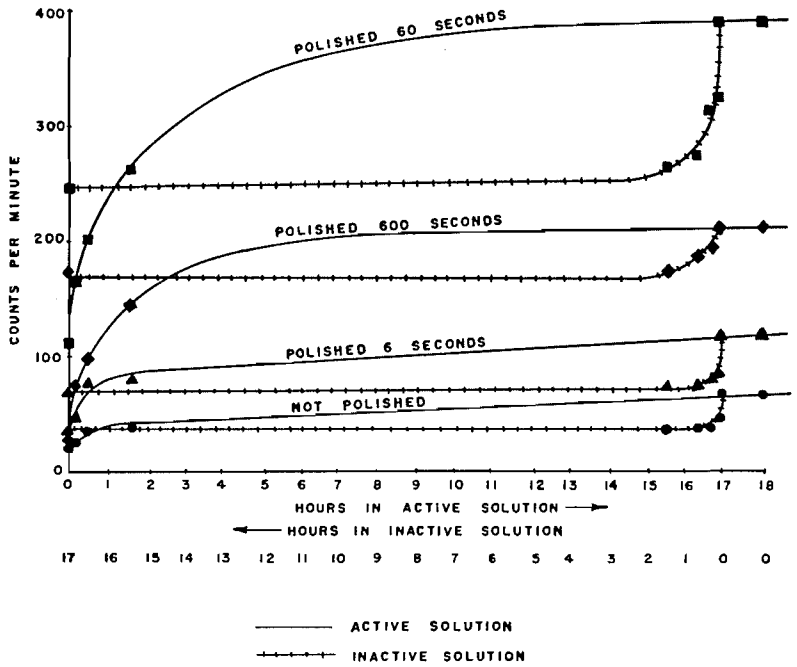

FIG. 7. Effect of vitreous to crystalline ratio upon activity uptake of surfaces.

Two more runs were carried out, in which the numbers of strokes with the polishing chamois were counted, and the foils exposed to solution No. 2 for 17 hr. The results are given in Table II. Another run was made with annealed slugs polished for different times on the Buehler polisher, and the surfaces exposed to solution No. 2 for $17\frac{1}{2}$ hr. The data are given in Table III.

An alternative to the Geiger counter in detecting radioactivity is the method of autoradiography, which has the advantage of indicating the location of the activity more precisely. This would be particularly useful in the case of "mixed" surfaces, it was thought. Autoradiographs of etched specimens of

unannealed foil having smooth streaks through the rougher crystalline surface, which had acquired a small amount of radioactivity in active solution No. 1, were made by placing the specimens down on pieces of dental X-ray film, and leaving them in the dark for periods of time necessary to get clear images.

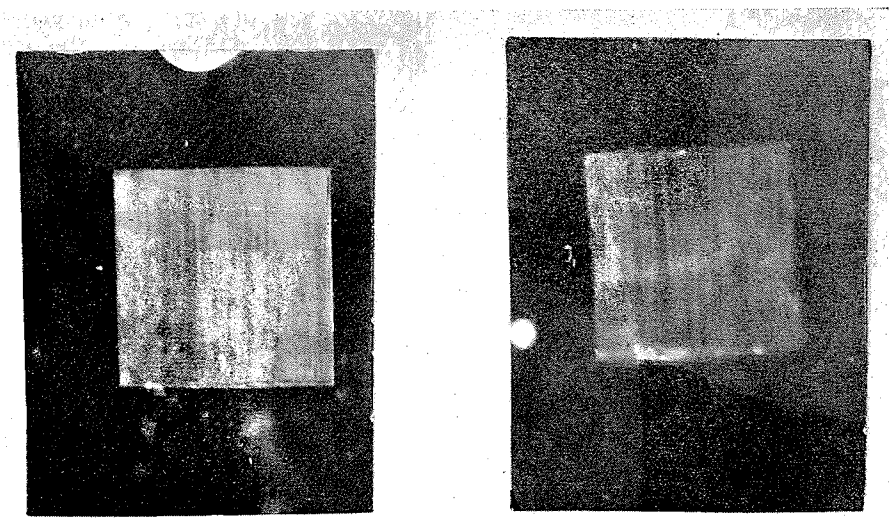

FIG. 8. Photograph and autoradiograph of unannealed etched silver surface. The picture on the left was taken with a camera, with the light placed so that the smooth lustrous streaks were in the shadows of the rougher, more crystalline portions. The autoradiograph, at the right, shows that the radioactivity was concentrated in these crystalline, unworked, cathodic portions of the metal surface.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

When the negatives were developed and compared with the silver surfaces, it was seen that the radioactivity was concentrated on the crystalline (unworked) portions of the surface. This result is similar to that obtained by Simnad and Ruder in their studies with cobalt surfaces and radioactive cobalt solutions (24). Fig. 8 shows a print from the autoradiograph and one from a photograph of the same surface. The smooth streaks were in the shadows of the rougher crystalline portions of the surface when the photograph was taken, and so appear darker in the print. In the autoradiograph they also appear darker, but for the reason that the radioactivity was concentrated on the rougher, crystalline portions, and affected the negative accordingly.

Pieces having surfaces consisting of alternate polished and etched strips were made up, the strips being about 2 mm. wide. These were immersed in radioactive solution No. 1 for several hours, and autoradiographs made of them. These showed that in general the activity was concentrated in the polished strips. However, one etched strip was almost completely active, others were much narrower on the autoradiographs than on the metal pieces, and when the widths of the etched strips on the foils and the widths of the light strips on the films were measured with a micromicrometer, it was found that all light strips on the negatives were narrower than the actual strips on the metal, the differences in width at various positions along the strips varying from 2 to 64%. This was not due to film shrinkage, as the total width of the film image was the same as that of the piece of metal. In these pieces the etched strips were really furrows, being at a lower level than the polished strips, due to the dissolving of the metal during the etching. Considerable radioactivity was probably acquired by the banks of these furrows, since there crystalline metal existed in closest contact with the polish material. Radioactive emanations from these banks would affect the film in such a way that the light streaks corresponding to the etched strips would be narrower than the strips on the metal pieces. This is diagramed in Fig. 9.

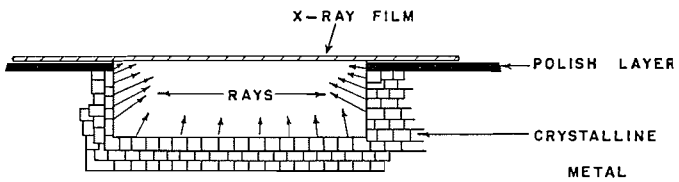

FIG. 9. Diagram of effect of etched and polished strips on film.

The experiments to determine the effect of the ratio of annealed to worked metal indicated that some 20% to 40% of the radioactivity acquired by the silver surfaces after 17 hours' exposure to radioactive solution No. 1 was lost when the surfaces were immersed for an equal period in inactive solution No. 3. The most crystalline surfaces lost the greatest percentage and the most highly polished one the least. Other experiments with well-annealed crystalline surfaces had indicated that such surfaces lost little or none of their acquired radio activity (5), but the low radioactivity taken up made the results highly uncertain. The deactivation phenomena were investigated further, with the more active solution, and the results appear in Table IV.

17 hr. lost 30% of their radioactivity in inactive silver nitrate solution. The radioactivity lost by polished surfaces in inactive solution was dependent on the time they had been in contact with the radioactive solution. This is shown graphically in Fig. 10. Partially polished foils and emeried surfaces lost the least, 5% to 20%.

The gradual uptake of activity by a polished surface could be nicely explained if atoms which entered the surface layer in the exchange process, including the radioactive atoms by which the exchange was detected, gradually diffused into the polish layer, to be replaced by other atoms both from the metal and from the solution. Diffusion in crystalline silver at room temperature is doubtless very slow (2), but in the disordered, amorphous polish layer it might be thousands of times as rapid as it is along grain boundaries (16). In this way the radioactivity of the metal would increase until the number of radioactive ions entering its surface equalled the number of active atoms re-entering the solution from the surface. In a search for evidence of such diffusion, silver disks which had been activated in an early run were recounted after 228 days. The original radioactivities of two such pieces had been 197 c.p.m. each, and after this lapse of time they counted 92 and 80 c.p.m., respectively, the decrease being accountable by the decay of Ag^{110}. The two disks were immersed in inactive solution for one and one-half hours, which according to previous experiments should have removed 30% of their radioactivity. On counting, however, the results were 97 and 85 c.p.m., respectively, which being within the statistical error limits of the previous counts, indicated that no radioactivity had been lost. To confirm that exchange was still taking place, the two disks were stirred in radioactive solution No. 1 for three hours, whereupon their activities increased to 200 and 210 c.p.m., respectively. Put back into inactive solution for 16 hr., they lost radioactivity to 150 and 148 c.p.m.; returned to the radioactive solution, after 18 hr. they gave 218 and 247 c.p.m.; and after a further 19 hr. in inactive solution 166 and 177 c.p.m. It was apparent that exchange was still going on, but as with new disks, after each exchange period some activity was retained in the foil and could not be removed by exchange with inactive solution.

To see if the original activity had penetrated to the crystalline interior, one of the disks was etched with 4 *N* nitric acid until the polish layer was removed. Upon counting, it gave only 4 c.p.m., which showed that practically all the radioactivity was removed with the polish.

Two more disks of the same age were counted, giving 75 and 77 c.p.m.; these were compared with two disks activated only a short time previously, which had radioactivities of 169 and 176 c.p.m. The old disks were stirred for three hours in inactive solution, and upon counting gave 74 and 78 c.p.m., while the new disks were put for five hours into radioactive solution, after which they gave 244 c.p.m. each. All four disks were then held for 15 sec. in 3.5 *N* nitric acid; no etching of the polish was visible after this. However, after counting, the new disks were seen to have 219 c.p.m. each, and the old ones 70 and 74 c.p.m. The radioactivities found after further periods in the acid are listed in Table V.

TABLE V

Total time in acid	Old disks (c.p.m.)		New disks (c.p.m.)	
0 sec.	74	78	244	244
15 sec.	70	74	219	219
30 sec.	70	73	218	206
90 sec.	68	63	173	196
450 sec.	38	52	143	162
630 sec.	26	47	87	122

After 450 sec. in the acid, the surface of the polished disks was just beginning to lose its mirror-like finish, while the activities had been cut down 33⅓% to 49% on all disks. It took 90 sec. with the old disks before appreciable removal of activity began, however, while with the new disks effective removal began at once. This would indicate that the penetration of the polish layer by radioactive atoms was only to a small depth for the most part, but that the radioactive atoms diffused into the polish layer with time, so that they were removed from the surface layers where exchange took place.

To determine whether the behavior of the polish layer was changed by heating, pairs of polished foils were heated at temperatures and for times indicated in Table VI before they were placed in solution No. 1 for 17 hr. Micro-

TABLE VI

Duration of heating	Temperature	Activity taken up (c.p.m.)	
None	25° C.	108	110
17 hr.	450° C.	29	76
17 hr.	540° C.	30	25
17 hr.	850° C.	30	25

scopic examination of the above surfaces before activation revealed that crystals were commencing to form in the polished surfaces of all the heated foils, suggesting that annealing of silver can be carried out at quite low temperatures. The data of Table VI confirm this, showing that the heated foils took up radioactivities comparable to those taken up by annealed foils.

Four highly polished silver slugs were heated to 850° C. for different times and then immersed in solution No. 2. After heating, the surfaces of the slugs still had a mirror finish. Table VII shows that heating to 850° C. for short times causes polished surfaces to revert to crystalline behavior with respect to the exchange with silver nitrate solution.

MISCELLANEOUS EXPERIMENTAL DATA

It was thought that if the polish layer was "vitreous" or, in effect, an undercooled liquid, the behavior of a silver amalgam would be similar. Four polished silver disks were placed on the wax block, and their surfaces amalgamated. The block was immersed in active solution No. 1 for one hour, and then one disk was removed. The disks were all covered with crystals, unevenly deposited, some of which were so loose that they washed off while the block was being rinsed with water. After a further two hours in the solution, a second disk was removed; its surface was as crystalline as if etched with nitric acid. Upon counting, both disks gave more than 9000 c.p.m., and it was concluded that the mercury was displacing silver from the solution.

Two "dumbbell" pieces, or connected pairs of disks, one of each pair polished, the other etched, were put into the same solution that was used in the experiment with the amalgamated disks. One was removed after $17\frac{1}{2}$ hr., and the two disks separated and counted. The etched disk had an activity of 1228 c.p.m., and the polished one 145 c.p.m. After a further $23\frac{1}{2}$ hr., the other pair was removed and counted, the results obtained being 1156 c.p.m. for the etched disk and 257 c.p.m. for the polished. To check this behavior, two more connected pairs and two separated pairs of disks were immersed in the same solution. After two hours, a pair of connected and a pair of unconnected disks were taken off and counted; the results were: etched connected, 101 c.p.m.; polished connected, 39 c.p.m.; etched unconnected, 438 c.p.m.; polished unconnected, 31 c.p.m. After another 20 hr., the remaining pieces showed the following radioactivities: etched connected, 891 c.p.m.; polished connected, 91 c.p.m.; etched unconnected, 649 c.p.m.; polished unconnected, 95 c.p.m. The abnormally high activity taken up by all etched disks, connected or unconnected, since the mercury was put into the solution, indicated that the mercury ions were interfering with the silver ion exchange.

Rollin introduced gold and platinum foils into the radioactive silver nitrate solution, and observed radioactivities taken up by the foils amounting to a penetration of 100 atomic layers. To check this, two gold and two platinum disks were annealed for 24 hr. at 900° C., etched with aqua regia, placed on the wax block, and one of each polished with wet alumina. (The platinum foil was so thin that not much pressure could be used in the polishing.) After immersion in radioactive solution No. 1 for 21 hr., the disks showed the following radioactivities: polished gold, 100 c.p.m.; etched gold, 20 c.p.m.; polished and etched platinum, 10 c.p.m. each. Examined under the microscope, the polished platinum disk showed a very crystalline surface. The counts obtained from the gold pieces seem to indicate that exchange takes place between gold metal and silver ions in silver nitrate solution.

The electrochemical behavior of polished and crystalline substrates of silver was investigated in the following manner: silver from a silver nitrate solution containing Ag^{110} was electroplated on polished and crystalline substrates, and was removed by making the electroplated surface the anode in the plating cell. The electrodes were silver slugs $\frac{3}{4}$ in. in diameter and $\frac{1}{8}$ in. thick. These were supported in the cell by 1/16 in. platinum rods which also served as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

electrical contact with the slugs. The plating bath was 0.002 *N* silver nitrate having a radioactivity of 1.5×10^4 c.p.m. per ml. In these experiments, sufficient silver was plated on the slugs at about 0.3 ma. to give them an activity of approximately 12,000 c.p.m., representing a charge transfer during plating of about 0.09 coulombs. Silver was removed from the slugs by reversing the polarity of the cell and passing about 0.03 coulombs per increment. To determine the amount of silver removed, a coulometer containing the same silver nitrate solution was placed in series with the removal cell, the coulometer cathode and removal cell anode being counted between increments. Activities were corrected for coincidence losses using the manufacturer's statement of the counter resolving time. The coulometer cathode was replaced by an inactive cathode when its activity exceeded 12,000 c.p.m., in order to reduce counting errors. The data are tabulated in Table VIII.

TABLE VIII

Run No.	Substrate type	Anode activity, %	Coulometer cathode activity (as % original anode)
1	Crystalline	100	0
		64.7	29.5
		45.3	54.5
		34.2	81.3
		27.5	103.5

		77.3	310.7
		74.4	383.4

The curves in Fig. 11, showing activity remaining on the anode plotted against coulometer cathode activity, were made from the data for runs 3 and 4, one employing a polished and the other a crystalline silver substrate. These curves reveal a difference in the behavior of silver electroplated on polished and crystalline substrates, since the silver electroplated on crystalline surfaces was removed much more readily than silver plated on the polished surfaces.

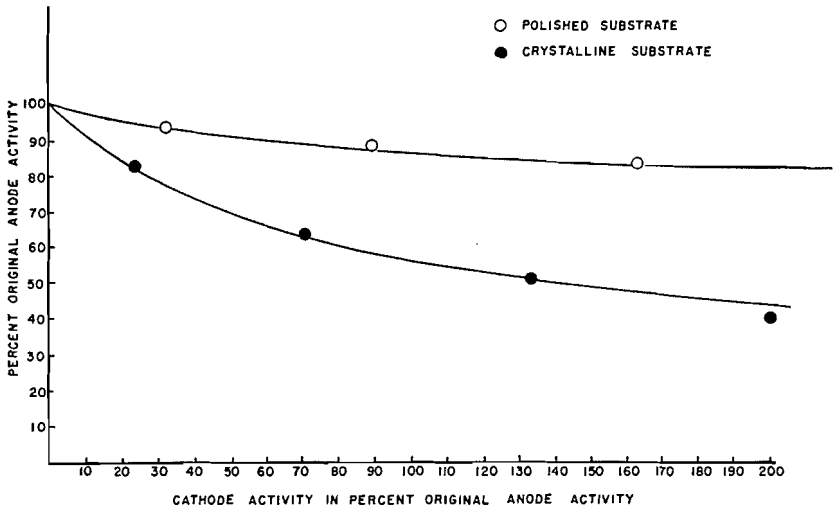

FIG. 11. Electrochemical removal of activity from polished and crystalline surfaces.

DISCUSSION

Of all the work on metal–metal ion exchanges reported to date, the experiments of the present authors seem to be the only ones where care was taken to produce either completely crystalline or completely "non-crystalline" surfaces. As was found in these experiments, etching silver foils in the "as-received" condition sometimes produces surfaces which contain a large percentage of "worked" material. The low extent of the exchanges with etched surfaces found by Baerg and Winkler indicates that the amount of "non-crystalline" material was small; this was merely fortuitous, however. In the experience of the present authors, some foils as received produced good crystalline surfaces when etched with nitric acid; however, the best crystalline surfaces, which take up the least radioactivity from a radioactive silver nitrate solution, can only be consistently produced by annealing the metal before etching.

As far as can be ascertained from the published reports, none of the other workers produced a really good polished surface either. The operation of polishing, as demonstrated years ago by Beilby (3), consists in more than a mere levelling of the surface by wearing down projections. The use of abrasives such as emery results in a cutting down of projections and a working of the surface to some extent, but crystalline metal is left exposed between the scratches made by the abrasive, as can easily be seen with a microscope. The true polishing action is performed only by using a very soft material such as chamois, kidskin, or the felt polishing cloths supplied for use on the Buehler metallographic polishers, and a very fine wet powder (alumina seems to be the best). With the microscope it can be seen that this process causes metal to flow like a liquid for a short distance. Hollows are bridged over or filled in, ridges disappear, and the whole surface becomes very smooth, lustrous, and

For personal use only.

noncrystalline. There seems to be little doubt that the Beilby layer is "vitreous", or, in effect, a supercooled liquid. The local pressures developed must be very high, and it was shown by Bowden and Ridler (4) that the local temperature rises to the melting point of the metal. In electron diffraction studies a pattern similar to that of a liquid was obtained from a polished surface (25), and Finch, Quarrel, and Roebuck discovered that a polished surface of copper dissolved zinc atoms to form a brass, while crystalline copper under the same conditions received only a deposit of zinc metal (9). Dobinski very carefully prepared polished specimens in the absence of oxygen, and showed that the surface was amorphous (7). It is of interest that for silver he found no evidence of oxide on surfaces polished in air. Lees (20) and Hopkins (17) performed experiments which indicated that the polish layer has a depth of 30 Å. For excellent modern ideas about the "Beilby layer" Reference (23) should be consulted (papers other than Simnad's and discussions).

The rapidity of the uptake of radioactivity by crystalline surfaces and the ease of removal of 75% to 90% of it in inactive solution suggests that most of the activity acquired by such surfaces is in the form of an adsorbed layer on the surface. King and Schochet have measured the amount of silver nitrate adsorbed on silver metal powder from solutions, and the results indicate that adsorption amounts to less than one monolayer of atoms (19). A comparable value was found by Baerg and Winkler for activity which seemed to be adsorbed, and could be "plated" onto the surface by rendering the surface cathodic in the Bowden–Rideal cell. The radioactivity which was not removable by exchange with inactive solution was held by Baerg and Winkler to be incorporated into the surface layers of the crystal lattice, and the theories of this crystal growth are well discussed in their papers. Equilibration of the surface for long periods in inactive solution reduced the initial rate of exchange, probably because of the formation of electrical double layers of adsorbed inactive ions, in their view. The present authors suggest it would be expected that exchange with such layers would, if anything, be more rapid than with the crystal lattice, and that the decrease of exchange after equilibration is due to levelling of potential differences on the surfaces, as discussed below in connection with mixed surfaces.

The different behavior of highly polished surfaces indicates a different mechanism for their uptake of radioactivity. That adsorption does take place at first is shown by the deactivation experiments, where it is seen that polished surfaces which had been in the active solution for short times, down to one minute, lost up to 80% of their radioactivity when transferred to inactive solution, and that the radioactivity lost by polished surfaces was dependent on the time they had been in contact with the radioactive solution. After 17 hr. in the solution only about 30% of the acquired radioactivity was removable in this way. The rate of uptake was slower at first—this may be due partly to the smaller surface, and partly to the fact that the lack of a regular lattice makes adsorption more difficult. The regular increase of radioactivity taken up, the longer time required, and the greater retention after equilibrium is reached show that 70% of the silver ions which enter the metal become

unavailable for exchange. This can be due to changing of the surface structure as proposed by Haïssinsky, or to diffusion into the polish layer and thus away from the surface. The changing of the surface structure would presumably result from the dissolution of the anodic polish layer and the plating out of the silver ions from the solution in a crystalline form. This mechanism might explain the phenomena observed in the "controlled exchange" (Table VIII). If the silver plated out in crystalline "trees", on reversal of polarity the less noble polish material would dissolve first, leaving most of the Ag^{110} on the metal surface. Several further experiments might check this mechanism. Silver is notorious for its tendency to plate out as large "trees" from nitrate solutions, but addition agents such as gelatin make more uniform deposition possible. Plating from cyanide solution also results in smooth, uniform deposits. If this mechanism is correct, silver plated on polished substrates from silver nitrate with gelatin or from cyanide solutions should be more readily removed when the current is reversed. Similarly, the exchange between metal surface and solution should be affected if such addition agents or complexing agents are used.

The other explanation of the behavior of highly polished surfaces is that a truly "kinetic" exchange takes place between the polish layer and the solution, analogous to that between a liquid metal like mercury and an aqueous solution of one of its salts. According to this view, silver ions on the polished surface change places with silver ions which strike the surface from the solution. Because of the amorphous or vitreous state of the metal in the polish layer, the atoms or ions in it have a much greater mobility than do those in crystalline metal. Besides enhancing the exchange activity, this increased mobility allows a more rapid diffusion into the interior of the polish layer, and thus a greater extent of radioactivity uptake. The behavior of the foils which had been left for 228 days after their first activation and then did not deactivate at first with inactive solution or even lose activity when etched with dilute acid, although in radioactive solution they rapidly acquired more activity part of which was removed if the foils were again immersed in inactive solution, seems to support the diffusion hypothesis. The dissolution of zinc atoms in the polish layer on copper, reported by Finch, Quarrel, and Roebuck, and the work of Finch and Sun on electroplating onto polished substrates (10) inclines to the view that the behavior of the polished surface is due to actual entry of the ions from the solution into the liquid-like polish layer. It should be possible by further experiments, such as by pretreatment of long duration of polished surfaces in inactive solutions, and by diffusion experiments, to establish one or other of these mechanisms as the correct one.

On mixed surfaces, such as are prepared by exposing the interior of cold-worked metal, or by abrading with emery or partially polishing a crystalline surface, much of the radioactivity would seem to be acquired by electrolytic deposition onto the more crystalline portions, due to the local potential differences between the anodic worked or vitreous areas and the cathodic crystalline portions of the surface. This is shown by the autoradiographs of the surface of the cold-rolled piece, Fig. 8, and those of Simnad and Ruder. On such

a worked surface the actual area of the metal is much greater than on an annealed surface, owing to fragmentation of the crystallites, and a virtually infinite number of crystal faces with completely random orientations, of both low and high indices, is exposed. This condition greatly enhances the exchange ability of the surface, but in addition there is the electrolytic action between the anodic worked material and the cathodic ordinary crystalline material. When potential differences have been evened out, and the local currents have ceased, exchange between any vitreous material remaining and the solution can still take place, so that the final amount of radioactivity uptake and the distribution of the radioactivity depend upon the relative amounts of worked and unworked metal on the surface. Tables II and III and Fig. 7 show how the ratio of vitreous and crystalline metal affects the rate and extent of activity uptake by the surface. When the vitreous material exceeds a certain proportion the uptake of radioactivity decreases, the surface behaving more like a completely polished one.

Heat treatment of polished surfaces resulted in a revision of their behavior to that of crystalline surfaces, although these surfaces still appeared highly polished after heat treatment. It would be interesting to see whether short heat treatment results in the formation of a mixed surface before truly crystalline behavior begins.

The retention of radioactivity up to 95% by mixed surfaces when transferred to inactive solution supports the belief in the electrolytic deposition mechanism, since ions when plated onto the crystalline metal would not exchange like those merely adsorbed as in the beginning of the ordinary exchange process.

The decrease in activity uptake after long immersion in inactive solution, observed by Baerg and Winkler using abraded foils, can be explained as due to the evening out of local potential differences, so that the electrolytic action does not take place when the surface is exposed to the radioactive solution. The result of the dissolving of anodic material and the deposition onto the crystalline metal should result in the surface becoming more crystalline, or completely crystalline, if the ratio of vitreous to crystalline metal is right. With a perfectly polished surface, however, there should be no electrolytic action, and in the absence of nuclei, no recrystallization, unless nuclei are formed by the action of the solution. Rollin's observation of the effect of sodium nitrate solution on his mirror surface would indicate that the surface was activated in some way by the solution, perhaps by the formation of an absorbed double layer of sodium and nitrate ions, which exchanged rapidly with the silver nitrate solution.

The exchange with gold and platinum surfaces must be due to either adsorption, intermetallic compound formation, or a purely kinetic exchange, resulting in the formation of a solid solution, as observed by Finch *et al.* with zinc and copper. These metals are too far below silver in the electrochemical series for any electrolytic action between them. The exchange experiments with the silver amalgam, on the other hand, seem to show much electrolytic action between mercury (with a standard potential of -0.7986 v.) and vitreous and crystalline silver. (The standard potential of silver is given variously in

tables as −0.7978 v. and −0.7995 v.) Rapid kinetic exchange between mercury and silver nitrate solution probably took place also, and perhaps initiated the electrolytic action, by allowing the mercurous ions to get into the solution. It would appear that the vitreous silver displaced mercury ions from the solution, which in turn displaced silver ions onto the crystalline silver metal. The papers of Groh (12) and Kayas (18) should be consulted for the behavior of amalgams other than silver.

The exchanges with polished and mixed surfaces all follow fairly satisfactorily the empirical equation $\log x = a \log t + b$, first stated by Haïssinsky (where x is the radioactivity of the metal, t is the time of immersion, and a and b are constants which differ for each run), until a maximum value is reached, when the curve levels off. The data for the highly polished surfaces also may be expressed by the equation $\log[(x_\infty - x)/x_\infty] = kt$, where x_∞ is the

maximum radioactivity taken up, and x is the radioactivity at time t. This latter equation is the one followed by mercury and amalgams, as well as by silver metal powder and copper, and indicates a kinetic type of exchange. The reverse exchange (radioactive metal – inactive solution) for a mixed surface also follows the equation of Haïssinsky (with different values for the constants), but that for a highly polished surface fitted the equation $\log x = at + b$ rather better. This of course is also a first order kinetic equation, being the integrated form of the equation $dx/dt = ax$, and indicates that the concentration of radioactive atoms, x, available at the beginning of the exchange remains so during the measurements. The differential form of Haïssinsky's equation, $dx/dt = ax/t$, shows that the rate of change of activity in the metal is inversely proportional to the time, as well as being directly proportional to the initial concentration. This seems to indicate that the number of active atoms at the surface available for exchange becomes smaller in a

regular manner with the passage of time. This might be due to the electrolytic action or to diffusion into the metal or to both. Pitts has derived a log–log equation to explain the exchange between silver salts and a silver solution, and concluded that a diffusion mechanism exists (21). Figs. 12, 13, 14, and 15 show how the data fit the various equations.

Gerischer and Vielstich calculated from their results the self-diffusion coefficient in silver metal. In view of the above discussion on the state of the metal, it seems to the present authors that what they measured was probably the self-diffusion coefficient in the distorted, worked metal, or along the grain boundaries, where dislocated atoms are also in a much more mobile state than in the interior of the grains (11). They would probably find a difference when they continued their work with single crystals. Winegard and Chalmers measured the self-diffusion of silver along a surface and obtained a value of 2×10^{-9} cm.^{2}/sec. (at 400° C.) (27). They took care in the preparation of their surface (of a single crystal) to avoid forming any "flowed" metal, however.

To recapitulate, the authors, from a study of their own work and that of others who have investigated the exchanges of metals with their ions in aqueous solutions, conclude that such exchanges depend upon the state of the surface. With completely crystalline surfaces, the exchange, if it takes place at all, is of very small extent. Activity is taken up by adsorption, and perhaps by electrodeposition due to small differences of potential between different positions on the crystals. With completely polished surfaces, either the ions from the solution are plated out in a crystalline form while the anodic polish material dissolves, or else a true kinetic exchange takes place, and ions which enter the metal surface from the solution diffuse into the polish layer at a rate very much higher than that of ions in the crystals. With mixed surfaces, partly crystalline and partly amorphous, these processes both occur and in addition there is much electrolytic action between the anodic amorphous material and the cathodic crystalline material.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of W. D. Jamieson in carrying out some of the experiments, and their indebtedness to the National Research Council of Canada for two bursaries and a summer research grant, and to the Defence Research Board of Canada for a grant, number 2-1-87-156, Project D44-75-35-03.

THE POLYMERIZATION OF ETHYLENE SENSITIZED BY ETHYL IODIDE[1]

By V. B. Sefton[2] and D. J. Le Roy

ABSTRACT

The polymerization of ethylene sensitized by the thermal decomposition of ethyl iodide in the presence of mercury vapor has been studied at 250°, 275°, and 300°C. C^{14}-labelled ethyl iodide was used in a number of experiments. The increase in the rate of decomposition of ethyl iodide in the presence of ethylene and the formation of butyl iodide are accounted for by equilibrium processes of the type $RI+Hg = R+HgI$. The important features of the reaction were established from the identity, quantity, and activity of the various products. The predominant formation of olefins is attributed to the isomerization and decomposition of large radicals. Very little of the butane is formed by the combination of ethyl radicals. Radical disproportionation is the most important chain termination step.

The decomposition of the lower alkyl iodides has been studied extensively (10) and it is generally agreed that in both the thermal reaction and in the photolysis in the region of the continuum (*ca.* 2600 Å) the primary process consists in the formation of alkyl radicals and iodine atoms. The quantum yields of the photochemical process are low because of the back reaction but can be greatly increased by trapping the iodine atoms with mercury or silver. The thermal or photochemical decomposition of alkyl iodides in the presence of ethylene and either mercury or silver should therefore afford a convenient method for studying the free radical sensitized polymerization of ethylene.

Jungers and Yeddanapalli (5) have studied the polymerization of ethylene sensitized by the photolysis of methyl, ethyl, *n*-propyl, and isopropyl iodides in the presence of mercury at temperatures in the range 130° to 275°C. Under conditions likely to yield low radical concentrations, viz. low iodide concentrations, high ethylene concentrations, and low light intensities, they found that the "yield", defined as the ultimate pressure decrease on prolonged irradiation divided by the initial pressure of iodide, reached maximum values which were in the approximate ratio 3.5 : 3.0 : 2.5 for methyl, ethyl, and the propyl iodides, respectively. They concluded from this that the final polymer had approximately the same molecular weight in each case and that for steric reasons the growing radicals formed by the successive addition of ethylene molecules underwent chain termination when they reached a more or less common critical size. According to their mechanism all the products should be saturated, for at low radical concentrations they assumed that chain termination would take place by the reactions

$$R+C_2H_5I = RH+C_2H_4I \qquad [1]$$

$$C_2H_4I = C_2H_4+I, \qquad [2]$$

while at high radical concentrations they assumed that it would occur by

[1]*Manuscript received September 22, 1955.*

[2]*Present address: Canadian Industries (1954) Limited, McMasterville, Quebec.*

radical combination. Radical disproportionation would also be expected to occur, in the light of more recent work (9).

Although Jungers and Yeddanapalli did not analyze their products their conclusions appeared to be well founded. However, because of the fundamental importance of polymerization reactions it seemed desirable to make a further study of the problem taking advantage of fractionation methods and infrared spectra as analytical tools. In the present work the polymerization of ethylene was initiated by the thermal decomposition of ethyl iodide in the presence of mercury. In order to obtain as much information as possible about the reactions of the ethyl radicals a number of experiments were performed using ethyl iodide labelled in the methylene group with C^{14}.

EXPERIMENTAL

The Reaction System

The reaction vessel used in most of the experiments consisted of a Pyrex cylinder having a volume of approximately two liters. The cylinder was mounted vertically and a cooling thimble was placed in the connecting tubing at the point where it emerged from the furnace. By passing compressed air through the thimble the mercury which distilled from the pool at the bottom of the cell was condensed and allowed to drop back into the cell. A mercury cutoff served to isolate the cell during an experiment and this was used as a manometer to give a rough measure of the amount of reaction taking place.

The initial ethyl iodide was measured accurately as a gas, using a separate calibrated volume and a modified Pearson gauge. It was then frozen into the cell by placing liquid air in the thimble. Ethylene was measured and admitted in the same way. The cell was filled at room temperature, and since the reaction was allowed to proceed from $4\frac{1}{2}$ to 38 hr. rapid heating was not considered essential. At the end of an experiment the temperature was lowered by cutting off the current and blowing air through the furnace. When the cell had cooled to approximately room temperature the final pressure was measured and corrected to 25°C.

For the experiments with ethylene and ethyl iodide in the absence of mercury and those with ethyl iodide and mercury in the absence of ethylene a special cell having a volume of 720 $cm.^3$ was used. The reagents were measured as described above and condensed into the cell by immersing it in liquid air. It was then sealed off and placed in the furnace. At the end of an experiment it was sealed to the apparatus at a breakoff valve.

Reagents

The ethylene used had a rated purity of 99.5%. It was treated with 2 *N* ammoniacal silver nitrate to remove traces of acetylene, dried over Drierite and phosphorus pentoxide, and subjected to a number of trap-to-trap distillations.

The inert ethyl iodide was distilled in an 18 plate column and thoroughly degassed before being placed in a storage vessel isolated with a mercury cutoff. The active ethyl iodide, labelled with C^{14} in the methylene group, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

obtained from Tracerlab. The original 0.3 gm. sample had an activity of one millicurie. It was immediately diluted to 2 gm. with inert ethyl iodide and the portion of this used in the experiments was condensed into a storage bulb and isolated with a mercury cutoff. Both the active and inactive iodides were kept frozen with dry ice to avoid decomposition.

In preparing a sample of active ethyl iodide for an experiment suitable amounts of the active and inactive materials were removed from the storage bulbs, measured in the gas burette, and mixed. An aliquot of this material was then used to obtain the activity of the material to be used in the experiment. In a number of cases aliquots were distilled to remove any active material other than ethyl iodide which might have been present in the original sample. Since no such products could be found the distillation was subsequently eliminated.

Distillation of the Products

Ethylene and ethane were removed by distillation at $-168°$ to $-170°$C. (7). Since no acetylene could be found the second fraction was taken off at an initial pressure of 1.0 mm. (*ca.* $-100°$C.), the cut being made at 0.2 mm. (*ca.* $-50°$C.). The second fraction and the residue remaining in the still were separately treated to remove iodides as described below and then redistilled into a number of fractions using initial and final takeoff pressures of the order of 0.2 and 0.05 mm., respectively. Only for the smaller fractions did the final takeoff temperature exceed the initial by as much as four or five degrees.

Separation and Analysis of the Iodides

A study of the infrared spectrum of the products showed that both ethyl and *n*-butyl iodide were present, although the initial material was free from the latter. Because of their different vapor pressures a fairly complete separation of the two was achieved in the fractionation referred to above. The iodides were removed from the fractions containing them in two ways. In the first method the fractions were frozen onto an aqueous paste of silver metanitrobenzoate which was then allowed to warm to room temperature and stand overnight, resulting in the formation of the ethyl or butyl ester and silver iodide. The residual wet gas was frozen onto solid potassium hydroxide and finally dried for 12 hr. in contact with phosphorus pentoxide. The infrared spectrum of the dried gas showed that the iodides were completely removed by this method.

To determine the amount of ethyl or butyl iodide the mixture of the ester and silver iodide was treated with warm concentrated nitric acid and then diluted with water and centrifuged. The supernatant liquid was then removed. The residual silver iodide was further extracted with 50% aqueous ethanol, filtered, dried, and weighed. Tests on known mixtures of hexane and ethyl iodide showed the method to be accurate to about 2%.

In some of the experiments with active ethyl iodide the silver metanitrobenzoate method was used in an attempt to obtain the activities of the two iodides. In this case the esters were extracted from the silver iodide with petroleum ether. After evaporating the solvent the esters were hydrolyzed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

with 2 *N* sodium hydroxide; the resulting alcohols were then converted to barium carbonate as described below. However, it was found that the silver metanitrobenzoate reagent also removes quantitatively compounds with terminal unsaturation, although it does not remove other olefins to any degree. Although it was apparent that the method could not be used for the determination of the activities of the iodides it was used to remove terminally unsaturated olefins, and this made it possible to determine the activities of the remaining 2-alkenes.

The method ultimately used to determine the activities of the iodides involved their reaction with hexamethylenetetramine in chloroform solution. The resulting quaternary salt is insoluble in chloroform and was filtered off and burned for the activity determinations.

Infrared Gas Analysis

A Perkin-Elmer model 12-C instrument was used, but because of the small samples obtainable the optical arrangement was modified. The glow bar was removed from its normal position to a point on the same optical axis but about 80 cm. from the light chopper. Between the two was placed the cell, consisting of a Pyrex tube 70 cm. long and 15 mm. in diameter. The end near the glow bar was flanged out to about 40 mm. Sodium chloride windows were sealed to each end of the cell and a stopcock and cold finger were sealed to the flanged end for freezing the gas into the cell and for obtaining the blank trace. Despite the very poor optical properties of this arrangement there was an appreciable net improvement in the accuracy with which small samples of gas could be analyzed.

In setting up the quantitative analysis scheme for the hydrocarbons the spectra of a number of standard samples obtained from the United States Bureau of Standards were taken at various pressures. Because of their small extinction coefficients at usable analytical wave lengths the amount of paraffin in a sample was usually determined by subtracting the amount of olefin from the total pressure. These results were checked by taking the spectrum of the residue from the treatment of the olefin–paraffin mixture with mercuric acetate, described below.

Activity Determinations

Samples for combustion were condensed into a gas burette consisting of a number of connected bulbs, one of which contained a cold finger which could be filled with liquid air. After measuring the volume of the gas oxygen was allowed to mix with it by opening a stopcock at the top of the burette. By slowly raising the mercury in the burette the mixture was fed into a continuous stream of pure oxygen which flowed through a conventional microcombustion tube. The carbon dioxide formed was bubbled through saturated barium hydroxide solution. The barium carbonate was collected and washed on a filter paper held in a Tracerlab E-8A precipitation apparatus. Carbon numbers calculated from the weights of dried barium carbonate were usually a few per cent low, presumably because of incomplete trapping of the carbon dioxide in the barium hydroxide solution.

The C^{14} activity of the ethyl iodide used in any particular experiment was arbitrarily given a value $A = 1$, and the activities of the various products were measured relative to this on a molar basis. To obtain A the measured number of counts per minute, C_{obs}, was first corrected for the background count C_b. A correction for self-absorption was then made using the data of Yankwick *et al.* (12). For a constant area of barium carbonate precipitate (2.83 cm.^{2}, compared to our value of 2.82 cm.^{2}) having various weights per unit area X, they obtained a function $J(X)$ such that $(C_{obs}-C_b)/J(X)$ is equal to the number of counts per minute corrected for background and self-absorption. To allow for any variation in the sensitivity of the geiger tube the count on the sample was always followed by one, C^*, taken on a standard reference sample of barium carbonate using the same geometry. A quantity S, proportional to the specific activity of the sample, was then obtained,

$$S = \frac{(C_{obs}-C_b)/J(X)}{(C^*-C_b)W},$$

in which W is the weight of barium carbonate in the sample. The molar activity of the sample relative to that of the ethyl iodide used, referred to in the text simply as molar activity, is then given by

$$A = (S_s/S_i)\ N/2,$$

in which the subscripts s and i refer to the sample and to the iodide, respectively, and N is the number of carbon atoms in a molecule of product. A typical result, found for the hexane obtained in one of the experiments, is illustrated in Table I. The value of the molar activity of the hexane indicates that it contains, on the average, one ethyl radical derived from ethyl iodide.

TABLE I

DETERMINATION OF THE MOLAR ACTIVITY OF HEXANE

Material	W, mgm.	X, mgm./cm.^{2}	$J(X)$	$C_{obs}-C_b$, c.p.m.	C^*-C_b, c.p.m.	S	A

Hexane	31.48	11.18	0.300	4350	4410	0.1045	0.95

Separation of Olefins from Paraffins

To determine the molar activity of a paraffin it was necessary to separate it from the unsaturated compounds present in the same fraction. This was accomplished by an adaptation of the hydroxy-mercurial method (8). The gas was frozen into a 100 ml. flask containing 20 ml. of saturated aqueous mercuric acetate and 10 ml. of 3% hydrogen peroxide which had previously been degassed. The flask was then warmed to room temperature and shaken, intermittently, over a period of 12 hr. The residual gas and 1 or 2 ml. of the liquid were then distilled onto solid potassium hydroxide. After several hours the contents were cooled with dry ice and the hydrocarbons distilled back into the system and measured. For compounds of higher molecular weight than bu-

tane the final drying was made with phosphorus pentoxide rather than dry ice. The infrared spectra showed complete removal of olefins by this method. Analysis of synthetic mixtures showed the method to be quantitative for mixtures of ethane and ethylene. For other olefin–paraffin mixtures there was a slight loss of paraffin; in these cases the quantity of paraffin was estimated by the infrared method.

Nonvolatile Products

After a series of experiments in which ethylene, ethyl iodide, and mercury had been used the nonvolatile material in the reaction vessel was extracted with carbon tetrachloride. The absence of an appreciable residue on evaporating the solvent indicated that no diiodoethane was present. Except for the mercury, the nonvolatile material was completely soluble in aqueous potassium iodide. Chemical tests showed the presence of mercurous iodide. The absence of diiodoethane was also confirmed in the experiments with ethyl iodide and mercury alone.

RESULTS

Products

In Table II are shown the results of pairs of experiments done at 250°, 275°, and 300°C. The amounts of the products are given in mm. pressure in the reaction vessel at 25°C. The values of $-\Delta P/-\Delta C_2H_5I$, analogous to the

"yield" of Jungers and Yeddanapalli (5), are seen to be sensitive to the initial iodide pressure but relatively insensitive to temperature, in agreement with their observations. The value of approximately three for low iodide pressures is identical with their value for low ethyl radical concentrations. However, instead of the products being all saturated, as they predicted, it is seen that there is considerably more olefin than paraffin. The proportion of olefin is greater for low than for high ethyl iodide concentrations, and even in the latter case the amount is greater than could be accounted for by disproportionation.

Qualitative infrared analysis of the fraction listed in Table II as "C_7 and higher" showed it to be composed of hydrocarbons containing the groups $CH_2{=}\underset{\displaystyle R'}{\overset{\displaystyle |}{C}}{-}R$ and $CH_2{=}CHR$, in which R and R′ are saturated radicals. The amount of this fraction was determined as the difference between the total final pressure and the sum of remaining individual product pressures. From the carbon balance of the reagents and products the average carbon number of this fraction was found to be approximately nine.

After treating the C_6 fraction with mercuric acetate it was possible to identify a hydrocarbon having an important band at 10.10 microns. Because of the small amount present it could not be positively identified, although the spectrum strongly resembled that of methyl cyclopentane. It was estimated that it could have amounted to 10 to 20% of the C_6 "paraffin".

Since the only products formed were alkanes, mono-olefins, cycloparaffins, and butyl iodide, it follows that the amount of paraffin produced must be equal to one half of the difference between the amount of ethyl iodide consumed and the amount of butyl iodide formed. The values of "Total paraffin calc." listed in Table II were obtained in this way; "Total olefin calc." was obtained by difference.

No evidence could be found for either methane or hydrogen. Pentane, if formed, did not exceed 5% of the sum of butane and hexane. The maximum amounts of pentene-1, cyclopentane, or cyclohexane that could be present were estimated to be less than 0.1 mm. The amount of *cis*-butene-2 could not exceed 20% of the *trans* isomer. The maximum amount of hydrogen iodide was estimated to be less than 0.01 mm.

Isotope Effect in the Decomposition of Ethyl Iodide

An appreciable carbon isotope effect has been observed in the thermal decomposition of a number of organic compounds (4) in which the decomposition has involved the rupture of C—C bonds. In the present instance a rupture of a C—I bond is involved. In most of the experiments a large part of the ethyl iodide was decomposed and hence, even if there were an isotope effect, the proportion of C^{14} in the ethyl radicals formed would be approximately the same as in the original ethyl iodide. However, the proportion of inactive ethyl radicals might be greater at the beginning of an experiment when the ethyl radical concentration is higher and the instantaneous value of the

For personal use only.

"yield" is lower. Erroneous conclusions might therefore be drawn from the final measured activities of the products. To ascertain if the isotope effect were significant experiments were performed in which considerably different amounts of active ethyl iodide were decomposed in the presence of mercury but in the absence of ethylene. The results are shown in Table III. The activities are given in terms of the quantity S, defined previously. It is clear from the table that the variations in S are within the probable error of its determination and that the decomposition of ethyl iodide does not involve an appreciable isotope effect.

Activity of the Products

The results of a series of experiments using active ethyl iodide are shown in Table IV.

The use of a tracer does not make it possible to determine the amount of ethylene *formed* in the reaction since it might not have originated from ethyl iodide. However, the minimum amount formed can be estimated on the assumption that it would have a molar activity of unity. The values given in Table IV for ethylene formed were obtained in this way. About all that can be said with certainty is that some ethylene is formed and that its amount is probably of the same order as that of the ethane.

Experiments 11 and 13 are of particular interest because of the very large amounts of *n*-butyl iodide formed when the concentration of ethyl iodide approaches that of the ethylene.

DISCUSSION

One would infer from previous work that the initial process involves the decomposition of ethyl iodide into an ethyl radical and an iodine atom. However, a comparison of the results of experiment 31 (Table III) and experiment 27 (Table II) shows that the presence of ethylene greatly accelerates the rate of decomposition of ethyl iodide, which suggests that equilibria of the following type may be involved.

$$C_2H_5I + Hg \rightleftharpoons C_2H_5 + HgI \quad [3]$$

$$C_2H_5I + HgI \rightleftharpoons C_2H_5 + HgI_2 \quad [4]$$

The addition of ethylene would lower the ethyl radical concentration and accelerate the decomposition of ethyl iodide.

Although the initial stages of the polymerization of ethylene undoubtedly consist in the successive addition of ethylene to ethyl radicals, a number of possible steps can be suggested for the formation of the ultimate products from the linear 1-alkyl radicals produced in this way.

(*i*) *Reaction with Ethyl Iodide to Form a Linear Alkane* (*Reaction* [1])

It has been suggested by a number of workers that reactions of this type play an important role in the photolysis of ethyl iodide (5, 11). However, their evidence is by no means convincing. West and Schlessinger (11) found that methylene iodide was formed in the photolysis of methyl iodide provided no "getter" was used to trap the iodine; in the presence of silver none was formed. In the case of ethyl iodide they found no ethylene iodide under either circumstance. Jungers and Yeddenapalli (5) did not subject their products to chemical analysis, but simply quoted the results of West *et al.* as showing that [1] would occur at high concentrations of ethyl iodide. We were unable to find ethylene iodide under any conditions.

If it were formed, the radical C_2H_4I could conceivably disappear in a number of ways. If it decomposed to form ethylene and an iodine atom, or if it reacted with mercury to form ethylene and mercurous iodide, then 1 mole of active

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

ethylene would have to be formed for every mole of alkane formed by [1] or every mole of ethyl iodide decomposed by [1]. However, it is evident from Table IV that the amount of ethylene formed with a molar activity of unity did not exceed one-eighth of the total alkanes even at high concentrations of ethyl iodide. The possibility that the C_2H_4I radical could react with ethyl iodide to form ethylene iodide can be eliminated since the latter was not formed. If it reacted with alkyl radicals to form higher alkyl iodides, then these, in particular butyl iodide, would be expected to have a molar activity of two, which was not the case. Furthermore, in experiments 11 and 13 (Table IV) the amount of butyl iodide formed far exceeded the amount of alkanes produced, which could not be the case if reaction [1] had occurred. A suggested mechanism for the formation of butyl iodide will be given later.

(*ii*) *Combination of Radicals to Form Linear Alkanes*

It is evident from the olefin/paraffin ratios given in Table II that this process does not play a leading role. It can also be shown that only a small proportion of the paraffin could be formed in this way. The molar activity of the butane is much less than two. If it were formed by the combination of ethyl radicals a considerable proportion of the latter would have to be inert, i.e. arise from processes other than the decomposition of ethyl iodide. Since it is reasonable to assume that ethane is formed from ethyl radicals, it would follow that the molar activity of the ethane would have to be of the order of 0.5 or less, in disagreement with the data of Table IV. The same argument applies to the formation of hexane and higher paraffins.

(*iii*) *Disproportionation of Radicals to Form Alkanes and Either Cycloparaffins or Olefins*

This process would lead to olefin/paraffin ratios of unity or, if any combination took place as well, less than unity. While disproportionation cannot account for the major part of the olefin (and cycloparaffin) it can account for the alkanes and the corresponding amount of olefin.

(*iv*) *Hydrogen Abstraction from Olefins*

Reactions of this type can be discounted since the radicals of the vinyl type formed in this way would be certain to yield, ultimately, some diolefin, and no evidence for this could be obtained.

(*v*) *Decomposition of Radicals to Yield Olefins or Cycloparaffins, and an Alkyl Radical*

Reactions of this type must account not only for the compounds having an odd number of carbon atoms but also for the major portion of the olefin produced. It is readily seen, however, that a simple C—C bond rupture followed by the isomerization of the biradical is not the most probable process, as only inert olefins would be formed in this way.

If the observed olefin activities were due to disproportionation reactions, which involve two radicals, then the ratio of active to inactive butene would be expected to increase markedly with the radical, i.e. the ethyl iodide, concentration. Evidence for this is not conclusive. The results of experiments 17, 27, and 15 given in Table IV indicate an increase in the activity of the butene when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

the ethyl iodide pressure is increased, but similar experiments at 275°C. show a decrease in the molar activity of the butene from 0.5 to 0.4 when the ethyl iodide pressure is increased from 11.2 to 34.2 mm.

In their experiments on tetramethylene biradicals Bawn and Milsted reported "butylene" as one of their products but did not identify the particular isomer (2). Benson and Kistiakowsky (3), on the other hand, found cyclobutane to be the only C_4 product from the photolysis of cyclopentanone and questioned the previous conclusions of Norrish *et al.* (1). It seems likely, therefore, that if tetramethylene biradicals were formed by the decomposition of a linear alkyl radical some evidence of cyclobutane would be found. This was not the case.

Kossiakoff and Rice (6) have pointed out that in many cases the activation energy for the isomerization of a long-chain free radical is much less than the activation energy for its decomposition and that as a result there should be an equilibrium process involving isomeric forms of the free radical. In particular, they suggest that 1-hexyl radicals should isomerize readily by a 1–5 shift of the free valence to form 2-hexyl radicals. Furthermore, the latter should decompose more readily than the 1-hexyl isomer since propylene and a propyl radical would be formed in a single step. The propylene formed in this way would be active.

It is evident that 1-hexyl-5-C^{14} radicals can give rise to 2-hexyl-2-C^{14} radicals by a 1–5 shift of the free valence, or to 1-hexyl-2-C^{14} radicals by a 1–6 shift. The latter could isomerize to 2-hexyl-5-C^{14} by a 1–5 shift. Similar considerations may be applied to other large radicals. Their disproportionation will yield paraffins and olefins with molar activities of unity; their decomposition will yield olefins with molar activities less than unity.

Isomerization of 1-alkyl radicals is undoubtedly involved in the formation of olefins containing the group $CH_2{=}\underset{\displaystyle R'}{\overset{\displaystyle |}{C}}{-}R$. If the 2-methyl butene-1 were produced by the addition of (active) ethyl radicals to propylene, followed by the disproportionation of the resulting 2-methyl butyl-1 radical with another radical, then its molar activity would be at least as great as unity. The observed activity of less than 0.5 suggests that it arises through the addition of ethylene to 2-hexyl-2-C^{14} or 2-hexyl-5-C^{14} radicals, followed by a 1–7 and then a 1–5 shift of the free valence. Subsequent decomposition of the radical could yield either 2-methyl butene-1 and a propyl radical, or 2-methyl hexene-1 and a methyl radical. The molar activity of the pentene would be less than that of the heptene. As mentioned previously, evidence for compounds of the latter type was found in the "C_7 and higher" fraction.

The postulate that radical decomposition is usually preceded by isomerization of the original 1-alkyl radicals also affords an explanation for the fact that the activities of the ethane and butane are slightly less than unity. The decomposition of large radicals into olefins will give rise to some radicals having molar activities less than unity. The ethane and butane formed by the disproportionation of ethyl or butyl radicals with larger radicals will then have activities somewhat less than unity. This is supported by the fact that in any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

particular experiment the molar activities of the ethane and butane were closely related, as shown in Table V. It is also seen that the activities of these

TABLE V

COMPARISON OF MOLAR ACTIVITIES OF ETHANE AND BUTANE

Expt. No.	Temp., °C.	Molar activity of ethane	Molar activity of butane	Olefin/paraffin calc.
27	250	1.0	0.92	1.3
21	275	0.83	0.74	2.7
28	300	0.71	0.68	3.3

products are lower in the experiments in which the olefin/paraffin ratio was high, i.e. in the experiments in which radical decomposition was more important.

(*vi*) *Formation of Butyl Iodide*

It is significant that no butyl iodide was formed in the absence of ethylene. Also, its molar activity is less than unity, whereas it would be greater than unity if it were formed by the reaction

$$C_2H_5+C_2H_4I = C_4H_9I. \quad [5]$$

In experiments performed at 250°, 275°, and 300°C. with ethyl iodide and ethylene but in the absence of mercury there was no butyl iodide formed, which shows that its method of production is not through the reaction

$$C_2H_5I+C_2H_4 = C_4H_9I. \quad [6]$$

Evidence has already been given to show that the decomposition of ethyl iodide in the presence of mercury and the mercury iodides involves equilibrium processes. If so, butyl radicals could take part in similar equilibria, viz.,

$$C_4H_9+HgI = C_4H_9I+Hg \quad [7]$$

$$C_4H_9+HgI_2 = C_4H_9I+HgI. \quad [8]$$

Reactions of this type appear to afford the most satisfactory explanation for the formation of butyl iodide. The fact that its molar activity is somewhat less than that of the butane suggests that a small amount of the latter is probably formed by the combination of ethyl radicals.

SUMMARY

The use of C^{14}-labelled ethyl iodide together with extensive chemical analysis of the products has revealed a number of features of the ethyl iodide sensitized polymerization of ethylene not previously established. Some of these features apply specifically to the use of alkyl iodides as sources of free radicals while others would be expected to apply quite generally to the free radical sensitized polymerization of olefins.

The primary process in the presence of mercury has long been considered to be a C—I bond rupture, followed by the reaction of the iodine atom with mercury,

$$RI = R+I \quad [9]$$

$$I+Hg = HgI. \quad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

However, the fact that butyl iodide was only formed in the presence of mercury (and ethylene), and the fact that ethylene accelerates the rate of decomposition of ethyl iodide suggest that [11] is the primary process in the decomposition of alkyl iodides.

$$RI + Hg \rightleftharpoons R + HgI \qquad [11]$$

It is evident that if [10], as well as [9], is considered to be a reversible process then in the absence of reactions other than those indicated it is immaterial whether [9] or [11] is considered to be the primary process, since $K_{11} = K_9 \cdot K_{10}$.

The present experiments confirm previous evidence that larger 1-alkyl radicals are built up by the successive addition of ethylene to ethyl radicals,

$$C_2H_5 + C_2H_4 = C_4H_9 \qquad [12]$$

$$C_4H_9 + C_2H_4 = C_6H_{13}, \qquad [13]$$

etc.

The concentrations of the radicals would be expected to decrease in the order ethyl, butyl, hexyl, etc., since radical growth can be terminated at any stage. This is in keeping with the fact that butyl iodide was formed (by the reverse of [11]), but not hexyl or higher iodides.

The large olefin/paraffin ratios and the formation of products containing an odd number of carbon atoms show that the decomposition of large radicals into olefins and smaller alkyl radicals plays a major role under the experimental conditions used. Furthermore, the structures and molar activities of these olefins indicate that in many cases the large 1-alkyl radicals isomerize by 1–5 and 1–6 (and presumably other) shifts of the free valence before they decompose. As would be expected, the radical decomposition reactions are more important at low than at high radical concentrations.

Chain termination occurs by both combination and disproportionation of radicals, but the latter appeared to be the more important.

ACKNOWLEDGMENT

THE EFFECT OF ATMOSPHERE DEPLETION IN SPHERICAL DIFFUSION FLAMES[1]

By R. J. Cvetanović

ABSTRACT

Solutions of the second order non-linear differential equation of spherical diffusion flames have been obtained for the range of conditions of experimental interest. Deviations from the simplified exponential solution are presented in a form suitable for their direct evaluation. Some recent contributions to the theory of the method are discussed.

INTRODUCTION

The diffusion flame method of Hartel and Polanyi (5) is used for determination of the rate constants of some fast gas reactions. It is based on a comparison of the rate of reaction with the rate of diffusion of one of the two reactants. The latter is introduced through a nozzle into the reaction zone where it spreads by diffusion and encounters the other reacting substance, the "atmosphere reactant". The original theoretical treatment of the method implied the following three simplifying assumptions:

1. The mass flow of the two reactants can be neglected.
2. There is a spherical symmetry in the distribution of the nozzle reactant in the reaction zone.
3. The concentration of the atmosphere reactant is constant throughout the reaction zone.

In the steady state the general diffusion equation reduces then to the form

$$[1] \qquad \frac{d^2y}{dr^2} + \frac{2}{r}\frac{dy}{dr} - \frac{k_p}{D_y} yz = 0$$

where y and z are the concentrations of the nozzle and the atmosphere reactant, respectively, D_y is the diffusion coefficient of the former in the gas mixture, k_p is the value of the rate constant to this approximation, and r is the radius of the spherical reaction zone. Since z is assumed constant and equal to z_∞, the concentration outside the reaction zone, and y vanishes as $r \to \infty$, the solution of [1] is

$$[2] \qquad y = (A_p/r)\exp(-rC_p), \qquad \text{where } C_p = (k_p z_\infty/D_y)^{\frac{1}{2}}.$$

From the values of y, y_1, and y_2 at two points, r_1 and r_2 ($r_2 > r_1$), the rate constant can be calculated using the expression

$$[3] \qquad C_p = \ln(y_1 r_1/y_2 r_2)/(r_2 - r_1).$$

Since its introduction in 1930 the diffusion flame method has been widely used and a large number of experimental determinations have been reported

in the literature. The method was originally devised and is particularly suited for determination of the rates of reaction of sodium atoms, which are introduced into the reaction zone through the nozzle in a stream of an inert carrier gas. The extent of penetration of sodium in the reaction zone for given steady state conditions is established by optical means. An important extension of the method has recently been proposed by Kistiakowsky and his co-workers (2, 3), who based the evaluation of the rate constant on an exploration of the temperature pattern of the spherical reaction zone. The particular significance of the temperature pattern method lies in its potential applicability to a wider variety of processes, possibly also to some atomic and free radical reactions which may be difficult to evaluate quantitatively by other means.

At present, it appears impossible to treat mathematically the general case of a diffusion flame and take into account all the details of the process. The quantitative usefulness of the spherical diffusion method depends, therefore, on how closely the simplified model suggested by Hartel and Polanyi can be approached experimentally. After the early realizations of a large uncertainty in this respect, a thorough empirical study by Heller (6) resulted in a specification of the ranges of experimental conditions within which the simple model was considered valid to a good approximation. An attempt to extend the use of the method to very fast reactions (4) resulted in the observation of the formation of "core" flames, the flames assumed to contain a core of unreacted sodium into which no atmosphere reactant did penetrate. The calculated rate constants were strongly pressure dependent and a drastic change in experimental conditions was necessitated.

In a previous paper (1) a more elaborate model was considered and the theoretical treatment extended to take into account the fact that the atmosphere reactant is consumed in the reaction and its concentration is not constant in the reaction zone. It was shown that when the mass flow of the reactants is neglected, the spherical diffusion process is described by the differential equation

$$[4] \qquad \frac{d^2y}{dr^2} + \frac{2}{r}\frac{dy}{dr} - \frac{k}{D_z}y^2 + \frac{ky_1r_1}{D_z}\frac{y}{r} + \frac{k(z_\infty - z_1)r_1}{D_y}\frac{y}{r} - \frac{kz_\infty}{D_y}y = 0,$$

where D_z is the diffusion coefficient of the atmosphere reactant and z_1 its concentration at some particular value of the radius (r_1), and of which Equation [1] is a special case. Analysis of the derived expressions and of the single numerical solution available at the time for a particular set of experimental results showed that for relatively slower reactions the effect of the depletion of the atmosphere reactant by virtue of its consumption in the reaction was not large and that more appreciable effects could be expected for very fast reactions. Any quantitative conclusions in this respect, however, required solutions of Equation [4] for a wide variety of experimental conditions.

A function representing the generalized solution of Equation [4] has now been tabulated for selected cases covering the range of experimental interest. In the present article summarized results of the performed computations are given and their implications discussed.

Solutions of the Non-linear Differential Equation of the Spherical Diffusion Process

The radius r_1 and the corresponding concentrations of the two reactants, y_1 and z_1, in Equation [4] are in no way specified. It is, therefore, permissible to take for r_1 the particular value of r at which $z_1 = 0$, without having to consider, for the moment, how the values of y_1 and r_1 can be ascertained. Defining r_1 in this manner and writing

$$[5] \quad v = \frac{r}{r_1}\,\frac{yD_y}{y_1D_y+z_\infty D_z},\quad x = \frac{r}{r_1}\,\frac{z_\infty D_z}{y_1D_y+z_\infty D_z},\quad K = \frac{kz_\infty}{D_y}\left(\frac{r_1}{x_1}\right)^2 = C^2\left(\frac{r_1}{x_1}\right)^2$$

and consequently

$$[6] \quad x(r_1) = x_1 = 1/(1+y_1\,D_y/z_\infty\,D_z), \quad 0 < x_1 < 1, \quad v(x_1) = v_1 = 1-x_1,$$

the differential Equation [4] is transformed into the following generalized non-dimensional form

$$[7] \qquad \frac{d^2v}{dx^2} = \frac{Kv}{x}(v+x-1).$$

In view of the relations [6] and subject to the condition that $v \longrightarrow 0$ when $x \longrightarrow \infty$, the solution of [7] is

$$[8] \qquad v = \phi(K, x_1, x).$$

The function v has been tabulated for the following values of K and x_1:

x_1	Values of K										
.99	.001	.005	.01	.05	.1	.5	1	5			
.8	.001	.005	.01	.05	.1	.5	1	5			
.6		.005	.01	.05	.1	.5	1	5	10		
.4			.01	.05	.1	.5	1	5	10		
.2				.05	.1	.5	1	5	10	50	100
.1					.1	.5	1	5	10	50	100

The solutions have been obtained numerically by the Computation Centre of the University of Toronto and the details of the computational technique employed are given elsewhere (9). The tables of the computed values will be supplied on request. They lend themselves to graphical interpolation and can be readily used for the calculation of the rate constants for any of the usual experimental conditions. For most experimental applications, however, the graphs and the tables in the following section will give directly the magnitude of the deviation from the rate constants obtained from the simplified exponential solution given in Equations [2] and [3].

Deviations from the Exponential Solutions

(*a*) *The Diffusion Flame Method (The "Two-point Boundary" Method)*

The rate constants, k_p, obtained from the exponential solution can be calculated from Equation [3]. Taking into account relationships [5] and [6] it is readily seen that

$$[9] \qquad \delta = \frac{k}{k_p} = K(x_2-x_1)^2 \Big/ \left(\ln\frac{v_1}{v_2}\right)^2.$$

because of overlapping of some of the curves. In Figs. 1 to 4 δ is plotted against K_p, where

$$K_p = K/\delta = C_p^2(r_1/x_1)^2, \quad [10]$$

and not against K, because K_p can be readily calculated for given experimental conditions as well as x_1 and v_2/v_1, and the use of the graphs is thus made quite simple. The values of the rate constants are obtained from the relationship $k = k_p \times \delta$, after calculating k_p from Equation [3] and establishing δ by the use of the graphs.

(*b*) *The Concentration Pattern Method*

In the application of the "temperature pattern" method of Garvin and Kistiakowsky (3) a quantity proportional to the product of the concentration of the nozzle reactant and r at different values of r is obtained experimentally. Inasmuch as the exponential solution [2] is valid, a plot of $\log_e$ of this quantity against r should yield a straight line the slope of which is equal to $(-C_p)$. Equally well, a plot of $\log_e v$ against x would result in a straight line with a slope of $(-C_p r_1/x_1)$. The latter plots for some of the computed cases are given in Figs. 5–8, in which $\log_{10}(v/v_1)$ is plotted against $(x-x_1)$, as shown by full lines, for the values of x_1 indicated by the numbers on the lines and several values of K. The broken lines show the corresponding plots which would be

obtained for different values of K provided the exponential solutions were valid. The deviations can be estimated by comparing the slopes, since the ratio of the slopes is equal to the square root of the ratio of the corresponding rate constants.

DISCUSSION

Deviations in the Hartel–Polanyi Method (The Two-point Boundary Method)

From their definition it is evident that the quantities K and x_1 under the usual experimental conditions will vary as the value of the rate constant varies. With increasing speed of the reaction K will in general increase and x_1 decrease. It is clear from Figs. 1–4 and Table I that the deviation factor differs appreciably from unity even for quite slow reactions and becomes large for very fast reactions. Furthermore, for larger v_2/v_1 ratios, which correspond to smaller "flames", the deviation is greater. These results confirm the previous intuitive qualitative conclusions. In addition, since K becomes smaller for smaller r_1, the deviation is also decreased, showing that not only the r_2/r_1 ratio is of significance but also the absolute value of r_1.

The so-called "core" flames (4) are readily qualitatively explainable in terms of the present results, although the published data are not sufficiently detailed to allow a quantitative treatment. Inasmuch as r_1 and y_1 are independent of pressure variations in the reaction zone, the values of k_p should remain also pressure independent. The "core" flames, however, were characterized by a large pressure dependence of the calculated values of k_p, this dependence being more pronounced for faster reactions. In view of variation of D_y with pressure, z_∞ has also to be varied to maintain the flame size and as a result x_1 and therefore also K will be altered leading, in turn, to a drift in the values of δ and of k_p. With increasing pressure, D_y becomes smaller and, therefore, z_∞ is also reduced (for the same C) making x_1 smaller and K larger, and as a result k_p will decrease. This will be noticeable in the case of very fast reactions when x_1 is small and quite sensitive to variations in z_∞ and when δ is large. A change in experimental conditions leading to an increase in x_1 (and a decrease in K and δ) will tend to reduce the pressure dependence. These conclusions are in agreement with the drifts observed by Haresnape, Stevels, and Warhurst (4) and with the necessary change in experimental conditions intuitively inferred by these authors in order to eliminate the pressure dependence of k_p.

Deviations in the Concentration Pattern Method

The deviations from the exponential solution in the concentration pattern method are shown in Figs. 5–8. It is evident that they are on the whole considerably smaller than in the two-point boundary method and for a considerable range of experimental conditions they are practically negligible. This result is in agreement with the view expressed by Smith (8). Only for some quite large values of K the deviations could become appreciable. In this case, the evaluated rate constants would appear smaller than they actually are, and any pressure dependence would be such that with an increasing pressure the rate constants evaluated to the exponential approximation would decrease. Here

again the smaller the absolute value of r_1 the smaller is K, and, consequently also the deviations. The necessity of selection of very small nozzle radii in the experiments of Garvin and Kistiakowsky (3) is, thus, well understandable.

Evaluation of r_1 and y_1

The solutions [8] are independent of the particular values which r_1 and y_1 may have and the foregoing results are, therefore, quite general. However, the constant A_p in Equation [2] which involves r_1 and y_1 has to be known for the calculation of k_p. The value of r_1 is also required for the quantitative evaluation of the deviation factor δ and of eventual deviations in the concentration pattern method.

Two distinct ways of assessing the values of these quantities have been suggested. Hartel and Polanyi (5) assumed that $r_1 = r_n$, where r_n is the radius of the nozzle, and $y_1 = y_n = y_s$, where y_s and y_n are the respective concentrations of the nozzle reactant in the saturator and in the nozzle. Hartel–Polanyi's boundary condition at the origin was used exclusively until very recently when Garvin and Kistiakowsky (3) proposed to assess the value of A_p by setting the consumption of the nozzle reactant in the reaction zone equal to the strength of the assumed point source of this reactant (expressed as the quantity introduced in unit time). Garvin–Kistiakowsky's boundary condition has been used further by Reed and Rabinovitch (7) and by Smith (8). The respective values derived by these authors differ somewhat between themselves. The treatment given by Smith is of particular interest since it is based on the extended theory of spherical diffusion (1) and takes into account the depletion of the atmosphere reactant. It leads to the results

$$[11] \qquad r_1 = \frac{v_n r_n^2}{4D_z}, \qquad y_1 = y_n \frac{D_z}{D_y}, \qquad A_p = \frac{v_n r_n^2}{4D_y} y_n \exp(C_p r_1),^*$$

where v_n is the streaming velocity of the gases in the nozzle.

The introduction of Garvin–Kistiakowsky's boundary condition and the subsequent work by Reed and Rabinovitch and by Smith represent a highly interesting new approach. At the same time, the importance of the distorting effect of the stream of the carrier gas leaving the nozzle, which tends to keep z away from the nozzle, is not yet fully understood. Smith thus proposes also an alternative way of normalizing the exponential solution (the first approximation of the general solution) to allow for the fact that depletion of y by reaction is insignificant inside some radius *not smaller* than r_n because of the effect of the jet. It is also likely that the physical conditions at the nozzle impose some upper limits on y_1 and r_1, such as $y_1 \leqslant y_n$ and $r_1 \leqslant r_n$, since at sufficiently high v_n a transition to "cylindrical flames" takes place. In view of this, it is possible that in much of the classical diffusion flame work, where larger nozzle radii were employed, the Hartel–Polanyi boundary conditions were valid to a good approximation. Use of smaller nozzle radii offers the advan-

**In the original treatment the factor ¼ appears to have been omitted accidentally and this value is given as $(v_n r_n^2/D_y)\, y_n \exp(C_p r_1)$. The value for y_1 is not given explicitly.*

tage of smaller deviations from the exponential solution and may be preferable for that reason and because of a smaller interference with the assumed rigorously spherical symmetry. The effect of a variation of the nozzle radius, however, ought to be subjected to a critical experimental study on the basis of the foregoing conceptions. The concentration pattern method, on the other hand, is largely free from any uncertainties and, inasmuch as it may prove experimentally feasible to extend it to sodium atom reactions by a suitable modification of the optical method, it could provide a valuable variant of the classical technique.

While the computations reported in the present article were in progress, Smith (8) succeeded in solving in terms of a tabulated function by successive approximations the second order non-linear differential equation of spherical diffusion derived by Cvetanović and LeRoy (1). In the region of its convergence the series representing this solution should yield results identical with the present after allowance is made for the particular boundary conditions adopted by this author.

ACKNOWLEDGMENT

The author is thankful to Prof. C. C. Gotlieb, Dr. Beatrice H. Worsley, and Mrs. Mary Burgess of the Computation Centre, University of Toronto, for the numerical solutions of the reported cases, and to Dr. J. F. Hart for assistance in the organization of the numerical processing of the data for the purpose of the present article. The author is indebted to Prof. D. J. LeRoy for his continued interest and encouragement.

THE PARTIAL SEPARATION OF Na^{22} FROM Na^{24} BY ION EXCHANGE CHROMATOGRAPHY[1]

By R. H. Betts, W. E. Harris,[2] and Margaret D. Stevenson

ABSTRACT

Mixtures of the radionuclides Na^{22} and Na^{24}, as the chloride salts, have been partially separated by chromatographic methods. A column 102 cm. in length containing the cation exchange resin Dowex 50 was used. The eluant was 0.7 *M* hydrochloric acid. Na^{22} is held more strongly by the resin than is Na^{24}. The most effective separations were obtained at 25°C. and 5.5°C.; experiments at 48°C. and 68°C. showed much smaller isotope effects.

INTRODUCTION

The separation of isotopes by ion exchange chromatography was first demonstrated by Taylor and Urey in 1938 (15). These workers obtained partial separation of Li^6 from Li^7, and K^{39} from K^{41}, by elution from a column 30 ft. in length. A naturally occurring zeolite was used as an ion exchange material. Subsequently, partial separations of Li^6 from Li^7 and Ca^{40} from Ca^{45} have been obtained by other workers with synthetic cation exchange resins (7, 9, 11). Very recently, a note has appeared describing the separation of nitrogen isotopes by elution of NH_4^+ from a column of Dowex 50 effectively 600 ft. in length (13). In this work, the nitrogen in the trailing edge of the elution band contained 74% N^{15}; the ratio N^{15}/N^{14} in the starting material was 0.365%, i.e. the natural abundance ratio. This is a very striking result.

In the present work we report experiments relating to the partial separation of 2.7 yr. Na^{22} from 15.0 hr. Na^{24} using the cation exchange resin Dowex 50. This system was chosen for study because the 9% difference in mass between Na^{22} and Na^{24} made it a priori a particularly favorable case in which to observe isotopic separation. An added attractive feature of this isotope pair is that the ratio of Na^{24} to Na^{22} in a given solution can be determined very precisely by radiochemical methods. This technique was in fact used earlier in an unsuccessful attempt to separate these nuclides by elution with ammonium citrate from a 207 cm. Dowex 50 column (4).

Our choice of experimental conditions was based on the following considerations: (i) Sodium ion in aqueous solution does not form complexes with any known anion; there appeared to be no advantage, therefore, in using such eluting agents as citrate or lactate, which have been used with marked success in separating adjacent lanthanide or actinide elements. (ii) Hydrochloric acid was chosen as the eluant mainly because of its experimental convenience. The particular concentration used (0.7 *M*) was chosen to give a K_D of about 8. (K_D is a dimensionless quantity given by the ratio: moles Na^+ per gram of resin/moles Na^+ per gram of solution, and describes the equilibrium distribution of sodium ion between the resin and the liquid phase.) A theoretical

[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*

analysis by Glueckauf (6) shows that for the size of resin particle used in the present work, increases in K_D beyond 8 or 10 have very little effect on the efficiency of the separation obtained. (iii) The flow rates chosen were in general the maximum which could be used while maintaining the column under near equilibrium conditions. Our criterion here was the shape of the elution curve; excessively high flow rates gave a markedly asymmetrical elution curve with a long tail. We have also made use of a theoretical analysis of this aspect (6) which indicated that the flow rates chosen were sufficiently low to obtain maximum efficiency of separation. (iv) The particle size of the resin has a profound effect on the separation achieved by a given length of column, maximum efficiency being obtained with minimum particle diameter. In this work we have used resin with the smallest available particle size.

EXPERIMENTAL

The resin used was 240–400 mesh Dowex 50 in the hydrogen form. After a preliminary purification (1), a small fraction of more uniform size was separated by elutriation with water. The average diameter of particles of this fraction was 25 microns, with 90% in the range 20 to 40 microns. The air dried resin had a capacity of 3.54 meq. of exchangeable hydrogen per gram.

The column was a Pyrex tube 0.90 cm. I.D., 107 cm. in length. It was jacketed with a second column, through which water at the required temperature was circulated from a constant temperature reservoir. The bottom of the column was sealed to a short capillary tube, without stopcock, to minimize dead space between the end of the resin bed and the exit from the column. The column, when operating, contained 36 gm. of resin in 102 cm., and 44 ml. of hydrochloric acid. The top 5 cm. was left free of resin to allow the eluting agent to attain the required temperature before it reached the top of the resin bed. Before each experiment, the resin was conditioned for one day by elution with 0.7 *M* hydrochloric acid.

Na^{22} was supplied as $Na^{22}Cl$ in dilute hydrochloric acid through the courtesy of Mr. R. C. Hawkings of these laboratories. It was purified before use by elution with dilute acid from a separate 60-cm. column of Dowex 50. The specific activity of this material was 25 μc. per mgm. of Na^{23}, i.e., $\sim 4 \times 10^{-4}$ atom % Na^{22}.

Na^{24} was prepared by irradiation of 1 mgm. quantities of analytical reagent sodium carbonate in the Chalk River NRX reactor. It was converted to $Na^{24}Cl$ by evaporation with dilute hydrochloric acid. The specific activity at the start of an experiment was about 2 mc. per mgm. of Na^{23}, corresponding to 2×10^{-5} atom % Na^{24}.

The eluant, 0.7 *M* hydrochloric acid, was prepared by dilution of reagent grade acid with doubly distilled water.

Procedure

Solutions of $Na^{22}Cl$ and $Na^{24}Cl$ were mixed in the required proportions, and the mixture evaporated to dryness twice with dilute hydrochloric acid to ensure that the two radionuclides were in equivalent chemical form initially.

The resulting residue (which amounted to about 3 mgm. of sodium chloride) was dissolved in water, and a portion set aside for later analysis. The remainder was adsorbed on 0.2 gm. of resin, and the resultant slurry transferred to the top of the column. When this added resin had settled in a thin layer, the supernatant water was replaced with 0.7 *M* hydrochloric acid, and the top of the column connected to an overhead reservoir of eluant. The rate of flow of liquid through the column was maintained constant to ±5% by applying a suitable hydrostatic pressure to the top of the column. Provision was made for removing dissolved air from the acid before it entered the column.

Up to 40 consecutive fractions of effluent containing sodium were collected. Samples were prepared from these fractions for measurement of the relative isotopic ratio Na^{24}/Na^{22} (see below). For fractions very close to either end of the elution band, 15–20 ml. of solution were used to obtain a sufficient amount of activity. This volume was evaporated to dryness and most of the sodium removed from the traces of resin left behind by extraction with small volumes of water. Finally this aqueous extract was evaporated in a central depression on a copper tray. For most of the fractions, this preliminary concentration was unnecessary, and 0.05–0.5 ml. samples were evaporated directly on the copper trays.

Estimation of the Relative Na^{24}/Na^{22} Atom Ratio

The method used depends on measurement of the disintegration rate of a sample when both nuclides contribute about equally to the observed activity, followed by a second measurement after most of the Na^{24} had decayed, leaving only Na^{22} activity. It may be useful to point out here that the initial value of the atom ratio Na^{24}/Na^{22} in each run has no "natural" value, and moreover, in a given solution containing these nuclides, this ratio decreases by a factor of two every 15.04 hr. Nevertheless, for any sample this ratio may be given a definite value *referred to a fixed time*. In the following we measure not the absolute atom ratio, but a quantity which is directly proportional to it, viz., the ratio of counts per minute (c.p.m.) from Na^{24} to the corresponding quantity for Na^{22}. We define this ratio as N^{24}/N^{22}.

The relative radioactivity of each sample was measured in a fixed and reproducible geometrical arrangement with a 3 in. NaI–Tl crystal scintillator, coupled optically to a photomultiplier tube (RCA-5819). The crystal and photomultiplier were mounted inside 3 in. of lead shielding. The output from the tube was fed into a scaling circuit and mechanical register. After the Na^{24} in the sample had decayed to about 1% or less of its initial activity, the sample was remeasured.

The method of calculation of the relative isotopic ratio from such data is illustrated below.

At time T_1 let N_1 be the observed c.p.m. for a given sample. Then $N_1 = N_1^{24}+N_1^{22}$, where N_1^{24} and N_1^{22} are the c.p.m. in the sample arising from Na^{24} and Na^{22}, respectively.

Similarly, at time T_2:

$$N_2 = N_2^{24}+N_2^{22}.$$

Since the half-life of Na^{22} is long relative to periods of time dealt with here, then

$$N_1^{22} \simeq N_2^{22},$$

and
$$\Delta N = N_1 - N_2 = N_1^{24} - N_2^{24}$$
$$= N_2^{24}\,[\exp(0.693\,\Delta T/15.04) - 1],$$

where ΔT (in hours) $= T_1 - T_2$, and 15.04 is the half-life of Na^{24} in hours (10).

If we let
$$\exp(0.693\,\Delta T/15.04) = f,$$

then
$$N_2^{24} = \Delta N/(f-1),$$

and

[1]
$$\frac{N_1^{24}}{N_1^{22}} = \frac{N_1 - N_2 + [\Delta N/(f-1)]}{N_2 - [\Delta N/(f-1)]},$$

which is the required result.

Since $(f-1)$ was generally of the order of 80 to 300 (ΔT = 95 to 125 hr.), the terms in f in Equation [1] represent small corrections to this ratio.

Finally, N_1^{24} for each sample in a run was adjusted to some common time in the vicinity of T_1 in the usual way. For this purpose, the half-life of Na^{24} was taken as 15.04 hr. (10).

In the foregoing we neglected the radioactive decay of Na^{22} which occurred during the time ΔT (4–6 days). While this procedure would lead to a 0.3 to 0.4% error in the calculation of *absolute* isotopic abundance, these errors cancel in the present case, since we are interested only in variations in the relative abundance among different samples for which ΔT was effectively constant.

Precision of the Measurement of N^{24}/N^{22}

As will be apparent from the results presented later, a maximum variation of 10% was observed in the ratio N^{24}/N^{22} between the leading and trailing edges of the sodium elution curve in a given run. We feel therefore that it is necessary to outline in rather more detail than is customary further particulars of the counting techniques used, and the precautions taken to minimize errors.

A sufficient number of counts were recorded for each sample to reduce the probable statistical error in the ratio N^{24}/N^{22} to $\pm 0.2\%$. Corrections were made when required for variations in the counting rate of a standard sample (Na^{22}) and for background. Coincidence corrections were applied when necessary. To make this latter correction, the dead time of the counter was measured with paired sources (5, p. 213) of both Na^{22} and Na^{24}, at counting rates comparable with those encountered in the present work. Systematic errors arising from uncertainties in the dead time were minimized by preparing, whenever possible, all comparable sources with nearly equal counting rates. To further reduce the effects of drifts in the counting equipment, the samples in each run were measured in a random progression, viz., the chronological order of counting the samples did not correspond to the order in which these samples came off the column. In addition, samples of the initial solution were measured at irregular intervals during the time in which the samples of effluent from the column were being assayed. Such a procedure served as a secondary "internal" standard to the whole scheme of radioassay.

For personal use only.

Since a ratio of counting rates at two times for a given sample is involved, the precision of the method is unaffected by pipetting errors, and more generally does not depend on quantitative transfers at any stage of sample preparation. For the same reason, errors due to slight variations in geometry from one sample to another are also mainly self-cancelling. Errors arising from variable self-absorption in the sources were also negligible because the counting arrangement responded only to γ-rays. In any event, the sources were essentially weightless.

As a measure of the reproducibility of the counting technique, we record below (Table I) typical results for the ratio N^{24}/N^{22} for triplicate samples of the initial solutions in each of three experiments.

TABLE I

VALUES OF N^{24}/N^{22} FOR TYPICAL STOCK SOLUTIONS

Sample No.	Run No.		
	11	12	13
1	1.227	1.889	4.245
2	1.228	1.884	4.251
3	1.230	1.885	4.233
Average	1.228 ± 0.001	1.886 ± 0.003	$4.24_3\pm0.007$

Another more general test of the counting methods was to assay a series of synthetic mixtures of $Na^{22}+Na^{24}$ which were prepared by mixing together weighed portions of solutions of each of these nuclides. A comparison of the observed and calculated values of the ratio N^{24}/N^{22} for these mixtures is given in Table II.

TABLE II

MEASUREMENTS OF N^{24}/N^{22} FOR SYNTHETIC SOLUTIONS

Solution No.	N^{24}/N^{22}	
	Obs.*	Calc.
1	0.980 ± 0.003	0.979
2	0.996 ± 0.002	0.994
3	1.023 ± 0.003	1.019
4	1.035 ± 0.003	1.039
5	1.055 ± 0.003	(1.055)†
6	1.074 ± 0.002	1.072

*Average of two values.
†Fitted value.

The results in Tables I and II suggest that the probable error in estimation of N^{24}/N^{22} does not exceed $\pm0.4\%$.

RESULTS

1. *General Features of the Elution of Sodium Ion*

Fig. 1 is a typical elution curve obtained in this work. This result is for Run 13 at 24.8°C. (See Tables III and V below.) The elution curves for other runs did not differ markedly from that shown in Fig. 1, although the curves

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

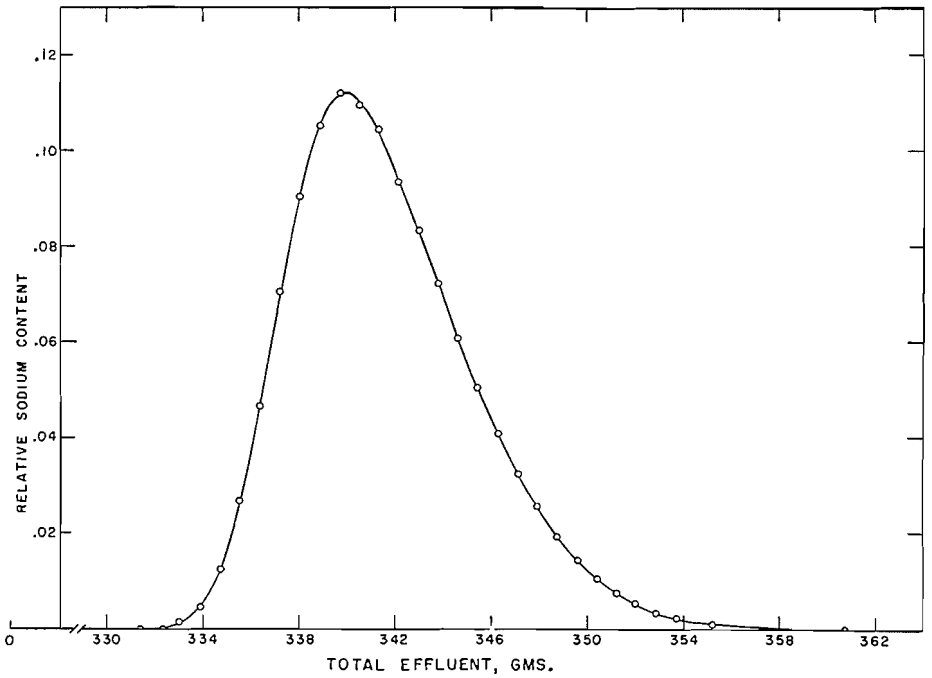

FIG. 1. Sodium elution curve for Run 13 at 24.8°C.

obtained at 5.5°C. showed a longer tail than those at higher temperatures. The position of the maximum decreased with increases in temperature, occurring at 400±5 gm. of eluant at 5.5°C., and at 290 gm. at 67.8°C. These shifts in position of the maximum are presumably caused by corresponding changes in the distribution coefficient of sodium ion between resin and solution. The magnitude of the change agrees with other measurements in the literature on the enthalpy change associated with the sodium–hydrogen exchange on Dowex 50 (3).

It was thought of interest, in passing, to calculate by standard methods (12, p. 190) the number of theoretical plates in the column. The position and width of the elution curve shown in Fig. 1 leads to a value of 10,000 theoretical plates, i.e., 100 per cm. of column length. For comparison, calculations based on physical parameters like particle size, flow rate, etc., according to Glueckauf's treatment of ion exchange chromatography (6) gave a value of 218 plates per cm. In a private communication, Glueckauf and Kitt (8) suggest that allowance should be made in the latter calculation for "wall" effects which cause a curvature in the advancing boundary of the elution band. Their experimental studies of this phenomenon point to a value of 100 to 120 plates per cm. for the flow rate and particle size used in the present study. This is in good agreement with the experimental value of 100 plates per cm. quoted above.

2. *Separation of Na^{24} from Na^{22}*

Table III summarizes the main results of the present investigation. The items listed are self-explanatory, except for (i) "$(N^{24}/N^{22})_{total}$ in effluent" and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

(ii) "Maximum separation, %". With respect to (i), the c.p.m. of Na^{22} and of Na^{24} in each fraction were calculated from the volume of the fraction, the total activity per ml., and the measured ratio N^{24}/N^{22} for each fraction. The total amount of both Na^{24} and Na^{22} in the effluent as a whole was calculated from these data. The ratio of these amounts is designated as $(N^{24}/N^{22})_{total}$ in Table III. The value of this ratio for each run agrees with N^{24}/N^{22} determined on aliquot portions of the corresponding stock solution before its passage down the column. This agreement is a further check on the experimental procedures, and, in addition, is indirect evidence that radioactive nuclides other than Na^{22} and Na^{24} were absent in the stock solutions. The "maximum separation" (ii) referred to in Table III was calculated from

$$\frac{(N^{24}/N^{22})_{max} - (N^{24}/N^{22})_{min}}{(N^{24}/N^{22})_{stock}} \times 100\%.$$

Table III shows that at 5.5°C. and 25°C., significant enrichment of Na^{24} occurred in the leading fractions, and depletion of Na^{24} in the trailing fractions. The separation of Na^{22} from Na^{24} is unquestionably less at 48° and 68°C., and may well be zero.

TABLE III

SUMMARY OF DATA

	Run No.							
	9	10	11	12	13	5	4	8
Temperature, °C.	5.5	5.5	5.5	5.5	24.8	24.9	48.4	67.8

Maximum separation, %	10	10	8	8	8	7	2	3

**Average of three values.*

To amplify the results in Table III, we list in Tables IV and V the relative isotopic analyses for all samples collected in each of two experiments. These tables show that the central fractions, corresponding to those near the peak in Fig. 1, emerge from the column essentially unchanged in isotopic composition. Only the leading and trailing fractions show significant changes in the atom ratios.*

**The slight rise in N^{24}/N^{22} in the last 0.5 to 1% eluted, shown in Table IV, was noted in several other runs, particularly those at 5.5°C. We believe this effect could arise, for example, by adsorption of traces of sodium on the glass surfaces of the column, followed by a slow removal by the eluting agent. Such effects would tend to cancel any isotopic separation. Similar behavior has been observed in the separation of americium from curium. These elements appear in the effluent in two distinct, well-separated peaks; nevertheless, the last 1 to 2% of material eluted contains both americium and curium (2).*

A useful way of displaying such results is to plot $\Sigma Na^{24}/\Sigma Na^{22}$ vs. % elution of sodium. The Σ refers to the cumulative fraction of Na^{24} or Na^{22} in the effluent from the beginning of the elution. Fig. 2 shows such plots for several runs. The meaning of these curves is best illustrated by example. In Runs 11 and 12 (upper curve in Fig. 2), an enrichment of 1.4% in Na^{24} relative to Na^{22} would be obtained by collecting the first 50% of the effluent, and a 2.6% enrichment if the first 10% of the sodium is collected. Successively higher enrichments are obtained as the % of total sodium eluted approaches a value of zero.

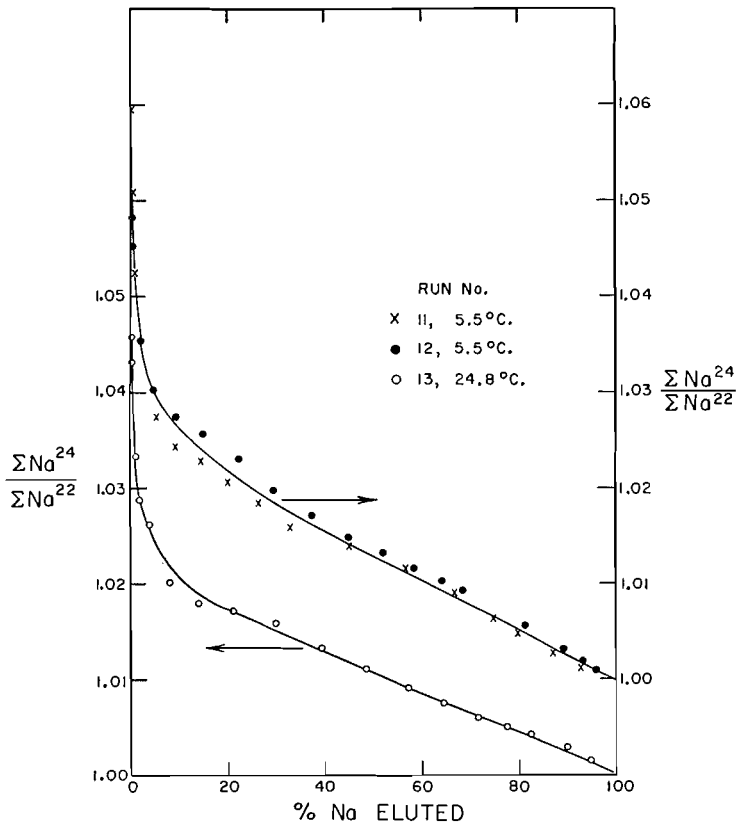

FIG. 2. Enrichment of effluent in Na^{24}.

DISCUSSION

An analysis of the results at 5.5°C. indicates that the peak of the Na^{24} curve is reached about 0.05 to 0.07 ml. earlier than the peak for Na^{22}. If the observed separation is ascribed solely to differences in K_D between the two nuclides, then this result implies that K_D for Na^{24} is 1 part in 6000 smaller than K_D for Na^{22}. This small difference presumably represents the net result of isotope effects on at least two equilibria: (i) the interaction of sodium ion with water molecules of the hydration sphere, and (ii) the reaction of the hydrated ion with the resin. In this connection it is pertinent to note that experiments with H_2O^{16}–H_2O^{18} mixtures have revealed isotope effects in the hydration of chromium (III) and certain other cations (14).

A further point of interest is the virtual absence of separation at 48° and 68°C. The distribution of sodium ion between the resin and acid is not markedly temperature sensitive (3); it is unlikely, therefore, that the difference in the temperature coefficients for the distribution of these nuclides would be sufficiently large to cancel out the isotope effect at 48°C., when it is clearly observable at 5° and 25°C. This absence of separation at higher temperatures may be due to convective mixing of the elution band due to slight temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

gradients in the system, or possibly to mixing caused by formation of bubbles at these temperatures. Although, as indicated earlier, precautions were taken to reduce such effects, further work with more careful attention to these points would be desirable.

A comparison of the present results with those referred to earlier (7, 9, 11, 13, 15) shows that on Dowex 50 the heavier nuclide is less firmly held by the resin for the pairs Li^6–Li^7 and Na^{22}–Na^{24}. The behavior of N^{14}–N^{15} is reversed, N^{15} being more strongly retained by the resin than is N^{14}. While perhaps not strictly comparable, the separation of K^{39} from K^{41} obtained with zeolitic (inorganic) material showed that the lighter isotope comes off the column first (15). The same trend is evident for the Ca^{40}–Ca^{45} separations, i.e., the lighter nuclide comes off the column preferentially (11). This result is also probably not comparable with the lithium and sodium studies, since a complexing agent (ammonium citrate) was used as an eluting agent. However it is clear that the order of elution of members of isotopic pairs in the mass range 6 to 45 is not a simple function of the relative masses of the nuclides involved. Further studies of other isotopic pairs above calcium, e.g., Fe^{56}–Fe^{59}, would be useful in this connection. Parallel studies of isotope effects concerned in complex ion formation would also be instructive.

ACKNOWLEDGMENTS

We should like to thank R. C. Hawkings for providing the Na^{22} used in this work. The assistance of J. E. Hardy in developing alternative radiochemical methods for assay of Na^{24}–Na^{22} mixtures is gratefully acknowledged. We are indebted to E. Glueckauf for permitting us to refer to his work before publication; we also acknowledge very useful private correspondence with E. Glueckauf and G. P. Kitt.

AN ISOTOPIC STUDY OF THE REDUCING ACTION OF THE GRIGNARD REAGENT[1]

By G. E. Dunn and John Warkentin[2]

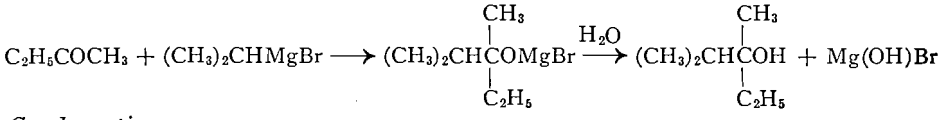
ABSTRACT

Benzophenone has been reduced to benzhydrol with three samples of isobutylmagnesium bromide containing deuterium in the *alpha*, *beta*, and *gamma* positions, respectively. Deuterium was found only in the benzhydrol obtained from β-deuteroisobutylmagnesium bromide. Comparison of the ratios of deuterium to protium in β-deuteroisobutylmagnesium bromide and in the benzhydrol obtained from it shows an isotope effect of about two. In the decarboxylation of hydroxyl-deuterated dimethylmalonic acid an isotope effect of 4.5 was observed. These results are considered in terms of the probable mechanisms of the reactions.

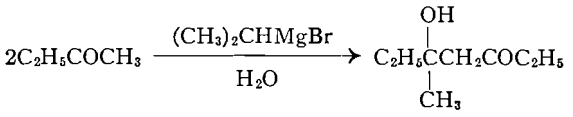
INTRODUCTION

Of the many reactions of the Grignard reagent, the most familiar and probably the most used is the addition to a carbonyl group. It has long been known, however, that this reaction is frequently complicated by side reactions which may replace some or all of the addition. The three most important of these side reactions are commonly referred to as condensation, enolization, and reduction (8). They are illustrated below in terms of methyl ethyl ketone and isopropylmagnesium bromide (15).

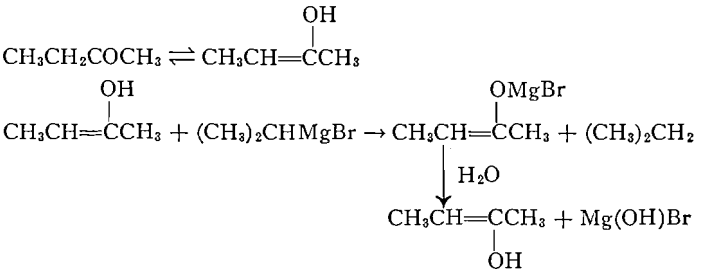
Addition



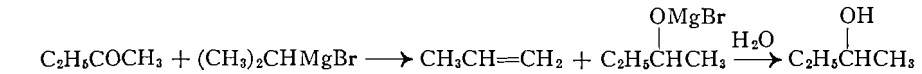
Condensation



Enolization



Reduction



[1]*Manuscript received September 12, 1955.*

Contribution from the Chemistry Department of the University of Manitoba, Winnipeg, Manitoba. This paper was presented at the May, 1955, meeting of the Chemical Institute of Canada at Quebec City, Quebec.

For personal use only.

The condensation reaction is, at least formally, analogous to the common base-catalyzed aldol condensation with the Grignard reagent as the base, and the enolization reaction is an example of the well-known tendency of the Grignard reagent to react with acidic hydrogen. The reduction reaction, however, shows a property of the Grignard reagent which is not illustrated among its better known reactions and, consequently, this side reaction has attracted more interest and experiment than the other two.

The equation written above for the reduction reaction indicates that the Grignard reagent is converted into olefin, and careful work by Noller, Grebe, and Knox has shown that, at least in the reduction of benzophenone by isobutylmagnesium bromide, the amounts of olefin and alcohol produced are exactly equivalent (14). It is also commonly observed that the double bond of the olefin has for one of its carbon atoms that one to which magnesium was originally attached. For example, γ-phenylpropylmagnesium bromide when used as a reducing agent is converted into allylbenzene (2). Evidently the net result of the reaction is the elimination of magnesium and hydrogen from adjacent carbon atoms. This conclusion is supported by the observation that, although the amounts of all three side reactions increase with increasing branching in the alkyl groups of both carbonyl and Grignard reagents, reduction does not occur when the Grignard does not contain a hydrogen atom on the carbon *beta* to magnesium (20).

Although the evidence considered above shows that the over-all result of the reduction is the transfer of the elements of magnesium halohydride from Grignard reagent to carbonyl compound, it does not, of course, prove that a hydrogen atom originally attached to the β-carbon of the Grignard is the one actually transferred to the carbonyl compound. It is conceivable that the actual hydrogen atom appearing in the carbinol product could come from the α- or γ-position of the Grignard reagent, from the solvent, or from the water used in the hydrolysis. However, in the absence of evidence to the contrary, attempts to devise a mechanism for the reduction have naturally been based on the simplest reasonable assumption: namely, that a hydride ion is transferred directly from the Grignard molecule to the carbonyl compound.

The objects of the present investigation have been: first, by substituting deuterium for hydrogen in various positions of the Grignard molecule to determine whether or not the hydrogen atom lost from the β-position of the Grignard reagent is, in fact, the one which appears in the carbinol product of the reduction; and, second, by observing the isotope effect in the hydrogen transfer to learn something about the sequence and relative speeds of the various steps in the reaction.

The reaction we have chosen to study is the reduction of benzophenone to benzhydrol by isobutylmagnesium bromide:

$$(C_6H_5)_2CO + (CH_3)_2CHCH_2MgBr \rightarrow (CH_3)_2CH{=}CH_2 + (C_6H_5)_2CHOMgBr$$

$$\downarrow H_2O$$

$$(C_6H_5)_2CHOH + Mg(OH)Br$$

It was chosen for a number of reasons: (*a*) the ketone cannot undergo condensation or enolization and gives an almost quantitative yield of the reduction

product; (*b*) this reaction is one of the very few for which it has been demonstrated that the amounts of olefin and alcohol produced are equivalent; (*c*) the Grignard has hydrogen in the α-, β-, and γ-positions which could, in principle, be transferred to the ketone; and (*d*) the halomagnesium salt of benzhydrol is insoluble in ether so that it can readily be separated from unreacted benzophenone and other reaction products, if any.

Three samples of isobutylmagnesium bromide were prepared which contained deuterium in the α-, β-, and γ-positions respectively. Benzophenone was reduced by each of these, using two equivalents of Grignard reagent to one of benzophenone. By analyzing the resultant benzhydrol samples for deuterium it could be determined whether or not hydrogen is transferred from the Grignard reagent and, if so, from which position in it. By comparing the deuterium to protium ratios in the Grignard reagent and in the benzhydrol obtained from it the isotope effect in the reaction could be determined.

EXPERIMENTAL

The deuterated Grignard reagents required for this work were prepared from deuterated isobutyl bromides obtained from the corresponding deuterated isobutyl alcohols. A variety of methods for the synthesis of these alcohols were explored, using undeuterated materials. The yields quoted in the procedures described below are those obtained from the undeuterated materials since the small quantities of deuterated compounds used were usually distilled directly into the reaction vessel for the next step in the synthesis without measurement.

α-Deuteroisobutyl Alcohol

This compound was made by reduction of isobutyraldehyde with lithium aluminum deuteride. Isobutyraldehyde (4.2 gm., 0.058 mole) in 20 ml. of dry ether was added dropwise to a stirring solution of 0.65 gm. (0.017 mole) of lithium aluminum deuteride in 20 ml. of ether. A 45 min. reflux period was followed by hydrolysis with dilute hydrochloric acid and extraction of the aqueous layer with ether. The dried ether extracts were evaporated and the residue distilled. The yield of isobutyl alcohol boiling in the range 96–107°C. was 70%.

β-Deuteroisobutyl Alcohol

This compound was synthesized by the following series of reactions:

$$CH_3CH(COOEt)_2 \xrightarrow[CH_3I]{NaOEt} (CH_3)_2C(COOEt)_2 \xrightarrow{KOH} (CH_3)_2C(COOH)_2 \xrightarrow{D_2O} (CH_3)_2C(COOD)_2$$

$$(CH_3)_2C(COOD)_2 \xrightarrow[-CO_2]{heat} (CH_3)_2CDCOOD \xrightarrow{LiAlH_4} (CH_3)_2CDCH_2OH$$

Methylmalonic acid diethyl ester (26.0 gm., 0.16 mole) was added to a solution of 3.8 gm. of sodium (0.16 gm-atom) in 100 ml. of absolute ethanol. Then 22.7 gm. (0.16 mole) of methyl iodide was added dropwise. After a three-hour reflux period 2 ml. of methyl iodide was added and refluxing continued for another hour. Ethanol was distilled off and the residue treated with water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

From ether extracts of the aqueous solution there was obtained 9.1 gm. of dimethylmalonic acid diethyl ester boiling at 186–190°C., a yield of 68%.

This ester was saponified by refluxing it for 2.5 hr. with an equal weight of potassium hydroxide dissolved in its own weight of water. Unsaponified ester was removed by extraction with ether. Dimethylmalonic acid was isolated by extracting the acidified aqueous solution with ether, evaporating the ether, and crystallizing the residue from benzene. It melted at 188–190°C. Yields were 90% or better. Recrystallization from ether raised the melting point to the literature value of 192–193°C. Neutral equivalent was 67.5±2.0 as compared to calculated values of 66 for dimethylmalonic acid and 59 for methylmalonic acid.

Dimethylmalonic acid (21.5 gm., 0.163 mole) was equilibrated with deuterium oxide by dissolving it in 60 ml. of dioxane (purified by the method of Fieser (4), containing 3.3 gm. (0.165 mole) of heavy water[3] and allowing the solution to stand at room temperature for 70 hr. Dioxane and water were removed at 90°C. under reduced pressure, and the residue of deuterodimethylmalonic acid was decarboxylated by heating the distilling flask containing it above 195°C. in an oil bath. The deuteroisobutyric acid which distilled over had a neutral equivalent of 91±2 compared to the calculated value of 89. The over-all yield of exchange and decarboxylation was 85%.

Deuteroisobutyric acid (12.0 gm., 0.14 mole) in 15 ml. of dry ether was added dropwise with stirring to a suspension of lithium aluminum hydride (7.0 gm., 0.14 mole) in 45 ml. of ether. The mixture was refluxed for an hour, then hydrolyzed with water, and acidified. From the ether layer was obtained 6.1 gm., a 60% yield, of β-deuteroisobutyl alcohol, b.p. 96–107°C.

γ-Deuteroisobutyl Alcohol

This compound was prepared by the following series of reactions:

$$(CH_3)_2CO \xrightarrow{D_2O} (CD_3)_2CO \xrightarrow{LiAlH_4} (CD_3)_2CHOH \xrightarrow{PBr_3} (CD_3)_2CHBr \xrightarrow{Mg}$$
$$(CD_3)_2CHMgBr \xrightarrow{CO_2} (CD_3)_2CHCOOH \xrightarrow{LiAlH_4} (CD_3)_2CHCH_2OH$$

Acetone (30 gm., 0.52 mole) was equilibrated with deuterium oxide (30 gm., 1.5 mole) containing 0.2 gm. of sodium hydroxide. After 48 hr. at room temperature the mixture was distilled through a 9×1.5 cm. column packed with 3 mm. glass helices, distillate being collected up to 95°C. This deuteroacetone was dried over calcium sulphate and filtered.

Deuteroacetone (14.0 gm., 0.24 mole) was dissolved in 20 ml. of dry diethyl carbitol and the solution was added slowly to a suspension of 3.0 gm. (0.08 mole) of lithium aluminum hydride in 20 ml. of diethyl carbitol. At the end of 1.5 hr. the mixture was acidified with dilute hydrochloric acid and distilled, distillate bieng collected up to 95°C. This distillate was redistilled through a 9×1.5 cm. column packed with 3 mm. glass helices. The yield of deuteroisopropyl alcohol boiling at 79–81°C. was 11.4 gm. (80%).

[3]*Heavy water was obtained from the Commercial Products Division of Atomic Energy of Canada, Ltd., and was reported by the supplier to contain 99.73 atom-% deuterium.*

Deuteroisopropyl alcohol was converted to the corresponding bromide, b.p. 56–60°C., in 55% yield by the method described below for converting deuteroisobutyl alcohol to its bromide.

Deuteroisopropyl bromide (24.5 gm., 0.20 mole) was converted to the Grignard reagent with 0.22 gm-atom of magnesium in 60 ml. of dry ether in the usual way. The yield by titration with standard acid was 85%. This was poured into a slurry of crushed Dry Ice in ether; the mixture was acidified and extracted with ether. From the ether extracts was obtained 11.6 gm. (78%) of deuteroisobutyric acid boiling at 145–150°C.

Deuteroisobutyric acid was reduced to γ-deuteroisobutyl alcohol by means of lithium aluminum hydride in ether as described above under β-deuteroisobutyl alcohol. The yield was 65%.

Conversion of Deuteroisobutyl Alcohols to Deuteroisobutyl Bromides

Phosphorus tribromide (19.5 gm., 0.072 mole) was added dropwise with stirring to 12.8 gm. (0.173 mole) of isobutyl alcohol over a period of 45 min. while the reaction was being cooled in an ice–salt bath. The mixture was then distilled, distillate being collected up to 96°C. This distillate was cooled to 0°C., washed with cold concentrated sulphuric acid, cold sodium carbonate solution, and cold water in turn, then dried and distilled. Yields of the various deuterated isobutyl bromides boiling at 88–92°C. ranged from 40% to 50%.

Reduction of Benzophenone by Deuterated Grignard Reagents

The three deuterated isobutyl bromides obtained from the above reactions were diluted with ordinary isobutyl bromide where necessary to give enough material for the subsequent reductions, then analyzed for deuterium. Three reductions with each bromide were attempted. In a typical run 3.0 gm. (0.022 mole) of deuterated isobutyl bromide in 5 ml. of dry ether was added to a 10% excess of magnesium (0.53 gm.) in 25 ml. of dry ether. Reaction was initiated by gentle warming, and completed by refluxing for three hours. Titration with standard acid showed the yield to be 75%. To this solution was added slowly one-half of the equivalent quantity (1.51 gm., 0.0083 mole) of benzophenone dissolved in 10 ml. of dry ether. The solution turned deep red as soon as the ketone was added, but the color disappeared when the addition was complete and the solution had been refluxed for a few minutes. After a few hours of reflux, the bromomagnesium salt of benzhydrol was allowed to settle out, filtered, washed with ether, and hydrolyzed with dilute acid. The liberated benzhydrol was extracted with ether and recrystallized from ligroin. The yield of benzhydrol melting at 66°C. was 1.2 gm. (80%).

Deuterium Analyses

The samples were burned in a standard macrocombustion apparatus using a Vycor tube and a plug of silver wool to trap halogens. The water of combustion was collected in a Dry Ice trap and purified by the method of Keston, Rittenberg, and Schoenheimer (6) except that calcium oxide and potassium permanganate were used instead of chromium trioxide and potassium hydroxide. The density of the water of combustion was determined by the gradient

density tube method described by Anfinsen (1). Two gradients were used, one covering the range 0–8% D_2O for samples rich in deuterium and another covering the range 0–2% D_2O for less concentrated samples.

RESULTS

Table I lists the analytical results. The three runs with α-deuteroisobutyl bromide used the same starting material so that the three analyses of α-deuteroisobutyl bromide are, in effect, triplicate analyses of the same material. Thus the three analyses illustrate the reproducibility of the method.

TABLE I

DEUTERIUM ANALYSES

Source of water sample	Run No.	Weight-% D_2O*	Atom ratio D/H in labelled position
α-Deuteroisobutyl bromide	1	0.70	0.029
	2	0.68	0.028

**A blank space indicates that a run or analysis was lost by accident.*

It is seen from the table that the benzhydrols obtained by reduction of benzophenone with β-deuteroisobutyl Grignard reagents contain deuterium while those obtained from α- and γ-deutero Grignard reagents do not. Therefore, the reduction occurs by hydrogen transfer from the β-position of the Grignard reagent, as has long been supposed.

The fact that the ratio of deuterium to protium in the labelled position of the benzhydrol is less than that in the β-deuteroisobutyl bromide from which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

it was obtained indicates that there is an isotope effect in the transfer.[4] The numerical value of the isotope effect can be calculated from the following considerations. If the reaction is assumed to be first order with respect to Grignard reagent, then

$$k_H t = \ln [a/(a-x)] \quad \text{and} \quad k_D t = \ln [a'/(a'-x')]$$

are the rate expressions for the reactions of normal and deutero Grignard reagents, respectively, where k_H is the rate constant for the transfer of hydrogen, k_D is the rate constant for the transfer of deuterium, a is the initial concentration of non-deuterated Grignard, a' is the initial concentration of deuterated Grignard, x is the concentration of non-deuterated product at time t, and x' is the concentration of deuterated product at time t. The isotope effect, k_H/k_D, is then given by the expression

$$[1] \qquad \frac{k_H}{k_D} = \frac{\log[a/(a-x)]}{\log[a'/(a'-x')]}.$$

If the substitutions $a'/a = A$, $x'/x = X$, and $(x+x')/(a+a') = P$ are made, the above expression becomes

$$[2] \qquad \frac{k_H}{k_D} = \frac{\log(1+X)-\log[1+X-P(1+A)]}{\log(1+1/X)-\log[1+1/X-P(1+1/A)]}$$

where A is the ratio of deuterium to protium in the labelled position of the reactant, X is the ratio of deuterium to protium in the labelled position of the product, and P is the fraction of reaction completed.

Since purified benzhydrol was isolated corresponding to 80% or more of the benzophenone used in the reactions, it is evident that the reduction of benzophenone must have been close to quantitative. And since two equivalents of Grignard were used to one of benzophenone, the fraction of Grignard reacted is one-half. Using this value for P and the values of X and A from Table I, the isotope effect, k_H/k_D, is found to be 2.0 in Run 1, and 2.2 in Run 2.

Equation [2] can also be used to calculate what fraction of the reduction could have taken place by transfer of hydrogen from the α- and γ-positions of the Grignard without producing a detectable amount (0.01% by weight) of deuterium in the water of combustion from the resulting benzhydrol. If it is assumed that the isotope effect in these hypothetical reductions is six, a value near the maximum allowed by theory and experience (3), then it is found that the maximum per cent of reduction which could have escaped detection is 17% from the α-position and 1% from the γ-position. The value is large in the α-position because a short supply of lithium aluminum deuteride necessitated a low concentration of deuterium in the α-deuteroisobutyl bromide. However, it seems reasonable to suppose that the reaction takes place by one mechanism and not several, and since it is evident that the reduction does involve the β-hydrogen and that not more than 17% of it can involve α-hydrogen, it is highly probable that the reduction takes place by transfer of β-hydrogen exclusively.

[4]*That deuterium is not lost from the alkyl groups of alkyl halides or alcohols during formation or hydrolysis of metal derivatives is shown by the work of Shiner (16).*

For personal use only.

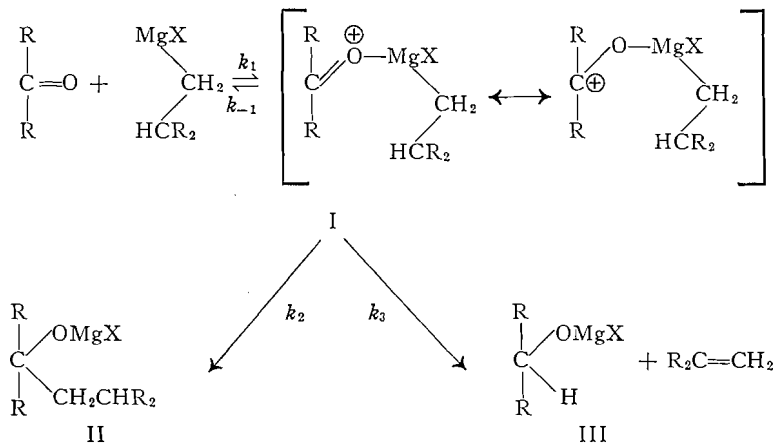
The deuterium analyses on dimethylmalonic acid and β-deuteroisobutyl alcohol can be used to calculate the isotope effect in the decarboxylation reaction

$$(CH_3)_2C(COOD) \xrightarrow[-CO_2]{\text{heat}} (CH_3)_2CDCOOD \xrightarrow{LiAlH_4} (CH_3)_2CDCH_2OH.$$

Here it is desired to compare the D/H ratio in the carboxyl groups of dimethylmalonic acid with that on the α-carbon atom of the isobutyric acid obtained from it. Since only carbon dioxide is lost during the decarboxylation itself, the over-all deuterium to protium ratio in the two compounds will be the same. Actually, isobutyric acid was analyzed and the result applied to both acids. Analysis of the isobutyl alcohol obtained from the isobutyric acid gave the D/H ratio on the β-carbon of the alcohol, which should be the same as that on the α-carbon of the isobutyric acid. Use of these ratios in Equation [2] gave a calculated isotope effect, k_H/k_D, of 4.5.

DISCUSSION

A variety of mechanisms have been suggested for the reducing action of the Grignard reagent, and these have been reviewed recently by Kharasch and Reinmuth (8). Probably the most satisfactory of these is the mechanism proposed by Whitmore, or some modification of it. Whitmore proposed (19) that the carbonyl oxygen co-ordinates with the Grignard magnesium forming a six-membered ring complex, I, which can either rearrange to addition products, II, or transfer a hydrogen from the β-carbon of the Grignard to the carbonyl carbon to give reduction products, III. This mechanism of reduction,



or something very like it, is given strong support by the asymmetric reductions accomplished by Mosher and LaCombe (12).

Our experimental results tend to support the Whitmore mechanism since they show that the reducing hydrogen does come from the β-carbon of the Grignard reagent as Whitmore (and many others) proposed. They do not, of course, support or contradict the theory that reduction takes place through hydrogen transfer within a complex. However, if it is assumed that such a complex is involved in the reaction, then our results show that the complex is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

in equilibrium with reactants, and that the rate of attainment of equilibrium is greater than the rate of decomposition of complex to reduction products. This is evident from the following considerations. The substitution of deuterium for protium on the β-carbon of the Grignard reagent should have no significant effect on the rate of co-ordination between magnesium and oxygen; hence deuterated and undeuterated complex should be formed in the ratio in which deuterated and undeuterated Grignard reagents were introduced. Then if every complex decomposed into reduction products (in our reaction there were no other products) the ratio of deuterium to protium in the labelled position of benzhydrol would be the same as that in the isobutyl bromide from which it was made. But an isotope effect of about two was observed, so that not every complex can decompose to alcoholate and olefin. That is, k_{-1} in the mechanism scheme above must be greater than k_3.

An interesting modification of the Whitmore mechanism has been proposed by Swain (17). From a consideration of the order of reactivity of a series of Grignard reagents toward nitriles and carbonyl compounds he concludes that, while reduction takes place by the decomposition of a complex as proposed by Whitmore, addition must take place by attack of a second Grignard molecule on the complex. Support for this theory was found in the observation that when magnesium bromide is added to the carbonyl solution prior to the Grignard reagent the yield of addition product is increased at the expense of reduction (18). This is explained by pointing out that magnesium bromide should be a better complexing agent than the Grignard reagent, and that a complex between carbonyl compound and magnesium bromide would be incapable of reductive hydrogen transfer but would still be subject to attack by a Grignard molecule leading to addition.[5]

McBee, Pierce, and Meyer have shown by a series of vapor pressure measurements in phenetole that magnesium bromide does complex some ordinary aldehydes and ketones, but that no complex is formed with analogous fluorinated carbonyl compounds (11). Since Grignard reagents should complex less readily than magnesium bromide, these authors conclude that reduction of fluorinated carbonyl compounds takes place without intermediate complex formation. Nevertheless, McBee, Pierce, and Higgins have shown that added magnesium bromide favors addition and hinders reduction of fluorinated aldehydes and ketones just as with non-fluorinated compounds (10). This seems to throw some doubt on the interpretation by Swain and Boyles of the mechanism of the action of added magnesium bromide.

However, it may be noted that the vapor pressure measurements on solutions of magnesium bromide and fluorinated carbonyl compounds actually show that the equilibrium concentration of complex is very low, not that no complex is formed. So long as the rate of attainment of equilibrium is fast the

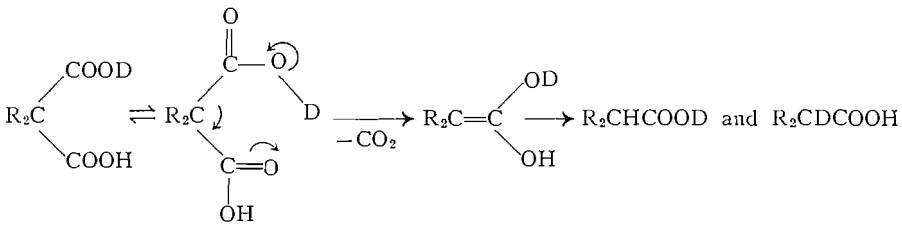
[5]*It has long been thought that magnesium halide is also in equilibrium with the Grignard reagent itself (5, 7).*

$$2RMgX \rightleftharpoons R_2Mg + MgX_2$$

If both RMgX and R_2Mg enter into reaction with carbonyl compound, and if R_2Mg is a better reducing agent (or poorer adding agent) than RMgX, then the results of Swain and Boyles can be explained simply by the effect of added magnesium bromide on this equilibrium. Some support, but certainly not proof, is given this alternative explanation by the work of Noller on the reducing action of diisobutylmagnesium on benzophenone (13).

reduction could still take place through a complex even though its concentration were never large. Thus the interpretation of the effect of added magnesium bromide could still be that of Swain and Boyles. The isotope effect observed in the present work shows that if a complex is formed it does reach equilibrium with its components rapidly, at least in the case of benzophenone and isobutylmagnesium bromide. Hence the possibility that Grignard reduction of fluorinated carbonyl compounds takes place through a complex is still open.

The isotope effect observed in the decarboxylation of dimethylmalonic acid throws little light on the mechanism of that reaction. A reasonable mechanism has been proposed by King (9) which predicts the observed isotope effect:



Indeed, the symmetry of the molecule is such that it is difficult to devise a mechanism which does not predict an isotope effect. The fact that one does exist is simply noted in passing.

ACKNOWLEDGMENT

The authors wish to thank the National Research Council of Canada for a grant in aid of this research and for the gift of the lithium aluminum deuteride used in it.

NOTES

PREPARATION OF D- AND L-GLYCERALDEHYDE FROM KETOHEXOSES*

By A. S. Perlin and Carol Brice

When D-fructose is treated in acetic acid with lead tetraacetate two moles of oxidant are consumed rapidly and the reaction then virtually ceases (6, 11). The product of this oxidation, isolated in approximately 90% yield, is a formic acid – glycolic acid diester of D-glyceraldehyde (11). Hydrolysis of the ester groups with dilute acid affords D-glyceraldehyde. L-Sorbose reacts with lead tetraacetate in the same way yielding a formate–glycolate diester of L-glyceraldehyde and finally, by hydrolysis, L-glyceraldehyde. The over-all yield from each ketose, as determined by hypoiodite titration and from the apparent chromatographic purity of the preparations, is 80 to 90% of theory. Each compound has been characterized as its dimedon derivative. Crystalline DL-glyceraldehyde is obtained in 85% yield by oxidation of an equimolar mixture of D-fructose and L-sorbose. This high degree of conversion may be contrasted with that of 16.2% over-all yield from acrolein (9) and of 17.5% from monoacetone glycerol (4).

Freshly prepared, the D- and L-isomers have specific optical rotations, respectively, of $+8.3°$ and $-8.6°$. According to Baer and Fischer (1), the specific rotation of D- and L-glyceraldehyde is $\pm 14°$ if the compound is first dried *in vacuo* at 55°C. This observation has been confirmed using the currently-described L-glyceraldehyde sample which, after the prescribed treatment, shows an initial specific rotation of $-14.3°$. The infrared absorption spectra of the D-, L-, and DL-compounds are identical. Absorptions at the carbonyl frequencies are very weak, which agrees with the known tendency of glyceraldehyde to dimerize by forming a hemiacetal linkage between the aldehyde group of one molecule and an hydroxyl group of a second molecule (16, 1). The spectrum of the crystalline DL-dimer differs slightly from that of the same compound as a sirup, and carbonyl bands are absent.

The present results show that the degradative oxidation of ketohexoses provides a facile method for preparing the relatively rare trioses directly from readily available sugars, which may be more advantageous in some instances than the procedures of Fischer and Baer (1, 3). Limited oxidation of D-glucose with periodate, reported recently by Schöpf and Wild (13), constitutes another convenient source of the D-isomer. The preparation of tetroses from aldohexoses and of trioses from aldopentoses has been described elsewhere (10) and is analogous to the present procedure. Oxidation of a pentose, however, is not quite as favorable to the formation of glyceraldehyde as is the degradation of a ketohexose since, with the former, some overoxidation occurs (11),

*Issued as Paper No. 210 in the Uses of Plant Products Series and as N.R.C. No. 3797. Presented in part before the 38th Annual Conference of The Chemical Institute of Canada, Quebec City, Quebec, 1955.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

the yield of triose is smaller, and traces of pentose and tetrose are also found together with the triose (10). Moreover, D-fructose and L-sorbose are among the least costly of sugars and they are therefore especially desirable as starting materials.

Oxidation of ketohexoses by the reaction described has been suggested (11) as a possible procedure for degrading D-fructose labelled with carbon-14.

EXPERIMENTAL

D-Fructose, L-sorbose, and all solvents were of reagent grade quality. Lead tetraacetate was prepared according to the procedure recommended by Vogel (14), or was obtained commercially (Matheson Co., Inc.), both samples being equally satisfactory.

Solutions were concentrated *in vacuo* at 35–40°C.

D-*Glyceraldehyde*

D-Fructose (5.0 gm., 0.028 mole) was dissolved in 8 ml. of water* and the solution was diluted with 500 ml. of glacial acetic acid. Lead tetraacetate (26.1 gm. dry weight, 0.059 mole) was added to the solution with vigorous stirring and, 20 min. after the oxidant had dissolved, the lead was precipitated by adding 50 ml. of a 10% solution of oxalic acid in acetic acid. Stirring was continued for a further 20 min. and the suspension was filtered. The filtrate was concentrated to the consistency of a thin sirup and the product was extracted into ethyl acetate, the insoluble lead salts being filtered off. Removal of the ethyl acetate afforded sirupy D-glyceraldehyde formate–glycolate diester, 4.6 gm. (94% yield). The diester (2.3 gm.) was dissolved in 75 ml. of 0.05 *N* sulphuric acid and the ester groups were hydrolyzed by heating for eight hours at 50°C. Sulphuric acid and the liberated formic and glycolic acid were removed by portionwise addition with vigorous stirring of Dowex-1 resin (200–400 mesh; regenerated with 1 *N* sodium bicarbonate). The resin was filtered off and washed well on the filter with water. Hypoiodite titration (15) indicated that the combined neutral filtrates contained 1.13 gm. of D-glyceraldehyde (89% yield based on D-fructose). The specific rotation of the D-glyceraldehyde in this solution was $[\alpha]_D^{27}$ +8.3° (*c*, 0.75).

On paper chromatograms, using ethyl acetate/pyridine/water (8) and methyl ethyl ketone/water (2) as solvents, the product moved at the same rate as L-glyceraldehyde prepared from L-arabinose (10), both compounds exhibiting some streaking. No other sugars appeared to be present, urea oxalate spray (5) being used to test for the presence of fructose. With aniline oxalate spray (7) D-glyceraldehyde gave a deep brown color and under ultraviolet light a mauve fluorescence which faded after a short period. The infrared absorption spectrum, obtained with the potassium bromide window technique (12), was identical with that of L-glyceraldehyde prepared from L-arabinose.

D-*Glyceraldehyde Dimedon*

A solution of 0.30 gm. of D-glyceraldehyde in 60 ml. of phosphate buffer

**Aqueous acetic acid has been shown to be suitable for many lead tetraacetate oxidations (E. Baer, J. M. Grosheintz, and H. O. L. Fischer, J. Am. Chem. Soc. 61: 2607. 1939).*

(containing 2 ml. of 1 *M* monopotassium phosphate and 1.2 ml. of 1 *N* sodium hydroxide) was treated with 1.1 gm. of dimedon dissolved in 10 ml. of ethanol, at 40°C. for five hours and then at room temperature for 18 hr. The crystalline product which settled out was filtered off, washed with water, and dried *in vacuo*. A second crop of crystals was obtained by concentrating the filtrate. The total weight of derivative was 0.82 gm. (73% yield); melting point, 194–200°C., undepressed by admixture with L-glyceraldehyde dimedon (10); $[\alpha]_D^{27}$ +208° (*c*, 0.6, ethanol). The infrared absorption spectrum of the derivative was identical with that of L-glyceraldehyde dimedon. Calc. for $C_{19}H_{26}O_5$: C, 68.24%, H, 7.84%; found: C, 68.26%, H, 7.81%.

L-Glyceraldehyde

L-Glyceraldehyde was prepared in 82% yield from L-sorbose by a procedure identical with that described above for preparing D-glyceraldehyde. Its specific rotation was $[\alpha]_D^{27}$ −8.6° (*c*, 3.6, water). An aliquot of the solution was concentrated, and the sirupy L-glyceraldehyde obtained was heated *in vacuo* at 55°C. for two hours and then redissolved in water; $[\alpha]_D^{27}$ −14.3° (*c*, 5.5).

The product appeared to be chromatographically pure and its infrared spectrum was identical with those of L- and DL-glyceraldehyde. It gave a 71% yield of L-glyceraldehyde dimedon; m.p., 197–198.5°C., undepressed by admixture with the derivative of the D-isomer; $[\alpha]_D^{27}$ −210° (*c*, 0.6, ethanol). Calc. for $C_{19}H_{26}O_5$: C, 68.24%, H, 7.84%; found: C, 68.27%, H, 7.78%.

DL-Glyceraldehyde

An equimolar mixture of D-fructose and L-sorbose (1.0 gm.) was oxidized under the conditions described above in the preparation of D-glyceraldehyde. The crude diester was taken up directly in 0.05 *N* sulphuric acid for hydrolysis of the ester groups, without previous extraction into ethyl acetate. The slightly turbid hydrolyzate was neutralized with the Dowex-1 resin and concentrated, yielding a clear, colorless sirup which was dried *in vacuo* over phosphorus pentoxide; weight 0.48 gm.; $[\alpha]_D^{27}$ 0°±0.1° (*c*, 3, water). Sirupy DL-glyceraldehyde (42 mgm.), spread as a thin film on a microscope slide, solidified completely in two weeks at room temperature; weight, 38.5 mgm. (87% yield from starting material), melting point, 117–122°C. A mixed melting point with authentic DL-glyceraldehyde* (m.p. 145–147°C.) was 122–132°C. The infrared absorption spectrum and the X-ray diffraction pattern of the crystalline compound were identical with those of authentic crystalline DL-glyceraldehyde. Calc. for $C_3H_6O_3$: C, 40.0%, H, 6.71%; found: C, 39.58%, H, 6.65%. The compound contained 1% ash. A purer specimen was obtained by extracting DL-glyceraldehyde sirup with acetone, the acetone extract depositing crystals which melted at 138–140°C., undepressed by admixture with authentic DL-glyceraldehyde.

ACKNOWLEDGMENT

The authors thank Mr. J. Baignee for carbon and hydrogen analyses, Miss A. Epp for preparation of infrared spectra, and Mr. M. Mallard for X-ray diffraction analyses.

It was originally attempted to suspend the fiber (in this case, glass) by bending one end into the form of a hook or loop. The fiber was then suspended at right angles from a fine glass hook between the platinum electrodes. Difficulty was encoutered because of friction at the point of contact of the hooks, which prevented the fiber from swinging freely. Deflections were measured by means of a travelling microscope.

A more satisfactory method of carrying out the measurements involved setting up a torsion balance. A fine quartz suspension was used as the torsion fiber. This was attached at the top to the torsion head with wax, and was held vertically by the weight of a quartz bead (W) glued to the bottom, as shown in Fig. 2. The fiber to be investigated (F), which was approximately 3 cm. in

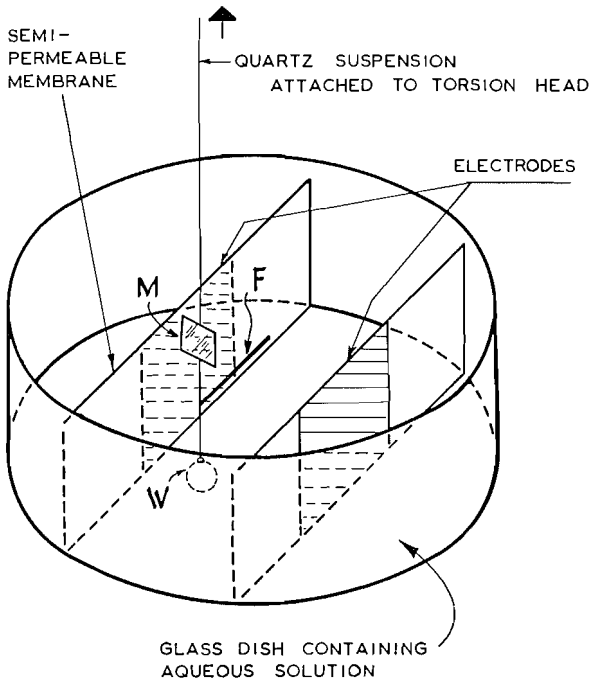

FIG. 2. Method of suspending the fiber between the electrodes.

length, was fastened at right angles to the quartz suspension. The whole system was arranged so that this fiber would be in the solution midway between the electrodes, which were of platinum foil. A small mirror (M) was attached to the quartz suspension just above the fiber, and a light beam was reflected from this mirror on to a circular scale. When the electrical field was applied, the degree of deflection could be measured by the twist of the calibrated quartz suspension, as indicated by the moving light beam.

It was immediately apparent that steady deflections could only be obtained in dilute solution, because of bubble formation and convection currents which interfered with the motion of the fiber when concentrated solutions were used.

The effect of convection currents was greatly reduced by separating each electrode from the fiber by a strip of semipermeable membrane, e.g., porous rubber. A flat electrophoresis cell was approximated by placing the fiber between two horizontally parallel glass slides (not shown in diagram). This also seemed to decrease the heating effect.

The quartz fiber was suspended inside a glass tube to eliminate any possible error due to draughts, and the whole system was placed on a wall mount to minimize vibration effects, to which it was extremely sensitive.

In order to use this torsion method, it is essential that the fiber whose deflection is to be measured be rigid. Glass and quartz were the fibers employed in the earlier exploratory runs; later terylene fiber was used.

The terylene fibers were cleaned by being placed in the thimble of a Soxhlet extractor, where they were washed with a propanol–water solution (60:40 by volume) for one hour. They were then stored in propanol until used. The fibers were always handled with tweezers in order to reduce risk of contamination.

The torsion constant (dynes/radian) for each quartz suspension used was determined by measuring the period of oscillation with and without a small body of known moment of inertia being attached to the quartz weight.

RESULTS

The results of these measurements were generally plotted as deflection (in centimeters of the circular scale, which was also calibrated in radians/cm.) against applied voltage. The actual potential gradient was not used (v./cm.). Since the electrode separation was always approximately 3.0 cm., it was felt that no great error was introduced by comparing results for different fibers at a given applied voltage.

An example of these plots for terylene in distilled water is given in Fig. 3, and shows that the deflections were reproducible in the opposite direction when

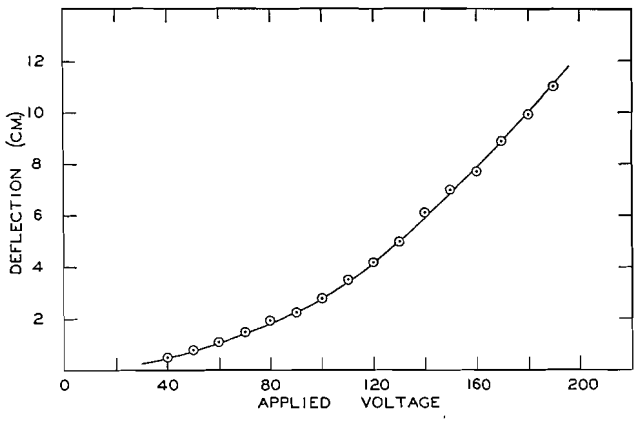

FIG. 3. Fiber deflection vs. applied voltage for terylene in distilled water. • Deflections to right: ○ deflections to left. Fiber length = 3.5 cm.; τ = 0.212 dyne/radian; scale calibration = 1.94×10^{-2} radian/cm.

the direction of the current was reversed. Consecutive measurements on a given fiber were also reproducible. As might be expected, the deflection for a given applied voltage increased with increasing fiber length. The relation between deflection and applied voltage appeared to be nonlinear.

All the fibers were found to possess a negative charge in distilled water and dilute HCl solutions. This charge was reversed when dilute $Th(NO_3)_4$ was the electrolyte.

Some measurements were also carried out using solutions of such detergents as sodium octadecyl sulphate and sodium dodecyl sulphate. Although a small concentration of sodium octadecyl sulphate ($\sim 2 \times 10^{-6}$ molar) seemed to increase slightly the negative charge on the fiber over that observed in distilled water, further addition of the solution had no appreciable effect.

Results of a representative run using varying concentrations of sodium dodecyl sulphate are plotted in Fig. 4. In each case an initial increase in the negative charge was observed, followed by a continuous decrease with increasing detergent concentration.

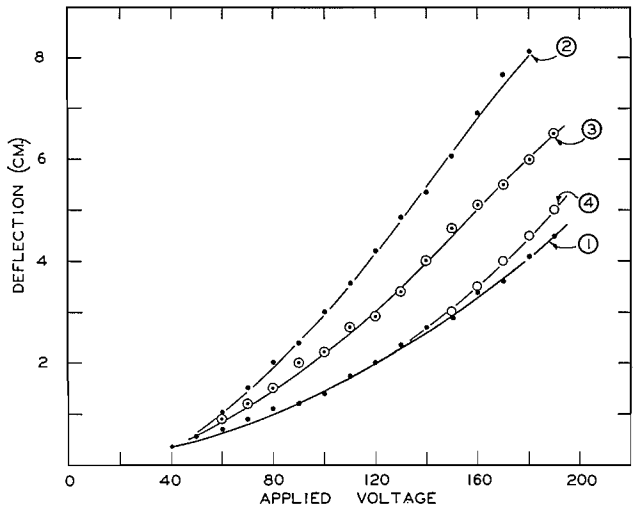

FIG. 4. Fiber deflection vs. applied voltage for terylene in (1) distilled water; (2) 4×10^{-5} M sodium dodecyl sulphate; (3) 8×10^{-5} M sodium dodecyl sulphate; (4) 2×10^{-4} M sodium dodecyl sulphate. Fiber length = 3.05 cm.; $\tau = 0.180$ dyne/radian; scale = 1.94×10^{-2} radian/cm.

Exploratory measurements were also made using solutions of orange II dye. Results of one run are shown in Fig. 5.

It had been hoped to investigate any variation in the charge on nylon fibers having different equivalent numbers of COOH and NH_2 groups. However the fiber samples obtained were not rigid, so that no convenient means of carrying out the measurements with the present system could be found.

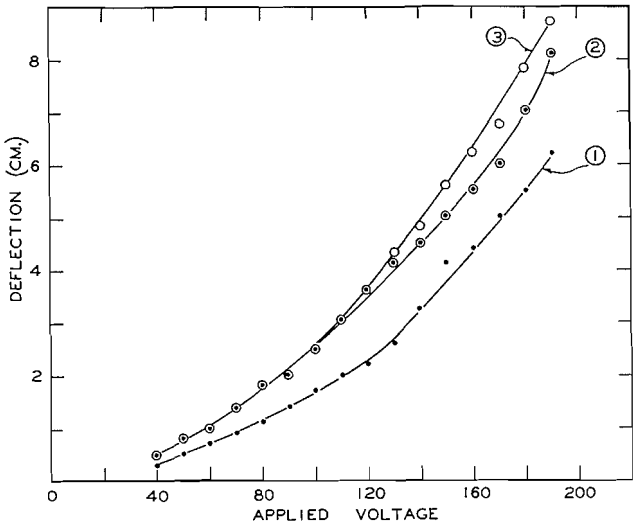

FIG. 5. Fiber deflection vs. applied voltage for terylene in: (1) distilled water; (2) 4×10^{-5} M dye; (3) 8×10^{-5} M dye. Fiber length = 3.2 cm.; τ = 0.19 dyne/radian; scale = 1.94×10^{-2} radian/cm.

DISCUSSION

The effect is recognized as an electrokinetic effect, comparable to electrophoresis.

However, since the equilibrium point of the deflection rather than the *rate* of deflection has been determined, it must be expected that this would represent a measure of the charge on the fiber rather than of the zeta-potential. The charge, q (e.s.u./cm.^{2}), would then be related to the fiber potential, ψ, which is not necessarily identical with the zeta-potential, by the equation:

$$q = \sqrt{\frac{2DnkT}{\pi}} \sinh\left(\frac{ze\psi}{2kT}\right).$$

Although the method appears to give a qualitative measure of the fiber charge, several difficulties are evident when an attempt is made to interpret the results quantitatively.

Considering first a spherical particle fastened to the end of an uncharged rod, the moving force on this particle would be:

$$F = E.q,$$

where E is the applied potential gradient and q the charge on the particle. The restoring force may be expected to be equal to $\tau\theta/h$, where h is the distance from the sphere to the torsion wire, τ is the torsion constant, and θ is the deflection of the fiber from an initial position parallel to the electrodes.

However, in the case of a charged cylindrical fiber, it is difficult to know what the moving force will be. The force per unit of fiber surface may again be $E.q$, but the correct expression for the total force would have to take into

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

account the fiber length. It would also be probable that the force on the part of the fiber nearest the torsion wire would be less than the force acting on the end of the fiber, which would be closer to the electrode.

Taking the force per unit of surface as $E.q.\cos\theta$, it should be equal and opposite to the restoring force, $\tau\theta/h$, where h in this case is the length of the fiber. Then

$$E = \frac{\tau}{hq}\frac{\theta}{\cos\theta}$$

and $\theta/\cos\theta$, rather than θ, should be plotted against E. In actual practice, however, θ is so small that $\cos\theta$ is very close to unity over the whole range of potentials; the plots are therefore no more linear than those shown in Figs. 3 to 5.

Thus, while the method outlined here gives promise of being useful for the determination of relative charge densities, no absolute values can be calculated from the measurements already made until more is known of the nature of the forces acting on the fiber. In any further work along this line, it is recommended that a means of temperature control for the system be introduced.

THE SYNTHESES OF SUGARS FROM SMALLER FRAGMENTS

PART X. SYNTHESIS OF L-GLUCOHEPTULOSE[1]

BY J. K. N. JONES[2] AND R. B. KELLY[3]

ABSTRACT

L-*Gluco*heptulose has been prepared by the action of muscle aldolase on a mixture of L-erythrose and hexose diphosphate.

INTRODUCTION

In a previous communication (1) it was shown that propionaldehyde and hexose diphosphate together with a crude pea aldolase extract yielded 5,6-didesoxy-D-fructose. We now show that L-erythrose and hexose diphosphate with crystalline muscle aldolase yield L-*gluco*heptulose phosphate from which the free sugar was prepared. It had been demonstrated previously (2) that if L-erythrose is replaced by its optical isomer, D-sedoheptulose phosphate resulted. We have confirmed this observation. These are further examples of the rule that aldolase of plant or animal origins will transfer dihydroxyacetone phosphate from hexose diphosphate to an aldehyde with the formation of a derivative of D-*threo*pentulose.

In experiments with crude pea aldolase preparations it was observed that L-erythrose condensed with hexose diphosphate with the formation of small amounts of a heptulose sugar which was identified chromatographically (cf. 4) as *gluco*-heptulose. Further work with a purer enzyme preparation will be required before this sugar can be positively identified.

EXPERIMENTAL

Crude pea aldolase was prepared according to the method of Hough and Jones (3). The crystalline muscle aldolase was supplied by Nutritional Biochemical Corporation.

Erythrose and threose were prepared by Ruff degradation (6) of the corresponding calcium arabonates and xylonates according to the method of Overend, Stacey, and Wiggins (5).

IR 120 resin and IR 4B resins were purified before use. The former was treated with ammonia, washed with water, and then treated with 2 *N* hydrochloric acid and again washed with water until the washings were neutral.

[3]*Merck & Company Limited, Montreal, Quebec.*

The latter was treated with 2 *N* sodium hydroxide, washed with water, and then converted to the acetate form before use by reaction with 8 *N* acetic acid.

Preparation of L-*Glucoheptulose*

A solution of the sodium salt of hexose diphosphate (5.0 gm.) and L-erythrose (2.5 gm.) in water (80 ml.) was adjusted by addition of acetic acid to a pH of 6.8. Dialyzed muscle aldolase (100 mgm.) in water (20 ml.) was added and the solution incubated first at room temperature for four hours and then at 37°C. for 14 hr. Sulphuric acid (100 ml., 2 *N*) was then added and the solution heated briefly at 80°C. to coagulate protein. After filtration the solution was boiled for three and a half hours, cooled, and neutralized with barium carbonate. Precipitated inorganic material was removed by filtration and the filtrate deionized on IR 120 and IR 4B acetate resins. Concentration of the resultant neutral solution gave a resin (1.7 gm.) which contained a heptulose sugar contaminated with traces of fructose (paper chromatography). After treatment with charcoal, the sirup crystallized from alcohol to yield L-*gluco*-heptulose (400 mgm.) with m.p. 171–173°C. (not depressed on admixture with an authentic sample) and $[\alpha]_D$ −65° (*c*, 1.0 in water). The powdered crystals gave an X-ray diffraction pattern identical with that of an authentic specimen, kindly supplied by Dr. N. K. Richtmyer.

Preparation of Sedoheptulosan

The sodium salt of hexose diphosphate (6.0 gm.) in water (50 ml.) was added to a solution of D-erythrose (3.2 gm.) in water (30 ml.). The resulting solution was adjusted by addition of acetic acid to a pH of 6.8. A dialyzed solution of muscle aldolase (100 mgm.) in water (20 ml.) was added and the solution incubated at 25°C. for four hours and then at 37°C. for 14 hr. The solution was then heated briefly to 80°C. to coagulate protein and filtered. Sulphuric acid (100 ml. 2 *N*) was added and the solution boiled for three hours. The cooled solution was then made alkaline by addition of barium hydroxide, solids were removed by filtration, and the filtrate was boiled for two and a half hours. The cooled solution was neutralized with dilute sulphuric acid, filtered, and the filtrate concentrated. The concentrate was deionized on IR 120 and IR 4B resins and the neutral solution decolorized with charcoal. Concentration of the filtrate gave a sirup which crystallized from 95% alcohol furnishing sedoheptulosan hydrate (520 mgm.). Recrystallization from methanol gave the pure sugar, m.p. 93°C. with $[\alpha]_D$ −130° (*c*, 18.5 in water). The material did not depress the melting point of an authentic sample, kindly supplied by Dr. N. K. Richtmyer; the two samples were indistinguishable on paper chromatograms. The powdered crystals gave an X-ray diffraction pattern identical with that of an authentic specimen.

Incubation of L-*Erythrose with Hexose Diphosphate*

A solution of L-erythrose (4.0 gm.) in water (25 ml.) was added to a solution of hexose diphosphate (sodium salt, 8 gm.) in water (40 ml.), the pH of the solution was adjusted to 6.8 by the addition of acetic acid, and to this solution was added a solution of pea aldolase (100 ml. from 100 gm. seed). The solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

was incubated at 37°C. for 14 hr. The pH was then adjusted to 5 (acetic acid) and the solution was heated briefly at 80°C. to coagulate protein. The precipitate was removed on the centrifuge and the supernatant solution was then passed down a column of IR 120 resin. The acidic solution was concentrated to 50 ml. and then boiled for two hours. The cooled solution was passed down a column of IR 4B resin and the neutral effluent concentrated to a sirup (1.12 gm.). The sirup contained heptulose which was separated on a column of cellulose using butan-2-ol–water (10:1) as solvent. The heptulose fraction was contaminated with fructose. Further purification was effected by chromatography on sheets of Whatman No. 1 paper using ethyl acetate – acetic acid – formic acid – water (4:3:1:4) as solvent. Elution of the appropriate section of the paper gave a sirupy heptulose (100 mgm.) which failed to crystallize. It yielded an osazone, m.p. 202–203°C. (sintering at 197°C.) with $[\alpha]_D$ −35° (*c*, 5.6 in pyridine alcohol 2:3). Anal.: Calc. for $C_{14}H_{24}N_4O_5$: C, 60.3; H, 6.2. Found: C, 59.9, H, 6.1. The osazone of D-*gluco*heptulose has m.p. 194–196°C. (sintering at 187°C.) with $[\alpha]_D$ +36°; that of D-*manno*heptulose has m.p. 193–196°C. (sintering at 190°) with $[\alpha]_D$ +36° (solvent as above).

Unfortunately well-defined X-ray diffraction patterns of the osazones could not be obtained. The rate of movement of the sugar was close to that of *gluco*heptulose and *manno*heptulose in several solvent systems. It could be differentiated from all other heptuloses except *allo*heptulose, no specimen of which was available.

The authors thank the National Research Council for financial assistance and for the award of a Postdoctorate Fellowship to one of them (R. B. K.). They also thank Dr. N. K. Richtmyer for the generous gift of heptulose samples.

ORGANIC DEUTERIUM COMPOUNDS

XIV. PREPARATION OF DEUTERATED METHYL BENZENES[1]

By R. Renaud and L. C. Leitch

ABSTRACT

The synthesis of toluene-α-d_3, *o*-chlorotoluene-α-d_3, and *m*-xylene-α,α'-d_6 from benzotrichloride, *o*-chlorobenzotrichloride, and α,α' hexachloro-*m*-xylene respectively is reported using zinc and acetic acid-*d* as the dechlorinating agent. The preparation of acetic acid-*d* of optimum isotopic purity is described.

The reduction of alkyl halides with zinc and acetic acid-*d* has been recommended by Schissler, Thompson, and Turkevich (4) for the preparation of deuterated methanes, ethanes, and propanes in preference to the hydrolysis of Grignard reagents with deuterium oxide, or else dehalogenation of halides with lithium aluminum deuteride or zinc and methanol-*d*. Their method has now been extended successfully to the preparation of methyl benzenes deuterated in the side chain.

According to the literature (1) benzotrichloride reacts with zinc, alone or in the presence of ether, to give tolane dichloride; toluene has never been reported to be a product of this reaction. Preliminary experiments using zinc dust and acetic acid in ether also gave predominantly tolane dichloride but traces of toluene as well. As a result of several experiments in which the effect of temperature, order of adding the reagents, and ratio of acid to halide were studied, a procedure was developed which consistently gave 70 to 80% yields of toluene. It consists in adding benzotrichloride slowly to a stirred suspension of zinc dust and acetic acid in absolute ether while keeping the temperature of the reaction mixture below +4°C. Under these conditions little if any tolane dichloride is formed. These experiments indicated that this reaction would be satisfactory for the preparation of deuteromethyl benzenes.

TABLE I

Source of acetic acid-*d*	Deuterium content of toluene-α-d_3			
	Mol. % $C_6H_5CD_3$	Mol. % $C_6H_5CHD_2$	Mol. % $C_6H_5CH_2D$	At. % D
1. Acetic anhydride	66.1	29.2	4.7	87.0
2. Freshly distilled acetic anhydride	79.7	18.7	1.6	92.6
3. Acetic anhydride distilled over Mg	82.9	15.8	1.3	93.3
4. Acetyl chloride redistilled	89.5	10.5	—	96.5
5. Acetyl chloride distilled over $C_6H_5NMe_2$	95.6	4.1	0.3	98.5
6. Silver acetate+DBr	39.3	41.5	16.5	70.5

The preparation of toluene-α-d_3 therefore depended upon obtaining acetic acid-*d* of high isotopic purity. With acetic acid-*d* prepared by the hydrolysis of

[1]*Manuscript received October 14, 1955.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3818.

freshly distilled acetic anhydride with deuterium oxide (99.6%) the deuterium content of the toluene was unexpectedly low as shown in the figures for experiment 2 in Table I. A slight improvement was evident using acetic anhydride that had been refluxed with magnesium turnings for two days before distillation. Acetic acid-*d* prepared by hydrolyzing redistilled acetyl chloride gave still better results. Toluene-α-d_3 of optimum purity was obtained from acetic acid-*d* which had been prepared by distilling acetyl chloride over dimethylaniline and hydrolyzing it with deuterium oxide. The dimethylaniline evidently combines with traces of dissolved hydrogen chloride in the acetyl chloride. With trifluoroacetic acid-*d* the yields of toluene were very poor and the isotopic purity was low. Acetic acid-*d* prepared by decomposing anhydrous silver acetate with deuterium bromide likewise gave a product of low deuterium content.

The same reaction was used to prepare *o*-chlorotoluene and *m*-xylene deuterated in the methyl groups and can probably be extended to the preparation of other related compounds if the required chloro derivatives are available. In this connection *o*-xylene deuterated in the methyl groups could probably not be prepared with a high deuterium content because in the chlorination of *o*-xylene by the method of Miller (5) the maximum number of chlorine atoms that can be introduced in the side chains is five, further substitution occurring in the ring.

In view of the high *m*-orienting capacity of the trichloromethyl group it is possible that the procedure just described may afford a new route to *m*-substituted derivatives of toluene which are at present accessible with difficulty. This aspect of the work is currently under investigation.

With respect to the mechanism of the reaction the formation of tolane dichloride would at first lead one to believe it is homolytic:

$$C_6H_5CCl_3 + Zn \rightarrow C_6H_5\dot{C}Cl_2 + ZnCl$$

$$2C_6H_5\dot{C}Cl_2 \rightarrow C_6H_5CCl_2CCl_2C_6H_5$$

$$C_6H_5CCl_2CCl_2C_6H_5 \xrightarrow{Zn} C_6H_5CCl{=}CClC_6H_5.$$

Toluene would be formed by attack of the dichlorobenzyl radical on acetic acid:

$$C_6H_5\dot{C}Cl_2 + CH_3COOH \rightarrow C_6H_5CHCl_2 + CH_3CO\dot{O}$$

$$CH_3CO\dot{O} + ZnCl \rightarrow ZnCl(OOCCH_3).$$

However, Kharasch has established that succinic acid is the chief product of the decomposition of acyl peroxides in acetic acid (2), i.e. the free radical initially formed by decomposition of the peroxide abstracts hydrogen from the methyl group of the acetic acid to give a new free radical, $\dot{C}H_2COOH$, which dimerizes to succinic acid. Consequently benzotrichloride and acetic acid-*d* should give ordinary toluene and succinic acid if the homolytic mechanism is correct. That is apparently not the case.

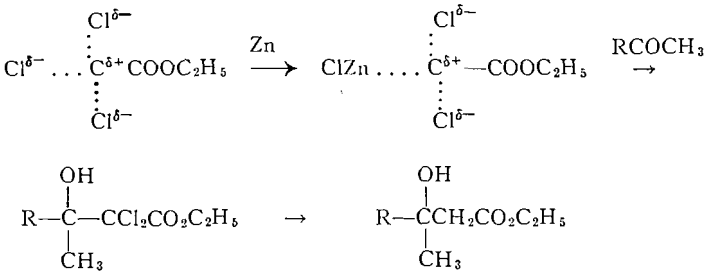
For personal use only.

An alternative mechanism, which proceeds via an organometallic intermediate, may be written thus:

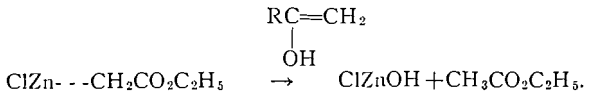
$$C_6H_5CCl_3 + Zn \rightarrow C_6H_5CCl_2ZnCl$$

$$C_6H_5CCl_2ZnCl + CH_3COOD \rightarrow C_6H_5CCl_2D + ZnCl(OOCCH_3).$$

It would be related to the mechanism proposed by Miller and Nord (3) for the Reformatsky reaction:



Ethyl acetate is formed as a by-product in Reformatsky syntheses by reaction of the enol form of the ketone with the organometallic complex:



EXPERIMENTAL

Toluene

In a 500 ml. four-necked round-bottomed flask equipped with a reflux condenser, a thermometer, a separatory funnel, and a stirrer with a thick glass blade (Tru-bor) were placed 200 ml. of anhydrous ether, 45 ml. of glacial acetic acid, and 30 gm. of zinc dust. While the stirred suspension of the zinc in the ether was kept at +3°C. by immersion of the flask in a bath of ice water, benzotrichloride (19.6 gm., 0.1 mole) dissolved in 100 ml. of ether was added over a period of four hours; stirring was continued for three hours longer. Water (200 ml.) was then added and the mixture was filtered through a wad of glass wool in a filter funnel. The ether layer was washed three times with 100-ml. portions of water, once with 10% aqueous sodium bicarbonate, and finally with water again. The ether solution was then dried over calcium chloride and distilled. The residue was distilled through a U-tube containing pellets of potassium hydroxide on the vacuum line. The distillate was fractionated through a Stedman column (12 in. $\times \frac{3}{8}$ in.). The main fraction, b.p. 110°C., n_D^{20} 1.4962, amounted to 7.8 ml. (78% of the theoretical amount). For pure toluene n_D^{20} is 1.49624.

Acetic Acid-d

(*a*) *From* $(CH_3CO)_2$ *and* D_2O

The preparation was carried out on a vacuum manifold. A mixture of 35 gm. of acetic anhydride, 1.0 gm. of zinc dust, 1 ml. of carbon tetrachloride, and a

trace of phosphorus pentoxide in a round-bottomed flask attached through a reflux condenser to a Stock trap to the vacuum manifold was stirred for three hours. Any water or acetic acid present reacts with the zinc and halide to give methane. Deuterium oxide (7.4 ml., 99.6%) was then added to the anhydride and the mixture was stirred at 60°C. for two hours, then overnight at room temperature. The acetic acid-*d* was distilled into the Stock trap, which was cooled to −50°C. by dry ice and acetone, while the manifold was continuously evacuated. Yield: 97.2%.

(*b*) *From CH_3COCl and D_2O*

Acetyl chloride (60 ml.), redistilled over 10 ml. of dimethylaniline to remove dissolved hydrogen chloride, was treated with 5 ml. of dimethylaniline in a round-bottomed flask attached to a vacuum manifold. The solution was stirred for two hours. The acetyl chloride was then distilled into a round-bottomed flask under a cold finger condenser attached to the line through a Stock trap by placing dry ice into the finger after the line was evacuated. Deuterium oxide (14.7 ml., 99.6%) was added slowly from a funnel to the acetyl chloride while the mixture was stirred with a bar magnet. The deuterium chloride evolved was allowed to escape but if desired it could be condensed on the manifold in a trap cooled by liquid nitrogen. The reaction mixture was stirred for two hours after the deuterium oxide was added. When the line was continuously evacuated while the Stock trap was cooled in dry ice and acetone to −50°C., the acetic acid-*d* distilled over practically free of dissolved deuterium chloride. The yield was nearly theoretical.

Toluene-α-d_3

Deuterated toluene was prepared from each sample of acetic acid-*d* as described in the preparation of the normal hydrocarbon using dry equipment and ether dried over sodium. The deuterium content of each sample of toluene is shown in Table I. The best sample of toluene-α-d_3 was prepared from acetic acid-*d* obtained by hydrolysis of the chloride. For this material, n_D^{20} is 1.4953.

o-Chlorotoluene-α-d_3

This compound was prepared from *o*-chlorobenzotrichloride exactly as described for the preparation of the parent compound.

α,α′-Hexachloro-m-xylene

This compound was prepared as described by Miller (5) by the chlorination of *m*-xylene exposed in a quartz tube to ultraviolet light.

m-Xylene-α,α′-d_6

The hexachloro-*m*-xylene (31.3 gm.) was dechlorinated as described for benzotrichloride using 65.7 gm. of acetic acid-*d* prepared by the hydrolysis of acetyl chloride with deuterium oxide and 55 gm. of zinc dust. The yield of product, n_D^{20} 1.4934, was 63%. The mass analysis indicated 94 mol. % $C_6H_4(CD_3)_2$.

ACKNOWLEDGMENTS

The authors are grateful to Miss F. Gauthier for the mass analyses and to Heyden Chemical Corporation for samples of *o*- and *p*-chlorobenzotrichloride.

THE REACTIONS OF TRIFLUOROMETHYL RADICALS WITH PROPANE, *n*-BUTANE, AND ISOBUTANE[1]

By P. B. Ayscough[2] and E. W. R. Steacie

ABSTRACT

A study of the reactions of trifluoromethyl radicals, produced by the photolysis of hexafluoroacetone, with propane, *n*-butane, and isobutane has been made. The rate constants of the hydrogen-abstraction reactions have been determined at temperatures between 27°C. and 119°C. and the activation energies found to be 6.5±0.5, 5.1±0.3, and 4.7±0.3 kcal./mole respectively. These values are compared with those obtained for the reactions with methane and ethane, and with the corresponding reactions of methyl radicals.

INTRODUCTION

Hexafluoroacetone has been shown to yield trifluoromethyl radicals and carbon monoxide when irradiated with ultraviolet light in the temperature range 25° to 300°C. The reactions of these radicals with methane and ethane have already been described (3), and the rate constant for their dimerization has been determined (1). This paper describes a further extension of this work in which more complex hydrocarbons were used. It is now possible to make a more detailed comparison of the rates of abstraction of hydrogen atoms from hydrocarbons by trifluoromethyl radicals with the rates of the corresponding reactions of alkyl radicals.

EXPERIMENTAL

The apparatus was described in the earlier paper (3) and the only significant modification was the illumination of the whole volume of the cell since the lower temperatures used eliminated any possibility of reaction of the radicals with the walls of the vessel. In order to achieve a higher radical concentration some of the experiments on propane and all of those with the butanes were made using the total illumination from the B.T.H. high-pressure mercury lamp. The same sample of hexafluoroacetone was used as before, and the hydrocarbons were again Phillips research grade, distilled before use in the vacuum system and degassed in the usual way. The analytical procedure was essentially the same, except that in this work the carbon monoxide and the fluorocarbons were separated completely from the hydrocarbons by distillation in Ward stills. Mass-spectrometric and infrared spectrophotometric analysis was used to determine the hexafluoroethane/fluoroform ratios (2).

RESULTS AND DISCUSSION

Fluoroform is a major product when hexafluoroacetone is photolyzed in the presence of hydrocarbons, and in the case of reactions with propane and butane the hydrogen-abstraction is so rapid that even at room temperature the fluoro-

[1]*Manuscript received September 30, 1955.*

form/hexafluoroethane ratio is undesirably high. The accuracy of the analyses is therefore reduced and the usable temperature range restricted, even at high radical concentrations which favor the formation of hexafluoroethane.

The proposed reaction scheme is as follows:

$$CF_3COCF_3 + h\nu \rightarrow 2CF_3 + CO \quad [1]$$

$$2CF_3 \rightarrow C_2F_6 \quad [2]$$

$$CF_3 + RH \rightarrow CF_3H + R \quad [3]$$

$$CF_3 + R \rightarrow CF_3R \quad [4]$$

$$2R \rightarrow R_2 \quad [5]$$

where RH is propane, *n*-butane, or isobutane. The products were not examined for compounds of the type CF_3R because these were present in a very small amount compared with the residual hexafluoroacetone and could not have been identified with any assurance. Some hexane was identified however when propane was the substrate, and since ethane and 1,1,1-trifluoroethane had

been detected in the earlier experiments with methane, and butane in the products of experiments with ethane as substrate it seems reasonable to assume the same general mechanism for all these hydrocarbons. The rate constants derived for the reactions [3] would not in any case be affected by the fate of the alkyl radicals unless there was built up an appreciable concentration of some other product which produced fluoroform at a rate comparable with reaction [3]. We have therefore calculated the rate constants from the following relation, derived in the usual way:

$$k_3/k_2^{\frac{1}{2}} = \text{rate } CF_3H/[(\text{rate } C_2F_6)^{\frac{1}{2}} (RH)].$$

The reaction volume was assumed to be the cell volume (190 ml.). The results are presented in Table I, and Arrhenius plots are shown in Fig. 1. The activation energy for the reaction of trifluoromethyl radicals with propane was found to be 6.5±0.5 kcal./mole, for reaction with *n*-butane 5.1±0.3 kcal./mole, and for reaction with isobutane 4.7±0.3 kcal./mole, all about 2–3 kcal. less than

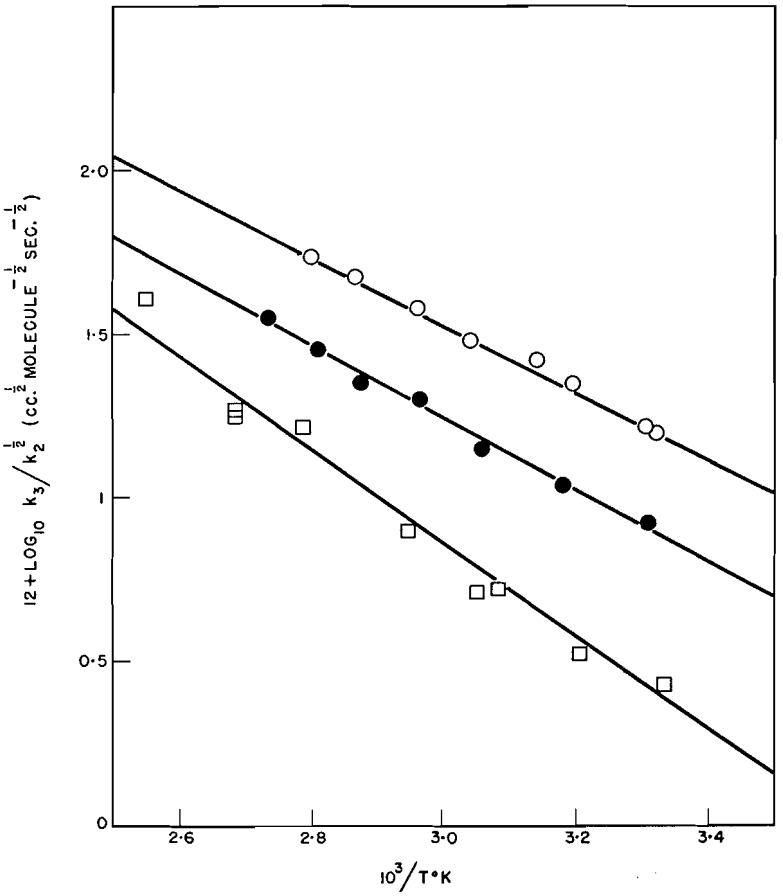

FIG. 1. Arrhenius plots of data.

the corresponding reactions of methyl radicals. This difference was noted in the case of reactions with methane and ethane (3), and in view of the work on the dimerization of trifluoromethyl radicals (1) it is certain that this difference is real and is not the result of a difference in activation energies for the radical recombination reactions.

In Table II the reactions of methyl and of trifluoromethyl radicals with hydrocarbons are compared. The steric factors have been calculated assuming

k_3 refers to the abstraction reaction, k_2 to the radical recombination reaction in each case.

the following collision diameters: CH_3, 3.5 Å; CF_3, 4.0 Å; CH_4, 3.5 Å; C_2H_6, 4.5 Å; C_3H_8, 5.2 Å; n-C_4H_{10}, 5.9 Å; iso-C_4H_{10}, 5.8 Å. The activation energies given assume zero activation energy for the radical recombination reactions. In order to calculate the absolute rate constants, $k_{400°K.}$, we have used the values 3.5×10^{-11} cm.^{3} molecule^{-1} sec.$^{-1}$ for the recombination of methyl radicals (8), and 3.9×10^{-11} cm.^{3} molecule^{-1} sec.$^{-1}$ for the recombination of trifluoromethyl radicals (1). There are some difficulties about the values for methyl radical reactions in Table II. A number of investigations, and particularly unpublished work by Kutschke and Whiteway (4), indicate that the value for the activation energy of $CD_3+CD_3COCD_3$ is higher than that previously reported (10). As a result the value for ethane (10) is too low, and has been corrected from 10.4 to 11.4 kcal. The value for C_3H_8 includes this correction. There is thus some inconsistency between the values for propane and those for n- and iso-butane. The latter compounds were investigated by a non-isotopic method, however, and are free from errors involving the reaction of CD_3 with CD_3COCD_3. As a result, until further work is done, there are uncertainties of the order of 1 kcal. in the values of activation energies for methyl radical reactions. The values of the rate constants at 400°K. are, however, affected very little by these uncertainties. Table II also shows for comparison some recent values obtained by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

Pritchard, Pritchard, and Trotman-Dickenson (6), using CF_3 radicals from the photolysis of hexafluoroazomethane. There is complete agreement between these values and those obtained with hexafluoroacetone. It will be seen from Table II that the abstraction of hydrogen from hydrocarbons by CF_3 radicals is about 100 times faster than the corresponding reaction of methyl radicals at 400°K. The activation energies for CF_3 reactions are 2–3 kcal. smaller than those for CH_3.

ACKNOWLEDGMENTS

The authors are grateful to Mr. R. Lauzon for performing the infrared analyses, and to Miss F. Gauthier for the mass-spectrometric analyses.

THE POLYMERIZATION OF STYRENE IN THE PRESENCE OF α- AND β-BROMOSTYRENE[1]

By M. H. Jones

ABSTRACT

A study of the polymerization of styrene in the presence of either α- or β-bromostyrene at 45°C. and 70°C. has shown that copolymerization does not occur. From the variation of molecular weight and rate of polymerization with bromostyrene concentration it is concluded that the bromostyrenes behave essentially as efficient transfer agents.

INTRODUCTION

The bromination of polystyrene in solution, both photochemically and thermally, is accompanied by some degradation and there is evidence that the resultant polymer may contain olefinic bonds in the carbon chain due to the concomitant elimination of hydrogen bromide (6). As an alternative means of preparing polystyrenes containing aliphatic bromine atoms for use as polyradical sources in grafting experiments (5, 6), an attempt has been made to copolymerize styrene with α- or β-bromostyrene. This would permit a close control of the position and frequency of the bromine atoms in the polymer backbone and would avoid the disadvantages resulting from the direct bromination method.

Although the aliphatic bromostyrenes do not polymerize by a radical mechanism alone (7, 11), it was considered that they may take part in a copolymerization reaction if the principal cause of their low reactivity is steric hindrance imparted by the bulky bromine atom. This is expected to be less in a transition state involving only one species containing a bromine atom adjacent to the reaction center, as in the unsymmetrical propagation step of a copolymerization reaction, than in the normal polymerization involving two species containing bromine atoms. However, in experiments at 45°C. and 70°C., no evidence of copolymerization was obtained and the bromostyrenes appeared to behave as efficient transfer agents.

EXPERIMENTAL

Materials

Styrene (Eastman Kodak Practical Grade) was shaken with a 10% sodium hydroxide solution to remove the inhibitor, washed with distilled water, and dried over anhydrous calcium chloride. It was distilled under reduced pressure in a stream of nitrogen and the middle fraction, b.p. 51.3°C. at 27 mm. pressure, was used for the polymerization experiments. Prior to use, the monomer was given a bulb-to-bulb distillation in vacuum.

α-Bromostyrene was prepared by the elimination of hydrogen bromide from styrene dibromide. Styrene dibromide (0.1 mole) was shaken for 20 min. with

[1]*Manuscript received October 11, 1955.*
Contribution from the Department of Chemistry, Ontario Research Foundation, Toronto 5, Ontario.

100 cc. of a 20% solution of potassium hydroxide in ethanol, the temperature being maintained below 20°C. The reaction mixture was poured into a large excess of ice-cold water and the oil separated and dried over anhydrous sodium sulphate. The product was distilled under reduced pressure in a stream of nitrogen, second fraction b.p. 77.0–77.2°C. at 9 mm.; $n_D^{22.5}$ 1.5868. The conditions described by Ashworth and Burkhardt (1) yielded a product consisting principally of phenyl acetylene.

β-Bromostyrene (Eastman Kodak Practical Grade) was purified in a similar manner to the α-compound, b.p. 85.0–85.1°C. at 7 mm.; $n_D^{22.5}$ 1.6063. As both the bromostyrenes were found to be sensitive to atmospheric oxidation, particularly the α-isomer, they were sealed in ampoules under vacuum and stored at −5°C.

α,α′-Azo-bis-isobutyronitrile was recrystallized twice from ethanol in the temperature range 30°–0°C. and dried under vacuum.

Procedures

Reaction mixtures of styrene and the required bromostyrene were thoroughly degassed on a high vacuum line and sealed in pyrex vessels at a pressure of 10^{-3}–10^{-4} mm. For experiments at 45°C., 1.0 gm./liter of α,α′-azo-bis-isobutyronitrile was used as initiator and the reactions were followed dilatometrically. The volume contraction – time curves were linear and the rates recorded in Table I were calculated on the assumption that polystyrene is the

only product of polymerization and that no copolymerization occurs. Using the data of Patnode and Scheiber (9) for the densities of monomer and polymer respectively, a contraction in volume of 15.4% at 45°C. corresponds to 100% polymerization. In all cases, conversions were limited to less than 7%. The polymer was recovered by precipitation in a 30–40 volume excess of methanol, filtered, and dried to constant weight in vacuum at room temperature. The rates of polymerization at 45°C. and 70°C. were also determined from the weights of polymer recovered in this way.

Intrinsic viscosities were measured in benzene solution at 25°C. using a modified Ubbelohde type viscometer incorporating a bulb to permit dilution

of the solutions *in situ*. No kinetic energy corrections were applied to the flow times as they were found to be less than 1%.

RESULTS AND DISCUSSION

The rates of polymerization for various styrene–bromostyrene compositions are recorded in Tables I and II together with the intrinsic viscosities of the

products obtained. The molecular weights given in the last columns of these tables were calculated from the intrinsic viscosity – molecular weight relationship suggested by Pepper (10) for unfractionated polystyrenes in the molecular weight range 2.10^3–2.10^6,

$$\text{i.e. } [\eta] = 4.37.10^{-4}\ M_n^{0.66}.$$

Microanalyses of the products from reactions with high bromostyrene concentrations showed that they may contain as much as 4.5% bromine. However, the ultraviolet absorption curve of the polymer from experiment No. 8 had peaks at 2850 Å and 2950 Å which occur in the absorption spectrum of β-bromostyrene but are not present in those of either polystyrene or a brominated polystyrene prepared by direct bromination. Assuming the product to be a mixture of polystyrene and β-bromostyrene, the percentage composition of the latter was determined from the optical densities at various wave lengths in the region 2550–2950 Å. The analyses were constant within the experimental accuracy and were in good agreement with the value obtained from the microanalysis for bromine. Two reprecipitations of the polymer from benzene solution in methanol reduced the absorption attributed to the bromostyrene by a factor of two. That there can be incomplete separation of the polymer and bromostyrene by precipitation was demonstrated by a blank experiment in which a sample of pure polystyrene was recovered and dried in the normal way from a benzene solution containing 20% β-bromostyrene. The presence of the bromo compound was detected in the ultraviolet spectrum of the product. Although the bromostyrenes are soluble in methanol they are insoluble in solutions containing more than 5–10% water. Presumably condensation of

atmospheric water vapor during filtration of the polymer under reduced pressure precipitates the bromostyrene which is then absorbed on the polymer. Because of its very low vapor pressure, it will not be completely removed when dried under vacuum at room temperature.

From the spectra of the products from experiments Nos. 1 and 8 it has been estimated that the true bromine contents are less than 0.7% and, consequently, there cannot be more than one bromostyrene unit in 110 units of the polymer chain, that is, in a molecular weight of approximately 11,000. As the molecular weights of these polymers from viscosity measurements are 4500 and 3500 respectively, they must contain less than one bromine atom per molecule. The bromine contents of the products from reactions with low bromostyrene concentrations, in which there was less contamination of the polymer by bromostyrene, were also lower than the requirement for one bromine atom per molecule. There is, therefore, no evidence that copolymerization occurs.

The rapid fall in molecular weight with increasing bromostyrene concentration, both for polymerizations at 45°C. and 70°C., suggests that the growing polymer radicals terminate by one or both of the following mechanisms.

(1) The addition of a bromostyrene molecule to a growing polymer chain produces a radical with a low reactivity towards propagation,

$$\underset{\text{Active}}{M_n^{\cdot}} + \text{B} \rightarrow \underset{\text{Inactive}}{M_n\text{B}^{\cdot}}$$

termination occurring by mutual interaction with a polystyrene radical or another of its own kind.

(2) The bromostyrenes act as efficient transfer agents,

$$M_n^{\cdot} + \text{B} \rightarrow M_n + \text{B}^{\cdot}.$$

With the catalyzed reactions at 45°C., where the rate of initiation is constant, there should be an exact correspondence between the decrease in molecular weight and the fall in rate of polymerization for mechanism (1), provided transfer to monomer is small and can be neglected (2). For the thermal reactions at 70°C., in which transfer to monomer is an important termination step, it can be shown that this mechanism requires the proportional decrease in molecular weight to be less than the decrease in the second order rate constant k_2, where $k_2 = \text{rate}/[\text{M}]^2$. It is generally accepted that the rate of initiation for uncatalyzed thermal polymerizations is proportional to the square of the monomer concentration. For reactions with both the β-isomer at 45°C. and the α- and β-isomer at 70°C., the fall in molecular weight is at least 20 times greater than required for these relationships (Tables I and II). Thus, the addition of a bromostyrene molecule to form an inactive radical is not the predominant chain termination process.

Although the reaction rates determined dilatometrically and from the polymer recovered are not strictly comparable, particularly for reactions with high bromostyrene concentrations, the trend is similar. It is probable that the greater rate decrease obtained by the second method is attributable to incomplete precipitation of low molecular weight material which is progressive as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

molecular weight decreases. Confirmation of this was obtained in two of the experiments at 70°C. (Nos. 7 and 9) in which 50% of each reaction mixture was transferred to a distillation apparatus, degassed, sealed under vacuum, and the volatile constituents removed in a bulb-to-bulb distillation. In both cases, gummy residues remained which consisted of very short chain polymers as they were partly soluble in methanol and readily soluble in acetone. This partial fractionation will also mean that the true molecular weights are somewhat less than the determined values in the low molecular weight range.

If the bromostyrenes act principally as transfer agents and the radicals formed in the transfer step are equally efficient in continuing polymerization, then, for the initiated reactions with a constant catalyst concentration, the rate of polymerization will be proportional to the monomer concentration. For the thermal reactions without initiator, the dependence will be second order with respect to monomer concentration, that is, k_2 will remain constant (3, 4). Although the rate measurements are not too precise, the rates as a function of monomer concentration are less than for first and second order relationships, which suggests that the probability of the radicals resulting from transfer continuing the kinetic chain is less than unity. This is particularly apparent for reactions with α-bromostyrene at 70°C. but the evidence for reactions with the β-isomer at the same temperature is not conclusive. In addition, it must be recognized that a similar effect would be observed in the catalyzed reactions if the bromostyrenes compete with the monomer for the initiator fragments, since this will cause a progressive reduction in the rate of starting chains. Transfer constants for the two bromo compounds have been determined from the variation of molecular weight with bromostyrene–styrene ratio (8). Although this method is strictly applicable only when each radical formed by transfer continues polymerization, it has been used to obtain approximate values. At 70°C., the transfer constants for the α- and β-bromostyrene are 1.0 and 0.2 and are respectively 100 and 20 times greater than that of carbon tetrachloride at this temperature (4).

THE PHOTOLYSIS OF KETENE IN THE PRESENCE OF HYDROGEN[1]

By H. Gesser[2] and E. W. R. Steacie

ABSTRACT

The photolysis of ketene in the presence of hydrogen has been investigated in the temperature range −40° to 207°C. The main products are CO, C_2H_4, C_2H_6, and CH_4, with some methyl ethyl ketone at the higher temperatures. Hydrogen and ketene compete for CH_2 radicals by the reactions

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad [2]$$

$$CH_2 + H_2 \rightarrow CH_3 + H \quad [3]$$

with $E_3 - E_2 = 0.8$ kcal. At the higher temperatures the reaction

$$CH_3 + H_2 \rightarrow CH_4 + H \quad [6]$$

leads to a chain reaction via

$$H + CH_2CO \rightarrow CH_3 + CO. \quad [4]$$

The value of E_6 is found to be 10.2±0.5 kcal. in good agreement with previous work.

INTRODUCTION

The recent study by Strachan and Noyes (10) of the photolysis of ketene and ketene–oxygen mixtures has greatly clarified the mechanism of the ketene photolysis and its dependence on wave length. In view of this it was believed that a re-examination of the ketene–hydrogen system, previously investigated by Rosenblum (7, 8), would perhaps distinguish unambiguously between the addition (1) and abstraction (8) reactions of CH_2 radicals with hydrogen.

Bawn and Milsted (1) studied the reaction of sodium atoms with the methylene halides and found that at 300°C. with hydrogen as the carrier gas CH_4 was the principal product, whereas with nitrogen as the carrier gas C_2H_4 was the main hydrocarbon product. They therefore postulated the reaction

$$CH_2 + H_2 \rightarrow CH_4. \quad [3a]$$

Rosenblum (8), however, postulated

$$CH_2 + H_2 \rightarrow CH_3 + H \quad [3]$$

to account for the high proportion of saturated hydrocarbons produced by the photolysis of ketene in the presence of hydrogen.

During the course of this investigation Chanmugam and Burton* (2) studied the photolysis of ketene in the presence of hydrogen and deuterium from 27° to 412°C. They conclude that reaction [3*a*] occurs to a small extent at 27° and has a low activation energy, while [3] only occurs at higher temperatures.

EXPERIMENTAL

The apparatus, essentially completely free of stopcocks, was similar to that of Strachan and Noyes (10). It consisted of a quartz cell 5 cm. in diameter and 10 cm. long enclosed in an insulated box which served as an air oven. The temperature was controlled by means of a mercury regulator to within $\pm 2°$ at temperatures above room temperature. A few experiments were performed at $-40°$C. by partial filling of the box with dry ice. Under these circumstances there was a slight amount of condensation on the quartz windows of the box which caused small variations in the intensity of illumination. The volume of the cell was 193 cm.^{3}, and the total volume of cell and connecting tubing was about 225 cm.^{3}.

The analytical units consisted of a furnace containing copper and copper oxide maintained at 210°C. for the analysis of CO, H_2, CH_4 mixtures, a hydrogenator (9) for the analysis of C_2H_4, C_2H_6 mixtures, and a platinum wire unit for the combustion of CH_4. The CO, H_2, CH_4 fraction was separated at $-215°$C., and the C_2 fraction at $-185°$C. by means of a LeRoy still.

Ketene was prepared by the thermal decomposition of acetic anhydride (4) at 500°C. It was degassed repeatedly at the temperature of liquid oxygen, and distilled from a trap at $-130°$C. into a bulb where it was stored in liquid nitrogen. When the ketene was allowed to react with acetic acid, CO_2 was detected as an impurity, present in the ketene to the extent of 0.1%.

Hydrogen was purified by passage of commercial cylinder hydrogen through three traps immersed in liquid nitrogen and through two palladium thimbles maintained at 320°C. Its purity was tested by means of the copper oxide furnace. It was found that approximately 0.0002% of the hydrogen did not disappear to form water in the presence of hot copper oxide. Traces of CO and CH_4 were found, and the yields of the products were corrected for them. Hydrogen was stored in a 5 liter bulb and was dosed into the cell by means of a 100 cc. mercury Toepler pump, with the ketene previously measured and frozen down with liquid nitrogen. The gases were then allowed to mix by warming to room temperature and repeated expansion into the Toepler pump.

The light source was a Hanovia S-500 medium-pressure mercury arc, collimated by means of two quartz lenses. The almost parallel beam was allowed to fill the cell. The intensity was checked by means of a General Electric type GL 935 phototube. The light was filtered with a Corning glass filter No. 9863 (3 mm.) and a chlorine filter in quartz (5 cm. long at 1 atm. pressure). The effective absorbed radiation was thus about 2700 Å, with about six per cent above 3600 Å. The intensity was varied by means of neutral density filters of aluminum sputtered on quartz.

RESULTS

The products of the photolysis of ketene in the presence of hydrogen at $-40°$ and 26°C. were CO, C_2H_4, and C_2H_6, together with some polymer detected by a slow drop in the transmission of the cell windows. The cell was occasionally flamed with half an atmosphere of oxygen to remove the polymer. At higher temperatures CH_4 was also produced. Experiments at 26°C. showed that the

addition of hydrogen to ketene undergoing photolysis had no effect on R_{CO} (the rate of formation of CO). However, at higher temperatures where CH_4 was produced, the addition of hydrogen to ketene caused an increase in R_{CO} such that R_{CO} for ketene alone was about equal to $R_{CO}-R_{CH_4}$ for ketene–hydrogen mixtures.

Mass spectrometric analysis showed that in experiments with ketene alone up to 207°C. the CO fraction contained less than 0.5% methane, and the C_2H_4 fraction contained less than 0.5% ethane with no detectable amounts of acetylene. The yields of CO_2 were always negligible compared with the impurity already present in the ketene.

In experiments at 149° and 207°C. relatively large amounts of products were obtained which were volatile above 125° and were not found in comparable quantities in the absence of hydrogen or at lower temperatures (except at 99°C. at very low intensities). Mass spectrometric analysis of this fraction showed that the gases volatile between −75° and −125°C. contained from 30 to 50% methyl ethyl ketone. The remaining gases which could not be positively identified were probably other mixed ketones.

The extent of decomposition was usually about two per cent, except at the highest temperatures where, because of the chain reaction, the decomposition was about six per cent under similar conditions.

The rates of formation of products are given in Table I. Table II shows the effect of intensity (a variation of about 500-fold). The filter used in this series

was a Corning No. 9863 alone, giving effective radiation from 3900 Å to 2600 Å. Experiments at 26°C. with ketene–hydrogen mixtures using 3660 Å and 3130 Å gave results similar to those with 2700 Å.

One experiment was performed at shorter wave lengths in which 54 mm. of ketene at 26°C. was photolyzed with the 2139 Å line of a low pressure zinc resonance lamp, the longer wave length resonance line 3076 Å being removed by means of a chlorine filter. The products were mainly CO and C_2H_4, and were analyzed by means of a mass spectrometer. The CO fraction was shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

to contain 0.75% H_2, and the C_2 fraction had the following composition: 3.5% C_2H_2, 5.4% C_2H_6, 91.1% C_2H_4. The value of $R_{CO}/R_{C_2H_4}$ was 2.38. There are thus small but definite differences as compared with the results at longer wave lengths, possibly owing to the onset of another primary process.

DISCUSSION

Consideration of the principal products of the photolysis of ketene in the presence of hydrogen leads to the following material balance:

$$(2R_{C_2H_4}+2R_{C_2H_6}+R_{CH_4})/R_{CO} = 1.$$

The values of this ratio are given in Tables I and II under the heading "Material balance". It is evident that the material balance decreases with increase in temperature (Table I), and increases with increase in intensity (Table II). Some polymerization occurred, and this resulted in a slight decrease in transmission in successive runs. This is reflected in the values of R_{CO} in Table I, but the ratios of rates are not affected. In view of the large variation in intensity in Table II, no appreciable error is involved in conclusions regarding the effect of intensity. The small increase in the ratio $R_{CO}/R_{C_2H_4}$ with increase in temperature is probably due to an increase in the amount of polymer formed at higher temperatures. The values of the material balance show that polymerization is never of major importance, especially at low temperatures.

The mechanism most consistent with our results is as follows:

$$CH_2CO + h\nu \rightarrow CH_2 + CO \quad [1]$$

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad [2]$$

$$CH_2 + H_2 \rightarrow CH_3 + H \quad [3]$$

$$H + CH_2CO \rightarrow CH_3 + CO \quad [4]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [5]$$

$$CH_3 + H_2 \rightarrow CH_4 + H \quad [6]$$

If ethane and methane are produced solely by reactions [5] and [6], then the following relation should be obeyed:

$$R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6} = k_6[H_2]/k_5^{\frac{1}{2}}. \quad [I]$$

Fig. 1 shows a plot of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ against $[H_2]$ at 99°, 149°, and 207°C. and it is evident that the above relationship is obeyed. The values of $k_6/k_5^{\frac{1}{2}}$ at the different temperatures were obtained from the slopes of the curves in Fig. 1, and are given in Fig. 2 in the form of an Arrhenius plot. The values of $k_6/k_5^{\frac{1}{2}}$ reported by Majury and Steacie (6) from an investigation of the photolysis of acetone–hydrogen mixtures are given for comparison. The agreement is excellent except at the highest temperature where Majury and Steacie's results are unreliable. The results of the present work lead to the expression

$$13+\log k_6/k_5^{\frac{1}{2}} = 5.96-(2.24\times10^3/T),$$

and to $E_6-\frac{1}{2}E_5 = E_6 = 10.2\pm0.5$ kcal. This agrees well with the value re-

ported by Whittle and Steacie (11) of 10.0±0.5 kcal. If collision diameters of 2.8 Å and 3.5 Å are assumed for H_2 and CH_3, the ratio of the steric factors, $P_6/P_5^{\frac{1}{2}}$, is 2.3×10^{-3}. The complete agreement with previous work is strong

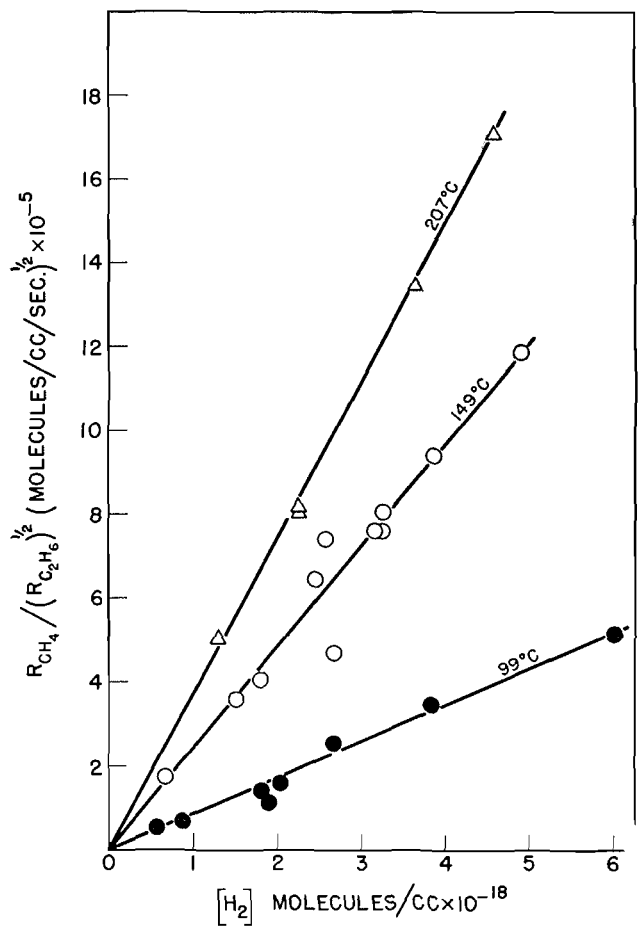

FIG. 1. Plot of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$ against $[H_2]$. For convenience in plotting, the values of the ordinate have been divided by 2 for the 149°C. curve, and by 5 for the 207°C. curve.

evidence that reaction [3*a*] is unimportant as a source of methane in the present work. This is to be expected from the work of Chanmugam and Burton (2) who showed that at 27°C. the total methane, amounting to about one per cent of the CO, is formed by reaction [3*a*], whereas at higher temperatures the methane is predominantly formed by a radical reaction.

A mechanism involving reactions [1] to [6] leads to the relationship:

$$R_{C_2H_6}/R_{C_2H_4} = k_3[H_2]/k_2[CH_2CO]. \qquad [II]$$

A plot of $R_{C_2H_6}/R_{C_2H_4}$ against $[H_2]/[CH_2CO]$ is shown in Fig. 3. The slopes of the lines, corresponding to k_3/k_2, are 0.28, 0.40, and 0.52 for −40°, 26°, and 99°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

respectively. An Arrhenius plot of these values is given in Fig. 4, whence $E_3 - E_2 = 0.8$ kcal., and $P_3/P_2 \sim 1$.

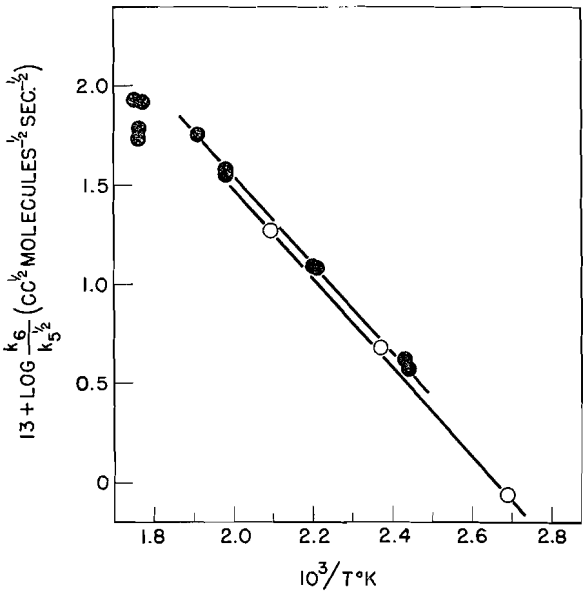

FIG. 2. Arrhenius plot of $k_6/k_5^{\frac{1}{2}}$. Open circles represent the present work. The filled circles are from the work of Majury and Steacie.

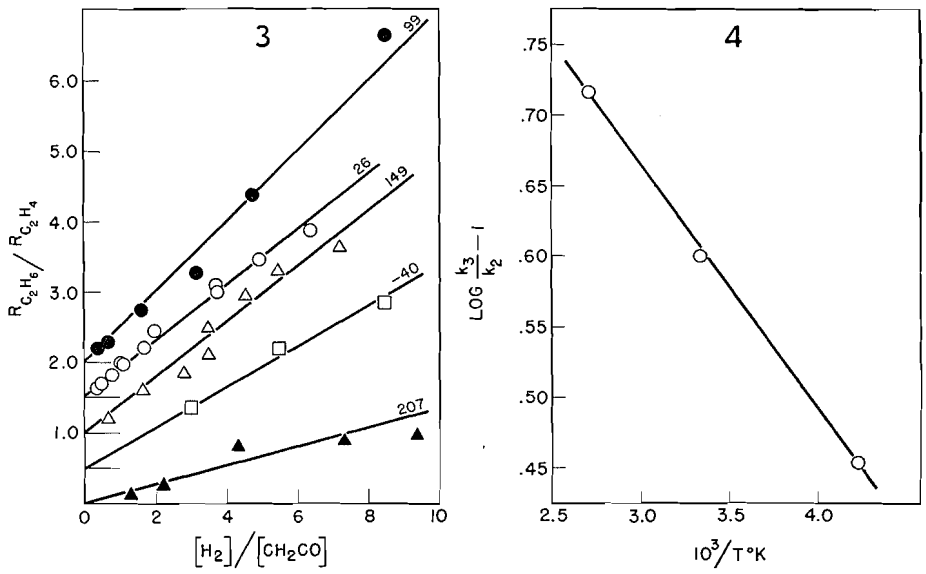

FIG. 3. Plot of $R_{C_2H_6}/R_{C_2H_4}$ against $[H_2]/(CH_2CO]$. The temperatures are indicated by the numbers on the lines. For clarity, the origin of each successive curve is displaced upwards by increments of 0.5 units.

FIG. 4. Arrhenius plot of k_3/k_2 from data in Fig. 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

At 99°C. appreciable methane is formed, and it is possible to check both equations [I] and [II]. The results agree excellently. It follows that a reaction sequence such as

$$CH_2 + CH_2CO \rightarrow CH_2CH_2CO$$
$$CH_2CH_2CO + H_2 \rightarrow C_2H_6 + CO,$$

as postulated by Chanmugam and Burton to account for the formation of ethane at 27°C., cannot be of any importance in the present work even at low temperatures.

The slopes of the lines in Fig. 3 give an excellent Arrhenius plot at the three lowest temperatures. At higher temperatures, however, the slopes decrease again, being 0.40 at 149° and 0.13 at 207°. Also, the plot in Fig. 3 is far from linear at 207°. The decrease in the apparent value of k_3/k_2 is almost certainly due to the formation of methyl ethyl ketone in view of the fact that both k_3/k_2 and the material balance (Table II) increase with increase in intensity. Methyl ethyl ketone presumably arises by the reactions

$$CH_3 + CH_2CO \rightarrow CH_2COCH_3 \qquad [7]$$
$$CH_3 + CH_2COCH_3 \rightarrow C_2H_5COCH_3. \qquad [8]$$

The rate of formation of methyl ethyl ketone, R_{MEK}, at 149° and 207°C. can be calculated by assuming that the material balance differs from unity solely because of the formation of methyl ethyl ketone. Hence $R_{MEK} = \frac{1}{2}R_{CO}$ (1 − material balance). The values thus calculated are given in Table I, and should obey the relationship

$$R_{CH_4}/R_{MEK} = k_6[H_2]/k_7(CH_2CO]. \qquad [III]$$

Fig. 5 shows that this relationship is obeyed satisfactorily. The slopes lead to $E_6 - E_7 = 3.8$ kcal., i.e. $E_7 = 6.4$ kcal., and to $P_6/P_7 = 30$ or $P_7 = 7 \times 10^{-5}$. Since these values are derived from results at two temperatures only, and involve rather drastic assumptions, they are to be regarded as correct in magnitude only.

It is, however, possible to obtain some confirmatory evidence from the work of Chanmugam and Burton (3). Their work on the photolysis of ketene–acetone mixtures showed that methyl ethyl ketone was an important product. From their yields of methane and ethane it can be shown that at the three highest temperatures used by them (200°, 298°, and 412°C.) an Arrhenius plot of

$$R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[\text{Acetone}]$$

gives an activation energy of 9.8 kcal. for reaction [9].

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3. \qquad [9]$$

This is in excellent agreement with their own (3) and previous work on the acetone photolysis. It follows therefore that either all methane comes from [9] or that if CH_3 radicals abstract hydrogen from ketene the activation energy must also be approximately 9.8 kcal. This latter alternative is ruled out, however, by the fact that R_{CH_4} is a function of $[H_2]$ and is independent of $[CH_2CO]$ in the present work.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

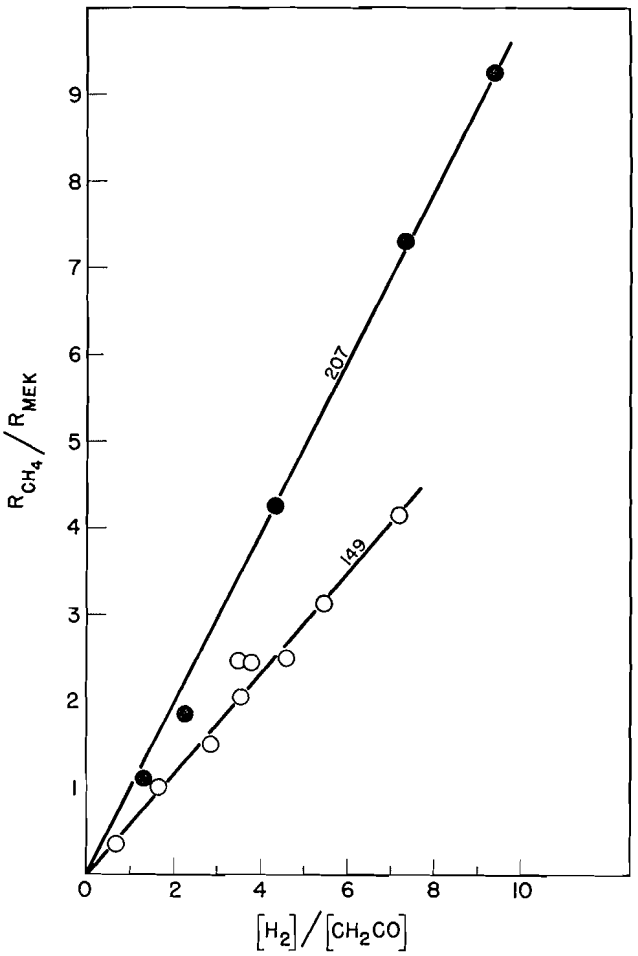

FIG. 5. R_{CH_4}/R_{MEK} plotted against $[H_2]/[CH_2CO]$. The temperatures are indicated on the curves.

If it is now assumed that [7] and [8] are the main method of forming methyl ethyl ketone (which is also assumed by Chanmugam and Burton) then an Arrhenius plot of

$$R_{CH_4}[CH_2CO]/R_{MEK}[\text{Acetone}]$$

using the results of Chanmugam and Burton leads to

$$E_9 - E_7 = 4.8 \text{ kcal.}, \qquad E_7 = 5 \text{ kcal.}$$

Considering the assumptions involved this is in excellent agreement with the value of 6.4 kcal. from the present work.

If equation [II] is now corrected to include reactions [7] and [8],

$$(R_{C_2H_6} + R_{MEK})/R_{C_2H_4} = k_3[H_2]/k_2[CH_2CO]. \qquad [IV]$$

Using equation [IV], we can correct the results in Fig. 3 for 149° and 207°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

In this way k_3/k_2 at 149° is raised to 0.66 in good agreement with the value of 0.59 obtained by extrapolation from Fig. 4. However, the results for 207° do not agree with equation [IV], since a straight line is not obtained when $(R_{C_2H_6}+R_{MEK})/R_{C_2H_4}$ is plotted against $[H_2]/[CH_2CO]$. Also, apart from the deviation from linearity the slope of the curve is much too small. A possible explanation is the formation of ethylene at the highest temperature by some process other than reaction [2], analogous to the unexplained formation of ethylene in the acetone photolysis at high temperatures.

In view of the uncertainties at the higher temperatures the exact value obtained for E_3-E_2 is open to some suspicion. There appears to be no doubt, however, that the difference between E_3 and E_2 is small.

The effect of intensity is in general agreement with the proposed mechanism. The competition between reactions [5] and [7] adequately explains the increase in the material balance, and the parallel increase in the apparent ratio k_3/k_2 as determined by equation [II] with increase in intensity.

Reaction [4] has previously been postulated by Knox, Norrish, and Porter (5) to account for the chain decomposition in the flash photolysis of ketene. To gain further evidence for its occurrence it was desirable to use a system in which hydrogen atoms were produced in the presence of ketene. With this in view an experiment was performed in which a 4:1 H_2–CH_2CO mixture was saturated with mercury vapor and illuminated with mercury resonance radiation (2537 Å) at 26°. Under these circumstances CH_4 was not formed, and the material balance was 1.0. The ratio $R_{C_2H_6}/R_{C_2H_4}$ was 4.2, about 2.5 times greater than that obtained for the photolysis of an equivalent mixture at 2700 Å. This is strong evidence for the occurrence of reaction [4].

The mechanism leads to $E_3-E_2 = 0.8$ kcal. All indications are that E_2 is small. Hence E_3 is of the order of 3 kcal. For reaction [3]

$$-\Delta H_3 = D(CH_2-H)-D(H-H)$$

$$= D(CH_2-H)-103 \text{ kcal.}$$

Hence E_3 can only be as small as 3 kcal. if $D(CH_2-H)$ is at least 100 kcal. If the high value of the latent heat of the sublimation of carbon, $L_C = 170$ kcal., is correct, as seems almost certainly to be the case, such a value for $D(CH_2-H)$ is reasonable. Recent unpublished work by Kistiakowsky in fact indicates that $D(CH_2-H)$ is probably greater than $D(CH_3-H)$.

AN OXYGEN-18 STUDY OF ACETAL FORMATION AND HYDROLYSIS[1]

By Fred Stasiuk,[2] W. A. Sheppard,[3] and A. N. Bourns

ABSTRACT

A tracer study has been made of acetal formation and hydrolysis. Benzaldehyde and *n*-butyraldehyde, enriched in O^{18}, on reaction with *n*-butyl and allyl alcohols, gave acetals of normal isotopic abundance. The label appeared in the water of condensation. Hydrolysis of benzaldehyde di-*n*-butyl acetal and *n*-butyraldehyde di-*n*-butyl acetal in O^{18} enriched water gave alcohols of normal isotopic content. A slight enrichment due to isotopic exchange was found in allyl alcohol produced by the hydrolysis of benzaldehyde diallyl acetal. These results establish that the reversible reaction proceeds by a fission of the aldehyde-carbon to oxygen bond.

INTRODUCTION

The rate-determining step in the acid-catalyzed formation of an acetal from aldehyde and alcohol is generally assumed to be the reaction of the second alcohol molecule with the conjugate acid of an intermediate hemiacetal. In the reverse of this reaction, that is, in acetal hydrolysis, the formation of the hemiacetal from the conjugate acid of the acetal is considered to be the slow step (4).

On the basis of the relative hydrolysis rates observed for a number of formaldehyde acetals (12), Hammett has suggested a unimolecular mechanism in which there is formed a carbonium ion intermediate derived from the alcohol component of the molecule (4).

$$[RCH(OR')—OHR']^+ \xrightarrow{\text{slow}} RCHOR'—OH + [R']^+$$

$$[R']^+ + H_2O \xrightarrow{\text{fast}} [R'OH_2]^+$$

Hydrolysis rates, however, are much more sensitive to structural changes in the aldehyde component. For example, the following relative rates have been observed in the hydrolysis of acetals of pentaerythritol: formaldehyde, 1; acetaldehyde, 6×10^3; acetone, 1×10^7 (13). Ingold (5) has pointed out that this kinetic effect can be understood if the carbonium ion is derived from the aldehyde component since then the methyl substituents would be joined directly to the electron deficient carbon.

$$[RCH(OR')—OHR']^+ \xrightarrow{\text{slow}} [RCHOR']^+ + R'OH$$

$$[RCHOR']^+ + H_2O \xrightarrow{\text{fast}} [RCH(OR')—OH_2]^+$$

This mechanism also accounts for the markedly greater ease of hydrolysis of acetals compared to ordinary ethers.

In acetal formation these reactions would be reversed with carbon–oxygen bond fission giving a carbonium ion again being the slow step.

The use of oxygen-18 provides a means of distinguishing between the two mechanisms since the oxygen appearing in the product, water, from acetal formation or in the product, alcohol, from acetal hydrolysis would have a different origin in the two cases. Benzaldehyde and *n*-butyraldehyde, enriched in O^{18}, have been reacted with *n*-butyl alcohol and allyl alcohol, and the O^{18} content of the resulting acetals and of the water of condensation determined for each of the four reaction systems. Allyl alcohol was chosen as an alcohol reactant since resonance stabilization of the allyl carbonium ion might be expected to provide a system most favorable for reaction by the Hammett mechanism. Hydrolysis in O^{18} enriched water of three acetals, benzaldehyde di-*n*-butyl acetal, *n*-butyraldehyde *n*-butyl acetal, and benzaldehyde diallyl acetal, has also been studied. The alcohol product was isolated and its oxygen isotopic abundance determined.

After the present investigation had been completed, O'Gorman and Lucas (9) reported a stereochemical study of acetal hydrolysis in which the acetal of D(+)-2-octanol was hydrolyzed to give D(+)-2-octanol of the same rotation as the original alcohol from which the acetal had been prepared. Since reaction by the Hammett mechanism would be expected to give extensive racemization, these authors conclude that it is the aldehyde carbon which forms the carbonium ion.

EXPERIMENTAL

Preparation of Benzaldehyde-O^{18} and Butyraldehyde-O^{18}

The aldehydes were shaken for three days with O^{18} enriched water containing approximately 0.8 atom % (0.6 atom % excess) of the heavier isotope. Water was separated and the aldehydes dried by azeotropic distillation with benzene. Their O^{18} content was determined in two ways: (1) by calculation from a knowledge of the O^{18} content of the water before and after equilibration, and (2) by determining the O^{18} content of the water produced on reaction of the aldehyde with phenylhydrazine under conditions which permitted its continuous removal by azeotropic distillation with benzene. Although there was good agreement between the two methods, the values obtained by the second have been used in Table I, since similar techniques were used in determining the O^{18} content of the water produced in acetal synthesis.

Acetal Formation

Carefully dried alcohol (0.32 mole) and the O^{18} enriched aldehyde (0.16 mole) were dissolved in 50 ml. of dry benzene and 0.5 gm. of anhydrous *p*-toluenesulphonic acid added. The solution was refluxed gently with continuous removal of the water of condensation using a Dean-Stark separator. The resulting acetal was recovered in the usual way, distilled, and converted to water and hydrocarbon in the manner described below.

Acetal Hydrolysis

The acetal (0.11 mole), enriched water (0.5 mole) containing approximately 0.4 atom % excess O^{18}, and two drops of concentrated hydrochloric acid were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

shaken together for two hours in a stoppered flask at 60–70° C. After the reaction mixture was cooled, it was neutralized with sodium hydroxide solution, water separated, and the alcohol product isolated by fractional distillation. The alcohol was dried azeotropically with benzene and converted to water and hydrocarbon by hydrogenolysis.

Hydrogenolysis of Organic Compounds and Mass-spectrometric Analysis of the Oxygen Isotopes

The acetals and alcohols were passed with a stream of dry hydrogen at 400° C. over a thoria-promoted nickel catalyst (11). Water, formed in 60-80% yields, was purified by distillation, and its O^{18} content determined by equilibration with carbon dioxide followed by a mass-spectrometric analysis of the oxygen isotopes in the carbon dioxide (3). The water removed azeotropically in the reaction of the aldehydes with phenylhydrazine and in acetal formation was purified by distillation over small quantities of sodium hydroxide and potassium permanganate before equilibration with carbon dioxide. Corrections were made for O^{18} dilution resulting from oxygen exchange with these compounds.

The isotopic analyses were made using a 180° direction-focusing Nier type mass spectrometer equipped with an automatic recorder (7). The precision of the mass-spectrometric analyses was $\pm 0.1\%$, while the over-all precision was considerably poorer, about ± 2–3%, owing to small and variable dilution of O^{18} during manipulative procedures.

Tests for Oxygen Exchange between Reactants and Products

Since exchange of oxygen between aldehyde and alcohol or acetal under the conditions of acetal synthesis would destroy the significance of the results insofar as mechanism considerations are concerned, the following tests for exchange were carried out:

(*a*) A synthesis of benzaldehyde di-*n*-butyl acetal using benzaldehyde containing 0.316 atom % excess O^{18} was carried to half completion, the unreacted *n*-butyl alcohol was separated, purified, and converted to water by hydrogenolysis, and the O^{18} content of the water determined in the manner previously described. The enrichment of the alcohol was found to be only 0.012 atom %.

(*b*) A benzaldehyde di-*n*-butyl acetal synthesis from benzaldehyde containing 0.346 atom % excess O^{18} was carried to half completion, the unreacted aldehyde and the acetal each separated, purified, and converted to water by methods already described. The benzaldehyde was found to contain 0.324 atom % excess, while the acetal was normal.

It is apparent from these results that, under the conditions used in the tracer study of acetal formation, there were no significant complications arising from exchange between normal and enriched materials.

Acid-catalyzed exchange between water and *n*-butyl alcohol during acetal hydrolysis experiments would certainly be too slow to appreciably affect the results (10, 2). Allyl alcohol, however, might be expected to undergo exchange much more rapidly and, therefore, an experiment was made to determine the extent of such exchange under the conditions used in the tracer studies. Allyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

alcohol, containing the normal abundance of the oxygen isotopes, was dissolved in five molar equivalents of water, containing 0.444 atom % excess O^{18}, and the solution maintained at 65° C. for two hours. At the end of this period the alcohol was isolated, carefully dried, converted into water, and the oxygen isotopic abundance determined in the usual way. The alcohol was found to contain 0.018 atom % excess O^{18}, showing that, although there was some exchange, it was not sufficiently rapid to invalidate conclusions based on the results of the tracer work.

RESULTS AND DISCUSSION

The results of the tracer study of acetal formation for the four different systems of aldehyde plus alcohol are shown in Table I. In each case, the acetal formed from the O^{18} enriched aldehyde has been found, within experimental error, to have the normal abundance of the oxygen isotopes. With the exception of the reaction of benzaldehyde with *n*-butyl alcohol, however, not all of the

TABLE I

OXYGEN-18 RESULTS FOR ACETAL FORMATION

†*Not determined.*

excess O^{18} originally present in the aldehyde reappeared in the water of condensation. This result and the trend of the values shown in the last column of the table can be readily understood on the assumption that, in competition with acetal formation, there is a reaction of the alcohol producing an ordinary ether and water of normal O^{18} abundance. Of the two alcohols, allyl and butyl, the former reacts more slowly in the acetal reaction (14), but is very much more reactive in simple ether formation. Furthermore, of the two aldehydes entering into the acetal reaction, benzaldehyde is the more reactive (1). Greatest dilution with normal water would, therefore, be expected in the *n*-butyraldehyde – allyl alcohol system, and least dilution in the reaction of benzaldehyde with *n*-butyl alcohol. This has been found to be the case.

The results of the acetal hydrolysis studies are shown in Table II. With the exception of the reaction of the acetal derived from allyl alcohol, the alcohol product contained, within experimental error, the normal abundances of the oxygen isotopes. Allyl alcohol was slightly enriched, a result to be ex-

**See first footnote to Table I.*

These results quite definitely establish that it is the bond of oxygen to the aldehyde carbon which undergoes fission in the reversible reaction of acetal formation and hydrolysis. Two mechanisms are consistent with this finding, namely the carbonium ion mechanism proposed by Ingold and a bimolecular process involving attack of the reagent on the conjugate acid of the hemiacetal or acetal. The latter mechanism, however, would appear to have been eliminated as a possibility by the recent observation of McIntyre and Long (6, 8) that the rate of hydrolysis of methylal is a linear function of the Hammett acidity function, H_0, indicating that no water molecules are firmly bound in the transition state. It is of interest that the present work shows that the carbonium ion is derived from the aldehyde part of the molecule even in systems involving allyl alcohol in which a carbonium ion derived from the alcohol would be mesomeric.

DEPOLARIZATION BY MERCAPTOACETIC ACID DURING ELECTRODEPOSITION OF COPPER[1]

By A. J. Sukava[2] and C. A. Winkler

ABSTRACT

Mercaptoacetic acid (MAA) in acid copper sulphate electrolyte decreased the cathode polarization throughout the course of electrolysis at all concentrations up to 20 mgm./liter. Addition of small amounts of chloride caused further depolarization. When present together with cystine, MAA showed an independence of action. The depolarization caused by MAA was ascribed to a decreased activation overpotential due to substitution of a more readily dischargeable MAA–copper complex for the aquo–copper complex. The additional depolarization due to chloride was ascribed to formation of a still more readily dischargeable chloro–MAA–copper complex. The depolarization in both cases increased with time during prolonged electrolysis, apparently due to surface roughening with, presumably, a consequent increase in surface area and decrease in true current density.

INTRODUCTION

Investigations have recently been made in this laboratory into the addition agent effects, during electrodeposition of copper, of some simple amino compounds (1, 5). These compounds are known to be positively charged in acid solution and to be capable of co-ordination with copper ions. In the course of these studies, it became of interest to inquire whether a sulphur-containing carboxylic acid lacking the amino group, and with no positive charge in the solution, would show any fundamental difference in behavior from that of the amino compounds studied. Preliminary experiments with mercaptoacetic acid (MAA) indicated an interesting behavior, more extended investigation of which gave the results reported in the present paper.

EXPERIMENTAL

The equipment and procedure were identical with those outlined previously (5). MAA was reagent grade. A stock solution of it in the standard electrolyte was made to a concentration of 0.05 gm./liter (the low solubility of a dark precipitate that formed limited the concentration to this value). This solution was diluted with standard electrolyte to give the desired concentration of MAA during electrolysis. All experiments were made at 24.5° C., with a current density of 2 amp./dm.^{2}.

RESULTS

MAA alone in the electrolyte reduced the total polarization below the 100-millivolt steady state value obtained with no additive (5). There was some indication of an indeterminate maximum in polarization during the initial 0.01 sec. (approximately), but the first distinct trace on the cathode ray oscilloscope showed a sharp drop in polarization and this depolarization by MAA continued throughout the electrolysis. The immediate effect of MAA

was to cause depolarization to about 50 to 60 mv. with a standard surface; the steady state polarization, established after electrolysis for an hour or more, was decreased to a limiting value of about 35 mv. as the concentration of MAA

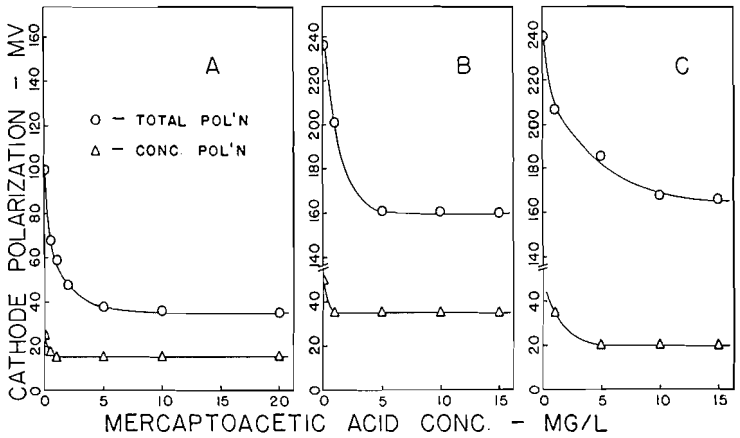

FIG. 1. Effect of mercaptoacetic acid concentration on steady state total and concentration polarizations.
A. Mercaptoacetic acid present alone.
B. Mercaptoacetic acid with 20 mgm./liter cystine.
C. Mercaptoacetic acid with 20 mgm./liter gelatin.

was increased, while the concentration polarization suffered a decrease of about 10 mv. (Fig. 1A). The steady state deposits obtained at these low polarizations had a characteristically coarse appearance under the microscope. These facts suggest that a gradual change in surface conditions, sufficient to decrease the true current density, is superimposed on the depolarizing action of the MAA. It seems reasonable to conclude that, in addition to the 15 mv. measured concentration polarization, there remains at the steady state about 20 mv. due to hydrogen ion interference (5).

The addition of chloride in low concentration caused further depolarization. Both the total and concentration polarizations at steady state, with 10 mgm./liter MAA, passed through a minimum at about 10 mgm./liter chloride ion (Fig. 2). The steady state polarization in the presence of chloride was also established slowly, just as in its absence. This greater depolarization due to chloride appeared to be accompanied by greater roughness of the cathode deposit. At the 20 mv. level of total polarization the crystal outgrowths were about 80 microns long. It should be noted, perhaps, that the concentration polarization at higher chloride concentrations increased to a limiting value of about 20 mv.

Since the polarization was decreased by MAA but increased by cystine (5) or gelatin (2), it was of interest to study the behavior when both depolarizing and polarizing addition agents were present. When various amounts of MAA were added with a fixed amount (20 mgm./liter) of cystine, the steady state polarization was lowered to a limiting value, the magnitude of the decrease being of the same order as that observed in the absence of cystine (Fig. 1B). Moreover, about 5 mgm./liter MAA gave maximum depolarization in either

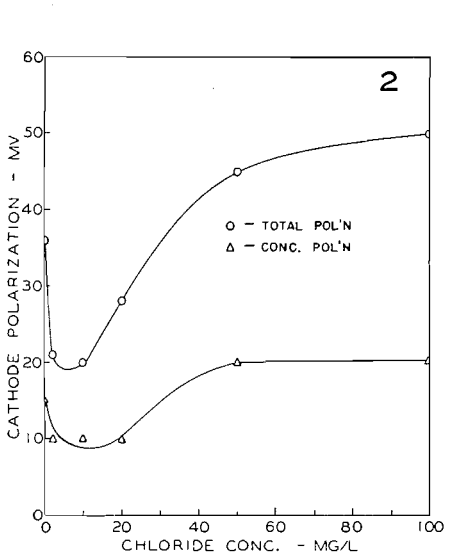
For personal use only.

case. The 75 mv. decrease in polarization caused by MAA in the presence of cystine includes a 15 mv. decrease in concentration polarization; the difference, 60 mv., is to be compared with the corresponding difference of 55 mv. obtained with MAA alone.



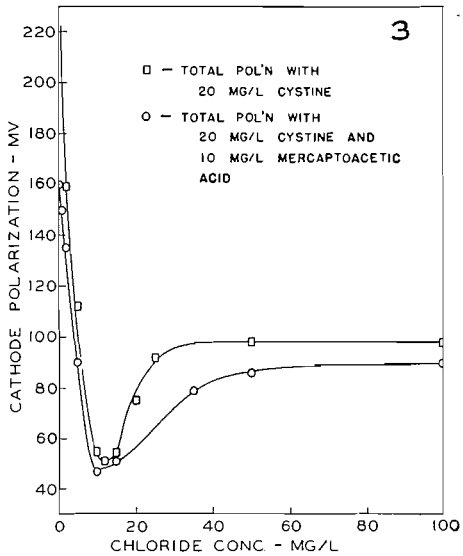


FIG. 2. Cathode polarization – chloride concentration relation in the presence of 10 mgm./liter mercaptoacetic acid.

FIG. 3. Cathode polarization – chloride concentration relation with 20 mgm./liter cystine and with 20 mgm./liter cystine and 10 mgm./liter mercaptoacetic acid.

Study of the polarization–time relations when both MAA and cystine were present showed that during the first few seconds of electrolysis the total polarization values were as low as 60 mv. A rapid increase to a maximum after one or two minutes was followed by approach to a steady state during the next two to three hours. The steady state deposits, when both addition agents were present, were smooth and had none of the gray tinge imparted to the deposit by cystine alone. The following data were obtained with 20 mgm./liter cystine and different concentrations of MAA:

Time	Total polarization (mv.) Mercaptoacetic acid concentration (mgm./liter)			
	1	5	10	15
0	(Initial maxima not measurable)			
2 sec.	80	85	73	60
¼ min.	155	132	113	93
½ min.	188	158	125	107

As indicated, the higher concentrations of MAA accentuated the depolarization during the early stages of electrolysis, though not at the steady state.

Addition of small concentrations of chloride practically eliminated the influence of MAA in the presence of cystine (Fig. 3). It should be noted, however, that with excess chloride the total steady state polarization in the presence of MAA was about 15 mv. lower than in its absence. Also, the levelling-off of the total polarization curve required a greater amount of chloride when MAA was added to the electrolyte. The presence of MAA with excess chloride and 20 mgm./liter cystine did not affect the concentration polarization, which was about 20 to 25 mv. The polarization–time curves with chloride present were essentially the same as those obtained with the same amount of cystine in the absence of MAA (5).

Experiments with a combination of 20 mgm./liter gelatin and different amounts of MAA showed an effect on the steady state polarization similar to that observed with cystine (Fig. 1C). Addition of chloride to such a system gave a polarization – chloride concentration relation similar in its essential features to that obtained with gelatin and chloride in the absence of MAA (4). The polarization–time relations were rather complex. They resembled those obtained with small concentrations of thiourea (5) in the respect that the polarization increased rather sharply after about one hour's electrolysis, after which it either increased further, or decreased slowly to the steady state value, depending on the concentration of chloride.

DISCUSSION

The immediate depolarizing effect of MAA, shown by initial polarization values, indicates that the activation overpotential was reduced to but a few millivolts. Accompanying the rough surface laid down, a further decrease in activation overpotential, hydrogen ion interference, and concentration polarization gradually occurred, probably because of decrease in true current density with an increase of true cathode area.

The behavior of MAA is in striking contrast with that of cystine, which appeared to leave the activation overpotential unaltered, but to increase the total polarization by adsorption on the cathode (5). If reference is made to the views of Lyons (3) the difference in behavior might be ascribed to a higher activity of cystine and a lower activity of MAA, relative to that of water, at the cathode surface. This might be expected since positively charged cystine, but not the neutral MAA, should tend to accumulate at the cathode surface. According to this point of view, such differences in activity of the co-ordinating species may be reflected in the relative activation overpotentials involved.

The observed additivity of the cystine and MAA effects at steady state gives clear indication that the two substances act in large measure independently. If, as argued previously (5), the aquo–copper complex is discharged in the presence of cystine, the reduction in activation overpotential with MAA is probably due to the ready discharge of the MAA–copper complex.

Although MAA should not accumulate at the cathode as a result of electrostatic attraction, it might well be readily adsorbed. Indeed, the behavior of MAA in the presence of cystine during the early stages of electrolysis suggests

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

that preferential adsorption of the MAA probably does occur prior to electrolysis. This could account for the observation that the depolarizing effect with higher concentrations of MAA is greater during the early stages than at steady state. However, the hindrance to the adsorption of cystine by such adsorbed MAA could be slowly overcome by gradual accumulation of cystine at the cathode surface. If MAA in the adsorbed phase were present as a readily dischargeable MAA–copper complex, it would not contribute to increase in polarization.

The additional depolarization caused by chloride in the presence of MAA apparently arises from increased roughening of the surface when chloride is present. This might be due to discharge of a more readily dischargeable chloro–MAA–copper complex, the presence of which is assumed, rather than the MAA–copper complex. Support for this assumption may be found in a previous argument (5) that chloride, when present alone, does not affect the activation overpotential. Hence, it does not appear that the depolarizing effect of chloride in the presence of MAA could be due to any readily dischargeable chloro–copper or chloro–aquo–copper complexes. For chloride concentrations above that corresponding to the minimum in the polarization – chloride concentration curve (Fig. 2), adsorption of cuprous chloride (5) might be expected to decrease the active surface area of the cathode, hence increase the true current density. This, in turn, might be expected to increase the difference between total and concentration polarization and this is observed. The 20-mv. plateau in the concentration–polarization curve (Fig. 2) might be regarded as a maximum diffusion and convection effect with increasing true current density.

Since the effect of low concentrations of chloride in the presence of both cystine and MAA more closely resembles its effect with cystine alone than with MAA alone (Fig. 3), the chloride effect is preferential in favor of cystine. For chloride concentrations above the minimum polarization point, more chloride appears to be necessary to produce the limiting maximum polarization (due to cuprous chloride (5)), when MAA is present with cystine than when cystine is present alone. Moreover, the effect of MAA in this combination is to lower the limiting maximum, which indicates a decrease in activation overpotential alone since the concentration polarization, hydrogen ion interference, and adsorption polarization due to cuprous chloride would be essentially the same in the two cases. These effects are to be expected if some of the chloride not tied up in the chloro–cystine–copper complex (5) associates with the MAA, possibly as the readily dischargeable chloro–MAA–copper complex.

THE CRYSTAL STRUCTURES OF SOME INTERMETALLIC COMPOUNDS OF PLUTONIUM[1]

By O. J. C. Runnalls

ABSTRACT

The crystal structures of the following binary intermetallic compounds of plutonium are reported: $PuAl_2$, $PuAl_3$, $PuAl_4$, $PuBe_{13}$, $PuCo_2$, $PuFe_2$, $PuMn_2$, $PuNi_2$, $PuNi_5$, and Pu_2Ni_{17}. In addition, the unit cell dimensions are reported for $PuAg_3$.

INTRODUCTION

It is now possible to report on the crystal structures of intermetallic compounds of plutonium, because of a recent declassification decision. X-ray data have been compiled in this paper for 11 such compounds. The present data are compared with American (5) and Russian (9) data released recently, in Appendix I at the end of the paper.

All X-ray powder photographs were taken on a 14.3 cm. diameter General Electric camera, using Ni-filtered Cu radiation. The single crystal photographs were taken on a G.E. rotation camera of 5 cm. radius. The wave-lengths used in the calculations were 1.5418 Å for Cu K_α and 1.5405 for Cu K_{α_1}.

EXPERIMENTAL

1. *Plutonium–Aluminum Alloys*

Plutonium–aluminum alloys were prepared in BeO crucibles by the reduction of 99.5% pure plutonium trifluoride with 99.99% pure aluminum in vacuum at 900° C. Three intermediate Pu–Al phases have been identified using X-ray diffraction analyses—$PuAl_2$, $PuAl_3$, and $PuAl_4$.

(*a*) *$PuAl_2$*

A powder diffraction pattern showed that $PuAl_2$ is face-centered cubic with $a_0 = 7.831 \pm 0.005$ Å. The compound is isostructural with UAl_2 (11) and, therefore, has the $MgCu_2$ structure. The face-centered positions in space group $Fd3m$ are

$$8 \text{ Pu in } 0, 0, 0; \tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{4}$$

$$16 \text{ Al in } \tfrac{5}{8}, \tfrac{5}{8}, \tfrac{5}{8}; \tfrac{5}{8}, \tfrac{3}{8}, \tfrac{3}{8}; \tfrac{3}{8}, \tfrac{5}{8}, \tfrac{3}{8}; \tfrac{3}{8}, \tfrac{3}{8}, \tfrac{5}{8}.$$

The calculated density is 8.10 gm. cm.$^{-3}$, assuming eight $PuAl_2$ molecules per unit cell. The interatomic distances are tabulated in Table I.

(*b*) *$PuAl_3$*

The powder diffraction pattern for $PuAl_3$ proved more complex than the simple cubic UAl_3, where $a_0 = 4.287$ Å (11). However, approximately one-third of the diffraction lines could be indexed on a simple cubic pattern of $a_0 = 4.30$ Å. Hence, it seemed probable that the $PuAl_3$ configuration was the result of a minor shift in the UAl_3-type cubic close-packing.

[1]*Manuscript received September 8, 1955.*
Contribution from the Chemistry and Metallurgy Division, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 267.

Single crystals of $PuAl_3$ were separated from a 40 wt. % Pu–Al alloy after dissolving the aluminum matrix in 3 *N* NaOH. Several of the hexagonal-

shaped crystals illustrated in Fig. 2 proved suitable as single crystal X-ray specimens. A series of rotation photographs revealed that the primitive cell was hexagonal with lattice dimensions

$$a_0 = 6.08 \pm 0.01 \text{ Å}$$

$$c_0 = 14.40 \pm 0.03 \text{ Å}.$$

The calculated density is 6.92 gm. cm.$^{-3}$, assuming six molecules per unit cell. A Laue photograph of a $PuAl_3$ crystal exhibited dihexagonal symmetry, identifying the point group as 622, $6mm$, $\bar{6}m2$, or $6/mmm$.

A model for the unit cell consistent with the observed dimensions was constructed using six close-packed planes, each containing one $PuAl_3$ molecule (Fig. 1). The model is derived by stacking the first four layers in cubic close-packed positions similar to UAl_3, and inserting a mirror plane at $c = \frac{1}{2}$, i.e.

The intensities of neighboring reflections only were compared, since no absorption correction was used in the calculations. Since the calculated intensities agreed with those observed on the powder diffraction film, the unit cell model appeared a reasonable one (see Table II).

The above solution may be considered only an approximate one, however, since weak reflections have been observed for 00.4, 00.8, 00.10, 00.14, and 00.16 by the Los Alamos group on Weissenberg patterns (8). Stambaugh found that the interplanar distances in the [00.1] direction were $0.162 \pm 0.002\ c_0$ for AB and CA, and $0.176 \pm 0.004\ c_0$ for BC, instead of the equiplanar distance of $0.167\ c_0$ (5). Unfortunately, this solution is not considered unique since satisfactory intensity checks for all *hk.l* values were not completed (5).

If all the Pu atoms were equidistant in the $PuAl_3$ cell the expected length of the c_0 axis would be 14.88 Å, instead of the observed 14.40 Å, to conform with the observed Pu–Pu separation in the [10.0] direction. Stambaugh's results indicate that the 0.48 Å shrinkage in c_0 is confined to those planes which do not have the UAl_3-type stacking sequence; i.e. if the shrinkage was distributed equally over the planes BAB and CAC the interplanar distances in the [00.1] direction would be $0.164\ c_0$ for AB and CA, and $0.172\ c_0$ for BC.

(*c*) *$PuAl_4$*

A 20 wt. % Pu–Al alloy was reacted with 3 *N* NaOH to dissolve the aluminum matrix. The powder diffraction pattern of the crystalline residue was complex, and similar to the UAl_4 pattern. Single crystals of $PuAl_4$ were prepared by cooling a molten 20% Pu–Al alloy at 100° C. per hr., and dissolving away the excess aluminum in NaOH. One of the small needlelike crystals (Fig. 3) was mounted in a quartz capillary.

A series of rotation photographs showed that $PuAl_4$ has an orthorhombic unit cell with dimensions similar to UAl_4 (see Table III). The calculated density is 6.10 gm. cm.$^{-3}$, assuming four molecules per unit cell. The spectra found missing by Borie (3) in the UAl_4 analysis were missing in the $PuAl_4$ pattern also; i.e. the reflections present were

(*a*) $h\ k\ l$, only for $h+k+l = 2n$
(*b*) $h\ k\ 0$, only for $h = 2n$ and $k = 2n$
(*c*) $h\ 0\ l$, only for $h+l = 2n$
(*d*) $0\ k\ l$, only for $k+l = 2n$.

TABLE III
UNIT CELL DIMENSIONS FOR $PuAl_4$ and UAl_4

	$PuAl_4$, Å	UAl_4 (3), Å
a_0	4.42 ± 0.02	4.41 ± 0.02
b_0	6.26 ± 0.02	6.27 ± 0.02
c_0	13.66 ± 0.03	13.71 ± 0.03

These data indicate that the cell is body-centered with an 00*l* glide plane and may be described by either the space group *Ima*2 or *Imma*.

2. *Plutonium–Beryllium Alloys*

Plutonium–beryllium alloys were prepared in BeO crucibles by the reduction of plutonium trifluoride with powdered beryllium metal, 99.8% pure, in vacuum at 1100–1200° C. At these temperatures the beryllium fluoride product readily distilled, leaving a fluoride-free alloy.

The powder diffraction pattern of the intermediate phase $PuBe_{13}$ was readily interpreted since the compound is face-centered cubic and is isostructural with UBe_{13}. The lattice constant, a_0, decreases from 10.284 ± 0.001 Å on the Be-rich side to 10.278 ± 0.001 Å on the Pu-rich side, indicating some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

small range of solid solubility. The calculated density, assuming eight formula weights of $PuBe_{13}$, is 4.35 gm. cm.$^{-3}$.

The compound UBe_{13} has been found isostructural with $NaZn_{13}$ and is described by the space group *Fm3c* (1). The $NaZn_{13}$ parameters reported by Zintl and Hauche (15) have been refined recently by Shoemaker *et al.* (14). These refined parameters, $y = 0.1806$ and $z = 0.1192$, were used in calculating the interatomic distances in the $PuBe_{13}$ cell (Table V).

TABLE V

INTERATOMIC DISTANCES IN $PuBe_{13}$

Atom	Neighbor	Number of neighbors	Distance, Å
$Be_I(0, 0, 0)$	$Be_{II}(0, y, z)$	12	2.22
Be_{II}	$Be_{II}(0, z, \frac{1}{2}-y)$	2	2.15
	$Be_I(0, 0, 0)$	1	2.22
	$Be_{II}(z, \frac{1}{2}-y, 0)$	2	2.25
	$Be_{II}(z, 0, y)$	4	2.31
	$Be_{II}(0, y, \bar{z})$	1	2.45
	$Pu(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$	2	2.99
$Pu(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$	$Be_{II}(0, y, z)$	24	2.99

The observed contraction of $PuBe_{13}$ on the Pu-rich side is somewhat surprising, since the Pu atom is about 35% larger than the Be atom. The isostructural $NpBe_{13}$ lattice also contracts, on the Np-rich side (12). A similar phenomenon has been observed by Bradley and Taylor (4) for the Al-rich side of the phase NiAl; i.e. the lattice spacing decreases rapidly with an increasing aluminum ratio. The latter effect has been attributed to the generation of nickel vacancies in the lattice as the aluminum ratio increases. A similar defect structure, Be-deficient, may exist in Pu-rich $PuBe_{13}$.

3. *Plutonium – Transition Metal Alloys*

Alloys of plutonium with the transition elements manganese, iron, cobalt, and nickel have been prepared by heating an intimate mixture of plutonium trifluoride and transition metal powder, 99.99% pure, in the presence of lithium vapor at 950° C. The product was then heated at 1100° C. for 15 min. Satisfactory Pu–Fe and Pu–Ni alloys were prepared in BeO crucibles. The best Pu–Co and Pu–Mn alloys, however, were prepared in Ta containers, since the latter alloys soaked into BeO.

(*a*) *PuX_2-type Phases*

X-ray powder photographs of alloys containing 65–70 wt. % Pu showed a face-centered cubic phase, isostructural with UFe_2 (2). Two separate preparations of $PuFe_2$ showed different lattice constants, indicating a range of composition for this phase. The observed lattice dimensions and calculated densities for the PuX_2 compounds are listed in Table VI. All four compounds have the $MgCu_2$ structure in space group *Fd3m*, with eight formula weights per unit cell. Interatomic distances are shown in Table VII.

TABLE VI

UNIT CELL SIZE AND X-RAY DENSITY FOR PuX_2-TYPE PHASES

Compound	Lattice dimension, Å	Calculated density, gm. cm.$^{-3}$
$PuMn_2$	7.290±0.005	11.96
$PuFe_2$	(*a*) 7.150±0.005	12.74
	(*b*) 7.190±0.005	12.53
$PuCo_2$	7.075±0.005	13.39
$PuNi_2$	7.16 ±0.01	12.90

TABLE VII

INTERATOMIC DISTANCES IN THE COMPOUNDS PuX_2 WHERE X = Mn, Fe, Co, or Ni

			Distance, Å				
				$PuFe_2$			
Atom	Neighbor	Number of neighbors	$PuMn_2$	(*a*)	(*b*)	$PuCo_2$	$PuNi_2$
Pu	Pu	4	3.16	3.10	3.12	3.06	3.10
	X	12	3.02	2.96	2.98	2.93	2.96
X	X	6	2.58	2.53	2.54	2.50	2.53
	Pu	6	3.02	2.96	2.98	2.93	2.96

(*b*) *$PuNi_5$*

A powder photograph of a Pu–Ni alloy near the composition $PuNi_5$, 45 wt. % Pu, showed a single phase which was indexed on a hexagonal lattice with dimensions

$$a_0 = 4.875 \pm 0.005 \text{ Å},$$

$$c_0 = 3.970 \pm 0.005 \text{ Å}.$$

The X-ray data resembled closely those for the compound $ThNi_5$, which has the $CaZn_5$ structure (6). Calculated intensities based on this structure are in reasonable agreement with the observed powder data for $PuNi_5$, as shown in Table VIII.

Thus, $PuNi_5$ may be described by the $CaZn_5$ structure with the following atomic positions in space group $P6/mmm$:

1 Pu in 0, 0, 0

2 Ni_I in $\frac{1}{3}, \frac{2}{3}, 0; \frac{2}{3}, \frac{1}{3}, 0$

3 Ni_{II} in $\frac{1}{2}, 0, \frac{1}{2}; 0, \frac{1}{2}, \frac{1}{2}; \frac{1}{2}, \frac{1}{2}, \frac{1}{2}$.

The calculated density is 10.82 gm. cm.$^{-3}$.

Interatomic distances are listed in Table IX.

(*c*) *Pu_2Ni_{17}*

Since $PuNi_5$ proved to be isostructural with $ThNi_5$, a search was made for a Pu–Ni compound isomorphous with Th_2Ni_{17}. A phase with an X-ray pattern

TABLE IX

INTERATOMIC DISTANCES IN $PuNi_5$

Atom	Neighbor	Number of neighbors	Distance, Å
Pu	Ni_I	6	2.82
	Ni_{II}	12	3.14
Ni_I	Pu	3	2.82
	Ni_I	3	2.82
	Ni_{II}	6	2.44
Ni_{II}	Pu	4	3.14
	Ni_I	4	2.44
	Ni_{II}	4	2.44

similar to, but more complex than, $PuNi_5$ was observed in alloys containing 30–35 wt. % Pu. This pattern was solved using a hexagonal lattice of dimensions

$$a_0 = 8.30 \pm 0.01 \text{ Å},$$

$$c_0 = 8.00 \pm 0.01 \text{ Å}.$$

The isomorphous phase Th_2Ni_{17} has $a_0 = 8.37$ Å and $c_0 = 8.14$ Å (6). Since the intensities in the powder patterns of Th_2Ni_{17} and Pu_2Ni_{17} are closely related it seems reasonable to assign the Th_2Ni_{17} structure to Pu_2Ni_{17}. The following approximate atomic positions apply in space group $P6_3/mmc$, for two molecules per unit cell:
2 Pu_I in (b), 2 Pu_{II} in (d), 6 Ni_I in (g), 12 Ni_{II} in (j) with $x = \frac{1}{3}$ and $y = 0$, 12 Ni_{III} in (k) with $x = \frac{1}{6}$ and $z = 0$, and 4 Ni_{IV} in (f) with $z = 0.11$.

4. *Plutonium–Silver Alloys*

Plutonium–silver alloys were prepared by heating in vacuum metallic Pu and fine-grain Ag of 99.97% purity in Ta crucibles at 1050° C. The Pu metal was prepared in 300 to 1000 mgm. amounts by the reduction of 99.5% pure PuF_3 with Li vapor at 950° C. During the alloying step the LiF slag covering the Pu metal distilled to the glass bulb surrounding the furnace assembly, leaving a clean alloy surface.

Powder diffraction patterns of Ag-rich alloys showed that a single phase existed at 40–45 wt. % Pu, i.e. $PuAg_3$. No attempt was made to apply graphical solution methods to the complex pattern since large hexagonal, columnar crystals could be separated from alloys approximating the composition $PuAg_3$. These proved satisfactory as single crystal X-ray specimens.

A series of rotation photographs showed that the $PuAg_3$ unit cell was hexagonal. Measurement of the layer line spacings gave lattice dimensions of

$$a_0 = 12.72 \pm 0.05 \text{ Å},$$

$$c_0 = 9.39 \pm 0.03 \text{ Å}.$$

These dimensions were refined by indexing the diffraction spots in the back reflection region of the zero layer lines. The diffraction angle, θ, was measured with a steel scale on a film which had been mounted in the camera according to the method of Straumanis. The pertinent X-ray data from a rotation about

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

the c_0 axis are given in Table X. The crystal was adjusted for a rotation about the a_0 axis so that all but the 00.l planes were tilted away from the vertical. The Cu K_{α_1} diffraction spot from 00.12 was indexed and θ measured on the resulting photograph. The measured d-spacing was 0.7835 Å. The refined unit cell dimensions are

$$a_0 = 12.730 \pm 0.003 \text{ Å},$$

$$c_0 = 9.402 \pm 0.005 \text{ Å}.$$

TABLE X

X-RAY DATA FROM A ROTATION PHOTOGRAPH OF $PuAg_3$ ABOUT THE c_0 AXIS

$hk.l$	$d_{obs.}$, Å*	a_0, Å
87.0, 13.0.0	0.8479	12.728
96.0	0.8431	12.730
12.2.0	0.8405	12.728
10.5.0	0.8333	12.729
13.1.0	0.8148	12.727
12.3.0	0.8017	12.727

97.0	0.7934	12.728
14.0.0, 10.6.0	0.7874	12.729
11.5.0	0.7776	12.730

**Obtained with Cu K_{α_1} radiation.*

The density of 450 mgm. of selected $PuAg_3$ crystals was measured with a pycnometer using ethylene dibromide as the immersion fluid. The resultant density was

$$\rho_{measured} = 11.16 \text{ gm. cm.}^{-3}.$$

If it is assumed that the unit cell contains 16 formula weights of $PuAg_3$, the density calculated from the X-ray data agrees closely with the measured value, i.e.

$$\rho_{calculated} = 11.33 \text{ gm. cm.}^{-3}.$$

The only systematic extinctions observed were of the type 00.l where $l = 2n+1$, indicating that the possible space groups for $PuAg_3$ are $P6_3$, $P6_3/m$, and $P6_322$.

Since a structure-type suggesting a solution for the $PuAg_3$ structure was not found in the literature, no further attempt was made to establish the atom positions in the unit cell.

DISCUSSION

Many more data on the binary intermetallic phases of neptunium, plutonium, and americium are required before the alloying systematics of the transuranic elements are understood. Sufficient information is available, however, to indicate that the alloying properties of the actinides are not necessarily similar in a specific alloy environment. The element plutonium, for example, exhibits isomorphism with uranium in the compounds $PuAl_2$ and $PuAl_4$ but not in $PuAl_3$, and with thorium in $PuNi_5$ and Pu_2Ni_{17} but not in $PuNi_2$. Further marked

*F.C.C. = *face-centered cubic.*

differences in alloying properties are illustrated by the absence of compounds of the type PuAl (5, 13) and AmAl (13), and Pu_3Al (5) in the systems U–Al and Np–Al.

Variable alloying characteristics in the early members of the actinide series might be expected, according to Mott (10), because of a variable valency resulting from an electron interchange between the 5*f* and 6*d* shells. Since existing evidence indicates that the binding energies for 5*f* and 6*d* electrons are nearly equal at neptunium, alloy data for neptunium and plutonium should prove especially important in characterizing the metallurgical systematics of the actinides.

SUMMARY

X-ray data for eleven binary intermetallic compounds of plutonium have been obtained. These are listed in Appendix I, and are compared with American results from the Los Alamos Laboratory (5). Russian results (9) for $PuBe_{13}$, $PuFe_2$, $PuMn_2$, and $PuNi_2$ are included in the Appendix.

Nine of the compounds are isostructural with the corresponding uranium compounds. $PuAl_3$ has a structure not previously reported. $PuAg_3$ appears also to have a new structure but a complete structure determination was not carried out.

ACKNOWLEDGMENT

The author is indebted to J. Baird and R. R. Boucher for their assistance in the preparation of the alloy specimens.

THEORY OF THE TRANSIENT PHASE IN KINETICS, WITH SPECIAL REFERENCE TO ENZYME SYSTEMS

II. THE CASE OF TWO ENZYME–SUBSTRATE COMPLEXES[1]

By Ludovic Ouellet and Keith J. Laidler

ABSTRACT

A theoretical treatment is worked out for the kinetic scheme

$$E + S \rightleftarrows (ES)_1 \rightleftarrows (ES)_2 \rightarrow E + P$$

in which two enzyme–substrate complexes are formed consecutively. The steady-state rate equations are obtained, and equations are given for the transient phase subject to the condition that the substrate concentration is greatly in excess of that of the enzyme. Some kinetic consequences of the resulting equations are discussed.

In a previous paper (3) the reaction scheme

$$E + S \rightleftarrows ES \rightarrow E + P$$

has been considered from the standpoints of the conditions under which the steady-state theory applies, and of the kinetic behavior during the transient phase which exists prior to the establishment of the steady state. Since several recent publications (1, 2, 4) have referred to the possibility that there may be several enzyme–substrate complexes formed in consecutive reactions we have thought it of interest to consider briefly the steady-state and transient-phase equations for such a system. We have confined our considerations to the case of two enzyme–substrate complexes, since the transient-phase equations become very complicated if more complexes are assumed.

THEORY

The system under consideration is

$$\underset{e_0-y_1-y_2}{E} + \underset{s_0}{S} \overset{k_1}{\underset{k_{-1}}{\rightleftarrows}} \underset{y_1}{(ES)_1} \overset{k_2}{\underset{k_{-2}}{\rightleftarrows}} \underset{y_2}{(ES)_2} \overset{k_3}{\rightarrow} \underset{e_0-y_1-y_2}{E} + \underset{p}{P}.$$

It is to be noted that the complexes are formed reversibly, the final products irreversibly. The concentrations of the various substances are indicated above. As discussed in the previous paper (3) the substrate concentration can be assumed to be essentially s_0 during the transient phase provided that the initial concentration of substrate is much greater than that of the enzyme.

The kinetic equations applicable to the above system are

$$[1] \qquad \dot{y}_1 = k_1 s_0 (e_0 - y_1 - y_2) - (k_{-1} + k_2) y_1 + k_{-2}\, y_2$$

$$[2] \qquad \dot{y}_2 = k_2\, y_1 - (k_{-2} + k_3) y_2$$

$$[3] \qquad \dot{p} = k_3\, y_2.$$

[1]*Manuscript received October 17, 1955.*
Contribution from the Department of Chemistry, The University of Ottawa, Ottawa, Canada.

Steady State

The steady-state equations are obtained by setting $\dot{y}_1$ and $\dot{y}_2$ equal to zero and solving Eqs. [1] and [2]. The solution for y_2 is

$$[4] \qquad y_2 = \frac{k_1 k_2 e_0 s_0}{k_1(k_{-2}+k_2+k_3)s_0+(k_{-1}k_{-2}+k_{-1}k_3+k_2k_3)}$$

and the rate is therefore

$$[5] \qquad \dot{p} = \frac{k_1 k_2 k_3 e_0 s_0}{k_1(k_{-2}+k_2+k_3)s_0+(k_{-1}k_{-2}+k_{-1}k_3+k_2k_3)}.$$

This may be expressed in the familiar form

$$[6] \qquad \dot{p} = \frac{V s_0}{K_m+s_0}$$

where V, the maximum rate, is given by

$$[7] \qquad V = \frac{k_2 k_3 e_0}{k_{-2}+k_2+k_3}$$

and K_m, the Michaelis constant, is

$$[8] \qquad K_m = \frac{k_{-1}k_{-2}+k_{-1}k_3+k_2k_3}{k_1(k_{-2}+k_2+k_3)}.$$

If k_3 is very large the second complex $(ES)_2$ has no stable existence, and the relationships then reduce to the familiar forms

$$[9] \qquad V = k_2 e_0$$

$$[10] \qquad K_m = (k_{-1}+k_2)/k_1$$

applicable to the case of the single complex.

The Transient Phase

The kinetic equations for the transient phase are obtained as follows. Elimination of y_1 between Eqs. [1] and [2] gives rise to

$$[11] \qquad \ddot{y}_2+\dot{y}_2(k_1 s_0+k_{-1}+k_2+k_{-2}+k_3) + y_2[k_1(k_2+k_{-2}+k_3)s_0+k_{-1}k_{-2}+k_2 k_3]-k_1 k_2 s_0 e_0 = 0.$$

This may be written as

$$[12] \qquad \ddot{y}_2+P\dot{y}_2+Qy_2-R = 0.$$

The solution of this is

$$[13] \qquad y_2 = +(R/Q)+M \exp\{\tfrac{1}{2}[-P+\sqrt{(P^2-4Q)}]\,t\}+N \exp\{\tfrac{1}{2}[-P-\sqrt{(P^2-4Q)}]t\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

where M and N are constants to be determined from the boundary conditions. The condition $t = 0$, $y_2 = 0$ leads to

$$M+N = -R/Q \tag{14}$$

and $t = 0$, $\dot{y}_2 = 0$ leads to

$$\frac{M}{N} = \frac{P+\sqrt{(P^2-4Q)}}{-P+\sqrt{(P^2-4Q)}}. \tag{15}$$

The solution of Eqs. [14] and [15] leads to

$$M = -\frac{R}{Q}\cdot\frac{P+\sqrt{(P^2-4Q)}}{-P+\sqrt{(P^2-4Q)}} \tag{16}$$

and

$$N = -\frac{R}{Q}\cdot\frac{\sqrt{(P^2-4Q)}-P}{2\sqrt{(P^2-4Q)}}. \tag{17}$$

The expression for y_2 is therefore

$$y_2 = \frac{R}{Q}\left[1-\frac{P+\sqrt{(P^2-4Q)}}{2\sqrt{(P^2-4Q)}}\exp\{\tfrac{1}{2}[-P-\sqrt{(P^2-4Q)}]t\}\right. \\ \left.-\frac{\sqrt{(P^2-4Q)}-P}{2\sqrt{(P^2-4Q)}}\exp\{\tfrac{1}{2}[-P-\sqrt{(P^2-4Q)}]t\}\right]. \tag{18}$$

This is of the form

$$y_2 = (R/Q)+M\,e^{Ft}+N\,e^{Gt} \tag{19}$$

where R, Q, M, and N are defined above and F and G are given by

$$F=\tfrac{1}{2}[P-\sqrt{(P^2-4Q)}] \tag{20}$$

$$G=\tfrac{1}{2}[+P+\sqrt{(P^2-4Q)}]. \tag{21}$$

Insertion of Eq. [19] in Eq. [3] followed by integration then gives rise to the following expression for p as a function of time:

$$p = \frac{k_3R}{Q}t+\frac{k_3M}{F}(e^{-Ft}-1)+\frac{k_3N}{G}(e^{-Gt}-1). \tag{22}$$

The general form of this relationship is as shown in Fig. 1. When t is sufficiently large the exponential terms vanish (since F and G are necessarily positive) and the equation reduces to

$$p = \frac{k_3R}{Q}t-\frac{k_3M}{F}-\frac{k_3N}{G}. \tag{23}$$

This linear relationship between p and t corresponds to the establishment of the steady state. If this linear portion of the curve is extrapolated back to the time axis the intercept, which may be referred to as the induction period for the reaction, is given by

$$\tau = \frac{Q}{R}\left(\frac{M}{F}+\frac{N}{G}\right). \tag{24}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

If the expressions for F, G, M, N, Q, and R are inserted into this relationship it is found that

$$[25] \qquad \tau = P/Q$$

$$[26] \qquad = \frac{k_1 s_0 + k_{-1} + k_2 + k_{-2} + k_3}{k_1(k_2 + k_{-2} + k_3)s_0 + k_{-1}k_{-2} + k_1 k_3 + k_2 k_3}.$$

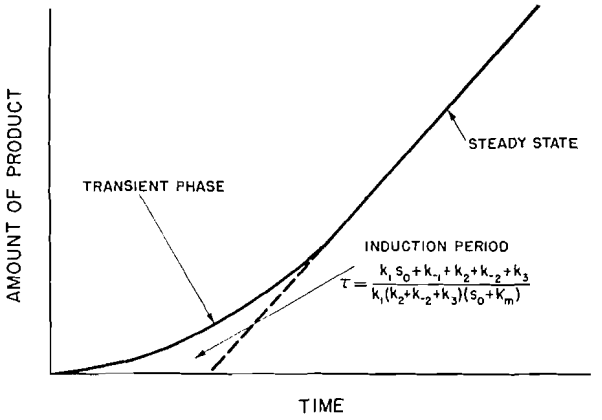

FIG. 1. Schematic plot of amount of product against time, for the case in which there are two successive enzyme–substrate complexes.

Using Eq. [8] this may be written as

$$[27] \qquad \tau = \frac{k_1 s_0 + k_{-1} + k_2 + k_{-2} + k_3}{k_1(k_2 + k_{-2} + k_3)(s_0 + K_m)}.$$

Periodic Solutions

The interesting possibility of periodic behavior can be shown to arise if $P^2 - 4Q$ is less than zero. Algebraic analysis shows that this can happen only if $k_2 > k_{-1}$. The necessary conditions can then be written as

$$[28] \quad k_2 + k_{-2} + k_3 - 2\sqrt{[(k_2 - k_{-1})k_3]} < k_1 s_0 + k_{-1} < k_2 + k_{-2} + k_3 + \sqrt{[(k_2 - k_{-1})k_3]}.$$

Under these conditions, Eq. [18] can be written as

$$[29] \quad y_2 = \frac{R}{Q} - \frac{R}{Q}\left[\exp -\frac{Pt}{2}\right]\left(\cos\frac{\sqrt{(4Q - P^2)}}{2} \cdot t + \frac{RP}{Q\sqrt{(4Q - P^2)}} \sin\frac{\sqrt{(4Q - P^2)}}{2} \cdot t\right).$$

This is the equation of a damped periodic variation, the period T of which is given by

$$[30] \qquad T = 4\pi/\sqrt{(4Q - P^2)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

Eqs. [25] and [30] yield, in terms of the measurable quantities τ and T,

$$Q = \frac{2 \mp 2\sqrt{[1-(4\pi^2\tau^2/T^2)]}}{\tau^2} \qquad [31]$$

and

$$P = \frac{2 \mp 2\sqrt{[1-(4\pi^2\tau^2/T^2)]}}{\tau}. \qquad [32]$$

P and Q are not complex quantities, so that

$$T \geqslant 2\pi\tau \qquad [33]$$

is a necessary relation between the measurable quantities T and τ. The fact that T must be so much greater than τ makes it difficult to detect the periodicity experimentally. In ideal cases a plot of P against s, by extrapolation to $s = 0$, gives

$$P_{s=0} = k_{-1}+k_2+k_{-2}+k_3 \qquad [34]$$

and the slope of the line will give k_1 directly. A similar plot for Q yields

$$Q_{s=0} = k_{-1}(k_{-2}+k_3)+k_2\,k_3 \qquad [35]$$

and the slope of the line is $k_1(k_2+k_{-2}+k_3)$. Equations [7], [8], [34], [35] and the slopes of P vs. s_0 and Q vs. s_0 provide six relations to determine five constants.

DISCUSSION

Certain special cases of the above equations are of some interest. In the first place, in the event that k_3 is very large (i.e. that the complex $(ES)_2$ has only a fleeting existence) the induction period is given by

$$\tau = 1/[k_1(s_0+K_m)]. \qquad [36]$$

This equation was previously quoted by Gutfreund (2), and it follows directly from Eq. [48] of the previous paper (3). Since Eq. [36] is of the same form as Eq. [27] it is clearly not possible to tell, from a study of the induction period, anything about the existence of the second complex.

Another result of interest is obtained if s_0 is sufficiently large. The induction period is then

$$\tau = 1/(k_2+k_{-2}+k_3). \qquad [37]$$

A plot of $\tau(s_0+K_m)$ against s_0 would give this quantity as its slope. In the event that one of these three rate constants is much larger than the others the induction period is thus, at high s_0, equal to the reciprocal of that constant.

VAPOR PRESSURES OF AQUEOUS SOLUTIONS OF SILVER NITRATE, OF AMMONIUM NITRATE, AND OF LITHIUM NITRATE[1]

By A. N. Campbell, J. B. Fishman, G. Rutherford, T. P. Schaefer,[2] and L. Ross

ABSTRACT

This paper is devoted to the direct determination of the vapor pressures of solutions of the nitrates of silver, of ammonium, and of lithium, at temperatures varying from 30° C. to 105° C. and at concentrations varying from 10 to 85 weight % (for lithium nitrate, the limited solubility precluded measurements beyond 65%). From the vapor pressures, the enthalpies of evaporation of water (by a modification of the Clapeyron–Clausius equation), the differential heats of dilution, and the activities of water (as compared with the mole fractions of the solvent) have been calculated. From the results we conclude that the water of hydration of the ammonium and silver ions (if, indeed, these ions are hydrated at all) is very loosely attached, while that of the lithium ion is strongly bound.

The present work was undertaken because it was thought that a knowledge of the vapor pressures at a series of temperatures would yield the heat of evaporation of water from solutions of different concentrations and hence throw some light, if only of a qualitative nature, on the firmness with which the different ions held their water of hydration. As the concentration of an electrolytic solution is increased there will be fewer molecules of water left for ionic hydration; at extremely high concentration there will be strong competition for the remaining water molecules. Using the concept of Stokes and Robinson (8) that the ions adsorb layers of water molecules in accordance with the Brunauer, Emmet, and Teller equation, it should become progressively more difficult to strip away the successive layers of water surrounding the ions; the last and most firmly bound layer should require a large amount of energy to remove it. Application of the Clapeyron–Clausius equation (though not in its normal form: see Discussion) to the vapor pressures of concentrated solutions should give the heat of evaporation and hence, perhaps, a measure of the difficulty of removing water from the ions.

The problem of finding vapor pressures was first attempted by finding boiling points at different fixed pressures. After spending a year, however, on this method of attack we abandoned it because we found that, although we could control pressure and boiling point to any desired degree of constancy, we had no certainty as to the composition of the equilibrium liquid. Indeed, the work about to be described showed that we occasionally had composition errors equivalent to an error of 0.5° in boiling point.

Because of this uncertainty in the composition variable of the boiling point method, we decided to turn to a method in which the composition factor would be known and invariable. The direct determination of vapor pressure in a closed system offers such a method. The loss of water by evaporation to produce one atmosphere pressure in a closed system is negligible, even in the strongest solutions used.

[1]*Manuscript received October 3, 1955.*

There has been surprisingly little experimental work done on the vapor pressure of aqueous electrolytic solutions, especially over a range of temperature. Most of that which has been done is confined to the isopiestic measurement of vapor pressures for the determination of activity at 25° C.

Our vapor pressure measurements have been utilized to calculate the heat of evaporation of water from the various solutions, the heat of dilution, and the activity of water as given by the ratio p/p_0.

EXPERIMENTAL PROCEDURE

The sources and purity of our materials have frequently been described elsewhere (1). All solutions were made up by direct weighing, using salts which, after purification, had been thoroughly dried; the lithium nitrate was always fused before use. For the determination of the vapor pressures of the more dilute solutions the differential manometer of Hartung (4) was used. It was possible to use this up to concentrations of 60% by weight for silver nitrate solutions but only up to 40% concentration for lithium nitrate. In the differential manometer one limb contains pure water and the other the solution.

Fig. 1 represents Hartung's apparatus as used by us. The method of use is described by Hartung but certain modifications are mentioned here. For instance, since we used mineral oil in our thermostat and worked up to temperatures of 105°, it was impossible to use ordinary rubber in the thermostat and neoprene was used for the bung through which the long limb of the mano-

For personal use only.

meter passes. The long limb was also severed, about 10 cm. above the mercury reservoir, and a ball and socket joint introduced; this facilitated the installation and dismantling of the apparatus, which had to be done every time a new solution was introduced. A little silicone oil was allowed to float on top of both mercury levels in the manometer. This had the dual advantage of preventing the condensation of small amounts of water on the mercury surfaces (which, we found, produced distortion in the field of vision of the cathetometer) and, when silver nitrate solutions were used, of preventing mercury vapor entering the solutions and causing decomposition, as it does very readily.

The necessity of removing the last trace of air in all vapor pressure measurements is well known, and for this purpose the procedure adopted was to freeze both bulbs in dry ice. The mercury level was then lowered and both bulbs evacuated continuously for the space of half an hour. The mercury level was then raised and the contents of the bulbs allowed to thaw. The above procedure was repeated at least four times. Finally the capillary leading to the pump was sealed off and the contents allowed to thaw for the last time. The solution was then agitated to ensure homogeneity.

With the more concentrated solutions (70% by weight for silver nitrate, 40% for lithium nitrate) it was impossible to use the differential manometer, since the limbs of the U-tube were only 20 cm. long, and with highly concentrated solutions at higher temperatures the difference in vapor pressure from that of water became greater than 20 cm. of mercury. A direct barometric apparatus therefore became necessary.

The apparatus is shown in Fig. 2. Dissolved air was removed by the same treatment as already described. In the more concentrated solutions now used,

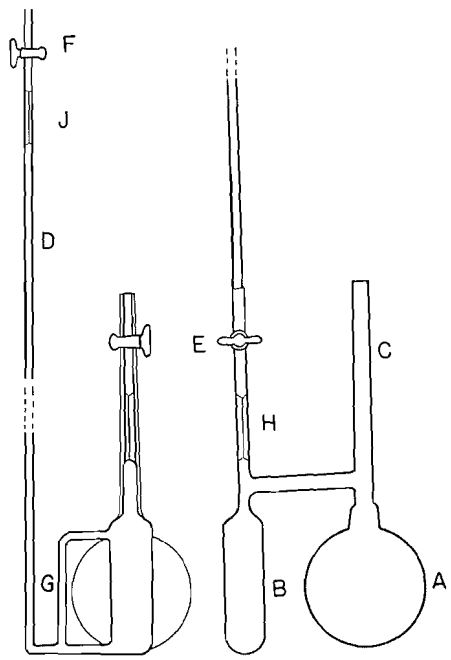

Fig. 2.

the 'salting-out' effect rendered the solubility of air much less and the difficulty of removing dissolved air was proportionately reduced.

All manometers were completely immersed in a tall rectangular copper tank furnished with glass sides. Because the thermostatic fluid was mineral oil it was necessary to use Buna-N rubber as gasket material for the glass windows. Measurements were made between 30° C. and 105° C. The usual procedure of using an immersion heater to keep temperature slightly below the operating temperature and controlling an electric light bulb as the source of extra heat, together with the use of three stirrers, gave a temperature fluctuation of not more than ±0.02° C., over the whole range of temperature.

Two cathetometers were used to measure differences in mercury levels, one a short range instrument which could be read to 0.01 mm., and another of greater range which could be read to 0.1 mm. Successive readings showed that it required about two hours to obtain equilibrium at the lower temperatures, while half an hour sufficed at the higher temperatures. All mercury columns were reduced to 0° C. The probable error does not exceed 0.2% and this makes the data good enough for most purposes.

EXPERIMENTAL RESULTS

The experimental results are given in Table I.

DISCUSSION

In order to obtain ΔH_1 (the molar enthalpy of evaporation of water from the different solutions) the following procedure was adopted: Using the Clapeyron–Clausius equation, in its classical form, the calculation must be restricted to a small range of temperature over which ΔH may be regarded as constant; such a restriction magnifies the experimental error. A very useful application of the Clapeyron–Clausius equation for the correlation of vapor pressure and latent heat data has, however, been given by Othmer (7). Using the symbols ΔH_1 and ΔH_2 for the molar enthalpies of evaporation of water from solution and from pure water respectively and rearranging the differential form of the Clapeyron equation, the following expression results:

$$[1] \qquad (1/\Delta H_1)(dP_1/P_1) = dT/RT^2.$$

The same expression may be written for any other material at the same temperature as:

$$[2] \qquad (1/\Delta H_2)(dP_2/P_2) = dT/RT^2.$$

P_1 and P_2 are the vapor pressures of the two substances at the same temperature T. Equating equations [1] and [2] and rearranging, equation [3] is obtained:

$$[3] \qquad dP_1/P_1 = (\Delta H_1/\Delta H_2)(dP_2/P_2).$$

With the usual assumptions as to the vapor being an ideal gas and the volume of the condensed phase being negligible, one obtains, in logarithmic form,

$$[4] \qquad d(\log P_1)/d(\log P_2) = \Delta H_1/\Delta H_2.$$

If $\Delta H_1/\Delta H_2$ is considered constant, equation [4] may be integrated to give equation [5],

$$[5] \qquad \log P_1 = (\Delta H_1/\Delta H_2) \log P_2 + C.$$

Hence, if the logarithm of the vapor pressure, P_1, of a solution is plotted against the logarithm of the vapor pressure of water, P_2, at the same temperature, a straight line results which has for its slope the ratio of the molar enthalpies of evaporation. This line is straight if the ratio $\Delta H_1/\Delta H_2$ is constant over the temperature range in question and this is reasonably near the truth for water and aqueous solutions. Knowing the value of the ratio, and that of the latent heat of evaporation of pure water, ΔH_1, the latent heat of evaporation of water from solution is obtained. The best data for the latent heats of evaporation of water, and for vapor pressure, are contained in a paper by Goff and Gratch (3); they give an equation for vapor pressure of water in terms of temperature, which we have used throughout. The slopes of log P_1 versus log P_2 were calculated analytically by the method of moments instead of by the more inaccurate graphical method.

In Table II are given the values of ΔH_1, the latent heat of evaporation of water from the various solutions, for a mean temperature of 50° C. For this temperature we have taken ΔH_2, the heat of evaporation of pure water, to be 10,245 cal.; this is the average of several direct calorimetric determinations by Johnson and Molstad (6). An examination of Table II shows that, for silver nitrate, ΔH for solution is not much different from that for pure water. The

slight difference is positive and increases with increasing concentration, i.e., less heat is required to evaporate water from solution than from pure water. Similar results have been obtained before. Thus, Hirschler (5) showed that the vapor pressures of certain saturated aqueous solutions, when plotted as

log P vs. $1/T$, give straight lines parallel to a similar plot for water. Since $\Delta H_2-\Delta H_1$ is a small positive quantity and increases with increasing concentration, this means that heat is adsorbed when a mole of water is added to a large amount of solution (differential heat of dilution) and this amount of heat increases with increasing concentration. For ammonium nitrate, the differential heat of dilution is also positive, but rather more pronounced, amounting to half a kilocalorie at the highest concentration. For lithium nitrate the heat of dilution is negative. Heat is evolved when lithium nitrate solutions are diluted and this seems to be in harmony with the accepted belief in the strongly hydrated lithium ion.

In Table III, the activity of the water in solution, derived from the vapor pressure and the corresponding vapor pressure of pure water, is compared with the mole fraction of water (calculated on the assumption of non-ionized salt).

For silver nitrate, the agreement is surprisingly good between the mole fraction and the activity coefficient and it is essentially independent of temperature, i.e., Raoult's law is obeyed, throughout the concentration range, far more closely than it should be for a solution of an electrolyte. Campbell and Kartz-

**Calculated on the assumption of no ionization, i.e., the weight of silver nitrate is divided by the molecular weight.*

mark (2) have calculated the extent of ion-pair formation in silver nitrate solutions, but this is far from complete at concentrations for which the calculation is valid and therefore it is impossible to account for the above observation on the assumption that silver nitrate is only slightly ionized. For ammonium nitrate, however, the activity drops markedly with rising temperature and, for concentrations of 80 and 90% (mole fractions of 0.6557 and 0.5262 water) the activity is much lower than the mole fraction. For lithium nitrate, the discrepancy between activity and mole fraction is still greater. Since activity and concentration are related, it would appear that the concentration of (free) water is somewhat less in ammonium nitrate solutions than the mole fraction would imply and, in lithium nitrate solutions, very much less. This

can be accounted for on the assumption that the silver ion is not (or very feebly) hydrated, the ammonium ion a little more, and the lithium ion very strongly hydrated.

Finally, in Fig. 3, the vapor pressures of all three electrolytes, at different temperatures, have been plotted against mole fraction of solute. The figure brings out very clearly the fact that, at corresponding mole fraction and

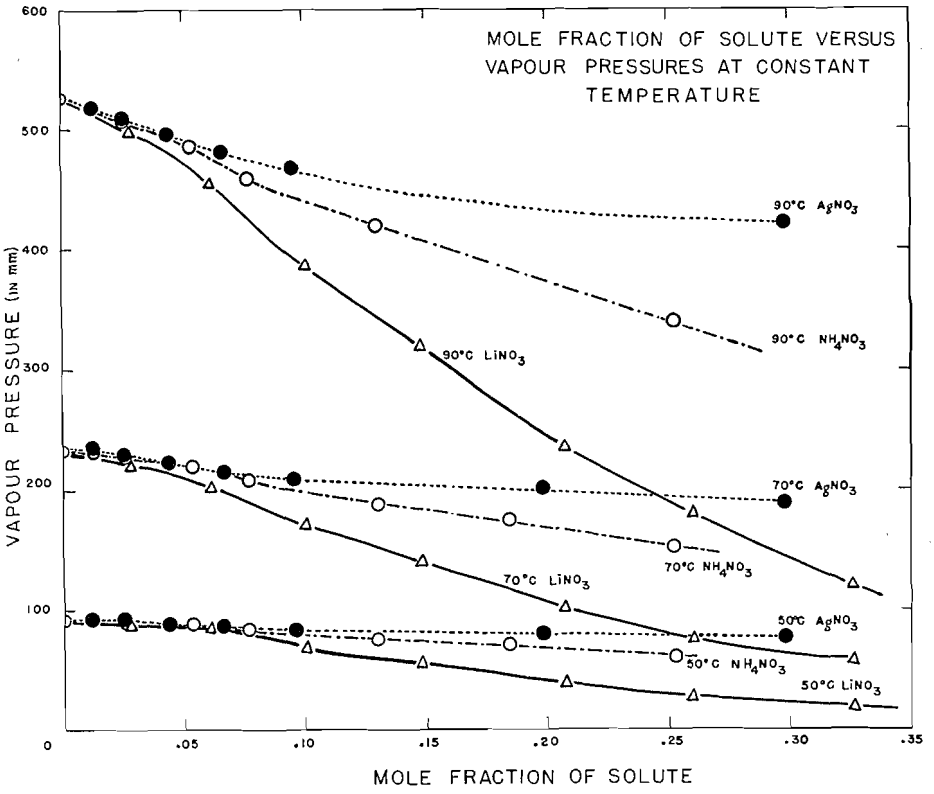

Fig. 3.

temperature, the vapor pressures of the lithium nitrate solutions are much lower than those of the silver nitrate and ammonium nitrate solutions. The most obvious explanation of this is the one given above, viz. that the lithium ion holds its water of hydration much more firmly than do the silver and ammonium ions. The high viscosity of lithium nitrate solutions points in the same direction.

THE NUMBER OF POLYPEPTIDE CHAINS IN BOVINE PLASMA ALBUMIN[1]

By M. E. Reichmann[2] and J. Ross Colvin

ABSTRACT

The molecular weight of performic acid oxidized bovine plasma albumin, dispersed in 0.08 *M* borate + 0.2 *M* sodium chloride buffer, pH 7.4, was estimated as 30,000 by light-scattering and sedimentation equilibrium methods, 19,000 by osmotic pressure. Sedimentation velocity analyses and electrophoresis showed that the component polypeptide chains of the material are similar in mass and charge density so the polydispersity must be attributed to labile aggregates. The results indicate that here are at least three and probably four similar polypeptide chains in the molecule of native bovine plasma albumin, held together by disulphide bonds.

INTRODUCTION

Knowledge of the number of polypeptide chains in a protein molecule is prerequisite to an understanding of its structure but unequivocal data are available for only a few of these substances (5). Even for readily available bovine plasma albumin (B.P.A.) information is scanty. Previous estimates from end group analyses (33, 37), or from viscosity measurements after the disulphide links between chains were broken by performic acid (19), agree that the most probable figure is one. However, the first method may be misleading because of terminal substitution, and unequivocal interpretation of the second is difficult. Therefore, the number of polypeptide chains in B.P.A. has been redetermined by estimating the molecular weight of the product of performic acid oxidation (29) of B.P.A. by light-scattering, sedimentation equilibrium, and osmotic pressure techniques. The results were supplemented by sedimentation velocity and electrophoretic measurements.

METHODS AND MATERIALS

Previous studies have shown that the disulphide links between amino acid residues in a protein may be destroyed without significant hydrolysis of the peptide bonds (3, 30). Accordingly, the component polypeptide chains were separated by a modification of Sanger's method of oxidizing disulphide bridges (30) on the assumption that any other covalent links, such as phosphate, (22) were absent.

Five grams of B.P.A. (Armour and Co., Chicago, Lot R370295B) was dissolved in 180 ml. of 90% formic acid and 30 ml. of 30% hydrogen peroxide was added. The reaction was allowed to proceed 25 min. at room temperature, then 50 ml. of 95% ethanol was added and the oxidized protein was precipitated by adding 200 ml. of 5 *M* NaCl. The addition of ethanol prevented frothing and loss of material. After the evolution of oxygen stopped, an additional 400 ml. of 5 *M* NaCl was added to ensure complete precipitation. The

precipitate was separated from the supernatant liquid by centrifugation, resuspended in water, and dialyzed against distilled water for 36 hr. Analysis of the outer liquid showed that less than 1.5% of the precipitated nitrogen passed through the membrane during dialysis. Similar analysis of the supernatant liquid from centrifugation showed that less than 2.0% of the total nitrogen failed to be precipitated by the salt solution. Finally, the oxidized, dialyzed B.P.A. was freeze dried. Ninety-five per cent of the initial nitrogen was recovered. The slightly yellow, fluffy powder was initially insoluble in water at neutrality to pH 9.5. However, the protein did not reprecipitate when the pH was adjusted to neutrality by dialysis. The oxidized protein was also readily soluble in formamide, and 90% formic acid. Three separate preparations, made as described above, plus one sample oxidized for 60 min. were examined during the study. No differences were observed between any of the preparations.

During the study, it was necessary to oxidize crystalline lysozyme (Armour and Co., Chicago) as above, except that the oxidized protein was precipitated by 180 ml. of saturated Na_2SO_4 per gram of lysozyme and dialysis times were extended in order to remove the sulphate ion completely.

An aliquot of the first preparation of oxidized B.P.A. was hydrolyzed by refluxing in 3 *N* HCl in 50% formic acid for 24 hr. and the hydrolyzate analyzed qualitatively for sulphydryl or disulphide bonds by the methods of Toennies and Kolb (35). Neither cysteine nor cystine was detectable with the nitroprusside reagent or potassium cyanide indicating complete conversion of these two amino acid residues to cysteic acid. Examination of trial preparations which were oxidized at room temperature for 5, 10, 15, and 20 min. showed that complete conversion to cysteic acid required about 20 min. under these conditions.

The free α-amino terminal groups were determined in both native and oxidized B.P.A., using Sanger's technique (29). Only aspartic acid residues were detected in both samples. Attempts to determine the number of aspartic acid residues per protein molecule by this method were unsatisfactory owing to appreciable breakdown of the D.N.P.-aspartic acid. However, for a given set of conditions, the number of N-terminal aspartic acid residues appeared to be equal in oxidized and native B.P.A., thus strengthening the assumption that no peptide bonds were broken during the oxidation reaction.

Protein solutions were prepared by dissolving oxidized B.P.A. in formamide and dialyzing against several changes of the appropriate buffer. Protein concentrations were estimated by micro-Kjeldahl analysis (accuracy, $\pm 1\%$ of the total nitrogen present) assuming the total nitrogen content of the protein to be 16.1% (36).

A Brice and Speiser light-scattering photometer (8) was used to estimate weight average molecular weights. A blue filter (Corning No. 3389, 2.5 mm.) inserted in front of the phototube eliminated fluorescent light. All measurements were made at 4360Å. The refractive index increment, dn/dc, of oxidized B.P.A. was measured in a B.S. differential refractometer. The same value was obtained as that reported for native B.P.A., 0.195 (23), giving $K = 2\pi^2 n_0^2 (dn/dc)^2 / N\lambda^4$ the value of 6.2×10^{-7} (n_0 = refractive index of solvent, N = Avogadro's number, λ = wavelength of light used). All measurements

were made in the standard 30 mm. square cells. Other details of the technique were as described previously (25).

Sedimentation coefficients were estimated from observations in a Spinco ultracentrifuge at 59,780 r.p.m. A one degree adjustment for adiabatic cooling of the rotor (6, 38) was included in the standard corrections of the coefficients to water at 20° (32). Three determinations of the sedimentation coefficient S_{20}, of native B.P.A. in 0.05 *M* phosphate buffer, 0.2 *M* NaCl, pH 6.6, at concentrations 0.33%, 0.50%, and 1.0% gave the values 4.10, 4.08, and 3.91×10^{-13} respectively. These values and their extrapolation to 4.3×10^{-13} at zero concentration are in agreement with previous determinations (21). However, repeated similar determinations of the coefficient of native B.P.A. in 0.08 *M* borate, 0.2 *M* NaCl, yielded a value of S°_{20} of 4.6×10^{-13}. The sedimentation coefficients reported for oxidized B.P.A. in 0.08 *M* borate +0.2 *M* NaCl, pH 7.4, may therefore be 10% too high. Cause of the discrepancy is unknown. In spite of this qualification, the borate buffer was used because of the difficulties of cleaning phosphate or more alkaline buffers for light-scattering.

Archibald (4) has shown that in sedimentation equilibrium experiments the weight average molecular weight may be estimated from the polymer concentrations near the ends of the cell, prior to complete attainment of equilibrium. The method has been applied successfully to bacitracin (24), digitonin (9), and lysozyme (31). In addition, the procedure gives information on polydispersity of the sample since, for heterogeneous samples, the molecular weight at the base of the cell will be higher than at the meniscus and the difference will increase with time. This technique was therefore applied to oxidized B.P.A. The ultracentrifuge and cells were the same as in the sedimentation velocity experiments. Speed of the rotor was 5300 r.p.m. Photographs were taken every four hours in the interval from 12 to 40 hr. From the sedimentation patterns, a function $\delta = (1/rc)\ (dc/dr)$ was calculated (9), (r is the distance of a given point in the cell from the center of rotation, c is the concentration in gm./ml. at that point, and dc/dr is the concentration gradient). The weight average molecular weights at the meniscus and base of the cell were estimated from the extrapolated values of δ by the relation $\delta = M(1-V\rho)/\omega^2RT$. (Here, V is the partial specific volume of the protein, ρ is the density of the solution, ω is the angular velocity, R is the gas constant, T is the absolute temperature, and M is the molecular weight.) Partial specific volume of oxidized B.P.A. was assumed to be the same as that of the native protein, 0.734 (11).

Osmotic pressures were measured at equilibrium using osmometers previously described (13). In some preliminary experiments (26), Visking dialysis bags were used but later proved unsatisfactory because of flexibility. Parloidin (Mallinckrodt Chem. Works) membranes prepared by Adair's method (1) were substituted. Pressures were determined at 7.5±0.1°C. after 16 hr. of equilibration and confirmed after an additional 12 hr. Equilibrium was reached from both sides and the osmotic pressures thus obtained agreed within experimental error.

Electrophoretic examinations were carried out at 0.15°C. in a Tiselius schlieren apparatus as modified by Longsworth (20). Dialysis for one day against buffer solutions prepared according to Clark's method (10) preceded examination. The pH of each solution was checked by a Beckman Model G pH meter calibrated by commercial standards.

RESULTS

Results typical of the light-scattering data for oxidized B.P.A. in concentrated salt solutions and in water at pH 7.4 are shown in Fig. 1. Kc/R_{90} is plotted as a function of protein concentration where R_{90} is the reduced intensity of

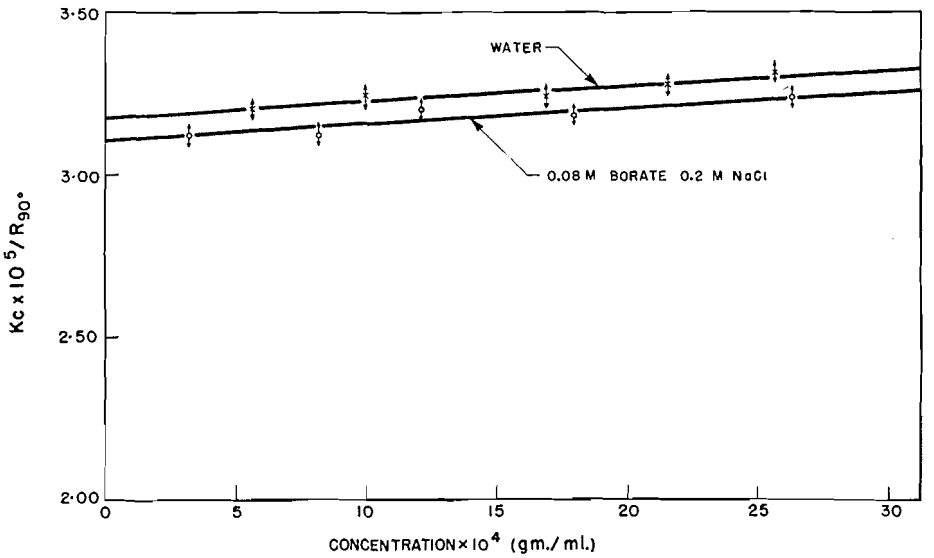

FIG. 1. Light-scattering of oxidized B.P.A. in 0.08 M borate + 0.2 M sodium chloride, and in water, both at pH 7.4.

the light scattered at 90°, K is as defined previously, and c is the concentration of the protein. The extrapolated value of Kc/R_{90} at zero protein concentration is an estimate of the reciprocal of the weight average molecular weight while the slope of the line is proportional to the second virial coefficient (14). The slope is therefore a measure of the net particle interactions.

Two preparations oxidized for 20 min. and one oxidized for 60 min. were studied by light-scattering. All three oxidized samples had identical weight average molecular weights, 32,000±2000. Under the same conditions native B.P.A. had a molecular weight of 77,000 in good agreement with previous results (16).

Results typical of osmotic pressure experiments on the three samples are shown in Fig. 2. Here P/cRT is plotted as a function of concentration; the osmotic pressure, P, being expressed in dyne/cm.^{2}. The extrapolated value of P/cRT at zero protein concentration was $5.2\pm0.4\times10^{-5}$ which corresponds to a number average molecular weight of 19,000±1500. Under the same

For personal use only.

conditions, native B.P.A. had a number average molecular weight of 67,000 in agreement with previous results (18). The difference between this value and that for the weight average molecular weight 77,000 has been attributed to a small proportion of high molecular weight material present in some

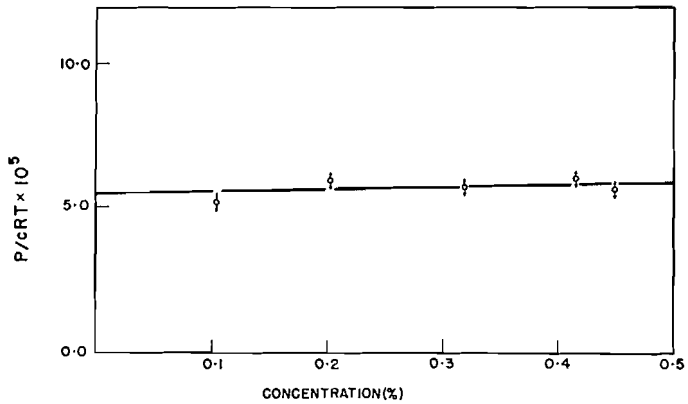

FIG. 2. Osmotic pressure of oxidized B.P.A. as a function of concentration, in 0.08 *M* borate buffer + 0.2 *M* NaCl, pH 7.4.

samples of native B.P.A. (16). Presence of this fraction in our sample was confirmed by sedimentation velocity experiments.

A single peak was observed in sedimentation velocity experiments with oxidized B.P.A. (Fig. 3), which sedimented with a mean coefficient, S°_{20}, of $1.49 \pm 0.05 \times 10^{-13}$ in 0.08 *M* borate, 0.2 *M* NaCl, pH 7.4. The sedimentation

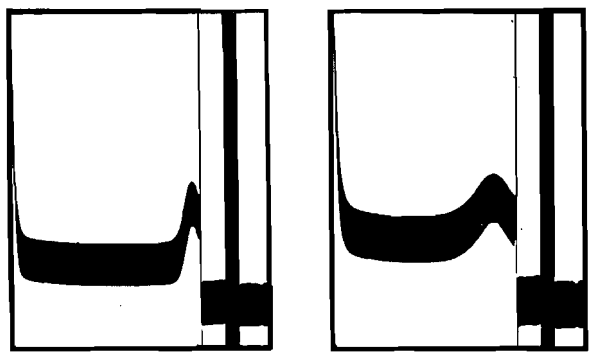

FIG. 3. Sedimentation boundary of oxidized B.P.A. in 0.08 *M* borate + 0.2 *M* NaC pH 7.4.

coefficient was independent of protein concentration over the range 0.3% to 1.0%. The threefold reduction in the value of the coefficient compared with native B.P.A. (21) suggested that oxidation separated the protein into fragments. An estimate of the distribution of the sedimentation coefficients of such fragments of oxidized B.P.A., made by the method of Williams *et al.* (39), showed only a single peak about the mean value. The peak was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

sharp but the significance which may be attributed to this is doubtful because of inherent uncertainties of extrapolation in the method. A justifiable conclusion is that the sedimentation differences among the molecules are small or else the various types are in rapid equilibrium (2).

Fig. 4 summarizes the data from an experiment using Archibald's approach to sedimentation equilibrium at pH 7.4. The function $(1/rc)(dc/dr)$ is plotted versus r, the distance from the center of rotation, and extrapolated

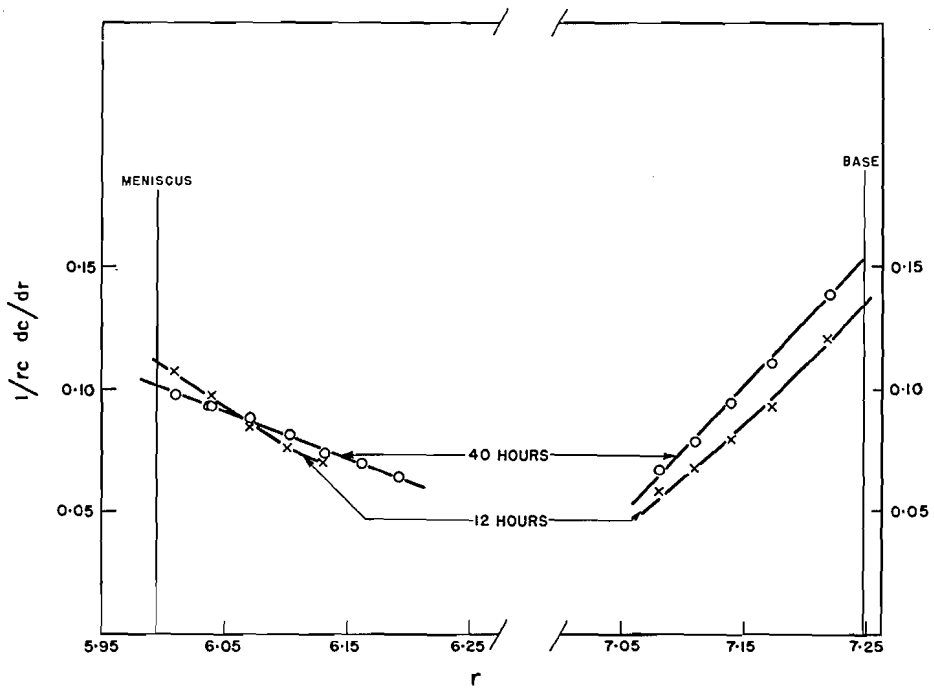

FIG. 4. Archibald's approach to sedimentation equilibrium with oxidized B.P.A. in 0.08 M borate + 0.2 M NaCl, pH 7.4.

to the meniscus and base of the cell. Twelve hours after the beginning of the run the molecular weight at the meniscus was 33,000 and at the base, 40,000. After 40 hr. of sedimentation, the molecular weight decreased to 30,000 at the meniscus and increased to 45,000 at the base. Similar results were obtained at pH 9.0 in aqueous ammonia. These observations are in agreement with those from light-scattering and are consistent with the sedimentation velocity experiments.

Oxidized B.P.A. was examined electrophoretically over the pH range from 4.7 to 7.4 in 0.05 M acetate, phosphate, or borate buffers. Varying concentrations of sodium chloride were added to adjust the field strength. A typical pattern for the material under all conditions is shown in Fig. 5. A single symmetrical peak was observed, suggesting that the charge densities of all the components of oxidized B.P.A. are similar.

Previous studies of the structure of insulin (30) and of ribonuclease (3) have shown that performic acid under the conditions employed does not hydrolyze peptide bonds appreciably. However these two proteins do not contain the labile tryptophane residue (34) whereas two such residues are found per B.P.A. molecule (36). Performic acid oxidation was therefore

FIG. 5. Ascending and descending electrophoretic boundaries of oxidized B.P.A. in 0.05 *M* acetate buffer, pH 5.5. Field strength 6.3 volts/cm. Time 116 min.

applied to lysozyme (8 tryptophane residues per 15,000 gm. (36)), to see if the single chain of the molecule (17) was broken by the procedure. The oxidized protein was insoluble in water from pH 2.0 to 8.0. Light-scattering measurements of native and oxidized lysozyme were therefore made in 90% formic acid. The molecular weight of the oxidized protein was about five times *higher* than that of the native protein assuming the same values for the refractive index increment in both materials. The data from two experiments using Archibald's approach to sedimentation equilibrium on oxidized and native lysozyme, dissolved in formamide, are summarized in Fig. 6. After 45 hr. at 12,000 r.p.m. the function δ at the meniscus is about 1.7 times higher for the oxidized protein compared to the native. Consequently, assuming the

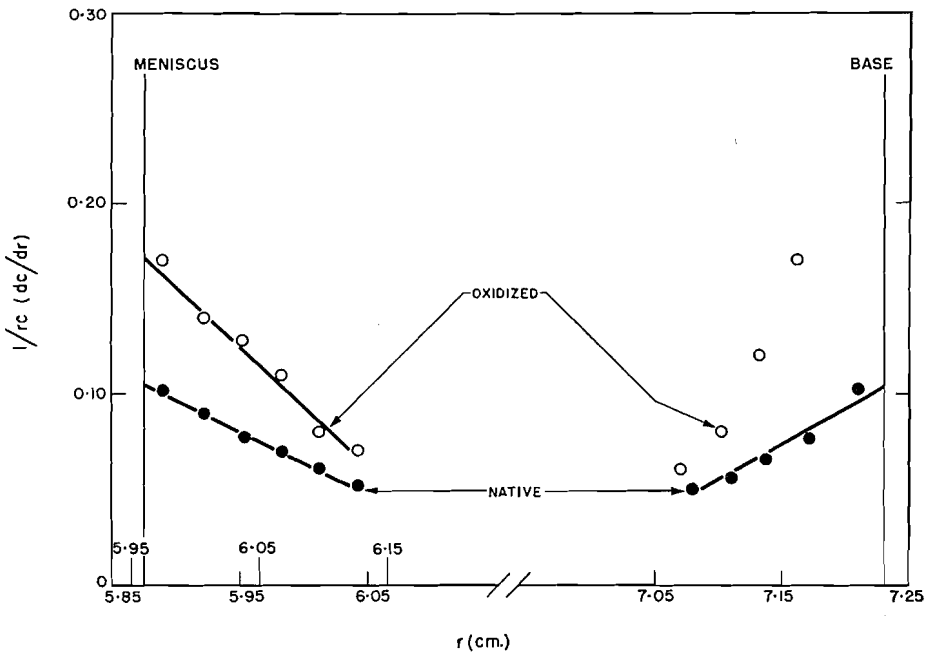

FIG. 6. Archibald's approach to sedimentation equilibrium with oxidized and native lysozyme in formamide.

For personal use only.

same partial specific volume for both proteins, the data indicate a molecular weight about 1.7 times that of the native for the oxidized protein. The values of δ at the base of the cell indicate monodispersity of the native sample and extensive aggregation in the oxidized sample. Similar results were obtained with globin (27) which contains 5 tryptophane residues per 68,000 gm. (36) but the extent of aggregation in the oxidized sample was much smaller than in lysozyme. This evidence together with the absence of additional α-amino terminal groups in oxidized B.P.A. strongly indicates that no scission of the polypeptide chain(s) occurred.

DISCUSSION

We tentatively assume, on the basis of the foregoing evidence, that no splitting of the polypeptide chains takes place during oxidation. Then the lower molecular weight of oxidized B.P.A., compared to that for the native albumin, indicates that previous suggestions that this protein consists of a single chain (19, 37) must be reconsidered. The earlier conclusions were based on either an assumption of fully accessible, completely unsubstituted terminal groups or the assumption of a Staudinger viscosity coefficient unmodified by the oxidation procedure. In the light of later work (7, 12, 28), it would not be surprising if either or both assumptions were invalid.

The electrophoretic patterns over a wide range of pH show that the polypeptide chains of oxidized B.P.A. are similar in charge density and therefore probably in amino acid composition. In addition, the single peak in the sedimentation patterns as well as the single maximum in the distribution function of sedimentation coefficients of oxidized B.P.A. indicates that the chains of native B.P.A. are approximately equal in weight. If the chains are similar in size, the discrepancy between the weight average and number average molecular weights of oxidized B.P.A. may be explained by interactions between the chains to produce a small proportion of aggregates of varying degrees of stability. Attractive forces, favoring formation of such aggregates, are shown by the difficulty of dissolving the material in water and by the zero value for the second virial coefficient in light-scattering experiments in water at pH 7.4, in spite of the high negative charge carried by the chains (15). Most of the aggregates are in rapid equilibrium with the smaller subunits, as shown by the single peak in sedimentation velocity experiments, and cause only a spreading of the boundary (2). However, the difference between the molecular weights at the meniscus and the base of the cell in the approach to sedimentation equilibrium shows that dissociation of a fraction of these aggregates is very slow, probably because of mechanical entanglement of the random coils. Thus the molecular weight at the meniscus in sedimentation equilibrium deviates only slightly from the light-scattering value, while at the base the weight average molecular weight increases with time.

Assuming therefore a molecular weight of 66,000 for native B.P.A. (15, 18) which contains polypeptide chains of equal size, the observed number average molecular weight shows that there are three or four such chains per molecule. However, four chains is the more probable figure because aggregation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

components would tend to raise the estimated number average molecular weight of the oxidized material. A larger number of chains is excluded because no diffusion of protein through the osmometer membranes could be detected after seven days, although ribonuclease (mol. wt. 13,000) (32) passed through fairly rapidly under the same conditions.

The chains are presumably held together by some of the 14 disulphide bridges in B.P.A. (36) but no information is yet available on their number and location. Furthermore, because Van Vunakis and Brand found only one N-terminal amino acid residue per molecule (37), the results indicate that the other three chain ends are either substituted or inaccessible to reaction with dinitrofluorobenzene under the conditions employed.

The foregoing conclusions rest on the assumption that no polypeptide bonds were broken by performic acid oxidation. Presently available evidence for this assumption is substantial but does not exclude the possibility that tryptophane residues in a polypeptide chain may be particularly labile when linked to specific amino acids. A general investigation of the possibility is desirable.

ACKNOWLEDGMENTS

The authors should like to thank their colleagues Dr. P. A. Charlwood and D. B. Smith for discussions, advice, and criticism at all stages of the study. They are also particularly indebted to Prof. J. T. Edsall of Harvard University, and Dr. W. H. Cook, Director of the Division of Applied Biology, for stimulating advice and criticism of the methods and manuscript.

The technical assistance of Mr. D. Muirhead and Mr. L. Sowden is gratefully acknowledged.

THE VIBRATIONAL SPECTRA OF THE FORMATE, ACETATE, AND OXALATE IONS[1]

By K. Ito[2] and H. J. Bernstein

ABSTRACT

The infrared spectra of the formate, acetate, and oxalate ions have been obtained for both the solid and aqueous solution. The Raman spectra of these ions with depolarization ratios have been obtained in aqueous solution. Vibrational assignments have been made which differ slightly for the acetate ion and more markedly for the oxalate ion from earlier work. The depolarization ratios confirm Fonteyne's assignment for the formate ion.

INTRODUCTION

The Raman spectra of aqueous solutions of formate (4, 7), acetate (16), and oxalate (5, 8, 11) ions, and the infrared spectra of solid metal-formate (3), -acetate (10), and -oxalate (2) have been studied in the past but no reliable assignment has been made for the oxalate ion and in some respects the rather complete assignments for CH_3COONa and CD_3COONa in the solid state (10) and that for the formate ion merit reinvestigation.

Infrared spectra of solid sodium formate, light and heavy sodium acetate, and sodium oxalate, and their saturated solutions in H_2O and D_2O were obtained from 3–35μ. The Raman spectra of the aqueous solutions with depolarization ratios were also obtained. From these more complete vibrational data and comparison of spectra with the isoelectronic molecules nitromethane and nitrogen tetroxide vibrational assignments have been made for acetate and oxalate ions. The depolarization ratios for the Raman bands of the formate ion confirmed the assignment of Fonteyne (7).

EXPERIMENTAL

The infrared spectra were obtained with a Perkin-Elmer Model 12C double pass spectrometer with CsBr, NaCl, and LiF optics. The Raman spectra were photoelectrically recorded on a White Raman spectrometer (18) and depolarization ratios measured by comparing Raman spectra obtained with polaroid film wrapped round the sample tube first with its axis in a direction parallel to the sample tube and then perpendicular to it (6). These ratios were corrected for convergence error in a manner previously described (1, 14).

The reported infrared spectra of the aqueous solutions are not as complete as those for the solids because of the strong H_2O and D_2O absorption. The solid infrared spectra were taken of films deposited from H_2O or CH_3OH on AgCl plates or polystyrene film. Raman spectra were obtained for the saturated aqueous solutions only and the depolarization ratios of all fundamentals measured.

The infrared spectrum of the saturated solution of CH_3COONa in H_2O and D_2O is shown also in Fig. 1. Only the part of the spectrum of the solid that differs sensibly from that of the solution is shown in Fig. 1. The band at 480 cm.$^{-1}$ in the spectrum of the solid is not found in solution because of the strong water absorption in this region. The spectrum of the solid agrees with that found by Jones and McLaren (10) and the band positions have been used in Table II in the column giving their assignment. The infrared spectrum of solid CD_3COONa is the same as that previously reported (10), and bands were observed at 2267 (m), 2288 (w), 1546 (s), 1408 (s), 1084 (w), 1043 (w), 940 (m), 883 (w), and 833 (m) cm.$^{-1}$ in the infrared spectrum of CD_3COONa in H_2O. In Table II the assignment for CH_3COO^- (solid) by Jones and McLaren

[a] *In this assignment the frequencies measured here have been used.*

(but using our measured frequencies), that for CH_3NO_2 by Wells and Wilson (17), and the present assignments for CH_3COO^- and CD_3COO^- are given. The assignments are based on C_{2v} point group symmetry (17). The new information provided by the above spectra and comparison with the fundamentals of the isoelectronic CH_3NO_2 molecule have been the basis for the present assignment and as can be seen from Table II it differs from that of Jones and McLaren for CH_3COO^- in several respects. In particular, ν_2, the fairly strong polarized Raman band at 1344 cm.$^{-1}$, is taken as a fundamental here instead of the rather weak infrared band at 1498 cm.$^{-1}$ which is not observed in the Raman spectrum. This band at 1498 cm.$^{-1}$ is then to be interpreted as a difference tone (see Table III). The present assignments for ν_2 and ν_3 were confirmed from the depolarization ratios and comparison of the Raman spectra of CH_3COO^- and CD_3COO^-. Other changes are to assign the band at 1429 cm.$^{-1}$, which is found to be depolarized, as ν_9 and the band at 1443 cm.$^{-1}$ in the infrared spectrum of the solid as ν_{13}. One other small

For personal use only.

modification is introduced by the fact that three bands in the CH stretching region are observed in the infrared and Raman spectra of the solution whereas there are only two in the infrared spectrum of the solid (see Fig. 1). Assuming all three to be fundamentals, ν_1 is readily assigned because of its depolarization ratio but a choice is left for ν_7 and ν_{12} as indicated in Table II.

Of the two COO rocking modes ν_{11} and ν_{15} the higher was taken as the out-of-plane mode ν_{15}, since it was expected that the π electron cloud in the COO^- group accumulating in the direction perpendicular to the COO^- plane gives rise to more repulsion in the potential energy function for the out-of-plane mode than for the in-plane mode. The moment of inertia argument used by Wells and Wilson for the corresponding assignment in CH_3NO_2 leads to this result also (which was recognized also by Jones and McLaren in their assignment).

Our assignment for CD_3COO^- is essentially the same as that reported by Jones and McLaren except for the CD stretching modes. From Raman spectrum and depolarization ratios (see Table I) the band at 2231 $cm.^{-1}$

assigned by the above authors to ν_1 must be either ν_7 or ν_{12}. In Table III the combination bands for CH_3COO^- observed in the infrared spectrum are given with plausible assignments.

The present assignments for light and heavy acetate ion (solution) are consistent with the product rule as shown in the last column of Table II. The theoretical ratios are taken from the paper of Jones and McLaren (10) which were calculated using dimensions of the solid ion. Since these ratios are very insensitive to small changes in molecular dimensions they will be very nearly the same for the solid ion and the ion in solution.

Oxalate Ion

The Raman spectrum of a saturated solution of potassium oxalate in H_2O is shown in Fig. 2 and the Raman data given in Table IV. The infrared spectrum of saturated solutions of potassium and cesium oxalate in H_2O

and D_2O is shown also in Fig. 2. The frequencies of the fundamentals are given in Table IV and those of the combination bands in Table V. The infrared spectrum of solid sodium oxalate is listed in Table IV (fundamentals) and

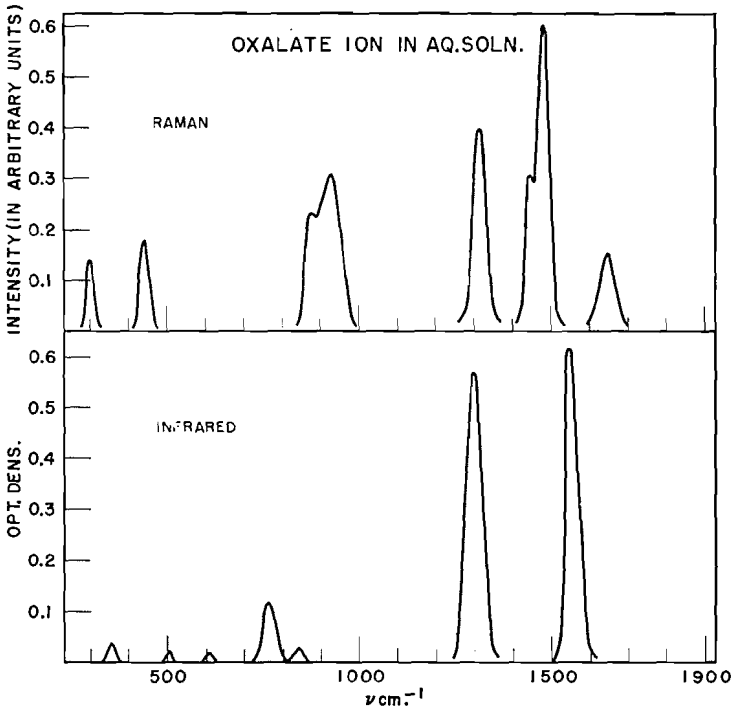

FIG. 2. The Raman and infrared spectra of the oxalate ion.

Table V (combination tones). The principal difference between the solid and solution infrared spectra is that the band at 507 cm.$^{-1}$ in the solid is by

far the strongest band in this region, whereas in solution it is weak (at 500 cm.$^{-1}$) and comparable in intensity to the bands at 361 and 605 cm.$^{-1}$. Because of its strong absorption in the solid this band was chosen as a fundamental. Another feature in the infrared spectrum of the solid is the doublet

1405 and 1640 cm.$^{-1}$ which may be explained on the basis of Fermi resonance of ν_9 (b_{2u}) with $\nu_{11}+\nu_5$ (B_{2u}). In solution, only one strong band at 1555 cm.$^{-1}$ is observed. The oxalate ion has D_{2h} symmetry in the solid sodium salt (9) and is assumed to have the same symmetry in solution. This is borne out by the infrared and Raman spectra which exhibit the character of mutual exclusion. In Table IV the assignment for $C_2O_4^{--}$ is given for the solid and solution made on the basis of the selection rules, depolarization ratios, and comparison with the spectrum of isoelectronic N_2O_4 (15). In the last column of the table the previous assignment of Lecomte *et al.* (2) is given for comparison. Since our infrared investigation covered a larger region than that investigated previously (2) and since our depolarization data are more complete than those of an earlier investigation (8), several differences between the present and the earlier (2) assignments are not unexpected. In particular the depolarization ratio of the band at 445 cm.$^{-1}$ established it as ν_3. By analogy with N_2O_4 the other low lying Raman band is ν_5 and the high one at 1305 cm.$^{-1}$ is then ν_6. The band at 665 cm.$^{-1}$ reported by Lecomte *et al.* (2) occurring in the region of CO_2 absorption was not observed here. As ν_8 we choose the strong infrared band (solid) at 507 cm^{-1}. The ν_{10} mode was calculated here as ~160 cm.$^{-1}$ and estimated previously (2) to be ~370 cm^{-1}. The calculation for ν_{10} follows from the Urey Bradley treatment by Shimanouchi *et al.* (12) for D_{2h} molecules. Here it was shown that the ratio of the product of the two b_{1g} frequencies to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

that of the two b_{2u} frequencies is a function of masses and geometry only and independent of force constants if the interaction between COO groups on different C atoms is neglected. The structural parameters used to calculate this ratio are given below (9):

$$r_{CC} = 1.56\,\text{Å},\ r_{CO} = 1.24\,\text{Å},\ \angle OCO = 125°.$$

The value of $\nu_{10} = 160$ cm.$^{-1}$ is further supported by the assignment of two observed combination tones at 1452 cm.$^{-1}$ in the Raman spectrum and 605 cm.$^{-1}$ (solution), 611 cm.$^{-1}$ (solid) in the infrared spectrum. Other interpretations of these bands are not readily forthcoming.

In Table V the combination bands observed in the infrared spectrum are listed with plausible assignments. The bands at 2862, 2479, 1885, 1029, and 873 cm.$^{-1}$ in the infrared spectrum of the solid cannot be interpreted in terms of binary combinations of the listed fundamentals.

Formate Ion

The Raman spectrum of a saturated solution of potassium or sodium formate in H_2O is shown in Fig. 3 and the frequencies and depolarization ratios

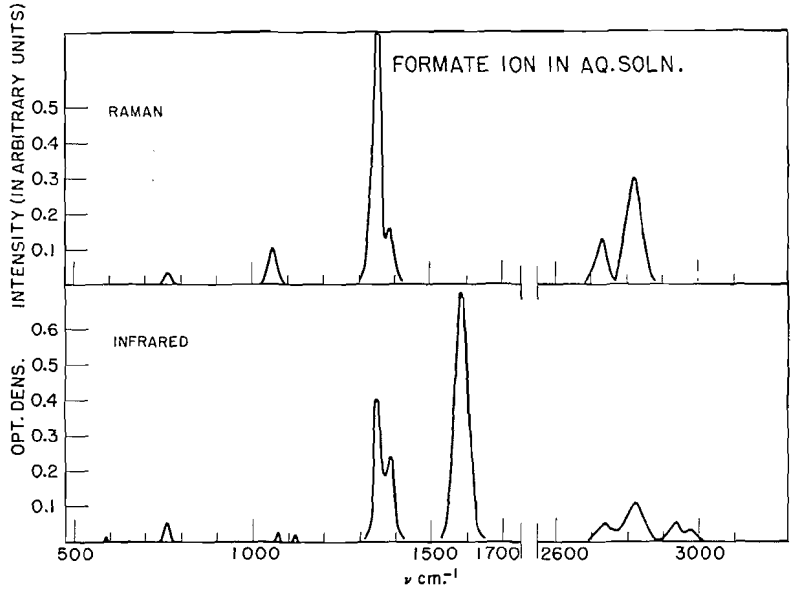

FIG. 3. The Raman and infrared spectra of the formate ion.

given in Table VI. The infrared spectrum of a saturated solution of these salts in H_2O and D_2O is given also in Fig. 3 and the frequencies in Table VI (fundamentals) and Table VII (combination tones). The infrared spectrum of solid sodium formate is given in Table VI (fundamentals) and in Table VII (combination tones).

The present assignment for the formate ion made on the basis of C_{2v} symmetry and the measured depolarization ratios is given in Table VI.

Of the two rocking frequencies, ν_5 and ν_6, the higher one might be expected to be the out-of-plane mode analogous to the acetate and oxalate ions but these were assigned as shown in the table because of the results of Newman (13) obtained from the polarized infrared spectra of solid sodium formate. The present assignment for the aqueous solution is the same as that by

The infrared spectra of solid sodium formate were obtained of the solid films deposited from H_2O, a mixture of H_2O and CH_3OH, or a mixture of H_2O and acetone, on AgCl and NaCl plates. All solid samples were dried over P_2O_5 in a desiccator and had no absorption band in the O—H stretching region, 3100–3800 cm.$^{-1}$, showing that the samples were indeed anhydrous. The infrared spectra of these samples seemed to change slightly from sample to sample depending on the method of preparation, in contrast to the infrared spectra of the acetate and oxalate salts. In particular the b_1 C—O stretching mode shows a rather complicated behavior and has two bands at 1567 cm.$^{-1}$ and 1514 cm.$^{-1}$ in some samples. The intensity of the latter band was increased by dehydration in a desiccator and was even stronger in some cases than that at higher wave numbers. However, the band at 1567 cm.$^{-1}$ was assigned as a fundamental by analogy with the fundamentals for the aqueous solution. The band at 1620 cm.$^{-1}$ which was assigned as a fundamental by Newman was observed only in some samples as a weak band or a small shoulder.

Table VII shows the combination and difference bands observed in the infrared spectrum and a possible assignment. In the case of the infrared spectrum of the solid, it is necessary to assume lattice vibrational modes coupling with the internal vibrational modes of the formate ion in order to explain the observed combination bands satisfactorily. Two lattice frequencies at 140 cm.$^{-1}$ and 60 cm.$^{-1}$ have been assumed in the seventh column of Table VII which are used to interpret 13 of the 21 combination tones. There are several possible choices of the assignments for some bands in the solid infrared spectrum but only one is shown rather arbitrarily.

NOTES

SYNTHESIS OF METHYL-d_3 FORMATE*

By R. Renaud and L. C. Leitch

In earlier papers of this series (1, 2) Nolin reported the preparation of several deuterated methyl and ethyl acetates from the alkyl iodides and silver acetate. On account of the instability of silver formate the method is not directly applicable to the synthesis of methyl-d_3 formate. This ester has now been prepared in moderately good yields by the acid-catalyzed transesterification of methyl-d_3 butyrate and *n*-butyl formate:

$$C_3H_7CO_2CD_3 + HCO_2C_4H_9 \rightarrow HCO_2CD_3 + C_3H_7CO_2C_4H_9.$$

The methyl-d_3 butyrate was prepared in nearly quantitative yield from methyl-d_3 bromide and silver butyrate. The methyl-d_3 bromide was in turn prepared by the brominative decarboxylation of silver acetate-d_3 in carbon tetrachloride as described in the experimental part rather than by the method reported in reference (3).

It is of interest to compare the mass spectra of methyl and methyl-d_3 formates:

$HCOOCH_3$		$HCOOCD_3$	
60	100	63	100.0
59	1.86	62	4.56
		61	0.1

Since the intensity of the 61 peak—due to loss of D—is so small in methyl-d_3 formate the peaks at 59 in the spectrum of methyl formate and 62 in the spectrum of methyl-d_3 formate must be due to loss of H in the formoxy group rather than in the methyl group.

EXPERIMENTAL

Silver Butyrate

Silver butyrate was prepared by adding a solution of 77 gm. of silver nitrate in 400 ml. of water in small portions to a stirred solution of 40 gm. of *n*-butyric acid in 200 ml. of water containing sufficient aqueous ammonia for neutralization. The salt was recrystallized from boiling water, dried for a day over phosphorus pentoxide in a vacuum desiccator, and stored in an amber bottle. The yield was nearly theoretical.

Methyl-d_3 Bromide

Silver acetate-d_3 (34.0 gm., 0.2 mole) was placed in a 500 ml. four-necked round-bottomed flask equipped with a funnel, a thermometer, a mechanical

*Issued as N.R.C. No. 3821.

stirrer with a graphite packed gland, and a reflux condenser. Three spiral traps, two of which were cooled in dry ice and carbon dioxide at −78° and the third at −30°C., were connected to the outlet of the condenser. A solution of 11 ml. of dry bromine in 75 ml. of dry carbon tetrachloride was added to the stirred silver salt at the rate of about a drop every two seconds. The temperature of the reaction mixture was kept at 27–30°. Addition of the bromine required about four hours. The reaction mixture was then slowly heated to the boiling point and refluxed from one to one and one-half hours while a current of dry nitrogen was passed in. The contents of the first trap were then distilled into the second. The third trap was generally empty. The crude product was distilled on the vacuum line through ascarite to remove dissolved carbon dioxide and bromine. The distillate was redistilled twice from a bath at −40°C. into a trap cooled in liquid nitrogen. The weight of crude methyl-d_3 bromide was 19.0 gm. After another distillation from a trap at −78° the vapor pressure of the product at 0° was 679 mm. There was little change in the vapor pressure of various fractions distilled at 0°C. The yield was 17.5 gm. (89.3% of the theoretical amount). Mass analysis showed a purity of 97.8 mol. % CD_3Br or 99.2 atom % D.

Methyl-d_3 Butyrate

Silver butyrate (8.3 gm., 0.04 mole) was heated with 4.1 gm. (0.04 mole) of methyl-d_3 bromide in a sealed tube for 16 hr. at 80°C. in a rocking furnace. The methyl-d_3 butyrate was isolated by attaching the opened tube to a Stock trap cooled in liquid nitrogen on a vacuum manifold and evacuating to a pressure of 0.1 mm. The yield of ester recovered in the trap, n_D^{20} 1.3879, vapor pressure 30 mm. at 22°C., was quantitative. Methyl butyrate prepared in the same way had n_D^{20} 1.3874.

Methyl-d_3 Formate

A mixture of 4.5 gm. of *n*-butyl formate, 4.1 gm. of methyl-d_3 butyrate, and three drops of concentrated sulphuric acid was distilled in a column packed with glass helices. The yield of methyl-d_3 formate, b.p. 31–32°C., n_D^{20} 1.3431, was 1.5 gm. (61% of the theoretical). Its mass spectrum gave a deuterium content of 97.6 mol. % or 99.07 at. %.

SYNTHESIS OF DEUTERATED DIMETHYL CARBONATE*

By R. Renaud and L. C. Leitch

The well-known synthesis of alkyl carbonates from phosgene and alcohols is not suitable for the preparation of deuterated dimethyl carbonate because methyl-d_3 alcohol is not readily available. Since methyl-d_3 bromide is now easily obtained by a method reported previously by one of us (2) it seemed worth while to attempt the preparation of dimethyl carbonate from methyl bromide and silver carbonate. Diethyl carbonate labelled with C^{14} was recently prepared by Eisenhauer, Pepper, Jaques, and Spinks (1) by refluxing a suspension of silver carbonate-C^{14}, ethyl iodide, and triethylamine under nitrogen. In the present work it was found that no reaction took place when methyl iodide and silver carbonate were heated under reflux for a day. However, when these reactants were treated for 65 hr. in a sealed tube at 60°, a 75% yield of dimethyl carbonate was obtained. With methyl bromide the yield was nearly quantitative, possibly because the product was more easily separated from unchanged methyl bromide. Similar results were obtained when methyl-d_3 bromide was employed. Dehalogenation of hexachloromethyl carbonate with zinc dust and acetic acid did not give the desired product. Evolution of carbon dioxide took place presumably because of hydrolysis of the ester and no dimethyl carbonate could be isolated.

EXPERIMENTAL

Dimethyl Carbonate

(*a*) *From Methyl Iodide and Silver Carbonate*

Methyl iodide (14.7 gm., 0.11 mole) was distilled on a vacuum manifold into a tube containing 13.8 gm. (0.05 mole) of dry silver carbonate. The tube was sealed and heated in a rocking furnace at 60°C. for 65 hr. The liquid phase was distilled off on a vacuum line into a distilling flask. Fractional distillation of the distillate through a small column packed with glass helices afforded a 75% yield of dimethyl carbonate, b.p. 89–91°C., n_D^{20} 1.3694.

(*b*) *From Methyl Bromide and Silver Carbonate*

A similar experiment with methyl bromide gave a nearly quantitative yield of dimethyl carbonate. An attempt to shorten the reaction time by raising the temperature to 90°C. resulted in decomposition of the silver carbonate with evolution of carbon dioxide.

Dimethyl-d_3 Carbonate

A mixture of 5.6 ml. (10.0 gm., 0.12 mole) of methyl-d_3 bromide prepared as described in reference (2) and 13.8 gm. of silver carbonate was heated for 65 hr. at 60°C. The reaction product was isolated and purified as already described. The yield of deuterated dimethyl carbonate, b.p. 89–90°C., n_D^{20}

CHOLESTEROL FROM ASCARIS LUMBRICOIDES (NEMATODA)*

BY DONALD FAIRBAIRN AND R. NORMAN JONES

Conclusive evidence for the existence of sterols in any species belonging to the phylum Nematoda was not available until it was shown (1) that the reproductive organs of the common pig roundworm, *Ascaris lumbricoides*, contain small amounts of a mixture of saturated and unsaturated sterols in the approximate ratio 1:3. Although infrared analysis of the mixed sterol acetates suggested that cholesterol might be one component of the mixture, insufficient material was available for positive identification.

An extension of the investigation has resulted in the isolation and identification of cholesterol as the dibromide. From the total lipids extracted from the blended muscle and reproductive tissues of mature female parasites, total sterols were precipitated as the digitonides and subsequently recovered in the free form (4). The recrystallized mixture was then brominated (3), insoluble bromides separated, and saturated sterols isolated as the digitonides. Recrystallization of the bromide from ether and glacial acetic acid yielded a product identical in melting point and mixed melting point with cholesterol dibromide. The saturated sterol(s) has not yet been identified.

The infrared spectra of the ascaris sterol dibromide and a sample of cholesterol dibromide prepared concurrently are shown in Curves A and B of Fig. 1. The similarity of these curves confirms the identification of the ascaris sterol, but both curves show absorption at 1705 and 1280 cm.$^{-1}$ which is not present in Fig. 2, obtained from a second sample of cholesterol dibromide immediately following crystallization from ethyl acetate – methanol at room temperature.* This difference is attributed to the partial photolysis or autoxidation of the first two samples during transshipment prior to analysis.

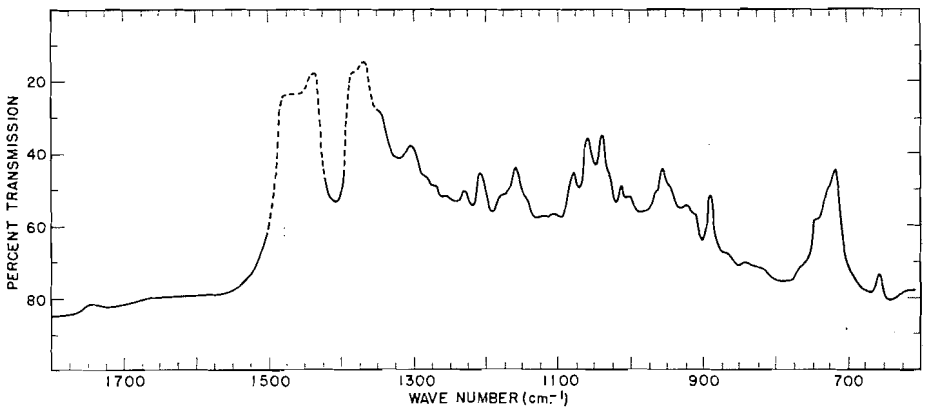

FIG. 2. Infrared spectrum of freshly prepared cholesterol 5α,6β-dibromide.

The bromination method employed resulted in characteristically low yields of ascaris sterol bromide, which were necessarily accepted because it was desirable to isolate saturated sterols quantitatively from the mother liquor. For this reason the identification of cholesterol as the main unsaturated sterol depended upon the provision of auxiliary evidence such as (1) the similarly low yield obtained by bromination of pure cholesterol, (2) the iodine number and rate and intensity of color development with the Schoenheimer-Sperry reagent (1, 2), and (3) the infrared spectrum of the mixed acetates (1), which resembled closely that of authentic cholesterol acetate. These observations led to the conclusion that large amounts of unsaturated sterols other than cholesterol were absent.

We wish to thank Dr. A. Nickon for the preparation of this material.

EXPERIMENTAL

Thirty grams of the fats obtained by extraction of 2 kgm. of ascaris muscle and reproductive tissue (representing 2.6 kgm. of adult female parasites) was shaken vigorously with five volumes of ethanol (twice), after which the clear solution was treated with 1% digitonin in ethanol. The sterol digitonides so obtained were washed twice by centrifugation with ethanol–ether (1:2) and three times with ether, dried, decomposed in a minimum volume of dry pyridine at 70°, and the free digitonin precipitated by addition of 10 volumes of dry, ethanol-free ether. The supernatant solution contained 260 mgm. of mixed sterols which were recrystallized once from 80% methanol (m.p. 123–124°). Bromination of 216 mgm. of this product provided 67 mgm. of sterol bromide (29% yield, calculated as cholesterol dibromide and including the necessary correction for saturated sterol content) which was recrystallized twice from ether and glacial acetic acid (1:3). Authentic cholesterol dibromide was prepared by the same procedure (yield, 31%). M.p. cholesterol dibromide 115.5–116°, ascaris sterol bromide 115–116°, mixed m.p. 115–116°; identical infrared spectra.

The mother liquor obtained from the bromination of ascaris sterols was treated with digitonin to remove saturated (unbrominated) sterol. From the resulting digitonide 54 mgm. of saturated sterol was recovered (iodine number, 2; m.p. 131–132°).

Financial assistance from the National Research Council of Canada is gratefully acknowledged.

EXPERIMENTAL

Thirty grams of the fats obtained by extraction of 2 kgm. of ascaris muscle and reproductive tissue (representing 2.6 kgm. of adult female parasites) was shaken vigorously with five volumes of ethanol (twice), after which the clear solution was treated with 1% digitonin in ethanol. The sterol digitonides so obtained were washed twice by centrifugation with ethanol–ether (1:2) and three times with ether, dried, decomposed in a minimum volume of dry pyridine at 70°, and the free digitonin precipitated by addition of 10 volumes of dry, ethanol-free ether. The supernatant solution contained 260 mgm. of mixed sterols which were recrystallized once from 80% methanol (m.p. 123–124°). Bromination of 216 mgm. of this product provided 67 mgm. of sterol bromide (29% yield, calculated as cholesterol dibromide and including the necessary correction for saturated sterol content) which was recrystallized twice from ether and glacial acetic acid (1:3). Authentic cholesterol dibromide was prepared by the same procedure (yield, 31%). M.p. cholesterol dibromide 115.5–116°, ascaris sterol bromide 115–116°, mixed m.p. 115–116°; identical infrared spectra.

The mother liquor obtained from the bromination of ascaris sterols was treated with digitonin to remove saturated (unbrominated) sterol. From the resulting digitonide 54 mgm. of saturated sterol was recovered (iodine number, 2; m.p. 131–132°).

We attempted to carry out this preparation with butanol, without success. It was then found that the ester could be readily prepared, in high (86%) yield, by reacting butanol and antimony trichloride.

Into a 500 ml. three-necked flask, equipped with a mechanical stirrer, reflux condenser, thermometer, and provision for solid addition, was weighed 74.1 gm.

(1.0 mole, Shaw. Chem. dried) *n*-butanol. With continuous stirring, 76.0 gm. (0.33 mole, Mallinckrodt A.R.) antimony trichloride was added over a 0.5 hr. period. The temperature rose from 26–30° C. No cooling was used. Stirring was continued for an additional 0.5 hr. Ammonia gas was then bubbled through the stirred mixture until no more gas was absorbed (excess ammonia coming through), using external cooling to keep the reaction below 25° C. During precipitation of ammonium chloride, 250 ml. of isoheptane was added to thin the mixture. The mixture was filtered on a Büchner funnel, and the precipitate washed with 5×50 ml. of isoheptane.

The filtrate was distilled without a column at 200 mm. up to a pot temperature of 140° C., to remove isoheptane and unreacted butanol. The pressure was then reduced to 5.5 mm. and the fraction boiling at 139–141° C., collected, 97.0 gm. (86% of theory), $n_D^{20} = 1.4792$. The previously reported boiling point is 138.5–139.5° C. at 5.5 mm. (1).

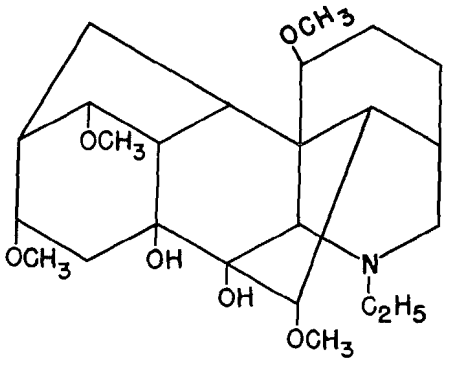
$-z$, unreal peaks at $-x$, $-y$, $-z$, and x, $\frac{1}{2}-y$, z. The interpretation of these results gave for its free base (des-(oxymethylene)-lycoctonine) the structure represented by the schematic drawing and by the photograph of the molecular model.



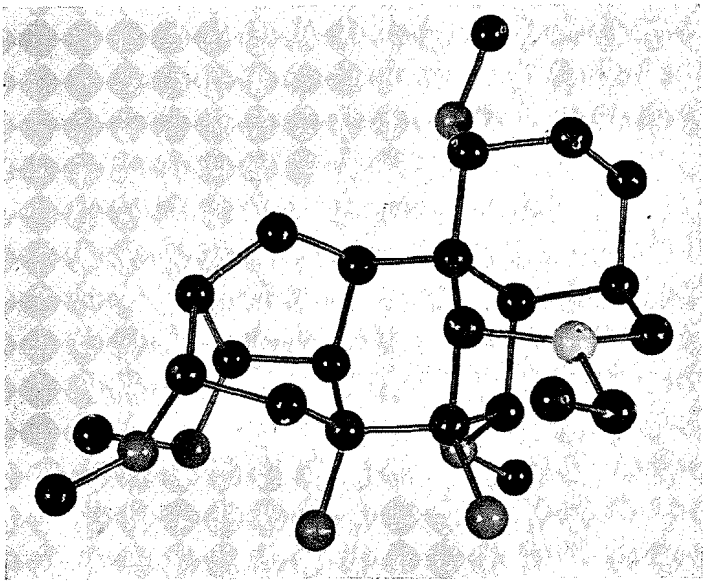


FIG. 1. The stereochemical configuration of des-(oxymethylene)-lycoctonine.

A $h0l$ difference synthesis using (F_0-F_c) as coefficients was then computed, the structure-factor calculations having been based on f values for carbon and iodine only. The pattern obtained indicated clearly all six oxygen atoms of the molecule and the oxygen atom of water of crystallization. Thus the ethyl group was identified and since it has been chemically proved to be attached to the nitrogen atom (2), the latter was indirectly located. No other chemical assumptions were made in this investigation.

CHEMICAL EFFECTS OF THE $C^{12}(\gamma,n)C^{11}$ REACTION IN CARBONATES[1]

BY W. J. EDWARDS[2] AND K. J. MCCALLUM

ABSTRACT

The chemical effects following the carbon photoneutron reaction in calcium carbonate and sodium bicarbonate have been studied. After solution of the irradiated crystals, C^{11} was found to be present in the forms of carbonate, carbon monoxide, formic acid, oxalic acid, glyoxylic acid, and glycollic acid. The relative amounts of C^{11} appearing in each form agreed closely with those found previously for irradiations of solid sodium carbonate.

The chemical effects following the photoneutron reaction in the carbon isotope of mass 12 have been previously investigated for a few substances (1, 2). In this process, high-energy gamma rays eject a neutron from the nucleus of a carbon atom contained in a compound. The radioactive C^{11} nucleus which results possesses a high kinetic energy arising from both the momentum of the gamma ray photon and the recoil due to the emitted neutron. The C^{11} nucleus will be ejected from its parent molecule, and after being slowed down by collisions with neighboring particles, may undergo a

[2]*Holder of C.I.L. Fellowship, 1953–1954.*

reaction to produce a stable molecule or radical which could react with the solvent when the substance is subsequently put into solution. An investigation of the chemical forms in which the C^{11} appears in the solution gives some information concerning these processes.

Rowland and Libby (1) studied the relative amounts of C^{11} appearing in the form of carbon dioxide and carbon monoxide following the irradiation of solid and liquid carbon dioxide, solid sodium bicarbonate, and solutions of sodium bicarbonate and sodium carbonate. Gamma rays from a betatron operating at a peak energy of 48 Mev. were used. It was reported that the irradiation of samples in the solid state yielded about equal amounts of C^{11} activity in the form of each oxide, while for samples in the liquid state, 95–100% of the activity appeared as carbon monoxide.

Sharman and McCallum (2) determined the compounds containing C^{11} which were present in solutions formed from water and crystals of sodium carbonate which had been irradiated with gamma rays from a betatron operating at a peak energy of 23 Mev. The percentages of the total C^{11} activity appearing in carbon dioxide and carbon monoxide were 22% and 1% respectively, the remainder of the C^{11} being present as formic acid, oxalic acid, glyoxylic acid, and glycollic acid. The relative amounts of carbon dioxide and carbon monoxide did not agree with the suggestion of Rowland and Libby (1) that approximately equal amounts should be present in each oxide following the irradiation of solid samples.

This paper reports the results of a study of the chemical forms containing C^{11} following the irradiation of solid sodium bicarbonate and calcium carbonate with betatron gamma rays of 23 Mev. peak energy.

EXPERIMENTAL AND RESULTS

The sodium bicarbonate was Baker and Adamson reagent and was dried at 110°C. for at least 10 hr. before use. Two samples of calcium carbonate were used. The first was Merck reagent and the other consisted of calcite crystals obtained from Central Scientific Company.

The samples were exposed to radiation from a betatron operating at a peak energy of 23 Mev. for a period of 10 min. The intensity at the position of irradiation varied from 1000 to 2000 roentgens per minute in different experiments.

Decay measurements on the irradiated samples indicated the formation of O^{15} (half-life 2.5 min.), C^{11} (half-life 20.5 min.), and a small amount of a long lived activity. When sodium bicarbonate was irradiated, the long lived activity was due to Na^{24} (half-life 14.8 hr.). The long lived activity produced during the irradiation of calcium carbonate had a half-life of several hours, and amounted to about 2% of the total activity 40 min. after the end of the irradiation. The emitter was not identified. The total C^{11} activity produced in each irradiation was determined by counting weighed samples with a mica window end-on counter under standard geometry. Measurements were made 40 min. after the end of the irradiation to permit decay of the short lived O^{15}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

activity. Corrections were made for the small amount of long lived activity also present. An empirical calibration curve was used to correct for different weights of material counted.

The chemical procedures used to isolate the compounds containing C^{11} activity were similar to those used by Sharman and McCallum (2) in the study of sodium carbonate, since it was found that the same compounds were produced.

Two procedures were used to mix the carbon monoxide carrier gas with the radioactive carbon monoxide in the solution. The first method was that used previously (2) in which the carbon monoxide carrier was mixed with air or oxygen, and bubbled through the solution while acid was being added to liberate carbon dioxide from the sample. In the second method, used in addition to the first for sodium bicarbonate, the irradiated sample was placed in an evacuated flask, and the carbon monoxide carrier gas was admitted. Enough water was then introduced to dissolve the sample, and the solution was stirred vigorously with a magnetic stirrer for 10 min. to permit equilibrium of the carbon monoxide liberated in the solution with the carrier in the gas phase. Acid was then added dropwise to liberate carbon dioxide, while oxygen was passed through the flask to sweep the gases into the gas separation train. In this train, carbon monoxide and carbon dioxide were separated and isolated as previously described (2).

The procedures used to isolate and measure the radioactivity following formic acid, oxalic acid, glyoxylic acid, and glycollic acid carriers were also those previously used (2). In the experiments on calcium carbonate, the presence of the high concentration of calcium ions in the solution interfered with the isolation of some of these compounds. The calcium ions were removed either by passing the neutralized solutions through a Dowex 50 ion-exchange resin, or by precipitation as calcium carbonate.

The percentages of the C^{11} activity following the various carriers are shown in Table I. For comparison the results for sodium carbonate (2) are included in the table.

DISCUSSION

Table I shows that the distribution of the C^{11} between the different chemical forms is very closely the same for irradiations of sodium carbonate, sodium bicarbonate, and calcium carbonate. Apparently the nature and relative

TABLE I

PERCENTAGE DISTRIBUTION OF C^{11} ACTIVITY

Compound	Na_2CO_3 (2)	$CaCO_3$	$NaHCO_3$
Carbon dioxide	22±1	21±1	22±1
Carbon monoxide	1±1	1±1	1±1

proportions of the radicals formed by the C^{11} in these crystalline carbonates are quite independent of the nature of the cation present and of the crystal structure.

The percentages of carbon dioxide and carbon monoxide containing C^{11} produced in the irradiation of sodium bicarbonate were 22% and 1% respectively. This does not agree with the result reported for the same compound by Rowland and Libby (1), who stated that approximately equal amounts of these two oxides were produced. In a private communication Rowland states that in their work the gases were liberated from the irradiated solid by boiling with a solution of sulphuric acid. He suggests that if the organic acids found in the work reported here were present in the solution, this treatment could have caused considerable decomposition of these acids, with the production of radioactive carbon monoxide and carbon dioxide. This, of course, could result in a change in the observed ratio of the two oxides, and might account for the disagreement.

THE RELATIVE YIELDS OF THE ISOTOPES OF XENON IN PLUTONIUM FISSION[1]

By W. H. Fleming and H. G. Thode

ABSTRACT

The relative fission yields of five isotopes of xenon in Pu^{239} fission have been determined. Fine structure, similar to that observed in U^{238} fission but smaller, occurs in plutonium fission in the xenon mass range. The yield of the 133 mass chain has been determined at xenon in order to permit the normalization of the relative xenon yields to the relative cesium yields.

INTRODUCTION

The first application of mass spectrometry to fission yield studies (14) showed that the mass yield curve for thermal neutron fission of U^{235} was not smooth. In particular, the yield of the 134 mass chain measured at Xe^{134} was found to be abnormally high compared to adjacent masses. More recent studies (5, 8, 11, 12, 18) employing both mass spectrometry and improved radiochemical methods have provided accurate fission yield data for the whole mass yield curve in U^{235} fission. Large deviations from a smooth curve (fine structure) are observed only in the neighborhood of the 82 neutron shell and in the region of the complementary fragments to 82 neutron shell fission products. Much smaller fine structure has been observed in the vicinity of the 50 neutron shell (15). Fine structure has also been observed in the spontaneous fission of U^{238} (2, 9, 16) and in the neutron fission of U^{233} (3, 13) and U^{238} (15).

The occurrence of fission yields differing widely from a smooth curve may be the result of a preference for a particular mass chain in the original fission process or may result from chain branching which occurs after the actual fission act. Chain branching after fission occurs by delayed neutron emission and by neutron capture processes. Corrections can be made for neutron capture processes, but, since most of the delayed neutron emitters have not been identified, correction for delayed neutron emission is difficult. It has also been suggested that additional chain branching may occur by the emission of an extra prompt neutron by fission fragments having 1, 3, 5, or 7 neutrons in excess of a closed shell after normal prompt neutron emission (4, 10).

Isotopes of xenon are the stable end products of many of the decay chains having 82 neutron members. The relative fission yields of the xenon isotopes can therefore provide considerable information about the fine structure in the mass yield curve. In addition to the stable isotopes of xenon occurring in fission, Xe^{133} and Xe^{133m} have sufficiently long half-lives to be suitable for mass spectrometric yield studies. The determination of the relative yield of the 133 mass chain at xenon makes possible the normalization of the relative yields of the isotopes of xenon to those for the cesium isotopes since Xe^{133} and Xe^{133m} subsequently decay to Cs^{133}.

[1]*Manuscript received November 16, 1955.*
Contribution from the Departments of Physics and Chemistry, Hamilton College, McMaster University, Hamilton, Ontario.

Several mechanisms have been suggested to explain the fine structure observed in the thermal neutron fission of U^{235} (4, 10, 18). The present investigation of the relative yields of xenon isotopes in Pu^{239} fission was undertaken to provide data required for the elaboration and testing of these mechanisms. In addition it was felt that a reinvestigation of the mass yield curve for Pu^{239} fission would be profitable at this time because the only available data is that obtained during the early work in the American Atomic Energy Project (1) and experimental techniques have since been greatly improved.

EXPERIMENTAL

Samples of plutonium in the form of plutonium–aluminum alloy containing approximately 10% plutonium were supplied by O. J. C. Runnalls of Atomic Energy of Canada Limited. Plutonium isotope abundance ratios for a sample of this alloy are given in Table I. Four samples containing 10 to 20 mgm. of

TABLE I

PLUTONIUM ISOTOPE ABUNDANCE SAMPLE 2 (AFTER IRRADIATION)

Isotope	Atom %
Pu^{239}	96.1
Pu^{240}	3.72
Pu^{241}	0.18

plutonium were irradiated in the N.R.X. reactor at Chalk River for a time sufficient to produce approximately 5×10^{16} fissions. Two of the samples were allowed to cool for a time sufficient for all the precursors of xenon to decay. These samples were used for the determination of the relative yields of Xe^{131}, Xe^{132}, Xe^{134}, and Xe^{136}. The remaining two samples were allowed to cool for four to five days following irradiation after which the rare gas fission products were extracted and the mass spectrometer analyses carried out. In these samples approximately one-half of the yield of the 133 mass chain was present as Xe^{133m} and Xe^{133} at the time of analysis.

The ratio of Xe^{133m} and Xe^{133} to any of the stable xenon isotopes occurring in fission can, of course, be determined mass spectrometrically. However, the presence of iodine and tellurium precursors with moderate half-lives in the 131 and 132 mass chains introduces unnecessary complications and possible errors due to uncertainty of decay schemes. While Xe^{136} has only short-lived precursors the observed yield of this isotope is strongly dependent on irradiation conditions because of the large (2.7×10^6 barns) (7) neutron capture cross section of Xe^{135}. For these reasons the yield of Xe^{133m} and Xe^{133} was only determined relative to Xe^{134} which has no long-lived precursors or other complicating factors.

Since the activity of the irradiated samples used for the determination of the relative yield of the 133 mass chain was expected to be in the neighborhood of one curie at the time of extraction it was essential that a procedure be adopted which required a minimum of handling. The extraction of the rare gas fission products was carried out by melting the irradiated Pu–Al alloy in a

For personal use only.

vacuum furnace. The samples could be removed from their shipping containers, opened, and the Pu–Al alloy transferred to the furnace in approximately one minute. The entire operation was carried out in a fume hood shielded with 4 in. of lead. The gases released from the melted alloy were condensed into a sample tube containing charcoal cooled to liquid air temperature and transferred to another vacuum line for purification in a calcium furnace prior to mass spectrometer analysis. The radiation from the rare gas samples themselves amounted to about 15 mr./hr. at 1 meter. Since the purification and mass spectrometer analysis involved handling the samples only for brief periods no shielding was used at this stage.

The samples were analyzed on a 180° direction focusing mass spectrometer. Magnetic scanning was employed. The ion currents were amplified by a vibrating reed electrometer and recorded on a strip chart recorder. At least 10 double scan mass spectrograms were recorded for each sample.

RESULTS

The irradiation data for the four samples used in this work and the cooling times involved are summarized in Table II. The longest lived precursor in the mass chains studied is eight day I^{131}. It is obvious that, for samples 1 and 2,

TABLE II

IRRADIATION DATA AND COOLING TIMES

Sample No.	Irradiation time (hr.)	Cooling time before extraction	Time between extraction and analysis	Approx. neutron flux, n./cm.^{2}/sec.
1	308.2	120 days	1 day	2.6×10^{12}
2	67.4	81 days	7 days	6.8×10^{12}
3	59.0	124.0 hr.	4.95 hr.	1.2×10^{13}
4	60.0	147.8 hr.	3.42 hr.	1.2×10^{13}

the observed yields need no correction for holdup along the decay chains. The relative yields of the stable xenon isotopes are given in Table III for samples 1 and 2. The Xe^{136} yields in column 6 have been corrected for neutron capture in Xe^{135} using the estimated neutron flux from Table II. In making this correction the assumption was made that the yields of the 135 and 136 mass chains in Pu^{239} fission are identical. The value of the capture cross section of Xe^{135} used in the calculations was 3.47×10^6 barns determined by comparison to the $B^{10}(n, \alpha)$ cross section (11) for an irradiation position intermediate between those in which samples 1 and 2 were irradiated. This value should be more appropriate than the monoenergetic 2200 m./sec. value of 2.7×10^6 barns (7). Because the neutron fluxes for the plutonium samples are only estimated values based on irradiation position and pile power, considerable error may be introduced into the corrected Xe^{136} yields. Additional error may arise from the assumption that the yields of the 135 and 136 mass chains are equal in plutonium fission. The deviations quoted in column 6, Table III, have been arbitrarily set at $\pm 25\%$ of the correction applied.

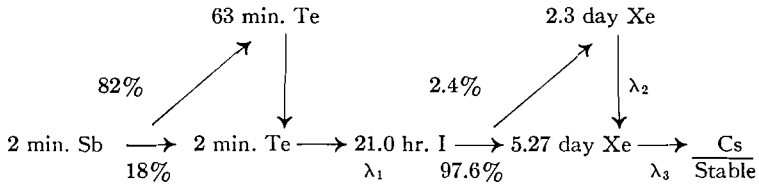
TABLE III

RELATIVE XENON YIELDS IN PLUTONIUM FISSION

Sample	Relative fission yield				
	Xe^{131}	Xe^{132}	Xe^{134}	Xe^{136}	Xe^{136} corrected
1	1.000	1.394±.002	1.978±.003	2.336±.005	1.83±.13
2	1.000	1.396±.004	1.984±.004	2.381±.003	1.70±.17

In order to calculate the relative yields of the 133 and 134 mass chains from the observed ratio of the xenon isotopes at these masses in samples 3 and 4, it is necessary that the disintegration constants of the 133 mass chain be known. A recent compilation (6) gives the following data for the 133 mass chain.

[1]



Two values are given for the half-life of I^{133} (20.5 hr., 22.4 hr.). The value 21.0 hr. has been arbitrarily chosen for use in this work. The actual value of the iodine half-life is not critical since, for the conditions of this experiment, a 10% uncertainty in this value introduces only 1% error in the final results. The times involved in the present work are such that negligible error will be introduced if the entire 133 mass chain is assumed to start at I^{133}.

Under these conditions it can readily be shown that the number of atoms of Xe^{133m} present at the time of extraction is given by

$$[2] \qquad N_2^* = 0.024R\left[\frac{(1-e^{-\lambda_1 T})e^{-\lambda_1 t_1}}{\lambda_2-\lambda_1} - \frac{\lambda_1(1-e^{-\lambda_2 T})e^{-\lambda_2 t_1}}{\lambda_2(\lambda_2-\lambda_1)}\right]$$

and the number of atoms of Xe^{133} by

$$N_3^* = 0.976R\left[\frac{(1-e^{-\lambda_1 T})e^{-\lambda_1 t_1}}{\lambda_3-\lambda_1} - \frac{\lambda_1(1-e^{-\lambda_3 T})e^{-\lambda_3 t_1}}{\lambda_3(\lambda_3-\lambda_1)}\right]$$

$$[3] \qquad + 0.024R\lambda_2\left[\frac{(1-e^{-\lambda_1 T})e^{-\lambda_1 t_1}}{(\lambda_2-\lambda_1)(\lambda_3-\lambda_1)} - \frac{\lambda_1(1-e^{-\lambda_2 T})e^{-\lambda_2 t_1}}{\lambda_2(\lambda_2-\lambda_1)(\lambda_3-\lambda_2)}\right.$$

$$\left. + \left\{\frac{1}{\lambda_2\lambda_3} + \frac{\lambda_1}{\lambda_2(\lambda_2-\lambda_1)(\lambda_3-\lambda_2)} - \frac{1}{(\lambda_2-\lambda_1)(\lambda_3-\lambda_1)}\right\}(1-e^{-\lambda_3 T})e^{-\lambda_3 t_1}\right]$$

where R is the fission rate multiplied by the fractional yield of 133 mass chain, Y^{133},

T is the irradiation time,

t_1 is the cooling time,

λ_1, λ_2, and λ_3 are as indicated in [1] above.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

From the time of extraction to analysis there is no production of Xe^{133} or Xe^{133m} from I^{133}. Therefore at the time of analysis the number of atoms of xenon of mass 133 is

$$[4] \qquad N_2 + N_3 = N_2^*\left[e^{-\lambda_2 t_2} + \frac{\lambda_2}{\lambda_3 - \lambda_2}(e^{-\lambda_2 t_2} - e^{-\lambda_3 t_2})\right] + N_3 e^{-\lambda_3 t_2}$$

where t_2 is the time between extraction and analysis.

Since the holdup in the 134 mass chain is negligible, the number of atoms of Xe^{134} at the time of analysis is R^1T where R^1 is the fission rate multiplied by the fractional yield of the 134 mass chain, Y^{134}. The relative yields of the 133 and 134 mass chains can therefore be calculated from the observed ratio

$$[5] \qquad 133/134 = (N_2 + N_3)/R^1T.$$

In practice, of course, the fission rate is not constant but varies because of pile shutdowns and variations in pile power. The effect of these variations on the final result will be small since the production rates of the 133 and 134 mass chains both vary with neutron flux in an identical manner. To provide an indication of the magnitude of this effect the calculations for sample 4 were carried through assuming a 50% decrease in flux during the last third of the irradiation time. The final result obtained differed from the value obtained assuming constant flux by only 2%.

The measured 133/134 ratios for samples 3 and 4 and the calculated yield ratios for the 133 and 134 mass chains are given in Table IV. The deviations quoted are the precision of the mass spectrometer measurements only and do

TABLE IV

RELATIVE YIELDS OF 133 AND 134 MASS CHAINS

Sample	Measured ratio $\frac{Xe^{133}+Xe^{133m}}{Xe^{134}}$	Calculated ratio Y^{133}/Y^{134}
3	0.4663±.0009	0.927±.002
4	0.4131±.0005	0.924±.001

not include possible errors arising from uncertainties in the half-lives involved in the calculations. Allowance has been made in the calculations for variation in neutron flux during the irradiations although, as stated above, the effect of such variations is small. Making allowance for possible systematic errors due to uncertainties in the decay schemes involved, it would appear reasonable to set the yield ratio of the 133 and 134 mass chains, Y^{133}/Y^{134}, equal to 0.925± .01.

DISCUSSION

Wiles *et al.* (17) have determined absolute fission yields for the heavy mass hump in Pu^{239} fission. Their value for the 133 mass chain determined at Cs^{133} is 4.97%. The xenon fission yields calculated using this value and the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

yield data given above are listed in Table V. The deviation shown for mass 136 arises from the uncertainty in the correction for neutron capture. The deviations at masses other than 136 arise mainly from the 133/134 yield ratio determination.

TABLE V

XENON FISSION YIELDS Pu^{239} FISSION

	Fission yield (%)	
Mass	Sample 1	Sample 2
131	2.71±.03	2.71±.03
132	3.78±.04	3.78±.04
133	4.97±.05	4.97±.05
134	5.37±.05	5.37±.05
136	5.0 ±.4	4.6 ±.5
Average value mass 136 = 4.8±.5		

Previous radiochemical yield studies (1) have given considerably higher yields for masses 131 and 132 in Pu^{239} fission (3.6% and 4.9% respectively). The possible sources of error in the present absolute value of the Cs^{133} yield are discussed by Wiles *et al.* (17). The conclusions drawn in the following discussion depend only on the relative yields of the xenon and cesium isotopes and are independent of the absolute fission yield values used. The absolute values are given only to convey some idea of the comparison between the fission yields for Pu^{239} fission and those observed with other fissioning nuclei.

Glendenin (4) suggested that the fine structure observed in the xenon mass range in U^{235} fission might be the result of chain branching due to the emission of the loosely bound 83rd neutron by the highly excited primary fission fragments having that configuration. This explanation was only in qualitative agreement with the observed yields. Pappas (10) later developed a quantitative explanation of the observed yields in U^{235} fission by combining the postulated primary fission preference for 82 neutron nuclei first suggested by Wiles (18) with a Glendenin type neutron boil-off mechanism extended to 85, 87, and 89 neutron species. In order to calculate the fission yield pattern expected on the basis of the Pappas treatment it is necessary to know the unperturbed smooth mass yield curve, the distribution of primary yields along each mass chain, and the extent of the various delayed neutron activities. There is, of course, considerable uncertainty in each of the above factors and hence the final calculated yields have a relatively large uncertainty. A comparison between the calculated and experimental xenon yields in Pu^{239} fission is shown in Fig. 1. It can be seen that the agreement is very good. Good agreement between the calculated and experimental yields has also been observed for U^{238} fission (15). However, in the case of $U^{233} + n$ fission (3) there is considerable discrepancy. Therefore it would appear that while the mechanism suggested by Pappas has considerable merit further modification is required before all experimental results can be explained.

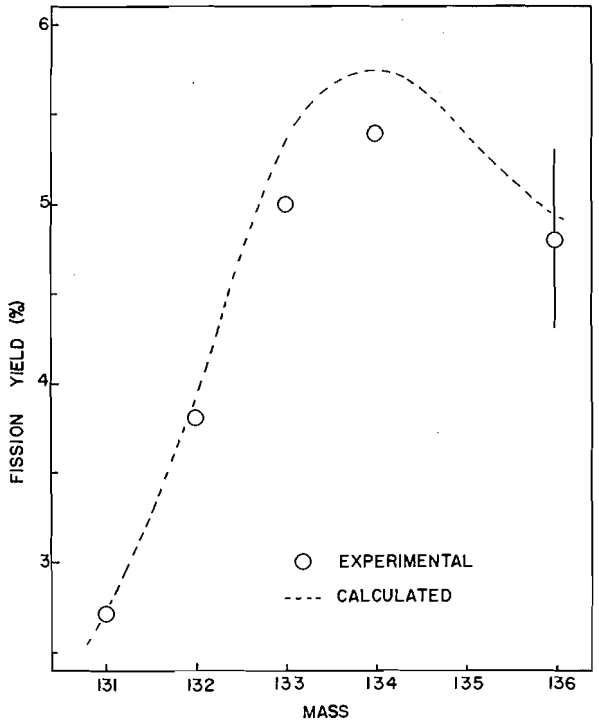

FIG. 1. Comparisons between observed plutonium fission yields and the values calculated after Pappas (10).

Further samples of Pu^{239} are now being irradiated under conditions in which neutron capture by Xe^{135} will be negligible in order to obtain a more accurate value for the yield of Xe^{136}. Possible variation of the xenon fission yields with neutron energy is also being studied.

ACKNOWLEDGMENTS

The authors are indebted to the National Research Council of Canada and to Atomic Energy of Canada Limited for financial assistance. This work would not have been possible without the wholehearted co-operation of the members of the staff of Atomic Energy of Canada Limited who supplied the samples and arranged for their irradiation.

THE YIELD OF Cs^{138} IN THERMAL NEUTRON FISSION OF U^{235} [1]

By Rosalie M. Bartholomew and A. P. Baerg

ABSTRACT

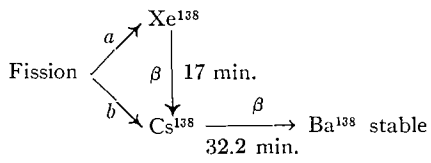
The yield of Cs^{138} in thermal neutron fission of U^{235} has been investigated using the 4π counting technique. The value obtained for the fission yield is $(7.22 \pm 0.29)\%$ based on a value of 6.32% for the fission yield of Ba^{140}. The half-life of Cs^{138} was determined and found to be 32.2 ± 0.1 min.

INTRODUCTION

Early radiochemical investigations of slow-neutron fission indicated that the familiar double-humped yield–mass curve was essentially smooth. Marked deviations from a smooth curve were definitely established, however, by Thode and co-workers (6, 11) in mass spectrometric determinations of fission product rare gases. Plausible interpretations of this fine structure have been evolved in terms of various closed shell effects on the fission process and also on the post-fission processes.

Pappas (7) has made quantitative estimates of the U^{235} fission yields in the heavy mass wing, based on the concept of primary prompt neutron emission from each fission fragment followed by additional prompt neutron emission from those fragments with 1, 3, 5, or 7 neutrons outside the closed 82 neutron shell. The estimates include, in addition, effects due to delayed neutron emission. Although only a few delayed neutron emitters have been identified, it is expected that all of them belong to a group of nuclides which have 2, 4, or 6 neutrons in excess of closed shells. The mass 138 chain is of particular interest in this connection because it may be expected to exhibit an enhanced fission yield due to delayed neutron emission from I^{139}. Pappas (7) has estimated this effect at about 5.5% of the yield estimate based on primary and secondary prompt neutron emission alone. In spite of this interesting possibility it is only very recently that measurements have been made on the yield of the mass 138 chain. We have made radiochemical measurements of the yield of 32 min. Cs^{138}, relative to that of 12.8 day Ba^{140}, in the thermal neutron fission of U^{235}, using 4π counting techniques.

The formation of Cs^{138} in fission may be represented as follows:



where the fraction of the 138 mass fragments leading to Xe^{138} is denoted by a and that leading directly to Cs^{138} by b.

[1] *Manuscript received November 16, 1955.*
Contribution from Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 275. This paper was presented at the Symposium on Nuclear Chemistry and Radiochemistry held at McGill University, Montreal, Que., September 7–9, 1955.

If a uranium sample is irradiated for a time, t_1, and then allowed to decay for a time, t_2, the number of Cs^{138} atoms present at time t_2 is given by:

$$[1] \quad \text{atoms } Cs^{138} = Y_{138}N\left[\frac{1-b}{\lambda_2-\lambda_1}\{e^{-\lambda_1 t_2}(1-e^{-\lambda_1 t_1}) - e^{-\lambda_2 t_2}(1-e^{-\lambda_2 t_1})\} + \frac{1}{\lambda_2}e^{-\lambda_2 t_2}(1-e^{-\lambda_2 t_1})\right]$$

where Y_{138} is the cumulative fission yield of Cs^{138}, N is the fission rate, λ_1 and λ_2 are the decay constants of Xe^{138}(17 min.) and Cs^{138}(32.2 min.) respectively. This equation may be more simply written in the form of equation [2] where k_1 and k_2 may be calculated from the experimental conditions and the known decay constants involved.

$$[2] \quad \text{atoms } Cs^{138} = Y_{138}N(k_1 b + k_2)$$

EXPERIMENTAL

Samples of uranium oxide (50–150 mgm. UO_2) were sealed in small quartz capsules and irradiated in a high flux position (about 5×10^{13} neutrons/cm.^{2}/sec.) in the Chalk River N.R.X. reactor for a few minutes and returned immediately to the laboratory by pneumatic conveyor. The capsule was crushed in 5 ml. hot 4 *N* HNO_3 solution containing about 50 mgm. Ba $(NO_3)_2$ and about 20 mgm. $CsNO_3$ carriers. The UO_2 was quickly dissolved upon the addition of HCl gas. The time of complete solution was noted as that at which the remaining Xe^{138} was removed (t_2 in equation [1]). The solution was then cooled in ice and $BaCl_2$ precipitated by saturating the solution with HCl gas. The barium was later further purified (2) for activity measurements.

The supernatant solution from the $BaCl_2$ precipitation was then diluted to 6 *N* HCl, cooled in ice, and the cesium precipitated by addition of 1 ml. of 0.125 *M* silicotungstic acid. This precipitate was washed twice with cold 6 *N* HCl and then dissolved in 2 ml. of 2 *M* LiOH and the cesium adsorbed on a Dowex-50 cation resin column (0.5 × 3 cm.) in the Li form. The column was washed with a few milliliters of water followed by 15 ml. of 1 *N* HCl. The cesium was finally removed with 5 ml. of concentrated HCl, made up to constant volume, and from this small aliquots were taken for counting.

The chemical yield of barium was determined gravimetrically by precipitation of barium sulphate. The chemical yield of cesium was determined by weighing as cesium chloroplatinate (9).

The disintegration rate of Ba^{140} and that of Cs^{138} was determined using the 4π counting technique. Counting samples were prepared by evaporation of known aliquots of the solution on thin films (5 μgm./cm.^{2}) of zapon which had a conducting film of gold (5 μgm./cm.^{2}) on each side. Self-absorption in the barium was essentially eliminated by the technique of successive dilution and by spreading the material as uniformly as possible, using insulin treated films (1).

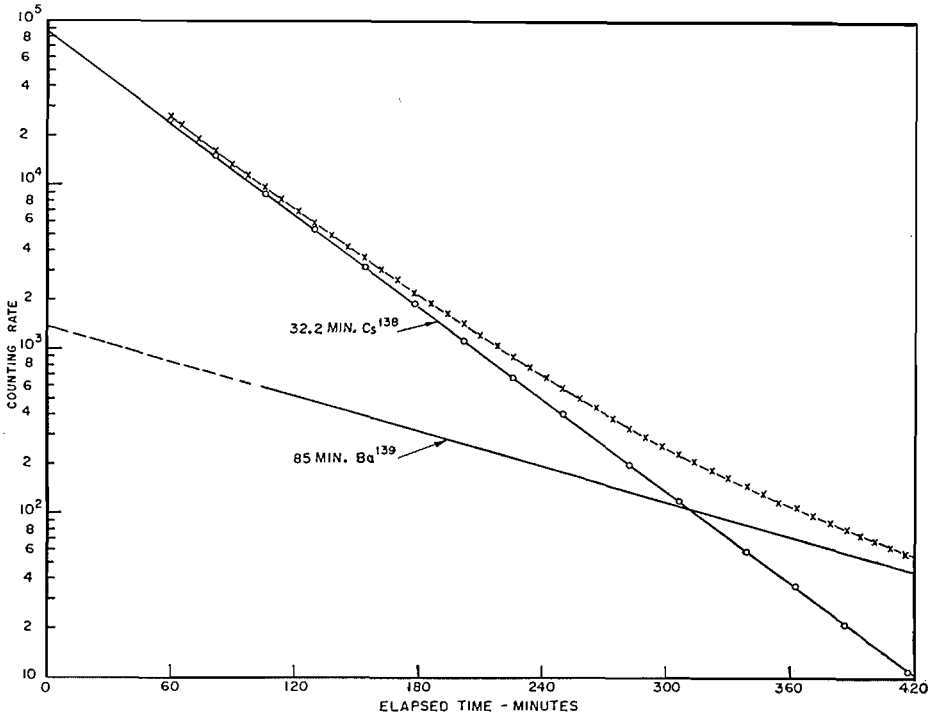

FIG. 1. Representative decay curve of a cesium source.

In Fig. 1 is shown a typical cesium source decay curve. The decay was followed for about 12 hr. to check on the purity of the Cs^{138} and to permit analysis of the curve for 85 min. Ba^{139} present in the sources as the product of the decay of some 9.7 min. Cs^{139}. The latter appears as a slightly greater counting rate at the start of the observed decay.

The disintegration rate of the Cs^{138} was calculated back to the time, t_2, at which the Xe^{138} was removed from the sample. The half-life of Cs^{138} was determined in a separate experiment in which the Cs^{139} had essentially all decayed before purification of Cs was started. The half-life found was 32.2 ± 0.1 min. over about 14 half-lives.

RESULTS AND DISCUSSION

The results of seven experiments are summarized in Table I. The value obtained for the fission yield of Cs^{138} is 7.22% with a standard deviation of 0.29%. In the yield calculations it was assumed that the fractional independent yield, b, for Cs is zero. Experimental conditions were varied so as to obtain a range of the ratio k_1/k_2. It is felt that this ratio varied sufficiently that an independent yield of Cs^{138} greater than 5% of the chain yield would have been detected. The independent yield of Cs^{138} may, however, be estimated to be about 20% of the chain yield before secondary prompt neutron emission, assuming the most probable charge, Zp, for the 138 mass chain to be 53.9.

5	300	1730	6.42	146.48	0.044	7.34
6	180	726	68.85	65.46	1.07	7.39
7	300	2250	−17.27	144.14	−0.12	7.36

Average = 7.22±0.29%

Pappas (7) has postulated that those nuclides with 83, 85, 87, and 89 neutrons which are formed independently in fission are removed from their mass chains by additional prompt neutron emission. Since the Cs^{138} nucleus contains 83 neutrons no observable independent yield would be expected. Our results are consistent with these ideas.

The value of 7.22% for the yield of Cs^{138} is considerably greater than that of 6.8% for the chain predicted by Pappas and it deviates markedly from the unpublished mass spectrometer value of 5.74% quoted by Steinberg and Glendenin (10) in their paper to the Geneva conference. Unless the accepted decay scheme (3) for Cs^{138} is incorrect it is difficult to account for this discrepancy at the present time. On the other hand a reasonable interpretation for the 7.22% value can be made in terms of delayed neutron emission in I^{139}.

If the 2.6 sec. I^{139} is not a delayed neutron emitter the predicted yield of the mass 138 chain would be about 6.44%, not significantly different from the yield of about 6.3% predicted from the smooth mass–yield curve. The estimated independent yield of I^{139} is 1.36% in fission assuming that the most probable mass 139 charge, Zp, is 54.3. Pappas has estimated that about 25% of the β-emission in I^{139} leads to neutron emission in the excited Xe^{139} daughter. This brings the estimated yield for mass 138 up to 6.8%. The neutron emission probability for I^{139} would have to be about 56% to bring the mass 138 yield to 7.22%. The yield of the mass 139 chain should then also be correspondingly lower—about 5.6%. Earlier radiochemical measurements on Ba^{139} indicated values of 5.9 and 6.1% (see Ref. 7). Reed and Turkevich (8) have found a value of 6.4% while Pappas (7) has measured the yield as 5.79%.

It seems significant that a recent analysis, at Los Alamos and Brookhaven, of the gross decay curve for delayed neutrons in U^{235} fission indicates a 2.11 sec. period with over 40% abundance (5). The total yield of delayed neutrons in U^{235} fission is about 0.755% of all neutrons (4). If this 2.11 sec. delayed neutron period, with its 40% abundance, is ascribed to I^{139}, the total yield of the mass 138 chain becomes 7.21%.

RECENT DEVELOPMENTS IN LOW BACKGROUND GEIGER–MÜLLER COUNTERS[1]

By W. E. Grummitt,[2] R. M. Brown,[3] A. J. Cruikshank,[3] and I. L. Fowler[2]

ABSTRACT

G–M counting assemblies have been constructed which give dependable low background operation in routine use. Possible construction materials have been examined in detail for radioactive content in an effort to achieve minimum inherent activity in the assembly. The cosmic ray component of the normal background has been eliminated by an anticoincidence arrangement. Increased reliability of the system is obtained through (*a*) use of a multiple anode anticoincidence counter in place of a bundle of tubes, (*b*) use of an electronic quench on both sample and shielding counters, and (*c*) operation of the assembly as flow counters in tandem. In the best arrangement to date a copper counter with a polystyrene seal gives a background of 0.9 counts per minute.

INTRODUCTION

There has been considerable information published during the last few years by workers using 1 to 10 liter gas filled counters to measure very low C^{14} and tritium activities (1, 4, 7). The present paper considers the design of a low background assembly suitable for use with a conventional end-window beta or 60 cc. tritium counter.

The data at present available indicate that three components contribute to the background in a counter: cosmic radiation, γ disintegrations in the shield and surrounding material, and α, β, and γ activities in the counter materials. The cosmic contribution can be eliminated electronically by rejecting pulses which occur coincidently with those in surrounding counters. Because of the present low efficiency of γ counting, this method cannot be used to eliminate the second component of the background and it is therefore necessary to shield against γ radiation. The third component must be controlled by careful selection of construction materials.

Very little information is available regarding radioactive impurities in metals and common insulating materials. Anderson, Arnold, and Libby (1) give some qualitative data for iron, steel, and brass, while Bearden (2) and more recently Fergusson (4) have measured the α counting rate of some metal surfaces. It is desirable to investigate such materials in some detail in order to be able to construct an assembly having minimum inherent radioactivity.

COUNTER MATERIALS

Two methods of examining materials are of value, direct counting of a sample of large area and chemical concentration of the radioactive contami-

nant. In the first instance the activity of the sample is compared with a known uncontaminated control. In the second, the sample is dissolved in acid and scavenging agents such as ferric hydroxide – barium carbonate precipitated by the addition of a suitable reagent. If the ferric hydroxide is counted in high geometry, the sensitivity can be increased 100-fold over direct counting. The K^{40} contribution is estimated from spectrographic analyses, although its contribution is negligible for metals. The β activity of plastics is readily measured by destructive distillation of the material in a covered nickel crucible and counting the ash.

Results obtained for a wide variety of materials are presented in Table I. Copper is superior to the other metals measured, probably as a result of

electrolytic refining. Numerous metals not included in the table, e.g. platinum, tin, cadmium, and antimony, have a rather high and variable level of activity. Values ranging between 10 and 200 c.p.m./100 cm.^{2} are observed. It is interesting to note that 16th century lead is appreciably better than 'superpure' aluminum.

There is extremely little variation in the activity remaining in the ash of various plastics. This is somewhat surprising since the ash weight varies from 1.7 mgm./100 gm. for Plexiglas UVA (ultraviolet absorbing) to 90 mgm./100 gm. for polythene. The present level for local dust is 25 dis./min./100 mgm. ash, comparable to the specific activity of Plexiglas ash.

Using a β/α ratio of 20, an average of that observed for aluminum, old lead, and local sand, it is possible to obtain a measure of the surface α activity.

For personal use only.

Calculated counting rates range from 3×10^{-3} c.p.m./100 cm.^{2} for oxygen-free copper to 6×10^{-4} for Perspex and Lucite. These values are a factor of 5 to 15 lower than those observed on counting "radioactively clean" materials (4, 2), and presumably represent minimal values which would be obtained for samples completely free from surface contamination.

SHIELDING MATERIALS

Numerous materials are in common use as γ ray shields and there are advantages associated with each. Radioactive impurities in lead, copper, and mercury can be estimated readily but this is more difficult with iron. In this case the shield is usually constructed and then tested for contamination by comparison with other shields. Lead is easily cast to shape and has a high density, but modern samples contain appreciable activities. The observed level of activity in old lead is presumably due to radium, while the major portion of the activity in modern lead is due to Pb^{210}. Using the ratio of activities in the two lead samples it is possible to calculate that the extent of removal of radium in the 16th century refining process was 96%, assuming that the original ores contained similar amounts of radium. Mercury is obtainable in very pure form, but requires a complex safe containing vessel and is expensive. The cost can be reduced by a factor of two to three by interposing the mercury between the counters. This may improve the background, but demands larger and somewhat more complex annular and top counters because of the increased radius.

A comparison of the backgrounds obtainable with lead and mercury is of interest. The best value achieved to date is 0.9 c.p.m. in a 30 cc. counter in a castle of 2 in. of mercury surrounded by 2 in. of modern lead. With the mercury removed this count increased to 1.8, a difference of 0.9 c.p.m. Since 16th century lead shows an improvement of 10 times over modern lead (Table I), the count inside 2 in. of 16th century lead surrounded by 2 in. of modern lead would be 1.0, an increase of only 0.1 c.p.m. over the mercury–lead combination. For a small counter such as the one used here, lead can provide a very satisfactory and economical solution.

COUNTERS

The end-window β counter shown in Fig. 1 is constructed of 0.1 in. oxygen-free copper tubing to which the copper end cap and flange are hard soldered. A polystyrene insulator which carries the tungsten or stainless steel center wire is cemented in place in the end cap with Biggs R313 or Armstrong A1 or A2 bonding agent.* There is some evidence that polystyrene is porous to hydrogen, helium, and possibly air. It has been found difficult to make counters with such insulators last for six months. Saran insulators appear to be much better. Mica is used as a window material for counters which are to be evacuated and filled, but a thin plastic such as saran film is used in flow counters which operate at atmospheric pressure. In both instances the windows are cemented in place and covered with a thin conducting film of aquadag to minimize charge effects which result in a form of instability.

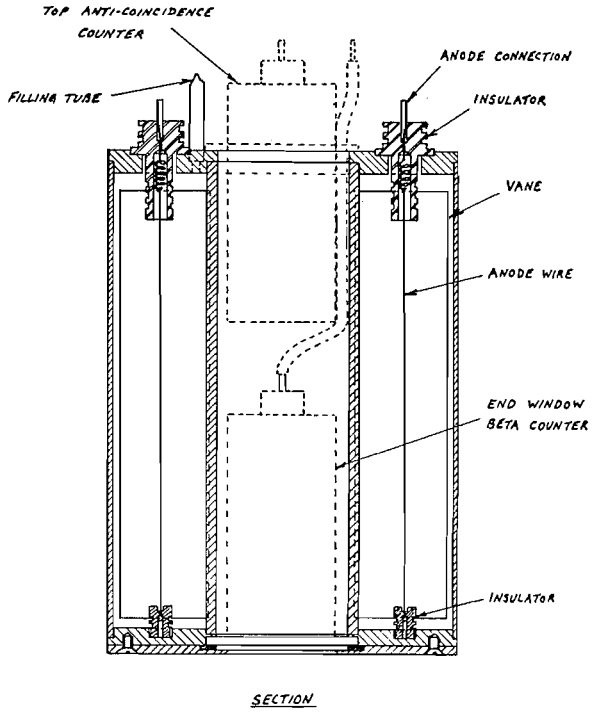

FIG. 1. Anticoincidence counter assembly.

The top anticoincidence counter is constructed in a similar manner except that the window is replaced with a copper plate. In the 60 cc. tritium internal gas counter construction is again similar but the wire is supported at both ends by having insulators in both end caps.

Initially, six separate shielding counters were used but these have been replaced with a multiple anode annular counter which has previously been described in detail (5). It is again constructed of copper with polystyrene insulators and eight wires are symmetrically disposed in a common envelope consisting of the annular volume between two concentric cylinders. As suggested by Raeth (6), shielding vanes may be interposed between the wires. These improve the plateau characteristics and allow the wires to operate independently of one another. However they constitute a small amount of dead volume and interfere with flushing when the assembly is used as a flow counter. Photographs of a sectioned early model of this counter are shown in Fig. 2.

In the operation of the assembly all the shielding counters are connected together and placed in anticoincidence with the end-window β counter or the 60 cc. tritium counter.

The anticoincidence background is, of course, a function of the coincident background and as this varies directly with the efficiency of the counters for cosmic rays, the stability of the latter is of the utmost importance. Thus if the

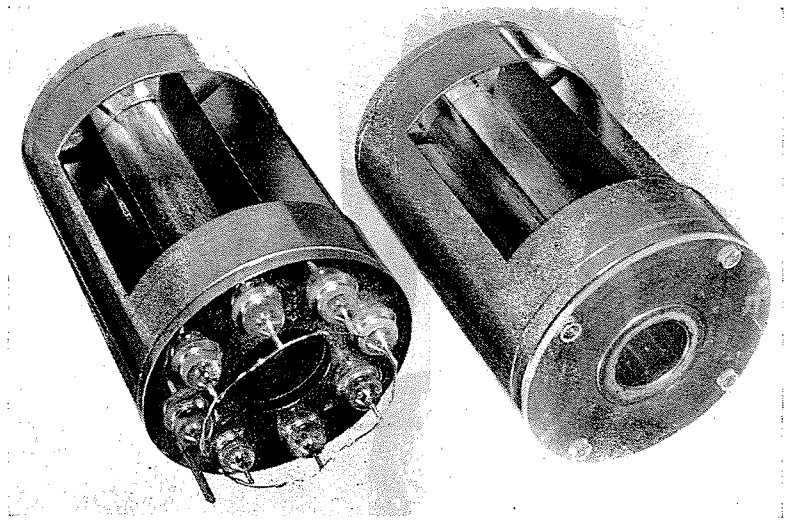

FIG. 2. Cutaway view of anticoincidence counter assembly.

anticoincidence background is equal to 1, and the coincident* equal to 10, a 1% change in the efficiency of the shielding counters will cause a 10% change in the anticoincidence background. An anticoincidence annular counter greatly increases the reliability of the system, being much more stable than six individual counters and having a relatively constant efficiency throughout its useful life. Furthermore if it fails, failure is immediately apparent. Failure of one counter from a ring of six separate counters connected together might go unnoticed for a considerable time.

COUNTER OPERATION

The use of an electronic quench unit (3) is found to be advantageous even with self-quenched G–M counters. During the discharge of such a counter, most of the positive charges are transferred from the noble gas atoms to the molecules of quench gas which dissociate on reaching the cathode thus avoiding photoemission of electrons by the cathode and subsequent secondary discharge of the counter. However, the concentration of quench gas may be insufficient to completely remove the positively charged noble gas ions, in which case a number of secondary spurious pulses may be expected. These are most likely to occur when the quench gas has been depleted by a large number of discharges, or when it is desired to introduce high pressures of some additional gas such as hydrogen. If a trace of air leaks into the counter spurious discharges may also result from oxygen negative-ion formation. Because of their lower mobility the negative ions may only reach the neighborhood of the wire after the discharge in which they were formed is complete and thus trigger a second and spurious discharge. To eliminate these spurious pulses the counter may be electronically quenched, holding the potential of the wire below threshold voltage after a discharge for a period longer than the

**The coincident background is that portion which is coincident in both counters and is removed by the anticoincidence circuit. The anticoincidence background is the portion remaining.*

transit time of the ions involved. This time is about 200 μsec. for hydrogen in a 1 in. diameter counter. In practice dead times of the order of 1000 to 2000 μsec. are used for both counters. Since the dead time is fixed by the quench unit and is always the same, counting losses due to it may be calculated with accuracy.

Wolfgang and Libby (7) have introduced the use of ethylene as a quench gas for hydrogen, suggesting that the charge transfer action is one of chemical absorption of the negative hydrogen ions. However, the system gives satisfactory counting characteristics only at limited hydrogen pressures. The beneficial effect of applying an electronic quench to this counting system is illustrated in Fig. 3. A flat plateau has been obtained with hydrogen pressures

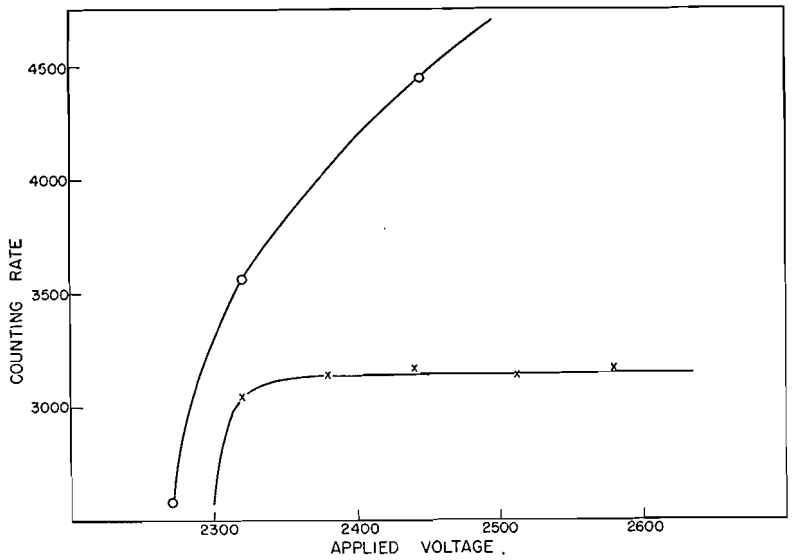

FIG. 3. Typical plateaus.
×—With external quench ○—Without external quench
Filling—6 cm. argon, 4 cm. ethylene, 40 cm. hydrogen.

up to 70 cm. Hg and there is every indication that considerably higher pressures could be used successfully with this circuit.

As the arrangement of shielding counters is unusual, a determination was made of the effectiveness of their distribution. Fig. 4 shows the effect of the vertical position of the end-window counter within the assembly as illustrated in Fig. 1. An increase in background is observed because of incomplete shielding from below (left), and because of incomplete top shielding (right) as the center counters are raised. A redesign of the annular ring which would lower its effective counting volume would thus be desirable. In a more recent model the effective volume has been lowered 0.42 in. by decreasing the thickness of the end plate and the projecting length of the bottom insulators.

One of the problems associated with the operation of G–M counters is the relatively short life expectancy* and this is accentuated in a low background

**Halogen quenched counters have very long lives but because of their somewhat lower cosmic ray efficiency and a delay phenomenon they are not suitable in anticoincidence arrangements.*

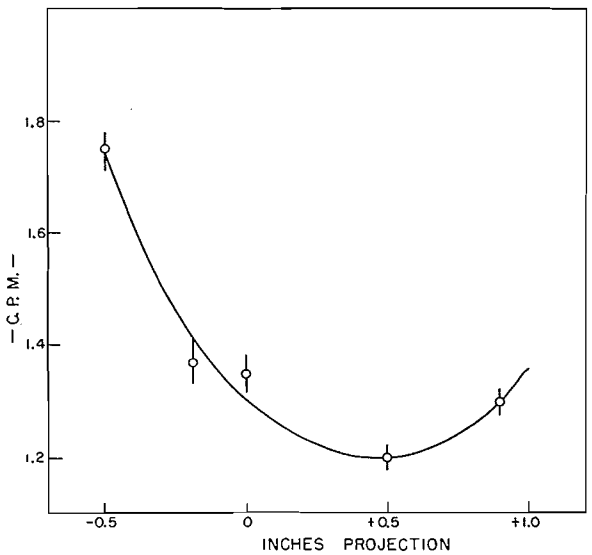

FIG. 4. Effect of the position of the center counter within the annular counter.

anticoincidence assembly because of the multiplicity of counters and limitations regarding materials. The use of the multiple anode counter substantially reduces the magnitude of this problem but a further improvement has been obtained by the operation of the whole assembly as flow counters in series using an isobutane–helium mixture. Fig. 5 shows the dependence of the G–M

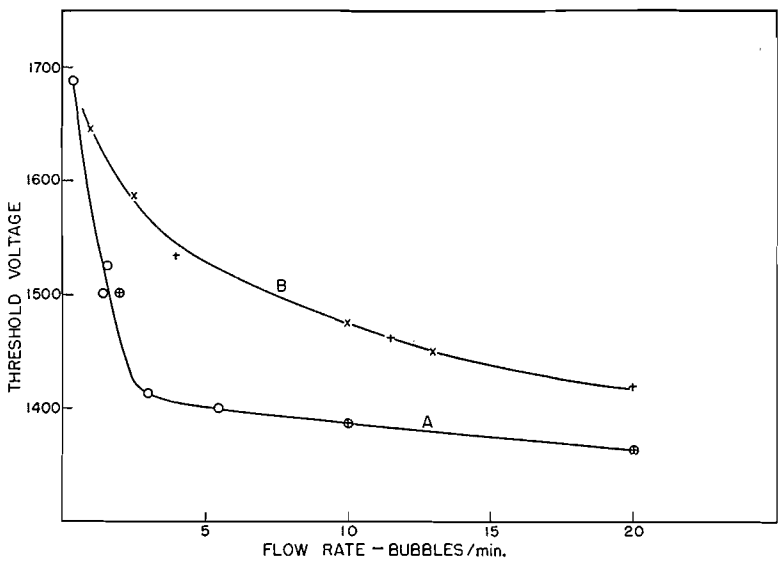

FIG. 5. Geiger threshold as a function of the rate of flow of gas through the counter.
⊕+—Increased flow ○×—Decreased flow

threshold on the gas flow rate, the lower curve being obtained with the multiple anode counter. It is desirable, of course, to operate in a region of minimum slope and consequently rates as low as five bubbles per minute (1 cc./min.) are satisfactory. The upper curve shows the deterioration of plateau length and slope by the introduction of 1 ft. of tygon tubing (a plasticized polyvinyl copolymer). At 1 cc./min. the plateau slope is increased from 2% to 14% per 100 v. This is typical of the effect of chlorinated hydrocarbons and is presumably due to negative-ion formation.

The increased life expected from the flow system will also result in a more stable counter because of the removal of two aging phenomena: increasing spurious counts in the end-window counter and increasing threshold voltage. Furthermore, plastic film can be substituted for the mica window, removing the last major source of activity from the counter and making the background of an end-window counter comparable with that obtainable in a gas counter.

PRODUCTION OF Be^7 IN THE ATMOSPHERE[1]

By A. J. Cruikshank,[2] G. Cowper,[3] and W. E. Grummitt[3]

ABSTRACT

The concentration of Be^7 in the atmosphere has been determined by measuring the activity associated with dust particles in ground level air. It is calculated that the observed concentration is maintained by a production rate of 2300 atoms $Be^7/cm.^2/day$ in northern latitudes.

Libby (4) in 1946 predicted the presence of radioactive nuclides in the atmosphere. C^{14} and H^3 have been widely studied and Be^7 has been reported recently in rain by Arnold and Al-Salih (1). We have investigated the Be^7 attached to dust particles in the air and calculate a production rate of 2300 atoms $cm.^{-2}$ day^{-1}. This is somewhat smaller than but compatible with Arnold's value from rain.

EXPERIMENTAL

Samples were collected over a period of 14 months at four widely separated stations north of geomagnetic latitude 55°. Air volumes of 10^7–10^8 liters were passed through efficient paper filters which removed essentially all of the mass of the dust in the atmosphere. The papers were ashed at 500°C. and inactive Be and Ce carriers were added. The mixture was fused with $NaHSO_4$, then digested with water, and treated with NH_3. The precipitate was dissolved in HCl and reprecipitated several times with NH_3 gas to remove excess $CaSO_4$ and SiO_2. A few milligrams $SbCl_3$ were added and precipitated with H_2S from slightly acid solution to remove interfering activities such as Ru and Te. A further NH_3 precipitation followed by solution in a minimum of HCl left further sulphides behind. Ce was precipitated from 3 *N* NaOH and Be was recovered by acidifying the solution and then precipitating with NH_3.

The $Ce(OH)_3$ was successively precipitated as fluoride, hydroxide, and oxalate. The oxalate was mounted, weighed, and beta counted through absorbers to estimate the Pr^{144} activity. This was used as a measure of the long lived fission products collected.

The $Be(OH)_2$ was dissolved in dilute HCl and scavenged twice with $Fe(OH)_3$ precipitated from 1.5 *N* NaOH. Be was then precipitated with NH_4OH, converted to the basic acetate by heating with acetic acid to 200°C., and then was extracted into $CHCl_3$. The $CHCl_3$ was evaporated, $Be(OH)_2$ was precipitated, ignited at 500°C., and weighed.

The 0.48 Mev. γ ray was counted in the central well of a 3 in. NaI crystal which was shielded with 2 in. Hg and 4 in. Pb. An 18 channel pulse analyzer

was used to scan the peak. Energy and efficiency calibrations were done with standardized Na^{22} and Cs^{137} sources. The Be^7 concentration at the time of collection was calculated using a 53 day half-life, γ counting efficiency of 0.50, and γ branching ratio of 0.11.

Several early samples showed Ru γ activity, but introduction of the sulphide scavenge and an extra $Fe(OH)_3$ scavenge produced pure Be activity. Three samples were put through the complete purification for a second time and showed the same specific activity. The yield of Be was usually 60–70% but in some samples containing an excessive amount (>100 mgm.) of Al much Be was lost in the acetate extraction and only 15–20% over-all yield was obtained.

In some cases where there was a considerable delay in analyzing the samples, the counting rates were low compared to the background and there is considerable statistical error.

RESULTS

The observed Be^7 and Ce^{144} concentrations in atoms per liter are given in Tables I and II. They are corrected for decay to the time of collection. The

stations are numbered from north to south. The limits of error given are the standard deviations of the counting rates, usually the principal source of error. Another source of error, the magnitude of which is difficult to estimate, is the plugging of the filter by an overload of dust or by small amounts of driven snow. Filters which were obviously snowbound were discarded. At Stations 3 and 4 about four times as much air was put through each filter as at Stations 1 and 2, and the dust loading was somewhat higher, so that less than the calculated volume may have been filtered. Hence the concentrations reported for Stations 3 and 4 may be somewhat low.

There is a considerable day-to-day variation in both Be and Ce concentrations and also a marked seasonal variation from winter to summer at Stations 1 and 2. The variation is greater at Station 1 than at Station 2 and at Station 3 there is little seasonal variation.

DISCUSSION

If the Be and Ce were produced artificially one would expect that subsequently the Be activity would decrease relative to the Ce, because of the difference in half-lives. This is not observed, so we conclude that Be^7 is produced naturally by the action of high energy cosmic rays in the atmosphere.

This being so, one would expect that the concentration would build up to an equilibrium value corresponding to the rate of production. However diffusion, gravity, electrostatic attraction, and rainfall will reduce the concentration by bringing the Be^7 to the earth's surface where it becomes fixed. Of these, rain and snow are by far the most efficient in removing dust from the air and Arnold has shown the presence of Be^7 in rain.

Day-to-day variation can probably be explained in terms of atmospheric stability as in studies of industrial air pollution. We will attempt to show that rain and snowfall can account for the seasonal variations in a satisfactory manner and thus arrive at an average value for the rate of production.

Since the yearly average Be^7 concentrations at Stations 1 and 2 are roughly equal and the total annual precipitation at 2 is three times that at 1, the total precipitation cannot be an important factor. We have introduced as the significant variable the function R, which equals the amount of rain or snow in the month previous to collection divided by the total annual rainfall. The physical basis for this is the assumption that the cleanup is proportional to the fraction of the available water which comes down as rain or snow. In cold climates with little water vapor, a small amount of rain may include nearly all the dust nuclei present, whereas in a warmer climate the same amount of rain may represent a much larger number of drops, many of which evaporate before reaching the ground, thus leaving their nuclei behind. The annual rainfall is taken as a rough measure of the absolute humidity.

The curves in Fig. 1 show the reciprocal of R, and the points are the Be^7 concentrations in atoms per liter. The points follow the curves fairly well but with an apparent time lag.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

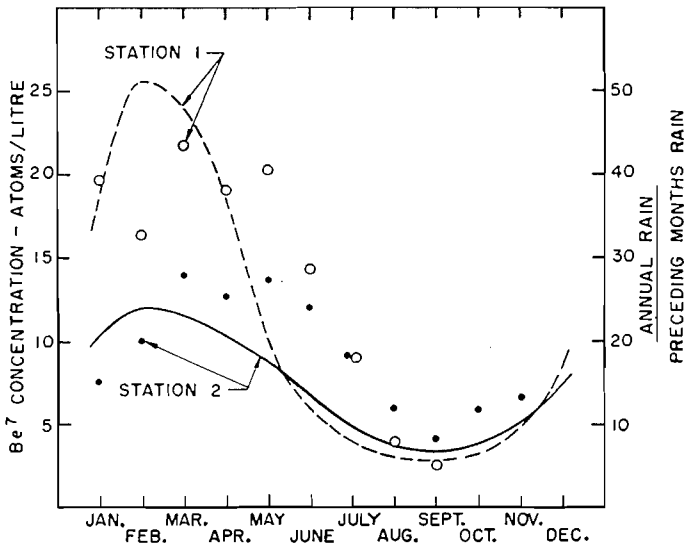

FIG. 1. Monthly variation of Be^7 concentration with rainfall. The curves indicate the fraction of the total annual precipitation which fell in the preceding month and the points indicate Be^7 concentration.

Consider the usual type of differential equation

$$dN/dt = Q - \Lambda N$$

where N = concentration of Be^7 in atoms liter^{-1}
Q = rate of formation of Be^7 in atoms liter^{-1} day^{-1}
Λ = rate of disappearance of Be^7
$\equiv \lambda + kR$
λ = disintegration constant of Be^7 in day^{-1}.

Integrated, this becomes

$$N_t = N_0 e^{-\Lambda t} + Q(1 - e^{-\Lambda t})/\Lambda$$

and at saturation

$$Q = \Lambda N$$

or

$$1/N = \lambda/Q + kR/Q.$$

At Stations 1 and 2, the winter snowfall is very low and equilibrium is approached slowly in the spring quarter with a period approximating $1/\lambda$. In the summer R is large, Λ becomes large, and equilibrium is quickly established.

Fig. 2 shows the reciprocal of the quarterly average Be^7 concentrations (slightly corrected for non-equilibrium conditions) plotted against R. The intercept gives $1/N = \lambda/Q = 0.02$ from which $Q = 0.655$ atom liter^{-1} day^{-1} and the slope gives $k/Q = 1.3$ or $k = 0.86$ day^{-1}. As the intercept is very close to zero there is some uncertainty in the value of Q.

may be low because of the overestimate of the air volumes mentioned earlier. The effective Q may be lower as well, because of considerable mixing with air from the Gulf of Mexico where the cosmic ray intensity is less.

In order to calculate the total rate of production of Be^7 to the top of the atmosphere we must make some assumptions as to the structure of the atmosphere and the mode of production of Be^7. The following assumptions are qualitative and do not apply rigorously to any given case. There is uniform vertical mixing in the troposphere to 40,000 ft. (200 mb.). There is a loss close to the ground due to the settling of dust in the absence of rain. This effect is being investigated further, but aircraft flights have shown that our ground level values are one half those in the bulk of the troposphere. The volume of the troposphere is assumed to be 640 liters/cm^2. The production rate in the troposphere is thus $2 \times 640 \times 0.655 = 840$ atoms cm.$^{-2}$ day^{-1} for northern latitudes, ignoring north–south mixing.

The contribution from the stratosphere is mainly by gravitational fall from the twilight zone (200–50 mb.). Vertical diffusion is very slow as shown by the relative humidity of 2–3% compared with nearly 100% a few kilometers lower in the troposphere (2). However this low humidity implies a circulation of about six months from the equator which means that the concentration will be affected slightly by the lower cosmic ray intensity below 50° latitude. Above 50 mb., there is probably no dust and hence the fallout time is very long compared with 53 days. It has been observed that volcanic ash in the stratosphere falls at 86 meters/day and from this we estimate a half time of about 85 days for fallout of Be^7 through the 200 mb. level.

The Be^7 is presumably formed by reactions such as $N^{14}(p,2\alpha)Be^7$. There are a large number of such reactions, all roughly equal in probability at high energies. The distribution of high energy nucleons in the atmosphere is fairly well known (3) and assuming that Be^7 production is proportional to the flux, one can estimate that 20% of the total is formed below the 200 mb. level and 48% between the 200 and 50 mb. levels. Allowing for the fallout time from the stratosphere, the troposphere concentration should be $0.20 + 0.33 \times 0.48 = 0.36$ times the total. Thus the total Be^7 production to the top of the atmosphere in northern latitudes is $840/0.36 \approx 2300$ atoms cm.$^{-2}$ day^{-1}.

H. Carmichael in a private communication has used data for star production in ion chambers to estimate a production rate for Be^7 of 1.1×10^4 atoms cm.$^{-2}$ day^{-1} for northern latitudes.

This value and Arnold's value of 3000 atoms cm.$^{-2}$ day^{-1} agree fairly well with ours, considering the differing assumptions made in each calculation.

THE DETERMINATION OF TRITIUM IN NATURAL WATERS[1]

By R. M. Brown[2] and W. E. Grummitt[3]

ABSTRACT

A study of the tritium content of rain- and sea-water samples collected during the past several years has been made. The tritium in 100–2000 gm. samples was concentrated 2000 to 20000 fold by electrolysis and the final concentrate counted as hydrogen in a Geiger counter. Good counter characteristics were obtained at hydrogen pressures up to one atmosphere by the use of an electronic quench unit of suitable deadtime in addition to the internal quench gas, ethylene. Rain and snow samples collected at Ottawa over the period 1951–1953 were found to range from 17.1 to 42.0 tritium atoms per 10^{18} hydrogen atoms, averaging 26.6. Tritium values for Ottawa rain-water for 1954 showed marked effects of the thermonuclear tests in the Pacific in the spring of that year, rising 10 to 100 fold during the test period, then gradually returning to normal, demonstrating a half time for washout of 35 days. The average tritium concentration of the year's rain is estimated to be 260×10^{-18} T/H. Surface sea-water samples collected at widely separated sites in the latter half of 1954 and early 1955 showed tritium concentrations in the range $3.0–4.2 \times 10^{-18}$ T/H, a value which corresponds with the amount of artificially produced tritium observed in Ottawa rain. Subsurface samples collected at one station off the coast of Nova Scotia in mid-1955 showed an unexpected concentration level and pattern, having a T/H value of 32.4×10^{-18} at the bottom depth of 600 ft., diminishing to a value of 5.4×10^{-18} at the surface. This is not thought to be a result of thermonuclear testing and warrants further investigation.

INTRODUCTION

Discovery of the radioactive nature of tritium in 1939 (1) seemed to eliminate any possibility of the existence of this nuclide in nature. However, in 1946 Libby (6) postulated the production of carbon-14 and tritium by cosmic ray interaction with constituents of the upper atmosphere, and the search for tritium in nature, which had been pursued in the 1930's, was resumed. Natural tritium was finally detected in water by von Grosse, Johnston, Wolfgang, and Libby (4) and in atmospheric hydrogen by Faltings and Harteck (3).

Kaufman and Libby (5) and von Buttlar and Libby (2) have subsequently measured the tritium content of a number of natural water samples. They report Chicago rain-water to have an average T/H ratio of 7.8×10^{-18} during 1953, and find five sea-water samples to range from 0.19 to 1.6×10^{-18} T/H.

Using the same general method as Libby and co-workers, i.e. electrolytic concentration and gas counting, we have measured the tritium content of Ottawa rain-water over the course of several years and have investigated a number of sea-water samples.

EXPERIMENTAL

(a) *Isotopic Concentration*

It is necessary to concentrate the tritium in natural water by at least 1000-fold to permit measurement of its radioactivity by conventional counting techniques. The electrolytic process for hydrogen isotope separation is the most attractive for this purpose. The T/H separation factor of ~14 gives a 40% recovery of tritium on simple electrolysis of a sample to 1/10,000 of its original volume. Initially, expecting a T/H ratio of about 10^{-18} or 7.3 disintegrations per minute per liter of water, it was felt that samples of at least one liter were necessary. It was found practical to electrolyze 1 liter down to 50 mgm. in a series of four cells of decreasing size.

These cells are illustrated in Fig. 1. Each cell consists of a glass vessel suitably shaped to maintain a high liquid level around a nickel anode and iron cathode. Foaming and capillary action between the electrodes in the smaller

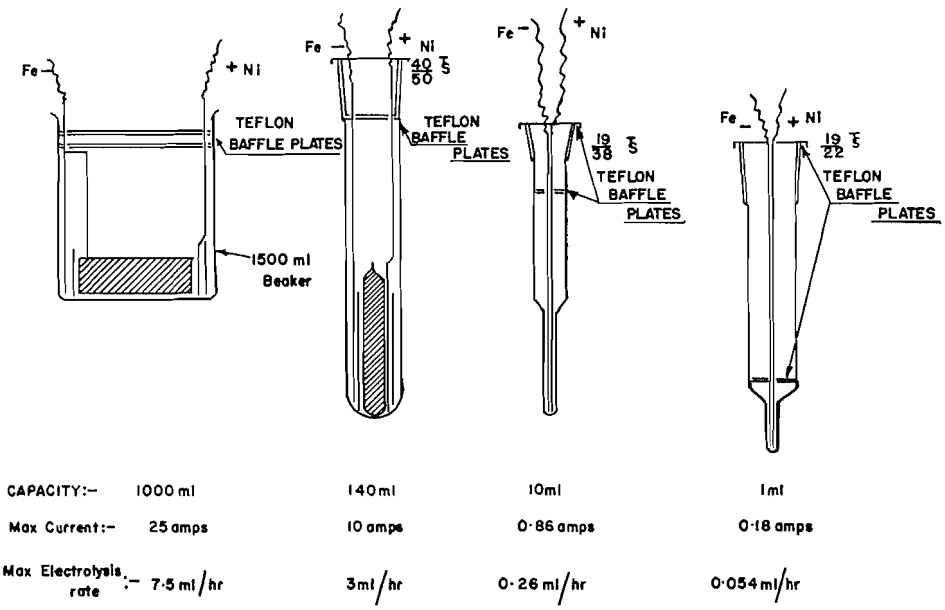

FIG. 1. Electrolysis cells.

cells permit electrolysis at a reasonable rate to a small volume. An initial electrolyte concentration of at least 1% (w/w) potassium hydroxide was found necessary to prevent corrosion of the anode. This limits volume reduction per stage to 10–20 fold, at which point the water is distilled into the next smallest cell, fresh potassium hydroxide added, and the electrolysis continued. Cells are cooled with running water to minimize evaporation losses and improve the separation factor, and current density is limited to 0.5 amp./in.^{2} to prevent local overheating at the electrodes.

Following the suggestion of Kaufman and Libby (5), we have used the

For personal use only.

natural deuterium in all water samples as a convenient tracer for tritium during the electrolytic concentration. It may be readily shown that

$$t/t_0 = (d/d_0)^{\alpha/\beta}$$

where d_0, d, t_0, t denote the initial and final number of moles of deuterium and tritium, and α and β the separation factors of deuterium and tritium, respectively, from protium. Thus, a measurement of the molar recovery of deuterium can be used to calculate the recovery of tritium, knowing the ratio α/β. While α and β are very dependent on experimental conditions they are likely to vary in a similar manner, hence the ratio α/β will be much less variable. In fact, Kaufman and Libby have shown α/β to be relatively constant over wide variations of α. Its value is close to 0.5 and it is sufficient for our purpose to replace the exponential α/β with a square root.

Deuterium analysis of the final concentrate requires only a few milligrams using an infrared spectrometric method developed by Stevens and Thurston (7).

(*b*) *Reduction to Hydrogen*

The remainder of the final concentrate is prepared for counting by conversion to hydrogen with zinc at 375°C. This reduction is rapid and complete, avoiding any isotopic fractionation and minimizing cross-contamination between successive samples. The hydrogen is then passed through a liquid nitrogen trap and introduced into a Geiger counter with 6 cm. argon and 5 cm. ethylene.

(*c*) *Counting*

Samples have been measured in a copper counter, $4\frac{1}{2}$ in. in length, $1\frac{1}{8}$ in. in diameter with a counting volume of 60 ml. defined by polystyrene shields around the central wire extending $\frac{3}{4}$ in. from each copper end plate. Cosmic ray shielding is provided by an annular anticoincidence counter but no further effort has been made to reduce the background below the 3.8 c.p.m. obtained in a 2 in. lead castle.

Good counter plateaus ($\sim$2%/100 v. slope over 300 v.) are obtainable using 6 cm. argon, 5 cm. ethylene, and 0–70 cm. hydrogen provided an electronic quench unit is used in addition to the internal quench gas. The quench unit applies a deadtime of 1200 μsec. to the counter to eliminate double pulses caused by photoemission on arrival of the positive ions at the cathode. The deadtime requirement is dependent on the counter diameter. In the 1 in. counter used in this work the majority of the double pulses occur within a period of 250 μsec., but the longer deadtime gives further improvement at high hydrogen pressures and is no disadvantage at slow counting rates. A 5% drop in counting efficiency, as indicated by an external γ source or a standardized tritium sample, occurs during the first 10 hr. of operation. The counter then becomes stable for an indefinite period and all counting is standardized at this lowered counting efficiency. This drop in efficiency is characteristic of the argon–ethylene mixture in our counting system and is not sensitive to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

the amount of hydrogen present. All counting has been done to $\pm 1\%$ statistical error.

The high hydrogen pressure feasible using the electronic quench unit has allowed the use of a relatively small counter with which a low background is obtainable without extensive effort. An alternative possibility is the elimination of the final stage of concentration and counting in a large volume counter.

RESULTS AND DISCUSSION

(*a*) *Ottawa Rain and Snow, 1951–1953*

The tritium concentrations found in rain and snow samples collected at Ottawa from 1951 to 1954 are presented in Table I. The two samples for 1951 were actually collected at Centre Lake, Petawawa, 100 miles west of Ottawa. All values are corrected for decay back to time of collection of sample.

TABLE I

TRITIUM CONCENTRATION OF OTTAWA RAIN AND SNOW, 1951–1953

Sample No.	Collection date and details	T/H × 10^{18}
80	Jan.–Feb., 1951* Composite snow sample	23.8
74	March 8, 1951* Surface snow sample	39.4
52	Nov. 12, 1952	21.1
66	Aug. 5, 1953	9.4
65	Aug. 23, 1953	28.1
58	Aug. 24, 1953	28.1

69	Nov. 11, 1953	42.0
75	Dec. 21, 1953	22.6
Average tritium concentration for 1953		26.6

**Collected from the surface of Centre Lake, Petawawa, 100 miles west of Ottawa.*

There is seen to be considerable variation from sample to sample, but there is no evident correlation with time. The average, unweighted for relative rainfall, of results for the latter half of 1953 is 26.6×10^{-18} and all values, with the exception of one at 9.4×10^{-18} T/H, lie within the range 17–42 $\times 10^{-18}$ T/H. This is about twice the average found by Libby and co-workers for Chicago rain-water of the same period. This may be explained by the fact that most Ottawa rain-water is passed on from the Chicago area and has probably had at least double the exposure to atmospheric tritium since leaving the common oceanic source, namely the Gulf of Mexico.

that year. Fig. 2 is a plot of these results on a semilogarithmic scale and includes results reported by von Buttlar and Libby (2) for comparison. The tritium concentration is seen to rise in an irregular manner up to 100 times the normal

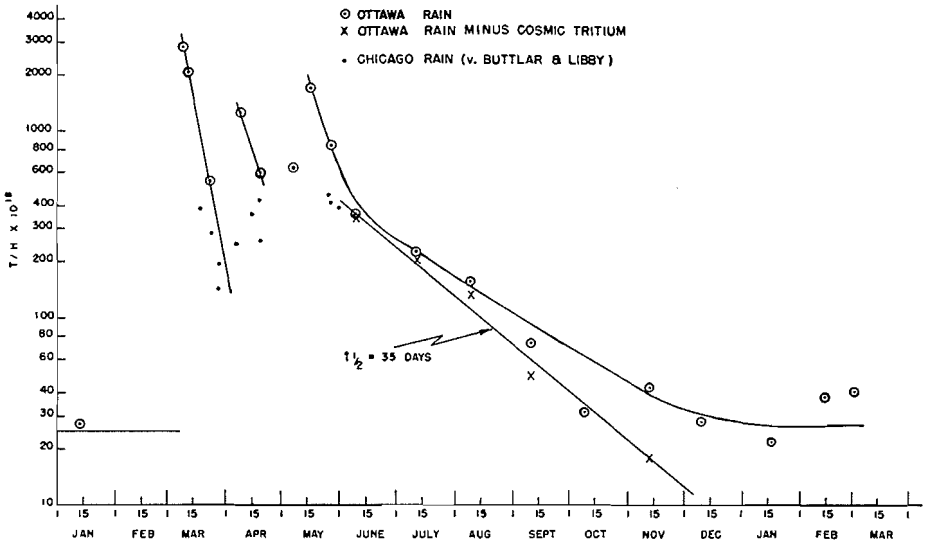

FIG. 2. Tritium content of rain, 1954–55.

level during the months of March, April, and May, then gradually falls back to normal during the summer months, demonstrating a half time for washout of approximately 35 days. The earliest sample collected in March indicates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

that the transport time from the western Pacific to Ottawa was something less than 10 days in this particular case. The lack of major fluctuations after the month of May indicates that the tritium was fairly uniformly distributed by June. This is consistent with meteorological estimates of time required for complete N.–S., E.–W. mixing. The fact that the tritium content of rainfall returned to much the same level as it had been previously indicates that the continued feed-in of artificially produced tritium from the oceans, and perhaps from the stratosphere, is small compared to the rate of production by cosmic processes.

From Fig. 2 we may estimate that the average tritium concentration of the year's rain was 260×10^{-18} T/H, approximately 10 times that of the previous year. At no time was the tritium in Ottawa rain a health hazard, the highest samples analyzed being 1/25,000 of tolerance level.

(*c*) *Surface Sea-water, Late 1954*

Table III presents results for surface sea-water samples collected in the Arctic, Pacific, Caribbean, and Atlantic during the latter half of 1954 and early

TABLE III

TRITIUM CONCENTRATION OF SURFACE SEA-WATER, LATE 1954

Sample No.	Date collected	Locale	Water temp., °F.	T/H $\times 10^{18}$
S1	Aug. 1, 1954	Arctic, 74°N. 91°W.		4.19
S4	Sept. 18, 1954	Arctic, Beaufort Sea		2.98
S2	Oct. 28, 1954	Pacific, west of Mexico		3.58
S3	Nov. 14, 1954	Atlantic, 19°30′N. 64°W.		2.97
S7	Feb. 9, 1955	Atlantic, 50°N. 31°W.	54	3.54
S6	Feb. 10, 1955	Atlantic, 47°N. 47°W.	40	3.60

1955. All results from this widespread series of samples lie in the range $3–4 \times 10^{-18}$ T/H, up a factor of 10 over most of von Buttlar and Libby's 1953 sea-water analyses. If the results for the Ottawa area are taken as representative for the whole northern hemisphere, then the artificially produced tritium deposited on the oceans corresponds to that contained in 1 meter of rain with a T/H ratio of 230×10^{-18}. In the oceans, this would be diluted to a T/H ratio of 3×10^{-18} by mixing to 70 meters. A slightly greater depth of mixing would be required to accommodate runoff from the land areas. Such a depth is consistent with the approximate known limit for rapid mixing of sea-water.

(*d*) *Subsurface Sea-water, 1955*

In an attempt to observe the limit of rapid mixing by tritium analysis, subsurface sea-water samples were taken at two stations, 3–4 miles apart, on the continental shelf about 50 miles southeast of Halifax. At each station the water consisted of two layers of appreciably different temperature and samples were obtained from the bottom, top, and intermediate waters. The rather unexpected results presented in Table IV were obtained. Careful

S8	46	590	32.4

review of the electrolytic and counting history of these and concurrent samples gives assurance of the validity of the results. Considerable differentiation is observed between samples from the various layers, but not in a manner consistent with the sole feed-in of tritium at the surface. The results suggest that tritium is being fed in at the bottom at Station B, is dispersing towards the surface, but is displaced towards Station A once it crosses the interface between the two layers. This is consistent with the southwesterly movement of surface water in this area. The locale of tritium feed-in at the bottom does not extend to Station A, just a few miles away, and there must be relatively little movement from B towards A on the bottom.

The observation of these high results casts some suspicion on the explanation offered for the level of tritium found in the earlier surface samples. However, the consistency of these results argues in favor of their being the result of a uniform deposition of a large amount of abnormal tritium.

SOME CUMULATIVE YIELDS OF ISOTOPES FORMED IN THE THERMAL NEUTRON FISSION OF Pu^{239} [1]

By D. M. Wiles,[2] J. A. Petruska,[3] and R. H. Tomlinson

ABSTRACT

The relative yields of the isotopes of cesium, cerium, neodymium, and samarium produced by the thermal neutron fission of Pu^{239} have been determined with a mass spectrometer. Preliminary values of the absolute yields of 16 isotopes of these elements together with four yields of the xenon isotopes have been assigned by means of isotope dilution techniques.

INTRODUCTION

The numerous papers reporting radiochemically determined yields of isotopes formed in the thermal neutron fission of Pu^{239} have been summarized by Steinberg and Freedman (10). Whereas the various values fix the general asymmetric nature of the yield–mass curve, the nature of the fine structure cannot be interpreted from the reported data. Accurate yield data have been reported for the thermal neutron fission of U^{235} (3, 9), and it is therefore of particular interest to obtain accurate fission yield data for other fissionable isotopes, such as Pu^{239}, in order that variations in the yields may be correlated with the nuclear properties of the fissionable isotopes and their products.

The present work reports the relative yields for three isotopes of cesium, three isotopes of cerium, six isotopes of neodymium, and five isotopes of samarium. By means of isotope dilution the number of atoms of each isotope of cesium and neodymium has been determined in a solution of plutonium fission products. From the relative amounts of these fission products, together with some interpolated relative yields, it was possible to normalize the total to 100% and therefore obtain absolute fission yields.

EXPERIMENTAL

A sample of plutonium dioxide (96.1% Pu^{239}) weighing 6 mgm. was sealed in quartz and irradiated for 305 hr. with a flux of 2×10^{13} thermal neutrons per cm.^{2} per sec. in the NRX (Chalk River) Reactor. About 14 months after irradiation the PuO_2 along with most of the fission products was transferred from the quartz capsule into a platinum crucible. The quartz was rinsed with HF so that some of the recoil fission products embedded in the quartz could be obtained. After several successive rinsings with HF and HCl about 80% of the beta and gamma radioactivity was transferred to the platinum crucible. The PuO_2 was converted to the fluoride by evaporation to dryness with HF, dissolved in HCl, and transferred to a polyethylene container. Aliquots of this stock solution were used for mass spectrometric analysis and isotope dilution. For some mass spectrometric analyses the plutonium was separated

[1]*Manuscript received November 16, 1955.*

[3]*Holder of Research Council of Ontario Scholarship 1953–54.*

from the fission products by precipitation with hydrogen peroxide, but it was found that the mass spectra of the fission products could be obtained in the presence of the plutonium, and therefore no separation was used for the second isotope dilution analysis. The details of the isotope dilution and mass spectrometric techniques used for the analysis of fission products have been discussed in previous papers (8, 9).

RESULTS AND DISCUSSION

The observed mass spectrometric data, together with corrections converting the ratios to relative fission yields, are shown in Tables I to IV for the elements cesium, cerium, neodymium, and samarium respectively. Isotope dilution data for cesium and neodymium are also shown in Tables I and III. The evaluated numbers of atoms of Cs^{133} and Nd^{143} per gram of fission product solution, which is shown with the isotope dilution data, give the normalization of the cesium to the neodymium yields which are shown in Table V. The relative yields of masses 140 and 142 given in Table V are obtained from the cerium isotope ratios given in Table II normalized to those of neodymium by means of the 144 mass chain whose yield has been determined with both elements. The relative yields of the samarium isotopes given in Table IV are shown in Table V normalized to those of neodymium in such a manner as to give a smooth curve when the yields are plotted against mass. The xenon

yields shown in Table V that were not obtained directly in this work have been interpolated from a plot of yield versus mass. The absolute fission yields were obtained by normalizing these relative yields to total 100%.

The accuracy of the relative yields shown in Tables I to IV is probably well represented by the precisions given, although the presence of natural cerium in the fission product solution could have increased the reported relative yield of Ce^{140} without being detected by the methods used. The complete absence of both natural neodymium and samarium, which could be detected by their isotopes which do not occur in fission, seems to indicate that contamination of the cerium is unlikely.

Assumed yields.

The relation of the xenon yields to those of the cesium isotopes, as well as the relation of the cerium and samarium isotope yields to those of neodymium, is probably accurate to within 1–2%. The accuracy of the absolute fission yields given in Table V is therefore largely dependent on the isotope dilution of the cesium and neodymium and to a lesser extent on the assumed yields of mass chains whose yields were not determined in this work. The reproducibility of the duplicated (and independent) isotope dilutions carried out for both the cesium and neodymium establishes the relative amounts of each of the isotopes of these elements in the stock solution analyzed. There is, however, some question as to whether this stock solution is representative of plutonium fission products or whether some fractionation of the fission product elements may have occurred. Since only about 80% of the fission product radioactivity was recovered from the quartz irradiation capsule, there may have been some preferential loss of fission products. Attempts to recover all the fission products by dissolution of the capsule were not carried out because of possible contamination which might be present in the quartz. Earlier work had shown that plutonium alloys, which could be dissolved without such losses, introduced large amounts of natural isotope contamination. The irradiation of plutonium dioxide in quartz was therefore specifically adopted in this work in order to minimize such contamination. Although there is no obvious reason why fractionation of the cesium and neodymium would occur with these conditions, further experiments must be carried out in order to establish this point.

The absolute yields given in Table V together with the radiochemically determined yields summarized by Steinberg and Freedman (10) are plotted in Fig. 1. A direct comparison of the two sets of data is difficult in view of the fact that the radiochemical yields only total 93% and the individual values have been considerably altered by the reviewers. Since many of the radio-

chemical yields were obtained by independent determinations it is not possible to renormalize them as a single group. It is therefore possible that most of the missing 7% of the radiochemical yields may be added in the region of mass 140, in which case, the two sets of data would appear more consistent. In this connection it is worth noting that the radiochemical yields which were deter-

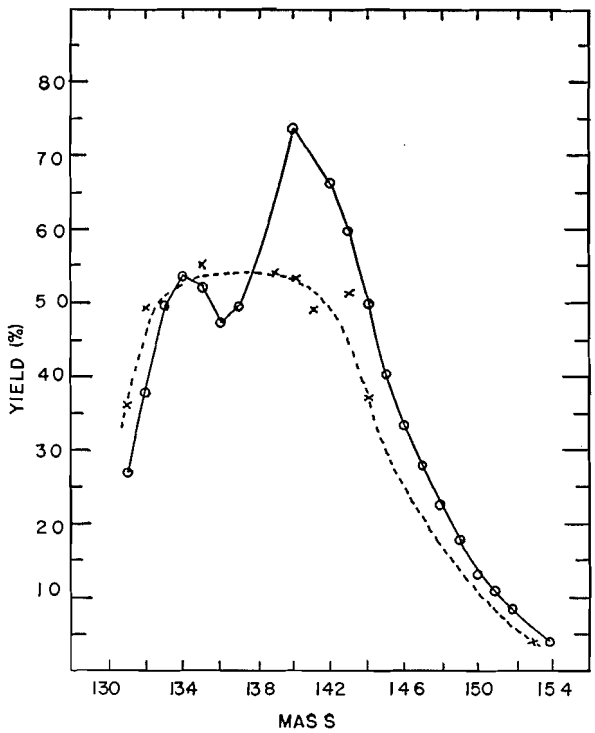

FIG. 1. Thermal neutron fission yields for Pu^{239}.
× Radiochemical ⊙ Isotope dilution

mined during this same period for the thermal neutron fission of U^{235} (10) failed to recognize the now well established fine structure in the region of mass 134.

In Fig. 2 the absolute yields for the thermal neutron fission of Pu^{239} are plotted along with the corresponding yields obtained from the fission of U^{235} (9). It is apparent that the fine structure which is so prominent in the fission of U^{235} is considerably depressed in the fission of Pu^{239}. The presence of fine structure in the U^{235} yield–mass curve has been explained in terms of a structural preference in the primary fission act for nuclides with the 82 neutron configuration (3, 4, 12), as well as various chain branching mechanisms which occur after fission (2, 7, 9). The fine structure of the Pu^{239} yield–mass curve may be qualitatively explained by these same effects.

It is important to note that the present work reports accurate relative yields of the isotopes of cesium, neodymium, samarium, and, to a somewhat lesser degree, those of cerium. The accuracy of the absolute yields can only be

established after further experiments have determined whether fractionation has occurred in the isotope dilution analysis of cesium and neodymium.

THE RATIO OF XENON TO KRYPTON IN U^{235} FISSION[1]

By A. T. Blades,[2] W. H. Fleming, and H. G. Thode

ABSTRACT

The ratio of the yield of Kr^{86} to the yield of Xe^{134} in U^{235} fission is $0.257 \pm .005$ determined by isotope dilution techniques. The corresponding yield ratio of total xenon to total krypton in the thermal neutron fission of U^{235} is $5.52 \pm .10$.

INTRODUCTION

An accurate value for the ratio of the quantities of xenon and krypton produced in fission is of considerable interest. Such a knowledge of relative yields in two widely separated mass regions can provide a check on independent absolute fission yield measurements in the light and heavy regions of the mass yield curve.

The relative amounts of the stable and long-lived isotopes of krypton and xenon produced in the neutron fission of U^{235} have been determined in two different ways. Thode and Graham (5), using a mass spectrometer calibrated with standard mixtures of xenon and krypton, obtained a value of 6.2 for the ratio of xenon to krypton in fission. Arrol, Chackett, and Epstein (1) obtained a value of 5.05 for the same ratio by separating the xenon and krypton and measuring their individual volumes. This later value has been considered to be the most reliable and the ratio of xenon to krypton from U^{235} fission has been taken as 5.05.

However, over the past few years the mass spectrometer measurements have been repeated on several occasions and the resulting value for the ratio of xenon to krypton in U^{235} fission has always been considerably higher than the 5.05 value obtained by Arrol, Chackett, and Epstein. For this reason, it was decided to carry out a measurement of the relative quantities of xenon and krypton arising in fission using isotope dilution techniques to eliminate possible errors introduced by mass spectrometer calibrations.

The actual ratio of xenon to krypton in a given uranium sample is a function of the past history of the sample. The relative amount of Xe^{136} in the sample will depend on the conditions under which the sample was irradiated because of the large neutron capture cross section of Xe^{135}. In addition, the amount of 10.27-year Kr^{85} present in the sample will, of course, depend on the age of the material. The remaining xenon and krypton isotopes have half-lives sufficiently short that they are normally not encountered in yield studies dealing with stable end products of the decay chains.

Because of the dependence of the total xenon to total krypton ratio on the above factors, it was more convenient in the present work to measure the relative yields of the two isotopes Kr^{86} and Xe^{134} which are not affected by

neutron capture processes and the time factor. The ratio of xenon to krypton (totals) is then calculated from the isotope abundances of fission product xenon and fission product krypton reported previously for thermal neutron fission of U^{235} (6). In this later work neutron capture processes and decay factors were taken into account.

EXPERIMENTAL

The determination of the amount of a given element in a particular sample by isotope dilution is carried out in the following manner. There is added to the sample a "spike" consisting of a known amount of the element to be determined but having isotopic composition differing from that in the sample. Separation and purification of the desired element from the sample plus spike is now carried out. From a mass spectrometric analysis of this purified material (sample plus spike) the amount of the element present in the original sample can be calculated if the isotopic constitutions of the sample and spike taken separately are known.

Since all chemical yields up to the point at which the spike is added must be 100%, it is important to add the spike as early as possible in the extraction procedure. Furthermore, complete mixing of the sample and the spike must be assured if accurate results are to be obtained. If these conditions are fulfilled, attainment of 100% yield in subsequent handling is not required.

Xenon and krypton of normal isotopic constitution provide suitable spiking material for the determination of fission product xenon and krypton because the isotopic abundance of the fission product material is radically different from that of the normal material (see Table I).

In order to ensure complete release of the fission product gases from the irradiated uranium metal and thorough admixing of the spike, the following procedure was adopted. The spike consisted of approximately 10^{-8} mole of a mixture of 16.8% krypton and 83.2% xenon prepared by Linde Air Products Company. This was added to about 100 cc. of chlorine gas in a sealed glass and quartz system containing the 0.4 gm. sample of irradiated uranium. The portion of the system containing the uranium metal was heated to 1100°C. for 12 to 24 hr. Under these conditions the uranium reacts completely with the chlorine and, since the chlorides formed are volatile, they distill out of the heated section of the apparatus. This procedure should result in a complete release of the fission gases and efficient mixing with the spike. The excess chlorine and any other gaseous impurities were removed by purification in a calcium furnace. The samples were then analyzed on a conventional 180° mass spectrometer.

RESULTS AND DISCUSSION

A sample of uranium metal irradiated in the NRX reactor was divided into several pieces of approximately 0.4 gm. each. The isotope dilution method described above was used to determine the amounts of xenon and krypton per gram of uranium in six of these pieces.

The isotopic composition of the normal xenon and krypton spike material is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

given in Table I, Column 2. The fission product xenon and krypton isotope abundance data determined on a separate piece of the irradiated uranium to which no spike was added are given in Table I, Column 3.

TABLE I

XENON AND KRYPTON ISOTOPE ABUNDANCE DATA

Isotope	Atom % abundance	
	Spike mixture (normal Xe and Kr)	Fission product sample*
Kr^{78}	0.336	—
Kr^{80}	2.242	—
Kr^{82}	11.34	—

**Abundance of stable fission product isotopes only.*
†Not corrected for neutron capture.

The isotope dilution data are summarized in Table II. The precision of each individual determination depends only on the precision of the mass spectrometer measurement which was in general less than ±0.2%. A better measure of the accuracy of the results is the standard deviations of the averages of the six determinations which are about two per cent (see Table II). The fact that the quantities of xenon and krypton per gram of uranium determined for the six samples agree well with each other indicates that both the extraction and

the mixing of the fission product and spike gases were highly efficient. Actually variations of a few per cent in fission gas content in the different pieces cut from the one uranium sample might be expected because of neutron flux variation in the sample due to self-shielding effects.

The isotope abundances of fission product xenon and krypton reported by Wanless and Thode (6) for samples irradiated in the thermal column (low neutron flux) of the NRX reactor (see Table III) have been corrected for decay

TABLE III

FISSION PRODUCT XENON AND KRYPTON ISOTOPE ABUNDANCE FOR URANIUM IRRADIATED IN THERMAL COLUMN, NRX*

Isotope	Atom % abundance	Absolute fission yield (%)
Kr^{83}	14.10	0.557
Kr^{84}	25.93	1.02
Kr^{85} (10.27 yr.)	7.59	0.300
Kr^{86}	52.38	2.07
Xe^{131}	13.42	2.93
Xe^{132}	20.08	4.38
Xe^{134}	36.91	8.06
Xe^{136}	29.59	6.46

**Fission product isotope abundance from Ref. 6.*

of the 10.27-year Kr^{85} and also for neutron capture by Xe^{135}. Using these data and the Kr^{86} to Xe^{134} ratio of 0.257 from Table II, the calculated ratio for xenon to krypton in thermal neutron fission of U^{235} is $5.52 \pm .10$. This ratio includes Kr^{83}, Kr^{84}, 10.27-year Kr^{85}, Kr^{86}, Xe^{131}, Xe^{132}, Xe^{134}, and Xe^{136} where the Kr^{85} has been corrected for decay and Xe^{136} for neutron capture in Xe^{135}. As stated in the introduction, the actual value of this ratio in a particular sample will depend on the irradiation conditions and decay time of the sample.

The ratio for total xenon to krypton of 5.52 determined in this work is considerably higher than the value 5.05 reported by Arrol, Chackett, and Epstein (1). The discrepancy is actually greater than the above figures indicate since the results reported by the latter workers were not corrected for neutron capture in Xe^{135}. This correction, however, would not be large since the amount of capture in the samples was found to be only 5% of the 136 yield (samples J and K in Ref. 6).

Finally, the absolute yields of the xenon and krypton isotopes given in Table III, Column 3, are obtained by using the xenon and krypton isotope abundances in Column 2, the ratio of Xe^{134} to Kr^{86} from Table II, and an absolute value of 2.93% for Xe^{131} yield. This yield value is based on an absolute yield determination of Xe^{133} by Katcoff and Rubinson (3) and of Cs^{133} by Petruska, Thode, and Tomlinson (4), the two values being 6.62 and 6.59% respectively. A recent determination of the ratio of Xe^{131} to Xe^{133} by Fleming (2) was also used.

PILE NEUTRON CAPTURE CROSS SECTION OF 33 HR. Ce^{143} [1]

By L. P. Roy[2] and L. Yaffe

ABSTRACT

Ce^{144} has been produced by the successive neutron capture reaction $Ce^{142}(n, \gamma)Ce^{143}(n, \gamma)Ce^{144}$. The pile neutron capture cross section of the 33 hr. Ce^{143} was determined by separating Pr^{144}, the daughter of Ce^{144}, from the rigorously-purified cerium at frequent intervals. The amount of Pr^{144} formed increased linearly with the square of the neutron flux in a manner consistent with that of a successive neutron capture reaction. The value for the pile neutron capture cross section of Ce^{143} was found to be 6.0 ± 0.7 barns.

A. INTRODUCTION

Ce^{143}, a radioactive nuclide with a half-life of 33 hr., is formed as a fission product of uranium and also by the reaction $Ce^{142}(n, \gamma)Ce^{143}$ in a nuclear reactor. A measurement has been made of the pile neutron capture cross section using the activation method. The application of this method to the case of stable nuclides is well known, e.g. Seren *et al.* (13). If a sufficient quantity of a radioactive substance is available, its pile neutron cross section may be measured by the same method, provided only that the radioactivity produced in the activation process may be separated or distinguished from that of the target. This method has been used extensively to determine the cross sections of many transuranic nuclides, e.g. (16), and of certain nuclides which can be prepared and separated readily, e.g. (8).

Unless both the target half-life and the resultant half-life are reasonably long, an experiment of this type necessitates proximity to a nuclear reactor. If the resultant half-life is long the experiment can be done by a second order neutron capture process in which the radioactive target nuclide is continuously generated by neutron capture in a sample of a stable element. This successive neutron capture method has been used to determine the cross sections of many unstable nuclides (1, 2, 3, 7, 9, 11, 15, 17), and higher order neutron capture processes have been used to produce many of the new transuranic nuclides and to determine some of their cross sections (5, 10, 14).

In our case the appropriate stable target is Ce^{142} (11.07% of natural cerium) and the pertinent nuclear reactions are:

$$\begin{array}{ccccc} Ce^{142} & & & & \\ (n, \gamma) & & & & \\ Ce^{143} & \xrightarrow[33\text{ hr.}]{\beta^-} & Pr^{143} & \xrightarrow[13.5\text{ day}]{\beta^-} & Nd^{143}\text{ (stable)} \\ (n, \gamma) & & (n, \gamma) & & (n, \gamma) \\ Ce^{141} & \xrightarrow[280\text{ day}]{\beta^-} & Pr^{141} & \xrightarrow[17.5\text{ min.}]{\beta^-} & Nd^{144}\text{ (stable).} \end{array}$$

This paper was presented at the Symposium on Nuclear Chemistry and Radiochemistry held at McGill University, Montreal, Que., September 7–9, 1955.

[2]*Holder of a Shawinigan Chemical Scholarship (1952–53), a National Research Council Studentship (1953–54), and a Province of Quebec Bursary (1954–55). Present address: Atomic Energy of Canada Limited, Chalk River, Ontario.*

The 17.5 min. Pr^{144} daughter of Ce^{144} (maximum β-energy = 3.0 Mev.) is very easily identifiable (6). Examination of reactions which take place with the other cerium isotopes shows that only by a second order neutron capture process on Ce^{142} can Pr^{144} be produced.

The relatively short half-life of Pr^{144} enables the determination of the cross section of Ce^{143} to be made without taking into account the cross section of Pr^{143}. This can be done by measuring the Pr^{144} in equilibrium with the Ce^{144} after a suitable decay period. It is much more suitable, from the radiochemical standpoint, to discard the first praseodymium fraction separated, since this will contain some impurities, to purify the cerium and do repeated parent–daughter separations. The relevant differential equations which apply during the irradiation are

$$[1] \qquad dQ/dt = nvP\sigma_0 - \lambda_1 Q - nvQ\sigma_1 \approx nvP\sigma_0 - \lambda_1 Q,$$

$$[2] \qquad dR/dt = nvQ\sigma_1 - \lambda_2 R - nvR\sigma_2 \approx nvQ\sigma_1 - \lambda_2 R$$

where P, Q, and R are the number of atoms of Ce^{142}, Ce^{143}, and Ce^{144} respectively at any time t during the irradiation in a neutron flux nv neutrons/cm.^{2}/sec., and σ_0, σ_1, σ_2 and λ_1, λ_2 are cross sections and disintegration constants respectively. The subscripts 0, 1, 2 refer to Ce^{142}, Ce^{143}, and Ce^{144} respectively.

Assuming P to be constant during the irradiation, and Q and R to be zero at the beginning of the irradiation, the integrated equations at the end of irradiation time T become:

$$[3] \qquad Q_T \approx \frac{nvP\sigma_0}{\lambda_1}(1 - e^{-\lambda_1 T}),$$

$$[4] \qquad R_T \approx \frac{(nv)^2 P\sigma_0\sigma_1}{\lambda_1\lambda_2}(1 - e^{-\lambda_2 T}) - \frac{(nv)^2 P\sigma_0\sigma_1}{\lambda_1(\lambda_1 - \lambda_2)}(e^{-\lambda_2 T} - e^{-\lambda_1 T}).$$

If the sample of cerium is purified from praseodymium at a later time t_1, and the praseodymium allowed to accumulate during a subsequent time t_2, then the amount of Pr^{144} at this time is given by

$$[5] \qquad V = \frac{\lambda_2 R_T}{\lambda_3 - \lambda_2} e^{-\lambda_2 t_1}(e^{-\lambda_2 t_2} - e^{-\lambda_3 t_2})$$

where V is the number of Pr^{144} atoms and λ_3 is the Pr^{144} disintegration constant. R_T is obtained from this equation and σ_1 is then determined by substitution into equation [4].

B. EXPERIMENTAL

Spectroscopically pure samples of cerium oxide, sealed in small quartz ampoules, were irradiated in the NRX nuclear reactor at Chalk River at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12

different neutron fluxes for different times. After irradiation, the cerium oxide was removed from the quartz ampoule and dissolved in boiling concentrated sulphuric acid to which 2–3 ml. 30% hydrogen peroxide had been added. The solution was made up to a known volume with distilled water and an aliquot withdrawn. Ten milligrams of lanthanum carrier was added and the rare earths precipitated with concentrated ammonia. The precipitate was dissolved in concentrated nitric acid, cerium was oxidized to the tetravalent state by the addition of solid potassium bromate and precipitated by the addition of a 0.35 *M* solution of potassium iodate. The precipitate was centrifuged, washed twice with a 0.035 *M* solution of potassium iodate, and dissolved in 8 ml. concentrated nitric acid, 0.1 to 0.2 ml. concentrated hydrochloric acid, and a few drops of 30% hydrogen peroxide. Cerium was precipitated from this solution by cautious addition of 12 *M* sodium hydroxide, centrifuged, and washed twice with water. The cerous hydroxide was dissolved in 1 to 2 ml. 6 *M* hydrochloric acid, sulphur dioxide was bubbled through the solution, and the cerium reprecipitated by the addition of ammonia. The above cycle was repeated 8 or 10 times in order to obtain a pure fraction of cerium, free from praseodymium and other rare earths. The cerium was finally converted to the oxalate, filtered, washed with water, ethyl alcohol, ether, and vacuum-dried. The precipitate was weighed as $Ce_2(C_2O_4)_3.10H_2O$.

The oxalate was dissolved in 8–10 ml. concentrated nitric acid, 10 mgm. of lanthanum or praseodymium carrier was added,* and the 17.5 min. Pr^{144} was allowed to grow from the Ce^{144} until equilibrium was established (a few hours). The cerium was oxidized to the tetravalent state by the addition of solid potassium bromate and precipitated as the iodate. The solution, containing the praseodymium, was neutralized with concentrated sodium hydroxide. The praseodymium precipitate was dissolved in concentrated nitric acid, cerium and zirconium carriers added, and an iodate precipitation performed. The praseodymium was precipitated as the hydroxide and the cycle repeated two or three times until a fraction reasonably free from cerium activities was obtained.

The final hydroxide precipitate was transferred as a slurry to an aluminum tray, where it was spread evenly, dried, and the counting-rate determined by a Geiger–Müller counter. The counter was the "end window" type with a mica window of mass 2.3 mgm./cm^2. The counter had previously been calibrated using a 4π-counter. The time of separation varied from 25 to 35 min.

The cerium iodate precipitate was again converted to the oxalate, weighed, dissolved, lanthanum carrier added, and the solution allowed to stand until it was time for another Pr^{144} separation.

C. RESULTS

The decay curves of Pr^{144} were followed for two or three hours, usually through a 221.4 mgm./cm.^{2} aluminum absorber which cut out less energetic

**Both lanthanum and praseodymium carriers were used without any difference being found in the values obtained for σ_1. Pr^{144} was separated from standard Ce^{144} solutions by the use of both lanthanum and praseodymium carriers with identical results. Successive precipitations showed that the removal of activity was complete in either case. Pr^{143} was used as a tracer to determine whether there was any difference in the amount adsorbed by the ceric iodate scavengers if lanthanum and praseodymium carriers were used. Identical results were obtained.*

radiations from impurities. Activities ranging from 100 to 1500 c.p.m. were found with half-lives between 17.0 and 17.5 min. after the subtraction of a small long-lived residual background (2 to 10%). Fig. 1 shows a typical decay curve.

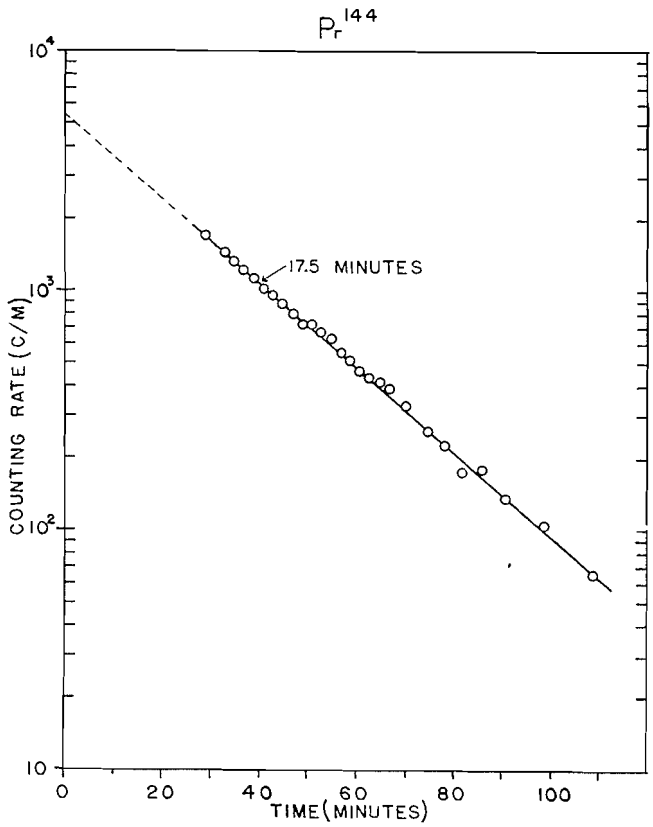

FIG. 1. Decay curve of Pr^{144}. A long-lived background of 35 c.p.m. has been subtracted from the original data to obtain this curve.

The absorption of the Pr^{144} β-radiation in the aluminum absorber was determined in an auxiliary experiment using a pure Ce^{144}–Pr^{144} source separated from fission products and obtained from Atomic Energy of Canada Limited. A correction factor of 1.58 was necessitated by use of the absorber. This agreed with that determined using the Pr^{144} extracted from the irradiated cerium samples.

Pr^{144} was further identified by its absorption characteristics. Decay curves were taken through various aluminum absorbers and the activity in each case was extrapolated to zero time, i.e. the time of separation. The resultant activities were then combined, as shown in Fig. 2, in an absorption curve where the extracted Pr^{144} was compared with the fission-produced Pr^{144}. The results are identical. Using P^{32} as a standard the range of the β-particles

of Pr^{144} was found to be 1520 mgm./cm.^{2} of aluminum by means of a Feather plot. This works out to a maximum energy of 3.05 Mev. for the β-particles if one uses the Coryell–Glendenin (4) range–energy relationship, in good agreement with spectrometer values (6).

step-by-step application of equations [3] and [4]. Fig. 3 shows the variation of Pr^{144} activity/mgm. Ce^{142} irradiated as a function of irradiation time normalized to one flux value. The linear relationship observed is consistent with a successive neutron capture reaction when the irradiation time is long compared with the half-life of the first order product and short compared with that of the second order product. (This does not prove the above reaction to be second order since, if for example, appreciable uranium impurities were present, the Ce^{144} would be formed as a first order product with the above time–yield relationship.) Fig. 4 shows the variation of Pr^{144} activity/mgm. Ce^{142} irradiated as a function of the square of the neutron flux. The linear relationship observed is consistent with the fact that we are studying a successive neutron capture process.

The average value of the cross section of 33 hr. Ce^{143} was found to be 6.0 ± 0.7 barns, assuming the cross section of Ce^{142} to be 0.95 barns (12). Both of these values are given relatively to $\sigma Co^{59} = 36.3$ barns. The limits shown are the standard deviations. The average value was obtained by weighting the value

THE MASS SPECTROMETRY OF THE ACTINIDE ELEMENTS[1]

By G. R. Hall and A. J. Walter

ABSTRACT

The problems involved in the mass spectrometry of the actinide elements and, in particular, the advantages of using a thermal ionization filament source are discussed. The relative behavior of each of the actinide elements from thorium to americium using this source is described and the results are considered with reference to the Saha equation.

INTRODUCTION

Whilst carrying out the isotopic analysis of large numbers of uranium and plutonium samples using a "solid source" mass spectrometer it has been interesting to observe the relative behavior of these elements in the ionization process. Subsequently a few experiments have been carried out on other elements in the series, i.e. thorium, protactinium, neptunium, and americium, and our aim in this paper is to discuss the results with special regard to the ionization process which occurs.

CONSIDERATION OF ION SOURCES

First it is worth while to review the types of source which might be suitable for isotopic abundance measurements of the heavy elements when high precision and a good sensitivity are required. Normally, unless a double focusing mass spectrometer is to be used, a source which will provide an ion beam with a small spread in ion energy, i.e. less than a volt, is required. This immediately eliminates the gas discharge or hot spark source where large spreads in energy occur, although the ions are produced with high efficiency. Taking into account also the requirement of a very stable ion beam size, then the only suitable source remaining is (1) an electron bombardment source *or* (2) the surface ionization source.

Substances which are either solid with a high vapor pressure or gas under normal conditions may be analyzed using the conventional gas source in which the ions are produced by electron bombardment. In the heavy element series, uranium hexafluoride (b.p. = 56°C.) has often been used and high precision may be attained in measuring the isotopic abundances of the uranium isotopes. Relatively large quantities are required, i.e. in excess of 50 mgm., as much decomposition and reaction of the dissociated and undissociated particles occur at the walls of the mass spectrometer tube. Considerable difficulties can also arise from memory effects. If routine analyses are required and gram quantities of uranium hexafluoride are available, then this source is of great use. No doubt plutonium hexafluoride could also be analyzed in this source but the difficulties would be great. Plutonium hexafluoride has been investigated in some detail (5) and the difficulty in its preparation and especially

For personal use only.

the rapid spontaneous decomposition rate, produced by its own alpha particles, rules out its use in a mass spectrometer source. In addition the use of a highly radioactive gas is not attractive, because of the stringent health precautions which would be necessary. There are no other suitable plutonium compounds which could be used in a gas-type source. It is possible, however, to use this source in conjunction with a crucible which volatilizes materials of high boiling point into the volume of electron bombardment, or, alternatively, to allow the gaseous product to be ionized at a hot metal filament surface. Thus several determinations of the isotopic abundances in natural uranium have been described using such a source, e.g. Nier (6) used samples of UCl_4 or UBr_4, and Palmer (7) has described a source where as little as 1 mgm. of uranium as U_3O_8 may be analyzed. No doubt each of the actinide elements may be analyzed by this method, but once more the main disadvantage is the relatively large size of sample necessary. This is especially so when the material is highly radioactive.

Undoubtedly the most convenient source is the thermal ionization filament source which has been described in the literature by numerous workers. One of the earliest descriptions of such a source was by Dempster (1) who produced positive ions of sodium and calcium from a platinum filament. Later Langmuir investigated electron and positive ion emission from hot filament surfaces and as a result of his work we have the Langmuir–Kingdon modification of the Saha equation [1] which explains the production of positive ions in the thermal ionization source:

$$[1] \qquad (n^+/n_0)\alpha \exp e(W - I)/kT$$

where n^+/n_0 = ratio of positive ions to neutral particles produced by evaporation at the filament surface,

e = electron charge,

W = work function of the filament surface,

I = ionization potential of the particles evaporated,

T = absolute temperature of the filament.

The equation expresses the chance that a particle evaporating from a metal surface will be emitted as a positive ion. It can be seen that a suitable source material is one possessing a low ionization potential and that a metal filament surface possessing a high work function is necessary. Thus, when W is greater than I positive ions are produced with high efficiency. Unfortunately neither of these quantities is usually known sufficiently well for the conditions occurring in a typical mass spectrometer source.

Although the work function for platinum (6.2 v.) is very high, it is necessary to have a filament of higher melting point, especially for the analysis of elements of low volatility. Thus tungsten or tantalum is normally used in heavy element work. The work function of tungsten (4.5 v. for the pure metal surface, *in vacuo*) varies markedly with the surface conditions. Thus for a tungsten surface covered by a monatomic layer of oxygen ions, which can be stable up to ~1800°C., a work function as high as 9.2 v. has been reported (Langmuir and Kingdon, 1925 (4)). As the heavy element is usually deposited

on the filament from nitric acid solution, it is likely that the surface of the filament will become attacked and so an accurate estimate of the work function is impossible.

In the actinide series the ionization potentials are only known for uranium (~4.5 v., an estimate from spectroscopic work), and for plutonium Dr. Dawton at Harwell has recently obtained a value 5.1 v.

These ionization potentials are similar to the possible values for the tungsten surface work function, and hence predictions from the Saha equation of the temperature dependence of positive ion production is difficult. If the ionization potential is greater than the work function of the filament surface (i.e. $I > W$), then the ionization efficiency becomes very small. By taking advantage of the temperature dependence of the Saha equation, however, and operating the filament at a high temperature, the efficiency n^+/n_0 can be considerably increased. Hence a refractory source material is necessary. Unfortunately the advantage to be gained by the increased temperature of the filament is only at the expense of a greatly increased evaporation rate and rapid loss of sample.

Inghram and Hayden (3) have discussed these difficulties and Inghram and Chupka (2) have described a multiple filament source in which the source material is evaporated from one filament at a relatively low temperature to another filament maintained at a very high temperature. It is thus possible to control the sample evaporation rate and yet still to take advantage of the temperature dependence of the Saha equation. This hot filament may be considered to act as a condenser of the particles received from the sample and an almost instantaneous emitter of positively charged ions. The Saha equation is therefore also applicable to this filament. The multiple filament source can produce a great increase in sensitivity for the analysis of small quantities of materials, because it enables a more economic use of the source material.

Thus a disadvantage of the single filament source is that the ions X^+, XO^+, and XO_2^+ are observed and it is not possible to control their formation. In the multiple filament source however, the relative abundance of each type of ion is readily controlled by the temperature of the center filament. It is usually possible to produce mainly X^+ ions and to reduce the number of XO_2^+ ions by a large factor. If the largest ion beam is for oxide ions, and these are measured, then it is necessary to make a correction for the effect of oxygen isotopes, e.g. $[Pu^{239}O^{16}O^{18}]^+$ ions are produced at mass 273, where $[Pu^{241}O^{16}O^{16}]^+$ ions are expected. Hence it is an advantage to measure the X^+ ion beam, where there is no such correction.

In our work with the actinide elements a multiple filament source, similar to that described by Inghram, has been used. The center filament or "hot filament" is of tungsten and is usually maintained at a temperature of 2500°C. or greater, corresponding to a tungsten ion beam of 2×10^{-14} amp. in our instrument. It is probable that we are dealing with a pure tungsten surface at this temperature and the work function can be expected to approach the value 4.5 v. Hence for plutonium we have $I > W$, and so we expect a better

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

yield of positive Pu^+ ions for a very hot filament surface. In accordance with these predictions, much larger plutonium ion beams are obtained when a multiple filament source is used than when a single filament source is used, and the size of the Pu^+ ion beam depends directly on the temperature of the center filament.

MASS SPECTROMETER

All the measurements reported below were made with a 60° sector field mass spectrometer with a 6 in. radius analyzing tube. Masses were scanned by varying the magnetic field and the ion current was measured using a vibrating reed electrometer.

MEASUREMENTS ON THE ACTINIDE ELEMENTS

In one series of measurements, a 1 μgm. sample of the actinide element in nitric acid solution was mounted on the sample filament. The solution was evaporated to dryness by passing a small current through the filament. The multiple filament source unit was mounted in the mass spectrometer and the temperature of the center filament was raised quite rapidly to 2500°C., and then the current through the sample filament was slowly increased. The filament currents at which the ions X^+, XO^+, and XO_2^+ were emitted and the variation in beam sizes during the life of the source were noted. After the analysis the multiple filament holder was removed and mounted in a bell jar which was then evacuated. A current was passed through the filaments and their temperatures for the previously recorded filament currents were measured using an optical pyrometer. The temperatures have been corrected for the emissivity of the tungsten surface. Values for the observed ratios X^+/XO^+, when the sample filament temperature was varied from 1000–1850°C., whilst the center filament was maintained at 2500°C., are given in Table I:

TABLE I

VALUES FOR THE RATIO X^+/XO^+ WHEN THE TEMPERATURE OF THE CENTER FILAMENT IS MAINTAINED AT 2500°C., AND THE SAMPLE FILAMENT TEMPERATURE IS VARIED

Ratio	1000°C.	1150°C.	1350°C.	1500°C.	1850°C.
Th^+/ThO^+	ni	ni	Only ThO^+	Only ThO^+	0.05
Pa^+/PaO^+	ni	ni	0.5	1	1
U^+/UO^+	0.2	1	1	1.5	2
Np^+/NpO^+	ni	1.5	4	4	—
Pu^+/PuO^+	ni	60	70	50	35
Am^+/AmO^+	ni	ni	60	100	90

ni = no indication of either X^+ or XO^+.

It is seen that, apart from thorium, it is possible to obtain X^+ ions for isotopic abundance measurements on each of the actinide elements.

As it is very difficult in these experiments to reproduce the exact experimental conditions from filament to filament, a further series of measurements were made in which pairs of the actinide elements (1 μgm. of each in nitric acid solution) were mounted on the sample filament. The results obtained for

For personal use only.

the ratios X^+/U^+ and XO^+/UO^+, respectively, when the sample filament temperature was once more varied, whilst the center filament temperature was maintained at 2500°C., are given in Tables II and III. The filament temperatures were obtained from an optical pyrometer calibration.

Whilst no great precision is claimed for the ratios in Tables I, II, and III, it has usually been possible to reproduce a set of ratios to within a factor of two. The temperature of the center filament is very critical; this effect is discussed later.

TABLE II

VALUES FOR THE RATIO X^+/U^+ WHEN THE TEMPERATURE OF THE SAMPLE FILAMENT IS VARIED

Ratio	1150°C.	1350°C.	1500°C.	1850°C.	2000°C.

Am^+/U^+	No Am^+	3	4	9	—

TABLE III

VALUES FOR THE RATIO XO^+/UO^+ WHEN THE TEMPERATURE OF THE SAMPLE FILAMENT IS VARIED

Ratio	1150°C.	1350°C.	1500°C.	1850°C.	2000°C.
ThO^+/UO^+	No ThO^+	No ThO^+	0.05	0.2	2
PaO^+/UO^+	No PaO^+	No PaO^+	0.1	2	—
NpO^+/UO^+	0.07	0.5	1	—	—
PuO^+/UO^+	0.1	0.1	0.1	0.2	—
AmO^+/UO^+	No AmO^+	No AmO^+	0.1	0.2	—

The main points to be drawn from Tables I–III may be summarized as follows:

(1) In general, increase in temperature of the sample filament, whilst the center filament is at a constant temperature of 2500°C., produces bigger ion intensities, with little change in the ratios. This is to be expected because more particles are being evaporated on to the center filament, but the ionizing conditions remain constant.

(2) As we move across the series from thorium to americium the optimum sample filament temperature is first high, is lowest for uranium, and then rises again for americium. For thorium it is necessary for the sample filament to be at about 1850°C. in order to get a reasonable ion current. Although uranium appears at a slightly lower temperature than neptunium and plutonium the latter appears to produce metal ions more readily. This is in part due to the ratio Pu^+/PuO^+ being so much greater than U^+/UO^+, i.e. a large proportion of the PuO and PuO_2 molecules reaching the center filament are decomposed to Pu^+ and the plutonium sample is therefore used more efficiently.

(3) For thorium, the ions ThO^+ are produced more easily than the Th^+ ions even when the sample filament is at a temperature greater than 1850°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

For uranium, the ion beams of U^+ and UO^+ are of similar size, but as we cross the series, the X^+/XO^+ ratio increases until for americium the ratio $Am^+/AmO^+ \simeq 100$. It would appear that the elements become more like gadolinium. Thus, whilst gadolinium produces primarily GdO^+ ions on a single filament, in the multiple filament source Inghram (3) has shown that the Gd^+ ion intensity is much greater than the GdO^+ ion intensity.

(4) It is usually found that, if the currents through the sample and center filaments are held constant for several hours, then the ratio X^+/XO^+ tends to increase. Similar increases in positive ion emission have been described by some of the early workers using filament sources. They are probably due to slow changes in the physical conditions of the tungsten surface, causing a change in work function.

(5) In experiments to determine the relative detection limits for the actinide elements, neptunium, plutonium, and americium appeared to be detected at a lower level than uranium and protactinium. Thorium was the most difficult element to analyze and this must be due, in part, to the refractory nature of the oxide.

(6) Very small samples of the actinide elements may be analyzed in the multiple filament source. Using an electron multiplier collector Tilton (8) has reported a lower limit of 10^{-13} gm. for the detection of uranium.

Several of the ratios which are given in Tables I, II, and III are strongly influenced by changes in the temperature of the center filament. The changes produced in these ratios when the temperature of the center filament is slowly reduced from 2800°C., whilst the sample filament is maintained at a suitable constant temperature, have therefore been investigated. It is found that the ion beams for all the metal ions (X^+) together with ThO^+ and PaO^+ decrease rapidly in size. This would indicate that I is greater than W; for plutonium, as we have seen, this appears to be so. The other monoxide ions behave differently. Thus the UO^+ ion beam remains approximately constant in size until the center filament is at 2200°C., then it decreases rapidly. The PuO^+ and AmO^+ ion beams first increase to a maximum at about 2200°C., and then decrease as the current through the center filament is further reduced.

The dioxide ions PaO_2^+, UO_2^+, and NpO_2^+ resemble the PuO^+ and AmO^+ ions in that the ion intensity increases to a maximum (when the center filament is at 1200°, for the PaO_2^+ ion) and then decreases rapidly. Focusing conditions are such that the dioxide ions which are being detected originate from the center filament. No ions are detected direct from the sample filament. No ThO_2^+ or AmO_2^+ ions are usually observed. The maximum at the relatively low center filament temperature may possibly be explained as follows. There is an initial rise in the ion intensity because the chance that the XO_2 neutral particles can be thermally decomposed to XO and X decreases as the temperature is reduced. Hence there is a greater chance of the XO_2 surviving at the filament surface and being converted to XO_2^+ ions according to the Saha equation. At temperatures below 1800°C. the work function of the tungsten surface may be increased because of the decomposition of the XO_2 molecules by chemical reduction at the tungsten surface and hence the possible formation

of a tungsten oxide film, which may be stable. If the work function then becomes greater than the ionization potential for the particle, then further decrease in the temperature of the filament causes an increase in the ratio n^+/n_0. Finally as the temperature of the center filament drops further, a point will be reached when thermal ionization is no longer possible; hence the final drop at temperatures of about 1000°C.

TABLE IV

VALUES FOR THE RATIOS X^+/U^+ AND X^+/XO^+ WHEN THE TEMPERATURE OF THE SAMPLE FILAMENT IS MAINTAINED AT 1300°C. AND THE CENTER FILAMENT TEMPERATURE IS VARIED

Ratio	2700°C.	2600°C.	2500°C.	2400°C.	2200°C.	2100°C.	2000°C.
Np^+/U^+	—	2	2	2	2	3	4
Pu^+/U^+	—	3	4	6	10	25	—
Am^+/U^+	—	2	3	6	8	28	80
U^+/UO^+	—	1.5	1	0.5	0.3	0.1	—
Np^+/NpO^+	—	4	4	1	—	0.5	0.2
Pu^+/PuO^+	—	70	50	40	20	8	5
Am^+/AmO^+	255	100	60	—	60	27	14

The relative behavior of the actinide elements as the temperature of the center filament is reduced is summarized in Table IV. The ratios for X^+/U^+ and X^+/XO^+ are only intended to indicate a trend of behavior and it should again be emphasized that ratio values are only very approximate. The Np^+/U^+ ratio appears to behave anomalously. Thus, whereas the Np^+ and U^+ ion beams decrease in intensity at about the same rate, the Pu^+ and Am^+ beams appear to decrease more slowly than U^+.

In conclusion it may be said that it is difficult to make predictions from the Saha equation, because, for a rigid application of the equation, it is necessary to include the ionization potential for each of the species under consideration, and these are unknown for the monoxide and dioxide ions and for the metal ions, with the exception of uranium and plutonium. It is possible, however, to explain the results qualitatively using the equation and to obtain a reasonable picture of the ionization process.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the technical advice of Mr. G. H. Palmer, who designed and built the mass spectrometer.

THE PREPARATION AND PROPERTIES OF Pu^{242} [1]

By J. P. Butler, M. Lounsbury, and J. S. Merritt

ABSTRACT

Three samples of plutonium rich in Pu^{242} and containing from 1.7 to 8.6% Pu^{238} have been prepared by the neutron irradiation of Am^{241}. From mass analyses and measurements of the alpha abundance of Pu^{242}, the alpha half-life of Pu^{242} was determined as $3.73 \pm .05 \times 10^5$ yr. The spontaneous fission half-life of Pu^{242} was also measured as $6.6_4 \pm 0.10 \times 10^{10}$ yr.

I. INTRODUCTION

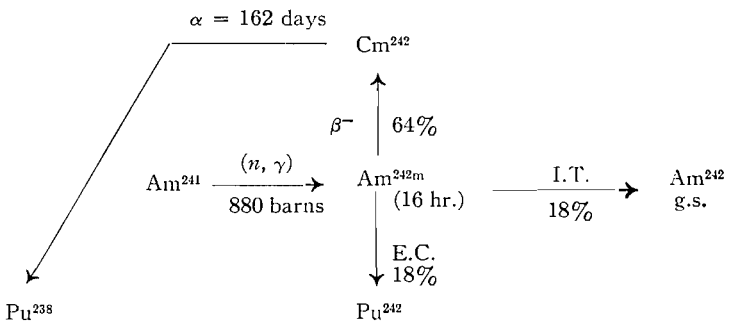
An estimate of about 5×10^5 yr. for the α half-life of Pu^{242} was made by Thompson *et al.* (12) in 1950. Later Asaro (1) reported a value of 9×10^5 yr. for this half-life, based on measurements of the α abundance and mass abundance of Pu^{242} in a sample of plutonium which was mainly Pu^{239}. Asaro determined the α abundance in an alpha-particle spectrograph which employed a 60° symmetrical magnetic analyzer. In a recent paper, Studier and Huizenga (11) summarize data on the spontaneous fission half-lives of the heavy elements, and report a value of 3.8×10^5 yr. for the α half-life and 6.7×10^{10} yr. for the spontaneous fission half-life of Pu^{242}. These values were privately communicated by Mech, and by Ghiorso and Thompson respectively.

In view of the differences and lack of precision in these reported values for the half-life of Pu^{242}, it was considered that a further investigation of this constant would be worth while.

II. PREPARATION OF Pu^{242}

(*a*) *Method*

Samples of plutonium rich in Pu^{242} were prepared by the neutron irradiation of Am^{241}. The nuclear reactions occurring in the neutron irradiation of Am^{241} are as follows (5, 9):



[1] *Manuscript received November 21, 1955.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 278. This paper was presented at the Symposium on Nuclear Chemistry and Radiochemistry held at McGill University, Montreal, Que., September 7–9, 1955.

For personal use only.

Am^{241} captures neutrons with an 880 barn cross section (3) to form the excited state of Am^{242}. The metastable state of Am^{242} has an over-all half-life of 16 hr. and decays by three modes: 18% by internal conversion to the ground state of Am^{242}, 64% by β^- decay to Cm^{242}, and 18% by electron capture to Pu^{242}. Since Pu^{242} is formed directly from the 16 hr. Am^{242m} while Pu^{238} is only formed through the intermediate 162 day Cm^{242}, it is clear that in the early stages of an irradiation the growth of Pu^{238} will be slow compared to that of Pu^{242}. Short irradiations followed by rapid separation of plutonium should therefore yield plutonium rich in Pu^{242}.

Quantitative calculations have shown that irradiations of two days would yield samples of Pu^{242}–Pu^{238} containing about 2% Pu^{238}. Plutonium of this composition is necessary for an accurate determination of the half-life of Pu^{242}. Larger amounts of Pu^{238} would make it difficult to measure the α activity of Pu^{242} since the α decay rate of Pu^{242} is about 4000 times slower than that of Pu^{238}. In addition, the α energy of Pu^{242} is less than that of Pu^{238}, so that in an alpha energy spectrogram the small Pu^{242} peak occurs superimposed on the low energy tail of Pu^{238}.

(*b*) *Experimental*

Samples of plutonium containing 98–99 atom % Pu^{242} were prepared by irradiating 50 mgm. of Am^{241} for two days in the N.R.X. nuclear reactor in a neutron flux of 6.5×10^{13} neutrons $cm.^{-2}$ $sec.^{-1}$. The Am^{241} which had been initially freed from all traces of plutonium was irradiated as AmF_3. The fluoride was used rather than the oxide since it had the advantage of being very easily dissolved after the irradiation.

In a two-day irradiation of 50 mgm. of Am^{241} large amounts of α, β, and γ activities are produced: $\alpha = 0.8$ curies, $\beta = 170$ curies, mainly Am^{242m}, and $\gamma = 10$ curies. The γ field of the sample immediately after the irradiation was 10 roentgens at 2 ft. Because of this high radiation field the initial separations were performed remotely in a dry box shielded with 2 in. of lead.

After the irradiation the plutonium was rapidly separated from the americium and curium to prevent further contamination of the Pu^{242} by Pu^{238} which grows in from the α decay of Cm^{242}. The AmF_3 was dissolved in a warm solution of saturated boric acid in 4 *N* nitric acid. The Am, Cm, and Pu were precipitated as hydroxides with NaOH and dissolved in concentrated hydrochloric acid which was 0.1 *N* in nitric acid. This solution was fed onto a Dowex A-1 anion resin column (area 1.1 $cm.^2$, length 6 cm.) which adsorbed the plutonium and allowed the Am, Cm, and most of the fission products to pass through (2). The column was washed with 12 *N* HCl – 0.1 *N* HNO_3 to reduce the amount of Cm held on the column.

The plutonium, which was about 15 μgm. in all, was eluted from the resin column with 1% NH_4I in 12 *N* HCl. The plutonium was reoxidized to Pu^{+4}, and readsorbed on a fresh Dowex A-1 column from which it was eluted with 0.2 *N* HCl. In these steps the plutonium was decontaminated from Am and Cm by a factor of 10^9. The final purification of the plutonium was accomplished by solvent extraction using thenoyltrifluoroacetone in benzene.

III. THE α HALF-LIFE OF Pu^{242}

(*a*) *Method*

From a knowledge of the relative alpha activities and abundances of the plutonium isotopes the half-life of Pu^{242} can be determined from the known half-life of Pu^{238}. For Pu^{242} the equation is as follows:

$$t_{\frac{1}{2}}(Pu^{242}) = \frac{Pu^{238}\text{-}\alpha}{Pu^{242}\text{-}\alpha} \times \frac{\text{atoms } Pu^{242}}{\text{atoms } Pu^{238}} \times t_{\frac{1}{2}}(Pu^{238}).$$

The best value for the half-life of Pu^{238} is 89.6 yr. determined by Jaffey (6).

(*b*) *Experimental*

The samples of plutonium were mass analyzed with a 60°-deflection, 8-in.-radius mass spectrometer with a resolution of 0.3% atomic mass unit (7, 10).

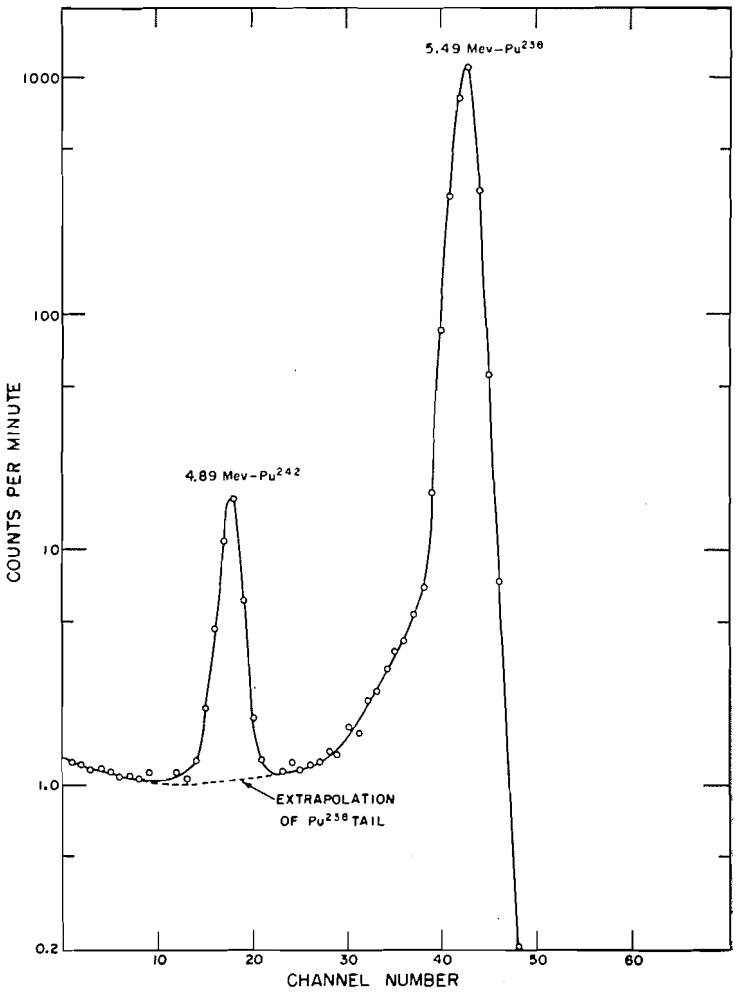

FIG. 1. Alpha spectrum of a sample of Pu^{242}–Pu^{238} containing 1.803 atom % Pu^{238}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

The surface ionization ion source employed a tantalum ribbon mounted on Kovar terminals. For each analysis a sample of about 15 μgm. of plutonium was used. PuO^+ ions were detected when a current of about 2.5 amp. d-c. was passed through the filament. The mass spectrum was scanned magnetically and the ion current amplified by a vibrating reed electrometer and recorded with a Type G Speedomax. The Pu^{238}/Pu^{242} abundance ratio was calculated from the ratio of the heights of the mass 254 ($Pu^{238}O^{16}$) and mass 258 ($Pu^{242}O^{16}$) ion current peaks. Ten determinations were made of the abundance ratio in each sample and the standard deviation from the mean was $\pm 1\%$. The abundance of Pu^{239} in each of the three samples was low, less than 0.1 atom % in sample 1, and less than 0.01 atom % in samples 2 and 3.

The α pulse analysis of the plutonium was determined with a gridded ion chamber (4) and a 30 channel pulse height analyzer. Thin sources were prepared by vacuum sublimation onto polished platinum disks. The resolution of the chamber was 0.6% full width at half maximum. Fig. 1 shows the alpha spectrum of a mixture of Pu^{238}–Pu^{242} in which the atom per cent of Pu^{238} was 1.8. To determine the α counting ratio of Pu^{238} to Pu^{242} only eight channels over each alpha group were used. In actual practice, to determine the relative abundance of the two alpha groups the same channels were used to obtain the counting rate in each group. This would eliminate errors introduced by differences in channel width. To estimate the α activity of Pu^{242} it was necessary to extrapolate the Pu^{238} α tail under the Pu^{242} peak. Since the Pu^{238} α tail is very flat in the region of 4.9 Mev., there is little uncertainty in this extrapolation. In Table I the reproducibility of the α pulse analysis is shown for a sample of plutonium. The values of the α abundance of Pu^{242} for repeated

TABLE I

REPRODUCIBILITY OF α PULSE ANALYSIS

Sample	Source	α % Pu^{242}
3	A	$1.28_5 \pm 0.01_3$
	A	$1.27_1 \pm 0.01_3$
3	B	$1.27_2 \pm 0.01_2$
	B	$1.29_3 \pm 0.01_3$
3	C	$1.27_2 \pm 0.01_3$
	C	$1.29_8 \pm 0.01_3$
	Average	$1.28_2 \pm 0.009$

counts on three different sublimed sources are listed. The errors quoted are the statistical error in the count plus an error in the extrapolation, about 0.5%. From the results in this table the α abundance of Pu^{242} was determined with a standard deviation of about $\pm 1\%$.

Combining the results of the mass analysis and the α pulse analysis with the known half-life of Pu^{238}, 89.6 yr., the half-life of Pu^{242} was calculated for three samples of plutonium. The results are summarized in Table II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

TABLE II

HALF-LIFE OF Pu^{242}

Sample	% of Pu^{242}-α's	Atom % Pu^{238}	$t_{\frac{1}{2}} \times 10^5$ yr.
1	$0.26_1 \pm 0.01_2$	$8.62_0 \pm .09_0$	$3.63 \pm .18$
2	$1.38_0 \pm 0.01_2$	$1.69_8 \pm .01_7$	$3.71 \pm .05$
3	$1.28_2 \pm 0.00_9$	$1.80_3 \pm .01_9$	$3.76 \pm .05$
		Weighted average	$= 3.73 \pm .05$

The values of the half-life of Pu^{242} listed in the last column of the table for the three samples agree within the error of the determination. The error for sample 1 (which was prepared by a 9.4 day irradiation of Am^{241}) is larger because the α abundance of Pu^{242} was much smaller and it could not be determined with the same precision as samples 2 and 3.

A weighted average gives a value of $(3.73 \pm 0.05) \times 10^5$ yr. for the α half-life of Pu^{242}. The error quoted is the standard deviation calculated from the experimental results and does not include the uncertainties in the α half-life of Pu^{238} used in the calculations.

IV. SPONTANEOUS FISSION HALF-LIFE OF Pu^{242}

The spontaneous fission half-life of Pu^{242} was determined using plutonium from sample 3 (see Table II). A thin source of about 4 μgm. of plutonium was prepared by electrolyzing a solution of plutonium in 0.3 M ammonium oxalate which was kept slightly acid to phenol red (8). A current density of 150 ma. per $cm.^2$ was used.

The source was fission counted in a simple ionization chamber filled with methane. The chamber was operated at a gas pressure such that both the α-particles and the fission fragments had ranges greater than the spacing between the electrodes. Using an amplifier with a time constant of 10^{-7} sec. the chamber gave good discrimination between α-particles and fission fragments in the presence of 2×10^8 α disintegrations per minute. The background of the chamber was less than 0.5 fission disintegrations per day. The effective geometry of the chamber for a fission source was determined as $96._4\%$ by counting an α source of known disintegration rate at an increased pressure.

The plutonium source which contained 4.05 μgm. of Pu^{242} and 0.0732 μgm. of Pu^{238} gave a spontaneous fission counting rate of 12.3 ± 0.1 disintegrations per hour. When a correction of 2.4% is applied to allow for the spontaneous fission of Pu^{238} ($t_{\frac{1}{2}} = 4.9 \times 10^{10}$ years (11)) a value of $6.6_4 \pm 0.10 \times 10^{10}$ years is obtained for the spontaneous fission half-life of Pu^{242}.

ACKNOWLEDGMENTS

The authors are indebted to Dr. J. Milsted of A.E.R.E., Harwell, England, for many valuable discussions and would like to thank him and Mr. A. Beadle for assistance in the preparation of some of the plutonium samples. The authors also wish to thank Mr. H. G. Jackson who improved the resolution of the α grid chamber.

THE NATURAL ABUNDANCES OF THE URANIUM ISOTOPES[1]

By M. Lounsbury

ABSTRACT

Using a surface-ionization mass spectrometer, the natural U^{238}/U^{235} abundance ratio in uranium obtained from Great Bear Lake Pitchblende has been measured to be 137.80 ± 0.14. From a survey of results reported in the literature on U^{234} a best value of $17{,}325 \pm 550$ was estimated for the natural U^{238}/U^{234} abundance ratio. The corresponding isotopic abundances are 0.7204 ± 0.0007 atom % and 0.00573 ± 0.00018 atom % for U^{235} and U^{234}, respectively.

INTRODUCTION

The first mass spectrographic analysis of uranium was made by Aston (1) in 1931. He observed only U^{238}, and estimated the abundance of other isotopes to total not more than two or three per cent. In 1932, von Grosse (9), from studies of the actinium $(4n + 3)$ series of natural radioactivity, predicted that U^{235} existed in natural uranium to the extent of 0.4 atom %. Dempster (5) in 1935 discovered U^{235} mass spectrographically and determined its abundance to be less than 1 atom %. He also predicted the existence of U^{234} from studies of the uranium $(4n + 2)$ series of natural radioactivity, and calculated that its abundance would be 0.008 atom %, "and therefore too faint to be observed by the mass spectrograph".

Nier (14) in 1939 made the first mass spectrometric analysis of natural uranium and obtained a value of 138.9 ± 1.4 for the U^{238}/U^{235} abundance ratio. Because it was at one time thought that the ratio might be a function of the age of the mineral in which the uranium was found, he measured the ratio for three samples of widely different geologic age. He found that for Swedish Kolm (4×10^8 yr.), Wilberforce Uraninite (1.0×10^9 yr.), and Dakeite (1×10^3 yr.), the ratio was constant to 0.07%, and therefore did not depend on the age of the mineral or its source. Nier also discovered the very rare isotope U^{234}, and determined its abundance to be 0.0059 atom %. Further determinations of the U^{234} abundance have been made by several authors (3, 6, 7, 8, 12) using both mass spectrometric and specific activity methods.

Subsequent mass spectrometric determinations of the U^{238}/U^{235} abundance ratio have been reported by Inghram (11), Fox and Rustad (7), and Chamberlain, Williams, and Yuster (3), all in 1946. Inghram's value of 137.8 was lower than the earlier determination by Nier by almost one per cent. Fox and Rustad actually obtained two values, 137.0 ± 0.7 by electron bombardment ionization, and 138.0 ± 0.3 by thermal ionization. Using the latter ion source they found, as did Nier, that the ratio was constant to 0.03% for two African ores, one Canadian ore, and one Colorado carnotite. Chamberlain *et al.* obtained a value of 139 for the U^{238}/U^{235} ratio, in agreement with the first determination by Nier.

[1]*Manuscript received November 14, 1955.*
Contribution from Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 280. This paper was presented at the Symposium on Nuclear Chemistry and Radiochemistry held at McGill University, Montreal, Que., September 7–9, 1955.

Three estimates of a best value for the U^{238}/U^{235} abundance ratio have been reported in the literature. Bainbridge and Nier (2) in 1950 in their table of isotopic abundances adopted a best value of 139.0 ± 1.4. Fleming *et al.* (6) in 1952 arrived at a best value of 138.0 ± 1.4, a composite of all the determinations, but close to the value of Inghram and the thermal ionization value of Fox and Rustad. In 1953, Hollander, Perlman, and Seaborg (10) in their Table of Isotopes reverted to the 1939 value of Nier.

In view of the difference between the best values of the natural U^{238}/U^{235} abundance ratio, and because of the importance of this ratio in such studies as geologic age determinations and the nuclear processes occurring in reactors fueled with natural uranium, a further investigation of the ratio appeared to be worth while. During the past year and a half, a number of mass spectrometric determinations of the natural U^{238}/U^{235} abundance ratio have been made in this laboratory. The results of these measurements are presented in this paper, along with a comparison of the earlier measurements of U^{234}, in order to estimate a best value for its abundance.

EXPERIMENTAL

A. Uranium Sample

The uranium sample used in this investigation was obtained from Pitchblende from the Eldorado mine at Port Radium on Great Bear Lake in northern Canada. The age of the Pitchblende has been determined by Collins, Farquhar, and Russell (4) to be 1400 ± 50 million years. A highly purified sample of $UO_2(NO_3)_2.6H_2O$ was prepared* and dissolved in 1 *N* HNO_3 to give a solution with a concentration of 5 mgm. U/ml., from which 3λ aliquots were taken for mass analysis.

B. Mass Spectrometry

A 60°-deflection, 8-in.-radius mass spectrometer (13) with a mass resolution of 0.3% was used for this work. The thermionic emission ion source employed a tantalum ribbon filament (0.001 in. × 0.030 in. × 0.250 in.) mounted on pickled Kovar terminals (Stupakoff No. 9807). Fifteen micrograms of uranium contained in 3 microliters of the stock solution was dried on the filament by passing a current of about 1 amp. through it in air.

The loaded filament was mounted in the ion source and by differential pumping the mass spectrometer tube was evacuated to about 2×10^{-7} mm. Hg as indicated by the ionization gauge. UO_2^+ ions were detected when a current of 2.0 to 2.5 amp. d-c. was passed through the filament. The ions were accelerated to 6,000 to 10,000 volts energy, collimated in a beam, and separated according to mass in a magnetic field of 9,000 to 12,000 gauss. The mass spectrum was scanned magnetically, and the ion current was amplified by a Vibrating Reed Electrometer (Applied Physics Corporation, Model 30) with a 2×10^{11} ohm input resistor. The output from the amplifier was fed through a calibrated attenuator system to a fast (0.8 sec. full-scale response) Speedo-

*The author is deeply indebted to Professor L. Yaffe, McGill University, Montreal, for supplying the purified sample of uranyl nitrate.

max Recorder (Type G). The mass spectrum was scanned slowly (10 sec. per peak) and continuously in the direction of increasing and decreasing mass alternately.

RESULTS AND DISCUSSION

At the relatively low ion source filament temperatures used in this work, the predominant ion emission was UO_2^+, with a very small emission of UO^+ ions. In the recorded mass spectrograms, ion current peaks were observed at the mass numbers shown in Table I. The peak at mass number 266, due to

TABLE I

IONIC SPECIES IN UO_2^+ MASS SPECTRUM

Mass No.	Ionic species
266	$U^{234}O^{16}O^{16}$
267	$U^{235}O^{16}O^{16} + U^{234}O^{16}O^{17}$
270	$U^{238}O^{16}O^{16}$
271	$U^{238}O^{16}O^{17}$
272	$U^{238}O^{16}O^{18} + U^{238}O^{17}O^{17}$

the very rare $U^{234}O^{16}O^{16}$ combination, was observed only if the total ion current was increased by operating the filament at a temperature above the optimum value for long sample life. Therefore the $U^{234}O^{16}O^{17}$ combination made a negligible contribution to the height of the mass 267 peak, and the U^{238}/U^{235} abundance ratio was calculated directly from the ratio of the heights of the mass 270 ($U^{238}O^{16}O^{16}$) and the mass 267 ($U^{235}O^{16}O^{16}$) ion current peaks.

The results obtained from the recorded mass spectrograms are presented in Table II. Each of the 11 determinations listed is the average obtained from 20 or more spectrograms. The error quoted in each case is the standard devi-

ation of the mean. The grand mean is the average of the 11 determinations with equal weight assigned to each of them. The error attached to the grand

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

mean is the standard deviation of the 11 determinations from it. Possible systematic errors which could affect the accuracy of the grand mean are: (*a*) isotopic fractionation in the vaporization process, (*b*) mass discrimination in the ionization process, (*c*) magnetic mass discrimination in the ion source, (*d*) electrostatic mass discrimination in the source, (*e*) magnetic mass discrimination in the analyzer, and (*f*) non-linearity in ion-current measurements.

Isotopic fractionation in the vaporization process could arise from possible preferential evaporation of the lighter $U^{235}O^{16}O^{16}$ molecule, caused by its higher thermal velocity, relative to $U^{238}O^{16}O^{16}$. If evaporation of the sample occurred from the liquid phase and there was perfect mixing at the surface of the liquid, isotopic fractionation could occur and cause a maximum change in the U^{238}/U^{235} abundance ratio of 0.5%, equal to the square root of the ratio of the masses 270/267. With the refractory oxide of uranium, evaporation is from the solid phase, and therefore mixing at the surface of the solid and isotopic fractionation should be negligible. To prove this, abundance ratios were measured from the time emission began until the sample was completely evaporated from the filament. If there were any isotopic fractionation, the U^{238}/U^{235} abundance ratio would increase with time. No such effect was detected.

Mass discrimination in the ionization process would occur if the ionization efficiency was a function of the isotopic mass. However for the thermal process, the ionization efficiency is a function of the ionization potential and not of the mass, and therefore this effect is negligible.

Magnetic mass discrimination could not occur in the ion source because the thermal source required no magnetic field as does a bombardment source with an electron focusing magnet.

There was no electrostatic mass discrimination in the ion source because the ion energy was held constant and the mass spectrum scanned magnetically. If the spectrum had been scanned electrostatically, the higher accelerating potential required to bring the lighter $U^{235}O^{16}O^{16}$ ion to focus on the collector would have resulted in increased ion source efficiency for the lighter ion, and caused the U^{238}/U^{235} ratio to be too low.

With magnetic scanning of the mass spectrum, the ion paths of $U^{235}O^{16}O^{16}$ and $U^{238}O^{16}O^{16}$ through the mass spectrometer tube are identical, and thus the condition for no discrimination in the analyzer is fulfilled.

Inaccuracy in measurements of the abundance ratio could be caused by non-ohmic response of input resistor of the vibrating reed electrometer, or by non-linearity of response of the electrometer and recording system. The input resistor showed no evidence of non-linearity in the range from 0.006 to 2 volts used in these experiments. Similarly the electrometer and recorder gave no evidence of non-linear response over a 10-fold range in total ion current. The measured U^{238}/U^{235} abundance ratio was completely independent of the magnitude of the ion current.

Therefore it is concluded that the various systematic errors discussed above either were not present, or were not greater than $\pm 0.1\%$, the standard deviation from the grand mean, and to this degree of accuracy, the measured ion current peak heights were proportional to isotopic abundances.

The value obtained for the U^{238}/U^{235} abundance ratio in uranium from Great Bear Lake Pitchblende was 137.80 ± 0.14. Because Nier (14) and Fox and Rustad (7) have shown that the ratio is independent of the age or the source of the mineral from which the uranium was obtained, the value of 137.80 ± 0.14 obtained for the ratio in this work, which is in agreement with the determination by Inghram (11), may be assumed to apply to all natural uranium. A summary of the various published values of the U^{238}/U^{235} ratio is given in Table III.

TABLE III

Six values of the U^{234} abundance, ranging from 0.00504 to 0.00591 atom %, have been reported in the literature (3, 6, 7, 8, 12, 14) as shown in Table IV. A best value is rather difficult to arrive at, because several authors, claiming

TABLE IV

ISOTOPIC ABUNDANCE OF U^{234}

Author	Reference	Atom % U^{234}
Nier, 1939	14	0.00591 ± 0.00059
Fox *et al.*, 1946	7	0.00555 ± 0.00017
Chamberlain *et al.*, 1946	3	0.00504 ± 0.00030
Goldin *et al.*, 1949	8	0.00590 ± 0.00008
Kienberger, 1949	12	0.00557 ± 0.00006
Fleming *et al.*, 1952	6	0.00545 ± 0.00004
Best value		0.00573 ± 0.00018

1% accuracy, differ from each other by about 10%. The first three values listed were obtained by the mass spectrometric method. The value of Chamberlain *et al.* (3) appears to be too low because the value of the half-life of U^{234} determined using their abundance of U^{234} is about 10% too low. The values of Nier (14) and Fox and Rustad (7) agree well within the quoted limits of error. Goldin *et al.* (8) calculated their value from the specific alpha-activity of pure U^{234} and U^{238}, using Nier's value for the U^{238}/U^{235} abundance ratio. The method required many operations subject to error, but the result is in remarkable agreement with the value of Nier. Kienberger's (12) value is based on specific alpha-activity and mass spectrometer analyses of samples of uranium highly enriched in U^{234}, and on the specific alpha-activities of U^{238} and natural urani-

um. The value thus calculated is in excellent agreement with the value of Fox and Rustad, but is significantly different from that of Goldin *et al.*, considering the low limits of error imposed on these two values. Fleming *et al.* (6) based their determination on the specific alpha-activity of natural uranium and of U^{234}. The value thus obtained is in agreement with the value of Fox and Rustad within the quoted limits of error.

Thus, excluding the value of Chamberlain *et al.* for the reason discussed above, the values obtained for the natural abundance of U^{234} fall into two groups, one giving 0.0055 atom %, and the other giving 0.0059 atom %. A best value of 0.00573 ± 0.00018 atom % is estimated to cover the most probable limits of the range.

Using the value of the U^{235} abundance obtained from this work, and the best value of the U^{234} abundance estimated from the survey of the literature, the natural abundances of the uranium isotopes are as given in Table V.

TABLE V

NATURAL ABUNDANCES OF THE URANIUM ISOTOPES

DISINTEGRATION-RATE DETERMINATION BY 4π-COUNTING

PART IV. SELF-ABSORPTION CORRECTION: GENERAL METHOD AND APPLICATION TO Ni^{63} β-RADIATION[1]

By B. D. Pate[2] and L. Yaffe

ABSTRACT

A method of preparing thin uniform sources of radioactive materials for use in a 4π counter is described. The radioactive nuclides are formed into organic compounds and are subsequently distilled on to thin VYNS films. Electron microscope photographs of the deposits are shown. The material is uniformly deposited in crystals of about 1 μ in diameter. The distillation can be rendered quantitative. The amount of material on the film can be estimated either spectrophotometrically *in situ* or by appropriate chemical means. Using this method a self-absorption curve for Ni^{63} (maximum beta energy 67 kev.) is obtained.

A. INTRODUCTION

In previous publications (15, 16, 17, 18) we have discussed the principles of 4π-counting and the errors to which disintegration-rate determinations by this method are subject. We have shown that the error from departure of the counter response probability from a value of unity can be reduced to less than 0.1% and that arising from absorption of radiation in the source-mount can be reduced to less than 0.2% of the source disintegration-rate, for beta-emitters of end-point energy down to 67 kev. Similar results were obtained for emitters of other forms of radiation. This paper will describe methods for correcting for the remaining source of error: absorption of radiation in the material of the source itself.

Owing in part to the recent advances in technique for correcting for other errors, self-absorption is at present and appears likely to remain for some time the factor limiting the accuracy of 4π-counting, and indeed all disintegration-rate determination methods involving solid sources (with the possible exception of coincidence counting).

Self-absorption effects become more important as the radiation energy is reduced, and in the 4π-counting system are generally much greater than in systems of smaller counting geometry owing to the ineffectiveness of self-scattering processes (1, 2, 3, 7, 14, 24). However very little systematic work on self-absorption by experimenters using 4π-counters has been reported.

Meyer-Schützmeister and Vincent (12) were aware of the significance of self-absorption in S^{35} sources however. Their method of source mounting (vacuum evaporation or "freeze-drying" of solutions) produced crystals of 2–3 μ in diameter. If the material was deposited so as to be concentrated into one crystal of 20 μ diameter, the apparent activity was observed to be lower by 30%. In order to allow for self-absorption, these authors assumed the

[2]*Holder of a National Research Council Studentship.*

crystals to be spherical in shape, and computed radiation absorption using an absorption coefficient value from external absorption measurements and assuming the absorption to be exponential.

However when this method of source preparation is used with thin films (5–10 μgm./cm.^{2}) numerous tears are produced in the film, owing probably to the rapid expansion of the droplet under the conditions of rapid evaporation.

Hawkings *et al.* (5) proposed a better method of correcting for, or rather ensuring the absence of, significant absorption effects. Their procedure was the progressive dilution of the stock solution from which sources were prepared until a constant specific activity (after correction for the dilution) was observed. Alternatively a plot of the logarithm of the counting-rate against the aliquot used could be extrapolated to infinite dilution. This method, applicable in general to high specific activity materials only, is however not infallible. Material from dilute solution will, unless elaborate precautions are taken, still crystallize into local aggregates, and even with such precautions, crystal size cannot be reduced indefinitely. Thus self-absorption may still be significant in residues from evaporation which are invisible, and further dilution will not necessarily lead to a true disintegration rate figure.

A recent paper by Seliger and Schwebel (22) emphasizes the importance of the method of source preparation. Different methods of mounting Sr^{90} were found to give sources differing in counting-rate by 5%, and similar but larger effects were found for Co^{60}, mounted by evaporation of a solution with and without prior precipitation by ammonia. Micrographic examination of even the best residues showed clumping of source material. No systematic attempt was made to determine and correct for absorption losses, such corrections as were made being mostly quite arbitrary.

Thus the subject of the determination of and correction for self-absorption in the 4π-counter is virtually untouched. The problem of making such a correction in a precise way divides itself into two parts,

(*a*) the preparation of samples of radioactive material in which self-absorption effects are minimal, uniform, and reproducible and

(*b*) the determination of the extent of self-absorption in the sample so prepared as a function of its superficial density, and consequent correction of the observed disintegration-rate.

B. EXPERIMENTAL TECHNIQUES AND RESULTS

(*a*) *Source Preparation*

The methods of sample mounting used in conventional counter systems, involving manipulations of material in the solid state, are not suitable for the most accurate work with a 4π-counter. This follows from the use of very thin and comparatively fragile plastic films for the source mount, described elsewhere (16). Handling of solids in the form of slurries is likewise unsatisfactory since these tend to form large aggregates, or tear the film on drying.

The usual method of mounting 4π-counter sources then is by drying a suitable aliquot of a stock solution (5, 12, 20). However, as mentioned above, such an evaporation procedure will usually lead to local agglomerates of crystals (most often at the periphery or near the center of the original drop)

rather than to an even layer of material. This is especially the case when the source-mounting film is particularly hydrophobic, like VYNS, as is seen in Fig. 1, a photomicrograph of a sodium sulphate deposit (~100 μgm./cm.²) produced by this method. Under these conditions self-absorption effects will be neither minimal nor reproducible.

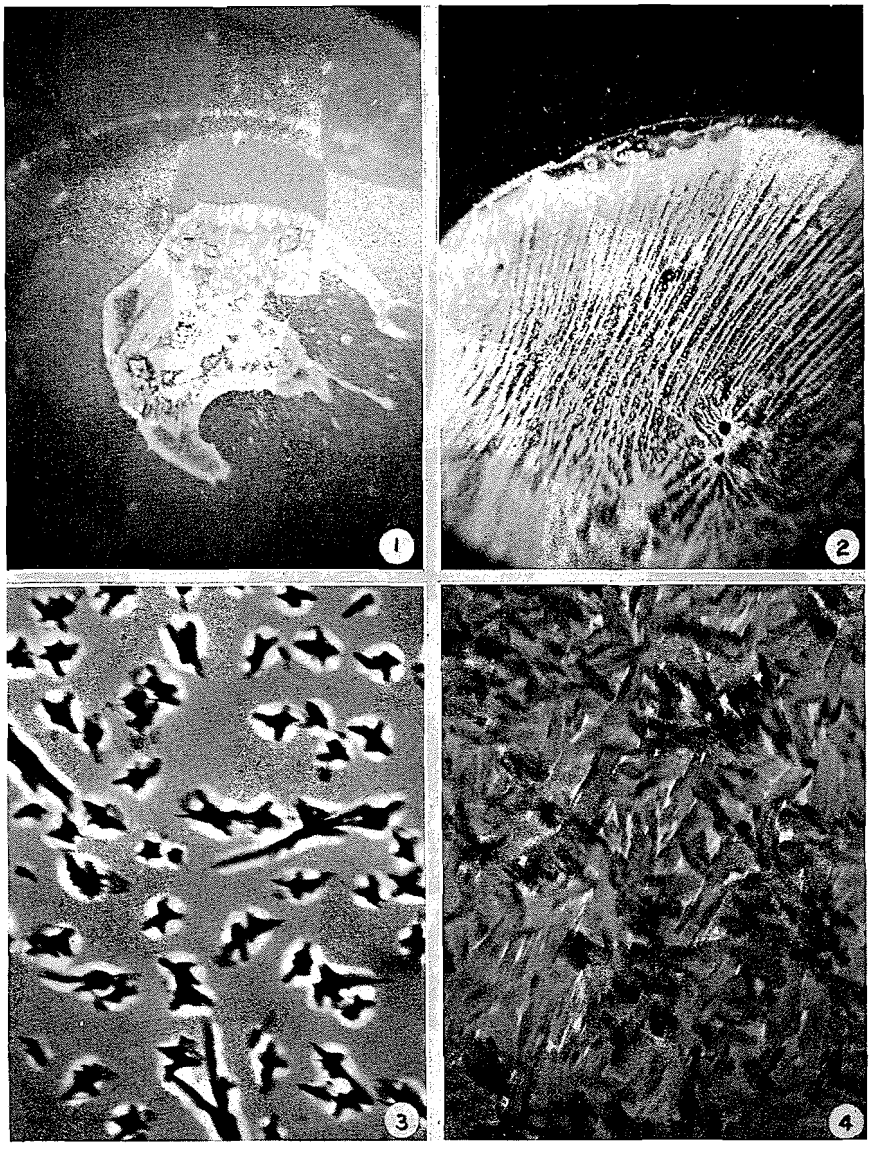

FIG. 1. Photomicrograph (×20) of deposit from the evaporation of Na_2SO_4 solution under infrared irradiation on 5 μgm./cm.² VYNS without insulin.

For personal use only.

A more evenly spread deposit is obtained (9) if the surface of the film is rendered hydrophylic, e.g. by treatment with a solution of a protein such as albumen or insulin (10, 11). Under these conditions the deposit is distributed over a wider area, and is more uniform in a macro sense. This is clearly seen in Fig. 2, a photomicrograph of a sodium sulphate deposit ($\sim$100 μgm./cm.^{2}) produced after insulin treatment of the film. However the actual crystal sizes obtained are still quite large and very variable (several millimeters long and 30 to 100 μ in diameter). The disadvantages of methods involving the freeze drying of solutions have already been discussed.

An improved method of source preparation is therefore desirable, particularly for use with very low energy particle emitters, and we find the vacuum distillation of solid source material directly on to the film, using compounds with large organic groupings, to be a suitable procedure. As a method of producing thin even layers of metals and salts, this procedure is of course both of long standing and of widespread employment (8). Its use in this laboratory to coat VYNS source-mounting films with gold has already been described (15). Further it has already been used to mount radioactive materials both for beta-spectrometry (10, 19) and in 4π-counters (6, 21). However no regular use of it nor any attempt to employ it in the present way for self-absorption studies has been reported.

The distillation apparatus used by us is shown diagrammatically in Fig. 5. The furnace consists of a vacuum jacket of pyrex glass containing a platinum crucible A. This contains a charge C of radioactive material to be distilled, and is heated by means of a radio-frequency generator and work-coil B. This coil consists of 12 turns of number 20 gauge copper wire, coated with

teflon in order that the insulation between turns might be unaffected by heating (by radiation from the interior of the furnace) to 200° to 300°C.* The crucible temperature is measured by means of a Chromel–Alumel thermocouple D and millivoltmeter.

The crucible is supported by an aluminum mount E, from which it is however thermally insulated by means of a mica ring. The mount allows the source-mounting gold-coated VYNS film to be positioned accurately 0.5 mm. from the mouth of the crucible. The lower end of the furnace is connected, via two traps in series cooled with liquid nitrogen to remove any activities carried in the gas phase, to a rotary pump capable of maintaining a pressure in the apparatus of 0.1 μ Hg. The exhaust from the pumping system was finally vented into the fume hood as a further precaution. Controlled crucible temperatures up to 1000°C. are at present attainable, and a 10 μgm./cm.^{2} VYNS mounting film shows no sign of deterioration in proximity to the hot crucible under vacuum for 10 min. The crucible is cooled very nearly to room temperature before the system is opened, by venting a small air leak above the furnace and allowing air to be pumped past the hot surfaces. It is found that with this design of furnace, transfer of material from the crucible to the film is very nearly 100% quantitative.

Of the materials that can successfully be distilled with the temperature range and pressure at present available to us, compounds containing large organic groupings, e.g. aromatic compounds and especially chelate compounds, have been found to be the most suitable. Such compounds can readily be prepared for most radioactive species, are frequently found to be readily volatile *in vacuo* at moderate crucible temperatures, and produce a deposit of which the mass and composition do not alter appreciably on exposure to the atmosphere.

Provided that reasonable temperature control is maintained during the distillation, charring of organic materials is not a problem. These compounds are generally of low mean atomic number with consequently low radiation-scattering characteristics, and also frequently exhibit optical absorption bands in the visible region. The latter are useful in the analytical applications to be discussed later.

As examples of the compounds used in specific cases, we may cite those on which we have already obtained preliminary results, namely nickel dimethylglyoxime for Ni^{63}, benzidine sulphate for S^{35}, and cobalt 1-nitroso-2-naphthol for Co^{60}, the $\bar{Z}$ values being respectively 4.19, 4.91, and 4.48. For the remainder of this paper, we will illustrate the techniques used mostly with data for nickel dimethylglyoxime, but much of the discussion is equally applicable in the case of other compounds also.

Nickel dimethylglyoxime is prepared (using microchemical techniques where necessary) according to the customary gravimetric analytical procedure, namely by the addition of alcoholic dimethylglyoxime and dilute ammonia to a warm slightly acid nickel solution. The precipitate is washed with warm

The authors are indebted to Mr. S. Fromson of Canadian Vickers Ltd. who prepared the wire from which the induction coil was made.

water, and then transferred to the distillation crucible as an aqueous or CCl_4 slurry. It is reslurried with CCl_4 and dried between distillations to re-establish thermal contact with the crucible. Distillation commences at a temperature of 120°C. under 1 μ Hg pressure.

The progress of the distillation can be followed for the first hundred micrograms of deposit by observation of the changing interference colors viewed from the reverse side of the film. These are quite brilliant even for compounds which are colorless by transmission. The distillation can be arrested at any time by admission to the apparatus of a small quantity of air via the leak referred to earlier.

In Fig. 6 are compared the optical absorption spectra obtained with a Beckman DU spectrophotometer from a colloidal solution of nickel dimethyl-

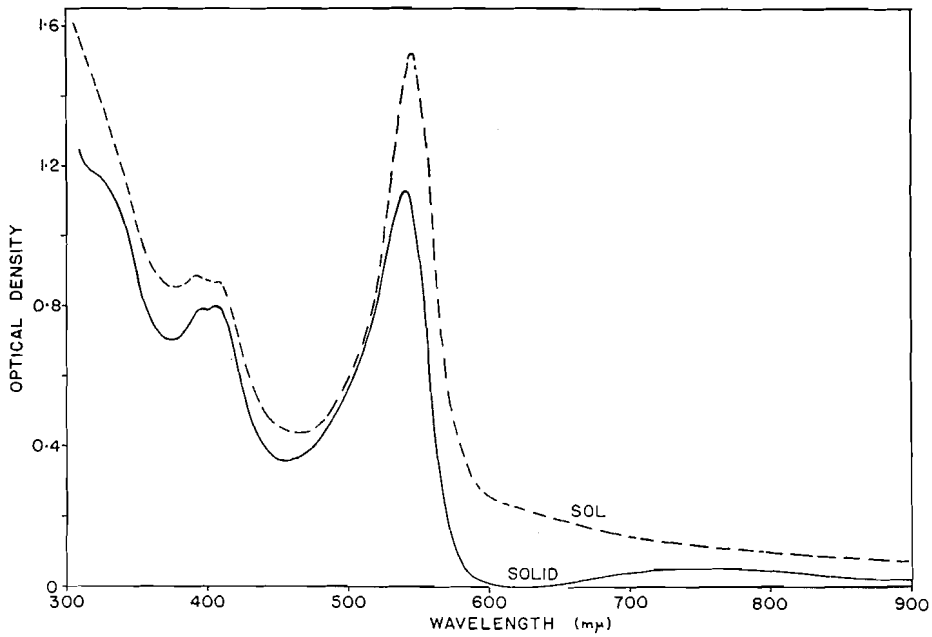

FIG. 6. Optical absorption spectrum of nickel dimethylglyoxime in the form of an aqueous colloidal solution protected by gelatin, and of the deposit after vacuum distillation.

glyoxime, and from the same compound as a deposit on VYNS film after distillation by the procedure outlined above. It is seen that the two are essentially identical (except for evidence of light scattering by the colloidal solution) indicating that the distillation process does not cause any significant decomposition.

Optical absorption on the 545 mμ peak is found in the deposit to be in accord with Lambert's Law for superficial densities up to about 150 μgm./cm.^{2}, and spectrophotometry may be employed to examine the thickness, evenness, and dimensions of the deposit. Fig. 7 shows a series of profiles or cross-sections of nickel dimethylglyoxime deposits of increasing superficial density, also

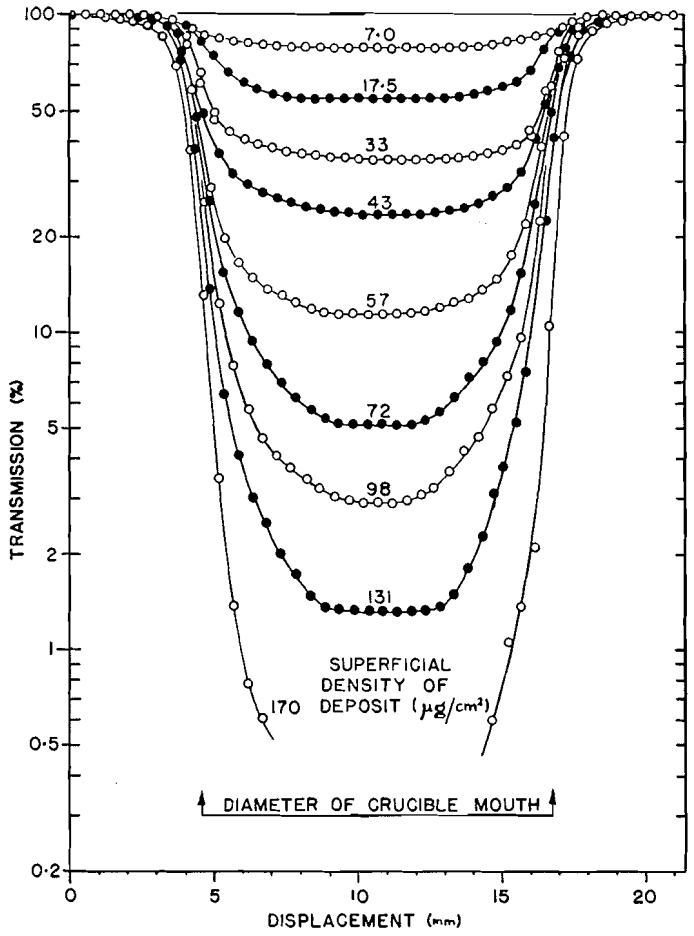

FIG. 7. Profiles of nickel dimethylglyoxime deposits of increasing superficial density, recorded with a slit width of 0.1 mm., and a wavelength of 545 mμ.

measured on a Beckman DU spectrophotometer. For these measurements the instrument was modified so that a micrometer screw and vernier scale controlled the movement of the film and deposit across the light path, and the slit was masked down to a length of 2 mm. at right angles to the direction of motion and a width of 0.1 mm. The transmission scale of this figure is logarithmic, so that vertical distances on this plot are proportional to deposit thickness.

It is seen that the diameter of the deposit does not alter sensibly with increasing superficial density, and profiles measured mutually at right angles show that the deposit is circularly symmetrical. Further, while the deposit departs considerably from the ideal of a right cylinder, the form of the profile is essentially constant with increasing thickness, and the mass of the deposit is nearly proportional to its effective superficial density for self-absorption purposes.

The microstructure of the deposit is shown in Figs. 3 and 4. These are electron micrographs of cobalt 1-nitroso-2-naphthol and nickel dimethylglyoxime deposits of 1.2 and 5 μgm./cm.^{2} superficial density respectively.* These pictures are representative of several taken over different areas of deposit all showing a uniform distribution of crystals of about 1 μ in diameter. A single crystal layer is completed apparently at about 5 μgm./cm.^{2} and the same crystal size is maintained throughout the completion of several crystal layers.

(*b*) *Estimation of Self-absorption*

The method of self-absorption estimation used in conjunction with the proposed source preparation technique is essentially similar to the conventional technique used with end-window counters. That is, the apparent source specific activity is plotted as a function of source superficial density, and extrapolated to zero superficial density to obtain the true specific activity. The major difference is that when using a 4π-counter, instead of milligrams of source material, one has frequently a few micrograms, which must be measured with an accuracy of better than $\pm$ 0.5 to 1%.

It is probable that direct spectrophotometric measurements on the deposit as outlined above, or direct weighing with a balance of the necessary sensitivity, could be made into a satisfactory procedure for superficial density determina-

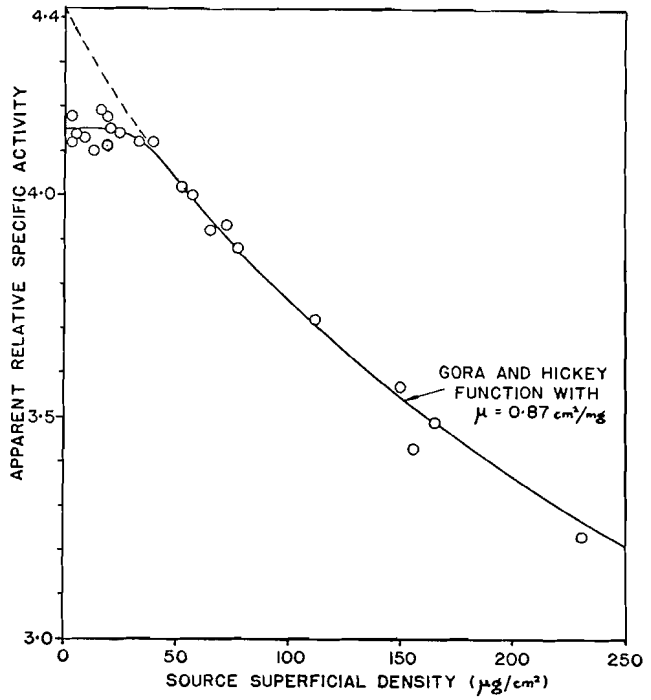

FIG. 8. Self-absorption curve for Ni^{63} beta-radiation in nickel dimethylglyoxime of 0–250 μgm./cm.^{2} superficial density.

The authors are indebted to Dr. A. W. Tickner of the Applied Chemistry Division, N.R.C., Ottawa, for use of electron microscope facilities.

tion. However in the case of nickel dimethylglyoxime we have found it more convenient to measure the apparent disintegration rate for each source prepared, and then to dissolve the deposit off the film with 1 N hydrochloric acid and determine the nickel colorimetrically by the procedure of Mitchell and Mellon (13), which can be made sensitive to 0.04 μgm. Ni. The efficiency of dissolution of the deposit from the film can be checked by drying the film again and making a second activity measurement in the counter. The activity found is generally a negligibly small fraction of the total originally deposited.

The results of such measurements on Ni^{63} beta-radiation and nickel dimethylglyoxime sources are shown in Fig. 8 for source superficial densities up to 250 μgm./cm^2.

C. DISCUSSION

Ni^{63} beta-radiation with an end-point energy of 67 kev. is the softest radiation studied in the present series of papers, and is with few exceptions as soft as any radiation liable to be encountered in 4π-counting work. It therefore forms a good test of any method for determining self-absorption losses, since absorption is at a maximum, the quantities of material handled are at a minimum, and any irregularities or irreproducibility of source material structure will produce a maximum scattering in the experimental data.

The data of Fig. 8 indicate that the proposed method of preparation produces sources in which self-absorption effects are satisfactorily reproducible. We have fitted to the data the self-absorption function given by Gora and Hickey (4) for a 2π-steradian geometry (which will be identical for a 4π-steradian geometry). This function was derived by integrating over a solid angle of 2π steradians the radiation intensity observed from a source of given thickness, making the usual assumption that absorption of beta-radiation is exponential with thickness. It is observed that the fit to our data is satisfactory above about 30 μgm./cm.^{2} and up to at least 250 μgm./cm.^{2} source superficial density. Our value of self-absorption coefficient, 0.87 cm.^{2}/mgm., is in reasonable agreement with the value predicted for a 67 kev. β-emitter by Baker and Katz (1), on the basis of self-absorption measurements on more energetic β-emitters in a rough approximation to a 4π-steradian counting geometry.

The anomalous absorption effects observed at superficial densities below 30 μgm./cm.^{2} we interpret as due to the finite crystal size of the source material. The method of plotting the data in Fig. 8 assumes that the method of source preparation results in a completely uniform distribution, whereas as is seen from Fig. 3 sources of very low apparent superficial density consist of well spaced crystals. Thus the true superficial density of the source material, i.e. of the crystals, is considerably greater than that measured. It is not until several crystal layers are built up that the measured superficial density approaches that of the source material proper, and regular self-absorption behavior is observed. Unlike the case with low-geometry counters, where self-scattering interferes (1, 2, 7, 14, 24), extrapolation of the curve obtained above 30 μgm./cm.^{2} to zero superficial density, as indicated by the broken line in Fig. 8, is expected to lead to the correct specific activity figure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

We consider that the extrapolation as indicated or any other method of extrapolating the data presented will lead to a disintegration rate accurate to probably $\pm 1\%$. This accuracy will improve with increasing energy of radiation, both since absorption effects are smaller and since the regular behavior referred to above will commence at relatively lower superficial densities. This will result in experimental points nearer the specific activity axis and hence a more accurate extrapolation. Further publications dealing with extension of these methods to emitters of more energetic radiation will elucidate this point.

As in the case of film absorption discussed earlier (17), the availability of a series of self-absorption curves for sources of emitters of a range of radiation energies, mounted by the method suggested above (i.e. using materials of low and relatively constant $\bar{Z}$), would allow a self-absorption correction to be made for any source encountered in routine work. Such a set of curves could be checked as suggested by Smith (23), if the series of radiation emitters included several amenable to coincidence measurements. The extent of beta self-absorption could then be measured directly for each source thickness prepared.

However such a generalized means of correction is necessarily an approximation, owing for instance to changes in radiation energy spectrum from nuclide to nuclide. For the most accurate working a plot and extrapolation such as in Fig. 8 will need to be made.

RECOMBINATION OF RECOIL FRAGMENTS IN NEUTRON-IRRADIATED POTASSIUM CHROMATE[1]

By A. G. Maddock and M. M. de Maine[2]

ABSTRACT

The kinetics of the process whereby the retention increases on heating previously neutron-irradiated potassium chromate have been investigated. The results cannot be explained by any unimolecular or bimolecular mechanism, nor by a combination of a few such steps. The data are not compatible with the commoner diffusion-controlled mechanisms. Experiments on solid solutions of potassium chromate in potassium fluoberyllate suggest that the process involves the recombination of the fragments from individual rupture events. A tentative hypothesis, analogous to the theory of the formation of very thin oxide films on metals, is advanced and it accounts for all the existing data.

INTRODUCTION

The salts of the oxy-anions, such as potassium chromate, are among the simplest compounds in which it is possible to study the chemical effects of radiative thermal neutron capture. Potassium permanganate was one of the first compounds in which these reactions, known collectively as the Szilard-Chalmers' Effect, were investigated (1). The nature of the fragments formed by the recoil following the dissipation of the excitation energy of the compound nucleus formed by thermal neutron capture, in one or more photons, has been studied (13). Libby proposed that the metal–oxygen bonds in those oxy-anions containing a normally electropositive central atom are broken heterolytically. Thus the recoil fragments formed in the permanganate include MnO_3^+, MnO_2^{+3}, MnO_3^{+5}, and possibly Mn^{+7} together with O^{-2} ions. The most convincing argument in favor of these fragments was based on the observation that upon solution of the irradiated permanganate in very alkaline solutions nearly all the activity was found as permanganate.

Since it is inconceivable that a species could be produced which could be oxidized to the heptavalent state by water, the observation suggests that the fragments all contain heptavalent manganese. An alternative explanation is, however, possible. The fragments may be able to undergo rapid exchange with permanganate ions in very alkaline solution. For example, this might be the case for a fragment containing pentavalent manganese, and giving MnO_4^{-3} in alkaline solution.

On Libby's hypothesis, the chromates should give CrO_3, CrO_2^{+2}, CrO^{+4}, and possibly Cr^{+6} ions. When the irradiated chromate crystals are dissolved in water prior to analysis, these fragments react with the water through hydration or reduction to give radioactive chromate and chromic ions respectively.

The first two of the fragments suggested by the hypothesis for the chromates are known to hydrolyze to chromate ions without reduction. But CrO^{+4}

and Cr^{+6} may be reduced before hydrolysis can take place. The fraction of the radioactive chromium found as chromate after solution is called the retention. Further investigations (2, 6, 7, 10, 12, 14) have been unsuccessful in the rigorous confirmation of Libby's hypothesis, but on the other hand it is not contradicted by any of the experimental evidence.

The proportions of the different kinds of fragments appear to depend on the nature of the crystals used. For instance different retentions are found for anhydrous lithium, sodium, and potassium permanganates (14). There is also evidence that the retention in irradiated crystals depends on the mean recoil energy, and may therefore be different for different isotopes formed by a single neutron irradiation (9, 15).

Although the identities of the fragments are still in doubt, it has proved possible to study some of their reactions in the irradiated crystals. It is now clear that these studies constitute a new and valuable chemical approach to the investigation of lattice abnormalities and reactions in the solid state.

It was discovered by Williams (18) that the retention in antimony pentafluoride and ammonium fluoantimonate was increased when the neutron-irradiated crystals were subsequently irradiated with ionizing radiation. A similar effect has been observed with potassium chromate and a preliminary study of the kinetics of the process suggests a unimolecular process (10).

A similar thermal annealing process was discovered by one of the authors (11), and has since been shown to be quite general (4, 8, 10, 14, 15). A similar study of the kinetics of the process in potassium chromate crystals led to the conclusion that a very complex mechanism was involved (10). More recent work by Zuber (19), using cobaltic tris-ethylene diamine nitrate, was analyzed in terms of two unimolecular processes with energies of activation of 25 ± 5 kcal. and 20 ± 5 kcal.

The chemical nature of the thermal annealing process has been discussed by one of the authors (10). It might consist of a simple recombination of the original fragments, which are seldom separated by many lattice units. Alternatively, reactions may take place with nearby inactive chromate ions. Thus $*CrO^{+4} + CrO_4^{-2} \rightarrow *CrO_2^{+2} + CrO_3$ converts a reducible species, $*CrO^{+4}$, into an hydrating $*CrO_2^{+2}$ species; and a radioactive chromium atom previously destined to form a chromic ion upon solution will give rise to a chromate ion. Finally it is conceivable that purely electronic reactions are involved.

It seemed possible that one of these alternatives might be discarded if the behavior of irradiated homogeneous mixed crystals of potassium chromate and potassium fluoberyllate were examined.

A number of very careful measurements of the variation in the retention with the time of heating of crystals of pure potassium chromate and of mixed chromate – fluoberyllate mixed crystals have been made.

EXPERIMENTAL

A. Irradiation

The neutron irradiations were all carried out in a carbon stringer in the thermal column in the Harwell Graphite Pile shield. All samples for irradiation

were pumped on a high vacuum line for about an hour before they were sealed off, still under high vacuum, in quartz ampoules.

The combined neutron and radiation doses received by the samples are not accurately known, but an indication is given in the PFW factor. The nominal flux of the pile given by the Harwell Isotope Office in units of 10^{11} neutrons/cm.^{2}/sec. is multiplied by the number of weeks spent by the samples in the pile at that flux to give the radiation dose in units of PFW or pile-factor-weeks.

B. Materials

Analytical reagent quality potassium chromate was used without further purification.

Potassium fluoberyllate was made by dissolving a molecular weight of beryllium carbonate in 4.5 molecular weights of hydrogen fluoride (17). An aqueous solution of two molecular weights of potassium carbonate was slowly added. The water and excess hydrogen fluoride were evaporated by gentle heating and the fine crystalline potassium fluoberyllate product was recrystallized twice from water.

Mixed crystals of the isomorphous potassium chromate and potassium fluoberyllate were made by preparing an aqueous solution 97% saturated at 20°C. with potassium chromate, and then saturating this solution at the boiling point with potassium fluoberyllate. The mixed crystals of potassium chromate and potassium fluoberyllate were allowed to form slowly. They were then filtered and washed thoroughly with cold distilled water to remove all traces of adsorbed chromate. The crystals were dried *in vacuo*.

Optical examination of the product revealed a high degree of uniformity, and spectrophotometric measurements on aqueous solutions made from weighed portions of material indicated that the mixed crystals contained approximately 1 mole % of potassium chromate.

C. Analysis Method

Neutron-irradiated potassium chromate and mixed potassium chromate – potassium fluoberyllate crystals were analyzed by the method devised by Green, Harbottle, and Maddock (10). The irradiated solid was dissolved in an acid solution containing chromic and chromate carriers. In one aliquot, lead chromate was precipitated and dissolved to provide a solution which gave a measure of radioactive chromate. Sodium hydroxide – peroxide treatment oxidized chromic ions to chromate, and measurements on the solution of the lead chromate precipitate gave a measure of the total chromium activity.

D. Measurement of Radioactivity

The 325 kilovolt gamma-ray of Cr^{51} was counted by the use of a sodium iodide – thallium activated scintillation crystal and an adjacent photomultiplier tube to record the gamma-ray scintillations (3). The pulses from the tube were amplified and fed into a dual-discriminator anticoincidence pulse-height analyzer (5). Aliquots of the solutions were counted in an annular polythene vessel which surrounded the cylindrical crystal.

RESULTS

The results are given as values of the retention. In previous work an insufficient number of values were obtained to permit a detailed study of the kinetics of the recombination reactions.

For potassium chromate irradiated for one week at a pile factor of 0.1, an average retention value of 69.1% was obtained. No change in this value was detected in material kept in air at room temperature for periods up to four months.

In Fig. 1 are given plots of the average retention values versus heating time at temperatures where a full range of determinations were made. During the first four hours, heat increases the retention quite rapidly to a value

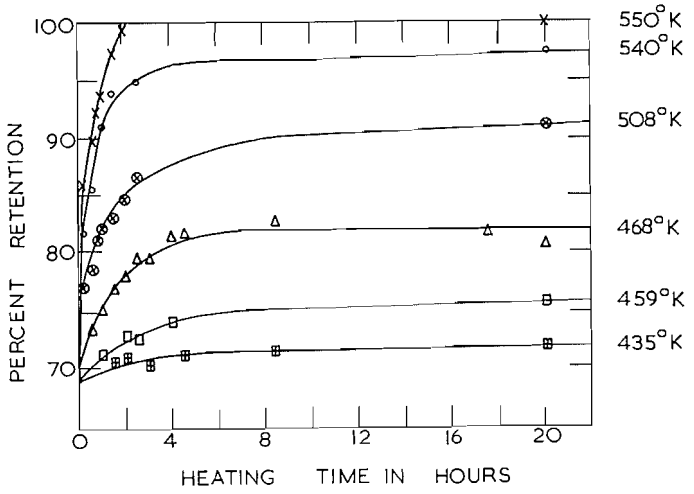

FIG. 1. Retention values versus time of heating at the temperatures indicated for potassium chromate irradiated for one week at pile factor of 0.1.

characteristic of each temperature. At times approaching a week, the effect has slowed to about a one per cent change per day. Fig. 2 shows that heat treatment at two different temperatures produces additive effects and that the retention value at which the rapid retention change ceases depends on the temperature of heating. Identically irradiated samples were heated *in vacuo* and in air. No differences in retention values were noted.

Potassium chromate – fluoberyllate mixed crystals irradiated for one week at pile factor 0.1 showed a 25.8% retention. Subsequent heating at temperatures similar to those used for the potassium chromate effected retention increases up to approximately eighty-five per cent. The heating curves for pure chromate and for the mixed crystals had a similar form, except that in the latter case the rate of retention increase "leveled-off" in approximately a quarter of the time.

DISCUSSION

Two questions are posed by these observations: the identity of the reacting species and the kinetic description of the process. The data does not provide

a real answer to the first of these questions; but the observation that the retention increases upon heating in a similar way in both irradiated potassium chromate and in irradiated dilute solid solutions of potassium chromate in potassium fluoberyllate suggests that the process does not involve the reaction of the "active" fragments with adjacent chromate ions but that it is due to recombination of the fragments following neutron capture. A reaction between a fragment destined to form a chromic ion upon solution (e.g. CrO^{+4}) and a fluoberyllate anion could conceivably produce a species which hydrolyzes to a chromate ion; but this appears to be a less likely explanation.

If it is supposed that the fragments formed by neutron irradiation are those suggested by Libby's hypothesis (13), and if it is assumed that Cr^{+6} ions could barely avoid electron capture for very long in the potassium chromate lattice, the reaction must be $CrO^{+4} + O^{-2} \rightarrow CrO_2^{+2}$.

Inspection of Fig. 1 shows that the process does not proceed by a simple unimolecular process, corresponding to the recombination of the fragments from individual eruptions, or by a bimolecular process such as would be found if the fragments from different primary events were as close to each other on an average as those from the same event. At each temperature the retention increases at first rapidly, and then more slowly until it reaches a nearly steady value after about six hours. With prolonged heating of the irradiated material, it can be shown that the retention continues to increase very slowly until it reaches 100%.

Zuber (19) has interpreted similar results in terms of two unimolecular processes. Two combinations of unimolecular processes are possible. If a single type of chromium fragment were liable to two processes leading to an increase in the retention, each characterized by a different activation energy, the kinetic behavior at any one temperature would be indistinguishable from that of a single unimolecular process. If, however, there were two kinds of chromium fragment, perhaps differing only in lattice situation, each with its characteristic activation energy for the process leading to an increase in the retention, then a plot of the logarithm of the proportion of unaffected fragments versus the time of heating should be capable of analysis into two linear portions. With this model, the second linear portion of the curves at different temperatures should extrapolate through a single point on the axis of the ordinate. This point would correspond to the proportion of the type of fragment responsible for the slower process and originally present in the irradiated crystals. These suppositions are obviously not true for the curves shown in Fig. 3.

These results cannot be interpreted in terms of even a small number of unimolecular processes. They are not compatible with a small number of bimolecular processes.

It might, however, be possible to interpret these results in terms of competing reactions. For instance, it is possible that the labile chromium fragments are liable to two reactions, one converting them to a chromate-forming species and the other to a chromic-forming species. A much slower reaction may be capable of converting the product of the second of these reactions into the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

product of the first reaction or into some similar body. If this model were correct, increasing the temperature after six hours heating, when the pseudo-equilibrium retention is reached, should have little effect on the retention except for the very slow process. In fact, Fig. 2 shows that the retention

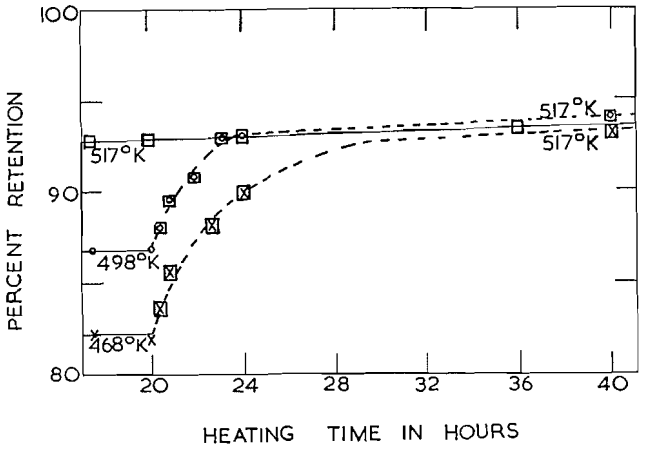

FIG. 2. For potassium chromate irradiated for one week at pile factor of 0.1; plots showing retention values in per cent versus heating time for material heated first at 468 °K. or 498 °K. and then at 517 °K. compared to the values for material heated only at 517 °K.

quickly rises to the pseudo-equilibrium value appropriate to the new temperature. The progress of this change is similar to that in the initial process. This behavior is not compatible with the explanations already proposed in connection with Fig. 1, which are based on the assumptions of competing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

reactions. Retention changes are irreversible and are always in the direction of increasing retention. Subsequent cooling thus does not lead to reduction.

The nature of the process is indicative of a diffusion-controlled mechanism. Under certain circumstances this may lead to a parabolic or third order dependence on the time. Fig. 4, however, shows that no such power relation

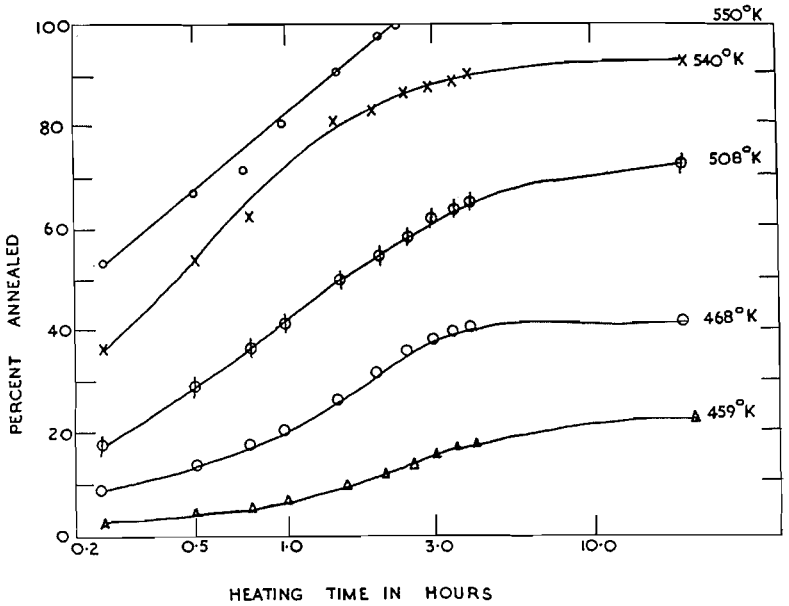

FIG. 4. For potassium chromate irradiated for one week at pile factor 0.1; plot of the percentage of the maximum retention change which has been effected versus the heating time in hours, on a logarithmic scale, for the heating temperatures indicated on the right of the figure.

For personal use only.

between the extent of the reaction and the time of heating exists. Other relations have been derived for a mechanism involving a small number of diffusion jumps, but none of these predicts the pseudo-equilibrium after a few hours heating at each temperature which appears to be so characteristic of the process.

It is noteworthy that a simple linear relation is found between the change in retention from the zero-time value to the pseudo-equilibrium value and the reciprocal of the absolute temperature of heating. Fig. 5 shows the results obtained in this investigation and Fig. 6 shows the only other data in the literature that is sufficiently extensive for this type of treatment (studies made on irradiated potassium bromate (8)).

With regard to the identification of the reaction responsible for these effects which have just been discussed, it is interesting to inquire as to the type of kinetic behavior which would be predicted for such a process. The hypothesis postulates that a single reaction is involved: the recombination of active CrO^{+4} fragments with the oxygen ions that they lost upon formation. As the fragments do not recombine at an appreciable rate at room temperature, it must be supposed that the process has an activation energy, U. The CrO^{+4} and oxygen ion fragments will be supposed to be separated by various distances, X. With their opposite charges they will be electrostatically attracted and thus the effective energy of activation for the recombination process will be reduced.

The process now becomes analogous to the growth of the very thin oxide films treated by Mott (16). The rate of recombination at time t after commencement of heating will be given by the product of two terms,

$$dR/dt = e^{-U/kT}\, e^{V/kTX},$$

where X is the smallest separation of the fragments at time t, T is the absolute temperature, k is Boltzmann's constant, and V will involve the charge on fragments, dielectric constant, and other terms. Now a relation between R and X appears to exist.

Suppose that all the chromium fragments are placed at some common origin and their oxygen ion partners will be strung out in a line drawn from this origin. None will be closer than some separation of X_0 as all at smaller distances will be assumed to recombine immediately after formation to give rise to the zero-time retention of R_0. None will be farther away than some value X_∞ since the initial recoil can effect such a maximum separation. As R changes from R_0 to 100% by heating, the oxygen ions with separations ranging from X_0 to X_∞ will recombine with their partners. If the oxygen ions are uniformly distributed between X_0 and X_∞, the change in retention will be a linear function of X.

$dR/dt = e^{-U/kT}\, e^{V/kT(\Delta R + S)}$, where ΔR is the retention and S is some constant term.

This expression cannot be integrated simply but it does fit the data reported above and it explains all the salient features of this data. The kinetic aspects

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

of the increase in retention on heating are therefore analogous to the formation of the very thin oxide films. When heating is begun, ΔR is small and the second term in the expression for dR/dt is large and dominates the rate of reaction. As ΔR increases the second term soon becomes approximately unity and the rate of retention increase is then determined by the first term which will be small if U is large. This corresponds to the ultimate very slow increase in retention.

Suppose we consider that the second term becomes effectively unity when $V/kT(\Delta R_e + S) = \alpha$. This expression will then relate ΔR_e, the pseudo-equilibrium change in retention to the temperature of heating, T. It also accounts for the experimentally observed linear relation between $1/T$ and ΔR_e.

A more detailed development of this model for the thermal recombination process and its relation to the kinetics of some of the processes in solids will appear in a subsequent publication.

ACKNOWLEDGMENT

THE SOLVENT EXTRACTION OF PROTACTINIUM[1]

By A. Goble, J. Golden, and A. G. Maddock

ABSTRACT

The variation of the experimental extraction coefficient for protactinium upon dilution of the solvent ketone with benzene has been determined for aqueous solutions at constant concentration of hydrochloric acid. The bromo complex has been shown to be far less readily extracted. The effects on the extraction of the nitrate complex by amyl acetate, of the nitric acid, of the nitrate and hydrogen ion concentrations in the aqueous phase, as well as of the dilution of the solvent with benzene, have been explored. The existence of a slow reaction in the extraction has been demonstrated. It is concluded that chloride solutions are the more reliable for the isolation of protactinium from concentrates.

Several observations on the extraction of the complex chlorides and nitrates of protactinium from aqueous solutions by organic solvents have been reported. The earliest of these to become generally available were two very brief documents declassified by the United States Atomic Energy Commission in 1948 (6, 7). No details were included in these notes. However, a few quantitative observations on the extraction of protactinium, by 2,2′-dichlordiethyl ether, from aqueous solutions containing various concentrations of chlorides and hydrochloric acid, and for eight other solvents under fixed conditions in the aqueous phase, appeared in the following year (5).

Until quite recently the only additional information to appear was the description of the extraction by tributyl phosphate, diisopropyl carbinol, and diisopropyl ketone contained in a brief report on the separation of natural protactinium due to Elson *et al.* (1). A great deal more information became available with the publication of Volume 14A of Division IV of the National Nuclear Energy Series. Few of the original papers quoted in this volume (8–19) are available in England. Many of the investigations refer to extraction from solutions at moderate or high salt concentrations. Some early work by Yaffe *et al.* (19) on the extraction by ketones, and by a number of later workers on tributyl phosphate (17, 8), are mentioned. Various investigators have made use of solvent extraction in the separation of natural protactinium from refinery residues (14, 18). Cyclic procedures for this purpose have been made possible by Kraus and Garen's discovery that the extraction could be suppressed by fluoride ion, but again became possible when the free fluoride was complexed by aluminum ions (11). The most extensive studies reported, however, refer to the extraction by diisopropyl ketone from nitrate solutions (9, 10). Hyde and Wolf have shown that extraction by diisopropyl ketone is possible from simple solutions in nitric acid. They have studied the variation of the percentage extraction with the concentration of acid and also with the concentration of additional nitrate ions at constant acidity. Kraus and Van Winkle (13) are reported to have extended these studies to chloride systems and a few of their results are tabulated in Volume 14A. Diisopropyl

carbinol is alleged to be preferable in some respects to the ketone but no quantitative information has been published (16, 15). Mention is also made of the extraction of protactinium by amyl acetate (Volume 14A, p. 126) but the reference quoted appears to be erroneous. Two years ago, before the above information became available, a detailed study of the solvent extraction of protactinium was commenced in connection with a program for the separation of a quantity of natural protactinium. The results are more extensive than and, in some respects, different from those reported in Volume 14A of the National Nuclear Energy Series. Part of the results referring to chloride solutions will appear elsewhere (3). In this paper some additional data on chloride solutions will be presented together with some observations on nitrate solutions.

Kraus and Van Winkle (13) have concluded that chloride solutions are preferable for work with natural protactinium and that their behavior is generally more reproducible than that of nitrate solutions. A number of experiments in the exploratory stages of this investigation led to the same conclusion but some quantitative investigation of the nitrate system seemed desirable.

EXPERIMENTAL

Materials

The benzene and amyl acetate were analytical reagent quality solvents and were not redistilled before use. The diisobutyl ketone was a technical quality material but was purified by fractional distillation. The fraction used boiled between 166° and 168°. The commercial manufacture of diisopropyl ketone ceased during this investigation and the material used was prepared by the careful oxidation of 2,4-dimethylpentane-3-ol with cold potassium dichromate. The product was purified by fractional distillation and the fraction boiling between 124° and 126° was used.

All the experiments were conducted with natural protactinium. The separation of the stock material will be described elsewhere (2). The final purification was conducted with solvent extraction cycles using diisopropyl ketone and chloride solutions (3). The product was stored in solution in 6 *N* hydrochloric acid in a polythene vessel. The stock solution contained about 1 mgm./ml. of protactinium. Spectroscopic analysis showed that less than 2% of impurities was present (2).

Procedure

The solutions of the solvents in benzene were made up by volume. In all cases one milliliter volumes of solvent and aqueous phases were used. The aqueous phases were prepared by the addition of a standard aliquot of the protactinium stock to a much larger volume of solution made up to contain the desired concentration of acid and, in some cases, salts. The acidity of the resultant solution was redetermined by titration of an aliquot.

Losses of material by adsorption, or possibly ion exchange, on the walls of the containers were greatly reduced by the almost exclusive use of polythene vessels. These and other precautions are described elsewhere (3). Equilibration was achieved by the agitation of the snap-closure polythene capsules, used to

For personal use only.

contain the mixture, in a vigorous mechanical shaker for 10 min. No attempt was made to thermostat the mixture, since previous work on the chloro complexes only showed an extremely small temperature coefficient (3). Room temperature varied between 18° and 22°.

The protactinium was estimated by the measurement of its alpha activity in the two phases. Suitable aliquots from each phase were evaporated onto copper or aluminum foils and counted under a scintillation counter with standard geometrical conditions. Care was taken to check the activity balance and losses were kept below 1%.

Results

The effect of dilution of the solvent with benzene was investigated in 6 and 8 *N* hydrochloric acid solutions with diisopropyl ketone and at the latter acidity with diisobutyl ketone. The diisopropyl ketone solutions were pre-equilibrated with the 8 *N* hydrochloric acid before use. The results are shown in Fig. 1.

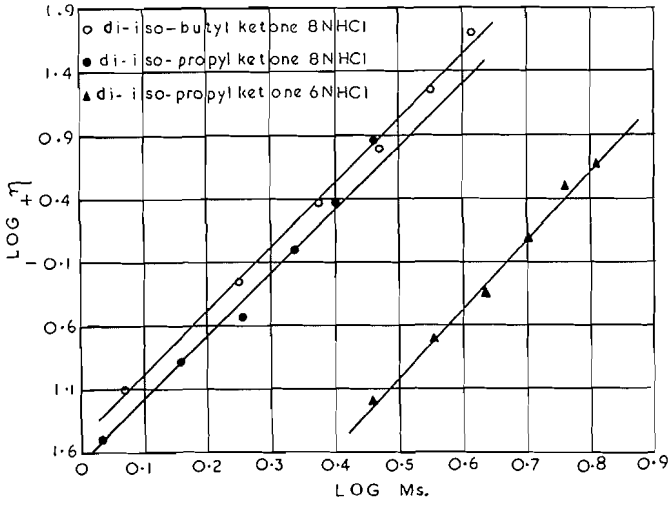

FIG. 1. Variation of η, the apparent extraction coefficient or ratio of protactinium in the organic and aqueous phases, with the molarity of the ketone in the benzene solution extractant.

A comparison of the behavior of the chloro and bromo complexes was made using diisopropyl ketone as solvent. The hydrobromic acid stock used was prepared by re-extracting a ketonic solution of the chloro complex with dilute hydrobromic acid and adjusting to 6 *N* in hydrobromic acid after separation. The original extraction was made from a sufficiently dilute acid solution to avoid any appreciable extraction of hydrochloric acid by the solvent. The results are shown in Fig. 2. The solvent was not pre-equilibrated with the various concentrations of acid used.

The extraction of protactinium from nitric acid or nitrate solutions by amyl acetate was found to increase with the time allowed for equilibration. Measurements were made at the end of the usual 10 min. agitation and also following a similar agitation after varying periods of time in quiescent contact. The

nitric acid stock was prepared in a similar manner to the hydrobromic acid solution. The results are shown in Figs. 3 and 4. In each case the solvent was pre-equilibrated with the appropriate concentration of acid before admixture with the active solution. The effect of the dilution of the amyl acetate with benzene was also studied after varying periods of equilibration. The results are shown in Fig. 5.

The effect of change in the acidity of the aqueous phase was studied at constant total nitrate concentration and approximately constant ionic strength by using various mixtures of nitric acid and ammonium nitrate. Measurements were made after various times of contact. The solvent was not pre-equilibrated with the aqueous phase before addition of the active solutions. The results are shown in Fig. 6. .

Finally the effect of increasing the nitrate concentration at constant acidity was studied. The influence of the time of equilibration was explored. The results are shown in Fig. 7.

DISCUSSION

Most of the data reported above were obtained during a study of the separation of natural protactinium. They refer, therefore, to systems of empirical interest rather than to those that might be most illuminating from the point of view of the nature of the solvent extraction process. Thus the effect of only one of the relevant variables has been studied at constant ionic strength of the aqueous phase. A more detailed study, suitable for analysis in the manner developed by Irving and his collaborators (4), will appear shortly.

The apparent extraction coefficients, or ratios of protactinium in the organic to the aqueous phases, are considerably greater for strongly acid solutions and diisopropyl ketone as the solvent than any previously reported values (13). Indeed, they compare favorably with the values for highly salted solutions with other solvents. Except at the highest concentrations of acid neither ketone showed any considerable mutual miscibility with the aqueous phase. Neither did they extract hydrochloric acid in appreciable amounts.

The extraction of protactinium from hydrobromic acid only takes place at considerably higher concentrations than are necessary with hydrochloric acid. In neither case does the apparent extraction coefficient decrease again at concentrations of acid less than 8 *N*. Measurements have not been extended beyond this concentration because mutual miscibility becomes important. Unlike the majority of metals it appears that the bromo complexes are less stable than the chloro complexes of protactinium. A logarithmic plot of the apparent extraction coefficient against the concentration of acid in the aqueous phase is surprisingly nearly linear for both acids. The slope of these curves is about 14 for the hydrochloric acid and nearly 26 for the hydrobromic acid. These high slopes are due to the high activity coefficients of the acids in this concentration region, thus the slope of a similar plot using the activity of the acid is only 5 for the hydrochloric and about 9 for the hydrobromic acid. Such a result is compatible with, for instance, $PaOCl_6^{3-}$ and H_2PaCl_7 as the principal protactinium containing species in the aqueous and solvent phases, respectively, ignoring solvation.

The slopes of the plots shown in Fig. 1 are 5.2 and 4.9 for 6 and 8 *N* hydrochloric acid for the benzene dilutions of diisopropyl ketone, and 5.0 for 8 *N* hydrochloric acid and the benzene dilutions of diisobutyl ketone. Although these observations do not extend to such dilute solutions as would be desirable they indicate that the complexes extracted by either ketone are solvated with 5 molecules of that ketone. It will be noted that this figure is different from the value, 3, previously reported for diisopropyl ketone (3). The difference has been shown to be due to the presence of a small quantity of diisopropyl carbinol in the earlier samples of the ketone. The behavior of such mixtures will be discussed in a subsequent publication.

In the amyl acetate – nitric acid system the apparent extraction coefficient increases with time, Fig. 3, and the nature of the extracting complex changes. As a result the dependence of the apparent extraction coefficient on the hydrogen and nitrate ion concentrations in the aqueous phase changes with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

the time of equilibration. A nearly linear relation is found between the logarithm of the apparent extraction coefficient and the concentration of acid in the aqueous phase, in the absence of added salts, Fig. 4. The slope of the line, however, changes with the time of equilibration. The extraction by varying dilutions of amyl acetate in benzene, Fig. 5, suggests that the number of amyl acetate molecules associated with the complexes does not change. The slope of each line is about 2.3. A similar logarithmic plot shows that the apparent extraction coefficient depends on the 1.9 power of the hydrogen ion concentration after 10 min., the 2.6 power after 12 hr., and the 3.3 power after three days, all experiments being conducted at constant protactinium and nitrate concentrations, Fig. 6. The nitrate dependence, at constant acidity, however falls from the second power at 10 min. to independence at 24 hr.

It is not difficult to suggest species satisfying the behavior of the protactinium after long periods of equilibration, for instance, the third power dependence on hydrogen ion concentration and independence of nitrate concentration would arise if the complex were $HPaO(NO_3)_4$ and the dominant species in the aqueous solution $PaO_2(NO_3)_4^{3-}$. It is more difficult to suggest plausible initial species since the dependence on the second power of both the hydrogen and nitrate ions requires that both complex and aqueous species are either charged or uncharged.

The possibility that this slow change is due to hydrolysis of the amyl acetate has been considered. No considerable decomposition of the ester takes place during the period of the experiments. Addition of acetic acid up to 5% has little influence on the extraction. Amyl alcohol does enhance the extraction but seems unlikely to be responsible for the above-mentioned changes.

Both the nitrate and bromide complexes appear to be weaker and less readily extracted than the chloride complexes. Solutions of the former complexes in both aqueous and organic solvents more readily lose protactinium on the walls of containers than do the chloride complexes. These disadvantages taken in conjunction with the evidence of slow changes in the nitrate systems clearly indicate that chloride solutions are most suitable for extraction purposes.

The work described in this paper was subsidized partly by the British Admiralty and partly by the United Kingdom Atomic Energy Research Establishment. One of the authors (J.G.) was attached to the Services Electronics Research Laboratory, Royal Naval Scientific Service, during the period of these studies, and another (A.G.) acknowledges a grant from the United Kingdom Atomic Energy Research Establishment.

THE YIELDS OF ^{129}I IN NATURAL AND IN NEUTRON-INDUCED FISSION OF URANIUM[1]

By B. C. Purkayastha[2] and G. R. Martin

ABSTRACT

Measurements have been made, by a radioactivation technique, of the ^{129}I formed in uranium by pile-neutron-induced fission, and in pitchblende by the natural fission of uranium. The amount found in the pile-neutron-irradiated uranium corresponds to a fission yield of 0.90% at mass 129. The natural production of ^{129}I in pitchblende is discussed in the light of the mass-spectrometric measurements of spontaneous fission xenon made by Thode and his collaborators. An upper limit of 1 part in 10^8 can be set for the occurrence of ^{129}I in natural iodine. The pile neutron capture cross section of ^{129}I has been measured as 35 barns.

INTRODUCTION

The measurement of the yield of one of the products of the spontaneous fission of uranium may be approached in one of two ways: by measurement of the activity in secular equilibrium with a known quantity of uranium, or by measurement of the rate of accumulation of a stable end product. The first method, although simple in principle, involves an extremely difficult decontamination problem in all but the most favorable cases. The second approach demands a degree of freedom from contamination by 'primordial' material isotopic with the substance sought which is unlikely to be attainable except in the case of the rare gases Xe and Kr. There is, however, a small intermediate class of nuclides with half-lives so long that a substantial mass of product can be accumulated, but at the same time short enough to ensure the complete absence of 'primordial' contamination. There are few such bodies amongst the products of the fission of uranium, and of these only one, ^{129}I, lends itself to estimation (by radioactivation (6)) in the extremely small amounts likely to be encountered.

The procedure adopted involved:

(*a*) the extraction of iodine from the sample, after addition of a known amount of carrier, using a method such that the chemical yield could be assessed in terms of the measured yield of carrier material, and

(*b*) the estimation of the ^{129}I by neutron activation, measuring the 12.6 hr. ^{130}I produced.

The same procedure was used to estimate the yield of ^{129}I in the pile-neutron-induced fission of uranium. Incidental to the main measurements are values obtained for the pile neutron capture cross section of ^{129}I, and for an upper limit to the natural abundance of this nuclide.

EXTRACTION OF ^{129}I FROM PITCHBLENDE

A rough calculation showed that it would be necessary to use about one kilogram of pitchblende for each determination, and it was necessary to

For personal use only.

extract from this a known (preferably high) proportion of its fission product iodine content without the addition of more than a few milligrams of carrier iodine.

Two means are available to ensure that the chemical yield of carrier shall be equal to that of the fission product iodine (which may, initially, be in any one of four valency states): (i) to recover virtually 100% of both; or (ii) to effect complete equilibration between carrier and trace material before any separation is made. In the method finally adopted, it was demonstrated that yields of better than 98% were obtained in a preliminary separation involving the distillation of elementary iodine from the pitchblende solution. Since, during this step, *all* the iodine was in the elementary form, equilibration must have been complete, and no fractionation of carrier from carried material could have occurred in the course of subsequent purification. This procedure was tested with small quantities of pile-irradiated pitchblende in which it may be assumed that the iodine resulting from neutron-induced fission is in the same form as that from spontaneous fission.

The method used was as follows:

(i) Two-hundred-gram lots of pitchblende were placed in a flask with about 0.1 mgm. carrier iodine in the form of potassium iodide and the mineral dissolved, under reflux, in nitric acid (the only reagent which satisfactorily attacked all our pitchblende samples). It is to be expected that during this process of dissolution iodide will be oxidized to elementary iodine, and some of this may well be further oxidized to iodate; in addition the spontaneous fission product iodine may, in part, have been present initially in this form.

(ii) Nitrous fumes were removed by a current of nitrogen and a further 0.1 mgm. of carrier iodine added. The solution was then distilled until 80% of the total volume had passed over. A curious feature of this process is the fact that, although the major part of the iodine comes over quite quickly, a substantial fraction distills only after about 60% of the original volume has come over. Table I shows a typical distribution of the activity from a sample

TABLE I

DISTILLATION OF IODINE FROM 1100 ML. OF SOLUTION OF PITCHBLENDE IN NITRIC ACID: DISTRIBUTION OF ACTIVITY IN DISTILLATE

ml. distilled	% of activity recovered
170	63
220	8
170	3.6
130	2
220	21
910 ml.	97.6%

of pitchblende treated in this way. Similar distributions of activity were obtained whether the active iodine was added as iodide, iodate, or in the form of neutron-irradiated pitchblende.

The carrier iodine was normally lightly labelled with 8 day ^{131}I to facilitate the estimation of chemical yields; this activity was in any event small, and was

allowed to decay away before the radioactivation measurements were made.

(iii) The iodine distilled from the pitchblende solution was trapped in caustic soda solution which was subsequently evaporated to small bulk, and a further distillation step (with nitric acid + oxalic acid) carried out. The distillate from this operation was trapped in carbon disulphide, from which the iodine was extracted by alkaline sulphite and reduced to a standard volume (10 ml.) for measurement by means of a liquid counter (by comparison with a further aliquot of the initial carrier solution).

(iv) Four or five such operations, using 200 gm. of pitchblende, were carried out and the products combined for the preparation of a source for radioactivation analysis.

EXTRACTION OF ^{129}I FROM PILE-IRRADIATED URANIUM METAL

The chemical problem here is a good deal simpler than in the mineral case, since one starts with a chemically pure material; one, furthermore, in which the iodine may be expected to be present in a reduced form (7). Three 5 gm. pieces of uranium metal which had been irradiated in the Harwell pile ('BEPO') and allowed to 'cool' for about one year were available. ^{129}I would be effectively the only remaining radioactive iodine isotope after such a period.

The uranium pellets were dissolved, under reflux, in 50% nitric acid containing 0.5 mgm. of ^{131}I-labelled iodine in the form of iodate. After dissolution, a further 0.5 mgm. of iodine was added (also as iodate) and the solution diluted fivefold. Oxalic acid was then added, and the iodine distilled from the solution and trapped in alkali as before. The subsequent purification of the iodine so collected was carried out in the manner already described for the pitchblende samples.

RADIOACTIVATION PROCEDURE

The relevant neutron-induced reactions are:

$^{129}I(n, \gamma)^{130}I$ (12.6 hr. β emitter)

$^{127}I(n, \gamma)^{128}I$ (25 min. β emitter)

$^{127}I(n, 2n)^{126}I$ (13 day β^+, β^- emitter).

Neutron irradiations were made in BEPO at a flux of $\sim 1.5 \times 10^{12}$ n./cm.^{2}/sec. for one day. Approximately 14 hr. elapsed between the end of the irradiation and the start of counting of the samples, largely accounted for by the time for transporting the irradiated material from Harwell to Durham. The 25 min. ^{128}I had by then decayed away to a negligible level, leaving only the 13 day ^{126}I to be resolved from the ^{130}I activity. The residual 13 day activity was in fact used to measure the chemical yield in the preparation of samples for activation analysis. In addition, small pieces of thin copper wire ($\sim$2 mgm. each) were simultaneously irradiated, to serve as a 'flux monitor'; the ^{64}Cu activity induced in the copper,

$$^{63}Cu(n, \gamma)^{64}Cu(12.8 \text{ hr. } \beta^-, \beta^+, K),$$

has a half-life value so close to that of the ^{130}I activity being measured that an accurate knowledge of the time-dependence of neutron flux is not needed.

(*i*) *Preparation of Samples for Radioactivation Analysis*

Iodide carrier was added to the samples, sufficient to bring the total iodine content to about three milligrams, and the solution made slightly acid with hydrochloric acid. Palladous iodide was then precipitated by the addition of a 1% aqueous solution of palladous chloride (16). The precipitate was filtered off on a small asbestos pad held in a constriction in 5 mm. tubing, and washed with a small quantity of water. The filter tube was cut, and the portion containing the precipitate dried thoroughly at 110°C. before placing inside a silica tube which was then evacuated and sealed. The end of the silica tube containing the palladous iodide was then heated for one hour at 370°C., during which time the iodine which was quantitatively liberated was distilled into the other end of the tube which was subsequently sealed off at a constriction. The elementary iodine contained in the small silica ampoule so formed was sent for irradiation together with

(*a*) a weighed sample of isotopically normal lead iodide, and

(*b*) a weighed piece of thin copper wire,

each being contained in similar silica ampoules, all of which were placed within the same aluminum capsule for irradiation.

(*ii*) *Treatment of Iodine Samples after Irradiation*

The following sequence of operations was designed to isolate the iodine activity free from any possible contamination by bodies with similar half-lives (especially 15 hr. ^{24}Na, 12.4 hr. ^{42}K, and Br (4.5 hr. + 36 hr.)) which might present difficulties in resolution.

The silica tube containing the iodine was crushed under water containing about 40 mgm. of carrier iodine as iodide. About one milligram of iodine was also added as iodate, and the whole reduced to iodide. The solution was made alkaline and boiled to ensure complete equilibration of the carrier with any iodine adsorbed on the silica of the ampoule. Potassium bromide was added as holdback carrier, and the iodine distilled from the solution after addition of sodium nitrite and sulphuric acid.

The distillate was collected in alkaline sulphite with more added bromide holdback, and iodine extracted into carbon tetrachloride after addition of sodium nitrite and sulphuric acid. The iodine was recovered from the organic layer after separation, by shaking with fresh alkaline sulphite containing more potassium bromide. This cycle of oxidation, extraction, reduction, and de-extraction was repeated four times to ensure that the iodine finally counted was free from impurities, especially from active bromine nuclides—bromide ion is not oxidized by acid nitrite solution, and does not therefore extract.

Iodine was finally precipitated as cuprous iodide by the addition of sulphur dioxide and cupric sulphate solution. The precipitate centrifuges well and spreads uniformly on the counting planchettes. Counting was carried out in a reproducible position close to the mica window of a 'bell-jar' type of Geiger–Müller tube, and was continued long enough to obtain a decay curve from which could be resolved the ^{130}I and ^{126}I activities.

(iii) Treatment of Lead Iodide and Copper Samples

The lead iodide ampoules were treated by essentially similar procedures to those outlined above although speed was no longer necessary, and the need for so rigorous a purification was less. Samples were finally mounted as cuprous iodide, and the 13 day ^{126}I activity measured.

The copper wire was dissolved in nitric acid containing a known weight of cupric ion as carrier. The solution was scavenged by precipitating from it small quantities of silver chloride and of ferric hydroxide, and the copper finally precipitated as cuprous thiocyanate. The precipitate was washed, slurried with acetone, and mounted on nickel planchettes for counting as above.

(iv) Treatment of Counting Results

Corrections were applied where appropriate

(*a*) for 'losses' due to the finite resolving power of the counting apparatus,

(*b*) for differences in self-absorption correction between sources (from an empirical correction curve),

(*c*) for radioactive decay,

(*d*) for chemical yield. (Chemical yields in the radioactivation procedure were estimated by comparison of the ^{126}I activities induced in the weighed lead iodide sample and in the unknown, respectively.)

Activities were finally expressed with reference to a hypothetical thinly-spread source containing the whole of the activity at an arbitrary zero-time.

(v) Calibration of Radioactivation Procedure

To render absolute the relative measurements made by the radioactivation procedure, an irradiation was carried out as described above, of a sample of palladous iodide prepared from iodine extracted from an old pile-irradiated uranium slug.*

Fission product iodine is largely ^{129}I (after the short-lived species have decayed away) and it is possible to calculate with fair precision the amount of this nuclide in the sample irradiated, and thus to obtain a value for the ratio

$$\frac{^{130}I \text{ activity/mgm.}^{129}I \text{ irradiated}}{^{64}Cu \text{ activity/mgm.Cu irradiated}}$$

needed for the absolute evaluation of the radioactivation measurements.

ESTIMATION OF NUMBER OF FISSIONS IN IRRADIATED URANIUM SAMPLES

In the absence of precise information as to the integrated neutron dose received by the irradiated uranium pieces, the total number of fissions which had occurred in each was estimated, after dissolution and extraction of the iodine, by an absolute measurement of the ^{144}Ce fission product β-activity in an aliquot of the resulting solution. A known quantity of cerium carrier was added and cerium precipitated as cerous fluoride. A succession of reprecipita-

*We are grateful to Dr. W. J. Arrol of the Atomic Energy Research Establishment, who carried out this extraction.

tions was then carried out (as fluoride, hydroxide, and iodate in turn) with holdback carriers for those elements represented by long-lived fission products, and an aliquot of the ultimate solution finally mounted for counting. A gravimetric determination of cerium in the remainder of the solution gave a value for the chemical yield of the purification procedure.

The β-particles from ^{144}Ce are rather soft, and the counting measurement was actually made on the much more penetrating β-particles from the ^{144}Pr daughter, the ^{144}Ce radiation having been filtered out from the equilibrium mixture. The efficiency of the counting apparatus was determined by means of the UX_2 β-radiation in equilibrium with a known mass of uranium.

RESULTS AND DISCUSSION

(*i*) *Capture Cross Section of ^{129}I for Pile Neutrons*

From the irradiation of the weighed sample of fission product iodine we obtain, after correction for chemical yield, radioactive decay, etc.:

$$\frac{^{130}\text{I activity/atom } ^{129}\text{I}}{^{64}\text{Cu activity/atom } ^{63}\text{Cu}} = 14.2$$

so $\sigma_{129} = \sigma_{63} \times 14.2$, since $\lambda_{130} \simeq \lambda_{64}$. Here σ_{129} is the pile neutron activation cross section for ^{129}I, and σ_{63} is the similar quantity for ^{63}Cu (relating only to that fraction of the product which decays by β emission). Recent values for the neutron capture cross section of copper are 3.4, 3.50, 3.66, 3.63, and 3.57 barns (1, 3, 10, 4, 11). Taking an average value of 3.5 barns, and using the ratio $\sigma_{63}/\sigma_{65} = 2.3$, obtained mass-spectrometrically by Reynolds (13), we obtain $\sigma_a^{63} = 4.24$ barns, in good agreement with the value 4.3 barns quoted by Pomerance (12). If allowance is made for the fact that 42% of the ^{64}Cu disintegrations go by K-electron capture (5), and will not be recorded in our measurement, the value of σ_{63} to be used is $4.24 \times 0.58 = 2.46$ barns (cf. 2.8 barns obtained by Seren *et al.* (15)).

Using this value, we obtain for the pile neutron capture cross section of ^{129}I the value of 35 barns.

(*ii*) *The Yield for Mass 129 in Pile-neutron-induced Fission*

From the ratio of ^{130}I activity induced in a known mass of ^{129}I to that induced in the samples of iodine extracted from neutron-irradiated uranium we deduce the yield of ^{129}I in pile-neutron-induced fission. Two independent measurements gave values 0.89% and 0.92%. It is known from the work of Thode and Graham (17) that the independent yield of ^{129}Xe in pile-neutron-induced fission is negligible, so that the value, 0.9%, represents the total yield for this mass.

(*iii*) *Upper Limit to Natural Abundance of ^{129}I*

From the absence of ^{130}I activity from the irradiated samples of natural iodine it is possible to set an upper limit to the natural abundance of ^{129}I. We conclude that the ^{129}I/^{127}I ratio in natural iodine is less than 10^{-8}. In view of the shortness of the half-life (8) of ^{129}I in relation to geological time, this result is not unexpected, but it does reduce by a factor of 30 the upper limit previously set by mass-spectrometric investigation (9).

(iv) The ^{129}I Content of Pitchblende

Three samples of pitchblende were investigated, of which only two yielded a final result from which could be calculated a value for the mass of ^{129}I in secular equilibrium with the uranium in the pitchblende. Table II summarizes the

TABLE II

RESULTS OBTAINED FROM TWO SAMPLES OF PITCHBLENDE

	Sample A	Sample B
% U_3O_8 in mineral	82%	64%
^{129}I yield (relative to spontaneous fission rate)	0.48%	0.54%
^{129}Xe yield (relative to total fission rate)* (adjusted to give ^{136}Xe yield = 6.5%)	0.222%	0.301%
Neutron fission rate as fraction of spontaneous fission rate†	0.32	0.49
^{129}Xe yield (relative to spontaneous fission rate)	0.29%	0.45%

**Mass-spectrometric results kindly made available by Dr. W. H. Fleming.*

†Calculated from ^{129}Xe yields on assumption that the fission yield for mass 129 is 0.90% for neutron-induced fission, and 0.01% for spontaneous fission.

results obtained for the two samples. On the assumption that secular equilibrium has been achieved, the apparent fission yield has been calculated as the ratio

$$\frac{\text{disintegrations of } ^{129}\text{I per second}}{\text{spontaneous fissions per second}} \times 100$$

using the ^{129}I half-life obtained by Katcoff, Schaeffer, and Hastings (8) and Segrè's value (14) for the spontaneous fission disintegration constant of uranium.

Dr. W. H. Fleming has kindly carried out mass-spectrometric examinations of the xenon from these two samples of pitchblende, with results also shown in Table II. It is clear from the work of Fleming and Thode (2), and of Wetherill (18), that in a mineral such as pitchblende by no means all the fissions occurring are spontaneous. Furthermore, it is clear that the distribution of products in this mass region is not by any means the same for spontaneous fission and for neutron-induced fission, and that, in particular, the yield at mass 129 in spontaneous fission is very small indeed. The mass-spectrometric measurements give only relative branching ratios for the various stable xenons, and it is necessary to assume a fission yield for one isotope. The values quoted have been adjusted to give 6.5% for mass 136, to agree with the 'smoothed' value for this mass in the neutron fission of uranium; since the yield curve for spontaneous fission has somewhat sharper peaks than the corresponding curve for neutron fission, this estimate may be slightly low. Fission yields obtained in this way have a significance somewhat different from that quoted for ^{129}I; for the mass-spectrometric values, the fission yield is given by the ratio

$$\frac{\text{atoms of } ^{129}\text{Xe formed per second}}{\textit{total} \text{ fissions occurring per second}} \times 100$$

and in Table II we quote also values which we have obtained by adjusting Dr. Fleming's results to the basis on which the ^{129}I yields were calculated.

This has been done by using his measured ^{129}Xe yield to deduce the proportion of neutron-induced fissions in the two samples, and then multiplying his yields by the factor

$$\frac{\text{spontaneous fission rate} + \text{neutron fission rate}}{\text{spontaneous fission rate}}.$$

Bearing in mind the various potential sources of error in this comparison (and especially the fact that the assumed value of 6.5% for the yield of mass 136 in spontaneous fission may be too low) the discrepancy between the two results for sample B is not excessive. The agreement is poorer for sample A, and is in a sense (more ^{129}I than would be expected from the ^{129}Xe result) difficult to explain by any reasonable geochemical hypothesis; it represents an increased yield from neutron fission of uranium during recent geological time whereas the most plausible natural changes (especially radioactive decay of ^{235}U) would tend to produce the opposite effect.

ACKNOWLEDGMENTS

We wish to acknowledge our indebtedness to Dr. H. G. Thode and Dr. W. H. Fleming for mass-spectrometric examination of the xenon from our pitchblende samples, and to Dr. W. J. Arrol for the sample of fission product ^{129}I used for calibration purposes. Thanks are due also to the Department of Scientific and Industrial Research for financial support.

One of us (B.C.P.) wishes to thank the University of Calcutta for the award of a Palit Travelling Scholarship, during the tenure of which this work was carried out.

CHEMICAL EFFECTS OF THE NUCLEAR TRANSFORMATION $N^{14}(n, p)C^{14}$ [1]

By Peter E. Yankwich

ABSTRACT

The physical and chemical behavior of energetic carbon particles in ionic lattices is investigated. Models of the process due to Libby and to Seitz and Koehler are compared for simple and complex ionic crystals. For simple crystals the models lead to practically identical chemical predictions; where polyatomic ions are present, the Seitz–Koehler model appears to give a more satisfactory account of the distribution of radiocarbon over various product species.

INTRODUCTION

There has been considerable experimental effort directed at the elucidation of the chemical consequences of radiative neutron capture reactions; there, the target and product atoms are similar chemically, the recoil energy of the product is modest, a few hundred electron volts at most, and re-formation of the parent molecules may occur. In the case of typical (n, p) reactions, the product recoil energies are of the order of tens of thousands of times chemical bond energies, the product fragment is a chemical impurity in the target substance, and the atomic number change makes it difficult to think of "retention" of the product atom. There has been comparatively little experimental or theoretical work published on (n, p) reactions. It is the purpose of this paper to attempt a correlation of the results of recent research in this area. As a matter of convenience, the discussion will be related to ionic crystals; the extension to molecular and valence solids can be made with little difficulty.

PHYSICAL PROCESSES

*Early History of a Carbon Hot-atom**

At the moment of its creation, the C^{14} particle is in the state of a quadruply charged negative ion with a kinetic energy of about 40 kev. The velocity of this particle is that of an electron of 1.56 ev. energy; therefore all electrons bound to it by less than that energy will be swept off by the field of the ions in the lattice (18), and it will be ineffective in causing the excitation of any electron unless the energy required for such a transition is close to 1.56 ev. (14). The electron affinity of the neutral C atom is about 1.2 volts (12), so a swiftly moving C^{14} archekine may exist as a C^- ion when its kinetic energy has been

[1] *Manuscript received November 17, 1955.*

Contribution from the Noyes Laboratory of Chemistry, University of Illinois, Urbana, Illinois. This paper was presented in part at the Symposium on Nuclear Chemistry and Radiochemistry held at McGill University, Montreal, Que., September 7–9, 1955.

**The problem of terminology in the field of "hot-atom chemistry" has been reviewed by Willard (27). In systems such as those which are the subject of this paper, one could apply terms such as: activated, energetic, hot, recoiling, to the C^{14} product particle with equal correctness. Each of these terms, however, is applicable not only to the C^{14} particle but to one or more others in each collision or nuclear event. While the present imprecise terminology is already hallowed by usage, it seems reasonable, though perhaps deplorable, that better terms might be found. In this spirit, we suggest that one can maintain the focus of one's attention on the C^{14} particle by applying to it the name* archekine (*archein + kinein = prime mover*).

reduced below about 30 kev.; since the electron affinity of C^- is negative, it seems unlikely that carbon more negatively charged than this can exist in the target matrix except where such a carbon fragment is surrounded by positive ions. In general, the electron affinities of doubly or more highly charged negative ions are negative and these ions would furnish the electrons required for the assumption of negative charge by the hot-atom. While the cross sections for ionization and electron excitation are extremely small, the species C^+ could be formed by direct electron exchange processes involving the positive ions of the lattice. Carbon more highly oxidized or reduced than when in the C^+ or C^- states results most likely from *chemical* processes involving the formation of binuclear or more complicated aggregates.

The initial energy possessed by the C^{14} recoil fragment is several thousands of times ordinary chemical bond energies; most of this energy is lost through collisions with or fragmentation of the ions of the target matrix. Occasionally one of these struck ions may thus acquire an energy sufficiently large to produce additional displacements in the lattice.

Libby's Hard-sphere Model

The chemical fate of the C^{14} archekine depends certainly upon the nature of the environment when its energy has been reduced to a level sufficiently low to permit the persistence of chemical combinations or electron displacements. Among other things, the nature of that terminal environment will be influenced by the amount of energy which the hot-atom possessed when trapped effectively by the lattice within some small volume. In an early paper dealing with these matters, Libby (16) assumed that the mean free path of an energetic recoil particle in a simple ionic lattice would be of the order of the mean ionic separation for hard-sphere (billiard ball) type collisions. For example: in beryllium nitride the mean ionic separation is a little over 2 Å* and about 8 hard-sphere collisions with lattice ions are required to reduce the energy of the archekine to the order of 25 ev. The mean separation between the site of production and the site of entrapment is about $2.2\sqrt{8} = 6$ Å. This corresponds to the release of 40 kev. in a volume which contains about 150 ions, an act equivalent to raising the temperature of the region to nearly 10^7 °K. The relaxation time for cooling of such a heated zone would be sufficiently long, about 10^{-9} sec., to permit considerable diffusion to take place. If one assumes that the C^{14} particle is at or near the hottest part of the region, thermal diffusion would tend to increase the influence on it of beryllium ions above that expected from the stoichiometry of the crystal.

The presence in the target of polyatomic lattice units would result in only slight modification of the picture sketched above, in that fragmentation of such ions in the immediate vicinity of the archekine is an energy-lowering phenomenon which must be considered. However, the local temperatures predicted are so high that complete fragmentation of such polyatomic ions would be expected; thus, the initial reactions of the entrapped C^{14} particle would be with atoms or ions of low charge, regardless of whether the target crystal contained simple or complex ions or both.

**Beryllium nitride crystals are of the anti-Tl_2O_3 type, $a = 8.13$; there are 16 Be_3N_2 in the unit cell (25).*

Model Based on Suggestions of Seitz and Koehler

While the collision cross section for archekine – lattice ion encounters may be of the order of the square of twice the mean ionic radius in the crystal when the archekine energy is a few electron volts, it must be much smaller when the energy is hundreds or thousands of electron volts. The model suggested by Libby must be modified in its reference to archekines with energies above, say, 100–200 ev., but seems essentially correct for energies below this range.

At the beginning of its travels in the lattice, the energy of the archekine is sufficiently high that encounters with simple ions are best described by classical Rutherford scattering (20). Small angle collisions are favored and the average energy transferred in a collision is below one electron volt; the hot-atom may be said to produce a *track* in the crystal. Occasionally, a struck ion receives enough energy, about 25 ev. in the case of a well-bound solid (19), to be displaced from its lattice site; detailed consideration shows that the average energy so transferred is of the order of 200 ev. The total collision cross section is of the order of 10^{-17} cm.^{2}, yielding a mean free path of *several tens of Å*. When the energy of the archekine has been reduced to about 6 kev. the collisions become hard-sphere in character.

When the archekine enters the hard-sphere range, its average distance from the site of its production may be several hundred Å; the track which it followed will be surrounded by a cylinder of heated crystal distorted here and there by the appearance of *displacement spikes* (10), spheroidal volumes in which the displaced ion secondaries and their progeny have dissipated their energy to the lattice. In the hard-sphere range, energy transfer is very efficient, 5 or 6 collisions, on the average (16), being sufficient to reduce the energy of a C^{14} hot-atom to 25 ev.; however, the collision cross section does not reach atomic dimensions until the archekine is almost at rest (20). As long as the mean free path is large compared with the mean lattice-ion separation, the motion of the recoil particle is diffusion-like. In Table I are shown some values

TABLE I

MEAN FREE PATH OF HOT-ATOM FOR HARD-SPHERE COLLISIONS; C^{14} IN Be_3N_2(s)

$E_{C^{14}}$ (ev.)	L_s (Å)	L_m (Å)
3000	230	240
1000	62	67
300	20	32
100	9	14
30	5	7

for the hard-sphere range of the mean free path L_s of a carbon hot-atom in the beryllium nitride lattice as computed from equations given by Seitz and Koehler (20). These L_s values are an order of magnitude larger than those one would expect on the basis of calculations by Brinkman (10); the difference arises in the choice of a value to be assigned to a coefficient in the calculation of a screening constant. Seitz and Koehler follow Bohr (9) in selecting a small value. There is indirect experimental evidence that the long mean free paths

calculated by the method of Seitz and Koehler are reasonable, in a now considerable body of experimental data on the collision cross sections of neutral atoms; we assume that the motion of a carbon archekine in an ionic lattice may be likened to diffusion of a neutral atom in a still atomic gas. Using this model one need but estimate the repulsive potential for the hot-atom interaction with the average lattice ion in order to compute a collision cross section, and from it a mean free path. The values of the mean free path L_m based upon H–H_2 (4, 7), He–He (1, 3), He–A (6), and A–A (2, 5, 8) high energy scattering data are given in Table I.

When we consider the slowing down of an archekine in an ionic crystal in which one of the species is polyatomic we see that the properties of this model are very different from those of the Libby hard-sphere model. In this case effective entrapment of the hot-atom is impossible much above energies of the order 100–200 ev.; thus, the amount of energy which can be dissipated to the lattice about such a site is quite modest, and atomization of the polyatomic ions nearby is not to be expected to be anything like complete. Fragmentation of these complex ions will occur, but the scale of the demolition process is of a much lower order than that predicted by Libby's model in which the entire recoil energy of the archekine is released from a very small volume.

As the energy of the archekine falls to a few hundred electron volts, its collision cross section becomes so large that the remainder of its kinetic energy will be dissipated within a compact volume whose radius is of the order of its mean free path, only two or three collisions with lattice ions being left to it. Each of these remaining collisions will produce within the volume mentioned a *hot-spot*, i.e. a region where the archekine and/or displaced secondary (*knock-on*) reach kinetic energies of the order of 25 ev. in coming to rest, or where a struck ion receives a little less than the threshold energy for displacement (20); the energy associated with the hot-spot in which the archekine is finally trapped by the lattice is thus 25–50 ev.

The 25–50 ev. in the terminal hot-spot is, at first, shared by the archekine and a few near neighbors; if 5 particles share this energy, their equivalent temperature is of the order of 10^5 °K. When the radial diffusion of this energy has progressed to the point where a volume about that of a unit cell is involved, the temperature of the region will have fallen to 2500°K., which, for example, is the fusion temperature of beryllium nitride. The chemical fate of the archekine must be determined largely during this cooling period, the relaxation time for which is of the order of 10^{-12} sec. This time is so short that the disorder characteristic of the molten state probably is not achieved except in the center of the hot-spot (20), but some disorder may be entrapped in the freezing process. About one electron volt per ion is tied up in a typical dislocation ring (21) and release of several electron volts from such a source could provide easily the activation energy required for reaction with the solvent of an entrapped archekine close by. If polyatomic ions are present the effective local temperature will be even lower than that calculated above because of the uptake of energy in fragmentation processes.

It is important to note the different possible effects of diffusion-like processes occurring before freezing of the hot-spot which would be predicted from the

Libby and Seitz–Koehler models. In the former case, where the archekine is trapped within a small volume at the very outset, a given kind of rate process would have many chances to occur in the 10^{-9} sec. lifetime of the region; in such a situation thermal equilibrium would be attained over quite an appreciable volume, and ions relatively far from the archekine might diffuse to it before cryosis set in. The Seitz–Koehler model of the process leads to the prediction that only a small part of the original energy of the archekine is available in the terminal hot-spot, and a given kind of rate process would have only a few chances to occur in the 10^{-12} sec. lifetime of the region; in such a situation thermal equilibrium is established over a volume containing only 5 or 10 ions, and only near neighbors of the archekine could diffuse to it before solidification of the hot-spot.

CHEMICAL PROCESSES

As has been mentioned above, the specifically chemical consequences of these two different final environmental situations would likely be quite similar for simple ionic targets. We would expect different chemical phenomena to occur were the targets molecular crystals or ionic solids containing molecular ions. As an example, consider the target ammonium bromide. Production of a long-lived, high temperature hot-spot would likely involve the complete demolition of ammonium ions in the vicinity of the hot-atom; as cooling occurred, competitive reactions among C, N, Br, and H would determine the spectrum of chemical species observed upon solution of the target. Where a short-lived, low temperature hot-spot is produced, only partial fragmentation of ammonium ions is possible energetically; upon cooling, competitive reactions among C, H, and fragments such as NH, NH_2, and NH_3^+ would determine the distribution of radiocarbon over various chemical forms upon solution of the irradiated material. The Libby model results in a concentration of energy sufficient to permit the formation of H^+ which might tend to oxidize the archekine; the Seitz-Koehler model predicts that much less energy than this will be available and, since it costs about one electron volt less to remove a hydrogen atom from an ammonium ion than to remove a proton (23, 26), the hydrogen made available would tend to reduce the carbon archekine.

In simple ionic crystals where the nature of the target is such that few carbon-containing aggregates can be formed and where only one or two kinds of terminal hot-spot environment can come into being, the amount of energy actually available in the terminal hot-spot may exert a critical influence upon the final chemical state of the archekine trapped there; in fact, the distribution of product radiocarbon over various oxidation states for such targets may be a simple reflection of the distribution of terminal hot-spot energies. For more complex systems, the Libby and Seitz-Koehler models again predict different results. Because of the long life of its kind of hot-spot, one would expect from the Libby model some dependence of the final chemical state distribution upon the recoil energy of the hot-atom (at the 10^3–10^5 ev. level); in the Seitz–Koehler model no processes have chemical significance before entrapment of the archekine (at the 10–100 ev. level), so no effect of recoil energy variation should be noted provided that energy was always

higher than the highest possible entrapment energy. In this regard it is interesting to note the results obtained by Schuler (24) and by Holmes and McCallum (13). Schuler studied the retention in liquid methyl and ethyl iodides of iodine activated by the processes (d, p), $(n, 2n)$, and (γ, n) and observed the same retentions as in radiative neutron capture (15); Holmes and McCallum obtained similar results when the retention of copper in solid copper salicylaldehyde-*o*-phenylenediimine after the process (γ, n) was compared with the effect of the (n, γ) reaction (11).

It may be difficult to unravel the effects of nature of target material and solvent. Where the ion charges in a simple ionic crystal target are not very different we would expect carbon hot-atoms to come to rest in terminal hot-spots exhibiting a more or less symmetrical distribution of oxidizing and reducing characters. This should result in a similarly symmetrical distribution of product radiocarbon among various oxidation states, provided that reactions of the entrapped radicals with the solvent are not entirely of one character; for water solvent, since both its oxidation and reduction can be effected, one should be able to see little modified the oxidation state distribution of the radiocarbon in the terminal hot-spots.

RADIOCARBON PRODUCT DISTRIBUTION

In Table II are collected the results of recently completed chemical fractionation studies of the radiocarbon compounds resulting from the solution in

TABLE II

DISTRIBUTION OF RADIOCARBON AMONG VARIOUS FINAL PRODUCTS

water of a number of irradiated ionic crystal targets. For the systems ammonium sulphate (28), ammonium bromide (30), beryllium nitride (29), and sodium nitrate (31), the nuclear reaction is $N^{14}(n, p)C^{14}$ and the initial archekine energy is 40 kev.; for the systems sodium carbonate (22), and sodium bicarbonate and formate (17), the nuclear reaction is $C^{12}(\gamma, n)C^{11}$ and the initial archekine energy under the irradiation conditions employed was about 0.5 Mev.

The sodium carbonate and ammonium chloride oxidation state distributions, the former peaking in the positive oxidation number range, the latter in the negative, indicate the relatively subsidiary role of the water solvent and the controlling nature of the terminal environment of the archekine; the relative inertness of the bromide and sodium ions is also reflected by the data.

The distribution of radiocarbon products in the beryllium nitride study confirms the expectation mentioned above concerning a symmetrical distribution of product radiocarbon among various oxidation states. An especially important result of the product distributions observed there and in the (γ, n) systems is that they furnish evidence that the skeletons of complex chemical species are formed and persist in the irradiated crystals; there seems to be no mechanism other than formation in the lattice which accounts satisfactorily for the appearance of skeletal types such as C—C, $NC(N)_2$, NCN, CN, and CNN among the final products. In this regard, the formation of methylhydrazine is important because it is the only nitrogenous species in which the oxidation number of N is different from -3 (that of ammonia and nitride ion); this compound may thus be a relic of a C–N electron transfer reaction. Another important feature of the beryllium nitride target results is that the oxidation state distribution peaks at the extremes rather than near neutral carbon. Thus it appears that the several oxidation states are not reached by random walks among adjacent oxidation states.

In ammonium sulphate, hydrogen and oxygen are present in the same ratio as in the solvent; ammonium bromide and sodium carbonate each contain but one element of water; and beryllium nitride contains neither. Table III

TABLE III

PER CENT OF RADIOCARBON VALENCES UTILIZED BY H, O, N, OR C^{12}

Bonded atom	Target						
	$(NH_4)_2SO_4$	Be_3N_2	NH_4Br	$NaNO_3$	Na_2CO_3	$NaHCO_3$*	NaOOCH*
H	24.9	41.3	71.3		5.8	6.5	22
O	63.3	24.4	6.4	98	74.8	76	60
N	10.7	34.3	21.2				
C^{12}					19.5	18.5	19

**At the time this paper is being prepared, degradation information on the two-carbon products in these target systems is not available. In making these rough calculations a random distribution of the radioisotope has been assumed.*

is a compilation for these and other target crystals of the per cent of radiocarbon valences in the final product state utilized by H, O, N, or C^{12}. To this

table we make the following annotations: (1) the ammonium bromide and sodium carbonate data show very good correspondence in the reactivities of the simple ion, central atom, and outer atom in each case; (2) comparison of the ammonium sulphate and beryllium nitride data indicates the powerful scavenging character of crystal oxygen as compared with water oxygen; (3) the shift in the sodium formate oxidation state distribution to a less positive peak compared with that of sodium carbonate is reflected in the sharp increase of bonds to hydrogen, and the lack of change in the carbon bonding percentage is probably an indication that C—C bonds are formed early in the lifetime of a terminal hot-spot when partially stripped carbon atoms are available; it is surprising that the sodium bicarbonate data resemble those for sodium formate in view of the availability of hydrogen in the crystal.

Only in the case of ammonium sulphate, among the nitrogenous targets, are all of the kinds of atoms found in the products present in the target substance; even so, there is no direct correlation between the thermodynamic stability of the several products and their final abundances in the solution of the target. This is probably an indication that, as in the case of beryllium nitride, only parts of the final molecules are stable in the target. Alternatively, the relative rates of competitive reactions with the solvent may determine the distribution of radiocarbon among several forms with the same carbon oxidation number.

ACKNOWLEDGMENTS

I am indebted to Professors H. S. Gutowsky and Frederick Seitz, and to Drs. J. D. Vaughan and W. R. Cornman Jr., for stimulating discussion of many of the points covered in this paper. It is a pleasure to acknowledge the interest of Professor J. L. Heller of the Department of Classics in the problem of terminology for the field of the research. The $N^{14}(n, p)C^{14}$ system studies which precipitated this article were sponsored by the U.S. Atomic Energy Commission.

A SYNTHESIS OF 5-*O*-METHYL D-GLUCOSE AND OF 2-*O*-METHYL D-GLYCERONAMIDE[1]

By J. K. N. Jones

ABSTRACT

A preparation of 5-*O*-methyl D-glucose from 1,2-*O*-*iso*propylidene D-glucurone is described. Oxidation of the D-glucose derivative with periodate gave 2-*O*-methyl D-glycerose from which 2-*O*-methyl D-glyceronamide was prepared.

INTRODUCTION

The reference compound 2-*O*-methyl D-glyceronamide (VIII) was required. Its preparation from a suitably substituted derivative of D-glucose was considered to be feasible and, accordingly, the preparation of 5-*O*-methyl D-glucose (VI) was undertaken. This compound had been prepared earlier (3) from D-glucose. The ready availability of D-glucurone made this substance a more attractive starting material. D-Glucurone (I) condenses with acetone to give the well-characterized 1,2-*O*-*iso*propylidene derivative (II) which possesses a free hydroxyl group on C-5. Previous workers (2) had indicated that this material could not be methylated with Purdies' reagents without decomposition. It was observed that when water was rigorously excluded and if the reaction was carried out in the presence of anhydrous calcium sulphate methylation proceeded in the normal manner. The resultant 5-*O*-methyl

VIII VII VI

derivative (III) on reduction with lithium aluminum hydride in ether gave 1,2-*O*-*iso*propylidene 5-*O*-methyl D-glucose (IV) which was characterized as its crystalline 3,6-di-*O*-acetyl derivative (V). Hydrolysis of this material gave 5-*O*-methyl D-glucose (VI), a sirup which on oxidation with bromine water yielded 5-*O*-methyl D-gluconic acid, characterized as the crystalline amide (VII). Oxidation of this product with periodic acid resulted in the formation of 2-*O*-methyl D-glycerose. Attempts to isolate this material by

[1]*Manuscript received November 28, 1955.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

extraction with either chloroform or ether were unsuccessful. Accordingly the aldehyde was oxidized *in situ* with bromine and the resultant glyceronic acid derivative converted first to the ester and then to the required amide (VIII). The racemic amide was prepared previously by Baker (1), and has a lower melting point, 71°C. compared with 87°C. The analytical values for methoxyl are likely to be unreliable as reported by Baker (1).

EXPERIMENTAL

The following solvents (v/v) were used to separate sugars on paper chromatograms: (A) ethyl acetate: acetic acid: formic acid: water—18: 3: 1: 4; (B) butan-2-ol: pyridine: water—10: 3: 3. Solvents were removed by evaporation at 40°C. or less and optical rotations were determined at 20 ± 2°C. and in water unless otherwise stated.

1,2-O-iso-Propylidene 5-O-Methyl D-*Glucurone*

1,2-*O-iso*-Propylidene D-glucurone (7 gm.) (II) was converted to the 5-*O*-methyl ether by methylating it with Purdies' reagents in the presence of drierite. The product, which was isolated in the usual manner, was a sirup which was purified by distillation, b.p. 140–145°C. at 0.01 mm. (bath temp.), $n_D^{29°}$ 1.4690, yield, 4.7 gm.; $[\alpha]_D$ 48° (*c*, 0.9). The lactone gave with alcoholic ammonia an amide, m.p. 174°C., $[\alpha]_D$ −29° (*c*, 2.5). Anal.: Calc. for $C_{10}H_{17}O_6N$: C, 48.7; H, 6.9; N, 5.7; OMe, 12.6. Found: C, 48.7; H, 6.7; N, 5.7; OMe, 14.5.

The lactone derivative on hydrolysis with dilute formic acid yielded 5-*O*-methyl D-glucurone which moved at 1.35 times the speed of rhamnose in solvent (A).

1,2-O-iso-Propylidene 5-O-Toluene-p-sulphonyl D-*Glucurone*

1,2-*O-iso*-Propylidene D-glucurone (1 gm.) was dissolved in pyridine (10 ml.) and toluene-*p*-sulphonyl chloride (1 gm.) was added. The solution became warm and, after the initial reaction was over, was allowed to stand at room temperature for a day. The reaction mixture was poured on to ice when the crystalline 5-*O*-toluene-*p*-sulphonyl derivative separated. It was collected on the filter, washed well with water, and recrystallized from methanol or aqueous acetone, m.p. 189°–194°C. not changed on further recrystallization, $[\alpha]_D$ 84° (*c*, 0.44 in acetone.) Anal.: Calc. for $C_{16}H_{18}O_8S$: C, 52.0; H, 4.9; S, 8.7. Found: C, 52.0; H, 4.8; S, 8.5. The product dissolved in aqueous alkali with the formation of an intense yellow color.

1,2-O-iso-Propylidene 5-O-Methyl D-*Glucose* (*IV*)

1,2-*O-iso*-Propylidene 5-*O*-methyl D-glucurone (4.4 gm.) was reduced by adding its solution in ether (25 ml.) to a solution of lithium aluminum hydride (4 gm.) in ether (25 ml.). The glucose derivative was isolated from the neutralized and filtered solution by extracting it continuously with chloroform. The sirupy product was purified by distillation, b.p. 160°C. (bath temp.) at 0.1 mm., $[\alpha]_D$ −8° (*c*, 1.0), yield, 4.1 gm. Anal.: Calc. for $C_{10}H_{14}O_6$: C, 52.2; H, 6.1; OMe, 13.5. Found: C, 52.2; H, 6.25; OMe, 13.7. Acetylation of the product with pyridine and acetic anhydride yielded the known crystalline 3,6-di-*O*-acetyl derivative (4.0 gm.) (V), m.p. 87°C. after recrystallization from

ligroin (b.p. 60–80°C.). Anal.: Calc. for $C_{14}H_{22}O_8$; C, 52.9; H, 7.0; OMe, 9.8. Found: C, 52.5; H, 7.0; OMe, 9.9. Pure 1,2-*O*-*iso*propylidene 5-*O*-methyl D-glucose was recovered from the diacetate after it had been deacetylated with *N* sodium hydroxide solution.

5-O-Methyl D-*Glucose* (*VI*)

1,2-*O*-*iso*-Propylidene 5-*O*-methyl D-glucose (2.0 gm.) was hydrolyzed with 0.1 *N* sulphuric acid (20 ml.) at 100°C., $[\alpha]_D$ $-8° \rightarrow -3°$ (constant value, 1 hr.). The sirupy product (1.77 gm.) was isolated after removal of the sulphuric acid as barium sulphate. Its rate of movement relative to that of rhamnose was 1.1 (in solvent A) and 1.2 (in solvent B). It was converted, without purification, to 5-*O*-methyl D-gluconic acid by oxidizing it with bromine water in the usual manner. Excess of bromine was removed by aeration when chromatographic examination of the solution (solvent B) showed that reducing sugar was absent. Hydrobromic acid was removed with silver carbonate and the solution filtered. The acid, isolated by the usual procedure, was converted to the lactone, which crystallized. This product was difficult to purify. The crude material, which had m.p. 130°C., was converted to the amide (VII) by saturating its solution in methanol with ammonia. The amide was recrystallized either from water or from methanol, m.p. 150°C., and had $[\alpha]_D$ 25° (*c*, 0.14) and therefore obeys Hudson's amide rule. Its rate of movement was identical with that of glucose in solvent (B). Anal.: Calc. for $C_7H_{15}O_6N$: C, 40.0; H, 7.2; N, 6.7; OMe, 14.9. Found: C, 40.2; H, 7.4; N, 6.2; OMe, 15.0.

Oxidation of 5-O-Methyl D-*Gluconamide with Periodate*

The amide (VII) (0.7 gm.) was dissolved in water (10 ml.) and oxidized with paraperiodic acid (0.7 gm.) at 24°C. during 24 hr. In a trial experiment attempts to isolate 2-*O*-methyl D-glycerose were unsuccessful. Accordingly bromine was added to the reaction mixture and the oxidation was allowed to proceed for 48 hr. Excess of bromine was then removed by aeration and the solution was neutralized with barium carbonate and filtered. The filtrate was shaken with silver carbonate, filtered, and silver ions removed from solution as silver sulphide. The filtered solution was then concentrated to a sirup which was boiled with methanolic hydrogen chloride for six hours in order to esterify the glyceronic acid derivative. The 2-*O*-methyl D-glyceronamide (VIII) was prepared from the resultant ester in the usual manner. Yield, 60 mgm. of white crystals, m.p. 86–87°C., $[\alpha]$ 71°±4° (*c*, 0.7 in methanol). Anal.: Calc. for $C_4H_9O_3N$: C, 40.3; H, 7.56; N, 11.8; OMe, 26.1. Found: C, 40.2; H, 7.6; N, 11.9; OMe, 26.7.

ACKNOWLEDGMENT

The author thanks the National Research Council and Queen's University for grants which made this work possible, and Corn Products Refining Co., for a gift of glucurone.

ON FLAME PROPAGATION IN EXPLOSIVE MIXTURES OF GASES

I. GENERAL THEORY[1]

By Robert Sandri[2]

ABSTRACT

The system of differential equations of flame propagation is set up and discussed. It is shown that, without any major influences being neglected, the energy equation can be reduced to the form

$$\zeta\left(\frac{d\zeta}{d\eta}+1\right) = \phi(\eta)$$

with the boundary conditions

$$\zeta = 0 \text{ for } \eta = 0 \text{ and for } \eta = 1.$$

Some qualities of the solutions of this equation are discussed and a simple numerical method of solution is described. The flame velocity V_0 is found as an eigenvalue of the energy equation. The temperature distribution in the flame zone can then be found by an ordinary quadrature. Further, an approximation formula for finding V_0 directly is derived

$$V_0 = \frac{1}{1-\eta_m}\left[2\int_0^1 F(\eta)d\eta\right]^{\frac{1}{2}}$$

where $F(\eta)$ is proportional to $\phi(\eta)$ and has a maximum for $\eta = \eta_m$.

1. INTRODUCTION

The processes involved in the propagation of flames in explosive mixtures of gases are very complex and an exact mathematical description of them is very difficult. It is true that with the help of electronic computers even highly complex systems of equations can be solved but some simplification is still desirable. In the first place, it is always interesting and useful to show up regularities and laws of nature underlying the great apparent complexity of the problem. Moreover, an entirely exact mathematical treatment is in most cases useless because the available kinetic data are incomplete and not entirely reliable.

On the other hand, the purpose of the theory sets a limit to simplification. It cannot be the primary object of a theory of flame propagation to calculate the flame velocity. This quantity can be measured rather easily and is well known in most cases. The principal purpose of the theory, on the contrary, should be to utilize this knowledge for obtaining information regarding kinetic data by comparison of the computed and observed values of flame velocity. If such conclusions are to be convincing and reliable, mathematical and physical simplification must not be exaggerated.

An exact theory of flame propagation has been worked out by Hirschfelder and his collaborators (3, 4, 5, 6, 7) and has been successfully applied to several cases of combustion. However, Hirschfelder's method requires a great many

[1]*Manuscript received October 17, 1955.*
Private contribution.
[2]*Canadian Westinghouse Co. Ltd., Hamilton, Ont. (WT).*

difficult computations. Recently, Kármán and Penner have shown that it is possible to simplify computations a great deal without losing much accuracy (11).

In the present paper an attempt is made to establish a theory which does not neglect any major influences acting in the phenomenon of flame propagation and at the same time is mathematically quite simple. It has been found to yield results which differ only by a few per cent from the results obtained by the exact method of Hirschfelder *et al.* while it is still simpler than the method of Kármán and Penner. Moreover, it involves a transformation which is universally applicable and is interesting from a theoretical point of view.

2. THE DIFFERENTIAL EQUATIONS OF FLAME PROPAGATION

Let us suppose that an explosive mixture of several gases is moving in the direction of the positive x-axis at such a speed that the flame zone remains motionless relative to the co-ordinate system. We shall consider the one-dimensional, steady-state process only which practically does not involve any restriction to generality. Let V be the average mass rate of flow at any point and ρ the specific mass. Then an equation for the conservation of mass applies, namely

$$[1] \qquad \rho V = M = \text{const.} = \rho_0 V_0 = \rho_f V_f$$

where the subscript 0 refers to the initial mixture and the subscript f to the flame gases, i.e., to the burned mixture.

Now let us consider the equation expressing the conservation of energy. Disregarding kinetic energy, viscosity, and thermodiffusion, we have

$$[2] \qquad \frac{d}{dx}\left(\lambda \frac{dT}{dx}\right) - \frac{d}{dx}\sum_i n_i m_i (V + V_i) H_i = 0.$$

Here, λ is the heat conductivity, T is the absolute temperature, n_i and m_i are the concentration (moles per cm.^{3}) and the molecular weight of the component i of the mixture, H_i is the enthalpy per unit mass, and V_i is the velocity of diffusion flow of the same component.

Further, there is a set of equations of continuity for all components

$$[3] \qquad \frac{d}{dx}[n_i(V + V_i)] = U_i$$

where U_i is the rate of production of the component i (moles per cm.^{3} per sec.) due to chemical reactions.

So far, our assumptions have been identical with those made by Hirschfelder *et al.* However, the above equations can be lumped together and greatly simplified as follows. Evidently

$$[4] \qquad \sum_i m_i H_i U_i = -Q,$$

Q being the heat developed by chemical reactions per second and cm^3. Furthermore

$$[5] \qquad \sum_i n_i m_i V \frac{dH_i}{dx} = V \frac{dT}{dx} \sum_i n_i m_i c_{pi} = M c_p \frac{dT}{dx}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

where c_p is the specific heat per unit mass of the mixture, at constant pressure.

Transforming the second term in equation [2] by means of equations [3], [4], and [5], we find

$$[6] \qquad \frac{d}{dx}\left(\lambda \frac{dT}{dx}\right) - Mc_p \frac{dT}{dx} + Q - \frac{dT}{dx}\sum_i n_i m_i V_i c_{pi} = 0.$$

From the definition of V it is clear that

$$\sum_i n_i m_i V_i = 0.$$

Hence, the last term in equation [6] will be very small compared to the other terms as long as the specific heats of the components of the mixture do not differ too much. Disregarding the last term, we obtain the energy equation in the form which has been used by many authors, e.g., Boys and Corner (1), Jost (8), Kármán and Millán (10), Lewis and Elbe (13), Roy (15), Semenov (16), Tanford (17), Zeldovitch and Frank-Kamenetzky (18). The discussion given here and numerical evaluation show that this simplified form will be applicable with a very good approximation in most practical cases, except for mixtures rich in hydrogen. (If hydrogen is present in low concentration, it does not contribute appreciably to the last term in equation [6]. It may, of course, play a very important role in the reaction mechanism and thus affect Q a great deal.) However, there is no need of neglecting the last term and no substantial complication is introduced by keeping it, as we shall presently see.

An expression for V_i is needed in order to evaluate equations [3] and [6]. According to Hirschfelder and Curtiss (3), we can place

$$[7] \qquad V_i = -\frac{D_i}{y_i}\frac{dy_i}{\omega x}$$

where y_i is the mole fraction of the component i and D_i can be calculated, with a very good approximation, by the formula

$$D_i = \left(1 - \frac{n_i m_i}{\rho}\right) \Big/ \sum_{k \neq i} \frac{y_k}{\mathfrak{D}_{ik}},$$

$\mathfrak{D}_{ik}$ being the ordinary binary diffusion coefficient of the components i and k.

In order to obtain a system of working equations, it is useful to place

$$[8] \qquad z = \frac{\lambda}{Mc_p}\frac{dT}{dx}$$

$$[9] \qquad \delta_i = \frac{\rho c_p D_i}{\lambda}$$

$$[10] \qquad m = \rho / \sum_i n_i = \sum_i y_i m_i.$$

The reduced diffusion coefficients δ_i are dimensionless quantities and m is the average molecular weight of the mixture.

Then, equation [6] assumes the form

$$[11] \qquad z\frac{dz}{dT} = \omega z^2 + z - \varphi$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

where

$$\omega = \frac{1}{c_p}\frac{dc_p}{dT} + \sum_i \delta_i \frac{m_i c_{pi}}{mc_p}\frac{dy_i}{dT} \quad [12]$$

$$\varphi = \frac{\lambda Q}{M^2 c_p^2}. \quad [13]$$

From [3] and [7] we obtain

$$z\frac{d}{dT}\left(\frac{\delta_i}{m} z \frac{dy_i}{dT} - \frac{y_i}{m}\right) + \psi_i = 0 \quad [14]$$

where

$$\psi_i = \frac{\lambda U_i}{M^2 c_p}. \quad [15]$$

If complete kinetic and physical data are available, ω, φ, and ψ_i are known as functions of T and y_i and dy_i/dT. Then equations [11] and [14] are sufficient to determine all y_i and z as functions of T. The initial concentrations y_{i0} are supposed to be known and the concentrations in the burned mixture y_{if} can be calculated from them.* Moreover, z must be zero at the hot boundary ($T = T_f$). Some controversy exists as to the assumption to be made for z at the cold boundary ($T = T_0$). However, as pointed out by Richardson (14), there can be little doubt that no appreciable error is introduced by assuming that $z_0 = 0$. This last boundary condition is supernumerary and makes it possible to determine M (or $V_0 = M/\rho_0$) as an eigenvalue of the problem.

3. THE REDUCED ENERGY EQUATION

The exact solution of the system of differential equations is a very difficult task even if the system of chemical reactions is rather simple. However, in most cases this task can be greatly simplified.

In the first place, one of the differential equations [14] can always be discarded because

$$\sum_i y_i = 1.$$

Further, it is often admissible to assume that the enthalpy of the mixture remains reasonably constant throughout the flame zone because the energy transport by diffusion is opposite in direction and approximately equal in size to the energy transport by heat conduction so that these two influences more or less cancel each other. This assumption was made by Lewis and Elbe (12), by Semenov (16), and by Zeldovitch and Frank-Kamenetzky (18). It has also been backed by Jost (9), by Hirschfelder (2), and by Kármán and Penner (11). It allows another of the differential equations of the system to be discarded.

However, other hypotheses often give better results. Very often, chemical reactions are confined to a comparatively narrow range of temperature near T_f. Then, as Kármán and Penner have shown, series expansions can be used

*The values of dy_i/dT at the hot boundary, which are also needed, can be found by series expansion at $T = T_f$, with $(dy_i/dx)_f = 0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

for the mole fractions y_i of which only the first terms need be considered. Thus, the y_i can easily be determined from equations [14] as functions of T in the interval near T_f and the system is reduced to the one equation [11] whose solution gives the eigenvalue V_0.

Stoichiometric relations and pre-established equilibria may also help to the same end. These methods will be further discussed in the applications of the general theory. Here, we shall assume that, by any of the methods referred to above, all y_i have been determined as functions of T.

Normally, the variables ω and φ, as defined by [12] and [13], are then also known as functions of T and equation [11] can be used to solve the problem completely.

Equation [11] is amenable to considerable simplification. To this end, we introduce the dimensionless variables

$$E = \exp\left(\int_T^{T_f} \omega \, dT \right) \tag{16}$$

$$\zeta = \frac{zE}{K} \tag{17}$$

$$\eta = \frac{1}{K} \int_T^{T_f} E \, dT \tag{18}$$

$$\phi = \frac{\varphi E}{K} . \tag{19}$$

The constant K is defined as

$$K = \int_{T_0}^{T_f} E \, dT. \tag{20}$$

Then, equation [11] assumes the form

$$\zeta \left(\frac{d\zeta}{d\eta} + 1 \right) = \phi \, (\eta) \tag{21}$$

with the boundary conditions

$$\zeta = 0 \text{ for } \eta = 0 \text{ (hot boundary)}$$

$$\zeta = 0 \text{ for } \eta = 1 \text{ (cold boundary).}$$

By equation [18] η is given as a function of T. All quantities known as functions of T, i.e., λ, c_p, y_i, and ϕ, are therefore also known as functions of η.

Equation [21] can be called the reduced energy equation. Methods for its integration and for the determination of the eigenvalue V_0 are given in Section 5.

When ζ has been determined as a function of η, the temperature distribution in the flame zone can be found, according to [8], [17], and [18], by the formula

$$x = \frac{1}{M} \int \frac{\lambda dT}{c_p z} = \frac{1}{M} \int \frac{\lambda d\eta}{c_p \zeta} . \tag{22}$$

Frequently, the last term in [6] can be neglected and c_p can be considered as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

constant. In this case, we have $\omega = 0$ and $E = 1$ and the substitutions [17], [18], and [19] assume the simple form

[17a] $$\zeta = \frac{z}{T_f - T_0}$$

[18a] $$\eta = \frac{T_f - T}{T_f - T_0}$$

[19a] $$\phi = \frac{\varphi}{T_f - T_0}.$$

Equation [21] with its boundary conditions and equation [22] remain unchanged.

Some complications may arise in the presence of equilibria because terms approaching the indeterminate form $\infty \times 0$ may appear in the expression for φ. It is then necessary to eliminate them by means of any of the equations [14]. The result can again be reduced to the standard form [21], with the same boundary conditions, by substitutions similar to formulae [16] to [20].

4. THE SOLUTIONS OF THE REDUCED ENERGY EQUATION

Equation [21] is known in mathematics as Abel's Differential Equation of the Second Type. Its integration by a finite expression is, in general, not possible but some statements can be made on the behavior of its solutions which, of course, depends solely on the function $\phi(\eta)$.

We shall assume for our discussion that η is a monotonic function of T and that ζ is always positive. This is certainly the case in the absence of such equilibrium reactions which would lead to indeterminate forms which would have to be eliminated (see equations [18], [17], and [8]).

The function ϕ is known from kinetic data save for the factor $1/V_0^2$ (see equations [19] and [13]). Evidently

$$\phi = 0 \text{ for } \eta = 0 \quad (T = T_f).$$

Under normal circumstances, all chemical reactions can be neglected for low temperatures up to a certain temperature T_s. So we have

$$\phi \equiv 0 \text{ for } \eta \geqslant \eta_s,$$

η_s being the value of η corresponding to T_s. Then, the general solution of [21] is

$$\zeta = C - \eta \text{ for } \eta \geqslant \eta_s.$$

For further discussion we shall confine ourselves to the family of solutions which satisfy the first boundary condition

$$\zeta = 0 \text{ for } \eta = 0.$$

This condition leaves no indefinite integration constant but the solutions still differ by the values chosen for V_0. The curves are shown in Fig. 1 for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

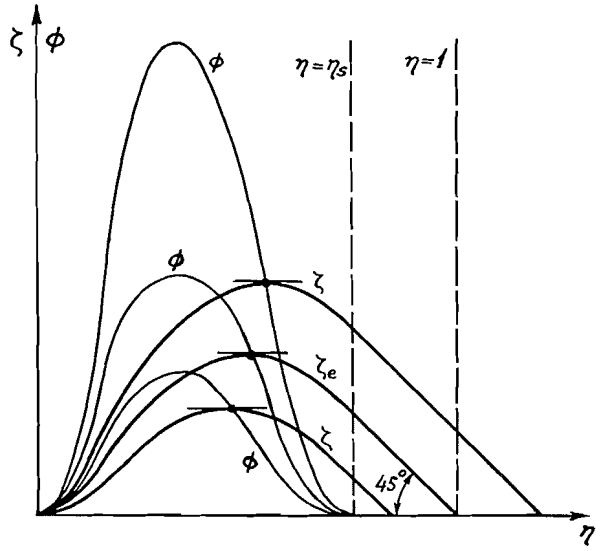

FIG. 1. Solutions of the reduced energy equation.

simplest case, namely, if ϕ is always positive. One of these curves ζ_e, for a particular value V_{00} of V_0, will satisfy also the second boundary condition

$$\zeta = 0 \text{ for } \eta = 1 \quad (T = T_0)$$

and is therefore the real solution of our problem.

For small values of η, $d\zeta/d\eta$ must be positive, otherwise ζ would become negative. Hence, for small η,

$$\zeta = \frac{\phi}{(d\zeta/d\eta)+1} < \phi.$$

From this formula it is evident that ζ increases with η as long as it is smaller than ϕ. Then, for a certain value of η, it becomes equal to ϕ and at the same time has a maximum value because $d\zeta/d\eta$ must be zero at this point. With η increasing further, ϕ decreases and finally becomes identically zero so that, for $\eta \geqslant \eta_s$, the ζ-curve coincides with one of the straight lines $\zeta = C-\eta$. The value of C depends on V_0 and we have only to find that particular value V_{00} for which C is equal to unity so that the second boundary condition is satisfied. Thus the eigenvalue V_{00} can be found by trial and error.

The physical interpretation of these mathematical facts is clear enough. A given burned mixture could have been obtained from quite different initial mixtures of the same components of appropriate initial temperatures. It is by these very initial conditions that the flame velocity is determined. Now, only for one particular value V_{00} we find $C = 1$ and hence $\zeta = 0$ for $\eta = 1$. Otherwise, ζ becomes zero for a value of η other than unity. This means that for a value of V_0 different from V_{00} the composition of the unburned mixture is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

different from that assumed originally and hence also the initial temperature is different.

The function ϕ may be positive in the whole interval between 0 and η_s but it may also change its sign. In this case, since ζ is always positive, we have

$$d\zeta/d\eta = -1 \text{ for } \phi = 0$$

$$d\zeta/d\eta < -1 \text{ for } \phi < 0.$$

Only in the immediate vicinity of $\eta = 0$, ϕ must be positive.

5. INTEGRATION OF THE REDUCED ENERGY EQUATION

The following method is recommended for the numerical integration of equation [21]. Integrating over an interval from η_1 to η_2 we obtain

$$[23] \qquad \tfrac{1}{2}\zeta_2^2 - \tfrac{1}{2}\zeta_1^2 + \int_{\eta_1}^{\eta_2} \zeta d\eta = \int_{\eta_1}^{\eta_2} \phi(\eta) d\eta = \tfrac{1}{2}\Delta Y.$$

Now we make the interval $\eta_2 - \eta_1 = \Delta\eta$ so small that the "Trapezoidal Rule" can be applied to the integral on the left-hand side. So

$$\tfrac{1}{2}\zeta_2^2 - \tfrac{1}{2}\zeta_1^2 + \tfrac{1}{2}(\zeta_2 + \zeta_1)\Delta\eta = \tfrac{1}{2}\Delta Y$$

$$[24] \qquad \zeta_2 = -\tfrac{1}{2}\Delta\eta + \sqrt{[(\zeta_1 - \tfrac{1}{2}\Delta\eta)^2 + \Delta Y]}.$$

By means of this formula, ζ can be computed step by step. The numeric calculation must be repeated with different values of V_0 until both boundary conditions are satisfied. The differences ΔY can be computed once for all and need only be changed by the factor $1/V_0^2$ for each run. On the other hand, the evaluation of formula [24] has to be repeated completely for each run but it is very simple and involves only additions and subtractions if a table of squares is used, in case no electronic computers are available.

Nevertheless it is desirable to derive a formula which makes it possible to dispense with the repeated numerical integration and to find V_{00} directly. To this end, we integrate both sides of equation [21] from $\eta = 0$ to $\eta = 1$. Then, for that solution ζ_e which satisfies both boundary conditions, we obtain

$$[25] \qquad \int_0^1 \zeta_e \, d\eta = \int_0^1 \phi_e \, d\eta = A.$$

Geometrically this means that the area A below the curve representing the real solution ζ_e of our problem must be equal to the area below the corresponding ϕ_e-curve. Now let

$$[26] \qquad V_0^2 \phi(\eta) = V_{00}^2 \phi_e(\eta) = F(\eta).$$

Since $\phi(\eta)$ is proportional to $1/V_0^2$, the function $F(\eta)$ does not contain this factor and is therefore completely known. Then

$$V_{00}^2 = \frac{1}{A} \int_0^1 F(\eta) d\eta.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

This formula can serve for computing V_{00} if the area A is known. In order to find A exactly, we should first have to find ζ_e as a function of η by repeated numerical integration. However, a very good approximate value for A can be found directly, because of our knowledge of the general qualities of the ζ_e-curve.

We shall at first assume that the function $F(\eta)$ is zero in the entire interval between 0 and 1, save for a narrow range of η on either side of η_m where $F(\eta_m)$ is a maximum so that

[27] $$\left(\frac{dF}{d\eta}\right)_{\eta_m} = 0.$$

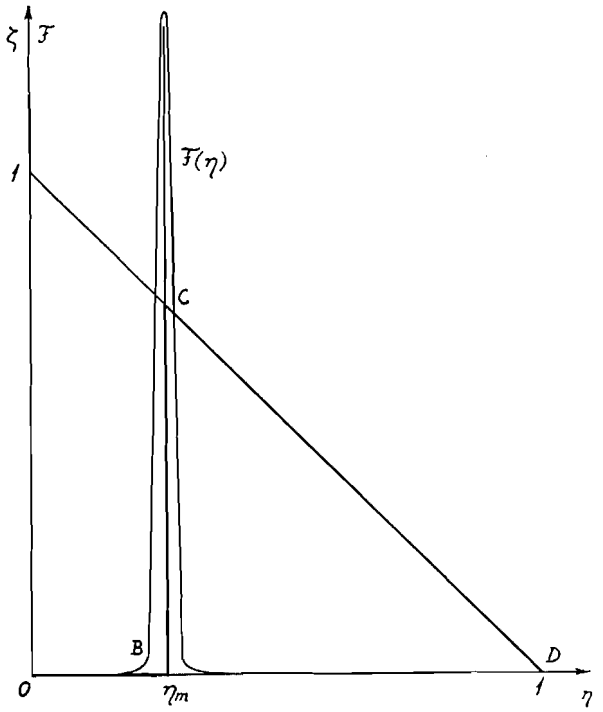

FIG. 2. Solution for a sharply peaked function $F(\eta)$.

Then, according to what has been said in the preceding section, the ζ_e-curve will approach the broken line OBCD (see Fig. 2), so that

$$A = \tfrac{1}{2}(1-\eta_m)^2.$$

Since no iteration is involved in the new formulae, we can now replace V_{00} by V_0. Thus we have

[28] $$V_0 = \frac{1}{1-\eta_m}\left[2\int_0^1 F(\eta)d\eta\right]^{\frac{1}{2}}.$$

This formula yields amazingly good values for V_0 even if the $F(\eta)$-curve is not as sharply peaked as shown. For instance, for the combustion of a stoi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

chiometric mixture of methane and air, we find $V_0 = 40.4$ cm./sec. while repeated numerical integration of equation [21] gives 40.8 cm./sec. The error is therefore only 1% although $F(\eta)$ in this case differs appreciably from zero up to $\eta = 0.4$.

In order to further test the accuracy of formula [28], let us assume that

$$F(\eta) = 1-\cos 2\pi\eta.$$

This function will, of course, never be found in any real combustion process but it can serve for a purely mathematical test under very adverse conditions because it differs substantially from zero in the whole interval between 0 and 1. It has a maximum for $\eta = \eta_m = \frac{1}{2}$. Formula [28] then gives the result $V_0 = 2\sqrt{2} = 2.8284$ whereas exact numerical integration gives $V_0 = 2.6782$, i.e., the error is 5.3% only.

In most practical cases of combustion, chemical reactions are confined to temperatures near the upper limit and therefore equation [28] will give very satisfactory results, the error being of the order of about 1%.

Formula [28] bears some resemblance to a formula which was derived by Zeldovitch (18) and by Semenov (16) by neglecting the second and the fourth terms in equation [6] and making other simplifying assumptions. Written in our symbols, the Semenov equation reads

[29] $$V_0 = \left[\frac{2\lambda_f\int_{T_0}^{T_f} U dT}{a_0\rho_0 c_p(T_f-T_0)}\left(\frac{1}{\delta}\right)^{\nu}\left(\frac{N_1}{N_2}\right)^{\nu}\right]^{\frac{1}{2}}.$$

Here a_0 is the initial concentration of fuel, N_1 and N_2 are the total numbers of molecules before and after the over-all reaction, ν is the order of this reaction, δ is an average value of the δ_t, and U is the rate of fuel consumption.

Direct comparison between [28] and [29] is possible if, in the derivation of [28], we disregard the fourth term in equation [6] and consider c_p as constant which is often admissible. Then, substituting from [18a], [19a], [26], [1], and [13], we can write equation [28] in the form

[28a] $$V_0 = \frac{1}{\rho_0 c_p(T_m-T_0)}\left(2\int_{T_0}^{T_f}\lambda Q dT\right)^{\frac{1}{2}}$$

where λQ is a maximum for $T = T_m$.

In the Semenov formula, we can place

$$a_0 = \frac{\rho_0 c_p(T_f-T_0)}{q}$$

where q is the calorific value of the fuel. The correction factors $(1/\delta)^{\nu}$ and $(N_1/N_2)^{\nu}$ can be disregarded for the comparison because in formula [28a] they will be taken care of by the expression to be substituted for Q. Then, if we place $qU = Q$, the Semenov equation appears in the form

[29a] $$V_0 = \frac{1}{\rho_0 c_p(T_f-T_0)}\left(2\int_{T_0}^{T_f}\lambda_f Q dT\right)^{\frac{1}{2}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

Formula [29a] differs from [28a] in two regards. First, the factor $1/(T_m - T_0)$ is replaced by $1/(T_f - T_0)$. This makes V_0 too small. Second, λ in the integrand is replaced by λ_f. This tends to make V_0 somewhat larger. However, since the integral appears under a square root and since λ is proportional to $\sqrt{T}$, the influence of the factor $1/(T_f - T_0)$ always prevails so that the Semenov formula gives too small values for V_0.

In the more complex cases, e.g., if the δ_i differ very much from each other or if there are indeterminate forms in the expression for Q, the Semenov formula is not applicable.

ON FLAME PROPAGATION IN EXPLOSIVE MIXTURES OF GASES

II. ON THE DECOMPOSITION FLAME OF OZONE[1]

By Robert Sandri[2]

ABSTRACT

The general theory developed in an earlier paper of the author is applied to the ozone explosion. Values of the linear flame velocity are computed under the assumption of constant enthalpy and, without this assumption, for different values of the reduced diffusion coefficient. The results do not differ very much and are found to be in very good agreement with experiments. They are further compared to the results which were obtained by Hirschfelder *et al.* by exact numerical integration and by Kármán and Penner by an approximation method and are found to be between the values obtained by these authors.

The principal object of the present paper is to test the accuracy and reliability of the general theory of flame propagation developed by the author (7) by applying it to a flame where complete and reliable information concerning kinetic data is available. The explosion flame of mixtures of ozone and oxygen is particularly useful for this purpose. Moreover, it has already served as a sort of "test case" for other theories of flame propagation and thus allows comparison between these and the present theory.

The kinetics of the ozone decomposition has been studied by Wulf (9), Schumacher (8), Kassel (3), and many others. The velocity of the decomposition flame has been measured by Lewis and Elbe (4) by the bomb method. The same authors have developed a theory of flame propagation for this case (5, 6) which is based on the assumptions that the enthalpy is reasonably constant and that an equilibrium is established between atomic oxygen, molecular oxygen, and ozone throughout the flame zone. The first of these assumptions has proved to be correct but the second seems hardly tenable in view of the results of recent research.

Recently, Hirschfelder, Curtiss, and Campbell (1) have applied their theory of flame propagation to the same reaction. Their treatment is virtually free from arbitrary assumptions and their results are in very good agreement with experiments. However, it involves a great many very difficult and complicated numerical computations.

Subsequently, Kármán and Penner (2) solved the problem on the basis of a simplified theory. Their results do not differ much from those of Hirschfelder, Curtiss, and Campbell.

As far as reaction kinetics is concerned, we shall adopt here the same hypotheses as Hirschfelder *et al.* and Kármán and Penner. The over-all reaction is

$$O_3 \rightarrow 1\tfrac{1}{2}O_2 + 34535 \text{ cal.}$$

[1]*Manuscript received October 17, 1955.*
Private contribution.
[2]*Canadian Westinghouse Co. Ltd., Hamilton, Ont. (WT).*

Actually, the following reactions take place:

$$O + O_2 + X \rightleftarrows O_3 + X \pm 24140 \text{ cal.} \quad [I]$$

$$O + O_3 \rightleftarrows 2O_2 \pm 93210 \text{ cal.} \quad [II]$$

$$O_2 + X \rightleftarrows 2O + X \mp 117350 \text{ cal.} \quad [III]$$

where X represents a molecule of any of the components of the mixture.

The rates of these reactions (in mole/sec. cm.^{3}) are given by the formulae

$$[1] \quad U^{(1)} = U_+^{(1)} - U_-^{(1)} = 10^{12} n\sqrt{T}(0.230 n y_1 y_2 - 10.56 y_3 e^{-24140/RT})$$

$$[2] \quad U^{(2)} = U_+^{(2)} - U_-^{(2)} = 10^{12} n\sqrt{T}(7.15 y_1 y_3 e^{-6000/RT} - 2.93 y_2^2 e^{-99210/RT})$$

$$[3] \quad U^{(3)} = U_+^{(3)} - U_-^{(3)} = 10^{12} n\sqrt{T}(8.92 y_2 e^{-117350/RT} - 0.482 n y_1^2)$$

where y_1, y_2, and y_3 are the mole fractions of atomic oxygen, molecular oxygen, and ozone, n is the total concentration (in mole/cm.^{3}), R is the gas constant, and T is the absolute temperature. If we suppose that y_1 is very small throughout the flame zone, it follows from the above formulae that

$$U_-^{(3)} \ll U_+^{(1)}.$$

This term $U_-^{(3)}$ can therefore be disregarded. Likewise it is obvious that $U_+^{(3)}$ and $U_-^{(2)}$ can be neglected because of the large negative exponents. Further, if the concentration of atomic oxygen is very small, its rate of formation or consumption must be near zero so that

$$[4] \quad U^{(1)} + U^{(2)} \approx 0 \approx U_+^{(1)} - U_-^{(1)} + U_+^{(2)}.$$

Consequently

$$[5] \quad y_1 = \frac{10.56 y_3 e^{-24140/RT}}{0.23 n y_2 + 7.15 y_3 e^{-6000/RT}} \approx 1.474 e^{-18140/RT}$$

because the first term in the denominator is found to be very small as compared to the second, except for a negligible range of temperature adjacent to the upper limit T_f where the concentration of ozone is approaching zero so that y_3 becomes comparable to y_1.

The values of y computed by formula [5] are virtually identical to those found by Hirschfelder, Curtiss, and Campbell. They make up only small fractions of a per cent of the mixture so that

$$[6] \quad y_2 + y_3 \approx 1.$$

Equations [5] and [6], together with the hypothesis of constant enthalpy or other assumptions which will be introduced later on, make it possible to compute y_1, y_2, and y_3. Substituting them in the terms for $U_+^{(3)}$, $U_-^{(3)}$, $U_-^{(2)}$, and $U_+^{(1)}$, we can easily verify that these terms are indeed quite negligible.

Thus the system of reactions is virtually reduced to the chain mechanism

$$O_3 + X \rightarrow O_2 + O + X$$

$$O_3 + O \rightarrow 2O_2.$$

In equations [1], [2], and [3], n should read n^2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

Atomic oxygen is present only as a trace, the concentration of which is determined by the condition that the rate of the above two reactions must be the same, i.e.,

$$U_-^{(1)} = U_+^{(2)}.$$

The concentration y_1 of the atomic oxygen attains a maximum at a temperature less than one degree below T_f. Above that temperature, atomic oxygen is finally consumed, together with the remaining ozone.

It should be emphasized that, although y_1 is very low, it is still far higher than the equilibrium concentration in the whole flame zone except for $T = T_f$, where, of course,

$$U^{(1)} = U^{(2)} = U^{(3)} = 0.$$

This last equation gives extremely low values for both y_{1f} and y_{3f} so that later on we shall place $y_{1f} = y_{3f} = 0$.

Lewis and Elbe (5), on the other hand, assumed that in the entire flame zone

$$U_-^{(1)} = U_+^{(1)}.$$

This could only be true if both $U_-^{(1)}$ and $U_+^{(1)}$ were far larger than $U_+^{(2)}$, which is not consistent with formulae [1] and [2] and leads to values for the flame velocity which are far too high (see Table I).

We can assume with a very good approximation that the specific heat per unit mass of each of the three components is the same. Moreover, no appreciable error is caused by considering c_p as constant. (The same assumptions were made by Hirschfelder *et al.* and by Kármán and Penner.)

In order to apply the general theory (7) we have to find a function $F(\eta)$ which, in this case, is given by the simple formula

$$F(\eta) = \frac{V_0^2\varphi}{T_f - T_0} = \frac{\lambda Q}{\rho_0^2 c_p^2 (T_f - T_0)} \qquad [7]$$

where

$$\eta = \frac{T_f - T}{T_f - T_0}. \qquad [8]$$

Here, λ is the thermal conductivity, Q is the heat produced per unit of time and volume, ρ_0 is the specific mass of the gaseous mixture at the temperature T_0 (the subscript 0 referring to the unburned mixture), V_0 is the linear flame velocity at the same temperature, and c_p is the specific heat per unit mass.

From [I], [II], [1], and [4] we find (disregarding U)

$$Q = -24140\,U_-^{(1)} + 93210\,U_+^{(2)} = 69070\,U_-^{(1)}. \qquad [9]$$

This formula, as we have seen, holds for the entire flame zone except for a very narrow range of temperature near T_f which is not important for the determination of the flame velocity V_0. For c_p an average value is chosen so that the correct flame temperature T_f is obtained:

$$c_p = \frac{y_{30} n_0}{(T_f - T_0)\rho_0} \times 34535 = \frac{y_{30}}{(T_f - T_0) m_0} \times 34535 \qquad [10]$$

In the line above equation [9], U should read $U_+^{(1)}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

where m_0 is the molecular weight of the unburned mixture. Moreover, in accordance with Hirschfelder *et al.*, we place

$$\lambda = 5.26 \times 10^{-6}\sqrt{T}.$$

Then, substituting in [7], we find

$$[11] \qquad F(\eta) = 3.23 \times 10^3\left(\frac{T_0}{y_{30}}\right)^2 (T_f - T_0)\frac{e^{-12150/T}}{T} y_3 = K\frac{e^{-A/T}}{T} y_3.$$

We have still to express y_3 as a function of η. To this end we shall first use the hypothesis that the enthalpy is reasonably constant throughout the flame zone. Then, since the concentration of atomic oxygen is negligible, a linear relationship must exist between y_3 and T and consequently

$$[12] \qquad y_3 = y_{30}\eta.$$

The function $F(\eta)$ is found to be virtually zero in the larger part of the interval between 0 and 1 except for small values of η, i.e., near the hot boundary of the flame zone. Under these circumstances the flame velocity can be found with a very good approximation by the formula

$$[13] \qquad V_0 = \frac{1}{1-\eta_m}\left[2\int_0^1 F(\eta)d\eta\right]^{\frac{1}{2}}$$

where $F(\eta)$ is a maximum for $\eta = \eta_m$.

In our case

$$F'(\eta) = \frac{dF}{d\eta} = \left[\frac{1}{\eta} + \frac{T_f - T_0}{T} - \frac{A}{T^2}(T_f - T_0)\right]F(\eta).$$

Placing $F'(\eta_m) = 0$, we find

$$[14] \qquad \eta_m = \frac{T_f^{\,2}}{(A+T_f)(T_f - T_0)}.$$

Further, we find

$$\int_0^1 F(\eta)d\eta = \frac{Ky_{30}}{(T_f - T_0)^2}\{(A+T_f)[-\mathrm{Ei}(-A/T_f) + \mathrm{Ei}(-A/T_0)] - [T_f e^{-A/T_f} - T_0 e^{-A/T_0}]\}$$

$$[15] \qquad \approx \frac{Ky_{30}}{(T_f - T_0)^2}[-(A+T_f)\,\mathrm{Ei}(-A/T_f) - T_f e^{-A/T_f}]$$

where, by definition,

$$-\mathrm{Ei}(-x) = \int_x^\infty \frac{1}{t} e^{-t}dt.$$

Tables for this "exponential integral" are available.

Formulae [13], [14], and [15] make it possible to find V_0. The results are very satisfactory (see Tables I and II). As a matter of fact, Hirschfelder *et al.* (1) found an almost linear relationship between y and T in the entire flame zone, which means that the enthalpy is indeed nearly constant, as supposed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

However, an even better accuracy can be attained by utilizing the fact that chemical reactions are virtually confined to temperatures near T_f, in order to find a more exact formula for y_3.

According to the general theory (7), the following equations hold:

[16] $$z\left(\frac{dz}{dT}-1\right)+\varphi = 0$$

[17] $$z\frac{d}{dT}\left(\frac{\delta}{m}z\frac{dy_3}{dT}-\frac{y_3}{m}\right)+\psi_3 = 0$$

where

$$z = \frac{\lambda}{V_0\rho_0 c_p}\frac{dT}{dx}$$

[18] $$\delta = \frac{D_{23}\rho c_p}{\lambda}$$

$$\psi_3 = \frac{\lambda U_3}{V_0^2\rho_0^2 c_p}.$$

Here, D_{23} is the diffusion coefficient of the binary mixture of oxygen molecules and ozone, the function φ is defined by equation [7], and U_3 is the rate of production of ozone. Evidently

[19] $$U_3 = U^{(1)}-U^{(2)} = -2U_-^{(1)}.$$

We have now to regard conditions in the neighborhood of T_f. Here the molecular weight of the mixture m is equal to 32. Moreover, λ and all functions of T in equations [1] and [2] can be regarded as constant. The only variable quantities are y_3 and the difference T_f-T or η as defined by [8]. So we have

[20] $$\varphi = \frac{T_f-T_0}{V_0^2}K\frac{e^{-A/T_f}}{T_f}y_3 = \frac{T_f-T_0}{V_0^2}Cy_3.$$

From [7], [9], [10], [18], [19], and [20] we find

[21] $$\psi_3 = -\frac{2c_p}{69070}\varphi = -\frac{y_{30}C}{m_0V_0^2}y_3.$$

Now let

[22] $$y_3 = k\eta$$

[23] $$z = h\eta.$$

Then, substituting in [16], we find

[24] $$h\left(\frac{h}{T_f-T_0}+1\right) = \frac{kC}{V_0^2}(T_f-T_0).$$

Now, it can easily be seen from equations [11], [13], and [22] that the value obtained for V_0 will be proportional to $\sqrt{k}$. With the assumption of constant enthalpy H, the factor of η was y_{30} (see equation [12]). Hence, if we denote by V_{H0} the value of the flame velocity found for H = const., we have

$$\frac{k}{V_0^2} = \frac{y_{30}}{V_{H0}^2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

Thus we can eliminate k from equation [24] and we find

$$[25] \qquad \frac{h}{T_f - T_0} = -\frac{1}{2} + \sqrt{\left(\frac{1}{4} + \frac{y_{30}C}{V_{H0}^2}\right)}.$$

Substituting from [21], [22], and [23] in [17], we find

$$[26] \qquad V_0^2 = \frac{m}{m_0} \frac{y_{30}C}{[h/(T_f - T_0)]^2\delta + h/(T_f - T_0)}.$$

By means of equations [25] and [26], an improved value V_0 can be computed from V_{H0}. The constant C is defined by equation [20].

The method used here for the improvement of V_0 is similar to the one employed by Kármán and Penner (2), inasmuch as y_3 is assumed to decrease linearly with η in the temperature interval near T_f and as the rate of decrease is determined at the point $\eta = 0$ ($T = T_f$). However, Kármán and Penner do not use equation [13] for the determination of V_0 but a quite different method.

The results obtained by the author of this paper and by other investigators are shown in Tables I and II. Table I shows the values of V_0 obtained for the

ON FLAME PROPAGATION IN EXPLOSIVE MIXTURES OF GASES

III. FLAME PROPAGATION IN MIXTURES OF METHANE AND NITROGEN AIR, HELIUM AIR, AND ARGON AIR[1]

By Robert Sandri[2]

ABSTRACT

The general theory developed in an earlier paper of the author is applied to the combustion of mixtures of methane and nitrogen air, helium air, and argon air where dissociation of the end products is negligible. The oxygen atom chain is assumed to be rate-determining. Absolute values of the flame velocity are computed for mixtures containing 8% of methane and for the stoichiometric mixtures. The results are found to be in very good agreement with experimental values. Dependence on pressure is likewise found to be in very good agreement with experiments. The temperature distribution in the flame zone is also computed.

The combustion of methane has recently been the object of intensive experimental and theoretical research. Measurements of flame velocities in methane–oxygen–nitrogen mixtures by the Bunsen burner method were made by Jahn (5) and by Sachsse and Bartholomé (10). By the same method, Clingman, Brokaw, and Pease (2) carried out measurements on mixtures of methane and nitrogen air, helium air, and argon air. Singer (13) used a careful extrapolation from Bunsen burner measurements to find flame velocities for methane and other hydrocarbons, and Manton, Elbe, and Lewis (7) made measurements by the bomb method.

Bartholomé, Dreyer, and Lesemann (1) calculated the flame velocity in the stoichiometric mixture of methane and air at 200 cm./sec. This value is far too high, chiefly because diffusion was neglected completely in the derivations.

Dugger and Simon (3) used the approximation formulae of Semenov, of Tanford and Pease, and of Manson for calculating relative values of the flame velocity in methane–air mixtures. Of these, the Semenov formula seems to give the best results.

The general theory of flame propagation developed by the author of this paper (11) can easily be applied to the combustion of methane and makes it possible to compute absolute values of the flame velocity which serve as a check for the validity of the assumptions made concerning the mechanism of the reactions involved.

Let us first consider the system of reactions. The over-all reaction is

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O + 191700 \text{ cal.} \qquad [I]$$

The actual reaction mechanism is, of course, far more complex. Sachsse (9) could explain the results of his experiments on the temperature dependence of the induction time of the methane–oxygen reaction by assuming a reaction

[1]*Manuscript received October 17, 1955.*
Private contribution.
[2]*Canadian Westinghouse Co. Ltd., Hamilton, Ont. (WT).*

mechanism which was first proposed by Norrish (8) and was also assumed by Bartholomé (1):

$$CH_4 + O \rightarrow H_2O + CH_2 \qquad [II]$$

$$CH_2 + O_2 \rightarrow CH_2O + O \rightarrow CO + H_2 + O. \qquad [III]$$

Reaction [II] is supposed to be far slower than [III]. Moreover, carbon monoxide and hydrogen are consumed by subsequent reactions proceeding at a much faster rate than [II], so that reaction [II] is really rate-determining. Since the oxygen atoms are always reproduced in this chain, the concentration of the atomic oxygen is determined by dissociation according to the oxygen equilibrium

$$O_2 \rightleftarrows 2O. \qquad [IV]$$

In view of the high activation energy of [IV], this mechanism holds only for high temperatures near the end temperature T_f where virtually all of the combustion takes place, while in the usual temperature range of kinetic experiments other systems of reactions prevail.

The equilibrium concentration according to [IV] is extremely low even at high temperatures.* Likewise, carbon monoxide and hydrogen are rapidly consumed by other reactions so that only the substances present in the over-all reaction [I] and the nitrogen of the air (or another inert gas replacing it) can exist in appreciable concentration in the gaseous mixture. Under these circumstances, the stoichiometric relations following from [I] must hold throughout the flame zone. Let y_1, y_2, y_3, y_4, and y_5 be the mole fractions of methane, oxygen molecules, carbon dioxide, water, and the inert gas, respectively. Then, since the other mole fractions are negligibly small,

$$[1] \qquad y_1+y_2+y_3+y_4+y_5 \approx 1.$$

Let the subscript 0 refer to the initial mixture of the initial absolute temperature T_0 and the subscript f to the burned flame gas of the temperature T_f. Then

$$[2] \qquad 2(y_{10}-y_1) = y_{20}-y_2 = 2(y_3-y_{30}) = y_4-y_{40}.$$

Since reaction [I] does not change the total number of molecules the mole fraction of the inert gas remains constant:

$$[3] \qquad y_5 = \text{const.} = y_{50}.$$

Equations [2] and [3] make it possible to express all mole fractions by one of them, e.g. y_1, while equation [1] is automatically satisfied.

In order to apply the general theory, it is necessary to express all mole fractions as functions of temperature. This can best be done by using the hypothesis that the enthalpy of the gaseous mixture is reasonably constant throughout the flame zone. This hypothesis has been backed by several authors. It has been found to give very satisfactory results for the ozone

Conditions here differ considerably from those in the ozone explosion (12), because of the absence of a high initial ozone concentration.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

explosion (12) and the very good agreement with experimental results which will be obtained will justify its introduction in the present case.

Therefore, if we disregard the enthalpy of the intermediate products whose concentrations are negligible, we have

$$q(y_{10}-y_1) = C_p(T-T_0). \quad [4]$$

Here, q is the heat produced per mole of methane and C_p is the specific heat per mole of the mixture.

According to the general theory (11), the linear flame velocity V_0 and the temperature distribution in the flame zone can be found by solving the reduced energy equation

$$\zeta\left(\frac{d\zeta}{d\eta}+1\right) = \phi(\eta) \quad [5]$$

with the boundary conditions

$$\zeta = 0 \text{ for } \eta = 0 \text{ and for } \eta = 1.$$

For mixtures which do not contain hydrogen in a high concentration, η and ϕ are given by the formulae

$$\eta = \frac{T_f-T}{T_f-T_0} \quad [6]$$

$$\phi = \frac{\lambda}{(V_0 n_0 C_p)^2}\frac{Q}{T_f-T_0}. \quad [7]$$

Here, λ is the thermal conductivity of the mixture, n_0 is the initial concentration of the mixture (mole/cm.^{3}), and Q is the heat produced per unit of time and volume.

We have now to find Q. Evidently

$$Q = qU_1 \quad [8]$$

where U_1 is the over-all rate of consumption of methane (in mole/sec. cm.^{3}) which can be computed from the number Z of collisions between methane molecules and oxygen atoms. According to the kinetic theory of gases

$$Z = 2N^2 n_1 n_6 \sigma^2 \sqrt{\frac{m_1+m_6}{m_1 m_6} 2\pi RT}. \quad [9]$$

Here, n_1 and n_6 are the concentrations and m_1 and m_6 are the molecular weights of methane and atomic oxygen, N is the number of molecules per mole, and σ is the molecular diameter effective in these collisions.

In order to eliminate n_6, we use the constant of the oxygen equilibrium [III]. According to Bartholomé (1), for the range of temperature under consideration,

$$n_6 \approx \sqrt{(670\, n_2)}\, e^{-58500/RT}. \quad [10]$$

Now let E be the activation energy of reaction [II]. Then

$$U_1 = \frac{Z}{N} e^{-E/RT}. \quad [11]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

The function ϕ, as given by equations [7], [8], [9], [10], [11], contains several factors which are always the same and can therefore be replaced once for all by their numerical values:

$$m_1 = m_6 = 16$$

$$R = 8.315 \times 10^7 \text{ ergs/mole degree}$$

$$N = 6.02 \times 10^{23}$$

$$\sigma = 2.6 \times 10^{-8} \text{ cm.}$$

Further, we place

$$\lambda = k\sqrt{T}.$$

The heat conductivity λ is not really proportional to $\sqrt{T}$ but increases faster with temperature. In spite of this, the above assumption is justified because the effective collision diameter σ decreases with increasing temperature so that the product $\lambda\sigma^2$ is very nearly proportional to $\sqrt{T}$.

The activation energy E of reaction [II], according to Harteck and Kopsch (4), is between 3000 and 9500 cal./mole. Sachsse (9) found the activation energy of the over-all process to be equal to 62000 cal./mole. In order to make the sum of the dissociation energy per oxygen atom plus activation energy equal to the experimental value, we place

$$E = 3500 \text{ cal./mole}$$

which is inside the above limits.

Substituting these values and applying the gas law, we find

$$[12] \qquad \phi = 1.557 \times 10^{15} \frac{T_0^2 k}{V_0^2 C_p \sqrt{p}} \frac{y_1\sqrt{y_2}}{y_{10}-y_{1f}} \frac{e^{-31000/T}}{\sqrt{T}}.$$

The pressure p is to be measured in megabars. The mean specific heat C_p varies somewhat with the methane contents of the mixtures and should therefore be computed separately for each mixture.

We have still to express y_1 and y_2 by η. We assume that the end products are not dissociated which is very nearly true if we confine ourselves to the combustion of methane in air or in helium air or argon air because in these cases the end temperature is not excessive.

We have to distinguish three cases: excess of air, stoichiometric mixture, and excess of methane. For an excess of air

$$y_{1f} = 0, \quad y_{2f} = 0.21 - 2.21\, y_{10}$$

and from [2], [4], and [6] we find

$$[13] \qquad \frac{y_1\sqrt{y_2}}{y_{10}-y_{1f}} = \sqrt{2y_{10}}\,\eta\sqrt{\eta+\frac{y_{2f}}{2y_{10}}}.$$

For an excess of methane

$$y_{2f} = 0, \quad y_{1f} = 1.105y_{10} - 0.105, \quad y_{20} = 0.21(1-y_{10}),$$

$$[14] \qquad \frac{y_1\sqrt{y_2}}{y_{10}-y_{1f}} = \sqrt{y_{20}}\left(\eta+\frac{2y_{1f}}{y_{20}}\right)\sqrt{\eta}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

For the stoichiometric mixture

$$y_{1f} = y_{2f} = 0, \quad y_{10} = 0.095,$$

$$[15] \qquad \frac{y_1\sqrt{y_2}}{y_{10}-y_{1f}} = \sqrt{2y_{10}}\,\eta\sqrt{\eta}\,.$$

By substituting these formulae in [12], we obtain ϕ as a function of η, because T is known as a function of η from equation [6].

The flame velocity V_0 is then computed as the eigenvalue of equation [5]. This can be done either by repeated numerical integration or by means of the approximation formula

$$[16] \qquad V_0 = \frac{1}{1-\eta_m}\left[2\int_0^1 F(\eta)d\eta\right]^{\frac{1}{2}}$$

where $F(\eta) = V_0^2\phi$ and ϕ is a maximum for $\eta = \eta_m$. The function $F(\eta)$ does not contain V_0 and is therefore completely known. The integral in [16] can best be evaluated by Simpson's formula.

Numeric calculations according to formula [16] were carried out for 8% methane and 9.5% methane (stoichiometric) in nitrogen air, helium air, and argon air. The results are shown in Table I. The experimental values are those found by Clingman, Brokaw, and Pease (2). The initial temperature was

TABLE I

FLAME VELOCITY V_0 (CM./SEC.)

		V_{exp}	V_{calc}	T_f	$k = \lambda/\sqrt{T}$
N-air	8% CH_4	28	26.5	2036°	3.64×10^{-6}

	9.5% CH_4	93.5	103.6	2514°	

chosen as 293°K. and the pressure as one megabar. The mean values of C_p were found by dividing the total heat developed per mole of the mixture by the temperature difference $T_f - T_0$, where T_f was calculated by thermodynamic methods. Thus, allowance was made for the slight amount of actual dissociation of the end products.

The excellent agreement between theory and experiments can be regarded as proof of the correctness of both the mathematical method used and the reaction mechanism and kinetic data assumed.

The present theory is not applicable for a substantial excess of fuel because in this case carbon is primarily formed in the flame zone which results in the presence of carbon monoxide in the burned mixture. The computed flame velocities are consequently too high. Formula [14] can therefore only be used for a very slight excess of methane. In this case the theory predicts an increase of flame velocity beyond the value for the stoichiometric mixture, a result which is well consistent with experience. This is due to the fact that for small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

values of η the function $F(\eta)$ becomes zero of the order $\frac{1}{2}$ while for the stoichiometric mixture it becomes zero of the order 3/2.

Formulae [12] and [16] imply that the flame velocity is proportional to $p^{-0.25}$. Lewis (6), who carried out exact measurements on the pressure dependence of the flame velocity, found for the stoichiometric mixture the pressure exponent $\nu = -0.18$ and for the 8% mixture $\nu = -0.26$. For mixtures containing more methane and oxygen and less nitrogen he found that ν increases and finally becomes positive. This is undoubtedly due to the fact that for these richer mixtures higher end temperatures are attained so that the influence of dissociation becomes considerable at low pressures, thus diminishing the flame velocity at low pressures.

The dependence of V_0 on the initial temperature T_0 and on the specific heat C_p, on the other hand, is not simply expressed by the factor $T_0/\sqrt{C_p}$ because T_0 and C_p also affect the end temperature T_f which in turn greatly affects V_0, so that V_0 increases faster than this factor. The flame velocity should further be proportional to $\sqrt{\lambda}$. The very good results obtained for helium and argon air seem to confirm the correctness of the theory in these regards.

For the stoichiometric mixture of methane and nitrogen air, equation [5] was also solved by repeated numerical integration. This gives an eigenvalue

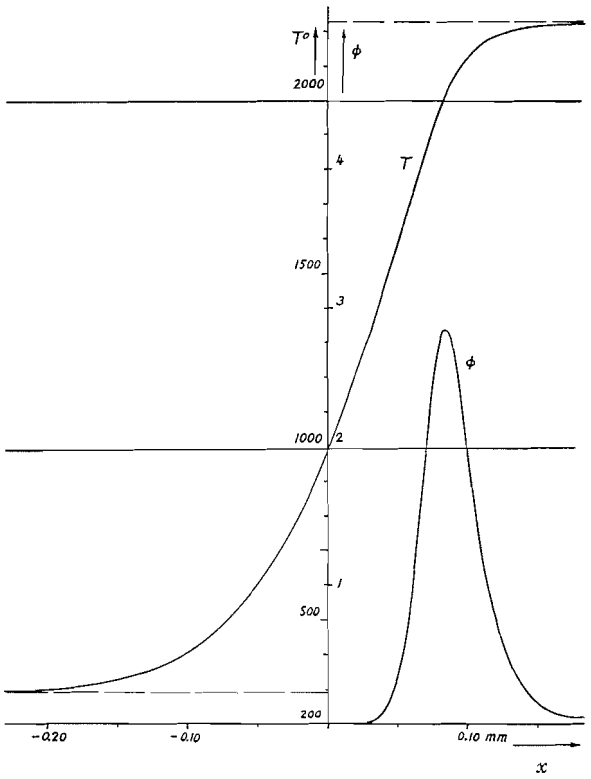

FIG. 1. Temperature and reaction rate in the flame zone.

For personal use only.

$V_0 = 40.8$ cm./sec., as compared to 40.4 obtained by formula [16]. The temperature distribution in the flame zone can then be found by an ordinary quadrature

$$[17] \qquad x = -\frac{1}{V_0 n_0 C_p} \int \frac{\lambda d\eta}{\zeta}.$$

The result is shown in Fig. 1. The integration constant was eliminated by placing $x = 0$ for $T = 1000°$. The temperature limits T_0 and T_f are attained only for $x = \mp \infty$. However, the thickness of the flame zone is practically very small (0.2 mm. for 95% of the total temperature difference), a result which is very well consistent with generally adopted ideas about the structure of flame zones.

The same figure shows also the quantity ϕ which is proportional to the rate of reaction [II] as well as to the rate of heat development, plotted against x. Most of the heat development takes place at temperatures near T_f.

THE ALDOBIOURONIC ACIDS OF HEMICELLULOSE B OF OAT HULLS[1]

By E. L. Falconer[2] and G. A. Adams

ABSTRACT

Partial hydrolysis of hemicellulose B from oat hulls yielded two aldobiouronic acids, which were identified as 2-*O*-(4-*O*-methyl-α-D-glucopyruronosyl)-D-xylose and 2-*O*-(α-D-glucopyruronosyl)-D-xylose respectively. In addition, two aldotriouronic acids were isolated, one yielding on hydrolysis xylose and 4-*O*-methylglucuronic acid, and the other, xylose, galactose, and glucurone.

INTRODUCTION

Previous investigations (2, 5, 8) have shown that the extractable hemicelluloses of oat hulls consist principally of xylan, with which small amounts of araban are either combined or admixed. Acid hydrolysis of the hemicelluloses also released uronic acids among which an aldotriouronic acid, containing D-galactose and D-glucuronic acid, was reported (2). This acid has never been reported as a component of other cell wall polysaccharides although similar acids have been isolated from plant gums. Since the previous investigations were carried out before the modern techniques of chromatography became available, it was felt that a further examination of the acid components of oat hull hemicellulose would be of interest.

In the present study the hemicelluloses of extractive-free, pectin-free oat hulls were isolated by successive extractions with 2% sodium carbonate, 5% sodium hydroxide, and 10% sodium hydroxide. These fractions were in turn separated into hemicellulose A, which was precipitated on slight acidification of the extracts with acetic acid, and into hemicellulose B, which remained soluble in the acidified extract but was precipitated with four volumes of ethanol. All hemicellulose fractions isolated by the various extraction procedures were composed primarily of D-xylose and L-arabinose residues. Two fractions (5B and 10A, Table I) also contained small amounts of D-galactose and D-glucose respectively. The fractions extracted with sodium carbonate (2A and 2B) had a high uronic acid content. A similar observation was made by Mitchell and Ritter (9) on the fraction of maple wood holocellulose soluble in 2% sodium carbonate. Since the uronic acids of fractions 5A and 5B showed similar compositions, the acidic oligosaccharides of fraction 5B, the largest hemicellulose fraction, were selected for further study.

The acidic components formed by partial hydrolysis of hemicellulose 5B were isolated by ion exchange resin and were separated by paper chromatography into four fractions. The relative proportion and analysis of the four fractions are shown in Table II. By equivalent weight estimations fractions I and III were shown to be aldotriouronic acids with fraction I containing

galactose, xylose, and glucurone and fraction III being composed of xylose and 4-*O*-methyl glucuronic acid. Fractions II and IV were aldobiouronic acids composed of glucuronic acid → xylose and 4-*O*-methyl glucuronic acid → xylose respectively. Reduction of these uronic acid fractions yielded the corresponding disaccharides after which the monosaccharide components were identified by hydrolysis and isolation of suitable crystalline derivatives.

Methylation and hydrolysis of the disaccharides obtained by reduction of fractions II and IV provided a means of locating the glycosidic bond attachments. An improved method of methylation was employed using dimethyl sulphate with solid sodium hydroxide in anhydrous tetrahydrofuran instead of water. Only one methylation treatment with these reagents was required to convert the methyl glucosyl-xyloside to a fully methylated product. Since the resulting methylated sugars from each fraction were chromatographically identified in three solvents and found to be identical only those from fraction IV were fully characterized as 2,3,4,6-tetra-*O*-methyl-D-glucopyranose and 3,4-di-*O*-methyl-D-xylose by physical constants and derivative formation. The results showed that fraction II was 2-*O*-(α-D-glucopyruronosyl)-D-xylose and that fraction IV was analogous to it but containing a methyl ether at C(4) of the glucuronic acid. Fraction IV was, therefore, identical with the aldobiouronic acid isolated from hemicelluloses of aspen wood (7), corn cobs (10), beechwood (3), scots pine, and black spruce (4). Fraction II was the same as the aldobiouronic acid obtained from sapote gum (12). Aldobiouronic acids identical with fractions II and IV have been found together previously only in hydrolyzates of wheat bran (1) and corn cob hemicelluloses respectively (10, 11).

The presence of galactose as part of the aldobiouronic acid (fraction I, hemicellulose 5B) could not be established because sufficient quantities of material were not available for a structural study. However, it seems clear that the main uronic acid component from oat hulls contains xylose and not galactose as its neutral sugar component. The results of the present investigation show that the main uronic acid components of oat hull hemicelluloses fit the general pattern of the glucuronic acid – xylose acids found in the cell wall hemicellulose of many plants.

EXPERIMENTAL

Paper Chromatography

Separations were performed by the descending technique on Whatman No. 1 filter paper. A saturated aqueous-butanol solution of aniline hydrogen oxalate was used as the spray reagent. The following solvents (v/v) were used: (A) ethyl acetate – acetic acid – formic acid – water (18: 3: 1: 4), (B) ethyl acetate – pyridine – water (2: 1: 2; upper layer), (C) 2-butanone–ethanol–water (20: 5: 2), and (D) benzene–ethanol–water (169: 47: 15; upper layer).

Preparation of Oat Hull Hemicelluloses

Finely-ground oat hulls were extracted with the benzene–ethanol azeotrope (2: 1) for two days in a Soxhlet apparatus. After being air-dried, the material was extracted for three hours with 0.5% ammonium oxalate at 80–85°C.

and for 16 hr. with the same extractant at room temperature, and was finally washed by stirring with large quantities of water at room temperature. The extractive-free, depectinized hulls were then consecutively and exhaustively extracted at room temperature with 2% sodium carbonate, 5% sodium hydroxide, and 10% sodium hydroxide; the alkali extractions being carried out in a nitrogen atmosphere. Acidification of the filtered extracts with glacial acetic acid yielded precipitates of hemicelluloses A, and concentration of the filtrates and precipitation into four volumes of ethanol yielded hemicelluloses B. The hemicelluloses were recovered by centrifuging, washed with 80% (v/v) aqueous ethanol, slurried with water, and dialyzed against distilled water. The resulting slurries were poured into four volumes of vigorously stirred ethanol, washed with ethanol, rinsed with ether, and dried *in vacuo*. Yields, based on the oven-dried, extractive-free oat hulls, and ash (sulphated) contents are given in Table I.

TABLE I

YIELDS AND ASH CONTENTS OF CRUDE HEMICELLULOSES FROM DRIED, EXTRACTIVE-FREE OAT HULLS

Extractant	Hemicellulose fraction	Yield, %	Sulphated ash, %
2% sodium carbonate	2A	0.10	38.01
	2B	0.40	28.53
5% sodium hydroxide	5A	12.3	4.78
	5B	14.9	12.00
10% sodium hydroxide	10A	0.49	2.21
	10B	1.86	8.91

Qualitative Examination of Hemicellulose Fractions for Sugar Components

The hemicellulose fractions were all light brown powders which were partially soluble in water. Hydrolysis with 3% sulphuric acid for 12 hr. and paper chromatographic examination of the hydrolyzates using solvent B showed xylose and arabinose to be the principal constituents of all fractions. Galactose occurred only in fraction 5B and glucose in fraction 10A. Fractions 2A and 2B had relatively high uronic acid contents. No other differences between the fractions were evident. The residue which remained after the alkaline extractions yielded glucose, xylose, and arabinose on hydrolysis. Insoluble lignin-like material remaining after acid hydrolysis amounted to 7.84% for fraction 5A and to 18.38% for fraction 5B. Isolation by means of an anion exchange resin (Amberlite IR-4B), and further paper chromatographic examination of the acid constituents of the hydrolyzates of fractions 5A and 5B using solvent A revealed that these fractions had similar compositions. Further study was therefore concentrated on fraction 5B where these components occurred in apparently larger amounts.

Separation of the Uronic Acid Constituents of Hemicellulose Fraction 5B and Identification of the Sugar Components

Hemicellulose 5B (75 gm.) was partially dissolved by stirring in hot water (2 liters) for one hour. A 4% solution of sulphuric acid (1850 ml.) was then added and the mixture was boiled under reflux for 11 hr. The insoluble material

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

was separated by centrifuging and again heated for an additional 10 hr. in 3% sulphuric acid (1 liter). The acid hydrolyzate was heated to about 80°C., brought to pH 5.6 by solid barium hydroxide and then to neutrality with barium carbonate. Decolorizing charcoal was stirred into the hot mixture, and after settling and cooling, the clear supernatant liquid was poured off and filtered. The filtrate was passed slowly through a double column containing Amberlite IR-120 cation-exchange resin (150 ml.) followed by an equal volume of IR-4B anion-exchange resin, and the resins were washed with large quantities of water until the washings were negative to the anthrone test (6). The column was dismantled, and the IR-4B resin containing the absorbed uronic acids was transferred to a beaker. The resin was stirred in 4% sulphuric acid (1060 ml.) for one hour after which the uronic acids were recovered by washing the resin, in a column, with 0.02 *N* sulphuric acid. The eluate was neutralized with barium carbonate, filtered, and finally passed through IR-120 cation-exchange resin (150 ml.) before being concentrated to a sirup (4 gm.). A paper chromatogram of the sirup developed in solvent A showed four components with R_x (rate of flow relative to xylose) values of 0.09, 0.27, 0.36, and 0.68 together with small amounts of D-xylose and a methoxyglucuronic acid, R_x 1.45.

A sample of the sirup containing the mixed uronic acids was converted to the methyl glycoside methyl ester mixture and reduced with lithium aluminum hydride in tetrahydrofuran (as described later). Hydrolysis of the reduced oligosaccharides and paper chromatographic examination using solvents B and C indicated the presence of D-glucose, D-xylose, and 4-*O*-methyl-D-glucose. Separation of the sugar mixture on large sheets of paper was carried out in solvent C for 17 hr. at 28°C. Recovery of the three materials yielded:

(*a*) Four parts (by weight) of a sirup corresponding to α-D-glucopyranose: $[\alpha]_D^{25}$ +44.1° (*c*, 3.6 in water); osazone, dec. 202–204°C. An X-ray powder pattern of the osazone confirmed its identity with that of an authentic sample of D-glucosazone.

(*b*) Nine parts of crystalline α-D-xylopyranose: $[\alpha]_D^{25}$ +56.6° (7 min.)→+19° (1.5 hr., constant) (*c*, 2.5 in water), m.p. and mixed m.p. 144–145.5°C. (from ethanol). The X-ray powder pattern of these crystals was identical with that of a known sample.

(*c*) Seven parts of a sirup of 4-*O*-methyl-D-glucopyranose: $[\alpha]_D^{25}$ +57.2 (*c*, 1.6 in water); osazone, $[\alpha]_D^{25}$ −32 (10 min.) → +9 (48 hr., constant) (*c*, 0.5 in 2% ethanolic pyridine); m.p. and mixed m.p. 158.5–159.5°C. (from benzene containing a little ethanol). The identity of the osazone was confirmed by comparison of its X-ray powder pattern with that of a known sample of 4-*O*-methyl-D-glucosazone.

These observations confirm the presence of D-xylose, D-glucuronic acid, and 4-*O*-methyl-D-glucuronic acid as the principal monosaccharide components of the acid fraction of hemicellulose 5B.

Chromatographic Separation of Uronic Acid Fraction Components from a Hydrolyzate of Hemicellulose 5B

The uronic acids from a partial hydrolysis of the hemicellulose were separated on 30 sheets of Whatman No. 1 filter paper (11.25 in. × 18.5 in.) using solvent

A and a developing time of 25 hr. The various fractions were eluted from the paper with water, the solutions were concentrated to small volume, decolorized with charcoal, and evaporated to dryness. Properties of these fractions are shown in Table II.

TABLE II

PROPERTIES OF THE URONIC ACID FRACTIONS FROM HEMICELLULOSE B OF OAT HULLS

Fraction	Weight ratio	R_x* (solvent A)	$[\alpha]_D^{25}$	Neutn. equiv.	OMe, %	Sugar components†
I	1	0.09	+40	440	1.42	Galactose, xylose, glucuronic acid
II	5	0.27	+88.4	332	1.00	Xylose, glucuronic acid
III	2	0.36	+79	440	6.76	Xylose, 4-*O*-methyl glucuronic acid
IV	6.5	0.68	+94.5	346	8.54	Xylose, 4-*O*-methyl glucuronic acid

*R_x = *rate of flow relative to* D-*xylose.*
†*Based on chromatographic identifications.*

Examination of Uronic Fraction IV

The material had a higher R_x value (0.68) than galacturonic acid (R_x 0.50) in solvent A in which glucuronic acid moved completely as glucurone (R_x 1.80). This observation was further evidence suggesting the presence of a methoxyl group. Anal.: Calc. for $C_{11}H_{17}O_{10}(OCH_3)$: OMe, 9.12%; equiv. wt. 340.3. Found: OMe, 8.54%; equiv. wt., 346.

Hydrolysis of the aldobiouronic acid with *N* sulphuric acid for 16 hr. in a sealed tube at 110°C. followed by paper chromatography with solvents A and B revealed the presence of D-xylose and 4-*O*-methyl-D-glucuronic acid in addition to some unchanged material.

A sample of the aldobiouronic acid (527 mgm.) was converted to the glycoside, ester form by heating with 2% methanolic hydrogen chloride (25 ml.) for six hours under reflux. The methyl glycoside methyl ester of the aldobiouronic acid (524 mgm.) in tetrahydrofuran (50 ml.) was reduced by dropwise addition of a solution of lithium aluminum hydride (600 mgm.) in tetrahydrofuran (25 ml.). The product (497 mgm.) was hydrolyzed by heating at 100°C. for six hours with *N* sulphuric acid and chromatographic examination (solvents B and C) of the hydrolyzate showed the presence of xylose and 4-*O*-methyl glucose.

Methylation of the Disaccharide

The 4-*O*-methyl-D-glucosyl-D-xylose (497 mgm.) in water (3 ml.) was methylated by dimethyl sulphate (1.5 ml.) and 30% sodium hydroxide (3.0 ml.). Three additions of reagents were made before the mixture was brought to pH 8.9 by sulphuric acid and the product was recovered by continuous extraction with chloroform. Evaporation of the chloroform extract yielded a sirup (463 mgm.) which exhibited a small infrared absorption maximum at 3480 $cm.^{-1}$ indicating the presence of free hydroxyl groups.

Complete methylation of the sirup (448 mgm.) was obtained by the dropwise addition over three hours of dimethyl sulphate (3 ml.) to a stirred solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

of the sirup in pure tetrahydrofuran (15 ml.) containing pulverized sodium hydroxide (2.6 gm.). The reaction was carried out for 16 hr. in a flask partially immersed in a water bath at 23–28°C., after which enough water was added to bring the solids into solution. The temperature of the water bath was raised to 60°C., the tetrahydrofuran was evaporated by a stream of nitrogen, and the temperature was maintained for an hour to ensure the complete decomposition of the dimethyl sulphate. The mixture was cooled, partially neutralized to pH 8.9 with sulphuric acid, and extracted with chloroform. Evaporation of the chloroform extract yielded a sirup which was freed from impurities by filtration of its methanol solution. Evaporation of the methanol and drying of the resultant sirup afforded a product (400 mgm.), $[\alpha]_D^{25}$ +114° (*c*, 1.4 in chloroform) whose infrared spectrum indicated only a slight trace of hydroxyl groups. Anal.: Calc. for $C_{11}H_{13}O_3(OCH_3)_7$: OMe, 52.92%. Found: OMe, 51.7%.

Hydrolysis of the Methylated Disaccharide and Separation of the Products

The methylated disaccharide (366 mgm.) was heated under reflux with 4% methanolic hydrogen chloride (25 ml.) for 15 hr., and after evaporation of the acid under reduced pressure, with boiling *N* hydrochloric acid (25 ml.) for six hours. The hydrolyzate was deionized by Amberlite resins IR-120 and IR-4B and the resulting solutions were evaporated to a sirup (221 mgm.). Paper chromatography of this sirup in solvents C and D indicated the presence of two components giving the same color reactions with the spray reagent and moving concurrently with 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose. The sugars were separated on large sheets of paper in solvent D (4.5 hr.). The individual sugars were recovered by removal and elution of the appropriate zones with water, treatment of the concentrated solutions with activated charcoal and with mixed resins (IR-120 and IR-4B) followed by evaporation to sirups. Filtration of the materials from ethyl acetate solutions and evaporation of the solvent yielded pure sirups of dimethylxylose (58.8 mgm.) and tetramethylglucose (86.3 mgm.). The tetramethylglucose sirup crystallized spontaneously on standing.

Identification of 3,4-Di-O-methyl-D-xylose

The dimethylxylose was a colorless sirup, $[\alpha]_D^{25}$ +19° (*c*, 1.6 in water), producing brick-red spots of R_g 0.38 on paper chromatograms developed with solvent D and sprayed with the aniline hydrogen oxalate reagent. The methylated sugars, 2,4-di-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2,3,4-tri-*O*-methyl-D-xylose, gave dark brown spots of R_g values 0.27, 0.31, and 0.89 respectively on similarly prepared chromatograms.

The 3,4-di-*O*-methyl-D-xylose (37.8 mgm.) in water (1 ml.) was oxidized with bromine (0.025 ml.) for 42 hr. at room temperature. The product (24.9 mgm.) crystallized after nucleation with 3,4-di-*O*-methyl-D-xylonolactone. Recrystallization from ether containing a small amount of *n*-hexane yielded colorless needles, $[\alpha]_D^{25}$ −48 (15 min.) → −20 (54 hr., constant) (*c*, 1.0 in water); m.p. and mixed m.p. 67–68°C. The dimethylxylose was therefore 3,4,-di-*O*-methyl-D-xylopyranose.

Identification of 2,3,4,6-Tetra-O-methyl-D-glucose

Recrystallization of the tetramethylglucose from ether – petroleum ether afforded light yellow needles, $[\alpha]_D^{25}$ +88.1 (15 min.) → +83.2 (4.5 hr., constant) (*c*, 1.4 in water); m.p. and mixed m.p. 83.0–95.5°C.

The 2,3,4,6-tetra-*O*-methyl-D-glucopyranose (60 mgm.) was converted to the anilide (7). Recrystallization several times from *n*-hexane and from ethanol yielded colorless needles of 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 116–117°C.; $[\alpha]_D^{25}$ +205 (*c*, 1.2 in acetone).

Characterization of Uronic Fraction II

A sample of fraction II was placed in a sealed tube with *N* sulphuric acid for 16 hr. at 110°C. Paper chromatography of the hydrolyzate in solvents A and B indicated the presence of D-xylose and D-glucurone. Treatment of the aldobiouronic acid with 2% methanolic hydrogen chloride produced the methyl glycoside methyl ester which was reduced with lithium aluminum hydride in tetrahydrofuran to the methyl glycoside of the corresponding disaccharide. Acid hydrolysis of this disaccharide liberated D-xylose and D-glucose as shown by examination of paper chromatograms developed in solvent B.

Complete methylation of the glucosyl-xylose methyl glycoside was accomplished by the same method as described for fraction IV and yielded a sirup (108 mgm.), $[\alpha]_D^{25}$ +110 (*c*, 1.1 in chloroform) whose infrared spectrum indicated the total absence of hydroxyl groups. Anal.: Calc. for $C_{11}H_{13}O_3(OCH_3)_7$: OCH_3, 52.92%. Found: OCH_3, 52.5%.

A solution of the hepta-*O*-methyl-glucosyl-xylose in 4% methanolic hydrogen chloride was heated in a sealed tube for 15 hr. at 80°C. Subsequent hydrolysis with aqueous *N* hydrochloric acid followed by chromatographic examination in solvents B, C, and D revealed the presence of two methylated reducing sugars moving adjacently to and producing the same color reactions with the spray reagent as did 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose.

Since these components were the same as those previously identified from fraction IV no further characterization was done.

FREE RADICALS BY MASS SPECTROMETRY

X. THE IONIZATION POTENTIALS OF METHYL SUBSTITUTED ALLYL RADICALS[1]

By C. A. McDowell,[2] F. P. Lossing, I. H. S. Henderson,[3] and J. B. Farmer[4]

ABSTRACT

The vertical ionization potentials of the β- and γ-methyl substituted allyl radicals as measured by electron impact are 8.03±0.05 v. and 7.71±0.05 v., respectively. From appearance potential data the following bond dissociation energies can be derived, assuming the dissociation processes to be free from complications:

$$D(CH_2{:}\,C(CH_3)CH_2{-}I) = 31.6{\pm}2 \text{ kcal./mole}$$
$$D(CH_3CH{:}\,CHCH_2{-}I) = 33.2{\pm}2 \text{ kcal./mole.}$$

With assumptions about the structure of the ions produced by electron impact from the corresponding butenes the dissociation energies of the C_4H_7—H bonds in these latter compounds can be estimated, and the heats of formation of the corresponding radicals derived, namely:

$$\Delta H_f^\circ(CH_2{:}\,C(CH_3)\dot{C}H_2) = 21{\pm}3 \text{ kcal./mole}$$
$$\Delta H_f^\circ(CH_3CH{:}\,CH\dot{C}H_2) = 26{\pm}3 \text{ kcal./mole.}$$

From data on the allyl halides we evaluate the heat of formation of the allyl radical to be:

$$\Delta H_f^\circ(CH_2{:}\,CH\dot{C}H_2) = 32{\pm}6 \text{ kcal./mole.}$$

INTRODUCTION

Of the eight structures possible for C_4H_7 radicals three can be regarded as methyl substituted allyl radicals and consequently should have a delocalization energy of about the same order as that attributed to the allyl radical itself. These three radicals are:

$$CH_3\dot{C}HCH{:}\,CH_2 \quad (\alpha)$$
$$CH_3CH{:}\,CH\dot{C}H_2 \quad (\gamma)$$
$$CH_2{:}\,C(CH_3)\dot{C}H_2 \quad (\beta)$$

As derivatives of the allyl radical by methyl substitution these can be called the α-, γ-, and β-methallyl radicals respectively. The first two structures are interconvertible by electron migration without a proton shift, and according to this view these radicals may be regarded as resonance hybrids with an intermediate structure rather than as separate entities.

It was thought to be of interest to attempt the preparation of the three methallyl radicals by pyrolysis of the corresponding iodides to see if the ionization potentials of the radicals produced from the α- and γ-methallyl iodides were in fact identical. It would also be of interest to determine the effect on the ionization potential of the allyl radical of substitution of methyl in these positions.

The β-methallyl radical has been suggested as an intermediate in the pyrolysis of isobutene (17, 16) and as a product of the primary dissociation in the same pyrolysis (23). From kinetic considerations it was concluded that the thermal dissociation of the radical led to the formation of allene and a methyl radical

$$CH_2{:}\,C(CH_3)\dot{C}H_2 \rightarrow CH_2{:}\,C{:}\,CH_2 + \dot{C}H_3. \qquad [1]$$

The γ-methallyl or crotyl radical does not seem to have been studied very much. The pyrolysis of 2-butene, in which its formation seems likely, has not been investigated as thoroughly as that of 1-butene. The pyrolysis of the latter compound has been shown to yield a methyl and an allyl radical (19, 9) instead of forming the α-methallyl radical by loss of a hydrogen atom. The equivalent process for 2-butene, namely

$$CH_3CH{:}\,CHCH_3 \rightarrow CH_3CH{:}\,\dot{C}H + \dot{C}H_3, \qquad [2]$$

would seem to be improbable since, without isomerization, the structure of this radical does not allow a delocalization energy of the order available to the allyl radical. The activation energy for the decomposition of 2-butene, based on preliminary work, was found by Molera and Stubbs (14) to be 57.4 kcal./mole as compared to 66.4 kcal./mole for 1-butene. This difference does not seem to be a measure of the dissociation energies of the bonds broken in the two primary processes, for the primary split for 2-butene is, probably,

$$CH_3CH{:}\,CHCH_3 \rightarrow CH_3CH{:}\,CH\dot{C}H_2 + H \qquad [3]$$

and, of course, the dissociation energy for the R—H bond in equation [3] is almost certainly greater than that of the allyl—CH_3 bond in 1-butene.

PREPARATION OF METHALLYL IODIDES

(*a*) *β-Methallyl Iodide* (*CH_2: $C(CH_3)CH_2I$*)

Commercial methallyl chloride was purified by distillation in a 100 cm. column packed with glass helices. In a second distillation a fraction having a boiling point of 71.9° C. at 756 mm. was collected. This fraction was refluxed for one hour with an excess of a saturated solution of sodium iodide in acetone. After the addition of water, the methallyl iodide was separated and washed with successive portions of water. It was then dried and distilled twice at reduced pressure, the middle fraction being retained. The mass spectrum showed that a trace of the dimer of the β-methallyl radical, 2,5-dimethyl 1,5-hexadiene, was present, but no other impurities were detected.

(*b*) *γ-Methallyl Iodide* (*CH_3CH: $CHCH_2I$*)

This was prepared (24) by passing butadiene through 57% aqueous HI at 20° C. The product was separated and purified by several bulb-to-bulb distillations. The infrared spectrum showed that this sample was the γ-isomer. The refractive index at 23° C. was 1.5500.

(*c*) *α-Methallyl Iodide* (*CH_3CHICH: CH_2*)

All attempts to produce this isomer resulted instead in the production of the γ-isomer. α-Methallyl bromide was prepared by the addition of butadiene to anhydrous HBr under antioxidant conditions (8). After being freed from

HBr and butadiene by bulb-to-bulb distillation, the product had a refractive index at 23° C. of 1.4617, in good agreement with $\eta_{23} = 1.4608$ given by Kharasch *et al.* The infrared spectrum showed that this product was the α-isomer, essentially free from γ-methallyl isomer even after several days' storage at 0° C. However when the bromide was treated with NaI in acetone the resulting methallyl iodide after low-pressure distillation was found by infrared analysis to have almost completely rearranged to the γ-isomer.

It was thought that the isomerization might have occurred during the low-pressure distillation. An attempt was therefore made to prepare the α-methallyl iodide directly from butadiene and anhydrous HI in a manner analogous to the preparation of the bromide. Anhydrous HI was prepared (1) by the reaction of iodine vapor and hydrogen on platinized asbestos. This was condensed into a trap containing butadiene and a little diphenylamine cooled in liquid nitrogen. The liquid nitrogen was then replaced by a dry-ice acetone mixture. As soon as the contents of the trap liquified, reaction occurred, as indicated by a sharp but temporary increase in pressure. The resulting methallyl iodide was freed from butadiene and HI by bulb-to-bulb distillation. The infrared spectrum showed, however, that this product was essentially pure γ-methallyl iodide. In view of the ease of isomerization of α-methallyl bromide (8) it is probable that the isomerization

$$CH_3CHICH{:}CH_2 \rightarrow CH_3CH{:}CHCH_2I \qquad [4]$$

is very rapid even at low temperatures.

PRODUCTION OF THE RADICALS

The methallyl radicals were produced by pyrolysis of the corresponding iodides in a low pressure reactor attached to the ion source of a mass spectrometer, the reactor being the same as that used earlier to produce the ethyl, isopropyl, and propargyl radicals (4). The modified mass spectrometer and its operation have been described (12, 11).

(*a*) *β-Methallyl Radicals*

At a reactor temperature of 825° C., the β-methallyl iodide was almost completely decomposed as indicated by the parent peak at mass 182. Using electrons of low energy, observations of the mass 55 peak showed methallyl radicals to be present in abundance. With electrons of 50 v. energy the dimerization product 2,5-dimethyl 1,5-hexadiene was also found to be present. From a pure sample, the ratio of peaks 55/95 in the mass spectrum of the latter was measured. Using this ratio and the ratio of peaks 55/182 in the spectrum of β-methallyl iodide, the net peak height at mass 55 attributable to methallyl radicals could be measured. A net peak of 8×10^{-12} amperes for the radical could be obtained without difficulty. With higher temperatures up to 1050° C., the amount of β-methallyl radicals decreased, the decomposition products being methyl radicals and allene as found by Szwarc (23).

(*b*) *γ-Methallyl Radicals*

The behavior of γ-methallyl iodide was essentially the same as that of the β-isomer, the iodide being almost completely decomposed at 825° C. Methallyl

radicals and a dimer, presumably 2,6-octadiene, were produced. The ratio 55/95 in the spectrum of 2,6-octadiene was obtained from a sample prepared by heating γ-methallyl iodide in contact with zinc dust, followed by vacuum distillation. With reactor temperatures up to 1050° C. the amount of methallyl radicals decreased, the products in this case being butadiene and hydrogen:

$$CH_3CH{:}\,C\dot{H}CH_2 \rightarrow CH_2{:}\,CHCH{:}\,CH_2 + H. \qquad [5]$$

It was not established whether the butadiene was the 1,2- or the 1,3-isomer. A net peak of 4×10^{-12} amperes for the radical could be easily produced.

MEASUREMENT OF THE IONIZATION POTENTIALS

Using 50 v. electrons, the net peak heights at mass 55 for the radicals were obtained by subtracting the contributions from the dimers and from the undecomposed fraction of methallyl iodides as described above. The method of measurement of the ionization potentials of the radicals was the same as that described previously (9). Ionization efficiency curves for the radical ion and for the krypton 84 ion were measured alternately. The voltage difference (δV) between these curves was plotted against the peak height (I) and the resulting curve was extrapolated to $I = 0$ (25, 13). For comparison the voltage difference of the β-methallyl radical ion was also determined by the "vanishing-current" method (20, 21). The appearance potentials for the β- and γ-methallyl ions from the iodides were also measured.

RESULTS AND DISCUSSION

(*a*) *Ionization Potentials*

In Table I are given the values found for the vertical ionization potentials of the methallyl radicals by the method of extrapolated voltage differences,

TABLE I

IONIZATION POTENTIAL OF β- and γ-METHALLYL

Radical	Ionization potential (volts)	
	Individual values	Average
$CH_2{:}\,C(CH_3)\dot{C}H_2$ (β)	8.03 8.03 8.02	8.03±0.05
"Vanishing-current" method	8.01	
$CH_3CH{:}\,C\dot{H}CH_2$ (γ)	7.72 7.73 7.68	7.71±0.05

each being the average of three determinations. The limits of error were estimated from the uncertainty in the extrapolation of the δV vs. I curves, the ones for the β-methallyl radical being shown in Fig. 2. Fig. 1 shows the ionization efficiency curves for krypton 84 and the β-methallyl radical, from which the "vanishing-current" method yields a value of $I(\beta\text{-methallyl}) = 8.01$ v., in good agreement with the values determined by the other method.

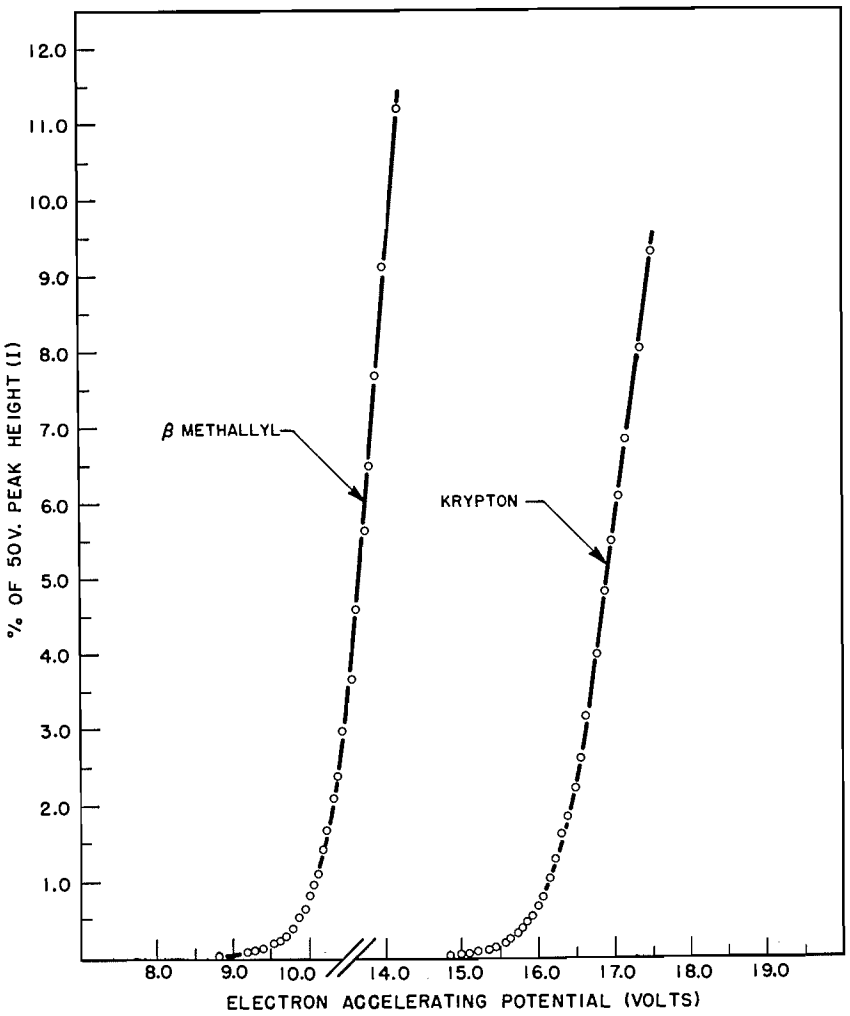

FIG. 1.

The conclusion that the difference in the ionization potentials of the β- and γ-methallyl radicals does not result from an error in the calibration of the voltage scale received confirmatory evidence from a preliminary experiment in which a sample of methallyl iodide prepared from commercial β-methallyl chloride was pyrolyzed. The ionization efficiency curve for mass 55 had a sigmoid shape at low electron energy, indicating the presence of two radical species of the same mass but with different ionization potentials. Using methallyl iodide prepared from a redistilled sample of the commercial β-methallyl chloride, the sigmoid shape was completely absent.

It is interesting to compare these ionization potentials with the 8.16 ± 0.03 v. obtained for the allyl radical (9). The substitution of a methyl group for the β-hydrogen in allyl causes a decrease of only 0.13 ± 0.08 v., while the substitution of a γ-hydrogen causes a decrease of 0.45 ± 0.08 v. Although there is some disagreement about the ionization potentials of the corresponding hydro-

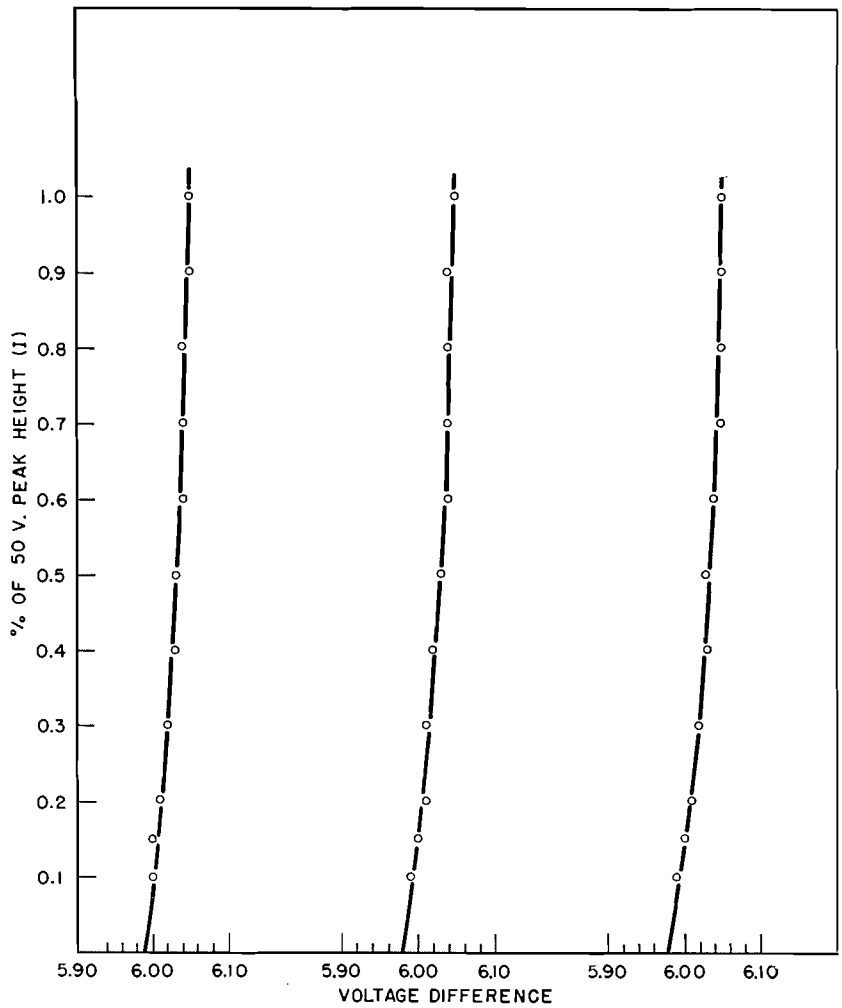

FIG. 2.

carbons isobutene and 2-butene, the values of Honig (7) appear to be the most consistent: I(isobutene) = 9.35 v. and I(2-butene) = 9.29 v. (average). This is a much smaller difference than is found for the radicals. The latter difference is evidently associated with the degree of delocalization energy permitted to the free electron in the two radical configurations. On simple grounds one might expect $I(\beta)$ to be less than $I(\gamma)$ rather than the reverse, since the forms

$$CH_2{=}C(CH_3){-}\dot{C}H_2 \leftrightharpoons \dot{C}H_2{-}C(CH_3){=}CH_2$$

are identical, while those for the γ-radical

$$CH_3{-}CH{=}CH{-}\dot{C}H_2 \leftrightharpoons CH_3{-}\dot{C}H{-}CH{=}CH_2$$

are not. This naive approach is, however, quite inadequate. It is obvious that hyperconjugational effects will be more important in the γ-methallyl radical

than with the β-isomer. This means that the delocalization energy of the γ-radical would certainly be slightly greater than that of the β-isomer; and since it is apparent that there is a definite correlation between the delocalization energy of a molecular species and its ionization potential (15, 2) it is, therefore, to be expected that $I(\gamma\text{-methallyl}) < I(\beta\text{-methallyl})$. This is in agreement with our experimental results.

(*b*) *Appearance Potentials*

The appearance potentials of the β- and γ-methallyl ions from the corresponding iodides are given in Table II. From the relation

$$D(\text{R—X}) \leqslant A(\text{R}^+) - I(\text{R}) \qquad [6]$$

TABLE II

APPEARANCE POTENTIALS AND BOND DISSOCIATION ENERGIES IN METHALLYL IODIDES

Compound	Appearance potential (volts) Individual values	Average	$D(C_4H_7—I)$ (kcal./mole)
β-Methallyl iodide	9.40 9.41 9.40	9.40±0.05	31.6±2
γ-Methallyl iodide	9.15 9.15 9.14	9.15±0.05	33.2±2

the bond dissociation energies given in Table II were derived. The values of $D(C_4H_7—I)$ are almost the same for the two radicals within the experimental accuracy, the γ-methallyl–iodine bond being possibly a little stronger. As would be expected, the bond dissociation energies are only a little lower than the 34–36 kcal. found previously for the allyl–iodine bond (10).

The appearance potentials of the C_4H_7 ion from isobutene and from *cis* and *trans* 2-butene have been reported as follows:

$A(C_4H_7^+)$ from isobutene	11.32±0.1 v.	(22)
$A(C_4H_7^+)$ from *trans* 2-butene	11.24±0.1 v.	(3)
$A(C_4H_7^+)$ from *cis* 2-butene	11.11±0.1 v.	(3)

If it is assumed that the $C_4H_7^+$ ion from isobutene is the β-methallyl ion, a value of $D(\beta\text{-methallyl—H}) = 76\pm3$ kcal./mole is obtained. This is in excellent agreement with the value of 76 kcal./mole suggested by Szwarc (23) on the basis of his work on the 1-butene pyrolysis. Similarly, using the average of the appearance potentials for *cis* and *trans* 2-butene, and assuming that the $C_4H_7^+$ ion produced has the γ-methallyl configuration, $D(\gamma\text{-methallyl—H}) = 80\pm3$ kcal./mole. For comparison with these values, from the pyrolysis of 1-butene D(allyl—H) has been found to be 76.5 kcal./mole and the heat of formation of allyl to be 30 kcal./mole (19). Support for these values can be obtained from recent electron impact data (10) from which

D(allyl—Cl) = 60.4±3 kcal./mole
D(allyl—Br) = 47.7±3 kcal./mole
D(allyl—I) = 35.2±3 kcal./mole (average).

Using the heats of formation for the allyl halides given by Gellner and Skinner (6)

$\Delta H_f°$(allyl chloride) = 0.6±3 kcal./mole
$\Delta H_f°$(allyl bromide) = 12.1±3 kcal./mole
$\Delta H_f°$(allyl iodide) = 22.0±3 kcal./mole

these data lead to the following values of $\Delta H_f°$(allyl)

32.0±6 kcal./mole
33.1±6 kcal./mole
31.7±5 kcal./mole

with an average of 32.3±6 kcal./mole. In view of the good agreement of these results, this limit of error appears to be extreme. From this average value and the heat of formation of propylene (4.88 kcal./mole (18)) the bond dissociation energy D(allyl—H) = 79±6 kcal./mole, in good agreement with the pyrolysis value.

By combining these data with the heats of formation of isobutene (−3.3 kcal./mole) and 2-butene (average of *cis* and *trans* −1.9 kcal./mole (18)), the heats of formation of the radicals are given as:

$\Delta H_f°(CH_2{:}C(CH_3)\dot{C}H_2)$ = 21±3 kcal.
$\Delta H_f°(CH_3CH{:}CH\dot{C}H_2)$ = 26±3 kcal.

A further calculation of interest involves the relation

$$I_{RH} - I_R = D(R—H) - D(R^+—H)\,. \qquad [7]$$

As discussed in an earlier publication (5) the variation of the quantity $I_{RH} - I_R$ with substitution gives a measure of the relative stabilization of the R—H bond in the neutral molecule and the ion. It was found that for benzyl radicals $I_{RH} - I_R$ = 1.47 v., for xylyl radicals ∼ 1.4 v., and for allyl radicals = 1.68 v. From the values of I_{RH} given above, $I_{RH} - I_R$ for β-methallyl = 1.32 and for γ-methallyl = 1.58 v. From equation [7], and assuming that the derived values of D(R—H) in Table III are correct, D(β-methallyl$^+$—H) = 46 kcal./mole and D(γ-methallyl$^+$—H) = 44 kcal./mole.

TABLE III

APPEARANCE POTENTIALS AND BOND DISSOCIATION ENERGIES IN ISOBUTENE AND 2-BUTENE MOLECULES AND IONS

Compound	Appearance potential of $C_4H_7^+$ (volts)	$D(C_4H_7—H)$* (kcal./mole)	$D(C_4H_7^+—H)$* (kcal./mole)
Isobutene	11.32±0.1 (22)	76±3	46
2-Butene	*cis* 11.11 *trans* 11.24 av. 11.18±0.1 (3)	80±3	44

**Assuming the $C_4H_7^+$ ion formed to have the β-methallyl structure from isobutene and the γ-structure from 2-butene.*

TABLE IV

HEATS OF FORMATION OF RADICALS AND IONS

Radical or ion	ΔH_f° (kcal./mole)
$CH_2{:}\,C(CH_3)\dot{C}H_2$	21±3
$CH_3CH{:}\,CH\dot{C}H_2$	26±3
$CH_2{:}\,CH\dot{C}H_2$	32±6
$CH_2{:}\,C(CH_3)CH_2^+$	206±3
$CH_3CH{:}\,CHCH_2^+$	204±3
$CH_2{:}\,CHCH_2^+$	220±6
$CH_2{:}\,C(CH_3)CH_3^+$	212
$CH_3CH{:}\,CHCH_3^+$	212
$CH_2{:}\,CHCH_3^+$	232

In Table IV are listed the heats of formation of the radicals, the radical ions, and the olefin ions, assuming that the electron impact data given above correspond to the assigned dissociation processes.

ACKNOWLEDGMENT

The authors wish to thank Mr. R. Lauzon of these laboratories for obtaining the infrared spectra of the methallyl halides.

ORGANIC DEUTERIUM COMPOUNDS

XV. SYNTHESIS OF SOME DEUTERATED ALKANES[1]

By Mary Elaine Leblanc, A. T. Morse, and L. C. Leitch

ABSTRACT

An improved method of preparing deuterated alkanes from the halides has been developed. Dehalogenation of ethyl iodide, 1,1-dibromoethane, and 1,1,1-trichloroethane with zinc dust in deuterium oxide – dioxane solutions, or even with deuterium oxide alone, gave excellent yields of ethane-d_1, ethane-1,1-d_2, and ethane-1,1,1-d_3. Methane-d_1, -d_2, -d_3, and -d_4 were prepared similarly from methyl iodide, dibromomethane, chloroform, and carbon tetrachloride respectively. The isotopic purity of the products was over 90 mol. %. The reaction is also applicable to higher alkyl halides.

The dehalogenation of alkyl halides has been used only to a limited extent for the preparation of deuterated alkanes. MacWood and Urey (6) synthesized mono-, di-, and tri-deuteromethane from the appropriate halides, deuterium oxide, and aluminum amalgam. The same compounds were later prepared by Benedict, Morikawa, and Taylor (1) by the action of zinc and ethanol-*d* on the polyhalides. Perhaps owing to the presence of ordinary ethanol in the ethanol-*d* none of the products they obtained was isotopically pure. According to Dibeler and Mohler (3) the dehalogenation of bromoform and methylene bromide with lithium aluminum deuteride leads to deuterated methanes which contain up to 40% of the less deuterated species. The action of deuterium oxide on a Grignard reagent has been used to prepare methane-d_1 (2).

Each of these methods has its own peculiar disadvantages. The aluminum–mercury couple used by MacWood and Urey (6) is probably difficult to prepare free of protium without impairing its activity. A serious disadvantage of employing a deuterated solvent such as ethanol-*d* is that it has to be recovered. Besides giving impure products, the method of Dibeler and Mohler (3) requires lithium aluminum deuteride which is still rather expensive. Finally, the decomposition of Grignard reagents is strictly limited to the preparation of monodeuterated hydrocarbons.

The action of zinc dust and acetic acid-*d* on halides was used by Schissler, Thompson, and Turkevich (9) in preference to these other methods to prepare a series of deuterated methanes, ethanes, and propanes. In our experience this method is also unsatisfactory, at least for the preparation of molar amounts of ethane-1,1,1-d_3 from 1,1,1-trichloroethane. Mass spectrometric analysis of successive samples of ethane showed a decrease rather than an increase in deuterium content. This discrepancy between our results and theirs seemed to warrant further study of this reaction.

In our experiments the reaction mixture always darkened as though a by-product were being formed. When a suspension of zinc dust in acetic

[1]*Manuscript received December 8, 1955.*

For personal use only.

anhydride – trichloroethane was stirred for a few minutes before adding any heavy water the temperature of the reaction mixture rose steadily and finally reached the boiling point. Hydrogen and ethane were evolved and darkening took place. Similar results were obtained when trichloroethane was added to a stirred suspension of acetic anhydride and zinc dust. Evidently a side reaction was taking place which gave rise to an acidic by-product, most likely hydrogen chloride. Elimination of hydrogen chloride as the reaction progressed would account for the observed depletion of the ethane in deuterium. It seemed futile to expect ethane-d_3 of high deuterium content to be formed under these conditions until some means was found of preventing the side reaction. Our next experiments were therefore directed to that end.

We found that the side reaction could be suppressed by adding trichloroethane to acetic acid-*d* in acetic anhydride or dioxane. The acetic acid-*d* was prepared by hydrolyzing the anhydride *in situ* with an equivalent amount of deuterium oxide and a trace of phosphoric anhydride. The yield of ethane-d_3 was 78% but its deuterium content was still far from satisfactory. It started at 21 mol. % CH_3CD_3 and rose slowly with successive samples to 70 mol.%. A slight improvement was observed using anhydrous dioxane as a solvent and less acetic acid-*d*, the purity rising from 51 to 81.8 mol.%.

It has been recently demonstrated (8) that very pure acetic acid-*d* cannot be prepared by hydrolysis of acetic anhydride—even after the latter has been heated under reflux for several days over magnesium turnings. On the other hand acetyl chloride previously distilled over dimethylaniline gives on hydrolysis acetic acid-*d* over 98% pure as judged by the preparation of 95+mol.% toluene-α-d_3 from benzotrichloride (8). However, even acetic acid-*d* prepared in this manner did not give ethane-d_3 as isotopically pure as the toluene-α-d_3. At this point further work with acetic acid-*d* seemed unjustified and we decided to re-examine the other methods of preparing deuterated hydrocarbons.

Dehalogenation with zinc and methanol-*d* (or ethanol-*d*) offered no advantage over the use of acetic acid-*d* for reasons mentioned earlier. Nevertheless, the work of Benedict, Morikawa, and Taylor (1) with this reagent indicated that iodides react with zinc dust in alcohols as well as in acids. Furthermore, MacWood and Urey (6) had shown that bromides and iodides react with water in the presence of aluminum amalgam. It seemed possible that zinc dust might react with halides in deuterium oxide – dioxane solutions and perhaps even with heavy water alone. Experiments first with ethyl iodide, then with ethylidene bromide, and finally with 1,1,1-trichloroethane fully substantiated this inference. Deuterated ethanes of higher purity than had been obtained by other methods were synthesized in good yields by this simplified approach.

This procedure was extended to the preparation in excellent yields of the four deuteromethanes analyzing 96 atom % D from carbon tetrachloride, chloroform, methylene bromide, and methyl iodide. The preparation of homologous deuterated hydrocarbons by this method appears limited only by the availability of the halides.

In the preparation of ethane-1,1,1-d_3 from trichloroethane, zinc, and heavy water, there always remained a small residue after the excess halide was distilled off. A sublimate of white crystals, m.p. 173–4°C., was obtained on distilling the residue under vacuum in a Spath bulb. The melting point of the product was not depressed on admixture of 2,2,3,3-tetrachlorobutane prepared by the chlorination of 2-butyne (7). A high boiling liquid was likewise obtained from the residue from the preparation of ethane-1,1-d_2. Analogy would indicate that this is 2,3-dibromobutane; the quantity isolated was too small to permit adequate characterization. These products are probably formed by doubling. Henne (4, 5) has reported a similar reaction when fluoroiodoethanes are heated with zinc dust in acetic anhydride. This is, however, believed to be the first time such doubling has been reported for chloroethanes.

EXPERIMENTAL

Ethane-1,1,1-d_3

(*a*) *From 1,1,1-Trichloroethane, Zinc, and Acetic Acid-d*

1. The procedure of Schissler, Thompson, and Turkevich (9) was followed but on a larger scale. Acetic anhydride and 1,1,1-trichloroethane were purified by distillation. The anhydride (30 ml.), zinc dust (15.0 gm.), and 1,1,1-trichloroethane (20 ml.) were placed in a 100 ml. round-bottomed flask under a cold finger reflux condenser which was attached to a vacuum line by a side arm. After the apparatus was evacuated deuterium oxide was added in 0.2-ml. portions to the reactants while stirring with a magnetic bar. Samples of deuterated ethane were collected after each addition of heavy water and analyzed by mass spectrometry. The deuterium content of successive samples fell rather than rose. At the same time the reaction mixture darkened considerably. On addition of water at the completion of the experiment a brown gummy polymer was precipitated. Several additional runs were made with the same results.

2. In this experiment acetic anhydride, zinc dust, and 1,1,1-trichloroethane in the same amounts as in (1) were stirred under a reflux condenser in a flask immersed in water overnight. By morning the mixture had turned dark brown. The suspended solid dissolved on adding 75 ml. of water and a brown gum was precipitated. It was not volatile and appeared to be a polymer. Apparently the reagents react before any water is added.

3. A suspension of zinc dust (20 gm.) in acetic anhydride (80 ml.) was stirred for three hours. No gas was evolved during this time. Trichloroethane (8.0 ml.) was then added and the contents stirred while the flask was kept immersed in cold water. A gas was now continuously evolved which condensed in a trap cooled in liquid nitrogen. It was identified by its boiling point as ethane. Yield: 0.4 ml. at −100°C. Addition of more trichloroethane gave 0.8 ml. of ethane. No further evolution of ethane took place on adding water.

4. In this experiment the acetic anhydride (100 ml.) was replaced in part by acetic acid-*d* (20 gm.) which had been prepared by hydrolyzing the anhydride in the presence of a trace of phosphoric anhydride as catalyst. Trichloroethane was then added to the stirred reaction mixture in four portions. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

yields of ethane-d_3 from 2.0, 3.0, 2.0, and 2.0 ml. of halide were 0.6, 1.1, 0.6, and 0.6 ml. respectively measured at the boiling point. The deuterium content of each sample analyzed by mass spectrometry was 21.5, 31.3, and 53 mol.% CH_3CD_3; the sample of fraction three contained air.

The deuterium content of the ethane now rose rapidly with each fraction collected but in terms of mol.% it was still unexpectedly low.

5. When the acetic anhydride was replaced by anhydrous dioxane (150 ml.) some improvement was noted in the isotopic purity. It started at 51.0 and rose steadily to 83.8 mol.% CH_3CD_3 with successive samples.

6. An experiment was carried out using acetic acid-*d* which had been prepared by hydrolysis of acetyl chloride (8). There was little improvement in the deuterium content over the preceding experiment.

(*b*) *From 1,1,1-Trichloroethane, Zinc, and Deuterium Oxide*

A suspension of 15.0 gm. of zinc dust in 25 ml. of 1,1,1-trichloroethane was stirred in a 100 ml. round-bottomed flask attached through a cold finger condenser to the vacuum line while 4.0 ml. of deuterium oxide (99.6%) was added dropwise over a period of about four hours. The ethane evolved was collected on the vacuum line in a U-tube cooled in liquid nitrogen. The zinc became spongy and after an hour or so it became very difficult to stir the mixture with a magnetic bar. The ethane was purified by two distillations from a trap cooled in liquid nitrogen and slowly warmed to −78°. Yield: 1.6 ml. at −100°C. The mass analysis of this product was 93.5 mol.% CH_3CD_3.

Ethane-1,1-d_2

1,1-Dibromoethane (15.0 ml.) was freed of traces of dissolved hydrogen bromide by distillation through a tube of Ascarite–Drierite on the vacuum line. It was then distilled into a small flask containing 5.0 gm. of zinc dust. Deuterium oxide (3.0 ml.) was then added dropwise from a funnel over a period of three hours to the zinc and halide mixture while stirring. The ethane-1,1-d_2 evolved was collected as described above for trideuteroethane. Yield: 1.0 ml. at −100°C. Mass analysis: 98.7 mol.% CH_3CHD_2.

Ethane-d_1

A suspension of zinc dust (15.0 gm.) in 40 ml. of ethyl iodide was stirred overnight attached to a vacuum line in a flask with a cold finger condenser. By the following morning the zinc had been completely converted into a white solid—zinc ethyl iodide. On adding deuterium oxide dropwise copious amounts of ethane-d_1 were evolved. It was collected and purified as described for trideuteroethane. Yield: 5.4 ml. at −100°C. Mass analysis: 97.0 mol.% C_2H_5D.

Methane-d_4

Deuterium oxide (8.0 gm.) was added dropwise over two hours to a boiling suspension of zinc dust (35 gm.) in carbon tetrachloride (60 ml.). The gases evolved were collected over water or mercury and then condensed in a U-tube cooled in liquid nitrogen on the vacuum manifold. After a small amount of air was pumped off the methane-d_4 was melted and the volume measured. Yield:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

2.0 ml. Mass analysis showed a deuterium content of 97.5 mol.% CD_4 and 2.5 mol.% CD_3H or 99.36 atom % D. Yield: 90% of the theoretical.

Methane-d_3

Chloroform (60 ml.) was freed of traces of ethanol or water by distillation through a U-tube containing phosphorus pentoxide on the vacuum line. A suspension of zinc dust (25 gm.) in the purified chloroform was heated under reflux for one hour on the vacuum line. After traces of ordinary methane in the line were swept out with dry nitrogen, deuterium oxide (6.0 ml.) was added dropwise over a period of two hours. The methane-d_3 evolved was collected and purified as described in the previous example. Mass analysis showed 93.2 mol.% CD_3H, 4.76 mol.% CH_2D_2, and 1.43 mol.% CH_3D or 96.87 atom % D. The yield was nearly theoretical.

Methane-d_2

Deuterium oxide (5.0 ml.) was added slowly to a stirred suspension of zinc dust (18 gm.) in 50 ml. of methylene bromide. The reaction mixture soon became warm and eventually refluxed. The yield of methane-d_2 which was isolated as described in the previous examples was nearly theoretical. The deuterated methane analyzed 93.1 mol.% CH_2D_2, 5.9 mol.% CH_3D, and 1.1 mol.% CH_4 or 96.0 atom % D.

Methane-d_1

Deuterium oxide (3.0 ml.) was slowly added to a stirred suspension of zinc dust (10 gm.) in methyl iodide (30 ml.). The yield of methane-d_1 analyzing 98 mol.% CH_3D was nearly theoretical.

ACKNOWLEDGMENTS

The authors are grateful to Dr. F. P. Lossing and Miss F. Gauthier of the Mass Spectrometry Section for all the mass analyses.

DETERMINATION OF PARAMETERS IN OVERPOTENTIAL STUDIES[1]

By H. B. Morley[2] and F. E. W. Wetmore

ABSTRACT

A simple method is reported for analyzing decay curves in overpotential studies. As well, equations have been derived for build-up and decay curves and for the overpotential–current relationship, based on an assumption which introduces less error than the simplifying assumptions used previously.

In studies of the behavior of cathodes exhibiting overpotential it has been usual to investigate the variation of the steady state overpotential, η, with applied current density, i, and to report the results in terms of Tafel's equation

$$\eta = a + b.\ln i = b.\ln(i/i_0). \qquad [1]$$

Much less attention has been paid to potential–coulomb build-up curves and to potential–time decay curves. In a recent study of the cathodic behavior of silver in aqueous sulphuric acid solution all three types of determinations were made. A comparison of the results has brought out some points of general interest in the field of overpotential studies.

Examination of the experimental results consistently showed the following behavior. Tafel's equation was found to hold over the entire range of current densities studied (5 to 500 μa. cm.$^{-2}$). Potential–coulomb curves were found to be linear over the first and greater part of the build-up, provided that the solution had been sufficiently purified by pre-electrolysis (2). In the examination of decay curves it was noted that those taken after build-up to the steady state at low current densities could be identically superimposed on those taken after build-up at high current density, simply by adding to the actual time t a quantity θ', as shown in Fig. 1. The upper curve shows the decay of the

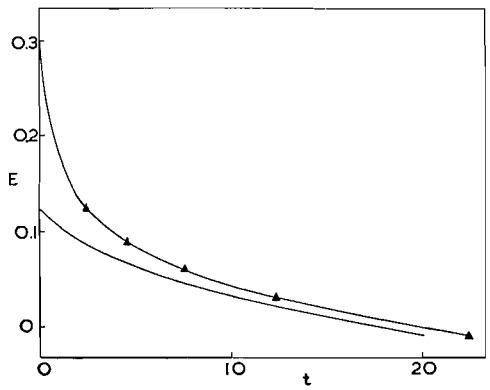

FIG. 1. Decay of cathode potential with time. E is defined as the potential of the reversible hydrogen electrode less the cathode potential (E is positive when the cathode is polarized); t is in seconds. Further details are given in the text.

potential of a 111 crystal face after build-up at 118 μa. cm.$^{-2}$. The lower curve corresponds to 4.7 μa. cm.$^{-2}$ and the triangles represent points from the lower curve with $\theta' = 2.3$ sec. added to the actual time t.

The quantity θ' was found to depend, of course, on the initial potentials of both curves involved in the superimposition. Since a decay curve from a large initial potential could be superimposed on one from a still larger initial potential, it was obvious that a value of θ' depending solely on the initial potential of the particular decay curve could be achieved only by superimposition on a curve falling from an infinite initial potential. Such a quantity will be designated by θ, to distinguish it from the directly determinable θ'.

Furthermore, in agreement with the observations of Armstrong and Butler (1), the decaying potential was found to be linear in log t, except for small values of t and E. This, along with the superimposition, suggested that the potential E might be linear in $\log(t + \theta)$, i.e.

$$[2] \qquad dE/dt = -k/(t + \theta).$$

The initial slope of the decay curve would then be $-k/\theta$, from which the value of θ can be derived as follows. The initial rate of build-up can be expressed by the equation

$$[3] \qquad dE/dq = 1/C,$$

in which q is the charge passed and C a constant having the dimensions of capacitance. At any time t after the current is applied,

$$[4] \qquad dE/dt = i/C - k/\theta^*,$$

in which θ^* is the value of θ appropriate to the instantaneous value of E considered as an initial potential in a decay. In the steady state of overpotential

$$[5] \qquad 0 = dE/dt = i/C - k/\theta,$$

in which θ is appropriate to the overpotential, or to the particular current used to produce it. Therefore

$$[6] \qquad \theta = kC/i$$

and θ has the value zero only for the imaginary case of infinite initial potential resulting from an infinite current; it is similar to the constant of integration t' mentioned by Grahame (4).

In effecting the superimposition of one decay curve on another the shift of the time scale, θ', is now seen to be actually $(\theta_2 - \theta_1)$, corresponding to the two current densities i_2 and i_1 used for the build-ups. Hence

$$[7] \qquad kC = (\theta_2 - \theta_1)/(1/i_2 - 1/i_1)$$

and the value of the product kC can be determined from the experimental quantities, θ', i_2, and i_1. Then θ for any value of build-up current can be calculated through equation [6]. Experiment demonstrated the validity of this interpretation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

With θ known it is of consequence to integrate equation [2] under the condition that $E = \eta$ at $t = 0$ to yield

$$[8] \qquad E = \eta - k.\ln(1 + t/\theta).$$

Thus a decay curve can be plotted as E against $\log(t + \theta)$ to give a straight line of slope $-2.303k$, as shown in Fig. 2 for three current densities. The

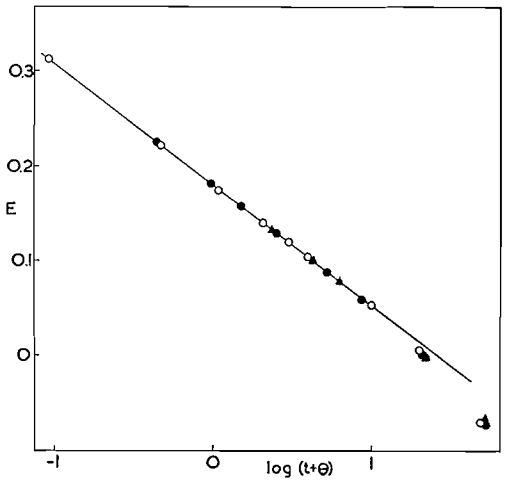

FIG. 2. Decay of cathode potential with time. The open circles refer to a polarizing current of 118, the blackened circles 23.5, the triangles 4.7 μa. cm.$^{-2}$; t and θ are in seconds.

identity of overlapping parts of the three lines shows clearly the accuracy of the superimposition. It should be noted that the value of k so found is much more precise than the value of θ used in the evaluation. As reported earlier (1), the value of k was found to be the same as that of b in the Tafel expression. Use of $\log(t + \theta)$, rather than $\log t$, as the abscissa has the distinct advantage that the curve remains linear even to $t = 0$.

A value of C, of the same precision as θ, can be obtained as $\theta i/k$; as well it can be evaluated from the slope of the linear initial portion of the build-up curve. From equations [1], [4], and [6]

$$[9] \qquad dE/dq = (1/C)[1 - \exp\{(E - \eta)/b\}],$$

which shows that the linearity of the build-up curve is lost as E approaches η. Values of C determined from build-up curves were not the same as those from decay curves; it is conceivable that the latter would be less susceptible than the former to the effects of reduction of constituents other than hydrogen ion.

Use of the analytical quantity θ arose from examination of experimental results, without appeal to mechanism. It is of interest to see how θ fits in with expressions developed from mechanisms involving potential barriers and exchange currents (3). In the mechanistic development the rate of build-up is given by

$$[10] \qquad dE/dt = i/C - (i_0/C)[\exp(E/b) - \exp(-E/b')],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

in which i_0 is interpreted as the exchange current density at zero overpotential and the terms b and b' are $RT/\alpha zF$ and $RT/(1-\alpha)zF$, respectively. The rate of decay is given by

$$dE/dt = -(i_0/C)[\exp(E/b) - \exp(-E/b')]. \quad [11]$$

In order to make these expressions more amenable to treatment, simplifying assumptions have been used. One of these (I) is to neglect the second exponential term completely; another (II) is to assume that $\alpha = 0.5$, so that $b = b' = 2RT/zF$. The latter assumption is always of doubtful validity. Assumption (I) will have no appreciable effect on build-up curves, except at extremely low current densities, and will be in error for decay curves only as E approaches zero. Use of (I) gives the slope of the decay curve as

$$dE/dt = -(i_0/C).\exp(E/b),$$

which on integration under the condition that $E = \eta$ at $t = 0$ yields equation [8]. Thus it is clear that use of θ embraces assumption (I). The distinction between equation [11] and the same modified by (I) becomes apparent only as E approaches zero. For purposes of determining b and C, equation [8] is satisfactory at values of i greater than $10i_0$.

An assumption more general and precise than either (I) or (II) is to take $b = b'$, without assuming a particular value of b and without neglecting the second exponential term completely. From assumption (III) it follows that the slope of the build-up curve is

$$dE/dt = i/C - (2i_0/C).\sinh(E/b), \quad [12]$$

that of the decay curve

$$dE/dt = -(2i_0/C).\sinh(E/b), \quad [13]$$

and the expression replacing that of Tafel is

$$\eta = b.\sinh^{-1}(i/2i_0). \quad [14]$$

Equation [12] shows that the build-up curve will be linear so long as $(2i_0/i).\sinh(E/b)$ is small in comparison with unity. Integration of equation [12] yields a cumbersome expression, but integration of equation [13] gives

$$\ln\coth(E/2b) = \ln\coth(\eta/2b) + 2i_0t/bC, \quad [15]$$

which suggests a convenient form for extrapolating decay curves to zero time. Since only the precisely determinable quantity b (k in equations [2] to [8]) is required to make the plot of $\log\coth(E/2b)$ against t, this form may have some advantage over equation [8]. Equation [14] differs from equation [1] only at very small values of i/i_0, for which it leads to the condition that $\eta = 0$ when $i = 0$.

The quantity θ can be derived from equation [15] in the form

$$t = (bC/2i_0).\ln[\coth(E/2b)/\coth(\eta/2b)].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

By definition, θ is the time required for the potential to fall from infinity to E, less the time for a finite potential to fall to the same value E. Hence

$$\theta = (bC/2i_0) \cdot \ln[\coth(\eta/2b)]. \quad [16]$$

Although there appears to be little resemblance between the members of the pairs of equations [1] and [14], [6] and [16], and [8] and [15], it will be found that they are arithmetically identical under the usual experimental conditions, in which i is substantially greater than i_0.

APPLICATION OF THE ARCHIBALD ULTRACENTRIFUGAL PROCEDURE TO LYSOZYME AND APURINIC ACID: EVALUATION USING A MECHANICAL INTEGRATOR[1]

By David B. Smith, G. C. Wood,[2] and P. A. Charlwood

ABSTRACT

The method outlined by Archibald for handling transient data in equilibrium ultracentrifugation yields a molecular weight for lysozyme that conforms to those given by other methods. A method for applying the Archibald procedure to apurinic acid which is polydisperse and has a concentration dependent sedimentation rate is outlined. The use of a mechanical integrator for reducing the computational work is described.

Advantages of the sedimentation equilibrium method of molecular weight determination include soundness of theory, wide molecular weight range covered, and the small amount of material (2–3 mgm. in conventional ultracentrifuges) required. A disadvantage has been the prolonged centrifuging time involved. Archibald (1), however has shown that molecular weights and information on homogeneity may be obtained from the concentration distribution in the ultracentrifuge cell before equilibrium is attained.

Archibald's method has been tested (4) on a saponin, digitonin, molecular weight 1229.3, and also (8) on raffinose, molecular weight 504.5, and bovine serum albumin. Porath (9) has used the method to obtain the molecular weight of bacitracin.

This communication records the testing of Archibald's method on lysozyme whose molecular weight, 14,100±500 (6), is well defined. The procedure has been extended to deal with a preparation of apurinic acid which shows, besides polydispersity, some concentration dependence of the sedimentation rate. The computational work may be greatly reduced by the use of a mechanical integrator.

The distribution of solute in the ultracentrifuge cell at equilibrium is given by

$$\frac{1}{rc}\frac{dc}{dr} = \frac{M(1-\bar{v}\rho)\omega^2}{RT} = \frac{\omega^2 S}{D} = \delta$$

where c is the concentration at distance r from the center of rotation, M is the molecular weight, $\bar{v}$ the partial specific volume, ρ the density of the medium, ω the angular velocity, R the gas constant, T the absolute temperature, S the sedimentation coefficient, and D the diffusion coefficient. Sedimentation and diffusion rates are assumed to be independent of concentration. Archibald showed that the function $(1/rc)(dc/dr)$ at the meniscus of the solution and at the base of the cell is equal to δ at all times and that values of $(1/rc)(dc/dr)$

[1]*Manuscript received November 23, 1955.*
Contribution from the Division of Applied Biology, National Research Laboratories, Ottawa, Canada. Issued as N.R.C. No. 3858.

found experimentally in regions near base and meniscus at any given time may be extrapolated to these limits to obtain δ_b and δ_m respectively. If the solute is monodisperse, δ_b and δ_m are equal and proportional to M. In polydisperse solutions, δ_b is higher than δ_m and each value is proportional to the weight-average molecular weight at base and meniscus respectively.

However, if the usual type of concentration dependence of the sedimentation rate exists, the values of δ obtained will be too low especially at the base where the higher concentration results in greater depression of S. Equality of the two values of δ does not therefore indicate monodispersity if the sedimentation rate is concentration dependent. The concentration dependence of D is normally much less than that of S, since a thermodynamic factor related to the second virial coefficient usually tends to oppose the hydrodynamic factor (11). These concentration effects can be eliminated by extrapolation to zero concentration.

Application of the Archibald method requires a knowledge of dc/dr and c at points at and close to meniscus and base. The usual diagonal schlieren method of observing refractive index gradients in the ultracentrifuge cell gives a pattern that may be taken to be a plot of dc/dr vs. r. The arithmetic evaluation of c as a function of r from such a plot is tedious and this fact has hindered the application of Archibald's procedure. The operation may be greatly simplified by the use of a mechanical integrator capable of measuring first and second moments besides areas. For this method, the equations of Brown, Kritchevsky, and Davies (4) were transformed as follows:

$$c_b - c_m = \int_{r_m}^{r_b} \frac{dc}{dr}\,dr$$

$$\int_{r_m}^{r_b} r\,c\,dr = \tfrac{1}{2}\left[c_b r_b^2 - c_m r_m^2 - \int_{r_m}^{r_b} r^2 \frac{dc}{dr}\,dr\right] = \frac{c_0}{2}\left[r_b^2 - r_m^2\right]$$

where r is the distance in cm. from the axis of rotation, c the corresponding concentration, c_b and c_m the concentrations at the base and meniscus, r_b and r_m respectively, and c_0 the initial concentration of the solution.

Concentrations c_b and c_m can thus be obtained from the area of the pattern and its second moment about the axis of rotation

$$\int_{r_m}^{r_b} r^2 \frac{dc}{dr}\,dr,$$

together with the other known or measurable quantities.

The second moment of part of the ultracentrifuge pattern about the axis of rotation enters the equations used by Baldwin (2) and by Klainer and Kegeles (8). Here too mechanical integration would simplify the computations.

MATERIAL AND METHODS

Lysozyme (Armour Lot No. 003L1) was examined in sodium phosphate buffer pH 6.6, ionic strength 0.2.

Apurinic acid prepared (12) from calf thymus sodium desoxyribonucleate was dissolved in sodium acetate buffer pH 5.0, ionic strength 0.15.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

Refractive index increment, dn/dc, of lysozyme is 1.88×10^{-3} ml. gm.$^{-1}$ (7). The value assumed for apurinic acid was that reported (10) for sodium desoxyribonucleate, also 1.88×10^{-3} ml. gm.$^{-1}$.

Partial specific volume, $\bar{v}$, of lysozyme is 0.688 ml. gm.$^{-1}$ (6). For apurinic acid, the value 0.55 ml. gm.$^{-1}$ was used. This value has been reported for sodium desoxyribonucleate (5).

The Spinco Model E ultracentrifuge using the standard cell was run at 12,590 r.p.m. Several photographs taken at different bar angles immediately after the rotor had attained full speed provided base lines since it was found that no detectable sedimentation of the buffer salts occurred over 18 hr.

Initial and final temperatures of the rotor differed by about 2° and the average value was used in subsequent calculations.

The optical system of the ultracentrifuge was calibrated by measuring the area of the pattern given by a boundary between a KCl solution and water in the Spinco synthetic boundary cell. The refractive index difference across this boundary was determined in a differential refractometer (3).

The ultracentrifuge patterns were enlarged at measured magnification (about 8×) and traced onto graph paper. The tracings were bisected, base lines were superposed, and the resulting outlines were analyzed both by the arithmetical method of Brown *et al.* (4) and by the use of an Amsler integrator, Type 626. Since the enlarged pattern is too large for the desired second moment to be obtained directly, the instrument was set on an axis parallel to the meniscus at a distance r_e from the center of rotation and chosen so as to approximately halve the outline. The second moment about the axis of rotation is

$$A\,r_e^2 + 2M\,r_e + I = I_0$$

where A is the area of the outline and M and I are its first and second moments respectively about the arbitrary axis.

RESULTS AND DISCUSSION

Lysozyme is an example of a material having relatively uncomplicated sedimentation behavior. Fig. 1 shows a set of ultracentrifuge patterns obtained

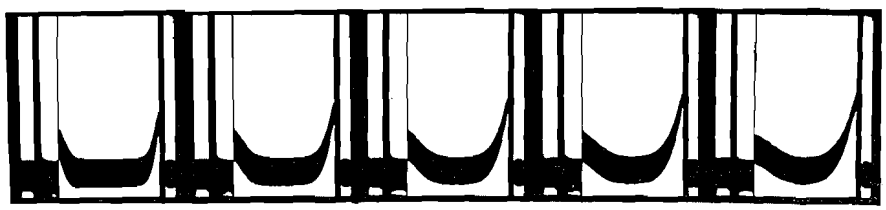

FIG. 1. Ultracentrifuge patterns obtained with lysozyme, initial conc. 1.06%. Sedimentation from left to right. Photographs taken at 58, 148, 238, 328, and 418 min. after attaining full speed.

with lysozyme. Fig. 2 shows a family of curves obtained by the arithmetical method of $(1/rc)(dc/dr)$ plotted against r. In Table I are shown values of δ obtained by both methods of computation after two separate runs with

lysozyme. The values from the arithmetical method are the intercepts at r_m and r_b of extrapolated curves of $(1/rc)(dc/dr)$ against r. The values obtained using the integrator are calculated from the determined values of c_m and c_b, the measured value of r_m, the value of r_b supplied by Spinco, and the values of dc/dr measured at r_m and r_b (extrapolation of the pattern to the latter point is required).

Molecular weights calculated from δ_m are in excellent agreement with that obtained by Colvin (6), 14,100±500, from separately determined S and D coefficients. The higher values calculated from δ_b may indicate the presence of small amounts of higher molecular weight contaminants from the egg-white source or may be due to concentration effects. The concentration at the base of the cell ranged between about 1.3 and 1.8% in Run 1 and 2.5 and 3.1% in Run 2. These concentrations are outside the range over which Colvin found no dependence of S on concentration. In any case, at these higher concentrations, it is unlikely that the sedimentation rate of lysozyme is greatly reduced. Light scattering measurements by Halwer, Nutting, and Brice (7) indicate that the second virial coefficient of lysozyme is appreciably negative in a medium of pH 6.2 and $\mu = 0.1$. A negative virial coefficient tends to reduce the diffusion coefficient at finite concentrations (11) and thus increase δ. The extrapolation necessary because the region close to the base is not recorded on the photographic plate introduces further error in the estimation of δ_b.

Preparations of apurinic acid are very heterogeneous (12). Fig. 3 shows a family of $(1/rc)(dc/dr)$ vs. r curves for a preparation of this material. The intercepts, δ_m and δ_b, are not the same. Moreover, sedimentation velocity

determinations on apurinic acid (12) show that its sedimentation rate has a concentration dependence of about 0.1 dl. gm.$^{-1}$ Sved.$^{-1}$. The negative slope of the δ_b vs. time curve (Fig. 3 inset) must arise from the depression of S as the concentration at the base rises since it has been found (12) that instability of the material can have only a small effect.

The concentration effect was eliminated by doing several ultracentrifuge experiments at different initial concentrations, and taking photographs at the same times (t) in each run. For each value of t, δ_b and δ_m were plotted against c_b and c_m respectively and the curves extrapolated to zero concentration to give $\delta_b(c \rightarrow 0)$ and $\delta_m(c \rightarrow 0)$. Since $\delta_b(c \rightarrow 0)$ was found to be greater than $\delta_m(c \rightarrow 0)$, indicating polydispersity, graphs of $\delta_b(c \rightarrow 0)$ and $\delta_m(c \rightarrow 0)$ against t were extrapolated to zero time, as suggested by Archibald, to give $\delta(c \rightarrow 0)(t \rightarrow 0)$ from which the weight-average molecular weight of the unfractionated material was calculated. The two extrapolations may conveniently be done on the same graph (Fig. 4) by plotting δ_b against $(c_b + 0.1t)$

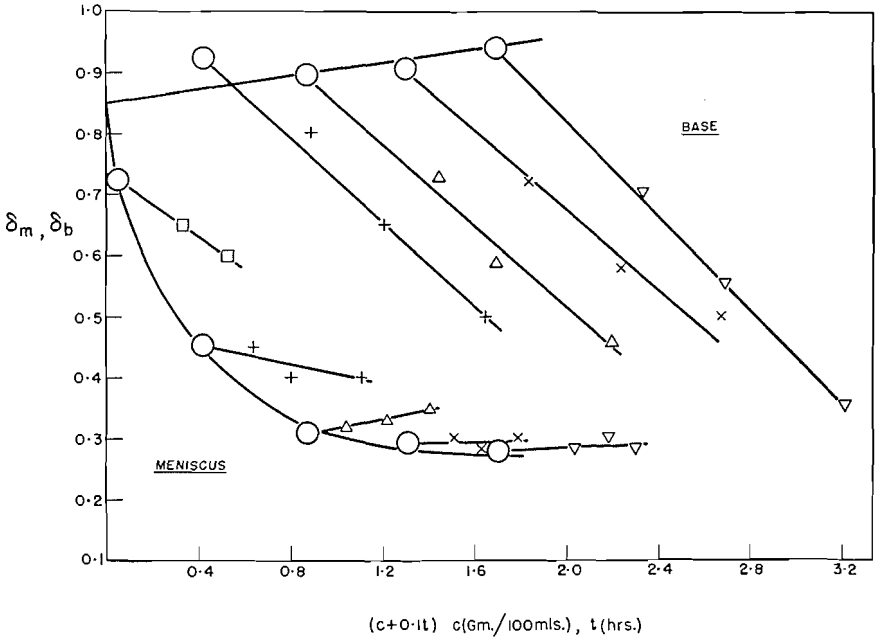

FIG. 4. Values of δ obtained from three ultracentrifuge runs with apurinic acid plotted against $(c + 0.1t)$, showing extrapolation to zero concentration and zero time. Photographs taken at 30 (□), 252 (+), 522 (△), 786 (×), and 1019 (▽) min. after attaining full speed.

and δ_m against $(c_m + 0.1t)$. The weight-average molecular weight, 27,000, is in good agreement with the value of 25,000 found by the light-scattering methods (12). The concentration dependence of δ_b is much greater than that of δ_m, because the species of highest molecular weight, whose sedimentation rates will be most dependent on concentration, tend to concentrate near the base. The value approached by δ_m as centrifugation proceeds corresponds to a molecular weight of 7000.

Extrapolation of plots of $1/\delta$ against concentration to zero concentration, corresponding to the linear relation between reciprocal sedimentation coefficient and concentration, may be preferable to the above treatment, where higher degrees of concentration dependence are involved.

CONCLUSION

This work has shown that the Archibald method gives molecular weight values for low molecular weight proteins that compare favorably with values obtained in other ways. A method for getting information on size and polydispersity for systems showing concentration dependence of the sedimentation rate has also been outlined. The computational work can be greatly reduced by the use of mechanical integration which also permits ready replication and reduces the opportunity for arithmetic error.

ACKNOWLEDGMENT

The authors wish to acknowledge helpful discussions with Dr. M. E. Reichmann.

A LOW-TEMPERATURE APPARATUS FOR SINGLE-CRYSTAL X-RAY GONIOMETERS[1]

By T. T. Harding[2]

ABSTRACT

An apparatus is described which may be used to grow and maintain single crystals at temperatures down to approximately −180°C. The crystals may be grown directly upon the head of the X-ray goniometer in order to permit the recording of data required for the investigation of the crystalline structure of substances which exist in the liquid or gaseous states at ordinary temperatures.

INTRODUCTION

Recent interest in the study of crystal structures of solids at low temperatures and of compounds which exist in the liquid state at ordinary temperatures has led to the construction of a number of low-temperature devices for powder and single-crystal X-ray goniometers (1–18). In this paper an apparatus is described which has been used successfully in a determination of the crystal structure of acetonitrile. This apparatus bears some similarity to that constructed by Owen and Williams (8).

CONSTRUCTION

The crystal is maintained at low temperatures by a stream of dry gas which is cooled by passage through a cooling chamber containing liquid nitrogen. The source of supply of dry gas may vary according to the availability of material, but during operation in this laboratory large amounts of liquid nitrogen were readily available and were used to supply dry nitrogen to the cooling system. A diagram of the gas circuit is shown in Fig. 1.

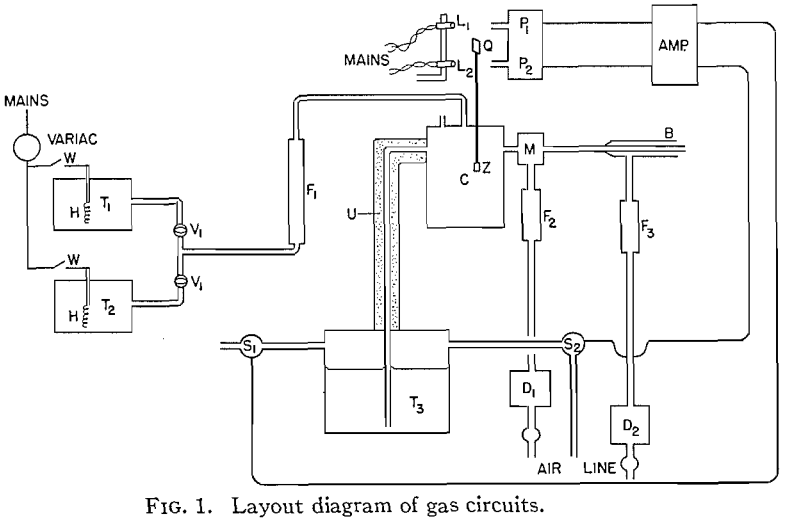

FIG. 1. Layout diagram of gas circuits.

Dry nitrogen was obtained by boiling liquid nitrogen in one of the large 50 liter dewar tanks T_1 and T_2 using electric heaters H, of 30 ohm resistance operating on mains current (110 volts). The current through the heaters and thus the flow of gaseous nitrogen was regulated by a variac. A constant flow of gas may be maintained when changing from tank T_1 to tank T_2 by opening and closing the appropriate valves V_1 together with the switches W and by adjusting the variac. The flow of gas through the system is indicated by a flowmeter F_1. The gas then passes into the cooling chamber C where it is cooled by liquid nitrogen, and into the mixing head M before being expelled through the delivery tube B to impinge upon the sample tube which is mounted on the goniometer head. In order to maintain a fairly high gas flow-rate around the crystal when the apparatus is operating in its higher temperature range and to assist in temperature control and variation, warm air is passed through a regulating valve through a series of drying agents D_1, including potassium hydroxide to remove carbon dioxide, and a flowmeter F_2 into the mixing head M. Here it is mixed with the cold nitrogen and then expelled through the delivery tube B.

In order to prevent ice formation around the sample tube and goniometer head a stream of air is passed through a regulating valve, a series of drying tubes D_2, and a flowmeter F_3, and finally into a tube mounted coaxially around the delivery tube so that a column of warm dry air surrounds the cold gas stream and serves to prevent ice formation.

The cooling chamber is shown in detail in Fig. 2. Nitrogen gas enters through the tube N and passes through the brass chamber H′ into the large dewar vessel R containing liquid nitrogen. Chamber H′ serves as a collecting point for any impurities in the incoming gas which are deposited on cooling and which may be removed after an experimental run by removing a plug at the bottom of the chamber; this is important when the source of cooling gas is other than liquid nitrogen. The nitrogen then passes from H′ into a coil of copper tubing C, consisting of 15 turns of $\frac{3}{8}$ in. diameter copper with a wall thickness of 1/32 in. The inside diameter of the coil is $3\frac{5}{8}$ in. It was found that the above dimensions for the cooling coil were the most satisfactory for cooling the gas without liquefying it. The cold nitrogen gas passes from the dewar vessel and cooling coil via the tube O into the mixing head M which is constructed with dewar walls. Here the cold gas may be mixed with warm air which enters through the tube O′ before being expelled into the delivery tube B. The dewar vessel R, encased in felt K, is placed in a copper container N. The mouth of the dewar is sealed by a lid J and cork I through which pass the inlet and outlet tubes etc., and a gas outlet X.

The level of the cooling liquid in the dewar vessel R is maintained by means of the following device. A float Z operating in a Pyrex glass tube within the dewar is connected by a fine wire to a shutter of brass foil Q within the closed glass system E which may be dismantled at the ground glass joints G_1 and G_2. The float and shutter rise or fall with the level of liquid in the dewar, the shutter Q being arranged to operate between the two lamps L_1 and L_2 and the photoelectric cells P_1 and P_2 which are connected via the amplifier AMP and

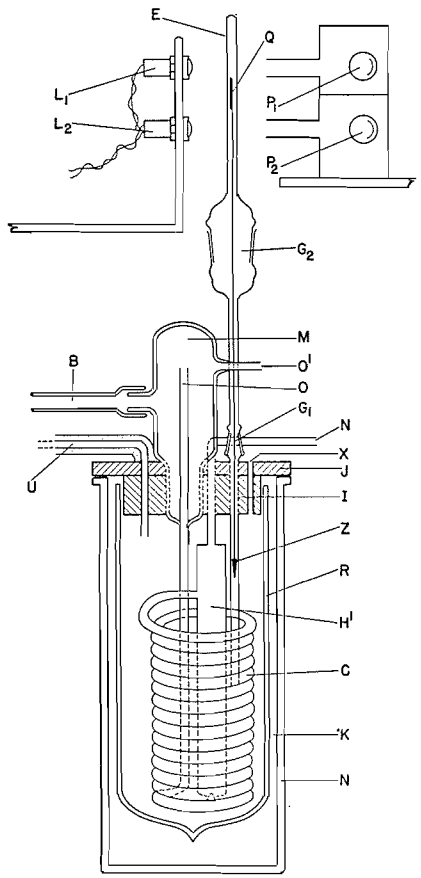

FIG. 2. The cooling chamber.

relays (see Fig. 1) to two solenoid valves S_1 and S_2 respectively. The circuit is arranged so that as the shutter Q falls, it covers the aperture of photocell P_2 and then uncovers it. The amplified impulse from the photocell opens the solenoid valve S_2 which admits air under pressure to the liquid nitrogen reservoir T_3 and forces the liquid into the dewar vessel through the lagged tube U, solenoid valve S_1 being closed. As the level of liquid rises, the shutter covers photocell P_1 and then uncovers it. The resulting impulse closes valve S_2 and opens S_1 to allow the excess pressure to escape from the reservoir T_3, and hence the flow of liquid nitrogen to the dewar vessel R ceases. It may be seen that the constant level device would operate efficiently with only one photocell coupled to a double-pole, double-throw relay. However the electronic arrangement described above was available from an experimental arrangement of a different type which was no longer required.

The construction of the delivery tube shown in Fig. 3 is similar to that described by Burbank and Bensey (2). It consists of a glass dewar-walled central tube of internal diameter 1.0 cm. which is enlarged at one end to fit the

For personal use only.

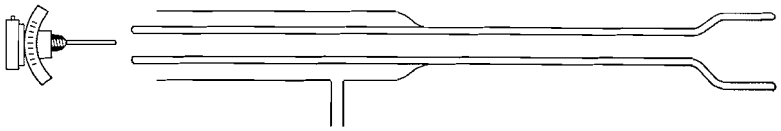

FIG. 3. Delivery tube.

exit tube of the mixing head (see Fig. 2). The nozzle of the delivery tube extends 0.6 cm. beyond the end of the outer jacket of inside diameter 2.5 cm. through which warm dry air is passed via D_2 and F_3 as shown in Fig. 1. It is important that the seal of the double-walled delivery tube should be smooth and well-rounded so that the flow of both columns of gas is as nearly streamline as possible. This ensures that the inside column of cold nitrogen is in contact only with dry air so that ice formation is prevented.

NOTES ON OPERATION AND POSSIBLE MODIFICATION

When in operation the delivery tube is mounted so that the stream of cold gas impinges upon the capillary tube containing the sample for examination. Care must be taken in using the precession goniometer that rotation of the camera through a $\bar{\mu}$ angle of 30° is not prohibited by the position of the delivery tube. Crystals may be grown by controlled cooling and warming of the liquid sample using the valves and flowmeters in the gas circuit to regulate the temperature of the gas impinging upon the sample tube. By noting the readings on the flowmeters the conditions of a particular experiment may be repeated precisely at a later date, or by using a thermocouple mounted upon the goniometer head in the position usually occupied by the crystal the rates of flow of cold gas may be calibrated against temperature. It was also found during operation that it was advisable to use a tube of indicating 'drierite' as the final drying agent in each drying system so that it was possible to have adequate warning when fresh drying agents were required. This was of particular importance in the drying tubes D_2 if ice formation around the specimen was to be prevented. During operation at −70°C. with a cooling stream of gas flowing at 0.5 cu. ft. per min. it was found that 50 liters of liquid nitrogen were sufficient for at least 48 hours' supply of gas whilst a further 50 liters were expended each 24 hr. as cooling liquid. Temperatures down to −180°C. were obtained using higher flow rates and could be maintained without difficulty without too much attention to the liquid nitrogen supply since it is possible to couple any number of reservoirs to the system. It may also be possible to achieve greater economy in the use of liquid nitrogen by making vacuum-jacketed connections between the reservoirs T_1 and T_2 and the cooling chamber. As previously pointed out, the gas supply to this apparatus may be varied according to the availability of materials. Some experiments were undertaken using banks of nitrogen cylinders. This was satisfactory when pure nitrogen was used and then passed through drying tubes containing 'drierite' and potassium hydroxide in order to remove final traces of moisture and carbon dioxide before the cooling chamber was reached. It is also suggested that the gas may be more con-

For personal use only.

veniently supplied by an air pump driving air through agents for the removal of moisture and carbon dioxide. Liquid air may then be used as the cooling agent.

It was found that the apparatus described above would maintain low temperatures for an indefinite period.

ACKNOWLEDGMENTS

The author wishes to express thanks to Dr. W. G. Schneider for his help and interest in this work, and to Mr. W. A. Stevenson for invaluable technical assistance in the construction of the apparatus.

REACTIONS OF SOME HALOGEN DERIVATIVES OF TETRAHYDROPYRAN-2-OL[1]

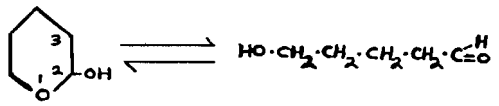
By E. H. Charlesworth and A. Giesinger

ABSTRACT

The 3-halotetrahydropyran-2-ols have been found to readily give derivatives of tetrahydrofurfural in aqueous alcohol under weakly basic or acidic conditions. In strongly alkaline solution tetrahydropyran-2,3-diol and its anhydro-polymers were formed. 3,3-Dichlorotetrahydropyran-2-ol and 2,3,3-trichlorotetrahydropyran have been converted by aqueous alkali to viscous sirups which appear to contain 2-hydroxytetrahydropyran-3-one and its tautomers. On oxidation with permanganate these sirups have yielded succinic acid.

INTRODUCTION

The aldehydic properties of tetrahydropyran-2-ol (I) were explained by Paul (7, 9) on the assumption that it existed in equilibrium with δ-hydroxyvaleric aldehyde (II). Paul's view has since been confirmed by other workers,



I II

particularly Schniepp and Geller (14) and Woods and Sanders (17). The latter authors obtained a crystalline 2,4-dinitrophenylhydrazone.

The 3-halotetrahydropyran-2-ols (IV), readily prepared by the hydrolysis of the corresponding 2,3-dihalides (III) in the presence of mild alkaline reagents, have been reported by Paul (8, 10, 11), by I.G. Farben (5), and by Hawkins and Bennett (1, 2). As these possess some aldehydic properties, it has been assumed that they exist in equilibrium with a δ-hydroxyvaleric aldehyde form (V). Crystalline derivatives, however, are not reported, although Paul (11) did isolate a liquid oxime of tetrahydrofurfural following the hydrolysis of the 2,3-dichloride. Paul (9) found that 3-bromotetrahydropyran-2-ol reacted rapidly with phenylhydrazine, but gave only crystals of phenylhydrazine hydrobromide. This latter reaction suggests that in the presence of an organic base the bromohydrin loses hydrogen bromide more rapidly than it acts as an aldehyde.

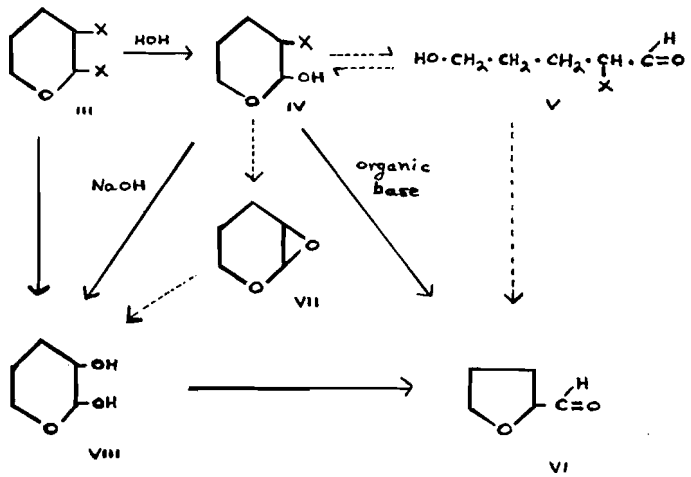
In view of their undoubted aldehyde properties, it seemed desirable to prepare crystalline derivatives of these halotetrahydropyranols and thus to determine the nature of the aldehydic substances derived from them. Both the chloro- and bromo-tetrahydropyranol were found to react with substituted phenylhydrazines to yield the same halogen-free derivatives, namely,

(i) a 2,4-dinitrophenylhydrazone, m.p. 133–134°;
(ii) a 2,4-dinitrophenylosazone, m.p. 242°;

[1]*Manuscript received November 14, 1955.*
Contribution from the Department of Chemistry, the University of Manitoba, Winnipeg, Man. This paper was read before the XIVth Congress of the International Union of Pure and Applied Chemistry in Zurich.

(iii) a *p*-nitrophenylhydrazone, m.p. 146°;
(iv) a *p*-nitrophenylosazone, m.p. 246°;
(v) a *p*-benzylphenylhydrazone, m.p. 74–75°.

In all cases these derivatives are identical with corresponding products made from an authentic sample of tetrahydrofurfural (VI) prepared by the method of Scheibler, Sotscheck, and Friese (13). Hurd and Edwards (3) obtained the same derivatives from tetrahydrofurfural produced by heating tetrahydropyran-2,3-diol (VIII) under reduced pressure.



The 3-halotetrahydropyran-2-ols lose hydrogen halide so readily that they can be titrated with aqueous sodium hydroxide. In each case it is possible to isolate a quantitative yield of the sodium halide salt. We had hoped at first to use this method to obtain the oxide (VII). However, in view of the fact that an organic base when extracting hydrogen halide leaves tetrahydrofurfural as a residue, it seemed that the effect of sodium hydroxide might be the same and thus represent a convenient method of preparing tetrahydrofurfural.

The organic product from the reaction proved to be rather elusive. Organic solvents do not extract it in appreciable amounts from the aqueous mixture. Even continuous extraction proved inadequate. The water had to be removed almost completely, either by absorption on drying agents or better by evaporation, before the product could be taken up in organic solvent.

The nature of the product varies somewhat according to the conditions. If the reaction mixture is kept near room temperature throughout the process, a considerable portion of the product is soluble, with some difficulty, in ether. This ether-soluble substance is aldehydic, but it is a higher boiling liquid than tetrahydrofurfural. It gives the same dinitrophenylosazone, m.p. 242°, as tetrahydrofurfural, but not the phenylhydrazone obtainable from that substance. It readily reduces periodic acid to iodate and forms a 3,5-dinitrobenzoate, m.p. 174°. This substance seems to be tetrahydropyran-2,3-diol (VIII), which Hurd and Kelso (4) prepared by hydrogen peroxide oxidation of dihydropyran.

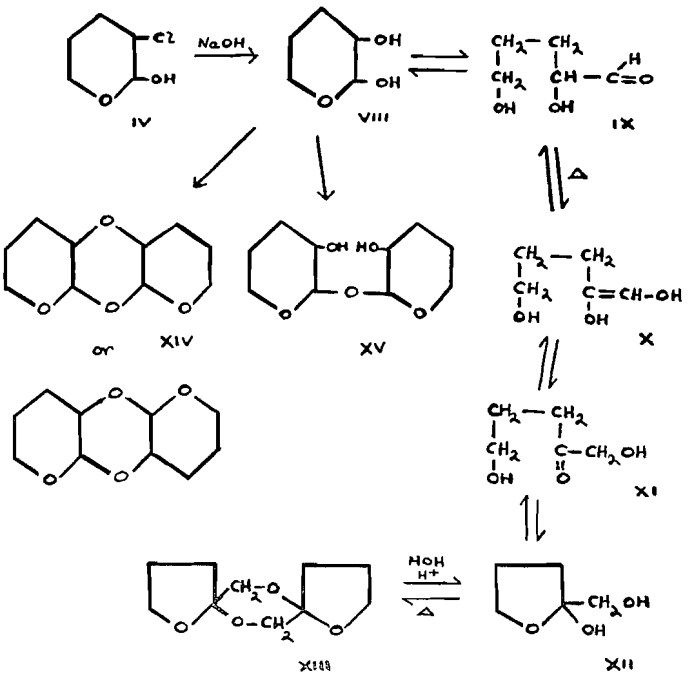
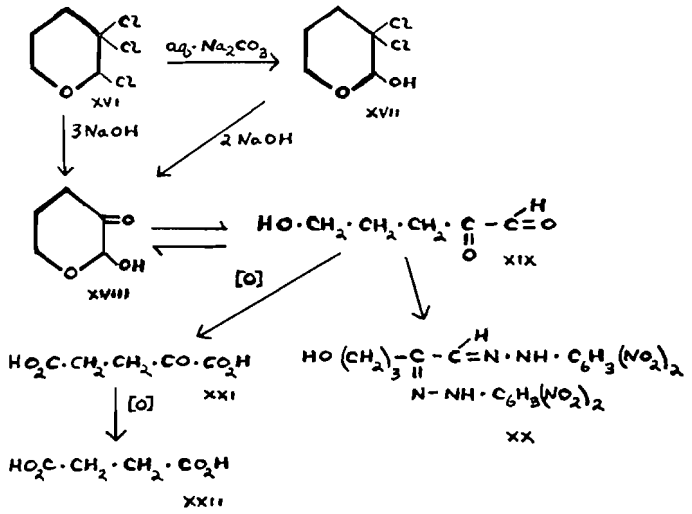
At higher reaction temperatures less of the product is ether-soluble. Small fractions can be extracted with other solvents, but the bulk is soluble only in alcohol and water. Evaporation of the solvent in each case leaves a high boiling sirup which is not easily purified by distillation. In one case a solid, m.p. 190°, precipitated from aqueous solution. In another case a chloroform extract yielded a solid, m.p. 101–102°. The properties of these substances indicate that they are the same $C_{10}H_{16}O_4$ materials as are reported by Hurd and Edwards (3), who obtained them by heating tetrahydropyran-2,3-diol. The lower melting of these two compounds was also obtained by Swadesh and Dunlop (16) from another source. The two groups of workers seem to agree that it has the structure XIII and that it is formed from the diol by the route shown. The structure of the higher melting compound has not been established, but the indications are that it may be XIV. Compound XV has been isolated by Hurd and Kelso (4). Our high boiling sirups are probably mixtures of compounds XIII, XIV, and XV and perhaps more complex structures.



No material was isolated that seemed to be the oxide (VII). If formed at all, it was apparently unstable and hydrolyzed to form the diol (VIII). Other attempts by Paul and Tchelitcheff (12) and by Hurd and Edwards (3) to obtain the oxide have not been too successful.

3,3-Dichlorotetrahydropyran-2-ol (XVII) is mentioned briefly in the literature in a wartime I.G. Farben report (6) and in a German patent (18). We have prepared this substance by warming the 2,3,3-trichloride (XVI) with an equivalent of sodium carbonate solution. It is less aldehydic than the simpler halohydrins discussed earlier, but resembles them in some of its properties. It reduces Fehling's solution when warmed for some time; it

forms the same dinitrophenylosazone, m.p. 242°, but does not form an intermediate hydrazone. When dissolved in warm alcohol, it can be titrated with aqueous sodium hydroxide solution and neutralizes two equivalents of the base. In this reaction the 3,3-dichlorotetrahydropyran-2-ol loses its entire halogen content.



When 2,3,3-trichlorotetrahydropyran (XVI) is warmed and stirred with 3 moles of aqueous sodium hydroxide solution, the organic layer gradually disappears and the alkali is neutralized. A dark red reaction mixture results. The organic product can be isolated by evaporating the water and extracting the residue with alcohol. A quantitative yield of sodium chloride is left behind. On evaporation of the alcohol a viscous dark red halogen-free sirup is left. This material is thought to contain an equilibrium mixture of tetrahydropyranone-3-ol-2 (XVIII) and α-keto-δ-hydroxyvaleric aldehyde (XIX), together with more complex substances. It is aldehydic, reducing Fehling's solution rapidly when warmed. With 2,4-dinitrophenylhydrazine it gives, near room temperature, an almost immediate precipitate of the expected 2,4-dinitrophenylosazone (XX), m.p. 242°. On oxidation with potassium permanganate, both in alkaline and acid solution, succinic acid (XXII) has been obtained. Intermediate compounds such as α-ketoglutaric acid (XXI) have not been isolated as yet from the above oxidations or with milder oxidizing agents.

EXPERIMENTAL

Derivatives of 3-Halotetrahydropyran-2-ols

Both 3-chloro- and 3-bromo-tetrahydropyran-2-ol were prepared by the hydrolysis of the corresponding dihalides with aqueous sodium carbonate solution, following the directions of Hawkins and Bennett (2) for the preparation of 3-chlorotetrahydropyran-2-ol. The methods used for the preparation of the derivatives listed below were essentially those described by Shriner and Fuson (15).

(*a*) *2,4-Dinitrophenylhydrazones*

The 3-chloro- and 3-bromo-tetrahydropyran-2-ol were treated at room temperature with 2,4-dinitrophenylhydrazine reagent. Voluminous orange-yellow precipitates were formed. Qualitative tests showed no halogen in the products. After repeated crystallization from absolute ethanol both products were obtained as yellow needles which melted at 133–134°C. There was no depression of the melting point when the two products were mixed.

(*b*) *2,4-Dinitrophenylosazones*

The 3-halotetrahydropyran-2-ols were refluxed with excess 2,4-dinitrophenylhydrazine in aqueous alcohol, in the presence of a few drops of concentrated hydrochloric acid. An orange-red precipitate formed in each case. On recrystallization from acetone or nitromethane orange needles were obtained which in both cases melted at 242°C. The mixed melting point indicated that the products from the two halotetrahydropyranols were the same.

(*c*) *p-Nitrophenylhydrazones*

The 3-halotetrahydropyranols were warmed for a few minutes with an alcoholic solution of *p*-nitrophenylhydrazine and a trace of acetic acid. The orange-red precipitates were halogen-free. Several recrystallizations from absolute methanol gave the same orange yellow needles which melted at 146°C.

(*d*) *p-Nitrophenylosazone*

This can be produced by prolonged heating (four hours) with excess *p*-nitrophenylhydrazine and a little concentrated hydrochloric acid. A dark red powder separated on cooling. On recrystallization from methanol it separated as fine dark red crystals which melted at 246°C. with slight decomposition.

(*e*) *Benzylphenylhydrazone*

The 3-halotetrahydropyran-2-ol in water (1 gm. in 7 ml.) was treated with benzylphenylhydrazine hydrochloride in 95% ethanol (1 gm. in 10 ml.). The mixture was warmed for a few minutes. On cooling a yellowish white precipitate formed. It was recrystallized from methanol in almost colorless needles which melted at 74–75°C.

(*f*) *Comparison with Tetrahydrofurfural Derivatives*

The derivatives from the halotetrahydropyranols described above were compared with the corresponding derivatives from tetrahydrofurfural, prepared by D. G. Hay in these laboratories by the method of Scheibler, Sotscheck, and Friese (13). Mixed melting points and other tests proved that the above products were identical in all respects with derivatives from tetrahydrofurfural.

Tetrahydropyran-2,3-diol (VIII) and Related Compounds

3-Chlorotetrahydropyran-2-ol (13.6 gm., 0.1 mole) dissolved in water (100 ml.) was treated with sodium hydroxide solution (4 gm. in 100 ml.) and allowed to stand for three to four hours at room temperature. The solution was made just acid with a few drops of dilute hydrochloric acid and allowed to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

evaporate at 35–40°C. The residue was extracted with absolute ethanol, leaving behind a quantitative yield of sodium chloride. The alcoholic extract was allowed to evaporate at room temperature. The residue (10 gm.) was extracted several times with ether. Evaporation of the ether gave a high boiling sirup (8 gm.) which is thought to be tetrahydropyran-2,3-diol. Found: C, 51.1; H, 8.07%; Calc. for $C_5H_{10}O_3$: C, 50.9; H, 8.47%.

The same product can be obtained more conveniently in larger quantities by treating crude 2,3-dichlorotetrahydropyran, made by direct chlorination of dihydropyran, with 2 moles of sodium hydroxide and isolating the product as described above.

The product gave the previously described dinitrophenylosazone (m.p. 242°) when refluxed with 2,4-dinitrophenylhydrazine. It reduced periodic acid to iodate and formed a 3,5-dinitrobenzoate, m.p. 174°C.

When the reaction with sodium hydroxide was carried out at 100° on the water bath, very little of the organic product was soluble in ether. The high boiling sirup obtained was probably a mixture of substances of higher molecular weight than the diol. In one trial a chloroform-extracted product solidified. When recrystallized from ethanol it separated in elongated plates which melted at 101–102°C. Found: C, 59.7; H, 8.10%; Calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.00%. The melting point and analysis indicates that this is one of the $C_{10}H_{16}O_4$ substances which Hurd and Edwards (3) obtained by heating tetrahydropyran-2,3-diol.

In another trial when excess solid sodium hydroxide was added to the chlorohydrin solution and the mixture left standing, a small quantity of very fine white powder settled out. This melted at 190°C. and could be the other $C_{10}H_{16}O_4$ substance obtained by Hurd and Edwards.

3,3-Dichlorotetrahydropyranol-2 (XVII)

2,3,3-Trichlorotetrahydropyran (9.5 gm.), prepared by the method of Hawkins and Bennett (2), was stirred with sodium carbonate solution (2.6 gm. in 100 ml. of water) at 35–40° for 10 hr. The reaction mixture was then subjected to continuous extraction with ether. After evaporation of the ether a solid recrystallized from aqueous alcohol in plates which melted at 88–89°C. The I.G. Farben chemists (6) reported 90° as the melting point of 3,3-dichlorotetrahydropyran-2-ol.

This product was less aldehydic than the halohydrins, but it did reduce Fehling's solution on warming for some time. When the product was treated at room temperature with 2,4-dinitrophenylhydrazine it did not form a dinitrophenylhydrazone, but when the reaction mixture was heated the previously described 2,4-dinitrophenylosazone (m.p. 242°C.) was precipitated.

When the dichlorotetrahydropyranol was dissolved in warm alcohol, it could be titrated slowly with aqueous sodium hydroxide solution and neutralized two equivalents of the base.

2-Hydroxytetrahydropyran-3-one (XVIII)

2,3,3-Trichlorotetrahydropyran (19 gm., 0.1 mole) was warmed to 35–40°C. so it would remain in the liquid phase, and sodium hydroxide solution (12 gm., 0.3 mole, in 150 ml. of water) was added. The mixture was kept at the

temperature indicated and stirred until the organic layer had disappeared—about 10 hr. The reaction mixture still slightly acid was then allowed to evaporate at just above room temperature. The residue was extracted with absolute ethanol, leaving behind a nearly quantitative yield (16 gm.) of sodium chloride. The alcoholic extract on evaporation gave a very viscous, dark red sirup (10 gm.). No method of purifying it has been found. Its reactions indicated that it was mainly 2-hydroxytetrahydropyran-3-one in equilibrium with an open chain aldehyde form.

It reduced Fehling's solution rapidly when warmed. With 2,4-dinitrophenylhydrazine it gave an almost immediate precipitate of the expected 2,4-dinitrophenylosazone (m.p. 242°), previously described.

The crude red sirup was treated at room temperature for several days with an alkaline solution of potassium permanganate. The manganese dioxide was filtered off and the filtrate acidified with dilute sulphuric acid. Further decolorization of the permanganate now occurred. When this acid oxidation was complete the excess permanganate was destroyed with a little sodium bisulphite, the solution evaporated to dryness, and the residue extracted with ether. On evaporation of the ether a solid acid (m.p. 186°) was left. This was identified as succinic acid by the preparation of the *p*-bromophenacyl ester (m.p. 210–211°) and the *p*-nitrobenzyl ester (m.p. 87–88°). Mixed melting points of these derivatives with samples prepared from an authentic specimen of succinic acid showed no depression.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council for a grant which has aided in this research, and to E. I. du Pont de Nemours and Company (Inc.) for a supply of dihydropyran.

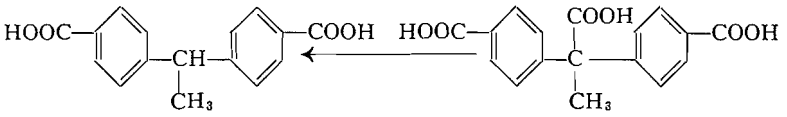
SYNTHESIS OF 1,1-DI-(*p*-CARBOXYPHENYL)ETHANE AND ITS ESTERS[1]

By Henry Bader[2] and W. A. Edmiston

ABSTRACT

The condensation of chlorobenzene with ethylidene diacetate in presence of fluosulphonic acid – hydrogen fluoride catalyst has been improved to give high yields of 1,1-di-(*p*-chlorophenyl)ethane, which was converted into the corresponding dinitrile by a modification of the cuprous cyanide method. Alkaline hydrolysis of the dinitrile gave 1,1-di-(*p*-carboxyphenyl)ethane. Its methyl and 2-ethylhexyl esters were prepared directly from the diacid or via the diacid chloride.

The interesting properties of the polyesters of terephthalic acid prompted us to prepare other aromatic *p*-diacids expected to possess similar properties, i.e. 1,1-di-(*p*-carboxyphenyl)ethane (I).



I II

This compound was previously obtained by Haiss (4) by partial decarboxylation of 2,2-di-(*p*-carboxyphenyl)propionic acid (II), which was produced by oxidation of the condensation product of toluene and pyruvic acid.

The simplest approach to the synthesis of compound (I) would be to oxidize 1,1-di-(*p*-tolyl)ethane to the diacid or to the dialdehyde, as described by Perron and Barré (8, 9) for the 2,2,2-trichloro-1,1-di-(*p*-tolyl)ethane. However, the stability of the ethylidene bridge is much lower than that of the trichloroethylidene group and it is the first one attacked on oxidizing 1,1-di-(*p*-tolyl)-ethane. Thus Anschütz (1) reported formation of di-*p*-tolyl ketone and of *p*-toluylbenzoic acid when hot chromic acid was used, and similarly in this laboratory (5) chromium trioxide in glacial acetic acid at 55° gave only di-*p*-tolyl ketone.

This synthesis was carried out successfully through the route outlined in the following scheme:

The starting material, 1,1-di-(*p*-chlorophenyl)ethane, was prepared by an improvement of the method previously evolved in this laboratory (2). The original method gives a 48.6% yield of the isomeric mixture of 1,1-di-(chlorophenyl)ethane by reacting chlorobenzene with ethylidene diacetate in presence of a mixture of fluosulphonic acid and hydrogen fluoride. It has now been found that the presence of sulphuric acid in the reaction mixture lowers the yield of the product. When the fluosulphonic acid is redistilled immediately before use and thus freed from the sulphuric acid it contains, the yield of mixed isomers can be raised to 71.5%. The solid *p,p'* isomer can be easily isolated and purified by crystallization.

When the conversion of the dichloride (III) into the dicyanide (IV) was attempted with cuprous cyanide in pyridine or quinoline under the standard conditions described in the literature (cf. *inter alia* Newman (7)), there resulted an extensive charring of the product and the reaction was incomplete, the monochlorocyanide being the main product. By using, however, at least a three times higher molar ratio of the organic base to cuprous cyanide than is customary, a good yield of 1,1-di-(*p*-cyanophenyl)ethane (IV) was obtained. While our work was in progress Lorz and Baltzly (6) reported improved yields of 4-alkoxy-1-naphthonitriles by doubling the amount of pyridine used by Newman (7) thus confirming our findings.

The dinitrile was hydrolyzed to the corresponding diacid (I) in almost theoretical yield by alkaline hydrolysis in the presence of glycol. Ethanol, propanol, or glycerol can also be used, the time of the reaction depending on the boiling point of the alcoholic component.

Some attempts were made to synthesize the diacid (I) or its esters by a one stage process from benzoic acid or methyl benzoate using ethylidene chloride, ethylidene diacetate, or acetaldehyde in presence of sulphuric acid, aluminum chloride, fluosulphonic acid, hydrogen fluoride, or the fluosulphonic acid – hydrogen fluoride mixture. Also condensations of acetylene in presence of aluminum chloride or mercuric chloride were tried, but no reaction took place under any of these conditions.

The dimethyl ester of the diacid (I) was best prepared by converting the diacid to its dichloride with thionyl chloride and treating the dichloride with methanol. The di-2-ethylhexyl ester was prepared directly from the diacid and 2-ethylhexanol in presence of sulphuric acid and of xylene as an azeotropic component.

EXPERIMENTAL*†

1,1-Di-(p-chlorophenyl)ethane

Chlorobenzene (1410 gm.) was charged to a stainless steel reaction vessel and cooled to 0°. Under vigorous stirring 1000 gm. of liquid hydrogen fluoride were first added, followed by 1675 gm. of freshly redistilled fluosulphonic acid, and then a mixture of ethylidene diacetate (490 gm.) and of chlorobenzene (770 gm.) was introduced dropwise over a period of 40 min. while the tempera-

All melting points are uncorrected.
†*The microanalyses were performed by Dr. Robert Dietrich of Zurich, Switzerland.*

ture rose slowly from 0° to 20°. The temperature was maintained at about 10° while the reaction mixture was agitated for another 30 min. It was then poured into 6 liters of ice water, the organic layer separated after the addition of some ether, and then washed with dilute caustic and water. After removal of the solvent the residue was fractionally distilled, yielding recovered chlorobenzene (1650 gm.) and 1,1-di-(chlorophenyl)ethane (603 gm.; 71.5% yield based on ethylidene diacetate) as a pale yellow oil, boiling point 138–142° at 1.0 mm.; refractive index, n_D^{21} 1.5920. The major portion of the product crystallized on standing a few hours at room temperature. The supernatant liquor was decanted and the solid crystallized from methanol yielding 1,1-di-(*p*-chlorophenyl)ethane (375 gm.; 56.8% over-all yield) as colorless prisms melting at 53–55° (Grummit *et al.* (3) give m.p. 54–55°).

1,1-Di-(p-cyanophenyl)ethane

A mixture of 1,1-di-(*p*-chlorophenyl)ethane (475 gm.), cuprous cyanide (415 gm.; dried before use for 36 hr. at 110°), and anhydrous quinoline (1200 ml.; distilled over potassium hydroxide) was refluxed for 70 hr., then poured while still hot into a solution of ammonium hydroxide (1800 ml.; d. = 0.88) and water (1800 ml.). Benzene (1600 ml.) was added, the mixture allowed to cool to room temperature, and then ether (1000 ml.) was added. A brown solid separated which was removed by filtration. The organic layer was washed with dilute ammonia solution (4 × 1200 ml.), with a hydrochloric acid solution (2 *N*; 2 × 1200 ml.; a precipitate which separated at this stage was removed by filtration), then with water (2 × 1200 ml.) and finally with saturated brine (2 × 1200 ml.). The solution was dried over anhydrous copper sulphate and the solvent removed by distillation yielding the crude dinitrile (312 gm.; 71% yield). Crystallization from ethanol gave 1,1-di-(*p*-cyanophenyl)ethane (249 gm.) as colorless prisms which had a melting point of 112–118°C. After one more crystallization, the melting point was increased to 120–122.5°. Calc. for $C_{16}H_{12}N_2$: C, 82.75; H, 5.2; N, 12.05. Found: C, 82.65; H, 5.05; N, 12.3.

1,1-Di-(p-carboxyphenyl)ethane

A mixture of 1,1-di-(*p*-cyanophenyl)ethane (216 gm.), sodium hydroxide (120 gm.), ethylene glycol (1200 ml.), and water (240 ml.) was refluxed for 10 hr. by which time evolution of ammonia ceased. After it was cooled to room temperature, the solution was separated from a small amount of solidified oily material, diluted with ice water, and acidified with dilute hydrochloric acid under vigorous stirring. The resulting precipitate was filtered under suction, washed several times with water, and brought to a consistency of a cake by applying suction for several hours. The latter was dried either in an oven at 110° or by azeotropic distillation with benzene or xylene. In this way 1,1-di-(*p*-carboxyphenyl)ethane (239 gm.; 95.1% yield) was obtained in microcrystals, which melted at 265–278°, and then, on crystallization from ethyl acetate, at 273–278°. Calc. for $C_{16}H_{14}O_4$: C, 71.1; H, 5.2. Found: C, 71.7; H, 5.2.

1,1-Di-(p-carboxyphenyl)ethane Dimethyl Ester

Thionyl chloride (150 ml.) was added slowly to the diacid (150 gm.) causing heat evolution and progressive dissolution of the solid. The mixture was refluxed for one hour, then the excess of thionyl chloride removed under reduced pressure. To the residue methanol (150 ml.) was slowly added and then the mixture refluxed for a period of one hour and the excess methanol distilled off. The residue was taken up in ether, washed twice with sodium carbonate solution and then with water, and finally dried over anhydrous magnesium carbonate. Evaporation of the solvent left 1,1-di-(*p*-carbomethoxyphenyl)-ethane (156.9 gm.; yield 94.3%) which crystallized on standing. Recrystallization from cyclohexane–ether mixture or from ether gave colorless plates which melted at 56.5–58.2°. Calc. for $C_{18}H_{18}O_4$: C, 72.5; H, 6.1. Found: C, 72.35; H, 5.95.

1,1-Di-(p-carboxyphenyl)ethane Di-(2′-ethyl)hexyl Ester

A mixture of 1,1-di-(*p*-carboxyphenyl)ethane (355.4 gm.), 2-ethylhexanol (2000 ml.), concentrated sulphuric acid (55 gm.), and dry xylene (500 ml.) was refluxed for 100 hr. while water was separated in a Dean and Stark trap. The resulting solution was then washed with sodium carbonate solution and the excess of xylene and alcohol was distilled. Fractionation of the residue under reduced pressure gave 1,1-di-(*p*-carboxyphenyl)ethane di-(2′-ethyl)-hexyl ester (496.0 gm.; yield 76%) which boiled at 220° at 0.05 mm.; refractive index, n_D^{23} 1.5252. Calc. for $C_{32}H_{46}O_4$: C, 77.7; H, 9.4. Found: C, 77.45; H, 9.05.

CROSS-LINKING OF COPOLYMERS FROM METHYL VINYL KETONE AND *n*-BUTYL ACRYLATE[1]

By W. Cooper and E. Catterall

ABSTRACT

Copolymers of *n*-butyl acrylate and methyl vinyl ketone can be cross-linked by a combination of sulphur and zinc oxide; the reaction is associated with the methyl vinyl ketone units in the polymer chain. From studies on the copolymers and model compounds, it is suggested that adjacent pairs or groups of methyl vinyl ketone units in the polymer cyclize to give $\alpha\beta$ unsaturated ketone groups. These contain reactive hydrogen which is attacked by sulphur; disulphide or zinc mercaptide cross-links are then formed. Water is produced in the cyclization reaction and hydrolyzes some of the ester groups; additional cross-links are thus formed by reaction of the acid groups with zinc oxide. The ease of cyclization and, therefore, the extent of cross-linking is dependent on the method of preparing the copolymers, emulsion copolymers being much more reactive than those prepared in solution. A comparison has been made between the sulphur + zinc oxide system and other cross-linking agents which may be used for polyacrylates.

INTRODUCTION

The elastomeric polymers and copolymers of acrylic esters are of growing importance and have attracted much attention in recent years. Some of the lower polyalkyl acrylates are attractive rubbers of reasonable strength with good resistance to heat and oils. Polymers containing high proportions of *n*-butyl acrylate possess in addition good resistance to freezing and high resilience. They are, however, usually difficult to process and give products of low strength. Efforts to improve these features have been made by copolymerization with a more polar type of monomer, such as acrylonitrile, methyl *iso*propenyl ketone, and methyl vinyl ketone, though with some sacrifice of other desirable properties.

The copolymers of *n*-butyl acrylate with methyl vinyl ketone are of some interest in that they can be cross-linked by means of sulphur + zinc oxide in addition to the more usual cross-linking agents (11) (such as lead oxide, calcium hydroxide, or polyamines), and give products of good strength when reinforced by means of carbon black or finely divided silica (4).

A preliminary study of the reactions involved indicated that they were rather complex and this paper describes the attempts made to elucidate those of greater importance and, as a practical measure, to compare the sulphur + zinc oxide vulcanizates with those prepared with other cross-linking agents.

DISCUSSION

Polymer

Methyl vinyl ketone and *n*-butyl acrylate copolymerize readily, the polymers containing a higher proportion of methyl vinyl ketone than in the initial monomer. Determination of the composition of low conversion copolymers for

[1]*Manuscript received October 24, 1955.*
Contribution from the Chemical Research Division, Dunlop Research Centre, Birmingham, England. This paper was read at the Sixth Canadian High Polymer Forum at St. Catharines, Ontario, April 14th, 1955.

monomer reactivity ratios proved to be difficult (see Appendix for details), and a completely satisfactory method has not been found. Reasonable agreement was found, however, between several methods of analysis, and values of $r_1 = 1.6 \pm 0.1$ and $r_2 = 0.65 \pm 0.07$ were obtained (MVK is monomer 1). The data are shown in the polymer composition curve (Fig. 1).

Integral and differential copolymer distribution diagrams (13) (Figs. 2*a* (i) and (ii) and 2*b* (i) and (ii)) show that, up to about 50% conversion, copolymers made with 20–35% by weight of methyl vinyl ketone (i.e. 30–50 mole %) have only a narrow distribution of polymer compositions. The copolymers were made by solution polymerization and in emulsion. Solution polymers were prepared in benzene solution at 70° using 0.5% benzoyl peroxide as catalyst and isolated by pouring into petroleum ether, or aqueous alcohol mixtures. They were normally of relatively low molecular weight ($[\eta] = 0.2$–0.3) and completely soluble in organic solvents. The emulsion copolymers were made at 50° using potassium persulphate (1% on monomers) as initiator. For copolymers of low methyl vinyl ketone content, the sodium salt of sulphated methyl oleate (4.2%) was used as the emulsifier, while for high ketone contents sodium lauryl sulphate (4%) was more suitable. The emulsion copolymers were

always gelled to a greater or lesser extent. This gel was broken down readily on milling, and, as with other acrylates (6), there was a steady fall in molecular weight with mastication (Fig. 3).

Cross-Linking Agents for Acrylate Copolymers

A variety of reagents have been used for cross-linking acrylate copolymers. Most of them attack the ester portions of the molecule and thus apply to all types, but some (e.g. hexamethylene tetramine (HMT) for copolymers with alkyl vinyl ketones) are more specific in their action. The more important substances used include the following:

(*a*) *Basic oxides and hydroxides* (e.g. lead oxide and calcium hydroxide) which form salt bridges between different chains (i). It has been suggested

$$\underset{\text{(i)}}{\{\text{—C(O)OMOC(O)—}\}} \qquad \underset{\text{(ii)}}{\{\text{—CO—}\}\text{—COOR}}$$

that strong bases from monovalent metals (e.g. KOH) may form cross-links by an acetoacetic ester type condensation (ii) (12). This has not been proved, however, and will be discussed later.

(*b*) *Polyamines.*—These presumably form amide bridges between the polymer chains (iii). Substances such as tetraethylenepentamine (TEP) and triethyl trimethylene triamine (Trimene Base) are the most commonly used.

$$\underset{\text{(iii)}}{\{\text{—CONH—R—NHCO—}\}} \qquad \underset{\text{etc.}}{R = [(CH_2)_2NH(CH_2)_2]_n}$$

(*c*) *Peroxides.*—Peroxides are used occasionally to effect cross-linking of polyacrylates. Abstraction of hydrogen atoms (probably skeletal hydrogen atoms adjacent to the carbonyl group) followed by dimerization of the radicals so formed is probably their mode of action. They are generally not very useful materials and tend to cause blowing.

(*d*) *Sulphur + zinc oxide.*—Pure polyacrylates will not cross-link with these reagents. The possession of halogen atoms, by incorporation, for example, of chloroethyl vinyl ether, or the presence of ketone groups renders them effective. This reaction is discussed in detail below.

(*e*) *Miscellaneous compounds.*—These include, for ketone copolymers, hydrazine (used as its organic salts in the presence of a base) which forms intermolecular azines (iv), hexamethylene tetramine + organic acids or paraformaldehyde which form interchain methylene bridges (v), trinitrobenzene + zinc oxide, and quinone dioxime + lead oxide. The mechanism by which the latter compounds react is not known.

$$\underset{\text{(iv)}}{\left\{ \begin{array}{l} \text{—C=N—N=C—} \\ \quad\;\; | \qquad\quad | \\ \quad CH_3 \qquad CH_3 \end{array} \right\}} \qquad \underset{\text{(v)}}{CH_3CO\text{—}\{\text{—}CH_2\text{—}\}\text{—}COCH_3}$$

Cross-linking by Sulphur + Zinc Oxide

Examination of vulcanizates from *n*-butyl acrylate and MVK quickly leads to the conclusion that rapid reaction occurs with sulphur and that concomitant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

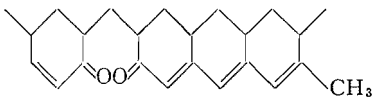
reactions associated with the polymer structure also occur. These latter reactions manifest themselves in greatly reduced heat-aging resistance of the copolymers. It is convenient, therefore, to discuss first the changes which occur on heating the copolymers alone.

(*i*) *Cyclization of MVK Polymers*

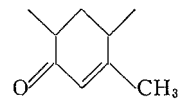
A feature of all compounded emulsion copolymers examined was a continuous and relatively large weight loss when heated above 100° C., accompanied by reduced swelling in a solvent such as benzene. This seemed to be in accordance with the view that the weight loss resulted from intermolecular condensation with consequent cross-linking and reduced swelling volume, until it was observed that weight loss – swelling volume measurements did not agree with estimates of cross-linking as judged from physical tests on cured slabs. This became further apparent when it was found that the pure gum copolymers themselves gave comparable weight loss and swelling volume curves but gave no sign of possessing a truly vulcanized structure. Furthermore, soluble copolymers (prepared by bulk or solution polymerization) when heated in the absence of air also lost weight. They became hard and resinous but, since they were completely soluble in methyl ethyl ketone and were thermoplastic, they were not cross-linked.

As a result of these observations, experiments were made on a solution copolymer containing 50–60% of MVK. (Initial monomer composition equimolar; for copolymer distribution curve see Fig. 2*a*.) On heating for 93 hr. at 160° C. in a sealed evacuated vessel, 5.1% of butanol and 4.0% of water were liberated. The polymer was transformed from a soft rubber to a hard resin, had a deep red-brown color, and was soluble in chloroform or methyl ethyl ketone. Titration showed the presence of 3.2% acid groups (calculated as acrylic acid).

Marvel and Levesque (10) studied the change in polymethyl vinyl ketone when heated at 270–360° C., and deduced the formation of polycyclic structures of the type (vi).



(vi)



(vii)

Infrared spectroscopic examination of the heated copolymer showed changes which were quite consistent with this type of structure (Fig. 4). Reduction of the intensities of the normal ketone absorption frequency and other associated bands was accompanied by new frequencies characteristic of $\alpha\beta$ unsaturated ketones; the ester carbonyl group remained essentially unchanged. It is clear therefore that reactions of the type described by Marvel occur quite rapidly at temperatures as low as 140°–160° C.[2] Calculation of the extent of this reaction by use of Wall's statistical theory for the isolation of carbonyl groups (15) in the copolymer shows that 6.1% of water would be eliminated;

[2]*The ultraviolet spectra of the copolymers were rather featureless, but an appreciable increase in absorption intensity, particularly at higher frequencies, occurred after only 30 min. at 140° C.*

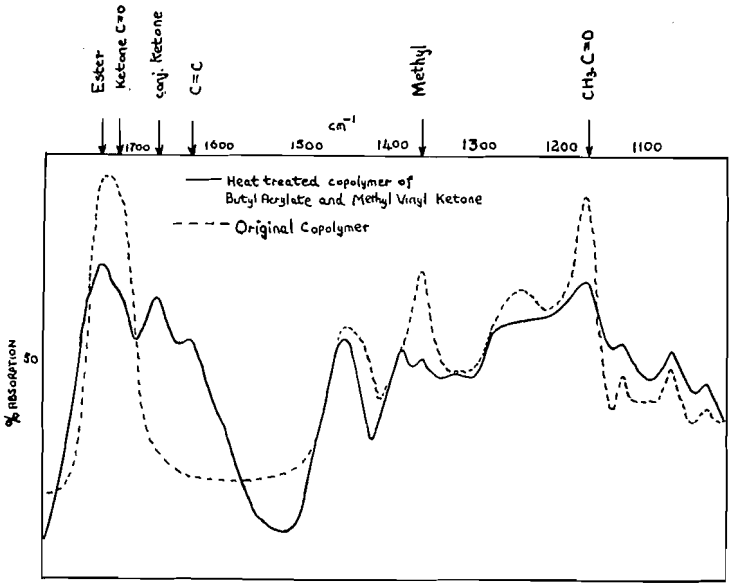


FIG. 4.

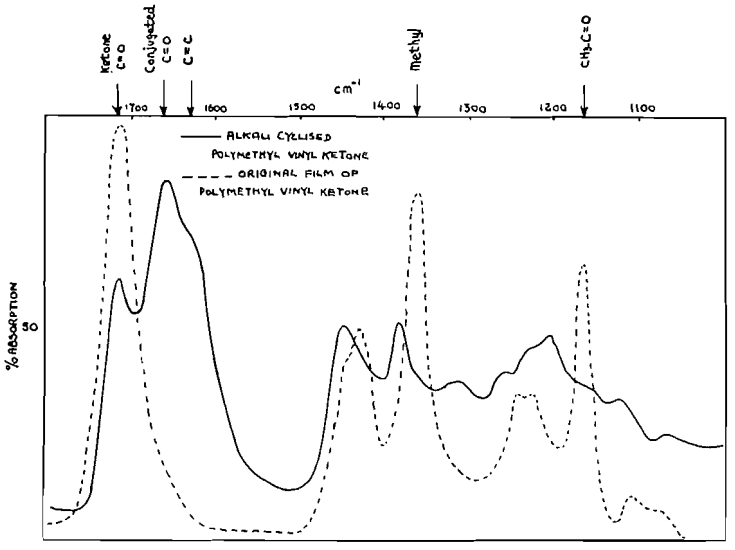

FIG. 5.

about two thirds of the residual carbonyl groups would be conjugated with ethylenic bonds. On the assumption that the monomer units were randomly distributed in the copolymer the experimental data show the reaction to have gone to about 80–85% completion.[3] This estimate is in agreement with the intensity changes of bands in the infrared spectrum of the copolymer corresponding to carbonyl and methyl groups.

[3]*The r_1, r_2 product for this system is not greatly different from unity; it follows that errors brought about by this assumption will not be great.*

This condensation proceeds very slowly at temperatures below 100° C., but it has been found that polymethyl vinyl ketone and its copolymers rapidly give polyunsaturated ketones at room temperature on treatment with alkali. (Polymethyl vinyl ketone is transformed in a few seconds from a tough thermoplastic resin softening at about 50° C. to a hard brittle resin softening at 260–270° C. (5).) Under these conditions not a great deal of multiple ring closure occurs and mono-ring structures predominate (vii) (the infrared spectrum of the alkali cyclized polymer is shown in Fig. 5) and, as insoluble polymers are easily obtained, it is possible for some intermolecular condensation also to occur. It is obvious then that polymers containing methyl vinyl ketone can undergo rapid condensation reactions at room temperature in the presence of alkalies, or alone at vulcanization or heat aging temperatures. A further consequence of the cyclization reaction is the formation of carboxyl groups by hydrolysis of ester groups. In the presence of metallic oxides or hydroxides, this will result in many cross-links being formed.

The combined effect of these reactions undoubtedly results in continued cross-linking on heating and thus poor heat aging resistance. Confirmation of these views is found in the large amount of butanol liberated on heating a copolymer with lead oxide compared with that from pure poly *n*-butyl acrylate under the same conditions (Table I).

(ii) Reaction of Sulphur with Acrylate–MVK Copolymers

Hydrogen sulphide is evolved when a polymer containing methyl vinyl ketone is heated with sulphur, and some sulphur becomes combined with the polymer. Zinc oxide when present reacts with the hydrogen sulphide to give zinc sulphide. The amounts of sulphur combined and that liberated as hydrogen sulphide have been determined and the results are shown in Table II. It was found that approximately twice the amount of sulphur remained combined

with the copolymer compared with that liberated as hydrogen sulphide, and that the reaction was substantially complete in about one hour; little hydrogen sulphide was liberated after this period.

As would be expected the amount of hydrogen sulphide evolved depended on the amount of MVK in the copolymer. This was determined for a number of high and low conversion copolymers and the results are summarized in Fig. 6.

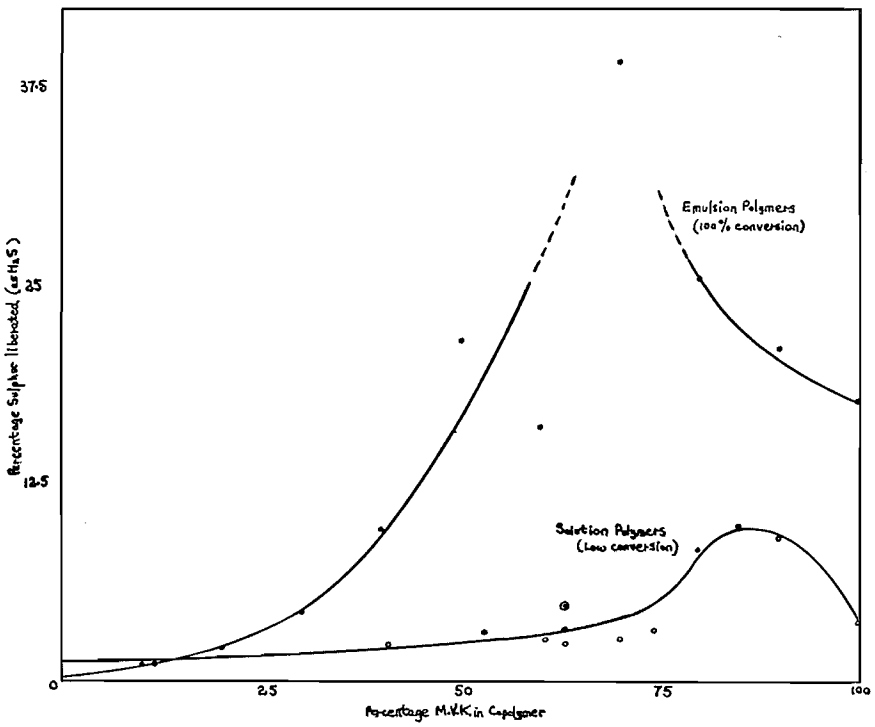

FIG. 6.

Two features are at once apparent, firstly that emulsion copolymers liberate much more hydrogen sulphide than those prepared in solution, and secondly that there is a maximum in the curve relating the amount of hydrogen sulphide liberated to the MVK content of the copolymer. With regard to the differences between emulsion and solution copolymers, it seemed possible that these may have arisen because of the different methods employed in incorporating the sulphur into the copolymers; in the case of emulsion polymers it was mixed on the mill while with solution polymers sulphur and polymer were dissolved in benzene and the solvent removed under vacuum. To test this point two 50/50 w/w copolymers were made, one in emulsion, the other in solution; both were taken to about 60% conversion. Sulphur (4%) was incorporated into both by milling and by use of a solvent. The hydrogen sulphide liberated on heating is given in Table III, together with the yields of volatiles liberated on heating the polymers alone at 150° C. It is apparent that a more intimate mixture of

polymer and sulphur is obtained by the solution technique and that under both conditions the emulsion copolymer liberates much more hydrogen sulphide. This is accompanied by the ready loss of water, undoubtedly from cyclization, on heating. (Evidence to support the view that cyclization to give an $\alpha\beta$ unsaturated ketone is a prerequisite for attack by sulphur is presented below.) The reason for the susceptibility of emulsion copolymers to this reaction is not fully understood since spectroscopic examination of the unheated emulsion copolymer shows no evidence of prior cyclization. It follows that either the emulsion copolymers have different compositions (MVK is a water miscible monomer) or traces of reagents from the emulsion system accelerate the cyclization. The latter is the more probable, as no evidence of heterogeneity was observed on fractionating an emulsion copolymer from the latex. Furthermore the refractive indices of emulsion copolymers containing 70% or more of butyl acrylate were the same as those of the corresponding solution copolymers. Mixtures of the two homopolymers were not homogeneous and gave refractive index values substantially the same as polybutyl acrylate, irrespective of composition.

The explanation for the maxima in the curves relating the hydrogen sulphide liberated vs. polymer composition is even less obvious. The most probable cause is a reduction in solubility of sulphur in the higher ketone copolymers, particularly after some cyclization has occurred. It is also possible that a change occurs in the ratio of sulphur eliminated as hydrogen sulphide to that which combines with polymer.

That the attack of sulphur on the copolymers is a free radical reaction is shown by the fact that the rate of liberation of hydrogen sulphide is increased by the addition of the conventional rubber accelerators (MBT, TMD) as shown in Fig. 8. A study of the change in modulus of the polymer with heating time (Fig. 7) shows clearly the influence of accelerator on the rate of cure.

In these systems zinc oxide has the effect of taking up hydrogen sulphide, which causes blowing and some reversion by reducing disulphide cross-links, reacts with acid groups formed by hydrolysis of the ester (separate experiments on the pure polyacrylates showed zinc oxide alone to have a negligible cross-linking effect), and forms mercaptide cross-links by the reaction with thiol groups along the polymer chain.

The above experiments show conclusively that sulphur reacts with MVK polymers and copolymers, and that cyclization with loss of water also occurs. The latter can be a major reaction and its effect, particularly in the presence of metallic oxides, can completely mask the influence of the sulphur.

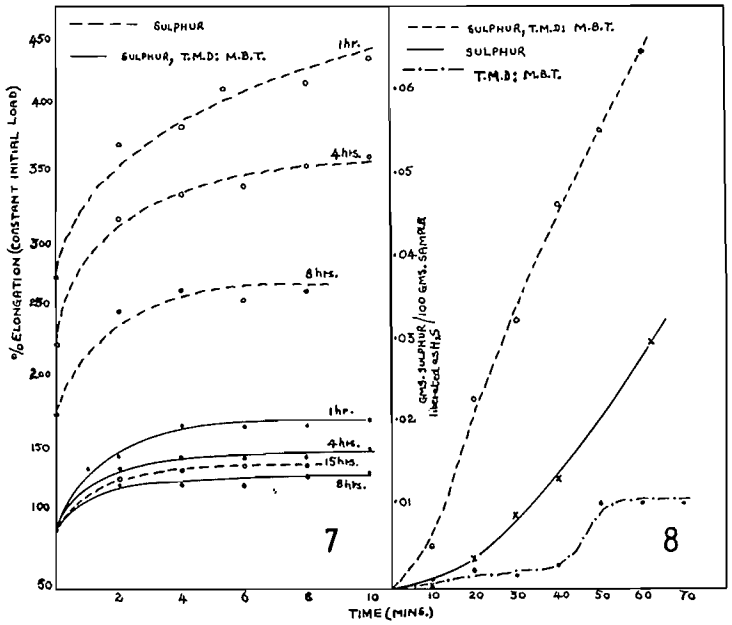
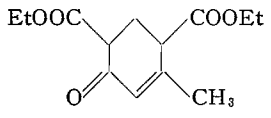


FIGS. 7 AND 8.

(iii) Mechanism of Sulphur–Copolymer Reaction

In order to decide the nature of the reaction a number of model compounds were heated with sulphur at 150° C. and the hydrogen sulphide evolution observed. The results are summarized in Table IV and show that the reaction of sulphur with ketones is not a general reaction. Stable aliphatic ketones do not react at the temperatures used in vulcanization of the copolymers, and it is interesting to note that those saturated ketones which do react possess two carbonyl groups in close proximity (e.g. acetyl acetone, dimethyl dihydroresorcinol), or can undergo condensation to give an unsaturated ketone. Thus cyclohexanone gives 2-(cyclohex-1′-enyl) cyclohexanone, 1,3-diacetyl diethyl glutarate can give 4,6-dicarboethoxy-3-methyl cyclohex-2-enone (viii), and, as already discussed, polymethyl vinyl ketone gives a cyclized polymer (v) on heating.



(viii)

It appears that not all unsaturated ketones liberate hydrogen sulphide under these conditions, as shown by the cases of mesityl oxide and its higher homologue 5-methyl-4-hexen-3-one, which differ from the other unsaturated ketones examined in that they do not possess a secondary or tertiary hydrogen atom adjacent to the double bond. It follows from the behavior of 5-methyl-4-

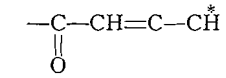
hexen-3-one, as with the saturated ketones, that the possession of a secondary hydrogen atom adjacent to the carbonyl group does not lead to the formation of hydrogen sulphide (unless of course it is instantly removed by rapid addition to the double bond—an unlikely possibility[4]).

[4]*Hydrogen sulphide reacts readily with αβ unsaturated ketones. Benzal acetone for example gives (xi) (2), and a comparable reaction with cyclized MVK would form (xii). This type of*

(xi) 
(xii) 
reaction seems sterically improbable however, in view of the ring structure elements and, of course, the ready evolution of hydrogen sulphide in the reaction is evidence against it.

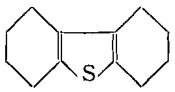
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

It seems therefore that the following structure grouping is necessary, ab-

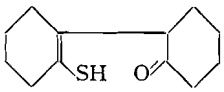


straction of hydrogen by sulphur occurring at the point marked by an asterisk.

The behavior of 2(cyclohex-1′-enyl) cyclohexanone is apparently anomalous, but it must be remembered that in this case the $\beta\gamma$ system is more than usually reactive.[5] This compound when heated with sulphur forms 1,2,3,4,6,7,8,9-octahydrodibenzothiophen (ix), in good yield (3). The formation of this compound, however, is not directly relevant to the reaction in question. It can be



(ix)



(x)

obtained directly from 2(cyclohex-1′-enyl) cyclohexanone (3) by addition of sulphur and loss of water, without any necessity of explaining the ready formation of hydrogen sulphide. A possible intermediate in the formation of (ix)

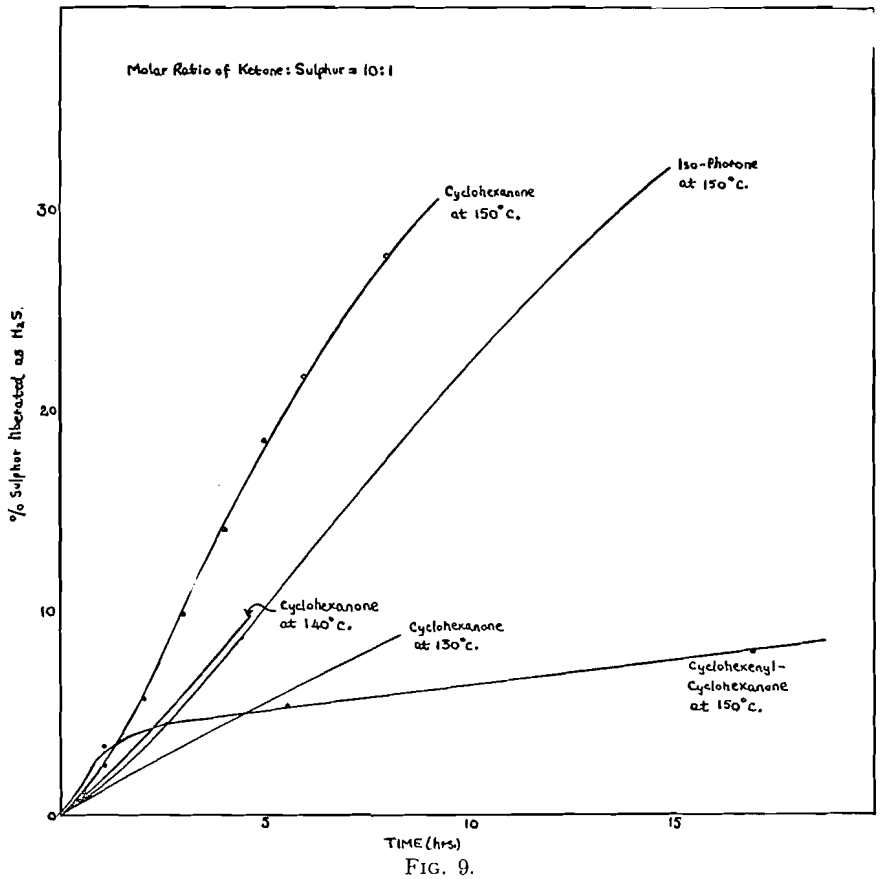


FIG. 9.

[5]*This is apparent from its formation from cyclohexanone on heating instead of 2-cyclohexylidene cyclohexanone.*

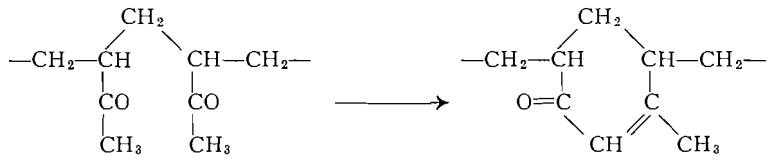
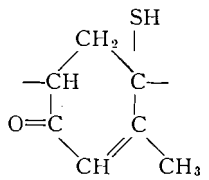
For personal use only.

would be the thiol (x). Hydrogen sulphide, on the other hand, would be liberated after attack on the hydrogen atoms alpha to the double bond (positions 2′, 6′, or 1) giving complex sulphides (7). It is probable that such reactions may also occur since hydrogen sulphide is evolved continuously on heating (see Fig. 9) but in smaller amounts than from cyclohexanone.

The following mechanism, which is supported by the above evidence, is that, initially, cyclization occurs between adjacent pairs or groups of MVK units.



The unsaturated structures are attacked by sulphur to give structure elements (xiii).



(xiii)

Oxidation of some of the thiol groups by sulphur could then occur with the formation of disulphide bridges and the liberation of hydrogen sulphide (xiv), while others would react with zinc oxide to form mercaptide cross-links (xv).

$$2RSH + S \rightarrow RS \cdot SR + H_2S \qquad \text{(xiv)}$$

$$2RSH + ZnO \rightarrow RSZnSR + H_2O \qquad \text{(xv)}$$

It is possible that this latter reaction is of some consequence in view of the necessity of using a combination of the zinc oxide and sulphur, which separately possess only weak cross-linking action under normal cure times and temperatures. The influence of the accelerator is presumably activation of the sulphur by opening the S_8 ring (8). The fact that, ultimately, vulcanizates of comparable state are obtained with or without accelerator, and that there is then no free sulphur available, supports this view.

It may be concluded that the effect of the ketone monomer is only to provide, by condensation, unsaturated groups which can then react with sulphur.

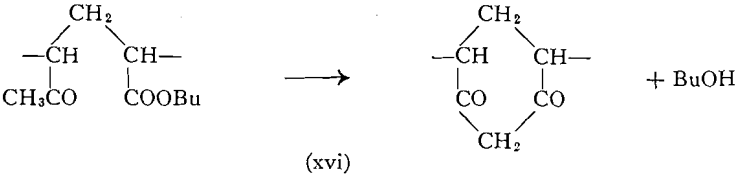
(iv) Other Reactions

Semegen and Wakelin (12) in a study of the cross-linking of polyethyl acrylate suggest an acetoacetic ester mechanism for the reaction. The conditions they used, high temperatures (300° C.) and the presence of strong bases, are not comparable with those used in this work and it must be noted that alcohol is produced by thermal cracking of polyacrylates themselves. (The depolymerization of thermally unstable methacrylates cannot be regarded as supporting their theory.) It should be pointed out, however, that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

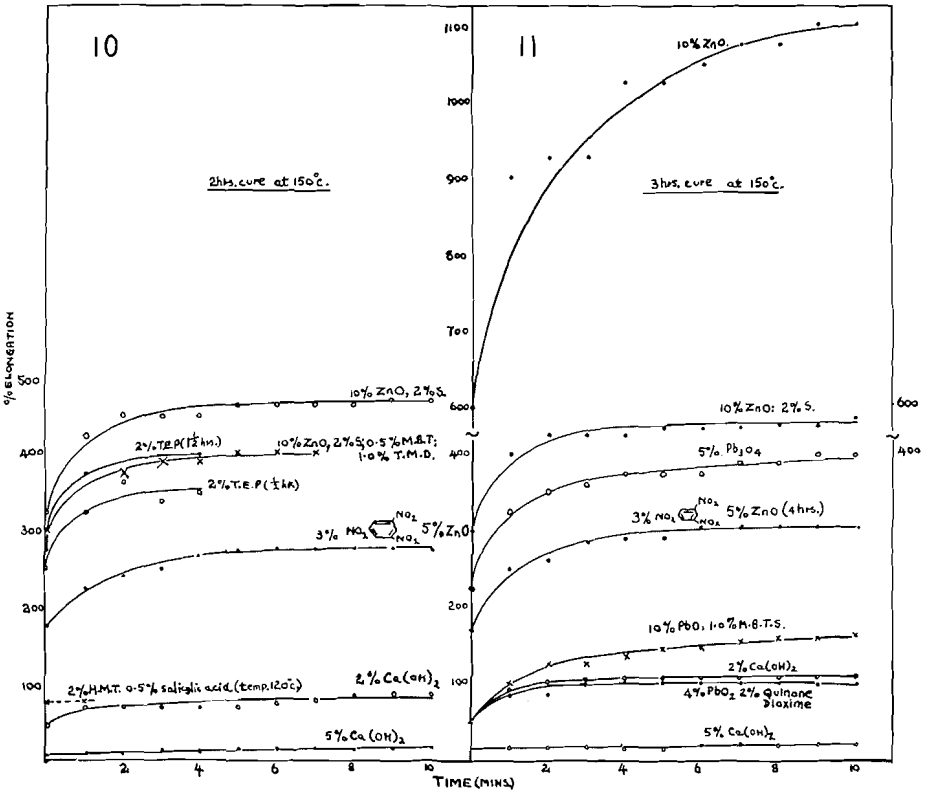
as yet no alternative mechanism has been suggested for the cross-linking of polyacrylates by bases such as potassium hydroxide.

In view of this it is therefore desirable to consider the possibility of a reaction of the following type (xvi) occurring.



(xvi)

The model compound *n*-butyl 5-ketohexoate was synthesized. Heating it alone or with sulphur at 150° C. produced no significant change, from which it may be inferred that there is no enhanced reactivity in the copolymer between adjacent MVK–acrylate units. On the other hand, heating with lead oxide at this temperature gave a fairly rapid reaction with liberation of butanol and the formation of a sticky solid soluble in chloroform, which proved to be mainly the lead salt of 5-ketohexoic acid. No evidence was found for dimethyl dihydroresorcinol, and it must be concluded that this reaction does not take place at vulcanization temperatures. A point of interest was the speed of hydrolysis by lead oxide.



FIGS. 10 AND 11.

Comparison with Other Cross-linking Systems

It was thought desirable to compare the effect of the sulphur + zinc oxide system with some of the other compounds which may be used to cross-link polyacrylates.

Compounded samples were heated for various times and subsequently extended under constant initial load per unit area, and the elongation (instantaneous and after various periods of time) measured. A full program, varying the conditions of cure and using a combination of several curing agents, would be necessary to obtain the optimum properties in the vulcanizates. However, the results obtained show the general order of activity of the reagents used (Figs. 10 and 11).

It was found that calcium hydroxide and lead dioxide + quinone dioxime gave the fastest cures, but that the sulphur + zinc oxide combination gave the best formed vulcanizates. The latter were comparable to those obtained using polyamines, but had a lesser tendency to reversion on heating. Paraformaldehyde and HMT gave very rapid cures, the polymers not then altering on further heating. Paraformaldehyde gave highly blown products and is thus of little value, but HMT would appear to be suitable as a fugitive curing agent. In the case of most of the other systems, particularly those containing lead oxides, the hardening on heating is progressive, as shown by the data in Table V.

CONCLUSIONS

The effect of methyl vinyl ketone in promoting the cross-linking of its copolymers with *n*-butyl acrylate by alkaline reagents or by sulphur + zinc oxide appears to depend initially on the cyclization of adjacent ketone monomer units. These furnish water which, particularly in the presence of metallic oxides, enables hydrolysis to occur and thus form a three-dimensional network with metal salt bridges. In the presence of sulphur, attack occurs on the unsaturated ketone formed by the cyclization reaction with the formation of disulphide cross-linkages and zinc mercaptide cross-links. Zinc oxide also takes up the hydrogen sulphide formed in the reaction but has in itself only a weak cross-linking action. There is no evidence to support the view that direct attack occurs on the skeletal hydrogen atom adjacent to the carbonyl group.

No reaction occurs between sulphur and the ester part of the molecule, and nothing to suggest acetoacetic ester condensation reaction has been observed. Emulsion copolymers have been found to be much more readily cyclized than copolymers prepared in solution, probably because of the presence of traces of alkali. This influences both the ease with which they are cross-linked and the aging resistance of the copolymers.

APPENDIX

Analysis of MVK–Acrylate Copolymers

As stated in the text the satisfactory analysis of these copolymers proved to be a task of some difficulty. Several methods were tried with the following results:

1. *Hydrolysis.*—A solution of the copolymer in dioxan, aqueous alcohol, or dioxan–benzene gave homogeneous solutions with alcoholic potash in the cold. On heating, the polymer was wholly precipitated from solution (even when containing as little as 5–10% of combined ketone). Before heating, hydrolysis was clearly incomplete, whereas on boiling, the skin of polymer formed caused the results to be poorly reproducible. It was established that no alkali was associated with the insolubilized polymer, and, in fact, many of the results (consistent between themselves) gave high values for the acrylate content. It is possible that under the influence of the alkali a variable amount of oxidation to carboxylic acid occurred, and in some cases lower acrylate contents were found using a nitrogen atmosphere. Attempts to carry out the hydrolysis in sealed containers or pressure vessels at 100–120° C. gave less reproducible results and dark-brown precipitates of polymer were formed. The results obtained were broadly in agreement with those obtained by other methods, but the lack of reproducibility obtained at present between repeat determinations on the same polymer makes the method unreliable.

2. *Infrared spectroscopy.*—Films cast from chloroform on to rock salts show overlapping of the carbonyl frequencies (1720 and 1740 $cm.^{-1}$) but here and with the 1440–1460 $cm.^{-1}$, 1400 $cm.^{-1}$, and 1070–1120 $cm.^{-1}$ bands, it was possible to carry out a determination of the ester contents with an accuracy of $\pm 5\%$.

3. *Refractive index measurements.*—In this method the basic assumption is that there is a linear relationship between refractive index and copolymer composition. It is possible that the relationship is curved but this cannot be verified until an absolute method has been obtained for determining the polymer composition. In fact, *a priori*, if Newton's law for the refractive index of mixtures holds, a linear relationship between molar composition and refractive index would be expected. A linear relationship between refractive index and weight composition has, of course, been found for butadiene–styrene copolymers (9), and, as it is reasonable to assume that there would be no interaction between adjacent ketone and ester groups, the deviation from linearity for the MVK copolymers should be small. Further evidence that refractive index measurements are satisfactory for copolymer analysis comes from the

fact that copolymers of ethyl vinyl ketone and methyl *iso*propenyl ketone, which can be analyzed accurately by oximation, give linear composition – refractive index changes (1). Refractive indices were measured on a series of low conversion (*ca.* 10%) copolymers. The polymerizations were carried out at 70° C. using a 50% solution of monomers in benzene and 0.25% benzoyl peroxide as initiator. Films were cast on glass plates and, after being thoroughly dried (at 10^{-2} mm. at 60–70° C.), were pressed directly on the upper prism of an Abbé refractometer. Those polymers containing 60% or more of MVK were warmed in order to obtain optical contact with the prism. Measurements were carried out at 25° C. using white light. Typical results obtained are shown in the following table. The accuracy of measurement was about 2×10^{-4} unit for the higher acrylate content polymer, and 5×10^{-4} unit for those of high ketone content. The values for the two pure polymers were obtained from a number of measurements carried out on polymers prepared in bulk, in emulsion, and in solution. In the examination of several

TABLE

Sample	Mole fr. MVK (monomer)	η_{25}	$\Delta n \times 10^4$	Mole fr. MVK (polymer)

samples of polymethyl vinyl ketone it was observed that one, obtained from B.A.S.F. Germany, gave slightly yellow colored polymers possessing a higher refractive index than normal (η_{25} 1.5137). Attempts to prevent this discoloration by fractionation of the monomer were not successful, but it was observed that on keeping, a quantity of cross-linked "popcorn"-like polymer formed throughout the commercial product. MVK recovered from the partly polymerized mass then gave polymers of normal refractive index. The ultraviolet spectra of the colored polymers and copolymers showed them to possess considerably greater absorption over the range 250–400 mμ and no appreciable maximum (pure polymethyl vinyl ketone possesses a maximum at 280 mμ and negligible absorption above 330 mμ). The cause of the differences has not yet been elucidated but is most probably due to copolymerization of impurities possessing two or more double bonds; the impurities would be concentrated in the low conversion copolymers examined.

Oximation

Quantitative oximation by a modification of the method of Trozzolo and Lieber (14) has been found to give satisfactory results with polymethyl *iso*-

propenyl ketone and polyethyl vinyl ketone, while polyethyl *iso*propenyl ketone does not react at all. MVK copolymers react readily but the tendency for the solutions to darken renders the end point difficult to observe and electrometric titration was employed. The main disadvantage of the method is the danger that a small amount of hydrolysis or oxamidation of the ester groups may occur. (It has been established, however, that no such reactions occur with polybutyl acrylate (1).)

Results obtained by the different methods on three copolymers are listed below. It can be seen that notwithstanding the scatter they are of the same order.

		% Butyl acrylate

Reaction of Copolymers with Sulphur

A series of low conversion solution polymers and high conversion emulsion polymers were made with varying proportions of MVK. The polymers were carefully dried under vacuum and sulphur (4%) incorporated by milling or in solution. Samples (0.2–2.0 gm. depending on ketone content) were placed in a thermostat at 150° C. and a gentle stream of nitrogen passed through. The gases were passed through ammoniacal cadmium acetate for three hours. At the end of this period excess iodine was added and the sulphide determined volumetrically.

Similar measurements on the simple ketones were made normally using a molar ratio of ketone to sulphur of 10:1. The greater amounts of hydrogen sulphide precluded the use of cadmium acetate as absorbent because of the formation of dense precipitates of sulphide, not readily soluble in iodine. It was found better to absorb the hydrogen sulphide in alkali and to estimate the sulphur gravimetrically after oxidation to sulphate. (Iodometric estimation of sulphide was not possible, since traces of ketone carried over by the gas stream reacted with iodine in alkaline solution.) In a typical experiment using 0.155 gm. of sulphur in 5 ml. of cyclohexanone at 150° C. hydrogen sulphide was liberated steadily; in seven hours 25% of the sulphur was eliminated as hydrogen sulphide. At 130° C. and 100° C. the corresponding amounts were 3.6% and 0.3% respectively.

The authors thank Mr. W. H. T. Davison and Mr. C. E. Kendall for spectroscopic examination of the copolymers and Miss R. K. Smith who carried out much of the analytical work. This paper is published by permission of the Dunlop Rubber Company Limited.

NOTES

THE OCCURRENCE OF 4-*O*-METHYL-D-GLUCURONIC ACID IN LEMON GUM

By G. G. S. Dutton

The natural occurrence of 4-*O*-methyl-D-glucuronic acid was first reported in 1948 when it was found to be a component of mesquite gum (5, 6) and it is now known to occur elsewhere (3). Lemon gum has been shown (1) to contain L-arabinose, D-galactose, and a methoxyuronic acid. While this work was in progress there have appeared two papers concerned with the isolation of aldobiouronic acids from the gum. The first (4) reported the isolation of an aldobiouronic acid whose structure was thought to be 4-*O*-(D-glucuronosyl)-D-galactopyranose (I) on the basis of methylation studies. However, since the aldobiouronic acid contained an appreciable methoxyl content it is likely that the acid isolated was 4-*O*-(4[?]-*O*-methyl-D-glucuronosyl)-D-galactopyranose (II) which would give the same fragments as I on methylation and cleavage.

The second paper (2) reported the isolation from lemon gum of 4-*O*-(4-*O*-methyl-α-D-glucuronosyl)-L-arabinose. The nature of the uronic acid moiety was inferred from paper chromatographic analysis. The present work provides definite proof of the existence of 4-*O*-methyl-D-glucuronic acid in lemon gum.

Prolonged hydrolysis of lemon gum with hot sulphuric acid (0.2 *N*) removed arabinose units and afforded a degraded gum. Methanolysis (8% HCl) of the degraded lemon gum yielded a mixture of methyl glycosides from which methyl (methyl 4-*O*-methyl-D-glucopyranosid)uronate was isolated (5, 6). When this ester was treated with methanolic ammonia there was obtained a mixture of the α- and β-forms of methyl 4-*O*-methyl-D-glucopyranuronamide from which the α-form was readily obtained in a pure state by fractional crystallization. The amide of the α-anomer was characterized by comparison with an authentic specimen (5) and its identity further confirmed by conversion into 4-*O*-methyl-D-glucose from which the characteristic crystalline osazone was derived (5).

A preliminary examination of methylated lemon gum has shown the polysaccharide to have a highly branched structure in which the main chain is composed of D-galactose units. These results will be reported more fully at a later date.

EXPERIMENTAL

Lemon Gum

The gum was received from the late Dr. E. Anderson as small dark brown lumps and was used without purification except for the removal of bark by filtration of an aqueous solution. A sample of the purified gum after electrodialysis had $[\alpha]_D^{27}$ +21° and equiv. wt., 785.

Methyl (Methyl 4-O-Methyl-D-glucopyranosid)uronate

Following the procedure of White (6) lemon gum (100 gm.) was hydrolyzed with sulphuric acid (0.2 *N*) and the degraded polysaccharide isolated by precipitation with ethanol after dialysis to remove arabinose and acid. The precipitated polysaccharide was refluxed with methanolic hydrogen chloride (8%), neutralized (Ag_2CO_3), filtered, and the filtrate evaporated to a thick sirup. Extraction of the sirup with acetone and ether (6) and evaporation of the solvents yielded a viscous sirup which was distilled under high vacuum. There was thus obtained methyl (methyl 4-*O*-methyl-D-glucopyranosid)-uronate (2.4 gm.) as a viscous, slightly yellow oil, b.p. 165–185°C. (0.1 mm.). Anal. Calc. for $C_9H_{16}O_7$: MeO, 39.4%. Found: MeO, 37.2%.

Methyl 4-O-Methyl-α-D-glucopyranuronamide

Methyl (methyl 4-*O*-methyl-D-glucopyranosid)uronate (2.3 gm.) was dissolved in methanol (5 ml.), and methanol saturated with ammonia at 0°C. (25 ml.) added. After the solution was kept at 5°C. for 36 hr. evaporation of the solvent and excess ammonia yielded a white solid.

The mixture of amides was recrystallized from methanol and yielded methyl 4-*O*-methyl-α-D-glucopyranuronamide. The crystals were washed with a little cold ethanol which preferentially removed the more soluble β-anomer. The amide had m.p. and mixed m.p. 236–237°C. and $[\alpha]_D^{23}$ +147° (*c*, 0.8 in water) (5). Anal. Calc. for $C_8H_{15}O_6N$: C, 43.5; H, 6.9; N, 6.3%; equiv. wt., 224. Found: C, 43.4; H, 6.9; N, 6.9%; equiv. wt., 228.

Methyl (Methyl 4-O-Methyl-α-D-glucopyranosid)uronate

Following the procedure of Smith (5) the α-form of the amide (1.33 gm.) was hydrolyzed to the acid and esterified with diazomethane. Distillation yielded the ester as a viscous oil (1.0 gm.), b.p. 145–160°C. (0.05 mm.). Anal. Calc. for $C_9H_{16}O_7$: MeO, 39.4%. Found: MeO, 39.2%.

4-O-Methyl-D-glucose

Methyl (methyl 4-*O*-methyl-α-D-glucopyranosid)uronate (220 mgm.) was dissolved in dry tetrahydrofuran (10 ml.) and slowly added with stirring to a solution of lithium aluminum hydride (500 mgm.) in dry tetrahydrofuran (25 ml.). After 15 min. at room temperature the excess hydride was destroyed by the addition of ethyl acetate and the inorganic salts precipitated by the addition of water. The mixture was filtered and the residue washed with ether. The combined ethereal solutions were evaporated to yield methyl 4-*O*-methyl-α-D-glucopyranoside as a colorless non-reducing sirup (110 mgm.) having $[\alpha]_D^{23}$ +121° (*c*, 2.0 in water). Hydrolysis of the glycoside with sulphuric acid (5 ml., 1 *N*) on a steam bath for six hours (constant rotation) and removal of the acid by passage through a column of Duolite A4 resin gave on evaporation 4-*O*-methyl-D-glucose (64 mgm.) as a colorless, reducing sirup having $[\alpha]_D^{23}$ +82° (*c*, 1.3 in methanol).

The 4-*O*-methyl-D-glucose (64 mgm.) was heated in water (2.5 ml.) containing acetic acid (0.25 ml.) at 70–80° for two hours with phenylhydrazine (0.2 ml.) and a few crystals of sodium hydrogen sulphite. On cooling, the reaction

mixture was poured into water and the precipitate isolated by centrifugation. Recrystallization from 25% aqueous acetone yielded 4-*O*-methyl-D-glucosazone as yellow needles, m.p. and mixed m.p. 158–159°C. (5).

THE MASS ASSIGNMENT OF THE CHAIN 2 MIN. Sb → 77.7 HR. Te → 2.25 HR. I

BY W. H. FLEMING AND H. G. THODE

The 77-hr. tellurium activity and its daughter 2.4-hr. iodine were first observed in fission by Abelson (1). He also showed that the 77-hr. activity grew in from a precursor of about five minutes' half-life, which might be antimony or some earlier member of the decay chain, and that the daughter of the iodine activity was either stable or had a half-life greater than several months. Katcoff *et al.* (3) showed that the 77-hr. tellurium had a mass of 132 or less from fission fragment range studies. Since definite assignments had been made for all β-active tellurium isotopes lighter than 132, the 77-hr. activity and its iodine daughter were assigned to the 132 mass chain. More recently Pappas and Coryell (4, 5) have given a value of 77.7 hr. for the half-life of Te^{132} and assigned a 2.0-min. antimony activity to Sb^{132} on the basis of energetic considerations. Emery and Veall (2) have carried out a careful determination of the half-life of I^{132} and report $2.250 \pm .003$ hr.

During the course of a determination of the fission yields of Xe^{133} at this laboratory, fission product xenon was extracted from neutron irradiated uranium and plutonium before all of the 77.7-hr. tellurium activity had decayed. By a comparison of the relative abundances of Xe^{132} and Xe^{134} in these samples with that observed when the irradiated material is allowed to stand for a time long compared to 77.7 hr., the effective half-life of the precursors of Xe^{132} can be determined assuming that there are no long-lived members in the 134 mass chain.

If there is only one member in the 132 mass chain with a half-life comparable to the time of irradiation and cooling, the number of atoms of Xe^{132} present at the time of extraction is given by

$$[1] \qquad (Xe^{132})_{t_1} = R\left[T - \frac{(1-e^{-\lambda T})e^{-\lambda t_1}}{\lambda}\right]$$

where R is the production rate of the 132 mass chain

T is the time of irradiation

t_1 is the cooling time

λ is the disintegration constant of the long-lived chain member.

If the sample is allowed to cool for a time sufficiently long for all the precursors to decay, then

$$[2] \qquad (Xe^{132})_{\infty} = RT.$$

Thus from the mass spectrometer ratios of Xe^{132} to Xe^{134} measured for samples extracted after short and long cooling and from equations [1] and [2] the disintegration constant λ can be calculated from:

$$\frac{(Xe^{132}/Xe^{134})_{t_1}}{(Xe^{132}/Xe^{134})_{\infty}} = \frac{(Xe^{132})_{t_1}}{(Xe^{132})_{\infty}} = 1 - \frac{(1-e^{-\lambda T})e^{-\lambda t_1}}{\lambda T}.$$

The details of the five separate irradiations used to determine λ are given in Table I.

TABLE I

Sample	Irradiation time T (hr.)	Cooling time t_1 (hr.)	$\frac{(Xe^{132})_{t_1}}{(Xe^{132})_{\infty}}$	Disintegration constant λ (hr.$^{-1}$)
1	59.0	124.0	0.753	0.00918
2	60.0	147.8	0.814	0.00955
3	48.0	92.8	0.669	0.00954
4	48.0	166.0	0.804	0.00861
5	48.0	139.9	0.780	0.00927
Average	—	—	—	0.00923±.00034

Greater accuracy could have been obtained if the extraction of xenon had been carried out when less of the 77.7-hr. activity had decayed.

The half-life corresponding to the average value of λ is 75±3 hr. This mass spectrometric detection of a precursor of Xe^{132} having a half-life of about 75 hr. is direct confirmation of the assignment of the 77.7-hr. tellurium activity (and its daughter 2.25-hr. iodine) to the 132 mass chain.

VOLUME 34 APRIL 1956 NUMBER 4

THE NUMBER OF SUBUNITS IN THE MOLECULE OF HORSE HEMOGLOBIN[1]

BY M. E. REICHMANN[2] AND J. ROSS COLVIN

ABSTRACT

The molecular weights of horse hemoglobin, horse globin, and performic acid oxidized horse globin were determined by osmotic pressure, by an approach to equilibrium sedimentation, and by light scattering (except hemoglobin) at pH 1.5 to 2.5 in 0.05 *M* NaCl. Sedimentation coefficients were determined for these materials over the same pH range and electrophoretic analyses were made from pH 1.5 to 4.0. The results show that in dilute salt solutions below pH 2.5 horse hemoglobin dissociates to four subunits all approximately equal in mass but at least two of which differ electrokinetically and therefore in composition. The subunits are probably held together in the native hemoglobin molecule only by non-covalent bonds.

INTRODUCTION

The effect of changes in pH of the medium upon the size, shape, and dissociation of a number of proteins has contributed to knowledge of their structure (11). In particular, the properties of mammalian hemoglobins in dilute acid solutions (13), in surface films (14), in solutions of urea (34), and in concentrated salt solutions (15) have indicated that the molecules may split into halves or smaller subunits. These observations, coupled with the presence of four hemes per molecule, have led to the plausible conclusion that there are four subunits in each hemoglobin (17), but definitive evidence has been lacking. In addition, Porter and Sanger's (27) observation of six N-terminal valine residues in horse hemoglobin suggests that, in some species, the subunits may be further dissociated to individual polypeptides or that branching of one or two chains occurs. To test previous conclusions, and to distinguish between the above possibilities, the molecular weights of horse hemoglobin, horse globin, and performic acid oxidized horse globin have therefore been determined by light scattering, osmotic pressure, and Archibald's approach to equilibrium sedimentation (5), at higher hydrogen ion concentrations than reported hitherto. The results were supplemented by velocity sedimentation and electrophoretic analyses.

MATERIALS AND METHODS

Crystalline horse hemoglobin was prepared by the method of Heidelberger (19). The filter cake of twice recrystallized oxyhemoglobin was stored frozen until used. All the filter cake dissolved in water at 0°C. except a small fraction of white flocculent material which was removed by centrifugation before preparation of the globin. Two determinations of the sedimentation coefficient of the sample, $S_{w,20}$, in 0.05 *M* phosphate, pH 6.8, at concentrations of 0.25% and 0.50%, gave 4.40×10^{-13} and 4.54×10^{-13} respectively. These values are in agreement with previous results (37). An electrophoretic analysis of a 0.2% solution of the hemoglobin in 0.05 *M* phosphate at pH 6.8, time 141 min., gave a single, slowly migrating peak for both ascending and descending boundaries. The molecular weight of the hemoglobin by osmotic pressure in 0.1 *M* NaCl, pH 7.0, was 65,000.

Globin was prepared by Anson and Mirsky's method (4) as modified from Jope, Jope, and O'Brien (22). Crystalline horse oxyhemoglobin was dissolved in ice water to give a 5% solution and the supernatant poured, with rapid stirring, into 10 times its volume of 0.7% HCl–acetone at −15°C. The precipitate was removed by filtration at −15°C. and most of the heme washed out at that temperature by HCl–acetone, followed by chilled acetone. The precipitate was redissolved in ice water, reprecipitated and washed again, as above, three times. After the final washing with acetone, the precipitate was dissolved in ice water, filtered through coarse filter paper, and freeze dried. The product, which was always a light tan in color, was initially soluble in water and 0.05 *M* NaCl but reprecipitated quickly if the pH was between 4.0 and 10.0. Outside this range, solutions of globin, 1% or lower in concentration, were stable indefinitely in 0.05 *M* NaCl. Increasing the salt concentration decreased solubility at all pH values. Native horse globin, in the sense that all the product was soluble indefinitely close to neutrality, was not obtained, in agreement with previous observations of the particular instability of horse globin (31).

A modification of Sanger's method (33) was used to oxidize any disulphide bridges in globin and thus promote separation of the polypeptide chains. Each gram of unoxidized globin was dissolved in 36 ml. of 90% formic acid to which 6 ml. of 30% H_2O_2 had been added one hour before. The mixture was allowed to stand at room temperature for 25 min. (one sample was over-oxidized by extending the time to 60 min.) and then poured into 10 times its volume of 0.7% HCl–acetone at −15°C. The precipitate was removed by rapid centrifugation at room temperature, immediately dissolved in water, and dialyzed against water for 48 hr. at 5°C., with frequent changes of the external solution. The resulting optically clear solution was then centrifuged and freeze dried. The solubility properties of the white product were similar to those of unoxidized globin except that the oxidized material was initially more readily soluble in water or dilute buffer solutions but also reprecipitated more quickly. Control experiments established that less than 2% of the initial nitrogen was lost during oxidation of the globin.

Only valine was detected as an N-terminal amino acid residue in both the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

unoxidized and oxidized globin by the DNFB technique (26). Since Porter and Sanger had previously found only valine as an N-terminal residue in horse hemoglobin (27) this observation is evidence that no appreciable degradation of the polypeptide chains occurred during the oxidation procedure. Other investigations have also shown that the peptide bond is resistant to attack by performic acid (3).

Both unoxidized and oxidized samples of globin were prepared for examination by dissolving the sample in water or the appropriate buffer, followed by dialysis against 10 times the volume of the buffer changed frequently.

All buffers were prepared from reagent grade materials by Clark's procedure (9) and checked frequently against commercial standards with a Beckman Model G pH meter. Where necessary, the pH of solutions of sodium chloride was adjusted by the addition of small amounts of HCl.

Crystallized bovine plasma albumin and crystallized bovine pancreas ribonuclease were used as purchased from Armour and Company, Chicago.

The techniques of molecular weight determination by light scattering were as previously described by one of us (28). All measurements were made at a wavelength of 4360Å. A monochromatic filter was also inserted in the phototube mouthpiece to eliminate fluorescent light. The refractive index increment, dn/dc, of unoxidized globin was measured in the Brice and Speiser differential refractometer (7) and found to be 0.200 ± 0.003 in 0.2 M NaCl, pH 2.5. With this value of dn/dc, K (28) had the value of 6.46×10^{-7}. The same figure was used for oxidized globin.

Osmotic pressures were determined by the equilibrium method. The osmometers as well as the technique used were as previously described (29). Determinations of the molecular weight of bovine plasma albumin in 0.1 M NaCl, pH 6.5, gave 68,000 in agreement with previously reported results (16). Prior adjustment of the osmotic pressure to close to the estimated final equilibrium value, which was then maintained for 12 hr. or more, showed the membranes to be impermeable to any component of the globin or hemoglobin preparations. The same technique showed that the membranes were readily permeable to ribonuclease, molecular weight 13,000.

Sedimentation coefficients were determined in a Spinco Model E ultracentrifuge at 250,000 g using a plastic cell to contain the more acid solutions. Boundary displacements were read directly from the photographic plates by a microcomparator accurate to ± 0.001 mm., but this overestimates the precision since rapid diffusion of the peak made the exact position of the mode uncertain. In calculating $S_{w,20}$, a 1° correction for adiabatic cooling of the rotor (6, 36) was applied as well as the usual adjustments for temperature and viscosity of the buffer (2). Three determinations of the $S_{w,20}$ of bovine plasma albumin in 0.05 M phosphate buffer, 0.2 M NaCl, pH 6.6, at concentrations 0.33%, 0.50%, and 1.0% gave the values 4.10, 4.08, and 3.91×10^{-13} respectively in agreement with previous results (24).

Molecular weights were determined by an approach to equilibrium sedimentation using Archibald's method (5) as recently applied by Brown, Kritchevsky, and Davies (8). All measurements were made at a rotor speed of 12,590 r.p.m.

The molecular weight of globin was calculated from the extrapolated values of $(1/rc)(dc/dr) = \delta = M\omega^2(1-V\rho)/RT$ (M = weight average molecular weight, ω = angular velocity, V = partial specific volume of protein, ρ = density of solution, R = gas constant, and T is the temperature) using the partial specific volume, 0.749, as reported for hemoglobin (37).

Concentrations of protein were estimated by micro-Kjeldahl, using Tristram's value for the nitrogen content of hemoglobin (35). The error in the nitrogen determination was less than 1% of the total nitrogen present.

Electrophoretic analysis was conducted in a constant current Tiselius apparatus as modified by Longsworth (23). Mobilities of the peaks were calculated by standard methods (1) from the migration distances of the descending boundary read directly from the plates. All peaks could usually be recognized on both ascending and descending boundaries, although, as usual, resolution was better on the ascending side.

RESULTS

Molecular Weight of Unoxidized and Oxidized Globin by Light Scattering

Preliminary investigation showed that above pH 2.5, aggregation of unoxidized and oxidized globin was considerable. Even at pH 2.5, in 0.2 M NaCl the negative second virial coefficient of the plot of Kc/R_{90} against concentration for unoxidized globin showed that interparticle attractive forces are greater than the Coulomb repulsion (Fig. 1). The apparent molecular weight under these conditions was 39,000. In 0.05 M NaCl at pH 2.65 for the same material the coefficient is slightly positive and the apparent molecular weight was 37,000 (Fig. 1). Fig. 2 shows corresponding data for unoxidized globin at pH 1.5 and 2.0 in 0.05 M sodium chloride. Taking the widest reasonable range of estimates of the intercepts, the molecular weight remains at about 21,000–23,000. Net interactions are not large as shown by the small second virial coefficient. Light scattering data for the oxidized globin in 0.05 M NaCl at pH 2.5 and 2.0 are shown in Fig. 3. At pH 2.5 the weight average molecular weight of the oxidized globin, 41,000, is approximately equal to that of the unoxidized material. However, contrary to the results for unoxidized globin, no further decrease in molecular weight was apparent at pH 2.0.

Molecular Weight of Hemoglobin, and of Unoxidized and Oxidized Globin by Osmotic Pressure

Osmotic pressure data for hemoglobin and oxidized globin at pH 1.8, and for unoxidized globin at pH 2.0, in 0.05 M NaCl are given in Fig. 4. The number average molecular weight of hemoglobin from the extrapolated value of P/cRT was $20{,}000 \pm 1000$, of oxidized globin about 21,000, and of unoxidized globin $16{,}000 \pm 1000$.

Velocity Sedimentation

Above pH 2.5 or in salt solutions above 0.05 M the sedimenting boundaries of solutions of unoxidized and oxidized globin became skew or separated into

poorly resolved peaks (Fig. 5). These features disappeared progressively upon decreasing the pH or salt concentration, thereby eliminating the possibility that they were evidence for stable components. At or below about pH

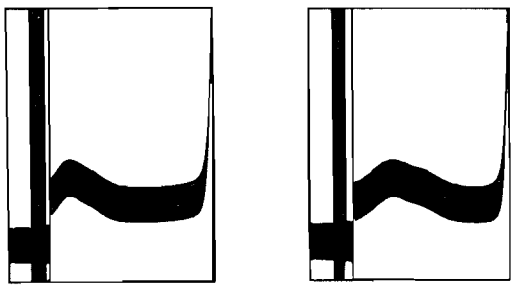

FIG. 6. Photographs of refractive index gradient distributions of unoxidized globin in 0.05 *M* sodium chloride.

2.5, the sedimenting peak for unoxidized globin was single, broad, and less asymmetric (Fig. 6) and the sedimentation coefficient was constant within experimental error (Table I). Its value is approximately one half that given by Gralén for the same material at pH 4.0 (13).

Table II gives the sedimentation coefficient of unoxidized globin in 0.05 *M* NaCl, pH 2.5, as a function of concentration. Clearly the coefficient is not a marked function of concentration under these conditions.

Tables III and IV give the results of a determination of the sedimentation coefficient of oxidized globin as a function of pH and concentration respectively. Table IV also gives the same data for a sample of overoxidized globin.

Typical patterns are shown in Fig. 7. The sedimentation coefficient of oxidized globin is not a strong function of either pH or concentration but the coefficient of the overoxidized sample is nearly double that of the less drastically treated one.

To assess the effect of removal of the heme groups on the sedimentation coefficient, the $S_{w,20}$ of hemoglobin was determined as a function of concentration at pH 2.5 in 0.05 *M* NaCl and in 0.2 *M* NaCl. Results are given in Table V.

TABLE V

THE SEDIMENTATION COEFFICIENT OF HORSE HEMOGLOBIN AT pH 2.5 IN 0.05 *M* NaCl AND 0.2 *M* NaCl AS A FUNCTION OF CONCENTRATION

0.05 *M*		0.20 *M*	
Conc., %	$S_{w,20}$	Conc., %	$S_{w,20}$
0.1	1.64×10^{-13}	0.1	3.26×10^{-13}
0.2	1.65	0.2	3.35
0.3	1.95	0.3	2.84

At pH 2.5 in 0.05 *M* NaCl the coefficient for hemoglobin is higher than for unoxidized globin but is comparable to that for oxidized globin (Table IV). Increasing the sodium chloride concentration to 0.2 *M* doubled the coefficient for hemoglobin.

This increase in sedimentation coefficient with increasing salt concentration may be attributed to either reassociation of subunits *or* a decrease in the electrostatic repulsion of subunits, without association. To distinguish between these possibilities, the sedimentation coefficient of ribonuclease was determined as a function of concentration in 0.05 *M* NaCl, pH 2.5. Ribonuclease was chosen because it has an isoelectric point close to that of hemoglobin (32), a molecular weight comparable with that of the suspected subunit of hemoglobin (10, 11), and is known to consist of one polypeptide chain (3). Results are given in Table VI. The mean value 1.85×10^{-13} at pH 2.5 is

mentation coefficient of hemoglobin and globin may be neglected, even under these rather drastic conditions and that the increasing sedimentation coefficient reflects increasing aggregation.

Equilibrium Sedimentation

The results of applying Archibald's procedure (5), for estimating equilibrium ultracentrifuge molecular weights, to unoxidized globin in 0.05 *M* NaCl, pH 2.0, are summarized in Fig. 8. The estimated values of δ are equal at the base and at the meniscus of the cell and correspond to a molecular weight of 22,000. Hemoglobin under the same conditions was polydisperse with an apparent molecular weight of about 23,000 at the meniscus and 50,000 at the base.

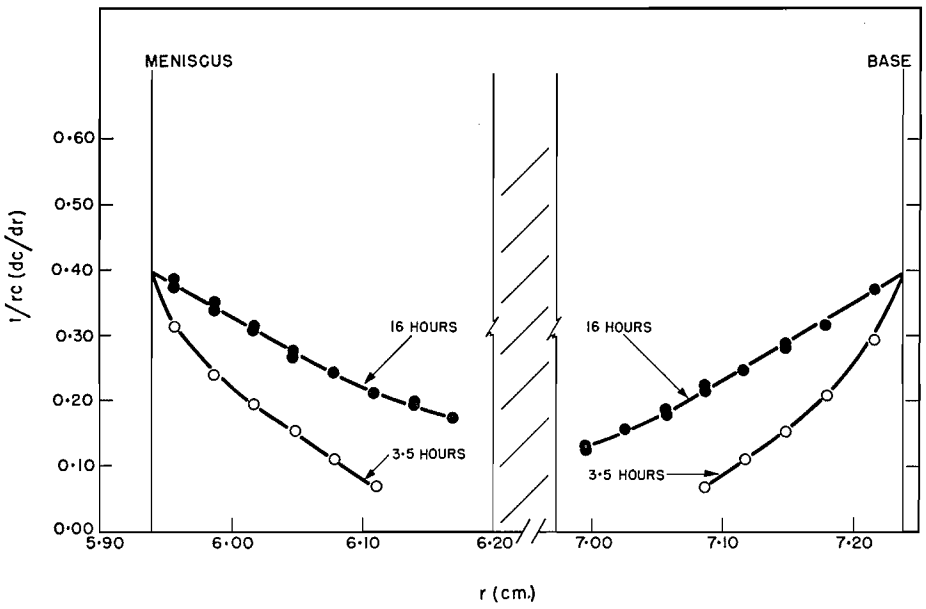

FIG. 8. Archibald's approach to equilibrium sedimentation for unoxidized globin in 0.05 *M* sodium chloride, pH 2.0.

Electrophoresis

Unoxidized and oxidized globin showed similar complex behavior when examined electrophoretically from pH 4.0 to pH 1.5 in dilute buffer or salt solutions. Resolution of the apparent components was better in the unoxidized material, however, presumably because of a decrease in the isoelectric point of the oxidized globin imposed by newly introduced negative groups. Increasing the salt concentration from 0.05 *M* to 0.2 *M* NaCl decreased resolution of some peaks in the pattern or eliminated them completely. At pH 4.0 in 0.05 acetate and 0.05 *M* NaCl, one large peak was observed, accompanied by a slower, smaller component (Fig. 9). In some experiments, this slower peak could not be resolved and only one peak was apparent, particularly at higher salt con-

centrations. As the pH decreased to 3.7 the apparent proportion of this slower component increased until the concentration of both components was approximately equal. These were presumed to be the two components previously observed in the hemoglobin of other species (18, 25, 30) at high hydrogen ion concentrations. A further decrease in pH was attended by separation of a third, faster component until at pH 2.5 the apparent concentrations of all three were approximately equal. Finally between pH 2.0 and 1.5, one component disappeared leaving only two well-defined peaks. Similar variation of components with pH was shown by the untreated horse hemoglobin. Approximate estimates of the mobilities of the three components of unoxidized globin in the descending boundary are given in Fig. 10 as a function of pH. Within experimental error the mobility of the intermediate peak remains constant from pH 1.5 to 4.0 while that of the slowest goes through a maximum at about pH 3.0. The mobility of the fastest peak apparently decreases from pH 3.0 where it is first evident to pH 2.0 below which it either disappears or incorporates all of the material of intermediate mobility.

DISCUSSION

The foregoing data from light scattering, osmotic pressure, and sedimentation velocity show that a net effect of oxidation of globin by performic acid is to *increase* the molecular weight of the material, at a given pH level, rather than decrease it, as would be expected if covalent bonds were being broken. The increase therefore implies that disulphide bonds do not link polypeptide chains in horse hemoglobin, in agreement with conclusions from sulphydryl determinations (21). The higher molecular weight may be attributed to reassociation of the subunits of hemoglobin, following reduction of their isoelectric points by the additional sulphonic acid groups. Since horse hemoglobin contains a negligible percentage of phosphorus (18, 38) it is therefore probable that the polypeptide chains are held together in the molecule only by secondary bonds or by mechanical entanglement.

The difference between the number average molecular weight and the weight average value for unoxidized globin in 0.05 *M* NaCl at pH 1.8–2.0, together with the ill-defined peaks and rapid spreading of the sedimenting boundary in the ultracentrifuge at higher pH levels, shows that the solutions are polydisperse. This heterogeneity must reflect an association of subunits of approximately equal size rather than a collection of independent particles of different molecular weights because (*a*) sedimentation velocity boundaries increase in symmetry as the pH decreases, (*b*) only the assumption of dissociation products of equal size is compatible simultaneously with the observed

molecular weights and the observation that the products do not pass a membrane which is readily permeable to ribonuclease. At pH 2.0 in 0.05 *M* NaCl however, the equilibrium point is far toward the side of dissociation as shown by the lack of effect of concentration change on $S_{w,20}$. For this reason, the observed number average molecular weight at pH 2.0, 16,000–17,000, will be a good approximation to the molecular weight of the dissociation products and indicates that the total number of dissociable subunits in the hemoglobin molecule under these conditions is four. A smaller number cannot account for the observed osmotic pressures and a larger number is incompatible with the retention of all the dissociation products by the membrane. The conclusion of four subunits of equal size in hemoglobin is likewise consistent with the approximately fourfold reduction in sedimentation coefficient of hemoglobin at pH 7.0 to that of globin at pH 2.0. These results therefore directly confirm previous inferences.* No evidence for further dissociation was found, even at pH 1.5. Consequently, unless two polypeptide chains are so closely intertwined as to prevent separation under these drastic conditions, Porter and Sanger's observation of six N-terminal amino acid residues in horse hemoglobin suggests that branching occurs in at least two of the polypeptide chains which comprise the subunits.

The equilibrium in the association between these subunits is not established instantaneously, as shown by the presence of transient and poorly resolved peaks in velocity sedimentation. It is complete, however, in 3.5 hr. at pH 2.0 as shown by the equality of δ for unoxidized globin at the base and the meniscus of the cell in the approach to equilibrium ultracentrifugation. Field and O'Brien have recently shown that the dissociation to half molecules is rapid in acid solution for human hemoglobin (12), in which the extent of splitting is much less than for horse hemoglobin (37). Consequently, these observations suggest that the dissociation of the horse hemoglobin molecule in acid solution takes place in two distinct stages under the influence of Coulomb repulsion; first a rapid, reversible dissociation to half molecules followed by a slower, not completely reversible separation of the components of the half molecules. This latter is probably the process to which the term denaturation has been applied (12).

As shown by velocity sedimentation, equilibrium sedimentation, and osmotic pressure experiments, heme tends to stabilize the association of the subunits of globin, even at pH levels far below 3.9, at which point the porphyrin ring begins to split from the protein (20).

The electrophoretic analyses show that the two half molecules of horse hemoglobin differ electrokinetically and also provide additional qualitative evidence for further splitting of half molecules into distinct subunits. No exact definitive interpretation of the patterns can be given but they are consistent with the assumption that at pH 4.0–3.7, the hemoglobin splits predominantly into half molecules of different mobilities. As the pH decreases,

**Gutter and Peterson have also very recently found indirect evidence for four subunits in horse hemoglobin from studies on the effect of mercaptoethanol and urea on the sedimentation rate, as reported at the American Chemical Society Meeting, Sept. 13, 1955, Minneapolis, Minn.*

an increasing proportion of both these half molecules dissociate to subunits. Of these four subunits, at least two must differ electrokinetically. If a larger number differ, they may reassociate to form new complexes of intermediate mobility. Such complexes would be an adequate explanation for the discordant observations reported on similar preparations of hemoglobins from other species (25, 30). Finally, at very low pH's (i.e. below 2.0), Coulomb repulsion is so strong between subunits that complex formation is repressed and the apparent number of components decreases.

One over-all conclusion from these experiments must be stressed. The tendency to association between the different subunits of the hemoglobin molecule is surprisingly strong, in spite of the absence of any covalent bonds and in opposition to Coulomb repulsion. This must confer a stability to the general configuration of the hemoglobin molecule, which may play a role in its physiological function.

ACKNOWLEDGMENTS

The authors would like to thank their colleagues Drs. P. A. Charlwood and D. B. Smith for advice and criticism of the work at all stages. They are also indebted to Dr. W. H. Cook, Director, Division of Applied Biology and to Professor P. Doty of Harvard University for reading and criticizing the manuscript.

SOME XANTHATE METHYL ESTERS OF GLUCOSE[1]

By Amiya K. Sanyal[2] and C. B. Purves

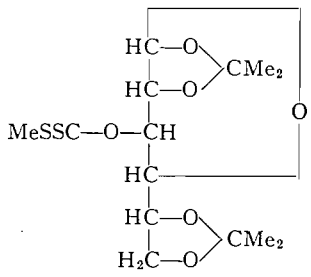
ABSTRACT

The following compounds were thought to be new: 1,2-mono-*O*-isopropylidene-D-glucofuranose-3-*S*-methyl xanthate, m.p. 102°, $[\alpha]_D^{24}$ −27.8°; methyl-4,6-*O*-benzylidene-α-D-glucopyranoside-2,3-di-*S*-methyl xanthate, m.p. 100°, $[\alpha]_D^{22}$ −18.1°; and 1,2;3,5-di-*O*-methylene-α-D-glucofuranose-6-*S*-methyl xanthate, m.p. 99°, $[\alpha]_D^{21}$ +27.3° in chloroform. Partial hydrolysis of the isopropylidene and methylene derivatives yielded some glucose-3-*S*-methyl xanthate and glucose-6-*S*-methyl xanthate as crude sirups. The 6-xanthate greatly excelled the 3-xanthate in stability toward acid. The chromatographic behavior of both was determined.

INTRODUCTION

Although xanthate salts are very readily decomposed by acid, a recent research (20) confirmed the claim that the *S*-methyl xanthate esters of simple alcohols are often remarkably stable in acidic conditions. The location of the substituents in cellulose sodium xanthates (viscose) might therefore be determined by conversion to the *S*-methyl esters, hydrolysis to the corresponding glucose derivatives, and identification of the latter. In order to explore this possibility, attempts have now been made to prepare some of the relevant glucose-*S*-methyl xanthates, to determine their stability toward acids and their behavior in chromatography.

In 1927 Freudenberg and Wolf (4) shook 3-sodio-1,2;4,5-di-*O*-isopropylidene glucofuranose first with carbon disulphide to form the 3-xanthate salt, and then with methyl iodide to obtain the crystalline 3-*S*-methyl ester (I). They



I

III

apparently did not succeed in selectively hydrolyzing the isopropylidene groups and therefore recovered neither glucose-3-*S*-methyl xanthate nor its monoisopropylidene derivative. A repetition of this work showed that the yield of I could be increased from 52% to nearly 90% of theory, based on the

diisopropylidene glucose that reacted. The substance (I) was then submitted to acetolysis in an attempt to replace the isopropylidene by acetyl groups, as Hann, Hudson, and their numerous collaborators succeeded in doing with similar cyclic acetals (6, 13, 22). Although analyses suggested that some of the isopropylidene had indeed been replaced by acetyl groups, the impure product failed to crystallize, and eventually the method was abandoned. The diisopropylidene methyl xanthate was then hydrolyzed with concentrated nitric acid in ethyl acetate as described by Coles, Goodhue, and Hixon (2) for the removal of the 5,6-isopropylidene group from 1,2;5,6-di-*O*-isopropylidene glucofuranose, but some xanthate groups were lost and the product was an impure sirup. The realization that this xanthate ester was not nearly so resistant toward acidic reagents as those studied by Vincent (20) led to an attempt to prepare a more stable derivative by oxidizing I with 30% aqueous hydrogen peroxide in glacial acetic acid. Unlike Vincent's experience with octadecyl-*S*-methyl xanthate, this oxidation failed to yield a stable crystalline derivative retaining all of the original sulphur, but produced extensive decomposition. Details of these and other negative experiments have been omitted from this account.

Freudenberg, Dürr, and Hochstetter (3) found that boiling methanolic hydrogen chloride removed the isopropylidene group in the 5,6-position of diisopropylidene glucose 40 times more rapidly than the one in the 1,2-position. By restricting the action of a 0.15% hydrogen chloride solution to eight minutes, it was found possible to prepare a pure, crystalline mono-*O*-isopropylidene glucose-3-*S*-methyl xanthate from the diisopropylidene derivative in about 35% yield, 30% of the starting material being recovered unchanged. When chromatographed on paper, using *n*-butanol saturated with water as the solvent and ammoniacal silver nitrate as the spray, the mono- and diisopropylidene methyl xanthates had R_f values of 0.92 and 0.97, respectively. The former compound produced a yellow spot with the spray immediately, but the latter developed a dark gray spot only after the paper had been heated at 100° for a few minutes. The two compounds could therefore be distinguished readily.

In order to study the hydrolysis of the monoisopropylidene methyl xanthate, a 2% solution in 0.05 *N* aqueous hydrochloric acid was boiled under reflux and the change in optical rotation was observed at intervals. After 105 min. the xanthate group was obviously decomposing but the specific rotation of 22.5° was not far from the value of 13° roughly estimated for glucose-3-*S*-methyl xanthate from the molecular rotations of its monoisopropylidene derivative, of 1,2-*O*-isopropylidene glucose, and of glucose, in water or alcohol. The crude product when chromatographed yielded faint spots corresponding to glucose (R_f 0.20), to the isopropylidene methyl xanthate (R_f 0.92), and to an unknown substance. The major spot, with R_f 0.65, was attributed to the desired glucose-3-*S*-methyl xanthate. This compound partly decomposed when an attempt was made to free it from the associated glucose by a fermentation with yeast (16). A product whose purity was estimated from its sulphur content to be about 90% resulted when monoisopropylidene glucose methyl xanthate was boiled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

for two hours in 50% methanol containing 1% of sulphuric acid, which was then neutralized with barium carbonate. Some of the starting material, 54%, was recovered unchanged, and the crude glucose-3-*S*-methyl xanthate was isolated by evaporating the frozen aqueous liquor. The most satisfactory method of preparing glucose-3-*S*-methyl xanthate proved to be the partial hydrolysis of the more accessible diisopropylidene compound (I) in hot 80% acetic acid, which was used by Ness, Hann, and Hudson (12) in a similar case. Although 55% of the monoisopropylidene derivative was recovered, it was easy to eliminate the acetic acid and to purify the glucose-3-*S*-methyl xanthate by chromatography on a cellulose column. The product gave only a single spot of R_f 0.65 when chromatographed on paper, but nevertheless persisted as an uncrystallized, light yellow oil containing somewhat less than the calculated amount of sulphur.

The xanthation of methyl-4,6-*O*-benzylidene-α-D-glucoside was next undertaken. Although attempts to prepare the intermediate 2,3-di-sodio derivative with sodium in liquid ammonia according to Muskat (11) were not successful, the derivative apparently formed in high yield when a solution of the benzylidene compound in dioxane was mixed with a colloidal suspension of sodium in toluene. The subsequent addition of carbon disulphide to the suspension, followed still later by the addition of methyl iodide, produced crude, crystalline methyl 4,6-*O*-benzylidene-α-D-glucopyranoside-2,3-di-*S*-methyl xanthate (II) in about 70% yield. All attempts to remove the benzylidene group, or the benzylidene and methyl glucosidic groups, selectively led to yellow, evil-smelling oils containing less sulphur than the amounts expected for glucose-2,3-di-*S*-methyl xanthate or for the corresponding methyl glucoside. No single substance could be detected in these oils by the chromatographic methods used, and the attempt to prepare glucose-2,3-di-*S*-methyl xanthate was abandoned owing to the instability of the xanthate ester groups.

The most suitable compound from which to attempt a synthesis of glucose-6-*S*-methyl xanthate appeared to be the di-*O*-methylene glucose-6-acetate synthesized by Hough, Jones, and Magson (7), which was characterized as the 1,2;3,5-di-*O*-acetal by Schmidt, Distelmaier, and Reinhard (17) and later by Shyluk, Honeyman, and Timell (18). The replacement of the *O*-acetyl group by a sodium atom proceeded smoothly in alcoholic sodium hydroxide, and subsequent treatments with carbon disulphide and with methyl iodide produced the new, crystalline 1,2;3,5-di-*O*-methylene glucofuranose-6-*S*-methyl xanthate (III) in 84% yield. This compound was difficult to hydrolyze and the methylene and xanthate ester groups appeared to be removed at roughly the same rate. The most economic procedure found for the preparation of glucose-6-*S*-methyl xanthate was to boil a solution of the dimethylene derivative in 6% aqueous-alcoholic sulphuric acid for about three hours; about 80% of the starting material was recovered and recycled, and the hydrolyzates were accumulated. When these hydrolyzates were chromatographed on a cellulose column, a substance was isolated which had a single R_f value of 0.84 in the system used, and a sulphur content close to that required by glucose-6-*S*-methyl xanthate (S, 23.7%). All attempts to crystallize the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

product, or its tetraacetate, failed. In addition to glucose (R_f 0.13) the hydrolyzate contained a minor amount of a sirup containing 9.2% of sulphur and with an R_f value of 0.70. This sirup was presumably a decomposition product of the methyl xanthate, because the product from a similar hydrolysis prolonged for 68 hr., when chromatographed on paper, yielded the spot expected for glucose, and others with R_f values of 0.30, 0.56, and 0.70, the one at R_f 0.84 being absent.

Ness, Hann, and Hudson (13) showed that acetolysis replaced the methylene acetal rings in a trimethylene mannitol with acetyl and acetoxymethyl groups, while Lieser and Leckzyck (10) found that acetolysis at 0° did not affect a xanthate group. By combining the techniques used in these researches, it proved possible to cleave di-*O*-methylene-glucose-6-acetate to a presumed tri-*O*-acetyl-di-*O*-acetoxymethyl derivative and to deacetylate the latter to glucose. A repetition of the work with the xanthate ester (III) produced a sirup with the composition of a diacetyl diacetoxymethyl glucose methyl xanthate, but attempts to deacylate this substance, even with very mild conditions, resulted in some dexanthation. According to a paper chromatogram, the product contained a little glucose, much of the 6-*S*-methyl xanthate of R_f 0.84, and a little of the related substance of R_f 0.70.

The *S*-methyl xanthates (I), (II), and (III) were also hydrolyzed with cold concentrated hydrochloric acid in conditions suitable for the complete hydrolysis of a cellulose-*S*-methyl xanthate to the corresponding glucose derivatives. As expected, the 3-*S*-methyl xanthate group in (I) was completely removed and nothing but glucose was detected in the product; no substance was recognized in the hydrolyzate of the 2,3-di-*S*-methyl xanthate (II), but the 6-*S*-methyl xanthate (III) yielded 70% of a sirup containing glucose, glucose-6-*S*-methyl xanthate (R_f 0.84), and the derived substance of R_f 0.70. These experiments confirmed the observation that an *S*-methyl xanthate group located in the sixth position of glucose was much more stable toward acid than were those in the second and third positions.

EXPERIMENTAL

Analytical

Sulphur was determined according to Waters (21) by oxidizing 0.05 to 0.1 gm. samples with bromine – nitric acid and estimating the resulting sulphuric acid as the barium salt. Microdeterminations on 1–5 mgm. samples containing 10–20% sulphur were fairly accurate when the Grote combustion to sulphur dioxide was used, as described by Sundberg and Royer (19). The dioxide was oxidized by 3% aqueous hydrogen peroxide to sulphuric acid, which was increased in amount by the addition of exactly 10 ml. of 0.01 *N* acid before being titrated to exactly pH 5.5 with 0.004 *N* sodium hydroxide. The determination of acetyl groups by saponification (9) was inaccurate in presence of *S*-methyl xanthates, but Clark's saponification followed by steam-distillation (1) gave good results. The almost complete failure of the *S*-methyl xanthate group to yield methyl iodide (20) in a customary determination of alkoxyl groups (15) was confirmed.

Techniques used in paper chromatography were based on the description given by Partridge (14), butanol saturated with water being the solvent and ammoniacal silver nitrate usually being the spray.

*1,2;5,6-Di-O-isopropylidene-*D*-glucofuranose-3-S-methyl Xanthate* (*I*)

The 1,2;5,6-di-*O*-isopropylidene glucofuranose was prepared from glucose, acetone, anhydrous zinc chloride, and phosphoric acid as described by Glen, Myers, and Grant (5). After several recrystallizations, the melting point and specific rotation in water attained the correct values of 112–113° and $[\alpha]_D^{20}$ −18.8° (*c*, 2.04), respectively.

An excess of sodium in the form of thin plates was added in nine installments during 24 hr. to a solution of 50 gm. of diisopropylidene glucose in 200 ml. of dry ether kept under reflux on a steam bath. The ether solution was decanted and the residual sodium was washed three times with ether. The solution and washings containing the sodio-derivative were combined, cooled, mixed with 50 ml. of carbon disulphide, and kept at room temperature for 12 hr. The ether layer containing any unchanged diacetone glucose was then decanted, and the residual semisolid, cream-colored mass of crude xanthate salt was mixed with 15 ml. of pure methyl iodide. After being vigorously shaken at intervals during an hour to disintegrate the mass, the suspension was kept near 20° for six hours and was then filtered. The combined filtrate and washings were evaporated under nitrogen, and the solid residue was distilled at 150–160° and 0.6–0.7 mm. pressure. When a solution of the yellow distillate in ether was allowed to evaporate slowly, 61 gm. of crystals melting at 57–60° separated. This yield of the *S*-methyl xanthate amounted to 90% of theory, instead of 52% as reported by Freudenberg and Wolf (4). After recrystallization from petroleum ether the substance had the correct sulphur content, melted at 58–60°, and had a specific levo rotation of $[\alpha]_D^{22}$ −15.5° in chloroform (*c*, 2.00). The recorded values (4) were m.p. 61° and $[\alpha]_{5460}^{16}$ −14.6° in acetylene tetrachloride.

One gram of the crystalline methyl xanthate dissolved within five minutes when shaken at room temperature with 50 ml. of 37% hydrochloric acid. After six hours, when the solution had become dark red and developed an unpleasant odor, an equal volume of water was added. Six days later, and after further dilution with water, the acid was neutralized with basic lead carbonate and evaporated to dryness under diminished pressure. Extraction of the residue with five 25 ml. volumes of ethanol removed 0.5 gm. of a red sirup, which when chromatographed on paper gave a single spot corresponding to glucose.

*Mono-O-isopropylidene-*D*-glucofuranose-3-S-methyl Xanthate*

(*a*) A solution of 135 gm. of the diisopropylidene derivative in 140 ml. of absolute methanol containing 0.15% of anhydrous hydrogen chloride was heated under reflux for eight minutes. The solution was cooled, neutralized with basic lead carbonate, and filtered, lead being later removed as the sulphide from the filtrate. After being evaporated near 20° and under reduced pressure, the clear liquor left a residue which partly crystallized within two days. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

residue was dissolved in hot ligroin (b.p. 80–110°) and the solution on cooling deposited 46 gm. (38.5%) of the product, m.p. 94–98°. Approximately 45 gm. (30%) of the unchanged diisopropylidene methyl xanthate was recovered from the mother liquor. A 3.3 gm. sample of the mono derivative when thrice recrystallized from 200 to 300 ml. of hot ligroin yielded 2 gm. of pure material melting at 101–102.5°. The specific levorotation was $[\alpha]_D^{24}$ −27.8° in chloroform (*c*, 2.00). Found: C, 42.5, 42.5; H, 5.9, 6.0; S, 20.7, 21.0%. Calc. for $C_{11}H_{18}O_6S_2$: C, 42.6; H, 5.8; S, 20.6%.

When a similar methanolysis of the diisopropylidene derivative was continued for about one hour, a 60–70% yield by weight was obtained of a white, evil-smelling, amorphous material which became liquid and discolored when exposed to the air. The substance was insoluble in ether but soluble in methanol. Found: S, 20.1; OCH_3, 2.8, 2.2%. The low value for apparent methoxyl made the formation of any methyl glycoside very doubtful.

Some of the crystalline monoisopropylidene glucose-*S*-methyl xanthate, 0.5 gm., was dissolved in 25 ml. of 0.05 *N* hydrochloric acid in aqueous ethanol (1 vol.: 1 vol.). Since the optical rotation as observed in a 2 dm. tube did not change within 12 hr. at room temperature, the solution was heated under reflux on a steam bath. After 0, 15, 30, 60, 75, and 105 min. the observed rotations corresponded to specific rotations of −27.5°, −12.5°, −3.8°, +5.0°, +7.5°, and +22.5°. The xanthate ester group was then decomposing, to judge from the odor and turbidity of the solution. The removal of hydrochloric acid from this solution by silver carbonate caused immediate blackening even at room temperature, and the use of Amberlite IR-4B anion exchange resin also removed half of the sulphur. The odor of mercaptan was strong when this resin was regenerated, first with alkali and then with acid. Basic lead carbonate was finally adopted as the neutralizing agent because no blackening occurred unless the solution was warmed. The lead was later removed as the sulphide, the clear filtrate was extracted with chloroform to recover most of the residual monoisopropylidene-glucose-*S*-methyl xanthate, and the aqueous phase was chromatographed on paper with the results already discussed.

(*b*) Following the method described by Ness, Hann, and Hudson (12), 2 gm. of diisopropylidene glucose-3-*S*-methyl xanthate was dissolved in 50 ml. of 80% acetic acid. The solution was heated under reflux for 30 min. in an oil bath kept at 120°, and was then evaporated to a sirup under reduced pressure. This sirup was extracted with 30 ml. of chloroform, and the dried extract on evaporation yielded 1.1 gm. (55%) of material which solidified on being stirred with ligroin. The solid, m.p. 75–88°, was shown by chromatographic methods to be the monoisopropylidene methyl xanthate contaminated with a small amount of the diisopropylidene derivative. The portion, 0.4 gm., of the above sirup which was insoluble in chloroform was saved (see below).

Glucose-3-S-methyl Xanthate

A solution of the above 0.4 gm. of sirup in 25 ml. of acetone was filtered, and a portion of the clear filtrate was chromatographed on paper. A small amount of glucose appeared to be present, together with a large amount of

the compound supposed to be glucose-3-*S*-methyl xanthate and a trace of a third substance of intermediate R_f value. An accumulation of 4.5 gm. of the sirup from several hydrolyses, and which had an average sulphur content of 20.45%, was then purified by passage through a cellulose column. The column was eluted with 1200 ml. of *n*-butanol saturated with water, and the eluate was collected in 21 fractions. Fractions Nos. 11 to 17 inclusive gave only one spot with an R_f value of 0.65 on a paper chromatogram. These fractions when combined and evaporated yielded 3 gm. of glucose-3-*S*-methyl xanthate as a light yellow sirup. Found: S, 20.1, 20.2%. Calc. for $C_8H_{14}O_6S_2$: S, 23.7%. The compound was not quite pure, and repeated attempts to crystallize it failed.

Methyl-4,6-O-benzylidene-α-D-glucopyranoside-2,3-di-S-methyl Xanthate

α-Methyl-D-glucoside and benzaldehyde were heated together as described by Irvine and Scott (8), and the resulting benzylidene derivative melted correctly at 163–164°. Eight grams of sodium, colloidally dispersed in 50% concentration in toluene, was added to a solution containing 8 gm. of methyl-4,6-benzylidene-α-D-glucoside in 50 ml. of dry, pure dioxane. The replacement of the dioxane by 800 ml. of dry benzene, or of the sodium by alcoholic sodium methylate followed by evaporation, was not successful. After being cooled in order to moderate the initial evolution of hydrogen, the suspension was kept warm on a steam bath for three hours, when a further 2 gm. of the dispersed sodium was added and heating was continued for eight hours. The suspension was then cooled, well mixed with 25 ml. of carbon disulphide, and kept overnight at room temperature to form the sodium xanthate. Methyl iodide, 9 ml., was added and after being kept for seven hours at room temperature the suspension was filtered free of sodium salts. The latter were washed three times with dry benzene, after which the filtrate and washings were evaporated under diminished pressure, finally in a desiccator. The red, viscous residue soon crystallized, yielding 9.2 gm. (72%) of crude methyl-4,6-*O*-benzylidene-α-D-glucoside-2,3-di-*S*-methyl xanthate melting at 65–84°. Two recrystallizations from 75% ethanol, followed by an extraction with ligroin and a recrystallization from 80% ethanol, left 4 gm. of the product as pure white crystals melting at 99–100.5°. The substance had a specific rotation of $[\alpha]_D^{22}$ −18.1° in chloroform (*c*, 1.66). Found: C, 46.9, 47.3; H, 4.7, 5.0; S, 27.3, 27.4%. Calc. for $C_{18}H_{22}O_6S_4$: C, 46.8; H, 4.8; S, 27.7%.

When chromatographed on paper, the dixanthate ester formed an intense spot near the solvent front. The parent substance, methyl benzylidene glucoside, left no record on this chromatogram. A 0.5 gm. sample of the dixanthate ester was then hydrolyzed with concentrated hydrochloric acid as described for the diisopropylidene glucose 3-*S*-methyl xanthate, and 0.23 gm. of an amorphous solid was recovered. Found: S, 10.3, 9.9%. When aniline phthalate was the spray, this solid produced no spot on a paper chromatogram, and presumably contained no glucose. Another hydrolysis involved heating a solution of 1 gm. of the dixanthate ester in a mixture of ethanol, 160 ml., water, 30 ml., and concentrated sulphuric acid, 6 ml., under reflux on the steam bath for two hours. After neutralization to pH 6 and complete evapo-

For personal use only.

ration, the liquor yielded salts and 0.3 gm. of a yellow sirup soluble in chloroform. Found: S, 16.0, 16.1%. This sirup when chromatographed on paper gave one spot of R_f 0.87, ammoniacal silver nitrate being the spray. No spot was developed with an aniline phthalate spray, as was the case when substituted glucose-3 and 6-*S*-methyl xanthates were hydrolyzed.

*1,2;3,5-Di-O-methylene-α-*D*-glucofuranose-6-S-methyl Xanthate*

The procedure of Hough, Jones, and Magson (7) was used to prepare the corresponding 6-acetate from glucose, 162 gm., paraformaldehyde, 165 gm., glacial acetic acid, 500 ml., and concentrated sulphuric acid, 75 ml. The crude, partly crystallized product, 83 gm. (37%), on recrystallization from methanol yielded 32 gm. of pure material melting correctly at 103–105°.

Five grams of sodium hydroxide, 25 gm. of the bismethylene-6-*O*-acetylglucose, and 50 ml. of absolute ethanol were shaken together until the bismethylene derivative went completely into solution owing to deacetylation. Water, 10–15 ml., was then added to dissolve the residual sodium hydroxide and two hours later the yellow solution was evaporated to dryness *in vacuo*, finally by the addition and evaporation of 25 ml. of benzene. The bismethylene glucose was extracted from this residue by dry benzene, 100 ml., boiling under reflux, and after the extract had cooled it was mixed with an excess of sodium colloidally dispersed in 25 ml. of dry benzene. After the initial reaction had subsided, 2 gm. of sodium dispersed in toluene was added, together with 25 ml. of benzene. The mixture was kept next day near 75° for four hours, cooled, and shaken with 25 ml. of carbon disulphide. The following day, when the formation of the sodium xanthate was judged to be complete, 30 ml. of methyl iodide was added to the suspension. After being shaken occasionally during a few hours, the suspension was filtered and the residual salts were washed three times with 25 ml. volumes of benzene. Evaporation of the filtrate and washings yielded 32 gm. (108%) of crude product melting at 77–88°, increased to 97–99° by recrystallization from 500 ml. of 70% ethanol followed by extraction with low-boiling ligroin. The yield of pure white needles was 25.1 gm., or 84%, and the specific rotation, $[\alpha]_D^{21}$ +27.3° in chloroform (*c*, 2.15). Found: C, 40.8, 41.1; H, 5.0, 5.1; S, 21.3, 21.7%. Calc. for $C_{10}H_{14}O_6S_2$: C, 40.8; H, 4.8; S, 21.8%.

A 1-gm. sample was hydrolyzed in concentrated hydrochloric acid as described for the diisopropylidene-3-*S*-methyl xanthate. A residue, 0.1 gm., (m.p. 81–92°) failed to dissolve within six hours and was removed. The cream-colored solution was then diluted with an equal volume of water and kept for six days, when the color had deepened only to light yellow. After being neutralized, this solution was evaporated to dryness, and an alcoholic extract of the residue yielded 0.7 gm. of a yellow sirup when evaporated in a desiccator. A portion of this sirup when chromatographed on paper, using an aniline phthalate spray, yielded a faint spot corresponding to glucose, and two major spots (R_f 0.84 and 0.70, see below) corresponding to glucose-6-*S*-methyl xanthate.

Glucose-6-S-methyl Xanthate

One gram of the pure bismethylene derivative was boiled under reflux after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

solution in 150 ml. of a mixture made up from absolute ethanol, 160 ml., water, 30 ml., and concentrated sulphuric acid, 6 ml. Although some of the xanthate survived when the solution was boiled for 68 hr., more was hydrolyzed to glucose or was decomposed, and the time was restricted to 165 min. The solution was evaporated near 35° to 10 ml., and was diluted with 100 ml. of water to precipitate 0.8 gm. of unchanged bismethylene derivative (m.p. 91–96°). After neutralization with barium carbonate and filtration, the filtrate on evaporation yielded 0.15 gm. (17%) of a sirup. An accumulation of such sirups from several hydrolyses was extracted with acetone, and 2 gm. of an oil was recovered from the extract. This oil was eluted from a cellulose column with a total of 1400 ml. of *n*-butanol saturated with water. Of the 34 fractions of eluate collected, Nos. 2 to 8 inclusive yielded a single spot of R_f 0.84 when chromatographed on paper, with ammoniacal silver nitrate as the spray. When these fractions were combined and evaporated, 1.1 gm. of crude glucose-6-*S*-methyl xanthate remained as a yellow sirup which could not be crystallized. Found: S, 20.7, 21.4%. Calc. for $C_8H_{14}O_6S_2$: S, 23.7%. Fractions Nos. 22 to 26 inclusive when chromatographed on paper each yielded a single spot of R_f 0.71; these fractions together gave 70 mgm. of a sirup whose nature was not determined. Found: S, 9.1, 9.3%.

The supposed glucose-6-*S*-methyl xanthate, 0.65 gm. (R_f 0.84), was acetylated with 20 ml. of acetic anhydride containing 0.4 gm. of anhydrous zinc chloride for 24 hr. at room temperature. The solution was poured into ice and water, the mixture was neutralized and extracted with ether. Evaporation of the extract left a yellow sirup which was dried in a vacuum desiccator over phosphorus pentoxide. Yield 0.9 gm. or 85%. Found: S, 12.2, 12.5; acetyl, 38.0, 38.1%. Calc. for 1,2,3,4-tetra-*O*-acetyl glucopyranose-6-*S*-methyl xanthate: $C_{16}H_{22}O_{10}S_2$: S, 14.6; acetyl, 39.3%.

Acetolysis of Bismethylene-glucose-6-S-methyl Xanthate

Anhydrous zinc chloride, 0.1 gm., was added to a solution of 1 gm. of the pure xanthate ester in 5 ml. of acetic anhydride. The mixture was warmed on a steam bath and shaken occasionally until the zinc chloride completely dissolved. After being left at room temperature for 16 hr., the product was precipitated by pouring the solution into ice and water. A yellow sirup, presumably a diacetyl diacetoxymethyl glucose-6-*S*-methyl xanthate, was obtained. Yield 1.6 gm. or 90%. Found: C, 42.9, 42.9; H, 5.0, 5.2; S, 12.7, 12.0%. Calc. for $C_{18}H_{26}O_{12}S_2$: C, 43.4; H, 5.2; S, 12.8%.

In order to deacetylate the above product, an accumulation of 5.2 gm. was dissolved in 100 ml. of absolute methanol, and a total of 2 ml. of 1.5 *N* barium methylate in methanol was added at intervals to maintain the pH between 7.0 and 7.5 for four days (23). The pH was then adjusted to 5.5 with dilute sulphuric acid, and the filtrate from the precipitated barium sulphate was cautiously evaporated to a sirup weighing 2.2 gm. (70%). The pungent smell of formaldehyde was evident during this evaporation. A paper chromatogram of this sirup showed that it contained a little glucose, while an intense spot at R_f 0.84 and a light one at R_f 0.70 suggested the presence of much glucose-

6-S-methyl xanthate. Aniline phthalate was the spray. No recognizable product was obtained when the deacetylation was carried out by Kunz and Hudson's method (9) employing 0.1 *N* sodium hydroxide in aqueous acetone at $-10°$.

ACKNOWLEDGMENTS

One of us (A.K.S.) wishes to thank the Visking Corporation, Chicago, for the Fellowship, and the Pulp and Paper Research Institute of Canada for the summer stipend, which enabled him to take part in the research. Both authors thank the National Distillers Chemical Company, Cincinnati, Ohio, for the gift of the sodium dispersed in toluene.

PHOSPHORYLETHANOLAMINE[1]

By Erich Baer and Harvey C. Stancer

ABSTRACT

A synthetic procedure is described that gives in excellent yield pure phosphorylethanolamine. Its X-ray diffraction pattern and infrared spectrum are reported.

Phosphorylethanolamine (PE) occurs in biological materials both in the bound and in the free state. The isolation of PE from malignant tumors by Outhouse (17), working with E. J. King in the Banting and Best Department, supplied the first evidence for the existence of free PE in nature. Subsequently it was also found in the intestines of rats and rabbits (13), in calf embryo muscle (15), in brain (2, 3, 22), and in various tissues of cows (24). Phosphorylethanolamine has been obtained by synthesis in yields ranging from 20% to 67%: (*a*) by phosphorylation of ethanolamine phosphate (17) or ethanolamine (19) with phosphorus oxychloride, (*b*) by phosphorylation of ethanolamine with a mixture of phosphorus pentoxide and phosphoric acid (19), (*c*) by treatment of phosphorylchloroethanol with ammonia (19), and (*d*) by the interaction of orthophosphoric acid and ethylenimine (11). The widely differing melting points reported for PE (228° (19), 230° (17), 232°–233° (19), 240° (11), and 244° (18, 12)) indicate, however, that these procedures give mixtures of organic phosphates from which it is apparently difficult to obtain the pure substance. In view of the biological interest that phosphorylethanolamine possesses it seemed desirable to develop a procedure for its synthesis that would give in good yield pure phosphorylethanolamine. This has been accomplished by substituting N-carbobenzoxyethanolamine for ethanolamine, and using diphenylphosphoryl chloride instead of phosphorus oxychloride as phosphorylating agent, thus preventing the formation of any by-product. The resulting O-diphenylphosphoryl carbobenzoxyethanolamine is freed of its protective benzyl and phenyl groups by consecutive catalytic hydrogenolysis with palladium in ethanol, and platinum in acetic acid, respectively. This procedure gives a chromatographically pure, crystalline phosphorylethanolamine in an over-all yield of 83%. Its melting point (244°–245°) agrees well with that reported by Outhouse (18) and Clarke *et al.* (12) for phosphorylethanolamine.

Attempts to simplify our procedure by removing the phenyl and carbobenzoxy groups by hydrolysis in boiling barium hydroxide solution were not successful, although the same procedure when applied to diphenylphosphorylcholine chloride (4) gives in good yield the barium salt of phosphorylcholine chloride. The protective carbobenzoxy group can be removed selectively, however, by the method of Albertson and McKay (1), using gaseous hydrogen bromide. The O-diphenylphosphorylethanolamine hydrobromide is obtained in a yield of approximately 90%. Since this compound might prove useful as a

Contribution from the Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario.

substrate in studies with phosphatases, its preparation is described in the experimental part.

In order to facilitate both the study of the structure and the quantitative estimation of natural phosphatides by infrared spectroscopy (14, 16, 21), the infrared spectra of pure individual phosphatides have been reported from this laboratory as these substances became available by synthesis (5, 6, 7). Possessing analytically pure specimens of phosphorylethanolamine and L-α-glycerylphosphorylethanolamine (8), both of which are of interest as moieties of cephalins and plasmalogens, their infrared spectra were recorded; these are shown in Fig. 1.

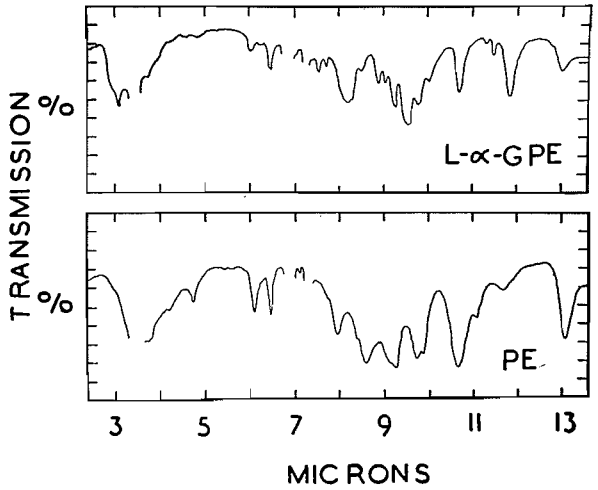

FIG. 1. Infrared spectra of phosphorylethanolamine (PE) and L-α-glycerylphosphorylethanolamine (GPE) in nujol mulls. Perkin-Elmer double-beam infrared spectrophotometer (model 21). Potassium bromide prism. Band positions and probable assignments: (PE) 2.90 μ (OH and NH stretching), 4.73, 6.08, 6.44 (NH bending), 7.10 (CH, OH bending), 7.94 (OH bending, P=O), 8.60 (C—O, C—N, C—C stretching), 9.25 (covalent phosphate), 9.72, 9.85, 10.64 (covalent phosphate), 11.08, 11.66, 13.08. (GPE) 3.10 μ (NH and OH stretching), 6.02, 6.48 (NH bending), 7.56 (CH, OH bending; primary and secondary alcohols), 7.74 (CH, OH bending; P=O), 8.18 (covalent phosphate), 8.55 (C—O, C—N, C—C stretching), 8.92, 9.08, and 9.30 (covalent phosphate), 9.58, 9.82, 10.06, 10.76 (covalent phosphate), 11.36, 11.52, 11.88, 13.06.

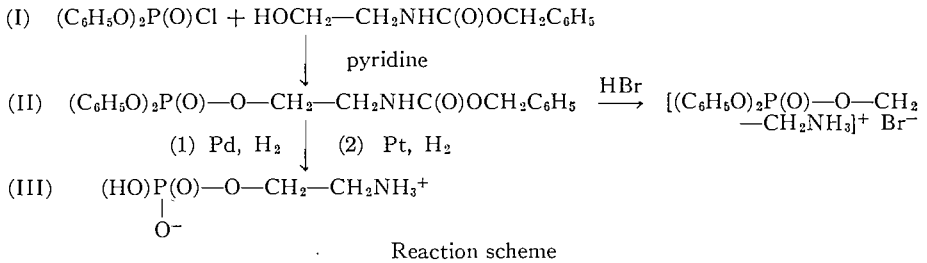

Reaction scheme

EXPERIMENTAL PART

O-(Diphenylphosphoryl)-carbobenzoxyethanolamine

To a solution of 9.75 gm. (5.0 mM.) of N-carbobenzoxyethanolamine (10,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

20) in 40 ml. (50 mM.) of anhydrous pyridine* was added with swirling and under anhydrous conditions 14.8 gm. (5.5 mM.) of diphenylphosphoryl chloride (9) over a period of 10 min. To prevent the temperature from rising above 40°, the mixture was cooled occasionally with cold water. After it had been left for two hours at room temperature, the excess of diphenylphosphoryl chloride was destroyed by the addition of 2 ml. of water. One hour later the reaction product was isolated by precipitating it with 300 ml. of water. It was purified by washing its solution in 175 ml. of ether in succession with two 25 ml. portions of ice-cold 5 *N* sulphuric acid, and one 25 ml. portion each of water, a half-saturated solution of sodium bicarbonate, and water. After the solution had been dried over anhydrous sodium sulphate, it was concentrated under reduced pressure and the remaining solvent was removed by keeping the substance at 30°–35° in a vacuum of less than 1 mm. Hg for a period of five hours. The O-diphenylphosphoryl carbobenzoxyethanolamine, an almost colorless oil, weighed 20.4 gm. (95.4% of the theoretical amount based on carbobenzoxyethanolamine) $n_D^{23°}$ 1.5555. The substance is readily soluble at room temperature in ether, ethanol, methanol, or acetic acid but is insoluble in water. $C_{22}H_{22}O_6NP$ (427.2). Calculated: C, 61.81; H, 5.19; N, 3.29; P, 7.25. Found:† C, 61.79; H, 5.16; N, 3.30, 3.25; P, 7.12, 7.23.

Phosphorylethanolamine

A solution of 21.3 gm. (50 mM.) of O-diphenylphosphoryl carbobenzoxyethanolamine in 200 ml. of 99% ethanol together with 3.5 gm. of palladium catalyst (23) was shaken vigorously in an all-glass hydrogenation vessel of approximately 1 liter capacity in an atmosphere of pure hydrogen under a pressure of 40–50 cm. of water until the absorption of hydrogen had practically ceased. After replacing the hydrogen with nitrogen and adding 75 ml. of water to dissolve the reaction product, the catalyst was removed and the solution was brought to dryness under reduced pressure at a bath temperature of 25°–35°. To complete the removal of the protective groups, the solid residue was dissolved in 175 ml. of glacial acetic acid and the solution, after it was returned to the hydrogenation vessel and 3.5 gm. of platinic oxide‡ (Adams' catalyst) added, was shaken until there was no further uptake of hydrogen. After replacing the hydrogen with nitrogen and removing the catalyst, the acetic acid was distilled off *in vacuo* (bath temperature 30°–35°). The crude phosphorylethanolamine, containing traces of potassium, was purified by dissolving it in 350 ml. of distilled water and shaking the solution with 35 gm. of Amberlite IR–120 (H) for 90 min. The filtrate was brought to dryness *in vacuo* (bath temperature 30°–35°) and the phosphorylethanolamine was recrystallized from 35 ml. of water by gradually adding several volumes of 99% ethanol, and placing the mixture in an ice-box. The crystals were filtered off, washed with a small amount of a cold mixture of

*Pyridine of good commercial grade was refluxed over barium oxide and distilled with the exclusion of moisture.

†Analyses of two independent preparations.

‡The catalyst was prepared as described in "Organic Syntheses", Coll. Vol. 1, 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1948, p. 463, with the exception that the sodium nitrate was replaced by an equimolecular amount of potassium nitrate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

ethanol and water (2:1), and dried *in vacuo* over phosphorus pentoxide. The phosphorylethanolamine weighed 6.0 gm. (87% of theory). Over-all yield 83%, m.p. 244°–245°.* $C_2H_8O_4NP$ (141.1). Calculated: C, 17.02; H, 5.71; N, 9.93; P, 22.0. Found: C, 17.10; H, 5.60; N, 9.88; P, 22.0.

X-ray Diffraction Pattern of Phosphorylethanolamine

The X-ray powder diffraction pattern was taken using Ni-filtered Cu K_α-radiation (λ 1.5418). The intensities of the diffraction rings were estimated visually on an arbitrary scale of 1 to 10 and are quoted in parentheses:
8.85 Å ($\frac{1}{2}$), 5.77 (7), 5.17 (4), 4.41 (10), 4.26 (10), 3.88 (8), 3.84 (8), 3.76 ($\frac{1}{2}$), 3.58 (5), 3.48 ($\frac{1}{2}$), 3.28 ($\frac{1}{2}$), 2.91 (1), 2.87 ($\frac{1}{2}$), 2.71 (3), 2.63 (2), 2.47 (3), 2.42 (1), 2.22 (3).

Diphenylphosphorylethanolamine Hydrobromide

Through a solution of 3.0 gm. of O-diphenylphosphoryl carbobenzoxyethanolamine in 20 ml. of glacial acetic acid was passed a stream of hydrogen bromide† gas for one-half hour. The solution was occasionally cooled. After the solution was left for one-half hour at room temperature, the solvent and excess of hydrobromide were removed under reduced pressure (8–10 mm. Hg) at a bath temperature of 35°–40°. To the solution of the residual oil in 5 ml. of 99% ethanol, ether was added until the solution was permanently turbid, and the mixture was placed in an ice-box overnight. The crystalline diphenylphosphorylethanolamine hydrobromide was collected with suction on a buchner funnel and was dried *in vacuo* over paraffin and calcium chloride. Yield 2.32 gm. (88% of theory), m.p. 115°–116.5° (with slight sintering at 114°). $C_{14}H_{17}O_4NPBr$ (374.2). Calculated: C, 44.93; H, 4.58; N, 3.74; P, 8.28. Found:‡ C, 44.96, 45.27; H, 4.75, 4.65; N, 3.79; P, 8.32.

This work was supported by a grant from the Lipotropic Research Fund, New York, to which the authors wish to express their sincere thanks. The authors express their thanks also to Professor E. W. Nuffield (Department of Geological Sciences, University of Toronto) for the X-ray diffraction measurements of phosphorylethanolamine, and to Dr. M. Look (Stanford University) for the infrared absorption spectra of phosphorylethanolamine and glycerylphosphorylethanolamine.

A SEARCH FOR THE CHEMICAL EFFECTS OF INTERNAL CONVERSION FOLLOWING RADIATIVE NEUTRON CAPTURE[1]

By A. G. Maddock and M. M. de Maine[2]

ABSTRACT

The possibility that neutron capture would lead to oxidation, because of internal conversion of the capture radiation, has been investigated in solid compounds of the lower valence states of antimony, arsenic, cerium, chromium, and thallium. Except in the hydrated compounds, negative results have been obtained. It is possible that oxidation is followed by electron-transfer exchange in the irradiated solids.

INTRODUCTION

When an atom captures a thermal neutron, there results a highly excited compound nucleus which quickly radiates its excess energy in one or more gamma-rays. Conservation of momentum requires that the emission of these gamma-rays imparts to the newly formed atom a recoil energy many times that required for breaking chemical bonds. It is also possible that one or more of the gamma-rays might be internally converted and in this instance, oxidation of the atom will result. Most studies on the chemical changes following thermal neutron capture have focused on the bond breaking mechanisms, but there could be oxidation effects due to internal conversion, even if simple ionic solids were irradiated (10).

The physical detection of internal conversion following radiative neutron capture is attended with some experimental difficulties; but with a 180° beta-ray spectrograph Hibdon and Muehlhause (7) have detected the conversion electrons from neutron capture in $_{48}Cd^{113}$, $_{66}Dy^{164}$, $_{64}Gd^{odd}$, $_{88}Hg^{199}$, and $_{62}Sm^{149}$. Thermal neutron irradiation of ethyl bromide and iodide at pressures of three microns leads to 12 to 50% of the radioactive atoms of the different isotopes becoming positively charged as a result of internal conversion (16). Most of the gold and iridium recoil atoms which escape from the surface of gold and iridium films during neutron irradiation are positively charged (12, 19).

It seemed possible that chemical methods might provide a more sensitive means of detection and estimation of the internal conversion. Radioactive perrhenate has been separated after dissolution of neutron-irradiated rhenium trichloride (6). Following the neutron irradiation of several hydrated chromic salts, 3 to 10% of the radioactive chromium atoms were found in the hexavalent state upon solution and analysis of the crystals (4).

EXPERIMENTAL

In the present work, neutron irradiation of several simple inorganic salts with the cation in the lower of its two stable chemical valences was followed by dissolution of the solids in solutions containing as carriers cations of both valence states. There followed a chemical separation of the cations by a method

[1]*Manuscript received December 12, 1955.*
Contribution from the University Chemical Laboratory, Pembroke Street, Cambridge, England.
[2]*Lately Miss M. M. Moodie.*

which was chosen to avoid exchange between the two valence states. Measurements of the fraction of the radioactivity associated with each of the valence states were made. It was hoped that these would indicate the fraction of events leading to internal conversion and a consequent valence increase. Table I gives the present results together with those of Harbottle (4) for the hydrated chromic salts.

TABLE I

PERCENTAGE VALUES OF ATOMS PASSING INTO HIGHER VALENCE STATES DURING THE CONTROL ANALYSIS AND AFTER THERMAL NEUTRON IRRADIATION AND ANALYSIS
The values denoted* are those obtained by Harbottle (4)

Compound irradiated	Percentage of atoms in higher valence after irradiation and analysis		Percentage of atoms passing into higher valence during control analysis
Sb_2O_3	Sb^{122}	0.4	0.6
	Sb^{124}	0.4	
$KSbC_4H_4O_7.\frac{1}{2}H_2O$	Sb^{122}	1.8	
	Sb^{124}	1.8	
As_2O_3	1.0		1.1
$Ce_2(SO_4)_3$	Ce^{141}	2.0	2.0
	Ce^{143}	2.0	
$CrCl_3.10H_2O$	1.1		1.2
$Cr_2(SO_4)_3.18H_2O$	2.9		
$Cr_2(SO_4)_3.18H_2O$*	3.7		
$Cr(NO_3)_3.9H_2O$*	7.6		
$Cr_2(SO_4)_3.K_2SO_4.24H_2O$*	8.4		
$Cr_2(SO_4)_3(NH_4)_2SO_4.24H_2O$*	9.8		
Tl_2CO_3	0.9		0.9
$TlNO_3$	0.9		
Tl_2SO_4	0.9		

The methods of analysis for compounds of the different cations are as follows:

Antimony.—A magnesium chloride – hydrochloric acid solution of the irradiated compound with inactive Sb^{+3} and Sb^{+5} carriers was shaken with isopropyl ether which extracted the pentavalent antimony (2).

Arsenic.—The arsenate was separated from arsenite by precipitation of magnesium ammonium arsenite according to the procedures of Wilson and Dickinson (18).

Cerium.—Ceric compounds were extracted from cerous compounds by the use of ether after solution in nitric acid (8).

Chromium.—In one aliquot chromate was precipitated on the addition of lead nitrate solution. A second aliquot was treated with sodium hydroxide – sodium peroxide to oxidize chromic ions to chromate, and the lead chromate was then precipitated (3).

Thallium.—Thallous chromate was precipitated from the first aliquot. Sodium bisulphite treatment of a second aliquot reduced thallic ions to thallous, and the total thallium was precipitated as thallous chromate (5, 14).

DISCUSSION

Negative results were obtained except where hydrated compounds were used. In these cases very strongly oxidizing species might be formed by the action of the ionizing radiations on the water. The same remarks apply to aqueous solutions in which oxidizing effects have also been revealed (13). Positive effects in anhydrous compounds are necessary if it is to be argued that internal conversion is responsible.

Unfortunately these negative results do not prove that internal conversion does not take place. Indeed, the physical investigations (7) suggest that it is sufficiently commonplace to have occurred in one or more of these isotopes. The detection method used is only valid if exchange by electron transfer does not take place in the solid or during dissolution. The control tests only show that it does not interfere after dissolution.

Very little evidence is available concerning exchange in solid systems. The phenomenon of induced exchange during precipitation is widely recognized (15), but it has not been investigated systematically. In fact, it is difficult to obtain reproducibility in such measurements. Nevertheless, the existence of this phenomenon suggests that exchange might take place during the solution of solids containing atoms in two valence states.

In a number of solids, containing different valences of one element, physical evidence such as the optical and electrical properties suggests that some delocalization of valence electrons takes place. Such a process might be expected to lead to exchange by electron transfer. In some cases a similar interaction of atoms in two valence states can occur in solution (9, 17).

However, exchange is not inevitable even when interaction between the atoms seems to occur. Thus the deep orange lead sesquioxide can be prepared and decomposed without exchange taking place (20). Similar results have been obtained with chromic chromate (1, 11). This latter result suggests that exchange need not occur, at least in oxygenated chromic compounds. Such salts are all hydrated, however.

Even the absence of exchange during precipitation and subsequent dissolution of the compounds studied does not preclude electron transfer within the solid lattice. The radioactive atom suffers a considerable recoil and frequently settles down in some interstitial or other abnormal lattice position. Nothing is known about the probability of electron transfer involving such atoms, but it is probably enhanced.

The previous observation on rhenium trichloride (6) seems all the more surprising in the light of these results.

One of us (M.M.M.) is indebted to the Royal Commission for the Exhibition of 1851 for a Science Overseas Scholarship which made possible her sojourn in Cambridge.

INFLUENCE OF METHANOL ON VISCOSITY AND LIGHT SCATTERING PROPERTIES OF DEXTRAN SOLUTIONS[1]

By W. Donald Graham, Odette Patry, and E. Helen Jackman

ABSTRACT

Failure to consider the presence of up to 16% by volume of methanol in solutions of dextran fractions had a very marked effect on *apparent* intrinsic viscosity determinations (the term *apparent* signifies that measurements were made assuming that the solvent was water only). Unless methanol were removed or otherwise taken into account, high erroneous results were obtained. *Apparent* weight average molecular weights determined by light scattering were not significantly affected at these alcohol concentrations. The relations found over the range 0 to 16% methanol for dextran samples with weight average molecular weights of 265,000, 155,000, and 72,000 held for the latter sample up to 44% methanol. In the higher range of alcohol concentration the *apparent* weight average molecular weight was depressed. The true intrinsic viscosity of dextran solutions decreased as methanol concentration was increased.

During the course of testing dextran plasma expanders for conformity with various specifications, fractions representing the upper and lower 5 to 10% of the molecular weight distribution of the polymer are separated, usually by fractional precipitation with methanol. In some procedures no definite recommendation is made to ensure removal of traces of methanol which may remain with the precipitated dextran. According to Wolff *et al.* (8) this sirupy residue may contain up to 15% of methanol. Where great care in the separation of the supernatant solution from the viscous dextran-bearing precipitate is not exercised, it may be appreciated that variable and quite significant amounts of methanol may find their way into the test solution. In practice, when sharp separation of the layers is recognized as essential, the concentration of methanol in the final test solution (approximately 1 to 2% dextran in 100 ml. of solution) would be unlikely to exceed 2%. If test fractions are freeze-dried before they are dissolved for viscosity determinations etc., the methanol content should be of no practical significance.

Some laboratories have used light scattering measurements to assess the weight average molecular weights of these high and low fractions directly: others have made intrinsic or inherent viscosity determinations and converted the values thus obtained to "weight average molecular weights" by the application of a mathematical relationship (2, 3, 4, 6). The question arose as to the possible effects of varying amounts of methanol in the solutions on the subsequent molecular weight determinations. In an attempt to answer this question the present investigation was undertaken.

It was considered that the presence of methanol might have a greater effect on high molecular weight fractions than on low molecular weight material since larger dextran molecules tend to precipitate at lower concentra-

[1]*Manuscript received December 5, 1955.*
Contribution from the Food and Drug Laboratories, Department of National Health and Welfare, Ottawa, Canada.

tions of methanol. Accordingly three dextrans with weight average molecular weights of approximately 265,000, 155,000, and 72,000 respectively were selected for this study.

EXPERIMENTAL AND RESULTS

Approximately 2.0% solutions of these dextrans were prepared in essentially dust-free, glass-distilled water and to 50 ml. aliquots of these solutions, varying amounts of methanol (B.P.C. grade, absolute) from 0 through 16 ml. were added. Sufficient water was added to bring each solution to 100 ml. These solutions were intended to represent dextran fractions which were obtained by methanol precipitation and in which varying amounts of contaminating methanol were present. From each of these solutions four dilutions were prepared in essentially dust-free water to contain approximately 0.15, 0.2, 0.25, and 0.35 gm. of dextran/50 ml. These dilutions were clarified by filtration through an ultrafine, sintered glass, pressure filter so that the dissymmetry of the filtered solutions in the Brice-Phoenix light scattering photometer, series 1000, was not greater than 1.15 at λ 436 mμ. It was noted that filtration became progressively slower as the amount of methanol present increased and the filters required frequent cleaning with hot nitric and sulphuric acid (1:1). The absolute turbidities of the solutions were measured and the solutions were reserved for polarimetric and viscosity measurements. Turbidities were corrected for the turbidity of the solvent* and the expression Hc/τ† was calculated for each dilution. From the Hc/τ vs. c data the intercept at $c = 0$ was calculated by least squares and the reciprocal of this intercept was recorded as the *apparent* weight average molecular weight.

No attempt was made to allow for the fact that measurements were made in a three-component system as no such correction would be made by the analyst who ignored or was unaware of the presence of methanol in his solutions. For the same reason, in the determination of the viscosities of these solutions as described below, the solvent was considered to be water rather than water–methanol mixtures.

The viscosities of the four dilutions were determined using Ostwald-Cannon-Fenske viscosity pipettes (1) series 50, all of which had flow times with water at 25°C. in excess of 240 sec. Duplicate determinations were required to check within 0.3 sec. The viscosity data were converted to *apparent* relative viscosities and thence to *apparent* specific viscosities (*app.* η_{sp}). The *app.* η_{sp}/c vs. c data were utilized in the least squares calculation of the intercept at $c = 0$ which was recorded as *apparent* intrinsic viscosity (*app.* $[\eta]$). Concentrations of the solutions under test were determined polarimetrically in a Rudolph precision photoelectric polarimeter assuming $[\alpha]_D^{20} = +200°$. The effect of methanol was ignored since it has been shown by Snyder *et al.* (5) that the specific rotation is increased by only about 1% by the presence of 40% methanol by volume. The data arising from the viscosity and light scattering measurements are recorded graphically in Fig. 1.

*Turbidities of the aqueous methanol solutions were not greatly different from that of water which commonly was 4 to 5 × 10^{-5} cm.$^{-1}$.

†$H = 0.624 \times 10^{-5}$, c = concentration in gm./ml., τ = turbidity in cm.$^{-1}$.

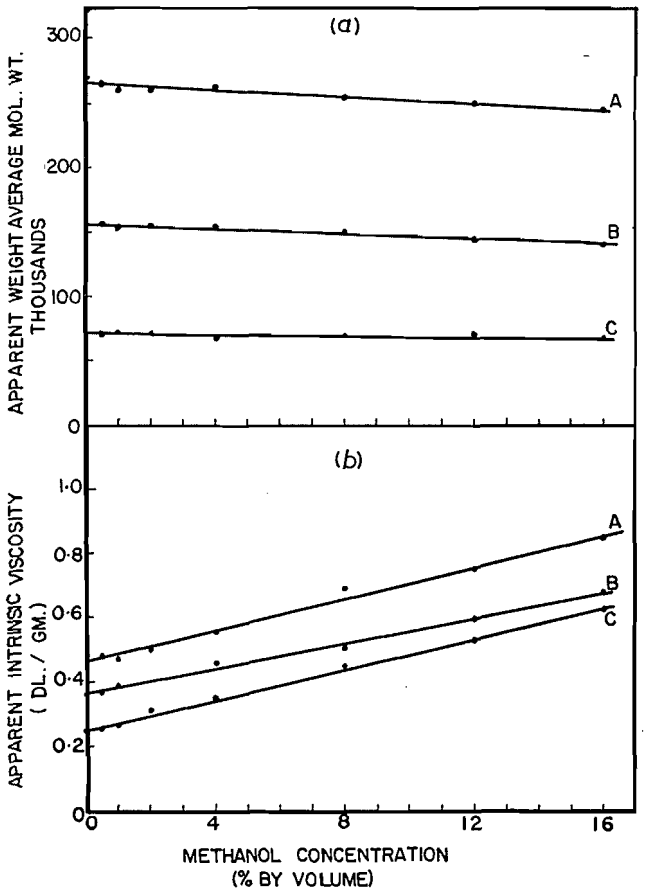

FIG. 1. Effect of methanol on (*a*) light scattering and (*b*) viscosity measurements on dextran solutions. Curve A—dextran sample 1, wt. av. mol. wt. 72,000; Curve B—dextran sample 2, wt. av. mol. wt. 155,000; Curve C—dextran sample 3, wt. av. mol. wt. 265,000.

It is obvious that the presence of amounts of methanol up to 16% by volume in the original dextran solution had relatively little effect on the *apparent* weight average molecular weight as determined by light scattering. The slight decrease in *apparent* weight average molecular weight with increasing methanol concentration is within the limits of reproducibility of the method (2) although the consistent trend suggests (*a*) increasingly serious loss of the larger molecules with increasing methanol concentration during filtration, (*b*) an error associated with ignoring the effects of the third component in the system, or (*c*) a combination of (*a*) and (*b*). Support for the first of these is found in the increasingly difficult filtration with increasing methanol concentration, particularly with the higher molecular weight dextran. The effect of the methanol *per se* might be expected to be small because the refractive index for aqueous methanol solutions in this concentration range is close to that of water (7). The gradual decrease in apparent molecular weight was associated with a small decrease in the second virial coefficients as the methanol concentration increased.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

Light scattering measurements on sample 3 were extended up to methanol concentrations of 44%. The initial trend, apparent in Fig. 1(*a*) curve C, was continued and, at a methanol concentration of 44% in the starting dextran solution, the *apparent* weight average molecular weight was further depressed to about 64,000 from the initial 72,000 measured in water. This would appear to be a significant degree of depression (2).

In the case of *apparent* intrinsic viscosity, Fig. 1(*b*), the values obtained ignoring the presence of methanol rose very steeply as the methanol concentration increased. While it is unlikely that methanol concentrations in the dextran fraction solutions, as obtained in practice, would reach 16%, measurements on sample 3 were extended up to the point of incipient precipitation at 44% methanol. The curve continued upward with the same trend shown in the lower ranges in curve C, Fig. 1(*b*).

In Fig. 2 have been plotted (curve A) the *apparent* relative viscosities of solutions containing 0.5% of dextran sample 3 and increasing amounts of methanol. The *apparent* relative viscosities were obtained by dividing

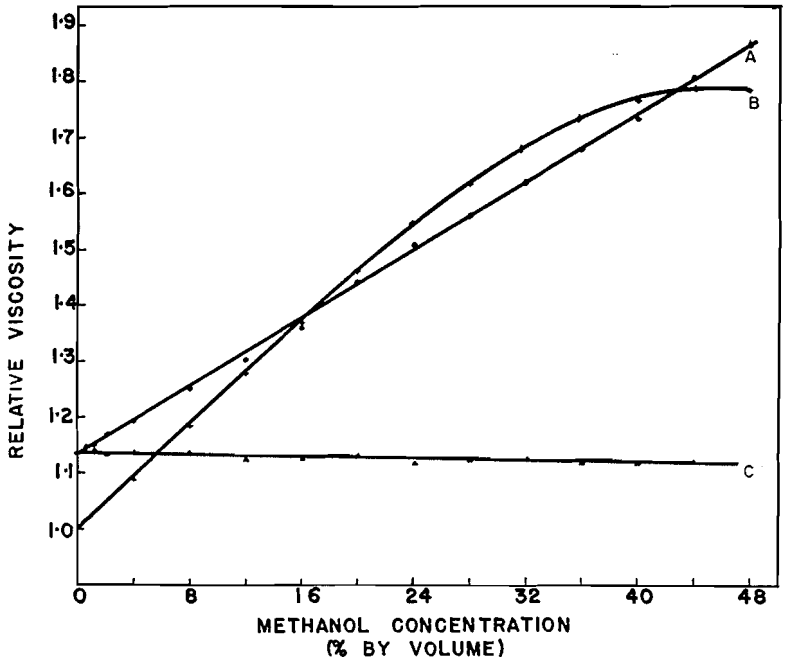

FIG. 2. Relative viscosities. Curve A—*Apparent* relative viscosity of a 0.5% solution of dextran sample 3 in the presence of increasing amounts of methanol. See text. Curve B—Relative viscosity of methanol solutions 0 to 48% by volume at 25°C. Curve C—Relative viscosities of solutions containing 0.5% of dextran sample 3 and varying amounts of methanol up to 44% by volume.

$\eta_{solution}$ by η_{water} ignoring the presence of methanol. The correction applied for density of the solutions was that applicable to dextran in water. In the same figure are plotted the true relative viscosities for aqueous methanol solutions with and without dextran (0.5% of sample 3) over the same range of methanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

concentrations (curves C and B respectively). Since the viscosities of water–methanol mixtures show a maximum for intermediate compositions, the increase in viscosity with increasing methanol content can be attributed to the solvent viscosity.

When appropriate aqueous methanol solutions are used to determine $\eta_{solvent}$, and the true $\eta_{relative}$ for each dextran dilution is determined, the η_{sp}/c may be calculated for each dilution. From these figures, by least squares extrapolation to $c = 0$, a value related to intrinsic viscosity may be obtained. Starting with the usual 1% dextran solutions containing increasing amounts of methanol up to 44% by volume, curve A shown in Fig. 3 was obtained for sample 3. Corrections for density were applied in the viscosity determinations.

It was of interest to see what deviation existed between curve A, Fig. 3, and the true intrinsic viscosity vs. methanol concentration curve. The necessary determinations were made with the four dextran dilutions used in obtaining $[\eta]$ at a specific methanol concentration, each containing that concentration of methanol. The curve B, resulting from these determinations, is shown in Fig. 3. As might be expected, curves A and B are somewhat similar.

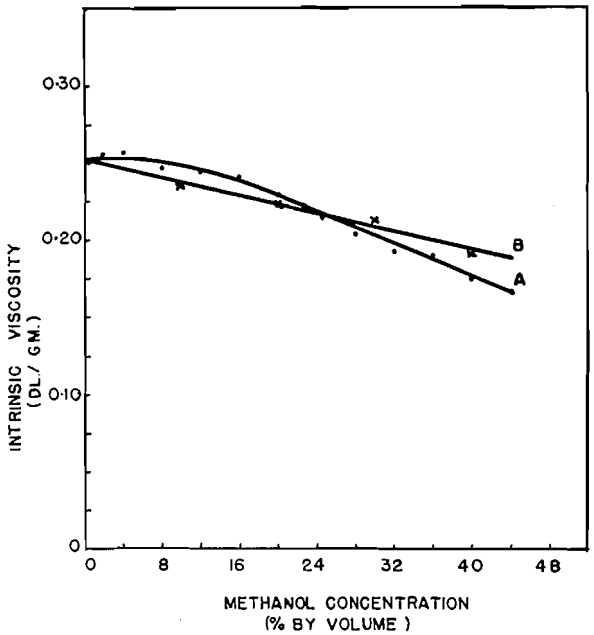

FIG. 3. Intrinsic viscosity of solutions of dextran sample 3 in the presence of 0 to 44% methanol by volume. Curve A—Pseudo intrinsic viscosity vs. methanol concentration. See text. Curve B—True intrinsic viscosity vs. methanol concentration.

Wales and co-workers have shown (7) that the $[\eta]$ of a similar dextran in 40.5% methanol in water was 0.17 as compared with 0.271 in aqueous solution. The results in the present instance are of the same general order. From curve B, which is directly comparable, the figures are, respectively, 0.193 and 0.253. From curve A, which is not directly comparable, the figures are 0.175 and 0.253.

The common purpose of performing viscosity determinations in the production of dextran plasma expanders is to control the molecular size of the product. The intrinsic or inherent viscosities so measured may be converted to a calculated viscosity average molecular weight for ease of comparison with other materials. If the formula derived by Wales and co-workers (6) for the relation between intrinsic viscosity and weight average molecular weight be used, the unknown presence of 2% of methanol in the test fraction for sample 3 will cause a more than 30% error in the calculated molecular weight. With the use of other formulae (2, 3, 8) the discrepancy will be even greater. The effect of 2% methanol on the light scattering weight average molecular weight is virtually nil. This example serves to emphasize the necessity for exercising great care in viscosity determinations on dextran fractions obtained by methanol precipitation.

ACKNOWLEDGMENT

The authors wish to thank Dr. S. G. Weissberg for constructive comments on the manuscript.

LEAD TETRAACETATE OXIDATION OF OLIGOSACCHARIDES[1]

By A. S. Perlin and A. R. Lansdown[2]

ABSTRACT

Lead tetraacetate oxidation is shown to be useful for examining some structural features of trisaccharides and higher oligosaccharides. Generally, the oxidations follow a course similar to that found with the corresponding disaccharide. In some oligosaccharides, however, glycol groups which resist oxidation are encountered. Such groups are 2,3-*trans* glycols of central residues which are linked to adjacent residues by 1,4-glycosidic bonds. The apparent inability to complex with lead tetraacetate suggests a conformation for these sugar residues in acetic acid solution which differs from that of the corresponding monosaccharide glycopyranoside. Lead tetraacetate oxidation of oligosaccharides in which central residues are unaffected by the reagent constitutes a unique stepwise degradation of these compounds, and possible applications of the reaction are suggested.

An earlier publication (11) described the use of lead tetraacetate oxidation (1, 4) for determining the structure of reducing disaccharides, and suggested that the reaction may also be of value for higher oligosaccharides. Subsequent examination of several oligosaccharides supports this contention.

In some respects the oligosaccharides show oxidation behavior which is closely similar to that of the disaccharides. Thus the yield and rate of production of formic acid from xylotriose and higher oligosaccharides of the same series are almost identical with those from xylobiose (11, Fig. 4). The rapid liberation of one mole of acid appears to result from cleavage of carbon–

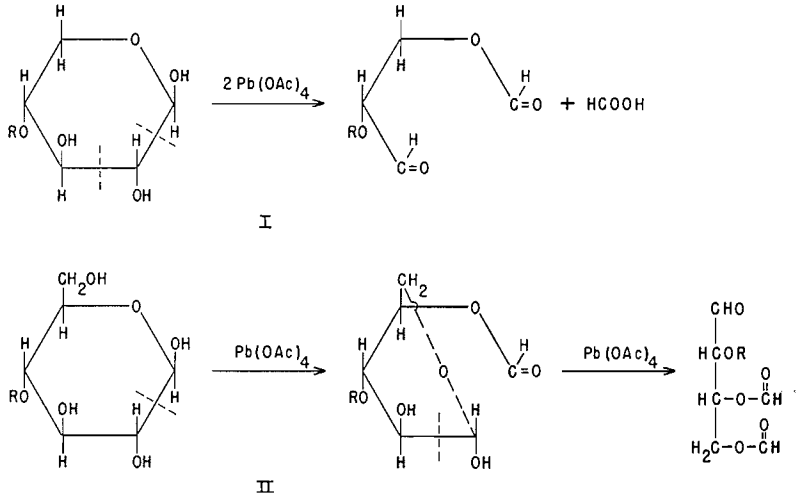

FIG. 1. I. Oxidation of the reducing end-unit of a (1 → 4) xylose oligosaccharide (R = non-reducing residue or residues). II. Oxidation of the reducing end-unit of a (1 → 4) glucose oligosaccharide (R = non-reducing residue or residues).

carbon bonds 1,2 and 2,3 of the reducing end-unit, carbon-1 being converted to a formate ester (I, Fig. 1) and carbon-2 released as formic acid; the second mole of acid is produced slowly from the non-reducing end. With oligosaccharides of the maltose and cellobiose series the formic acid produced appears to originate almost exclusively from the non-reducing end and, in each instance, at a rate approximately equal to that found for maltose (11, Fig. 1). In these compounds it appears that carbon-2 as well as carbon-1 of the reducing end-unit produces a stable formate ester (II, Fig. 1), and a total yield of only one mole of free acid is obtained.

From the standpoint of formic acid production the oligosaccharides considered above may be regarded as disaccharides since the central residues are glycosidically linked 1,4- and can yield no acid. However, it would be expected that the free 2,3-glycol group of the central residues should cleave oxidatively and lead tetraacetate consumption accordingly increase by one mole for each central unit. That is, xylobiose consumes four moles of oxidant but xylotriose should consume five moles, xylotetraose, six moles, and so on. In fact, however, all three compounds consume approximately four moles of lead tetraacetate per mole during the reaction period examined (Table I). Since this quantity is

TABLE I

LEAD TETRAACETATE OXIDATION OF OLIGOSACCHARIDES*

Compound	Total $Pb(OAc)_4$ consumed†	Formic acid produced	$Pb(OAc)_4$ consumed by compound
Xylobiose	5.8	1.9	3.9
Xylotriose	5.9	2.0	3.9
Xylotetraose	5.3	1.8	3.5
Xylopentaose	5.6	1.9	3.7
Xylohexaose	6.5	2.1	4.4
Maltose	5.2	1.1	4.1
Maltotriose	5.4	1.2	4.2
Maltotetraose	3.9	0.7	3.2
Maltopentaose	5.0	0.9	4.1

†Includes $Pb(OAc)_4$ consumed in oxidation of formic acid to CO_2.

sufficient only to account for the two moles of formic acid produced it appears that the central residues are not attacked by the oxidant. In agreement with this suggestion, after the oxidation of xylotriose one mole of pentose remains intact. Similar results are obtained with compounds of the maltose and cellobiose series (Table I). Approximately four moles of lead tetraacetate are consumed which again corresponds to oxidation only of reducing and non-reducing end-units. In a few instances, the values are only 80–85% of those generally found which is probably due to the fact that these compounds are

For personal use only.

difficult to purify or are highly hygroscopic. Maltohexaose appears to consume an additional mole of oxidant per mole, suggesting that one of the four central residues is attacked.

Benzyl β-D-maltoside also exhibits a similar resistance to oxidation by lead tetraacetate. One mole of formic acid is liberated at a rate close to that of the methyl glucoside, and two moles of oxidant are consumed. These data account only for oxidation of the terminal unit, and one mole of glucose is recovered after hydrolysis of the reaction product.

The resistant sugar residues in these oligosaccharides have one common structural feature—a 2,3-*trans* glycol group subtended by glycosidic linkages at carbons 1 and 4. Lead tetraacetate is known to cleave *trans* glycol groups although less readily than *cis* glycols (4, 7). This has been explained in part by assuming that the cleavage reaction involves formation of a cyclic intermediate (4) which is more easily accommodated by a *cis* than by a *trans* glycol group. Accordingly, the configuration of the 2,3-*trans* glycol of the resistant units of the oligosaccharides may be distorted sufficiently to prevent complex formation. The 2,3-*trans* glycol group of the non-reducing end-unit, however, is readily oxidized and must therefore possess a more favored configuration.

Raffinose affords an oligosaccharide in which the central unit possesses a 2,3-*trans* glycol group but is linked through the 6- rather than the 4-position to an adjacent residue. If the latter linkage position is important for inducing resistance to oxidation, normal attack of the central unit in raffinose would be expected. This, in fact, is found to occur; two moles of formic acid are liberated and a total of five moles of lead tetraacetate consumed (Table I), corresponding to cleavage of all glycol groups in the molecule.

It appears, therefore, that the presence of a glycosidic bond at carbon-4 of a non-reducing sugar unit markedly alters the configuration of the 2- and 3-hydroxyl groups from that normally encountered in the corresponding monomer glycopyranoside. A critical evaluation of glycol-cleavage oxidations by Heidt, Gladding, and Purves (7) led to the assignment of optimal dimensions in glycol groups for complexing with an oxidant. Studies by Reeves on cuprammonium complexes of glycosides likewise suggest conformations which are likely to be less or more prone to glycol-cleavage (12). From these data, the observed resistance of glycol groups in oligosaccharides to oxidation suggests that the sugar units concerned may possess a conformation in acetic acid solution other than Reeves' C-1 form, most commonly encountered with the glycopyranosides of these sugars (12). Steric hindrance to complexing of the glycol group with the oxidant by neighboring sugar residues appears unlikely because differences in the degree of resistance should then have been expected between α- and β-linked compounds, e.g. between maltotriose and cellotriose. It will be of interest to examine other oligosaccharides which have structural features somewhat different from those described above. For example, a trisaccharide in which mannose constitutes a central residue linked 1,4- to the adjacent units would provide a 2,3-*cis* glycol group which would be expected to cleave readily. Considerations of this kind have been recorded

by Dimler (5) in explaining the resistance of ⟨1,4⟩⟨1,6⟩ anhydrohexofuranoses to periodate and lead tetraacetate oxidation. In these hexosans the resistant glycol group is also *trans* but, in contrast to those of the oligosaccharides described, occurs on a furan ring and hence is more likely to have a highly unfavorable bond angle, i.e. about 120° or greater (12).

The current results show that lead tetraacetate oxidation under the conditions described may be of value for determining some structural features of higher oligosaccharides. Limitations are imposed, however, by the resistance to oxidation of some types of glycol groups. For example, distinction between a 1,3- and 1,4-glycosidic linkage in central sugar residues may prove difficult in such instances, requiring collaborative evidence from methylation or periodate oxidation. On the other hand, this behavior can facilitate the determination of the linkage position of the reducing end-unit, as indicated above, or the identification of the central residues of oligosaccharides containing more than one type of monosaccharide residue. The reaction also constitutes a unique means for effecting a partial degradation of many oligosaccharides. Application may therefore be found, for example, in studies with isotopically-labelled compounds. Thus, the specific activity of the central unit in maltotriose could be determined by treating the compound with lead tetraacetate and isolating by hydrolysis the unoxidized glucose. The observed instances of resistance to oxidation, however, question the practice of using lead tetraacetate to test for glycol groups in partially substituted polysaccharide derivatives. Polysaccharides examined, including glycogen and a water-soluble pentosan, did not consume lead tetraacetate during a reaction period of several days' duration. However, these instances of unreactivity may be attributed chiefly to insolubility of the carbohydrates in acetic acid, for otherwise, by analogy with the oligosaccharides, end-groups of the polymers should be oxidized.

EXPERIMENTAL

The oligosaccharides of the cellobiose, maltose, and xylobiose series were kindly furnished, respectively, by Dr. D. R. Whitaker, Dr. R. L. Whistler, and Dr. C. T. Bishop, who have described the compounds elsewhere (15, 14, 2). Benzyl β-maltoside was prepared by the procedure of Lemieux and Lansdown (8). Lead tetraacetate was prepared according to the procedure recommended by Vogel (13), or was obtained commercially from Matheson, Coleman, and Bell, New Jersey.

Oxidation of Oligosaccharides

Reactions were carried out in duplicate at 28°C. in a constant-volume type of Warburg respirometer as described previously (10, 11) using aqueous acetic acid as solvent (1) to facilitate solution of the carbohydrates. In a typical experiment, one milliliter of 90% acetic acid containing 20 mgm. of lead tetraacetate and 10 mgm. of potassium acetate was placed in the vessel, and 1.24 mgm. of xylotriose, dissolved in 0.2 ml. of 90% acetic acid, was placed in the side-arm. After initial equilibration the reaction was initiated by mixing the two solutions and changes in pressure due to evolved carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

dioxide were noted at desired intervals, the readings being corrected for pressure changes in the respirometer blank. The rate of evolution of carbon dioxide is represented approximately by curve 2 (11, Fig. 4); in six hours' reaction time the rate had become slow and the yield of carbon dioxide corresponded to a value of 2.0 moles of formic acid per mole of xylotriose. The contents of the vessel were transferred to a glass-stoppered flask by washing with 10 ml. of "stopping" solution (3), and the quantity of lead tetraacetate consumed in the reaction was determined by titration with thiosulphate. The difference in titer between the blank and sample was 7.10 ml. of 0.005 *N* thiosulphate corresponding to 5.9 moles of oxidant consumed per mole of xylotriose. Since 2.0 moles of lead tetraacetate were used in converting the formic acid to carbon dioxide the corrected consumption of oxidant was 3.9 moles per mole (Table I).

In a duplicate experiment, at the end of the six-hour period the reaction mixture was treated with 20 mgm. of oxalic acid, dissolved in 0.2 ml. of glacial acetic acid; this simultaneously reduced excess lead tetraacetate and precipitated the divalent lead. An aliquot of the supernatant solution was then used for colorimetric determination of pentose with the orcinol reagent (9). The quantity of pentose formed using xylobiose, oxidized under the same conditions, as blank corresponded to 0.89 moles of xylose per mole of oxidized xylotriose.

The quantity of glucose remaining after oxidation of benzyl maltoside was determined as follows: after the treatment with excess oxalic acid, as above, the acetic acid was distilled and the residue was dissolved in water and heated at 100°C. for 3.5 hr. The hydrolyzate was then analyzed for glucose by quantitative paper chromatography (6); the glucose content of the solution corresponded to 0.96 mole per mole of benzyl maltoside.

ACKNOWLEDGMENTS

The authors express their appreciation to Dr. C. T. Bishop for his kind interest in this work and, in addition, to Dr. R. L. Whistler and Dr. D. R. Whitaker, for providing oligosaccharide samples.

THE PAPILIONACEOUS ALKALOIDS

XXII. PUSILLINE; ITS IDENTITY WITH β-ISOSPARTEINE[1]

By R. Greenhalgh[2] and Léo Marion

ABSTRACT

l-Pusilline is shown to be identical with β-isosparteine by direct comparison of the bases and of their salts. By mild oxidation with mercuric acetate followed by catalytic hydrogenation, pusilline is converted to *d*-sparteine, thus confirming its identity with *l*-β-isosparteine. The sparteine obtained from β-isosparteine derived from lupanoline was *d*-sparteine, and not the *l*-form as reported. Oxidation of β-isosparteine with potassium permanganate gives rise to a hydrated 10,17-dioxo-derivative.

l-Pusilline, first isolated from *Lupinus pusillus*, was described as a completely saturated alkaloid yielding analytical figures in agreement with either $C_{15}H_{26}N_2$ or $C_{15}H_{28}N_2$ (3). Since an imino-methyl determination indicated the presence of one such group, the latter empirical formula was adopted (4). Because of the marked similarity between its properties and those of sparteine, pusilline was tentatively represented as 3-(N′-methyl-2′-piperidyl)-quinolizidine. Of the four possible racemates of this structure, one has been synthesized by Winterfeld, Wald, and Rink (9) and two racemates were synthesized by Šorm (8). These, however, were different from the alkaloid.

Reduction of lupanoline, an isomer of hydroxylupanine (5), with lithium aluminum hydride has been shown by Moore and Marion (6) to produce β-isosparteine which was isolated as a diperchlorate. Recently, Carmack, Douglas, Martin, and Suss (1) have established the identity of the alkaloid spartalupine occurring in *L. sericeus* with β-isosparteine and thus recorded the first natural occurrence of the alkaloid. Spartalupine and pusilline both give rise to monoperchlorates which have the same melting point. It has now been shown that pusilline monoperchlorate can be converted to a diperchlorate having the same melting point as β-isosparteine diperchlorate, and having an X-ray powder pattern identical with that of the latter. A comparison of the infrared absorption spectrum of β-isosparteine (see Fig. 3 in Ref. 2) with that of pusilline revealed that each peak appearing in one was present in the other. Furthermore, mild oxidation of *l*-pusilline with mercuric acetate followed by catalytic hydrogenation gave rise to *d*-sparteine identified by comparison of its infrared absorption spectrum with that of an authentic specimen, and also by comparison of its dipicrate with those of both *l*- and *d*-sparteine. This conversion had already been described as occurring with β-isosparteine[3] (6).

A complex picrate had been obtained from pusilline (4). It has now been

[1]*Manuscript received December 16, 1955.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3894.
[2]*National Research Council of Canada Post-doctorate Fellow.*
[3]*Through an error, Moore and Marion (6) reported that the β-isosparteine obtained from lupanoline gave rise in this conversion to l-sparteine. This should read d-sparteine. The dipicrate melted at 209° and the melting point was not depressed on admixture with d-sparteine dipicrate; it melted at 203–204° when mixed with l-sparteine dipicrate. It had* $[\alpha]_D$ *+22 (c = 0.09 in methanol). An authentic sample of d-sparteine dipicrate had* $[\alpha]_D$ *+24.5 (c = 0.092 in methanol).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

shown that pusilline also forms a dipicrate identical with that prepared from β-isosparteine by Dr. Carmack who kindly sent us a specimen. The previously reported analytical determination of an N-methyl group was spurious since repeated determinations with pusilline and pusilline monoperchlorate gave negative results so long as *freshly distilled* hydriodic acid was used.

It has been previously reported by Moore and Marion (6) that the oxidation of β-isosparteine with potassium ferricyanide gives rise to oxo-β-isosparteine ($C_{15}H_{24}ON_2$), which by mercuric acetate oxidation followed by catalytic hydrogenation is converted to 17-oxo-sparteine. If, on the other hand, pusilline was oxidized with potassium permanganate it gave rise to a dioxo-compound which was neutral, and therefore a dilactam. It gave analytical figures in agreement with the formula $C_{15}H_{24}O_3N_2$. Its infrared absorption spectrum showed strong absorption in the region indicative of lactam carbonyls, and also a band in the hydroxyl region. When this compound was distilled *in vacuo* and crystallized from hexane it yielded two forms of crystals which were separated by hand. The first was the hydrate of a dioxo-compound ($C_{15}H_{22}O_2N_2.H_2O$) and the second the anhydrous product. An attempt to hydrogenate the dioxo-hydrate in acid solution over Adams' catalyst at room temperature proved unsuccessful, and this would seem to indicate a 10,17-dioxo structure, particularly in view of the potassium ferricyanide oxidation product.[4]

It can therefore be concluded unequivocally that *l*-pusilline and *l*-β-isosparteine are identical.

EXPERIMENTAL

Pusilline isolated from *L. pusillus* (3) consisted of a colorless oil, b.p. 110–115° at 4 mm., $[\alpha]_D^{32}$ −15.3° (*c*, 2.3 in abs. ethanol). It formed a monoperchlorate, m.p. 216°; a dihydrochloride, m.p. 270–273°; a monohydrochloride hydrate, m.p. 88–90°, resolidified and melted again at 235.5–236.5°; a monohydriodide, m.p. 252.5°; and a complex picrate, m.p. 183.5–185.5° (4).

Conversion of l-Pusilline to d-Sparteine

A small quantity of pusilline in 5% aqueous acetic acid was oxidized with an excess of mercuric acetate according to the usual procedure (6), and the dehydro-base was hydrogenated over Adams' catalyst in acid solution. The base thus obtained was distilled *in vacuo*; its infrared absorption spectrum was superimposable on that of *d*-sparteine. The base formed a dipicrate, m.p. 207–208°, either alone or in admixture with an authentic sample of *d*-sparteine dipicrate. Calc. for $C_{15}H_{26}N_2.2C_6H_3O_7N_3$: C, 46.82; H, 4.66. Found: C, 46.91; H, 4.88%. In admixture with *l*-sparteine dipicrate it melted at 202–203°.

Pusilline Diperchlorate

A quantity of the monoperchlorate of pusilline was dissolved in methanol and the solution neutralized to Congo red with perchloric acid. On standing,

[4]*Dr. Carmack informs us that he has established that the derivative so obtained from β-isosparteine is 10,17-dioxo-β-isosparteine, by comparison with one of the dl-dioxo-intermediates obtained in Sorm and Keil's synthesis (7) of sparteine. A sample kindly supplied by Dr. Carmack did not depress the melting point of our product on admixture.*

the liquor slowly deposited the diperchlorate. It was recrystallized from boiling methanol from which it separated as small, stout, colorless prisms, m.p. 247–249° (dec.), when immersed at 195°. In admixture with authentic *l*-β-isosparteine diperchlorate (6), m.p. 246–248°. The X-ray powder patterns of the two diperchlorates were identical.

Pusilline Dipicrate

Freshly distilled pusilline (15 mgm.) was dissolved in methanol and added to a methanolic solution of picric acid (30 mgm.). The resulting liquor was concentrated on the steam-bath and allowed to cool. It deposited a crystalline picrate which, after recrystallization from methanol, melted at 132–133°. The melting point was not depressed by admixture with a sample of β-isosparteine dipicrate kindly supplied by Dr. M. Carmack.

Oxidation of Pusilline (β-Isosparteine)

A quantity of pusilline in aqueous medium was oxidized with finely powdered permanganate. The addition of permanganate was stopped when the color was retained by the solution for several hours. The precipitated manganese dioxide was filtered, washed with water, and then with chloroform. The filtrate was extracted repeatedly with chloroform and the extract evaporated to dryness. There was left a crystalline product, m.p. 163–165°, which distilled at 90–110° at 0.04 mm. to a hygroscopic, opaque glass. On recrystallizing from hexane this product gave two forms of crystals which were separated by hand. One form consisted of long colorless needles, m.p. 170–171°, which was not depressed in admixture with a sample of dioxo-spartalupine (dioxo-β-isosparteine) hydrate kindly supplied by Dr. M. Carmack. Calc. for $C_{15}H_{22}O_2N_2.H_2O$: C, 64.26; H, 8.63; N, 9.99. Found: C, 64.55; H, 8.52; N, 10.21%. The other forms of crystals consisted of very small clusters, m.p. 154–155°, which gave a large depression when mixed with the substance melting at 170–171°. The analysis of this substance was not too satisfactory. Whereas the hydrogen and oxygen results showed good agreement with the figures required for the anhydrous compound, carbon was somewhat high.

ACKNOWLEDGMENTS

We wish to acknowledge our indebtedness to Dr. Maria Przybylska for the X-ray powder patterns and to Mr. R. Lauzon for the infrared spectra; also to Dr. Marvin Carmack for his courtesy in giving us samples of β-isosparteine dipicrate and dioxo-β-isosparteine hydrate.

COMPOSITION OF DELPHINIUM SEED OIL[1]

By Mary J. Chisholm and C. Y. Hopkins

ABSTRACT

The fatty oil of delphinium seed (*Delphinium hybridum* (Hort.)) was examined. Fresh seed gave an oil composed mainly of glycerides but having 2.8% of free fatty acids. The oil from older seed contained about 50% of free fatty acids, apparently as a result of lipase action in the seed. The total fatty acids were found to include *cis*-11-eicosenoic acid (18%) and eicosadienoic acid (1%), the latter identified as tetrahydroxyeicosanoic acid. Other acids that were identified and the estimated percentages were: 9-hexadecenoic <1, palmitic 4, linoleic 16, oleic 53, and stearic 1. Spectroscopic analysis indicated a content of 2.5% of octadecatrienoic acid. Eicosoic acids have not been observed previously in the seed oils of this plant family (Ranunculaceae).

INTRODUCTION

The seeds of various plants of the Ranunculaceae have been observed to contain from 20 to 40% of fatty oil and to have a high lipase activity. Little is known of the composition of the oils. The constants of oils from *Delphinium* species have been recorded by Markwood (9, 10), Ivanov (8), and Hunter (7). One species, *Delphinium staphisagria*, has been studied further by Nath (11) who identified several of the fatty acids of the oil.

In the present work, the fatty acids of *Delphinium hybridum* (Hort.) have been studied in a quantitative manner and some attention has been given to the action of the lipase.

EXPERIMENTAL

Properties of the Oil

The seed examined in the main part of the work (Sample 1) was that of the cultivated delphinium, described as *D. hybridum* (Hort.). It was obtained from a commercial seed house and remained in storage for four years under dry conditions before the oil was extracted. On extraction with petroleum ether the seed yielded 36.1% of oil (basis 10% moisture). Constants of the oil are shown in Table I.

TABLE I

Properties of oil of *D. hybridum* (Hort.), Sample 1

Iodine value	101	Glycerol yield, %	5.0
Saponification value	194	Acetyl value	24.8
Unsaponifiable matter, %	1.0	Acetyl value of methyl esters	6.5
Acid value	100	Peroxide value (iodide method)	3.5
Free acid as oleic, %	50.3		

The high content of free fatty acid, considered to be the result of lipase action in the seed, is accompanied by a low glycerol yield, since glycerol liberated in the seed is known to disappear rapidly. The acetyl value is unusually

[1]*Manuscript received December 27, 1955.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3883. Presented at the Annual Conference of the Chemical Institute of Canada on May 30, 1955.

high, probably because of the presence of partially hydrolyzed glycerides. It is reduced considerably when the glycerides are converted to methyl esters.

Seed of another strain of *D. hybridum* (Sample 2) was examined within a few months of harvesting. It yielded 25.7% of oil having iodine value 123 and acetyl value 4.7. This oil gave a glycerol yield of 9.7%. The acid value was 5.5, corresponding to 2.8% of free fatty acid. Evidently lipolysis had progressed to only a slight extent.

Seed of *Delphinium ajacis* (Sample 3) had 39.9% oil of iodine value 95 and acid value 72.1, corresponding to 36.3% of free fatty acid. This seed was more than one year old.

A portion of Sample 1 was saponified and the total fatty acids were freed from unsaponifiable matter. Their ultraviolet absorption, before and after

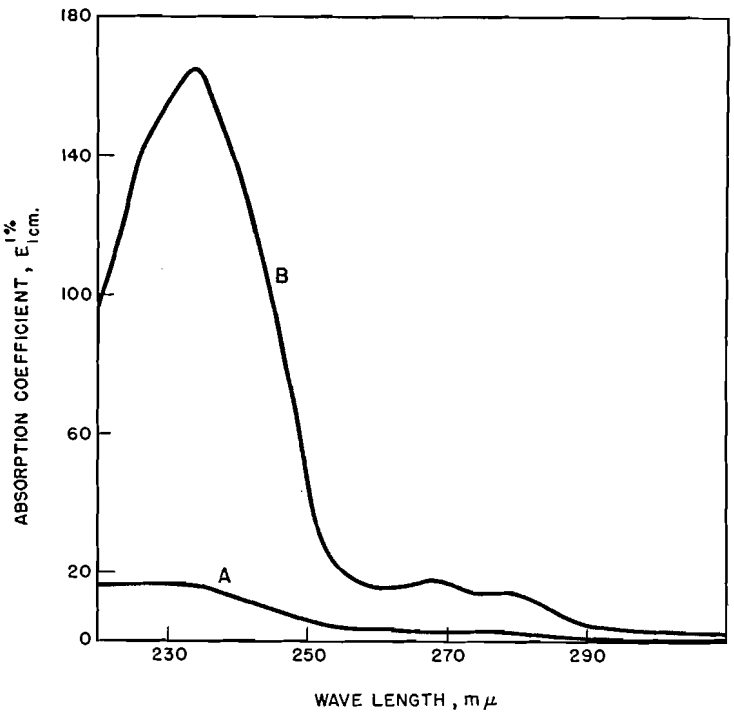

FIG. 1. Ultraviolet spectrum of delphinium fatty acids freed from unsaponifiable matter. *A*, before isomerization; *B*, after isomerization (in glycerol 45 min. at 180°).

alkali isomerization, is shown in Fig. 1. The absorption coefficients ($E^{1\%}_{1\,cm.}$) after isomerization were 164.5 at 233 mμ and 18.1 at 268 mμ, indicating a content of 15.9% of dienoic acid(s) and 2.5% of trienoic acid(s), calculated as octadecoic acids. The calculation is based on absorption coefficients for natural *cis* acids.

Examination of the Methyl Esters

The oil (Sample 1) was converted to methyl esters by methanolysis with acid catalyst (6). The esters (300 gm.) were distilled through a Podbelniak

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

Heli-Grid column at a pressure of 0.4 mm., and the residue was transferred to a smaller flask and distilled through a spinning band column. The distillation curve is shown in Fig. 2. It indicates an appreciable content of C_{20} esters. A further lot of esters was hydrogenated and distilled, giving a curve almost identical with the one for the original esters.

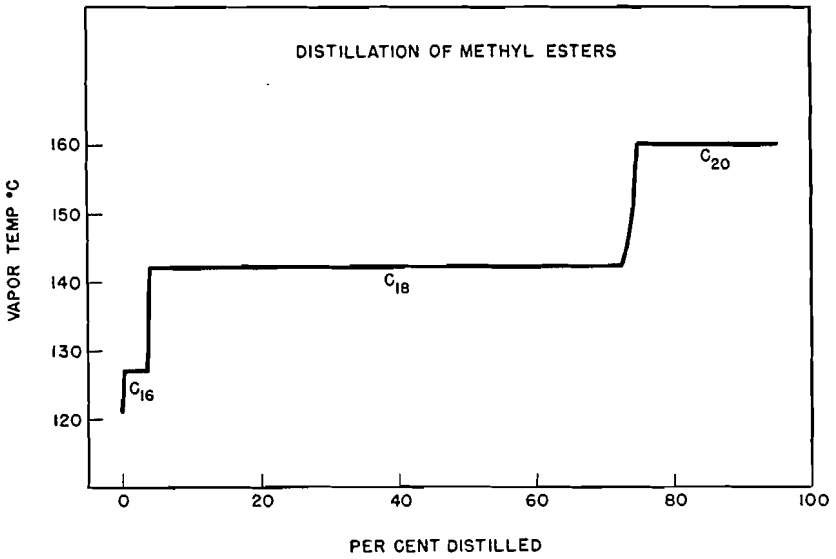

FIG. 2. Distillation of methyl esters.

Distillation data for one lot of the original methyl esters are given in Table II. The distilled fractions were examined individually by the methods

TABLE II

DISTILLATION OF METHYL ESTERS

Fraction	Temp., ° C. (0.4 mm.)	Weight, gm.	Chain length	Iodine value	Refractive index, 25°
1	120–127	1.1		20.3	—
2	127	10.0	C_{16}	6.4	Solid
3	142			116.7	1.4541
4	142	206.0	C_{18}	103.4	1.4528
5	142			95.1	1.4519
6	142–151	4.4		60.9	Solid
7	151–160	1.8		91.4	1.4585
8	160	26.7	C_{20}	81.2	1.4535
9	160	22.9	C_{20}	77.4	1.4529
R	–	17.0			

described previously (3) and the component acids were identified as shown in Table III. Identity of the products was confirmed by mixed melting point except in the case of tetrahydroxyeicosanoic acid, which has not been prepared previously.

TABLE III

IDENTIFICATION OF ACIDS

Fraction	Acid	Identified as:	Melting point, °C.
1	9-Hexadecenoic	9,10-Dihydroxypalmitic	123.5–124.5
2	Palmitic	Palmitic	62.5– 63
3	Linoleic	Tetrahydroxystearic	172 –173
	Oleic	Dihydroxystearic	129 –130
6	Stearic	Stearic	69 – 70
8	Eicosadienoic	Tetrahydroxyeicosanoic	172 –173
8	11-Eicosenoic	11,12-Dihydroxyeicosanoic	129.5–130.5
9	11-Eicosenoic	11-Eicosenoic N-hydroxyamide	69 – 70

Examination of C_{20} Fractions

Fractions 7 and 8 were found by ultraviolet absorption to contain some diene acid. Fraction 8 was recrystallized from acetone at −45°, giving 22.9 gm. of methyl eicosenoate, iodine value 77.9 (theory 78.2). After saponification and hydroxylation by permanganate, it yielded dihydroxyeicosanoic acid, m.p. 129.5–130.5°. The melting point was not depressed by mixing with authentic 11,12-dihydroxyeicosanoic acid.

The acetone filtrate from the recrystallization of Fraction 8 gave 2.8 gm. of methyl esters of iodine value 102.6, evidently containing the dienoic acid. After saponifying, hydroxylating with permanganate, and boiling the product with ethyl acetate to dissolve dihydroxy acids, the residue was recrystallized from ethanol. It melted at 172–173°. When mixed with tetrahydroxystearic acid of m.p. 172–173°, the melting point was lowered to 162–164°. Accordingly the substance is considered to be tetrahydroxyeicosanoic acid. Calc. for $C_{20}H_{40}O_6$: C, 63.79; H, 10.70. Found: C, 63.99; H, 10.74. Its infrared spectrum is consistent with this structure. The spectrum, determined in Nujol mull, is very similar to but not identical with that of 9,10,12,13-tetrahydroxystearic acid of m.p. 144° (R. N. Jones, to be published).

Fraction 9 was almost pure methyl eicosenoate. Its infrared spectrum showed no peak at 965 cm.$^{-1}$ and accordingly it is judged to be the *cis* form. The molar extinction coefficient ϵ at 965 cm.$^{-1}$ was 12.0 (methyl oleate 12.2).

The C_{20} fraction from the distillation of the hydrogenated esters was pure methyl arachidate, m.p. 45–46°. The small distillation residue was saponified. The acids had equivalent weight 318.9 (arachidic acid, 312.5), indicating that there is a small proportion of acid of greater chain length than C_{20}.

Percentage Composition

Distillation of the hydrogenated esters and examination of the residue gave the following percentages by chain length: C_{16} 5, C_{18} 70, C_{20} 19, C_{22} 1, loss and unidentified residue 5.

Estimation of the fatty acid composition from the entire data, including only those acids actually identified, gives the percentages shown in Table IV (in the order in which the esters distill).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12

TABLE IV

ESTIMATED FATTY ACID COMPOSITION (% OF TOTAL FATTY ACIDS)

Acid	%	Acid	%
9-Hexadecenoic	< 1	Stearic	1
Palmitic	4	Eicosadienoic	1
Linoleic	16	11-Eicosenoic	18
Oleic	53	Undetermined	6

The undetermined portion includes about 2.5% of trienes, as indicated by the spectrometric data, mainly in the C_{18} range. There was also some distillation loss and some unidentified material in the residue.

Glyceryl Residue and Lipase Activity

A sample of oil from seed sample 1 was saponified and the fatty acids were removed. The aqueous residue was concentrated and treated with benzoyl chloride. It yielded glycerol tribenzoate, m.p. 71–72° alone and mixed with an authentic sample. Oil from fresh seed was analyzed for glycerol by the method of Colson (4). It gave a glycerol yield of 9.7%.

The free fatty acids were extracted from the oil of Sample 1 and compared with the acids of the remaining glycerides to determine whether the enzyme acts preferentially with respect to type of acid. The free acids were 2 units lower in equivalent weight and 4 units lower in iodine value but it is doubtful whether these differences are sufficient to show any specificity.

There was no appreciable change in acid value during storage of the oil. Evidently the enzyme is destroyed or separated from the oil during the solvent extraction process.

DISCUSSION

The oil examined in this work is unusual in having a considerable content of eicosenoic acid (18%) but only a small amount of acids higher than C_{20}. Two studies of the composition of Ranunculaceae seed oils have been reported by earlier workers. *Nigella sativa* oil was found to contain palmitic, stearic, oleic, and linoleic acids (12). *Delphinium staphisagria* oil was reported by Nath (11) to contain oleic, elaidic, and linoleic acids. Thus there has been no previous record of C_{20} fatty acids in this plant family.

The eicosenoic acid isolated in the present work is the ordinary Δ^{11} isomer. It is now known to occur in appreciable amounts in one or more species of the following plant families: Crucifereae, Buxaceae, Tropaeolaceae, and Ranunculaceae.

The occurrence of eicosadienoic acid, $C_{20}H_{36}O_2$, in animal fats and phospholipids has already been established by several workers. It is considered to be of importance in nutrition. Some evidence of its presence in vegetable fats had been noted when determining unsaturation of C_{20} fractions by iodine values and ultraviolet absorption (1, 5). Until now, however, it does not appear to have been definitely identified as a constituent of a vegetable fat. The amount in the delphinium oil is about 1%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

D. ajacis seed was shown by Bamann and Ullmann to contain a highly active lipase which was more than twice as effective as *Ricinus* lipase (2). It is considered probable that this enzyme is responsible for the unusually high free fatty acid content found in the oil of *D. ajacis* in the present work. The oils of *D. hybridum* (present work), *D. consolida* (9), and *D. staphisagria* (10) have shown similar high acid values, equivalent to 45% or more of free fatty acids.

It may be pointed out that delphinium seed oil ordinarily contains a small percentage of alkaloids.

ACKNOWLEDGMENTS

The authors are indebted to Mr. R. Lauzon and Dr. R. N. Jones for the determination of the infrared spectra.

DECOMPOSITION OF SODIUM HYPOCHLORITE: THE UNCATALYZED REACTION[1]

By M. W. Lister

ABSTRACT

The decomposition of sodium hypochlorite has been re-examined. The results show that Foerster and Dolch's mechanism of the decomposition to chlorate and chloride is correct; they postulated a slow bimolecular reaction to chlorite and chloride, followed by a faster reaction of chlorite with more hypochlorite. Values of the rate constants of both steps are reported; they make the activation energies 24.8 kcal./gm-molecule for the first step and 20.8 kcal./gm-molecule for the second. The rates are such that at 40° C. a solution of sodium hypochlorite will contain about 1% as much chlorite as hypochlorite. The rate is strongly affected by changing ionic strength; at low ionic strengths it is nearly constant or falls slightly; above about 0.8, the rate rises and at high ionic strengths the rise is quite rapid. No signs of specific catalytic effects of sodium chloride, hydroxide, or carbonate could be observed, and it seems probable that earlier reports of this were due to variations in ionic strength. The decomposition to chloride and oxygen has been measured and is a unimolecular reaction, which is possibly, but not certainly, uncatalyzed. Values of its rate constant are reported; they also are much altered by changing the ionic strength.

Although this reaction was first investigated a considerable number of years ago, there are several matters connected with it that are still not entirely clear. Briefly, the position seems to be this. The best early work on the subject was that of Foerster and his co-workers, particularly Foerster and Dolch (2). They found it to be a second order reaction, and consequently deduced that the mechanism was:

$$2NaOCl \rightarrow NaClO_2 + NaCl$$
$$NaOCl + NaClO_2 \rightarrow NaClO_3 + NaCl\,.$$

The first step is the slower. They showed by an independent experiment that the second step was indeed faster, and their rate constants gave activation energies of $22\frac{1}{2}$ and $20\frac{1}{2}$ kcal./gm-molecule for the first and second step respectively. In addition to the reactions given above it has long been known that decomposition to sodium chloride and oxygen also occurs. Foerster and Dolch's rates are the total reaction rates, though they knew that the reaction to chlorate was very much the more important. They also found that the rate increased as they added sodium hydroxide. Later Giordani (3) investigated the reaction, and concluded that it was a combination of a termolecular reaction giving chlorate, and a bimolecular reaction giving oxygen. He also found a marked effect of sodium hydroxide, but in the opposite direction from that found by Foerster; and, at least from about 0.5 to 1.0 *M* sodium hydroxide, obtained rate constants proportional to $(NaOH)^{-2}$. He therefore assumed that hypochlorous acid was essential to the reaction, and that it went in one step, as follows:

$$OCl^- + 2HOCl \rightarrow ClO_3^- + 2HCl\,.$$

He proposed that the reaction to oxygen was

$$2OCl^- \rightarrow 2Cl^- + O_2\,.$$

Skrabal and Skrabal (6) examined the dependence of rate on pH, and agreed with Foerster (and Giordani) that the rate was second order at high pH. Pierron (5) examined the relative stability of lithium, sodium, and potassium hypochlorites. He seemed to favor Giordani's mechanism, but supposed that alkali metal peroxides were formed in the alkaline solutions, and that these promoted the reaction. Barredo (1) examined the reaction and found it to be second order; but he also found the rate to be altered by addition of chloride, and over a certain range the rate was proportional to the chloride concentration. He believed that this explained Giordani's results. Such a dependence on chloride concentration would of course make the reaction autocatalytic. The present author (4) has examined the rate of decomposition of neutral or slightly acid hypochlorite solutions, and found that under these conditions the main decomposition was of hypochlorous acid molecules, by a second order reaction. It can be calculated from these results (combined with those in the present paper) that once quite a small excess of sodium hydroxide is present, the concentration of hypochlorous acid is so slow as to make only a negligible contribution to the total decomposition.

It seemed possible that these reported effects of sodium hydroxide and chloride might really be due to changes in the ionic strength. In earlier work the ionic strength was not always kept constant from run to run; and it is not always possible in re-examining the data to deduce what the ionic strength really was. Accordingly the effect of ionic strength on the rate of reaction was examined in the present work. Foerster and Dolch's results seemed to establish that the reaction was second order; however, in view of contradictory later results, this point was checked.

Sodium hypochlorite decomposes both to chlorate and chloride, and to oxygen and chloride. The relation between these reactions was by no means clear, and the oxygen evolution had been relatively little investigated. Hence in the present work the two reactions were measured, so that their kinetics could be determined separately. Since the reaction to oxygen is strongly catalyzed by certain metallic oxides, notably copper or nickel oxides, there has always been some doubt that there really is any appreciable uncatalyzed evolution of oxygen. Hence in the present work, an attempt was made to be sure that the oxygen evolution was not catalyzed; and to find the order of this reaction, and the effect on the rate of varying temperatures or ionic strength.

MATERIALS AND EXPERIMENTAL METHODS

Sodium Hypochlorite

This was produced in solution by the usual method of passing chlorine through cold sodium hydroxide solution. The product always contained a small excess of sodium hydroxide to avoid hydrolysis to hypochlorous acid. The chief uncertainty with these solutions was that they might contain traces of metallic oxide which could act as a catalyst. Such impurities could easily be present in any commercial sample of sodium hydroxide to an extent that would be undesirable, and it would be very difficult to measure how much

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

was present accurately enough to allow for its catalytic effect. It was found however that if nickel or copper salts were added to the hypochlorite solution, they could be removed by the following procedure. A small amount of calcium chloride was added, and then enough aqueous sodium carbonate to precipitate all the calcium. The calcium carbonate was filtered off by a sintered glass disk. It was found that if this procedure was repeated four or five times, the rate of gas evolution fell rapidly to a constant low value; further precipitations did not reduce the rate any more. Presumably this procedure removed the copper or nickel salts by coprecipitation with the calcium carbonate. The fact that a final slow rate was reached is some evidence that this was the rate of the uncatalyzed reaction. It was checked that calcium carbonate did not affect the rate; nor did pyrex glass, since the same rate was obtained in a polyethylene flask.

Sodium Chlorite

This was the best available commercial material, manufactured by the Mathieson Alkali Works, recrystallized from water. It contained about 0.04% of chlorate, and a trace of chloride.

Sodium Carbonate

The reagent grade of sodium carbonate, manufactured by Merck Chemical Co., was recrystallized from water.

Sodium Chloride

The reagent grade of sodium chloride, manufactured by the General Chemical Co., was recrystallized from water.

Apparatus

The solutions were contained in a 1-liter flask fitted with (i) a mercury sealed stirrer, (ii) a side arm, normally closed, through which samples could be taken, and (iii) a glass capillary tube leading to a water-jacketed gas burette. The flask was immersed in a water thermostat of conventional design, which was found to maintain the temperature over long periods of time to $\pm 0.1°$ C., though the swing during any on–off cycle was only about 0.02° C. The temperature was read on a thermometer graduated to 0.1° C.

The oxygen evolved was measured in a gas burette graduated in 0.1 ml. In practice the volume could be easily read to 0.05 ml. In reducing the observed volumes to N.T.P. it was always assumed that the oxygen was saturated with water vapor at the temperature of the burette. The confining liquid was mercury, but during a run a trace of water usually condensed out of the oxygen, especially in the runs at higher temperature. The pressure of the oxygen was adjusted to atmospheric pressure, as shown by a small mineral oil manometer; the atmospheric pressure was noted to the nearest $\frac{1}{2}$ mm.

Analytical Methods

The solutions were analyzed at various times for sodium chloride, hypochlorite, chlorite, chlorate, hydroxide, and carbonate. The methods were the same as those outlined by the author in a previous paper (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

EXPERIMENTAL PROCEDURE

The general procedure in almost all runs was as follows. A quantity of the stock hypochlorite solution was poured into the reaction flask, the amount added being weighed to the nearest 0.1 gm. Sodium chloride, sodium carbonate, or water (as required) were also weighed out and added. The final volume was always close to 900 ml. When appreciable additions were made to the stock hypochlorite solution, a sample was pipetted out and its density determined; from this the volume of solution could be found, so that the oxygen evolution per liter of solution could be calculated.

The flask was then brought to the right temperature in the thermostat, and at intervals samples were taken for analysis. Between samples the gas evolution was followed by means of the gas burette. It was found that the gas evolution was usually slower at first but built up to a practically constant rate. It is believed that this is due to the building up of a certain degree of supersaturation in the solution, and that eventually the steady rate of gas evolution equals the true reaction rate; it is always the steady rate that is reported in the following data.

The only exceptions to this procedure were in two runs intended to discover whether the pyrex flask catalyzed the reaction. In one of these the flask was filled with pyrex beads, and in the other a polyethylene flask was used. These runs are not reported in detail, but it was found that they gave the same rates as in the ordinary pyrex flask. It was also checked that calcium carbonate, which might be present in traces from the purification process, did not affect the rate. In a few runs sodium chlorite solutions were used, but the general procedure was the same.

EXPERIMENTAL RESULTS

The results for the decomposition of the stock hypochlorite solution at various temperatures are given in Table I. Table II gives various rates of gas evolution. In this table are given data on some runs which were done with filtered hypochlorite solution, but which had not had the complete calcium carbonate treatment. These gas rates are high relative to later runs, so their rate constants for oxygen evolution have little significance; however the data are needed for calculations on the rates of reaction leading to chlorate. It is believed that the rate constants of the reaction to chlorate obtained from these runs are reliable, since (i) it was found that the purification process did not affect the rate of chlorate production, but only that of oxygen, and (ii) it was found (to anticipate results which will be reported later) that catalysts such as copper oxide did not affect the rate of chlorate formation. These runs are also of interest because they show that the rate of gas formation is proportional to the hypochlorite concentration, at least in these solutions; and they throw some light on the activation energy of the (presumably) uncatalyzed reaction to oxygen. Table III shows the effect of ionic strength on the rate constant to chlorate, and Table IV shows the effect of ionic strength on oxygen evolution. Table V gives results on the effect of sodium carbonate, and sodium hydroxide. Table VI gives data on the chlorite–hypochlorite reaction.

DISCUSSION OF RESULTS

It is apparent from these results that the main reaction in the decomposition of sodium hypochlorite is the one to chlorate, and only a small part goes to oxygen. Consequently the over-all kinetics are those of the reaction to chlorate, and the results of Table I fit the equation of a second order reaction: this can be seen from the long run, run 7, or by comparing runs 1 and 4, or 3 and 5. The possibility of catalysis by chloride, or effects of sodium hydroxide, will be considered later when the rate constants have been evaluated. Table II shows that for these runs the reaction to oxygen is first order, though owing to the relatively small amounts of gas evolved the rates are not very accurate. Any comparisons of this sort must be made between runs at the same ionic strength; fortunately the decomposition of hypochlorite does not change the ionic strength during a run.

The mechanism of the reaction is evidently that proposed by Foerster, with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

the addition of the reaction to oxygen. Let the rate constants of the various reactions be k_1, k_2, and k_0 as follows:

$$\begin{aligned} 2NaOCl &\rightarrow NaCl + NaClO_2 && k_1 \\ NaOCl + NaClO_2 &\rightarrow NaCl + NaClO_3 && k_2 \\ NaOCl &\rightarrow NaCl + \tfrac{1}{2}O_2 && k_0 \end{aligned}$$

and let the concentrations be: $(ClO^-) = x$, and $(ClO_2^-) = y$. Then the rate equations are (assuming no effect of chloride):

[i] $$dx/dt = -k_1x^2 - k_2xy - k_0x$$

[ii] $$dy/dt = \tfrac{1}{2}k_1x^2 - k_2xy.$$

These equations are difficult to solve rigorously, but various simplifying assumptions can be made appropriate to the conditions of the reaction. In particular the chlorite concentration is low and changes very little during a run; so approximately $dy/dt = 0$. Equation [i] then becomes:

$$dx/dt = -\tfrac{3}{2}k_1x^2 - k_0x$$

whose solution is most useful in the form:

[iii] $$\frac{1}{x} = \frac{1}{x_0} + \frac{b}{k_0}(e^{k_0 t} - 1)$$

where $x = x_0$ at $t = 0$; and $b = \tfrac{3}{2}k_1 + k_0/x_0$.

To evaluate k_1 it seemed simplest to plot $1/x$ against t, and to determine the slope of the best line through the points. Calling this slope s, we get:

$$s = \frac{1/x - 1/x_0}{t} = \frac{b}{k_0 t}(e^{k_0 t} - 1) = b(1 + \tfrac{1}{2}k_0 t + \tfrac{1}{6}k_0^2 t^2 + \ldots).$$

As $k_0 t$ is always small (never above 0.04), to a good approximation:

$$s = b(1 + \tfrac{1}{2}k_0 t)$$

and

[iv] $$\tfrac{3}{2}k_1 + k_0/x_0 = s(1 + \tfrac{1}{2}k_0 t)^{-1}.$$

k_0 was determined as explained in the next paragraph, and k_1 was then found from equation [iv]. It will be seen that k_1 could also be obtained from the chlorate concentrations, and this was occasionally done, but the hypochlorite analyses are probably the more accurate.

For the determination of k_0, let v be the quantity of oxygen evolved at time t, in units of gm-atoms of oxygen per liter of solution. Then:

$$dv/dt = k_0x.$$

Putting in the value of x from equation [iii], integrating, and since $v = 0$ at $t = 0$, we get:

[v] $$v = \frac{2k_0}{3k_1} \cdot \ln\left[\frac{3k_1x_0}{2k_0}(1 - e^{-k_0 t}) + 1\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

This is awkward to apply, but suppose we take as an approximate value of k_0:

$$[vi] \qquad k_0(\text{approx.}) = \frac{v/t}{\frac{1}{2}(x+x_0)},$$

i.e. the average rate of gas evolution divided by the mean hypochlorite concentration during the measuring period; then from equations [iii] and [v], expanding in powers of t up to t^2:

$$k_0(\text{approx.}) = k_0[1+\tfrac{1}{4}(k_1x_0+\tfrac{2}{3}k_0)(3k_1x_0-k_0/2)t^2] .$$

The term in t^2 gives the error introduced by this approximation for k_0. Using typical figures for 60° C., this term is about $2.5\times10^{-8}t^2$. The gas collection period never ran above 400 min., when the error is about 0.4%. Hence this approximation is sufficiently accurate. The values of k_1 and k_0 given below are from equations [iv] and [vi]. The evaluation of k_2 will be discussed in a later section.

The results in Table II give values of k_0 which are appreciably higher than those obtained for the most carefully purified solutions. Nevertheless these results are of interest as showing that the gas rate is proportional to the hypochlorite concentration (at least for these solutions); and the data are needed in evaluations of k_1. The mean k_0 values for each run are:

Run	1	4	7	2	3	5	
Temp.	40	40	50	50	60	60	° C.
k_0	2.28	2.48	6.95	6.81	19.45	19.4	$\times10^{-6}$ min.$^{-1}$

The average k_0 at each temperature was used in obtaining k_1 for these runs. It is interesting to note that although a trace of impurity must be present, these runs give an apparent activation energy of about 21 kcal./gm-mol., which is considerably higher than for any of the catalyzed reactions that were examined.

The effect of ionic strength can be obtained from Tables III and IV. From the gas rates in Table IV, we get:

Run	9	10	14	15	16	21	17	18	
Ionic strength	5.83	4.84	4.71	3.69	2.76	1.75	1.74	0.59	
k_0 (60° C.)	25.1	19.2	17.6	9.4	5.7	4.2	4.7	5.0	$\times10^{-5}$ min.$^{-1}$

k_0 varies considerably with ionic strength. As will be seen in the next section, a parallel change is also found for k_1. The results in runs 21, 22, and 23 enable k_0 to be found at different temperatures but the same ionic strength. The results are:

Temp.	60	70	75	° C.
k_0	4.2	9.2	16	$\times10^{-6}$ min.$^{-1}$

These make the activation energy about 20 kcal./gm-mol. Rather surprisingly this is lower than from runs 1 to 7, but possibly the difference is due to experimental error, for the actual rates are very small. However the value seems to be about 20 to 21 kcal. It is also surprising that the activation energy seems to be lower than for the reaction to chlorate. This makes it doubtful that we have an uncatalyzed reaction; the catalyst is not pyrex glass, nor cobalt,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

nickel, or copper (which give lower activation energies). However it is impossible to be sure that traces of some unknown catalyst are not present, and there must remain this element of doubt in the interpretation of the results.

The runs in Table I give the k_1 values in Table VII. It will be seen, for instance by comparison of the rate constants of runs 3, 5, and 11, that the

TABLE VII

Run	Temp., ° C.	k_1, min.$^{-1}$(gm-mol./l.)$^{-1}$	(NaCl), *M*		Ionic strength
			Initial	Final	
1	40	1.04 $\times 10^{-5}$	1.80	1.83	3.79
4	40	1.00	2.05	2.08	3.79
2	50	3.54	1.84	1.89	3.79
6	50	3.68	1.84	1.90	3.79
7	50	3.62	1.96	2.28	3.79
3	60	11.46	1.94	2.02	3.79
5	60	11.32	2.09	2.31	3.79
8	60	10.48	2.48	2.61	3.63

purification did not affect k_1; to anticipate results reported in another paper, addition of catalysts such as copper also did not affect k_1. Table VII also gives the sodium chloride concentrations during the runs. All these runs except run 8 were at an ionic strength of 3.79; in run 8 it was 3.63. Hence it is possible to discover whether sodium chloride has a specific catalytic effect, apart from its contribution to the ionic strength. Although the range of concentrations might perhaps have been profitably extended, these runs definitely show that sodium chloride has no effect on k_1, provided the ionic strength remains unchanged. In particular, run 8 gives a value of k_1 perhaps slightly low for this ionic strength, although the sodium chloride concentration is some 25% higher than in run 3. The long runs 5 and 7 show no sign of autocatalysis, although the sodium chloride increased 10–15% during them. Further evidence in support of this contention is provided by the runs with sodium carbonate present. At an ionic strength of 3.79 the mean rate constants are:

Temp.	40	50	60	° C.
k_1	1.02	3.61	11.4	$\times 10^{-5}$ min.$^{-1}$(gm-mol./l.)$^{-1}$

These give a good linear plot of log k_1 against $1/T$, and make the activation energy 24.8 (to the nearest 0.2) kcal./gm-mol. Foerster's constants at 25° and 90° C. give a value close to 26 kcal., but his result at 50° C. does not fall on a straight line with these values in a plot of log k_1 against $1/T$.

Turning now to the effect of ionic strength on k_1, we get from Table III for k_1 at 60° C.:

Run	9	10	14	19	11	15	8	16	12
Ionic strength	5.83	4.84	4.71	4.16	3.79	3.69	3.63	2.76	2.73
k_1	17.4	16.75	15.65	12.1	11.4	11.2	10.5	7.7	7.8

Run	20	17	21	18	13	
Ionic strength	2.61	1.74	1.75	0.59	0.515	
k_1	7.6	5.5	5.4	3.85	4.3	$\times 10^{-5}$ min.$^{-1}$(gm-mol./l.)$^{-1}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

These values give somewhat the same type of trend that might be expected for the activity coefficients of sodium hypochlorite over this range of ionic strengths. The trend in k_0 is somewhat, though not very, similar.

Run 24 makes $k_1 = 1.98 \times 10^{-5}$ min.$^{-1}$(gm-mol./l.)$^{-1}$ at 50° C. and an ionic strength of 2.61. This is proportionally a somewhat larger drop than at 60° C., but not very much. Runs 25 and 26 (Table V) give the effect of adding sodium carbonate; they make k_1 at 50° C.:

Run	25	26	
Ionic strength	4.57	4.25	
k_1	4.25	3.95	$\times 10^{-5}$ min.$^{-1}$(gm-mol./l.)$^{-1}$
(NaCl) initial	1.58	1.99	M

Relative to the more carefully measured rate at an ionic strength of 3.79 these runs show an increase in k_1 which is nearly what might be expected purely from the increase in ionic strength. The increase is perhaps a little less than in the runs when sodium chloride was added: of course specific effects are bound to occur, and one would not expect two different salts to give exactly the same change in k_1 for the same change in ionic strength. This is especially so when the two salts, as here, are not of the same ionic type. Nevertheless the main changes in k_1 do seem to be attributable to the changes in ionic strength.

Runs 21, 22, and 23 enable us to evaluate k_1 at three temperatures at another ionic strength (1.75):

Run	21	22	23	
Temp.	60	70	75	° C.
k_1	5.4	16.0	24.0	$\times 10^{-5}$ min.$^{-1}$(gm-mol./l.)$^{-1}$

The figures at the higher temperatures are rather rough; they give a moderately linear plot of log k_1 against $1/T$, with a slope corresponding to an activation energy of about 24 kcal. The experimental error is too large to say whether there is any real difference between the activation energies at ionic strengths of 3.79 and 1.75.

Table V gives the data at low sodium hydroxide concentrations. The bulk of the runs in this paper were done in the presence of 0.32 M sodium hydroxide. Some of the runs at low sodium hydroxide concentrations have already been considered, and found to fall into line with the other runs (e.g. runs 8 and 21). The k_1 values for various runs which provide evidence on the effect of sodium hydroxide are as follows:

Run	(mean)	27	8	21	17	(mean)	28	
Temp.	60	60	60	60	60	50	50	° C.
Ionic strength	3.79	3.70	3.63	1.75	1.74	3.79	3.73	
(NaOH)	0.32	0.023	0.042	0.057	0.19	0.32	0.275	M
k_1	11.4	10.9	10.5	5.42	5.48	3.60	3.48	

These results show that sodium hydroxide has a negligible effect apart from its contribution to the ionic strength. At very low sodium hydroxide concentrations hydrolysis to hypochlorous acid and its decomposition become important; but the rate of this reaction has been measured (4), and it can be calculated that the sodium hydroxide would have to be close to 0.001 M before this reaction made much difference to the total rate.

Finally the results in Table VI give information on the hypochlorite–chlorite reaction. Firstly runs 29 and 30 show that the decomposition of chlorite by itself is entirely negligible. From the remaining runs k_2 was evaluated as follows. As one molecule of chlorite removes one of hypochlorite, and since this reaction is much faster than the decomposition of hypochlorite (k_1), then approximately:

$$dx/dt = dy/dt = -k_2xy$$

where, as before, x is hypochlorite and y is chlorite. The solution of this equation is:

[vii] $$\frac{\ln (x-c)x_0}{xy_0} = \frac{\ln\ yx_0}{y_0(y+c)} = -ck_2t$$

where $c = x_0-y_0$. In reactions of this sort k_2 is normally obtained from this equation, but in the present case a small correction has to be applied for the decomposition of the hypochlorite, which is slow but not negligible in comparison. It therefore seemed simpler to take an approximate value of k_2 defined by

$$k_2(\text{approx.}) = \text{corrected rate}/(\text{mean } x)(\text{mean } y)\ .$$

By "corrected rate" is meant dx/dt between any two successive readings minus the part of the rate due to decomposition of hypochlorite, which can be calculated from k_1. If the values of x and y from equation [vii] are substituted in this expression, and the exponentials expanded in powers of t, we get:

[viii] $$k_2(\text{approx.}) = k_2[1-(x_0^2+x_0y_0+y_0^2)(k_2^2t^2/12)+\ \ldots\ ]\ .$$

This gives the error in k_2 in this approximation: in the runs reported it rose to about 1%, but the error could then be allowed for. To examine the validity of our method of allowing for k_1 and k_0, we can subtract equations [i] and [ii] to get:

$$dy/dt-dx/dt = \tfrac{3}{2}k_1x^2+k_0x\ .$$

Substituting the value of x from [vii], integrating, and expanding in powers of t, it is found that the fractional error in k_2 so introduced is:

$$\text{Fractional error} = \frac{(6k_1y_0+3k_1x_0-k_0)}{3k_1x_0+2k_0}\ .\ x_0y_0k_2t.$$

The size of this error was checked for runs 31 to 34, and in no case was above 0.3%. Consequently it was assumed to be adequate to obtain k_2 simply by taking the observed slope of x (or y) over each interval between analyses, correcting for the decomposition of hypochlorite if the slope of x is used, and dividing the slope by the mean x times the mean y over the interval. A small correction was applied in accordance with equation [viii]. The mean values of k_2 for each run were:

Run	31	32	33	34	
Temp.	50	50	45	40	°C.
k_2	2.75	2.77	1.64	0.97	$\times 10^{-3}$ min.$^{-1}$(gm-mol./l.)$^{-1}$

These results give an activation energy of 20.8 kcal. In all these runs the ionic strength was 3.79, and the sodium hydroxide concentration was 0.32 *M*. Foerster's results made the activation energy $20\frac{1}{2}$ kcal., in good agreement. However his constant at 50° C. is about 8.3×10^{-4}, but the difference may be due to a different ionic strength. These values of k_2 mean that a decomposing sodium hypochlorite solution will contain about 1/100 as many chlorite ions as hypochlorite ions at 40° C.; this was roughly found. If the constants k_1 and k_2 are written as $Ae^{-E/RT}$, the A factors are fairly similar:

$$k_1 = 2.1\times10^{12}.e^{-24.8\ \text{kcal.}/RT};\quad k_2 = 3.2\times10^{11}.e^{-20.8\ \text{kcal.}/RT}.$$

To summarize these conclusions, it is believed that these results show that (i) the mechanism of Foerster *et al.* via chlorite is well established; (ii) the first stage to chlorite has an activation energy of 24.8 kcal., and is slower than the second stage, which has an activation energy of 20.8 kcal.; (iii) the rates are strongly influenced by the ionic strength; (iv) added sodium hydroxide, carbonate, or chloride changes the rate by changing the ionic strength, but apart from this they exert no specific catalytic effect; and (v) there is a simultaneous unimolecular decomposition to oxygen, which is possibly, but not certainly, uncatalyzed.

DECOMPOSITION OF SODIUM HYPOCHLORITE: THE CATALYZED REACTION[1]

By M. W. Lister

ABSTRACT

The catalyzed decomposition of sodium hypochlorite has been examined; the catalysts tried were manganese, iron, cobalt, nickel, and copper oxides. It was shown that in no case was the decomposition to chlorate and chloride accelerated, only the reaction to chloride and oxygen. Manganese and iron did not catalyze even the latter reaction, or only to a very small extent; this was in fairly concentrated sodium hypochlorite containing some sodium hydroxide. The manganese and iron are largely oxidized to permanganate and ferrate under these conditions. It was found that copper could catalyze the formation of permanganate and ferrate, and nickel the formation of permanganate. Cobalt catalyzed the reaction going to oxygen, and the rate was proportional to the cobalt added, but little dependent on the hypochlorite concentration; the same is true of nickel. Copper (as reported earlier) gives a catalyzed reaction not far from first order in hypochlorite. The activation energies were measured, and were consistent with the relative catalytic activity of these metals. The mechanism of the reaction is briefly discussed.

The decomposition of sodium hypochlorite is catalyzed by the oxides of transition elements such as cobalt. Qualitatively this was first known a long time ago, but quantitative measurements on the catalysis are much more recent. Howell (3) made a careful study of the catalysis by cobalt oxide. He added the cobalt oxide as a fine, almost colloidal, suspension in water, and measured the rate of oxygen evolution from the vigorously stirred mixture. At fairly low catalyst concentrations (about 2 mgm. cobalt in 60 ml. of solution), he found the rate to be proportional to the catalyst and to the hypochlorite concentrations. The activation energy of the catalyzed reaction was 16.6 kcal./gm-mol. Moelwyn-Hughes (10) was able to calculate that Howell's rate constants are fairly near what one would expect if the catalyst were present as particles of 5×10^{-7} cm. diam., and if every collision with a hypochlorite ion with sufficient energy were effective. Chirnoaga made somewhat similar measurements for cobalt and nickel oxides (1). He found the rate to be independent of the stirring speed, provided this was moderately rapid. His rates were not proportional to the hypochlorite concentration: with nickel oxide they were proportional to $(ClO^-)^{0.47}$ at low concentrations (0.02 to 0.04 M). With cobalt oxide the rate was proportional to $(ClO^-)^{0.9}$. The activation energy was 15.8 kcal. for cobalt oxide, and 16.6 kcal. for nickel oxide. Both Howell and Chirnoaga reported that if the catalyst was washed for a long time till all alkali was removed, it was more active. This may be a peptizing effect due to removal of electrolyte. However all the hypochlorite solutions used contained free alkali. Chirnoaga reported that the order of catalytic activity was Ni > Co > Cu > Fe > Mn, although nickel and cobalt might be expected to be in the reverse order from the activation energies.

Dixon and White (2) examined the conversion of Mn(II) to permanganate by hypochlorite, and noted that copper could catalyze this. Lewis (5, 6) examined cobalt, copper, and iron oxides as catalysts. At fairly high concen-

[1]*Manuscript received November 14, 1955.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

trations he found the rate to be independent of the hypochlorite concentration, and it seems difficult to reconcile his results with those of Howell. He was also particularly interested in the effect of adding substances, ordinarily inert, as promoters.

The present author (8) made measurements on the catalysis by copper, during some investigations of the complex copper tellurates and periodates. As these results were obtained under conditions comparable to the measurements reported in this paper, they will be discussed briefly later.

One of the difficulties in interpreting the results of these measurements (either the earlier or the present work) is the uncertainty in the size of the catalytic particles. The apparent gross size is, of course, no certain indication of the true surface area, as pores are probably present. Comparisons with previous rate measurements always contain this element of uncertainty. Consequently the present work was confined to some more limited matters about the reaction. Firstly, although the decomposition to sodium chloride and oxygen is certainly catalyzed, it is not clear whether the decomposition to sodium chloride and chlorate is similarly catalyzed. Secondly, it has sometimes been suggested that qualitatively the mechanism of catalysis is through unstable higher oxides, which are formed, decompose, and are reformed by further oxidation, and so on. However manganese and iron do not have such unstable higher oxides, so their degree of catalytic activity was investigated. Thirdly, the energies of activation of all the catalyzed reactions were measured again. Finally, some further evidence on the dependence on hypochlorite concentration was obtained, which supports Lewis's views at least over a certain range of conditions; but there are several factors which can affect the rate, and a complete study of the matter would require a great many experiments.

EXPERIMENTAL METHOD

The materials used were the same as in the previous paper, with the addition of the salts of various metals used as catalysts. Reagent grade samples of manganese chloride, ferric nitrate, cobalt chloride, nickel chloride, and copper chloride were used. Stock solutions of these salts were made up, and various amounts were pipetted out, and added to well-stirred alkaline sodium hypochlorite. Precipitates of the oxides immediately formed, except with copper. These precipitates were finely divided, but not colloidal; as far as possible the conditions of addition were the same each time. The solutions were then brought to the desired temperature in a thermostat, with continual stirring, and the rate of gas evolution was measured. Samples were taken for analysis from time to time. The apparatus was the same as described in the first paper on the uncatalyzed reaction (9). The analytical methods have been described in another previous paper (7).

The sodium hypochlorite was the same as in the investigation of the uncatalyzed reaction; its ionic strength was 3.79, and it was 0.32 M in sodium hydroxide.

EXPERIMENTAL RESULTS AND CONCLUSIONS

Before describing the quantitative runs, a few qualitative observations might be included. Dixon and White (2) observed that copper catalyzed the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

formation of permanganate. Manganese dioxide is, of course, first formed, starting with Mn(II); and even without copper, permanganate is formed slowly at room temperature. It was noticed that nickel also catalyzed the formation of permanganate, though less efficiently than copper. Sodium chlorite does not oxidize Mn(II) beyond manganese dioxide.

Iron is similarly slowly oxidized to ferrate in the cold, and quite rapidly at 80° C.; as would be expected the reaction goes faster in strongly alkaline solution. Although the ferrate is unstable on boiling, it decomposes only very slowly at 60° C. Copper also accelerates the formation of ferrate, but nickel seems to be unable to do this. The qualitative behavior of copper was described in the paper mentioned earlier (8). As is well known, cobalt and nickel are oxidized to higher oxides by sodium hypochlorite, which are almost completely insoluble in the alkaline solution. Sodium chlorite will not accomplish any of these oxidations.

In the quantitative runs, it is probably simplest to consider each element separately; the results will be given and any conclusions drawn from them before going on to the next element.

Manganese

The data on manganese as a catalyst are given in Table I. The conclusion that must be drawn from these results is that manganese does not catalyze

TABLE I

Run	Temp., ° C.	Mn added, mgm.	Solution volume, ml.	Time, min.	(ClO^-), M	(ClO_2^-), M	(ClO_3^-), M
1	50	3.32	796	0	1.285	0.009	0.122
				286	1.261	0.008	0.128
2	60	3.32	786	0	1.240	—	—
				278	1.171		

Run	Temp., ° C.	Mean (ClO^-), M	Gas rate, ml. N.T.P./min. per liter soln.
1	50	1.273	0.0568
2	60	1.21	0.145

the reaction at all. If we use the same equation that was applied to the uncatalyzed runs (9),

$$-dx/dt = \tfrac{3}{2}k_1x^2+k_0x,$$

where $x = (ClO^-)$,

k_1 = rate constant for first stage of reaction to chlorate,

k_0 = rate constant for reaction to oxygen,

then the results above give for the constants:

Temp.	50	60 ° C.
k_0	4.0	10.7×10^{-6} min.$^{-1}$
k_1	3.25	10.75×10^{-5} (gm-mol./l.)$^{-1}$ min.$^{-1}$

By "reaction to chlorate" is meant the reaction

$$3OCl^- \rightarrow ClO_3^- + 2Cl^-$$

of which the first step is

$$2OCl^- \rightarrow ClO_2^- + Cl^-.$$

This is the slow rate determining step, and k_1 is its rate constant. By "reaction to oxygen" is meant the reaction

$$2OCl^- \rightarrow 2Cl^- + O_2.$$

This was found to be a first order reaction, and k_0 is its rate constant. These reactions are the ones meant in all references in later sections to "reaction to chlorate" or "reaction to oxygen".

The ionic strength of the solution after addition of catalyst was 3.78. The k_0 values are just about right for this ionic strength, and make the energy of activation 21 kcal., in agreement with results obtained earlier. The k_1 values are a little low, but certainly show that manganese does not catalyze the reaction under these conditions. The reason for the difference between these results and those of Chirnoaga probably lies in the higher concentration and sodium hydroxide content of the present solutions. Chirnoaga's sodium hypochlorite was only 0.042 *M*, and his manganese dioxide was 0.0061 *M*, so an appreciable fraction of the hypochlorite could be used up in oxidizing the manganese; indeed over half of the decomposition that he observed could be explained in this way. However the present results do show that manganese is not catalytic in concentrated solutions of hypochlorite.

Iron

The data on iron as a catalyst are given in Table II. Again we can treat these results by the method for uncatalyzed runs, which gives values for the rate constants as shown below. Values of k_1 from the chlorate analyses are also included, as these help to distinguish the catalytic effect (if any) on the two reactions. It may be added that constants obtained from the chlorate analyses have the advantage of not needing a value of the gas rate for their

TABLE II

Run	Temp., °C.	Fe added, mgm.	Time, min.	(ClO^-), *M*	(ClO_2^-), *M*	(ClO_3^-), *M*

For personal use only.

calculation; but against this must be set the fact that the chlorate concentrations are obtained by the difference of two analyses, one of which does not have a very easily observed end point. The values of the constants are:

Temp.	50	60 ° C.
k_0	5.2	12.0×10^{-6} min.$^{-1}$
k_1	3.59	11.6×10^{-5} (gm-mol./l.)$^{-1}$ min.$^{-1}$
k_1 (from chlorate)	3.70	11.5×10^{-5} (gm-mol./l.)$^{-1}$ min.$^{-1}$

There may be some catalytic effect on the reaction to oxygen, but it is very slight. As compared with, for instance, cobalt, the iron is at most 1/200 times as active as a catalyst. There is no sign of any catalysis of the chlorate reaction: the uncatalyzed rate constants at this ionic strength (3.79) are 3.61×10^{-5} at 50° C., and 11.4×10^{-5} at 60° C. We must add, of course, that these conclusions only apply to the conditions of these experiments; that is to say in fairly high hypochlorite concentrations, moderate alkalinity, and not too high temperatures; but under these conditions iron does not catalyze the chlorate reaction, and it catalyzes the oxygen reaction very slightly, if at all.

Cobalt

The data obtained are given in Table III. Cobalt, of course, catalyzes the oxygen reaction, but its effect on the chlorate reaction is not so obvious. The rigorous determination of k_1 from these data is not easy because of the high

gas rate. However a reasonable approximation can be obtained by observing the total rate of decomposition between any two analyses; we then put:

$$\text{total rate} = \text{rate to oxygen} + \text{rate to chlorate}$$

and:

$$\text{rate to chlorate} = \tfrac{3}{2}k_1\bar{x}^2$$

where $\bar{x}$ is now the mean hypochlorite concentration between the two analyses. Hence k_1 can be calculated. The error from taking this approximate equation, and not an integrated equation, is small. This was checked by integrating the above equation for various plausible expressions for the dependence of the rate to oxygen on x; then the approximate k_1 could be expressed in terms of the true k_1 and known quantities such as x or the time. This enables an estimate of the error in the approximate k_1 to be made, and in the actual runs this never exceeded 1%. Although k_1 could have been obtained from these integrated equations, they were rather cumbersome expressions; and it was felt that the approximate equation allowed for the actual observed gas rate in a more direct manner.

Considering first runs 5 and 6, we get the following values of k_1, averaged over the entire run (ionic strength 3.79):

Run	k_1 from ClO^-	k_1 from ClO_3^-
5	3.74 $\times10^{-5}$	3.68 $\times10^{-5}$ (gm-mol./l.)$^{-1}$ min.$^{-1}$
6	3.66	3.61

These values are near enough to the uncatalyzed rate constant (3.61×10^{-5}) to be within the experimental error. Hence cobalt does not catalyze the chlorate reaction to a detectable extent.

If we look at the oxygen reaction, a comparison of runs 5 and 6 shows that at the same hypochlorite concentration, the rate is proportional to the cobalt added. This agrees with all previous work. The dependence on hypochlorite is more obscure, but a few tentative remarks can be made. Firstly, it is difficult to distinguish, during any one run, an 'aging' effect in the catalyst from a dependence of the rate on the hypochlorite concentration. Howell avoided this difficulty in some of his runs by filtering off a catalyst at the end of a run and re-using it; he found its activity had fallen a few per cent. The 'aging' is presumably due to agglomeration of the catalyst particles, thereby reducing their surface area; or to poisoning of the catalyst by impurities. Howell found that typical catalyst poisons had no effect, so probably changes were due to agglomeration. The following observation supports this view. It was found that if a catalyst was used for some time, then left overnight without stirring, and stirring was started next day at a fairly low temperature, then the rate of gas evolution was low (run 9*a* at 30° C.). If the temperature was increased in steps, then the rate rose towards what was found for fresh catalyst, and at 50° C. the catalyst had recovered (runs 9*b*, 9*c*). The simplest explanation is that the vigorous gas evolution at 50° C. had broken up the agglomerated particles. If the temperature was subsequently decreased, the fresh catalyst rate was more or less maintained (compare runs 8*a*, 9*g*), at least for long enough

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

to observe the gas rate. Hence it is impossible to say with any confidence whether the fall in rate during runs 5 and 6 is due to aging of catalyst or fall in (ClO^-). However run 7 does provide some evidence on this, as the two rates in this run were measured on the same solution to which water was added between the measurements. The rate only fell 7% for a decrease in hypochlorite concentration of 45%. Similarly a comparison of runs 5, 8*c*, and 9*c* shows nearly the same rates over a moderate range of concentration. On the whole it seems fair to conclude that, under the conditions of these experiments, the rate is very little dependent on hypochlorite, in agreement with Lewis.

This in no sense contradicts Howell's results for his experimental conditions. The difference does not lie apparently in the concentrations used, which were much the same as in the present work. The difference is probably in the method of preparation of his catalyst: per milligram his catalyst was about three times as active as that in Lewis's or the present work. Even so the degree of difference seems surprising, and the matter cannot be regarded as settled.

Runs 8 and 9 give the temperature dependence of the rate; they make the energy of activation 15.9 (±0.5) kcal./gm-mol. This is to be compared with 15.8 kcal. found by Chirnoaga, 16.6 kcal. by Howell, and (in effect) 13.3 kcal. by Lewis.

Nickel

The data on nickel are given in Table IV. The first point to settle is whether nickel catalyzes the chlorate reaction. If we calculate the rate constant, k_1, as for cobalt, the result is:

Run	Temp., ° C.	k_1 from ClO^-	k_1 from ClO_3^-
10	40	1.35 $\times 10^{-5}$	1.29 $\times 10^{-5}$ (gm-mol./l.)$^{-1}$ min.$^{-1}$
11	50	3.52	3.62
12	60	10.5	13.0

The experimental error at 40° C. is fairly large, as an error of 0.001 in the hypochlorite concentration would alter k_1 by nearly $2\frac{1}{2}\%$. However it seems possible to conclude that within the experimental error, nickel does not catalyze the chlorate reaction. Runs 11 and 13 show that the rate is proportional to the nickel added, in agreement with all previous work.

The dependence of the catalyzed rate on hypochlorite concentration is best seen from runs 11, 12, and 14. Over the range of concentrations examined (0.81 to 1.23 *M*) there was no observable change in the catalyzed rate with hypochlorite concentration. Again this does not mean that under other conditions such a dependence might not be found. Chirnoaga found the rate to be proportional to $(ClO^-)^{0.47}$, at low concentrations; this is a lesser degree of dependence on concentration than he found with cobalt.

The mean gas rates at about 1 *M* hypochlorite, with 3.39 mgm. of nickel, at various temperatures are:

Temp.	40	50	60	° C.
Gas rate	0.50	1.17	2.64	ml./min.

These make the activation energy 17.2 kcal./gm-mol. A little (about 4%) of the total rate can be attributed to the uncatalyzed reaction, and if allowance is made for this, the activation energy is reduced to 17.1 kcal.

Copper

In another paper (8), the writer has given details of the effect of copper as a catalyst. The only point that will be dealt with here is whether copper catalyzes the reaction to chlorate. Table V gives the experimental results. From these results we can calculate k_1, using interpolated values of the rate of oxygen evolution at the appropriate hypochlorite concentration. The values so obtained are:

Run	15	16	17(0–1162′)	17(1162–2921′)	18	19	
k_1 from (ClO^-)	3.88	3.61	3.35	3.65	3.82	3.44	$\times 10^{-5}$
k_1 from (ClO_3^-)	4.08	—	3.82	3.60	—	—	$\times 10^{-5}$

The long run (17) was arbitrarily divided into two parts for this calculation as the range of concentration is large, but similar results would be obtained from other time intervals in this run. The accuracy of k_1, as obtained above, is not very great, as small changes in the analytical results would give relatively large changes in k_1. However it seems reasonably certain from these results that copper does not catalyze the reaction to chlorate.

As mentioned above, the dependence of rate on concentration has been reported by the writer in an earlier paper on another aspect of the chemistry

	0.99	5.33
17	1.05	2.42
	0.81	2.12
	0.71	1.97
	0.44	1.45
18	1.09	2.75
19	0.95	2.25
	0.84	2.00

of copper. Briefly, it was found that the rate could best be represented by an equation of the form:

$$\text{rate} = (\text{Cu})\{a+b(ClO^-)\}$$

where a and b are constants, and b is larger than a. The over-all energy of activation was 15.5 kcal./gm-mol.

GENERAL REMARKS

Comparison of the results with various metals enables us to make a few general comments on these reactions. In the first place, it was found that in no case was the chlorate reaction catalyzed (or only to a very small extent). This suggests that the mechanism of the catalysis is through oxidation of the metal to a higher oxide, which then loses oxygen, and is subsequently re-oxidized, and so on. The inertness of iron and manganese where there is no unstable higher oxide supports this view. Unfortunately, if we calculate the rate of decomposition of the higher oxide which would provide the observed gas evolution, it seems to be impossibly high. For instance in run 5, 5.4×10^{-5} gm-atoms of cobalt gave 2.2×10^{-4} gm-atoms of oxygen per minute. If the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

change is from Co(III) to Co(II), this means that the half life of the oxidized cobalt atom is only 5.2 sec., even if all the Co(II) is instantaneously re-oxidized. As $Co_2O_3.H_2O$(or CoO.OH) is reported (4) to have been isolated, and to be stable on drying at 150° C., the above theory of the reaction seems to be untenable. Similar remarks apply, though with somewhat less force, to nickel and even to copper. Of course, we cannot entirely dismiss the possibility that the reaction is due to some still higher oxide, but this is hypothetical.

The only alternative seems to be that the reaction goes in the stages (M is any catalytic metal):

$$\text{(i)}\quad 2MO + ClO^- \rightarrow M_2O_3 + Cl^-$$
$$\text{(ii)}\quad M_2O_3 + ClO^- \rightarrow M_2O_3.ClO^- \text{ (adsorbed)}$$
$$\text{(iii)}\quad M_2O_3.ClO^- \rightarrow 2MO + Cl^- + O_2$$

This, of course, was realized by earlier workers on the reaction. If the reaction rate is independent of the hypochlorite concentration, then (iii) must be the slow stage, and much the same amount of hypochlorite must be adsorbed in (ii) over a range of concentration. While there is really no direct evidence of this, the simplest picture is one in which the entire catalyst surface is kept covered with adsorbed hypochlorite ions at the rather high concentrations actually used. If the catalyst surface is not completely covered, it is impossible to predict what the reaction kinetics would be without knowing the dependence of adsorption on concentration. Only if the adsorption were proportional to the hypochlorite concentration could we expect a first order reaction; this might happen in dilute solutions. Thus cobalt and nickel, at the concentrations used, behave as though the catalyst were fairly completely covered with adsorbed ions. Copper is entirely, or nearly entirely, in solution; and the reaction, as might be expected, is not far from being first order in both copper and hypochlorite. Manganese and iron do not catalyze the reaction, and this is at least in part attributable to their oxidation to stable states.

It is interesting to compare the rates with the activation energies. At 50° C., 10^{-4} gm-atoms of metal in 1 *M* sodium hypochlorite would give gas rates as follows:

Metal	Co	Ni	Cu	
Rate	4.0	2.0	7.4	ml./min.
Activation energy	15.9	17.1	15.5	kcal./gm-mol.

Thus the rate increases as the activation energy decreases. The rate with nickel seems somewhat large compared with the others, as the activation energy is over 1 kcal. larger.

THE REACTION BETWEEN CYANATE AND HYPOCHLORITE[1]

By M. W. Lister

ABSTRACT

The reaction between sodium hypochlorite and potassium cyanate in the presence of sodium hydroxide has been examined. The main products are chloride, and carbonate ions and nitrogen; but, especially if much hypochlorite is present, some nitrate is formed as well. The rate of reaction is proportional to the cyanate and hypochlorite concentrations, but inversely proportional to the hydroxide concentration: the rate constant is 5.45×10^{-4} min.$^{-1}$ at 65° C., at an ionic strength of 2.2. The rate constant increases somewhat as the ionic strength rises from 1.7 to 3.5. The effect of temperature makes the apparent activation energy 25 kcal./gm-molecule. The kinetics of the reaction suggest that the slow step is really a reaction of hypochlorous acid and cyanate ions, and possible intermediate products of this reaction are suggested. Allowing for the different extent of hydrolysis of hypochlorite at different temperatures, the true activation energy is found to be 15 kcal./gm-mol., which is consistent with the observed rate of reaction.

In a recent paper (4), the writer reported some observations on the oxidation of potassium cyanate by sodium hypochlorite in the presence of small amounts of alkali. It was found that there was at first a marked induction period, after which a rapid reaction took place which approximately followed the equation:

$$2OCN^- + 3OCl^- + H_2O \rightarrow 2HCO_3^- + 3Cl^- + N_2.$$

The time required for the rapid reaction to develop depended on the concentration of sodium hydroxide, and was much less at low hydroxide concentrations. It was suggested that the acceleration of the reaction was due to the liberation of large amounts of hypochlorous acid, which oxidized the cyanate rapidly. It has since been found that the pH when the reaction accelerates is about 10. This is much too high a pH for cyanic acid to be formed, but would be reasonable for the liberation of hypochlorous acid. The reaction produces bicarbonate ions which are acid enough to lower the pH below this critical value.

A slow reaction took place even in the presence of excess alkali, and it is this reaction that is the subject of the present paper. The products are carbonate and chloride ions and nitrogen, at least in the predominant reaction. It is hardly likely that a complicated reaction of this sort would go in one step; and it was hoped that a knowledge of the kinetics would help to elucidate the mechanism, for there are no very obvious intermediate products. It is thought that the present work provides a fair amount of information on the reaction, though a detailed mechanism cannot yet be given.

EXPERIMENTAL METHOD AND RESULTS

The reagents used in these experiments were as follows. The same potassium cyanate was used as in the preceding paper (4). Sodium hypochlorite solution

[1]*Manuscript received December 5, 1955.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

was made in the usual way by passing chlorine into cold aqueous sodium hydroxide. A reagent grade of potassium hydroxide was used to control the hydroxide concentration. In some runs reagent grade sodium chloride or carbonate was added to alter the ionic strength.

The general procedure in any run was as follows. Solutions of potassium cyanate with added potassium hydroxide were made up as required. To these were added varying amounts of sodium hypochlorite solution, and in most runs solid sodium chloride or carbonate also, to control the ionic strength. The reaction mixture was contained in a 1 liter flask, fitted with (i) a mercury sealed stirrer, (ii) a side arm, normally closed, for taking samples, and (iii) a capillary lead to a water jacketed gas burette. The flask was immersed in a water thermostat of conventional design, whose temperature was controlled to $\pm 0.1°$ C.

During a run samples were taken at intervals and analyzed. Three sorts of analysis were used to follow the reaction: these were for (i) hypochlorite, (ii) cyanate, and (iii) total alkalinity. In addition the stock hypochlorite solution was analyzed for chlorite, chlorate, hydroxide, and carbonate, as it was necessary to know its ionic strength. The methods, except for cyanate and total alkalinity, have been described in an earlier paper (5). These are all well known titrations with minor modifications. To determine cyanate, a sample was run into 20 ml. of 3% hydrogen peroxide, to destroy hypochlorite. The mixture was acidified, and heated nearly to boiling to convert all cyanate to ammonium ions. Excess alkali was then added, and the ammonia distilled into a known amount of standard sulphuric acid, and the remaining acid was titrated in the usual way. 'Total alkalinity' was determined by the following procedure. A sample was pipetted out and titrated with standard sulphuric acid. Near the end point the solution was heated to boiling, and acid was run in until the green color of bromcresol green, which was used as indicator, was maintained even in the hot solution. At this point all hydroxide and carbonate have been titrated (the latter to carbonic acid), and the cyanate just converted to ammonium ions and carbon dioxide:

$$2KOCN + 2H_2SO_4 + 2H_2O \rightarrow K_2SO_4 + (NH_4)_2SO_4 + 2CO_2.$$

In one run the reaction of sodium chlorite and potassium cyanate was examined. This was done because hypochlorite always contains a small amount of chlorite, and it seemed possible that a reaction of this sort might contribute appreciably to the total rate. The procedure was the same except that a solution of recrystallized sodium chlorite was used.

The results are given in Tables I to V, which are arranged as follows. Table I gives the main series of runs, which were made to determine the kinetics of the reaction. All these runs were at 65° C., and an ionic strength of 2.2. Table II gives the results of varying the ionic strength, and Table III the results of varying the temperature. The observations on gas evolution are given in Table IV. Finally the single run with chlorite is given in Table V.

DISCUSSION OF RESULTS

Although the reaction approximates to

$$2OCN^- + 3OCl^- + 2OH^- \rightarrow 2CO_3^{--} + 3Cl^- + N_2 + H_2O$$

the amounts of cyanate and hypochlorite disappearing do not agree at all closely with this equation. In general more hypochlorite reacts than would be expected. Part of this must be due to the spontaneous decomposition of hypochlorite to chlorate and chloride, but this can only account for part of the discrepancy. The rate of gas evolution is also generally lower than is required by this equation. The most plausible secondary reaction is probably this:

$$OCN^- + 4OCl^- + 2OH^- \rightarrow CO_3^{--} + 4Cl^- + NO_3^- + H_2O.$$

Indeed it is difficult to suggest any other simple compound of nitrogen, except

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

possibly nitrous oxide, that might reasonably appear in this reaction mixture, and that would not be oxidized further.

The possibility of nitrous oxide formation was examined by collecting the gas evolved in a special gas burette, at the top of which was a coil of wire that could be heated. Hydrogen was added to the gas, and the wire heated to convert any nitrous oxide to nitrogen and water, and any oxygen to water. Then excess oxygen was added, and the wire was heated again. From the volumes at the various stages of this procedure it is possible to determine how much oxygen and nitrous oxide was present in the original gas. A little oxygen was detected (from decomposition of hypochlorite), but no nitrous oxide, within the experimental error.

Support for the suggestion that nitrate was formed was provided in two ways. First, the reaction mixture from a run with high hypochlorite was treated with enough 3% hydrogen peroxide to destroy the remaining hypochlorite ions. The mixture was then made very acid with concentrated sulphuric acid, and boiled. This removes any cyanate and the excess hydrogen peroxide, but the main object of this procedure was to remove chlorate. The boiling was continued until all chlorine and chlorine dioxide had boiled out of the solution, and addition of more sulphuric acid gave no further yellow color. After the solution was cooled, it was tested for nitrate by (i) the 'brown ring' test with ferrous sulphate and concentrated sulphuric acid, and (ii) 'nitron' acetate solution (7). The second test was applied both to the solution directly after it had been cooled, and to a portion of it which had been neutralized with sodium bicarbonate and then made just acid with acetic acid. Both tests gave a strong reaction for nitrate. Secondly, the amounts of substances appearing and disappearing agreed, roughly, with this secondary reaction. This second line of evidence is not very strong, as we are dealing with small differences in the analyses, or in the rates of gas evolution. The gas evolution itself can be easily measured, but there is always uncertainty as to whether this represents the true rate of reaction to nitrogen, because some of the gas can remain in solution. There was always some lag in the gas evolution at first (as has been noticed in other similar reactions), presumably because the concentration of gas in solution was building up. However after the reaction has been running for some time, the rate of gas evolution must be close to the true rate of reaction.

The calculations which were made to test the suggestion of this secondary reaction were as follows. Suppose we have $2a$ gm-molecules of cyanate reacting by the first reaction:

$$2OCN^- + 3OCl^- + 2OH^- \rightarrow 2CO_3^{--} + 3Cl^- + N_2 + H_2O \qquad \text{I}$$

and b gm-molecules by the second:

$$OCN^- + 4OCl^- + 2OH^- \rightarrow CO_3^{--} + 4Cl^- + NO_3^- + H_2O \qquad \text{II}$$

i.e. $2a$ gm-molecules of cyanate react with $3a$ gm-molecules of hypochlorite by the first reaction, etc. Then the total changes involved would be:

OCl^-: $-3a-4b$; OCN^-: $-2a-b$; total alkalinity: $-2a-2b$; nitrogen (gm-atoms): $2a$.

As the analyses for hypochlorite and cyanate were probably the most reliable,

For personal use only.

values of a and b were obtained from them with the results in Table VI. Table VI also makes allowance for the amount of hypochlorite reacting to

TABLE VI

give chlorate and chloride, which is calculated using a rate constant of 11×10^{-5} (gm-mol./l.)$^{-1}$ min.$^{-1}$. This constant is obtained from results of the writer (6) on this reaction. If x is the concentration of hypochlorite ion, then the rate of the reaction to chlorate is given by

$$-dx/dt = \tfrac{3}{2}k_1x^2$$

where k_1 is the rate constant. The value of x used was the average over the period investigated; that is, the correction used was:

$$\text{correction to hypochlorite used up} = \tfrac{3}{2}k_1[(x_{\text{initial}}+x_{\text{final}})/2]^2.\ (\text{time}).$$

The correction is small enough for this to be sufficiently accurate.

The agreement between the observed and calculated changes in the total alkalinity is very moderate; but we are, of course, dealing with small differences between large quantities. However the results in Table VI do provide some support for the suggested secondary reaction.

Table V shows that there is a slow reaction of chlorite and cyanate ions, but this is quite slow even at 98° C., and with 0.2 to 0.3 M chlorite present. As the chlorite present in hypochlorite from its decomposition is only about $\frac{1}{2}\%$ of the hypochlorite (6), the reaction of chlorite and cyanate is much too slow to contribute appreciably to the total reaction.

Turning to the gas rates, we see that these are generally lower than they would be if all the nitrogen from the cyanate were evolved as gas. If the alternative reaction is as suggested above, then the ratio of the rate of gas evolution (in gm-atoms/min.) to the rate of disappearance of cyanate would be $2a/(2a+b)$. Table VII(a) gives the results of such a comparison. The rates of cyanate disappearance were obtained by plotting the cyanate analyses and drawing smooth curves through them: the rates were read off these smoothed curves. Again there is moderate agreement, but on the whole the gas rates support the reaction proposed above.

The values of b/a are of some interest. Many of these are in the neighborhood of 0.1 to 0.2, which means that the reaction to nitrate is a minor one but not negligible. In runs 2 and 3, when (ClO^-) was high, so was b/a; thus a high concentration of hypochlorite favors, as might be expected, the more extreme oxidation to nitrate. Conversely, when (OCN^-) was very high in run 5, the ratio b/a was diminished. The apparent negative value of b in this run is presumably due to experimental error. When the sodium hydroxide concentration is varied, b/a does not change in any systematic manner, so sodium hydroxide does not affect the relative chances of the reaction going to nitrogen or nitrate. Thus, so far as they go, these values of b/a are consistent with the suggested reactions.

If we now examine the rates of reaction in runs 1 to 10, we find from runs 1 to 3 that the rate is at least roughly proportional to (OCl^-), if the other concen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

trations are the same. Similarly from runs 1, 4, 5, and 6, the rate is roughly proportional to (OCN^-). If we obtain (OH^-) from the total alkalinity at the start, we find from runs 1, 7, 8, 9, and 10 that the rate is roughly inversely proportional to the hydroxide concentration. Then if x is the hypochlorite concentration (initially x_0); y is the cyanate concentration (initially y_0); and z is the hydroxide concentration (initially z_0); these results would mean that

$$-dx/dt = k^*xy/z$$

where k^* is a constant. If the first reaction (I above) is followed, we should write

$$-dx/dt = 3kxy/z$$

where k is the correct rate constant, since three hypochlorite ions are used up in the reaction, but presumably only one in the first stage. We also have:

$$2\ dx/dt = 3\ dy/dt = 3\ dz/dt.$$

These equations integrate to give:

$$[i] \qquad -kt = \frac{1}{2x_0-3y_0}\left[(\tfrac{2}{3}x_0-z_0)\ln\frac{x}{x_0}+(z_0-y_0)\ln\frac{(2x-2x_0+3y_0)}{3y_0}\right].$$

The best way to check this equation is to calculate kt for various values of x, and then to fit the experimental points to this curve for each run by taking some value of k. This was done (see Fig. 1), and in general an adequate fit was

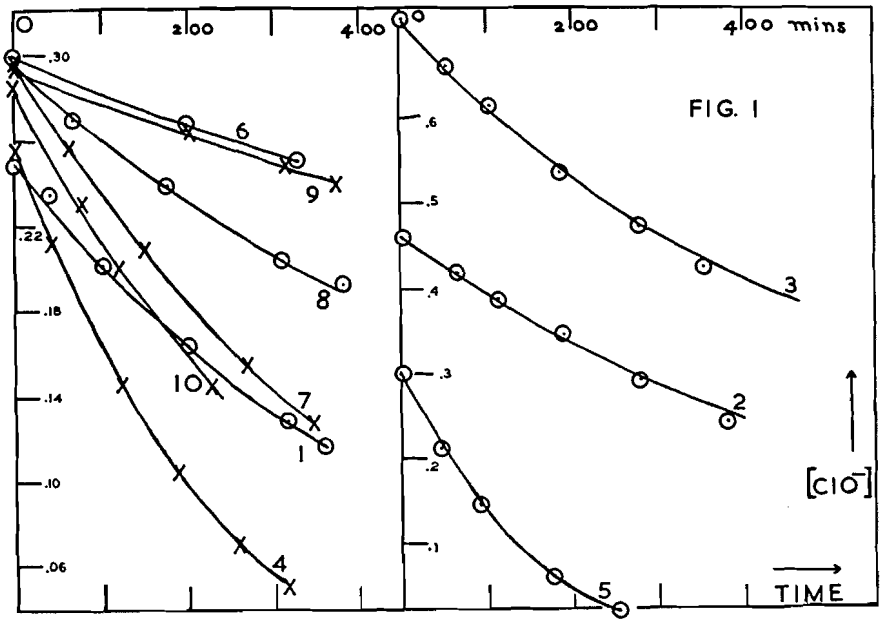

FIG. 1. Comparison of hypochlorite concentrations calculated by equation [i] with experimental points.

obtained. This supports the above rate equation, and gives the following values of k:

Run	1	2	3	4	5	6	7	8	9	10	
k	6.28	6.99	6.94	6.17	5.67	6.07	5.58	6.72	6.40	5.65	$\times 10^{-4}$ min.$^{-1}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

Before accepting these values of the constants, we must correct them for the effect of the decomposition of hypochlorite to chlorate, and for the effect of the secondary reaction. If the total reaction followed the second equation to nitrate and carbonate, the rate equations would be:

$$-dx/dt = 4kxy/z, \qquad dx/dt = 4\,dy/dt = 2\,dz/dt.$$

These give on integration:

$$[\text{ii}] \qquad -kt = \frac{1}{x_0-4y_0}\left[(\tfrac{1}{2}x_0-z_0)\ln\frac{x}{x_0}+(z_0-2y_0)\ln\frac{(x-x_0+4y_0)}{4y_0}\right].$$

This equation gives a curve only a little different from equation [i], if we take the best value of k to fit the experimental points. In runs 2 and 3 where the secondary reaction is the most important, equation [ii] gives a curve which deviates from the experimental points in the opposite direction from equation [i], so a combination of both gives an excellent fit.

In a more general way, if c is the chance that the second reaction will occur (i.e. $c = b/a$), and $(1-c)$ is the chance that the first reaction will occur; then $(3+c)$ hypochlorite ions, $(2-c)$ cyanate ions, and 2 hydroxide ions will be used up for each initial step. This leads to the more general equation:

$$[\text{iii}] \quad -kt = \frac{1}{(3+c)\,y_0-(2-c)\,x_0}\left[\left(z_0-\frac{2x_0}{3+c}\right)\ln\frac{x}{x_0} + \left(\frac{2y_0}{2-c}-z_0\right)\ln\frac{(3+c)\,y_0}{(3+c)\,y_0+(2-c)(x-x_0)}\right].$$

If $c = 0$ this reduces to equation [i], and if $c = 1$ it reduces to equation [ii]. It is assumed that reaction II has the same initial step as reaction I. The evidence for this is not very definite because reaction II is masked by the predominant reaction I. However it will be shown in the calculations which follow that in the runs (runs 2 and 3) when the second reaction is most important, the rate constant of reaction I is still in reasonable agreement with that found in other runs; nor is there any apparent relation between this rate constant and b/a. Also, in various runs values of b run roughly parallel to those for a, measured at the same time. For these reasons, and in the absence of definite evidence to the contrary, it seemed simplest to suppose that the two reactions had the same initial step.

Calculating k from equation [iii], we get:

Run	1	2	3	4	5	6	7	8	9	10	
k	5.94	5.27	5.58	5.90	5.67	5.53	5.17	6.04	6.14	5.27	$\times 10^{-4}$ min.$^{-1}$

The reaction to chlorate can be corrected for as follows. The amount of hypochlorite reacting in this way was calculated earlier in obtaining the b/a ratios. This was between $\frac{1}{2}$ and $8\frac{1}{2}\%$ of the total hypochlorite reacting; and it was assumed that the rate constants (which are proportional to the rate of disappearance of hypochlorite) would be too high by the same per cent, as obtained above from equation [iii]. As a result the corrected values were:

Run	1	2	3	4	5	6	7	8	9	10	
% corrn.	1.47	3.98	6.79	0.65	0.53	8.37	1.63	3.51	6.82	1.29	
k(corr.)	5.85	5.06	5.20	5.86	5.64	5.07	5.09	5.83	5.72	5.20	$\times 10^{-4}$ min.$^{-1}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

The mean value of k was 5.45×10^{-4}, with an average deviation of 0.33×10^{-4}. These values of k can be described as only moderately constant, but it is believed that this is due to the experimental errors in the analyses, and not to the selection of the wrong kinetic scheme. It will be noted that run 7, when a considerable quantity of sodium carbonate was added, gave the same constant, so presumably sodium carbonate and chloride do not catalyze the reaction, apart from their effect on the ionic strength.

We can apply similar calculations to the results in Tables II and III. The data that determine the relative extent of the two reactions are given in Table VIII. The values of b/a in Table VIII show much the same trends as

TABLE VIII

Run	Ionic strength	Temp., ° C.	Change in (OCl^-)	Change in (OCN^-)	Corrn. to OCl^-	Corrected change in (OCl^-)	a	b	b/a
11	1.7	65	0.2125	0.140	0.005	0.2075	0.0705	(−.001)	0
12	2.0	65	0.123	0.066	0.008	0.115	0.0298	0.0064	0.21
13	2.9	65	0.306	0.126	0.046	0.260	0.0488	0.0284	0.58
14	3.5	65	0.0995	0.054	0.0015	0.098	0.0236	0.0068	0.28
15	2.2	55	0.0775	0.036	0.002	0.0755	0.0185	0.0050	0.27
16	2.2	75	0.193	0.0945	0.003	0.0190	0.0398	0.0184	0.46
17	2.2	50	0.2355	0.128	0.0135	0.222	0.0580	0.0136	0.23

before. In run 13, for instance, the high hypochlorite concentration makes b/a high. The run at 75° C. seems to have a high value of b/a, and it is of course reasonable to suppose that temperature could alter the extent of these reactions. The numbers do give some indication that high temperature or ionic strength both increase b/a, but the results are too few for any firm conclusions to be drawn.

If we evaluate k precisely as before, the final corrected results are:

Run	11	12	13	14	15	16	17	
Temp.	65	65	65	65	55	75	50	° C.
Ionic strength	1.7	2.0	2.9	3.5	2.2	2.2	2.2	
k	4.22	4.85	5.52	6.20	1.89	16.8	1.00	$\times 10^{-4}$ min.$^{-1}$

The results for run 13 cannot be very accurate because of the large correction for the reaction to chlorate. The values of k show an upward drift with ionic strength; the extent of the change is comparable with that found in similar reactions, e.g. that of hypochlorite going to chlorate.

If log k is plotted against $1/T$ in the usual way, a fairly straight line is obtained. The over-all (50° C. to 75° C.) value for the activation energy is 25.3 kcal./gm-mol. If we allow a little more weight to the value at 65° C., because it was more carefully measured, the activation energy is reduced a little: probably the best value is $25(\pm\frac{1}{2})$ kcal./gm-mol.

Comparison of the observed and calculated gas rates for runs 11 to 17 as given in Table VII(b) shows about the same degree of agreement as before. The calculated rates were obtained in the same way as in Table VII(a).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

The next question is that of what one can conclude about the mechanism of this reaction. The kinetics suggest that the slow step is really a bimolecular reaction of HOCl and OCN^-. If k_t is the true rate constant of this reaction, then comparison with the rate equations used earlier shows that:

$$k_t(HOCl) = k(OCl^-)/(OH^-)$$

[iv] or $$k_t = K_a.k/K_w$$

where K_a is the ionization constant of hypochlorous acid, and K_w is the ionization constant of water. At 65° C., k is 5.45×10^{-4} and K_w is 1.25×10^{-13} (2). There are no values of K_a reported for 65° C., but it is 3.8×10^{-8} at 27° C. (5). If we use the value of the heat of ionization given below, the calculated ionization constant at 65° C. is 8×10^{-8}. Hence k_t at 65° C. is 350 min.$^{-1}$ M.p.l.$^{-1}$, or 5.8 sec.$^{-1}$ M.p.l^{-1}. This is a fairly fast reaction, and the question arises whether this is consistent with the observed temperature dependence on the rate. By taking $-1/R \cdot d \ln/d(1/T)$ of both sides of equation [iv] we get:

$$E_t = E + q_a - q_w$$

where E_t is the true activation energy of the reaction of HOCl with OCN^-, and E is the apparent activation energy (25 kcal.) obtained above. q_a is the heat of the reaction:

$$H^+ + OCl^- \rightarrow HOCl + q_a$$

and q_w is the heat of recombination of the ions of water: 13.8 kcal. (1). There seem to be no direct values for the heat of ionization of hypochlorous acid, but data given by Latimer (3) make q_a = 3.9 kcal. Substituting these values, E_t = 15.1 kcal./gm-mol. This cannot be considered to be very accurate, chiefly because of uncertainty in q_a. If, as is usual, we suppose that k_t and E_t are related by $k_t = Ae^{-E_t/RT}$, then the value of log A is 10.5. This is quite a plausible value for A; and, while no great accuracy can be claimed, it seems safe to conclude that there is no inconsistency in the observed rates and temperature dependence.

Finally, if the first step is a reaction of hypochlorous acid and cyanate ions, it is natural to consider what might be the intermediate products of such a reaction. Unfortunately these products are not obvious, and what follows is largely speculation. However it is perhaps reasonable to assume that chloride ions are formed, as in other oxidations by hypochlorous acid. The reaction might then be:

$$HOCl + OCN^- + H_2O \rightarrow Cl^- + HO_2CNHOH$$

followed by further rapid oxidation. Alternatively, HOCl might possibly add across a double or triple bond in a cyanate ion, to give the rather awkward looking ion $(O{=}C.OH{-}NCl)^-$ which would doubtless rearrange to $(O_2C{-}NHCl)^-$. The first suggestion looks rather more plausible. At least one can conclude that such products are not wholly ridiculous, and the kinetics presumably show that some such reaction really occurs.

ÉTUDES SUR LA SYNTHÈSE DE L'HYDROXYPROLINE À PARTIR DE DÉRIVÉS DE L'ACIDE 2-AMINO-4-PENTÈNOÏQUE[1]

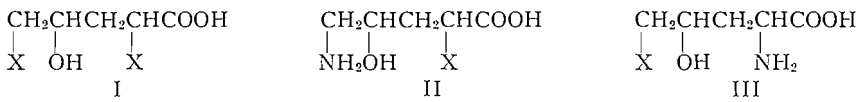
PAR ROGER GAUDRY, LOUIS BERLINGUET, ANDRÉ LANGIS ET GÉRARD PARIS

ABSTRACT

A systematic investigation of the synthesis of 4-hydroxy-DL-proline and 2-amino-4-dihydroxyvaleric acid has been made, starting from the following derivatives of 2-amino-4-pentenoic acid: ethyl allylacetamidomalonate, ethyl allylacetamidocyanoacetate, 2-phthalimidopentenoic acid, allylacetamidomalonic acid, acetylallylglycine, 5-allylhydantoin, and 3-phenyl-5-allylhydantoin. Chlorine or bromine was added to the double bond of these compounds, and the reaction products were either derivatives of 5-halogenated-4-valerolactones or derivatives of 4,5-dihalogenated pentanoic acids, depending on whether the carboxyl group of the pentanoic acid was free or not when the halogenation reaction was carried out. Acid hydrolysis followed by treatment with barium hydroxide always gave mixtures, in different ratio, of 4-hydroxy-DL-proline and 2-amino-4,5-dihydroxyvaleric acid which were analyzed and isolated as the copper salts. In the case of 5-(2,3-dibromopropyl)hydantoin and 3-phenyl-5-(2,3-dibromopropyl)hydantoin, no cyclization could be obtained.

INTRODUCTION

Nous avons entrepris d'étudier systématiquement la synthèse de la 4-hydroxyproline dans le but d'élaborer une synthèse permettant l'obtention facile de grandes quantités de cet acide aminé naturel. On peut ramener à trois méthodes générales les synthèses de l'hydroxyproline publiées à date. La première consiste à cycliser par l'ammoniac un dérivé 2,5-dihalogéné de l'acide 4-hydroxyvalérianique (I), donc un produit ne contenant pas d'azote. La deuxième consiste à cycliser par une base un dérivé 2-halogéné de l'acide 4-hydroxy-5-aminovalérianique (II), c'est-à-dire une substance renfermant de l'azote aminé en position 5. La troisième consiste au contraire à cycliser par une base un dérivé 5-halogéné de l'acide 2-amino-4-hydroxyvalérianique (III), renfermant par conséquent de l'azote aminé en position 2.



Dans une publication antérieure (5), nous avons discuté de la synthèse de l'hydroxyproline à partir de dérivés 2,5-dihalogénés de l'acide 4-hydroxyvalérianique (I) et 2-halogénés de l'acide 4-hydroxy-5-aminovalérianique (II). Nous exposons maintenant les résultats de nos travaux sur la préparation de l'hydroxyproline en passant par les dérivés 5-halogénés de l'acide 2-amino-4-hydroxyvalérianique (III).

On trouve dans la littérature quatre synthèses de l'hydroxyproline qui utilisent l'acide 2-amino-4-hydroxy-5-halogénovalérianique comme intermédiaire: celle de Fischer et Krämer (3), Hammarsten (6), McIlwain et Richardson (9) ainsi que Feofilaktov et Onishchenko (2). Mais celle de Hammarsten est la seule à utiliser comme produit de départ un dérivé de l'acide 2-amino-4-pentènoïque: l'acide allylhippurique ou acide 2-benzamido-4-pentènoïque.

[1]*Manuscrit reçu pour la première fois le 18 août 1955, et sous forme revisée le 29 décembre 1955.*
Contribution du Département de Biochimie de la Faculté de Médecine, Université Laval, Québec, P.Q.

Nous avons repris la méthode de Hammarsten, et nous l'avons appliquée, avec modifications appropriées, à plusieurs types de dérivés de l'acide 2-amino-4-pentènoïque, soit: l'allylacétamidomalonate d'éthyle (IV, $R=C_2H_5$, $R'=CO_2C_2H_5$), l'allylacétamidocyanoacétate d'éthyle (IV, $R=C_2H_5$, $R'=CN$), l'acide 2-phtalimido-4-pentènoïque (IV, $R=R'=H$, $-N(CO)_2C_6H_4$ remplace $-NHCOCH_3$), l'acide allylacétamidomalonique (IV, $R=H$, $R'=COOH$), l'acétylallylglycine (IV, $R=R'=H$), la 5-allylhydantoïne ainsi que la 3-phényl-5-allylhydantoïne.

Par addition de chlore ou de brome à l'allylacétamidomalonate d'éthyle (IV, $R=C_2H_5$, $R'=CO_2C_2H_5$), on obtient les esters correspondants à l'état cristallin: le dichloré avec 18% de rendement; le dibromé avec 50% de rendement.

Par addition de chlore ou de brome à l'allylacétamidocyanoacétate d'éthyle (IV, $R = C_2H_5$, $R' = CN$), on obtient les esters correspondants à l'état cristallin mais qui sont beaucoup plus faciles à cristalliser et à isoler que les produits analogues provenant de l'allylacétamidomalonate d'éthyle (IV, $R = C_2H_5$, $R' = CO_2C_2H_5$). L'ester dichloré est obtenu avec un rendement de 70% et l'ester dibromé avec un rendement de 75%.

L'addition d'halogènes sur l'acide 2-phtalimido-4-pentènoïque (IV, $R = R' = H$, $—N(CO)_2C_6H_4$ remplace $—NHCOCH_3$), sur l'acide allylacétamidomalonique (IV, $R = H$, $R' = COOH$) et sur l'acétylallylglycine (IV, $R = R' = H$) donne surtout les dérivés de la 2-amino-4-valérolactone-5-halogénée, les acides dihalogénés se cyclisant avec le groupement carboxyle libre.

L'hydrolyse acide des dérivés 4,5-dihalogénés donne surtout l'acide 2-aminovalérianique-4,5-dihalogéné. Et par chauffage en milieu alcalin, on obtient la 4-hydroxyproline (IX) avec de l'acide 2-amino-4,5-dihydroxyvalérianique (X) comme sous-produit.

Par contre, l'hydrolyse acide des dérivés de la 2-amino-4-valérolactone-5-halogénée (VII), suivie de chauffage en milieu alcalin, mène de préférence à l'acide 2-amino-4,5-dihydroxyvalérianique (X), avec la 4-hydroxyproline (IX) comme produit secondaire. On peut expliquer ces résultats en considérant que, par traitement alcalin, l'anneau des lactones doit s'ouvrir avant que l'anneau de pyrrolidine puisse se former. Il y a alors réactions compétitives entre l'hydrolyse de la lactone et le remplacement de l'atome d'halogène en position 5 par une fonction alcool. Lorsque l'atome d'halogène est un atome de brome, il semble que dans la majorité des cas, il soit en bonne partie éliminé avant l'ouverture de l'anneau de l'acide 2-amino-4,5-dihydroxyvalérianique. Lorsque l'atome d'halogène est l'atome de chlore, il réagit lentement avec l'alcali. Dans ce cas, il peut se former une quantité appréciable d'acide 2-amino-4-hydroxy-5-chlorovalérianique qui se cyclise aussitôt en hydroxyproline.

En conséquence, les lactones bromées mènent presque exclusivement à l'acide dihydroxylé tandis que les lactones chlorées mènent à des mélanges d'hydroxyproline et d'acide dihydroxylé.

Les essais de séparation de ces deux acides aminés au moyen des picrates (7), des sels de reineke (10), des chlorhydrates, ainsi que la séparation sur des colonnes de résines se sont avérés infructueux.

Nous avons réussi à effectuer la séparation des deux acides aminés par cristallisation fractionnée des sels de cuivre de l'hydroxyproline et de l'acide dihydroxylé dans l'eau puis dans l'alcool méthylique anhydre. Ainsi nous avons pu isoler le sel de cuivre de l'acide dihydroxylé, qui jusqu'alors n'avait jamais été isolé de façon certaine (3,6) et le sel de cuivre de l'hydroxyproline. Nous n'avons toutefois pas tenté la séparation des formes "allo" et "DL".

Quant à l'étude des meilleures conditions expérimentales pour ces synthèses, nous avons déterminé les rendements des deux acides aminés, hydroxyproline et acide 2-amino-4,5-dihydroxyvalérianique, par dosage chimique au moyen respectivement des méthodes de McFarlane et Guest (8) et de N. W. Rees (11). Cette dernière méthode avait été tout d'abord employée pour doser la sérine

et la thréonine. Nous l'avons adoptée au dosage de l'acide 4,5-dihydroxylé avec tout autant de succès.

Ces analyses ont été effectuées sur les liqueurs provenant de l'hydrolyse acide et du traitement alcalin des produits dihalogénés (Tableau I). Elles ont aussi été déterminées sur les solutions obtenues après halogénation, hydrolyse acide, traitement alcalin des dérivés de l'acide 2-amino-4-pentènoïque (Tableau II). Les différences entre les valeurs des deux tableaux, proviennent évidemment des difficultés rencontrées lors de l'isolement des produits intermédiaires.

TABLEAU I

RENDEMENTS EN HYDROXYPROLINE ET EN ACIDE 2-AMINO-4,5-DIHYDROXYVALÉRIANIQUE PAR ANALYSE DE LA SOLUTION APRÈS HYDROLYSE ACIDE ET CYCLISATION ALCALINE DU PRODUIT DIHALOGÉNÉ ISOLÉ

Dans une publication récente portant sur la proline, l'un de nous (4) a démontré qu'on peut cycliser la 5-(3-chloropropyl)hydantoïne en l'hydantoïne de la proline, et que la 3-phenyl-5-(3-bromopropyl)hydantoïne se cyclise spontanément en phénylhydantoïne de la proline. Nous avons voulu appliquer ces réactions à l'hydroxyproline. Nous avons préparé la 5-(2,3-dibromopropyl) hydantoïne, ainsi que la 3-phenyl-5-(2,3-dibromopropyl)hydantoïne. Mais tous nos essais de cyclisation de ces hydantoïnes en dérivés de l'hydroxyproline se sont avérés infructueux.

Il ressort de ces travaux que la préparation des acides 2-aminovalérianique-4,5-dihalogénés, conduisant à l'hydroxyproline ne peut se faire sans qu'une certaine partie de l'acide ne se cyclise en 2-amino-4-valérolactone-5-halogénée, laquelle lactone, par traitement alcalin, donne surtout l'acide 2-amino-4,5-dihydroxyvalérianique. Les quantités d'hydroxyproline obtenues, quoique élevées, sont toujours accompagnées de l'acide 2-amino-4,5-dihydroxyvalérianique qu'on peut fort heureusement séparer par la méthode décrite plus haut.

PARTIE EXPÉRIMENTALE

Allylacétamidomalonate d'éthyle (*IV*, $R = C_2H_5$, $R' = CO_2C_2H_5$)

Dans un ballon à 3 cols de 300 ml. muni d'un agitateur, d'un réfrigérant surmonté d'un tube de chlorure de calcium et d'un entonnoir à décantation, on place 100 ml. d'alcool anhydre dans lequel on dissout du sodium (4.6 g., 0.20 mole). On ajoute ensuite de l'acétamidomalonate d'éthyle (43.4 g., 0.20 mole). Après environ une demi-heure, on laisse tomber goutte à goutte du bromure d'allyle (28 g., 0.23 mole) en maintenant la température à 25° C. L'addition terminée on chauffe la solution à 40° C. pendant 20 h. L'alcool est évaporé sous pression réduite, puis on dissout le résidu dans 10 ml. d'eau distillée. Après avoir acidifié la solution avec de l'acide sulfurique, on extrait l'allylacétamidomalonate d'éthyle à l'éther. On sèche la solution éthérée sur du sulfate de sodium anhydre. L'éther est ensuite évaporé sous pression réduite et le produit de condensation cristallise lentement. On le recristallise de l'alcool éthylique aqueux. Rendement: 37 g., 72%. P. f.* 46° C., Litt.: 46° C. (1). Calculé pour $C_{12}H_{19}O_5N$: N, 5.45%. Trouvé: N, 5.41%.

Lorsqu'on substitue le chlorure d'allyle au bromure d'allyle, le rendement est de 45%.

Ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique (*V*, $X = Cl$, $R = C_2H_5$, $R' = CO_2C_2H_5$)

Dans un ballon à large col de 300 ml., on dissout de l'allylacétamidomalonate d'éthyle (9 g., 0.035 mole) dans 50 ml. de chloroforme. On refroidit la solution à 10° C. et on y fait barbotter du chlore jusqu'à addition du poids théorique. On évapore le solvant sous pression réduite et on dissout le résidu gommeux obtenu dans 25 ml. d'alcool éthylique. On verse la solution alcoolique dans de l'eau glacée. Le produit dichloré cristallise. Après recristallisation de l'alcool dilué le rendement est de: 2 g., 18%. P. f. 54–61° C. Calculé pour $C_{12}H_{19}O_5NCl_2$: N, 4.28%; Cl, 21.4%. Trouvé: N, 4.25%; Cl, 22.2%. On peut aussi faire l'addition de chlore au moyen de chlorure de sulfuryle.

**Les points de fusion ne sont pas corrigés.*

Ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dibromovalérianique (V, $X = Br$, $R = C_2H_5$, $R' = CO_2C_2H_5$)

On place de l'allylacétamidomalonate d'éthyle (20 g., 0.078 mole) et 50 ml. de chloroforme dans un ballon à large col de 500 ml. Après dissolution, on ajoute goutte à goutte du brome (15 g., 0.094 mole) dissous dans 10 ml. de chloroforme, en maintenant la température à 20° C. Le solvant est ensuite évaporé. On se débarrasse de l'excès de brome en utilisant une solution aqueuse de bisulfite de sodium. On dissout le résidu gommeux dans 25 ml. d'alcool éthylique et on verse la solution dans de l'eau glacée. Le produit dibromé cristallise. On le recristallise de l'alcool dilué. Rendement: 17 g., 50%. P. f. 85° C. Calculé pour $C_{12}H_{19}O_5NBr_2$: N, 3.35%; Br, 38.3%. Trouvé: N, 3.47%; Br, 39.3%.

Hydrolyse et cyclisation alcaline

(*a*) *A partir de l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique*

L'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique (1 g., 0.0031 mole) est dissous dans 15 ml. d'acide acétique glacial, puis hydrolysé par 25 ml. d'acide chlorhydrique concentré pendant quatre heures. On évapore la solution à sec sous pression réduite et on reprend le résidu à l'eau. On ajoute un excès d'hydroxyde de baryum (0.8 g., 0.0047 mole) et l'on chauffe à reflux pendant 16 h. L'hydroxyde de baryum est précipité avec du carbonate d'ammonium. Après avoir filtré le carbonate de baryum, la solution est évaporée à sec sous pression réduite. Le résidu est repris à l'eau, traité au noir animal, filtré et analysé par la méthode de McFarlane and Guest (8) pour l'hydroxyproline et la méthode de M. W. Rees (11) pour l'acide 2-amino-4,5-dihydroxyvalérianique. Le dosage de la solution donne les rendements suivants: hydroxyproline, 69%; acide 2-amino-4,5-dihydroxyvalérianique, 13%.

Lorsque l'on additionne à 25° C. du chlorure de sulfuryle (2.7 g., 0.020 mole) à l'allylacétamidomalonate d'éthyle (5 g., 0.019 mole) sans isoler le produit dichloré, l'on obtient, après hydrolyse et cyclisation alcaline, les rendements suivants calculés par analyse à partir de l'allylacétamidomalonate d'éthyle: hydroxyproline, 78%; acide 2-amino-4,5-dihydroxyvalérianique, 17%.

(*b*) *A partir de l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dibromovalérianique*

En procédant de la même façon l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dibromovalérianique (1 g., 0.0024 mole) donne par hydrolyse et cyclisation alcaline les rendements suivants calculés par analyse: hydroxyproline, 57%; acide 2-amino-4,5-dihydroxyvalérianique, 33%.

Lorsque l'on additionne à 25° C. du brome (3.6 g., 0.0225 mole) à l'allylacétamidomalonate d'éthyle (5 g., 0.0195 mole) sans isoler le produit dibromé, l'on obtient après hydrolyse et cyclisation alcaline les rendements suivants calculés par analyse à partir de l'allylacétamidomalonate d'éthyle: hydroxyproline, 28%; acide 2-amino-4,5-dihydroxyvalérianique, 49%.

Acétamidocyanoacétate d'éthyle

L'acétamidocyanoacétate d'éthyle a été préparé par la méthode de l'hydrosulfite (12). L'isonitrosocyanoacétate d'éthyle formé par l'action de l'acide nitreux sur le cyanoacétate d'éthyle n'a pas été isolé mais immédiatement réduit par l'hydrosulfite de sodium en présence d'anhydride acétique. Rendement: 51%. P. f. 129° C. Le produit est recristallisé de l'acide acétique 15%.

Allylacétamidocyanoacétate d'éthyle (*IV*, $R = C_2H_5$, $R' = CN$)

On place 75 ml. d'alcool anhydre dans un ballon à 3 cols muni d'un agitateur et d'un réfrigérant surmonté d'un tube de chlorure de calcium. On y dissout du sodium (4.6 g., 0.2 mole), puis on refroidit la solution à 10–15° C. On ajoute de l'acétamidocyanoacétate d'éthyle (34 g., 0.2 mole). Après 15 min. on élève la température à 30–35° C. et on laisse tomber goutte à goutte du chlorure d'allyle (25 g., 0.33 mole). L'addition du chlorure terminée, on élève la température à 60–65° C. et l'on chauffe ainsi la solution pendant huit heures. On verse la solution dans un mélange d'eau et de glace et on obtient des cristaux d'allylacétamidocyanoacétate d'éthyle que l'on filtre et que l'on lave à l'eau froide. Rendement: 39 g., 93%. P. f. 89° C., Litt. 89° C. (1). Calculé pour $C_{10}H_{14}O_3N_2$: N, 13.3%. Trouvé: N, 12.9%. En substituant le bromure d'allyle, le rendement est à peu près le même.

Ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dichlorovalérianique (*V*, $X = Cl$, $R = C_2H_5$, $R' = CN$)

L'addition de chlore gazeux sur l'allylacétamidocyanoacétate d'éthyle (25 g., 0.12 mole) dissous dans le chloroforme à 10° C. suivant la méthode décrite pour l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique donne le produit dichloré avec un rendement de: 25 g., 70%. P. f. 100–105° C. Calculé pour $C_{10}H_{14}O_3N_2Cl_2$: N, 10.27%; Cl, 25%. Trouvé: N, 9.80%; Cl, 26.1%.

Ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dibromovalérianique (*V*, $X = Br$, $R = C_2H_5$, $R' = CN$)

De la même façon que pour l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dibromovalérianique, l'addition de brome (16 g., 0.1 mole) à l'allylacétamidocyanoacétate d'éthyle (20 g., 0.095 mole) à 20–25° C. dans le chloroforme donne 26 g. de produit. Rendement: 75%. P. f. 114–115° C. Calculé pour $C_{10}H_{14}O_3N_2Br_2$: N, 7.56%; Br, 43.3%. Trouvé: N, 7.56%; Br, 43.2%.

Le produit isolé contient un mélange des deux isomères possibles. Si l'on fait la bromuration à −5°–0° C. le produit dibromé fond à 131° C. Si par ailleurs la bromuration est effectuée à 40–45° C. l'isomère dibromé obtenu fond à 98–99° C.

5-Bromo-2-acétamido-2-cyano-4-valérolactone (*VII*, $X = Br$, $R' = CN$)

L'ester éthylique de l'acide 2-cyano-2-acétamido-4,5-dibromovalérianique (7.4 g., 0.02 mole) est dissous dans 100 ml. d'alcool absolu bouillant. On ajoute un équivalent de potasse alcoolique (1.12 g., 0.02 mole) puis l'on chauffe le

For personal use only.

mélange à reflux pendant quatre heures. On laisse refroidir et on filtre le précipité de bromure de potassium. On évapore le solvant. On reprend le résidu à l'éther pour enlever les dernières traces de bromure et on filtre. L'éther est évaporé et l'on obtient comme résidu une huile blanche difficile à cristalliser. Poids: 1 g. P. f. 85° C. Calculé pour $C_8H_9O_3N_2Br$: N, 10.7%; Br, 30.6%. Trouvé: N, 10.9%; Br, 30.1%.

Hydrolyse et cyclisation alcaline

(*a*) *A partir de l'ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dichlorovalérianique*

L'ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dichlorovalérianique (2 g., 0.0071 mole) hydrolysé et cyclisé de la même façon que l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique donne les rendements suivants obtenus par analyse: hydroxyproline, 79%; acide 2-amino-4,5-dihydroxyvalérianique, 17%.

Lorsque l'on additionne à 25° C. du chlorure de sulfuryle (2 g., 0.015 mole) à l'allylacétamidocyanoacétate d'éthyle (2 g., 0.010 mole) sans isoler le produit dichloré, l'on obtient après hydrolyse et cyclisation alcaline les rendements suivants calculés à partir de l'allylacétamidocyanoacétate d'éthyle et obtenus par analyse: hydroxyproline, 64%; acide 2-amino-4,5-dihydroxyvalérianique, 24%.

(*b*) *A partir de l'ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dibromovalérianique*

L'ester éthylique de l'acide 2-acétamido-2-cyano-4,5-dibromovalérianique (2 g., 0.005 mole), p.f. 131° C., en procédant de la même façon qu'à partir de l'ester éthylique de l'acide 2-carbéthoxy-2-acétamido-4,5-dichlorovalérianique, donne les rendements suivants obtenus par analyse: hydroxyproline, 25%; acide 2-amino-4,5-dihydroxyvalérianique, 63%.

Par addition de brome à 25° C. (2 g., 0.0125 mole) sur l'allylacétamidocyanoacétate d'éthyle (2 g., 0.0095 mole) et sans isoler le produit dibromé, on obtient par analyse, après hydrolyse et cyclisation alcaline, les rendements suivants: hydroxyproline, 48%; acide 2-amino-4,5-dihydroxyvalérianique, 37%.

Allylglycine

Dans un ballon de 300 ml., on place de l'allylacétamidocyanoacétate d'éthyle (10 g., 0.047 mole). On y ajoute 150 ml. d'eau distillée et 10 ml. d'acide sulfurique concentré. Après avoir chauffé la solution à reflux pendant quatre heures, on la neutralise avec de l'hydroxyde de baryum. On filtre le précipité de sulfate de baryum et on se débarrasse de l'excès d'hydroxyde de baryum en le faisant réagir avec un excès de carbonate d'ammonium. On filtre et on évapore la solution à sec sous pression réduite. On reprend le précipité avec 25 ml. d'eau distillée. On décolore la solution au noir animal et on précipite l'acide aminé en ajoutant 75 ml. d'alcool éthylique à la solution aqueuse. On filtre l'allylglycine et on sèche à l'air. Rendement: 2.5 g., 46%. P. f. 246–248° C. Calculé pour $C_5H_9O_2N$: N, 12.16%. Trouvé: N, 12.13%.

Acide 2-phtalimido-4-pentènoïque (*IV*, $R=R'=H$, $—N(CO)_2C_6H_4$ *remplace* $—NHCOCH_3$)

Dans un ballon de 100 ml., on place un mélange intime d'allylglycine (11.5 g., 0.1 mole) et d'anhydride phtalique (14.8 g., 0.1 mole) que l'on chauffe à une température de 180° C. pendant 10 min. Après avoir refroidi le produit, on le cristallise de l'alcool éthylique aqueux à 40% (125 ml.). Rendement: 21 g., 85%. P. f. 120–121° C. Calculé pour $C_{13}H_{11}O_4N$: N, 5.73%. Trouvé: N, 5.89%.

2-Phtalimido-5-chloro-4-valérolactone (*VI*, $X=Cl$, $R'=H$, $—N(CO)_2C_6H_4$ *remplace* $—NHCOCH_3$)

Dans un ballon à large col de 50 ml., on place de l'acide 2-phtalimido-4-pentènoïque (7.35 g., 0.03 mole) que l'on dissout dans 100 ml. d'acide acétique glacial. On y ajoute goutte à goutte, à la température de la chambre, du chlorure de sulfuryle (5 g., 0.037 mole). Le produit de la réaction cristallise de la solution à mesure qu'il se forme. On le recristallise de l'acétone. Rendement: 1.7 g., 20.5%. P. f. 187–188° C. Calculé pour $C_{13}H_{10}O_4NCl$: N, 5.02%; Cl, 12.71%. Trouvé: N, 5.10%; Cl, 12.68%.

2-Phtalimido-5-bromo-4-valérolactone (*VII*, $X=Br$, $R'=H$, $—N(CO)_2C_6H_4$ *remplace* $—NHCOCH_3$)

On dissout de l'acide phtalimidopentènoïque (24.5 g., 0.1 mole) dans 200 ml. d'acide acétique glacial. On ajoute goutte à goutte du brome (12.6 g., 0.079 mole) dans 50 ml. de tétrachlorure de carbone, en maintenant une bonne agitation. Le produit de la réaction cristallise de la solution à mesure qu'il se forme. On le recristallise d'un peu d'acétone. Rendement: 10.2 g., 31%. P. f. 189–190° C. Calculé pour $C_{13}H_{10}O_4NBr$: N, 4.32%; Br, 24.3%. Trouvé: N, 4.33%; Br, 24.4%.

Hydrolyse et cyclisation alcaline

(*a*) *A partir de la 2-phtalimido-5-chloro-4-valérolactone*

La 2-phtalimido-5-chloro-4-valérolactone (1 g., 0.0035 mole) est dissoute dans un mélange de 20 ml. d'acide acétique glacial et de 20 ml. d'acide chlorhydrique concentré. On chauffe à reflux pendant quatre heures, on évapore à sec, on reprend à l'eau et on filtre l'acide phtalique. On neutralise le filtrat avec de l'hydroxyde de baryum et on ajoute un excès d'hydroxyde de baryum 1.8 g. (0.0105 mole). On chauffe à reflux pendant six heures, on précipite le baryum au moyen d'un excès de carbonate d'ammonium et on filtre le précipité de carbonate de baryum. La solution est évaporée à sec sous pression réduite. Le résidu est repris à l'eau, filtré et analysé. Le dosage de la solution donne les rendements suivants: hydroxyproline, 27%; acide 2-amino-4,5-dihydroxyvalérianique, 38%.

Lorsqu'on additionne du chlorure de sulfuryle (2 g., 0.015 mole) à l'acide 2-phtalimido-4-pentènoïque (3 g., 0.012 mole) sans isoler le produit chloré, l'on obtient par analyse après hydrolyse et cyclisation alcaline les rendements suivants: hydroxyproline, 21%; acide 2-amino-4,5-dihydroxyvalérianique, 57%.

(*b*) *A partir de la 2-phtalimido-5-bromo-4-valérolactone*

De la même façon, par hydrolyse et cyclisation de la 2-phtalimido-5-bromo-4-valérolactone (1 g., 0.0031 mole), l'analyse donne les rendements suivants: hydroxyproline, 7%; acide 2-amino-4,5-dihydroxyvalérianique, 65%.

L'addition de brome (2 g., 0.012 mole) sur l'acide 2-phtalimido-4-pentènoïque (3 g., 0.012 mole), sans isoler le produit bromé, donne par analyse après hydrolyse et cyclisation alcaline les rendements suivants: hydroxyproline, 24%; acide 2-amino-4,5-dihydroxyvalérianique, 48%.

Acide allylacétamidomalonique (*IV*, $R=H$, $R'=COOH$)

On dissout de l'allylacétamidomalonate d'éthyle (25.7 g., 0.1 mole) dans de l'hydroxyde de sodium (11.2 g., 0.28 mole) solubilisé dans 50 ml. d'eau distillée et 50 ml. d'alcool éthylique. On laisse la solution à la température de la chambre pendant 24 h. en maintenant une bonne agitation. A la solution, on ajoute de la glace ainsi que 200 ml. d'acide chlorhydrique concentré. On évapore l'alcool sous pression réduite en ne chauffant que légèrement. L'acide allylacétamidomalonique cristallise lorsqu'on refroidit la solution. Rendement: 13.2 g., 65%. P. f. 100–103° C. Calculé pour $C_8H_{11}O_5N$: N, 6.96%. Trouvé: N, 7.00%.

Acétylallylglycine (*IV*, $R=R'=H$)

Dans un ballon de 300 ml., on place de l'acide allylacétamidomalonique (37 g., 0.185 mole) que l'on chauffe sur un bain de cire à une température de 125° C. jusqu'à ce que le dégagement de CO_2 cesse. Le produit est dissous dans 150 ml. d'eau distillée. On décolore la solution au noir animal et on évapore le solvant sous pression réduite. On dissout le résidu dans du chloroforme et on précipite l'acétylallylglycine avec de l'éther de pétrole. Rendement: 16.5 g., 57.0%. P. f. 112° C. Calculé pour $C_7H_{11}O_3N$: N, 8.92%. Trouvé: N, 8.97%.

Bromuration, hydrolyse et cyclisation alcaline

On dissout de l'acétylallylglycine (8.5 g., 0.054 mole) dans 100 ml. d'acide acétique glacial. A la température de la chambre, on ajoute goutte à goutte du brome (9 g., 0.057 mole) dissous dans 25 ml. de chloroforme en maintenant une bonne agitation. L'addition de brome terminée, on évapore le solvant sous pression réduite et on obtient un résidu gommeux qui se refuse à cristalliser. On y ajoute 150 ml. d'eau distillée et 10 ml. d'acide sulfurique concentré. Après une hydrolyse de quatre heures, on cyclise en milieu alcalin tel que déjà décrit.

La chromatographie sur papier et l'analyse des acides aminés libres montrent que ces sels sont un mélange en parties à peu près égales d'hydroxyproline et d'acide 2-amino-4,5-dihydroxyvalérianique.

On obtient le même résultat à partir de l'acide allylacétamidomalonique au lieu de l'acétylallylglycine.

Formation des sels de cuivre de l'hydroxyproline et de l'acide 2-amino-4,5-dihydroxyvalérianique

Après avoir fait l'hydrolyse acide et la cyclisation alcaline des dérivés dihalogénés ou des lactones halogénées, on précipite les ions halogénés par le carbonate d'argent. Les bromures ou chlorures d'argent sont filtrés et le filtrat

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

est saturé d'hydrogène sulfuré. Après filtration, on évapore la solution à sec. Le résidu est dissous dans un minimum d'eau. On prépare les sels de cuivre des acides aminés par ébullition de la solution ainsi obtenue, en présence d'un excès de carbonate cuivrique et on évapore la solution à sec sous pression réduite. On cristallise les sels de cuivre par dissolution dans un petit volume d'eau chaude et addition d'alcool éthylique. Si après quelques heures au froid rien ne précipite, on évapore un peu d'alcool.

Suivant les produits de départ utilisés, les rendements en mélange des sels de cuivre de l'acide dihydroxylé et de l'hydroxyproline varient entre 40 et 60%. Le pourcentage respectif de l'un et de l'autre des acides aminés dans ces mélanges varie suivant les produits de départ (voir les tableaux I et II).

Séparation des sels de cuivre de l'hydroxyproline et de l'acide dihydroxylé

Hydroxyprolinate de cuivre

On sèche à 110° C. un mélange de sels de cuivre (8.5 g.) des deux acides aminés obtenus suivant la méthode décrite plus haut. On reprend par un minimum d'eau à chaud et on porte au froid. Le sel de cuivre, couleur violet, de l'hydroxyproline est insoluble. On le filtre. Poids obtenu: 3.5 g. Calculé pour $C_{10}H_{16}O_6N_2Cu.\frac{1}{2}H_2O$: N, 8.42%. Trouvé: N, 8.40%.

Une partie du sel de cuivre est solubilisée dans l'eau, acidifiée par l'acide acétique, puis saturée par l'hydrogène sulfuré pour précipiter le cuivre. Après filtration, la solution est décolorée au noir animal puis évaporée à sec. On reprend le résidu à l'eau et on fait un chromatogramme. L'hydroxyproline fut identifiée par chromatographie ascendante avec le phénol comme solvant. Seule la tache jaune caractéristique de l'hydroxyproline apparaissait après révélation à la ninhydrine. R_f 0.66. La méthode employée pour isoler l'acide aminé sous forme cristalline fut celle décrite par Gaudry et Godin (5).

2-Amino-4,5-dihydroxyvalérianate de cuivre

Le filtrat, obtenu lors de la filtration de l'hydroxyprolinate de cuivre, est concentré à très faible volume. On ajoute un grand excès d'alcool éthylique et on porte au froid. Un sel de cuivre bleu très pâle précipite. Poids obtenu: 4.4 g. Par ébullition du sel de cuivre dans l'alcool méthylique absolu, on solubilise les dernières traces d'hydroxyprolinate de cuivre. Après avoir filtré, on sèche le sel de cuivre de l'acide 4,5-dihydroxyvalérianique. P. f. 200–205° C. (déc.). Calculé pour $C_{10}H_{20}O_8N_2Cu$: N, 7.78%. Trouvé: N, 7.70%.

La chromatographie révèle la présence d'une seule tache violette, soit l'acide 2-amino-4,5-dihydroxyvalérianique. R_f 0.42.

Le fractionnement des sels de cuivre par la méthode décrite plus haut donne un rendement excellent. Ainsi en partant d'un mélange de 8.5 g. on sépare 3.5 g. d'hydroxyprolinate de cuivre et 4.4 g. de 4,5-dihydroxyvalérianate de cuivre, soit un rendement total de 93%.

Chlorhydrate de la 2-amino-5-hydroxyvalérolactone

L'acide dihydroxylé sous forme libre, obtenu à partir du 2-amino-4,5-dihydroxyvalérianate de cuivre (1 g.), suivant la méthode décrite précédemment, donne une huile visqueuse qu'il est impossible de cristalliser. On reprend à l'alcool éthylique absolu et on fait barbotter de l'acide chlorhydrique gazeux

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

jusqu'à ce que le tout se soit solubilisé. A ce stage, on évapore à sec. Le résidu cristallin est repris par un minimum d'alcool anhydre et filtré. Poids du chlorhydrate de la lactone obtenue: 0.4 g. Rendement 43%. P. f. 203–205° C. Calculé pour $C_5H_{10}O_3NCl$: N, 8.36%; Cl, 21.1%. Trouvé: N, 8.40%; Cl, 20.7%.

Acide 2-phényluréido-4-pentènoïque

On dissout de l'allylglycine (1.8 g., 0.015 mole) dans une solution de 0.62 g. d'hydroxyde de soude dans 50 ml. d'eau distillée. A la température de la chambre, on ajoute à la solution de l'isocyanate de phényle (1.9 g., 0.015 mole) en agitant pendant 15 min. On acidifie la solution avec 1.5 ml. d'acide chlorhydrique concentré et on refroidit ensuite sur un bain de glace. On agite le précipité au froid pendant quelques minutes et on filtre le produit. Rendement: 3 g., 85.0%. P. f. 162–163° C. Calculé pour $C_{12}H_{14}O_3N_2$: N, 11.9%. Trouvé: N, 12.1%.

5-Allylhydantoïne

On dissout de l'allylglycine (8.6 g., 0.075 mole) dans 75 ml. d'eau distillée. On ajoute du cyanate de potassium (6.5 g., 0.08 mole) et on chauffe à une température de 65° C. pendant deux heures. On ajoute ensuite à la solution 17.5 ml. d'acide chlorhydrique concentré et on chauffe à 90° C. pendant deux heures. La solution est évaporée à sec sous pression réduite et le résidu est agité dans de l'acétone chaude. Le chlorure de potassium insoluble est filtré et l'acétone est évaporée à sec sous pression réduite. On reprend le résidu avec 100 ml. d'eau bouillante et on décolore la solution au noir animal. On évapore la solution à petit volume, 25 ml. environ, et on place le tout au froid. L'hydantoïne cristallise rapidement. Rendement: 7.4 g., 72%. P. f. 104° C. Calculé pour $C_6H_8O_2N_2$: N, 20.0%. Trouvé: N, 19.5%.

5-(2,3-Dichloropropyl)hydantoïne

On place de la 5-allylhydantoïne (5 g., 0.035 mole) dans 100 ml. de chloroforme. On fait barbotter du chlore gazeux dans la solution jusqu'à saturation, en maintenant cette dernière à la température de la chambre. On évapore à sec sous pression réduite en ne chauffant que légèrement. On recristallise le résidu d'un petit volume d'eau bouillante. Rendement: 3.55 g., 48.5%. P. f. 150–152° C. Calculé pour $C_6H_8O_2N_2Cl_2$: N, 13.25%; Cl, 33.3%. Trouvé: N, 13.20%; Cl, 33.2%.

5-(2,3-Dibromopropyl)hydantoïne

Dans un ballon à large col de 300 ml., on place de l'allylhydantoïne (8.55 g., 0.061 mole) dans 100 ml. de chloroforme. On ajoute goutte à goutte du brome (10.0 g., 0.062 mole) en maintenant la solution à la température de la chambre. On évapore la solution à sec sous pression réduite en ne chauffant que légèrement. On recristallise le résidu d'un volume minimum d'eau bouillante. Rendement: 17 g., 93%. P. f. 155° C. Calculé pour $C_6H_8O_2N_2Br_2$: N, 9.3%; Br, 53.0%. Trouvé: N, 9.3%; Br, 51.1%.

3-Phényl-5-allylhydantoïne

On dissout de l'allylglycine (3.5 g., 0.03 mole) dans une solution de 1.2 g. d'hydroxyde de soude dans 50 ml. d'eau distillée. On ajoute goutte à goutte

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

de l'isocyanate de phényle (3.62 g., 0.03 mole) en maintenant la solution à la température de la chambre. La solution est agitée pendant environ 15 min. et ensuite acidifiée avec 15 ml. d'acide chlorhydrique concentré. On chauffe la solution sur un bain-marie bouillant pendant une heure, puis on l'évapore à sec sous pression réduite. Le résidu est recristallisé de l'alcool dilué. Rendement: 4 g., 61%. P. f. 97–98° C. Calculé pour $C_{12}H_{12}O_2N_2$: N, 12.9%. Trouvé: N, 12.8%.

3-Phényl-5-(2,3-dichloropropyl)hydantoïne

A la température de la chambre, on fait barbotter du chlore gazeux dans une solution de 3-phényl-5-allylhydantoïne (2 g., 0.0092 mole) dans 100 ml. de chloroforme. Lorsque la solution est complètement saturée de chlore, on l'évapore à sec sous pression réduite. On cristallise le résidu huileux de l'alcool dilué. Rendement: 1 g., 38%. P. f. 142° C. Calculé pour $C_{12}H_{12}O_2N_2Cl_2$: N, 9.78%; Cl, 24.5%. Trouvé: N, 9.28%; Cl, 20.3%.

3-Phényl-5-(2,3-dibromopropyl)hydantoïne

Dans un ballon à large col de 300 ml., on dissout de la 3-phényl-5-allylhydantoïne (2 g., 0.0092 mole) dans 100 ml. de chloroforme. A la température de la chambre, on ajoute goutte à goutte du brome (1.5 g., 0.0094 mole). L'addition terminée, on évapore la solution à sec sous pression réduite. On recristallise le résidu de l'alcool dilué. Rendement: 2.75 g., 79%. P. f. 130–135° C. Calculé pour $C_{12}H_{12}O_2N_2Br_2$: N, 7.45%; Br, 42.5%. Trouvé: N, 7.46%; Br, 42.0%.

REMERCIEMENTS

Les auteurs remercient l'Office des Recherches Scientifiques de la province de Québec (A.L.), le Conseil National de Recherches (G.P.) pour l'octroi de bourses, ainsi que la compagnie Shell Oil Limited qui a gracieusement fourni le chlorure d'allyle utilisé au cours de ce travail.

THE VOLATILIZATION OF PLUTONIUM FROM NEUTRON-IRRADIATED URANIUM[1]

By D. E. McKenzie

ABSTRACT

The volatilization of plutonium from neutron-irradiated uranium has been examined at 1540°, 1650°, and 1769°C. The observed rates of evaporation of plutonium have been compared with calculated rates based on the Langmuir equation and Raoult's law. Experimental and calculated results agree within the precision of the experimental measurements, indicating that the plutonium in neutron-irradiated uranium follows the ideal solution laws.

INTRODUCTION

In some types of nuclear reactors uranium metal is used as fuel. The processing of the resulting neutron-irradiated uranium and return of the separated plutonium and uranium to the reactor may become important if such reactors are to produce economic power. Current processing methods require dissolution of the neutron-irradiated uranium and solvent extraction or ion exchange techniques to achieve the separation (1, 4). The uranium metal for re-irradiation must be prepared from the resulting aqueous solution. Alternative separation methods, in which uranium is retained as metal throughout, may offer advantages.

One possible method is the volatilization of plutonium from the uranium. This technique is suggested by the fact that, at, for example, 1540°C., the vapor pressure of plutonium (5) is 300 times that of uranium (6). This paper describes an investigation of the rate of evaporation, in vacuum, of plutonium from neutron-irradiated uranium. The results are in qualitative agreement with those obtained at the North American Aviation Laboratories in Downey, California (3).

EXPERIMENTAL

Materials and Apparatus

Neutron-irradiated uranium was obtained from rods which had been irradiated for various periods in the NRX reactor. The beryllia crucibles which were of the vertical-wall type were obtained from the Atomic Energy Research Establishment at Harwell, England. The evaporating area of a melt was calculated from the average of a number of diameter measurements of each crucible.

The apparatus for the distillation is illustrated in Fig. 1. The uranium was heated by a tungsten resistance coil, surrounded by beryllia thermal shields and molybdenum radiation shields. The assembly was mounted in a glass bulb which was evacuated by diffusion and mechanical pumps through a trap cooled by liquid air. The pumping equipment gave pressures of less than

[1]*Manuscript received December 29, 1955.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 297.

5×10^{-5} mm. of Hg in the system when the charge was at temperature. The system was contained in a dry box in which the glass bulb was surrounded by lead.

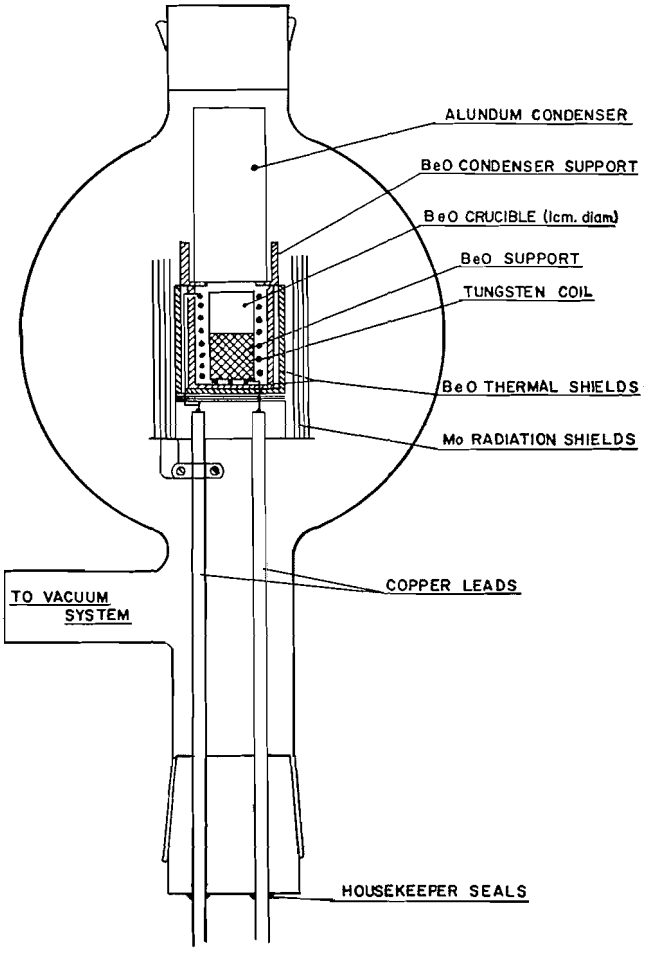

FIG. 1. Diagram of bulb and crucible assembly.

Distillations were carried out at 1540°, 1650°, and 1769°C. The temperatures 1540° and 1769°, the melting points of iron and platinum respectively, were reproduced by careful determinations of the power required to melt these metals in the crucible assembly. An interpolation of these values gave the power required for 1650°. The coils were always restandardized after two or three runs. A constant temperature during a run was maintained by observing the uranium charge with an optical pyrometer which was sighted through an optical window in the top ground-glass joint and a hole in the condenser. The maximum error in the temperature is ±15°C.

Procedure

The procedure for an experiment was as follows: A piece of neutron-irradiated uranium was etched in nitric acid to remove at least 25% of its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

weight for a reference solution. The remaining uranium was washed with water and with acetone before being placed in a beryllia crucible and put in the apparatus. The bulb was pumped down to a pressure of 10^{-6} mm. of Hg and power applied to the coil to degas the crucible and associated shields. The uranium was then heated to temperature to perform the distillation. The pressure in the system did not exceed 10^{-4} mm. of Hg during the degassing operation.

After distillation the charge was cooled to room temperature and the vacuum broken. The uranium residue was removed from the crucible and dissolved in nitric acid. Also the crucible was leached in nitric acid. These solutions and the reference solution were analyzed for plutonium by standard radiochemical procedures.

RESULTS

The data for the various runs are given in Table I. The total amount of plutonium distilled was determined from the plutonium content of the original uranium and the plutonium content of the uranium residue. Only that portion

of the distilled plutonium that collected on the sides of the crucible was recovered for analysis. This plutonium fraction is due to distillation since in one run, the top of the crucible, which had been sawed directly above the uranium residue, contained essentially all the plutonium found in the crucible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

Plutonium balances were made in two runs by crushing and leaching the alundum condenser. In run 116, 94% of the original plutonium was recovered and in run 117, 85% was recovered.

DISCUSSION

The results have been correlated with theory in the following manner. W, the theoretical rate of evaporation per unit area of a pure substance in vacuum, is given by the Langmuir equation (2)

[1] $$W = 0.0583\, p_0\sqrt{(M/T)}$$

where W has the units gm. cm.$^{-2}$ sec.$^{-1}$ for the constant 0.0583,

M = the molecular or atomic weight of the vaporizing species, and

p_0 = the vapor pressure of the pure substance in mm. of Hg at the temperature T°K.

In the derivation of this equation a clean evaporating surface and uniform temperature in the melt are assumed. Although these conditions, in particular the clean surface, are not strictly adhered to, the equation will be used for the present experiments.

To apply the Langmuir equation to the evaporation of a particular component from a solution it is necessary to replace the vapor pressure of the pure substance, p_0 in equation [1], by the partial pressure of that component above the solution. For dilute metallic solutions the solute (i.e. the less concentrated component) generally obeys Henry's law which defines this partial pressure as

[2] $$p = k\, n$$

where k is a constant and n is the mole fraction of the component in solution. If the component obeys Raoult's law then k is equal to p_0. For convenience in comparing the results with Henry's and with Raoult's laws we introduce a new constant k' such that $k = k'p_0$. Thus, assuming the component follows Henry's law, the Langmuir equation for the evaporation of that component from a solution becomes

[3] $$W = 0.0583\, k'\, p_0\, n\sqrt{(M/T)}.$$

Equation [3] has been integrated, for application to the distillation of plutonium from neutron-irradiated uranium, with the following result:

[4] $$\log Y/Y_0 = -\left(\frac{0.0583}{2.303}\, p_0\sqrt{(M/T)}\right) k'\, \frac{tA}{U_0}$$

where Y/Y_0 = the fraction of the original plutonium in the residue,

t = the time of distillation in seconds,

A = the evaporating area in cm.^{2}, and

U_0 = the initial weight of the uranium in grams.

It was assumed in the integration that k' and U_0 are constants, i.e. k' is independent of plutonium concentration in the range studied, and the amount of uranium distilled is a negligible fraction of the original charge. The mole fraction of plutonium was assumed to be weight of plutonium/weight of uranium. In addition, the assumptions in applying [4] are (1) neutron-

For personal use only.

irradiated uranium behaves as a binary solution of plutonium in uranium and (2) plutonium distills in monatomic form.

The experimental results have been correlated with equation [4] by (1) assuming Raoult's law, i.e. $k' = 1$, and calculating a theoretical value for the plutonium distilled and (2) assuming Henry's law and calculating a value for k'. The equation $\log p_{mm} = 7.895 - 17590/T$ has been used for the vapor pressure of pure plutonium (5). The correlations are summarized in Tables II, III, and IV (the units of time have been changed to hours). The experi-

mental results are compared with calculations based on Raoult's law in Figs. 2, 3, and 4 where log Y/Y_0 is plotted against tA/U_0. The effect of an uncertainty in temperature of ± 15°C. is shown in these figures.

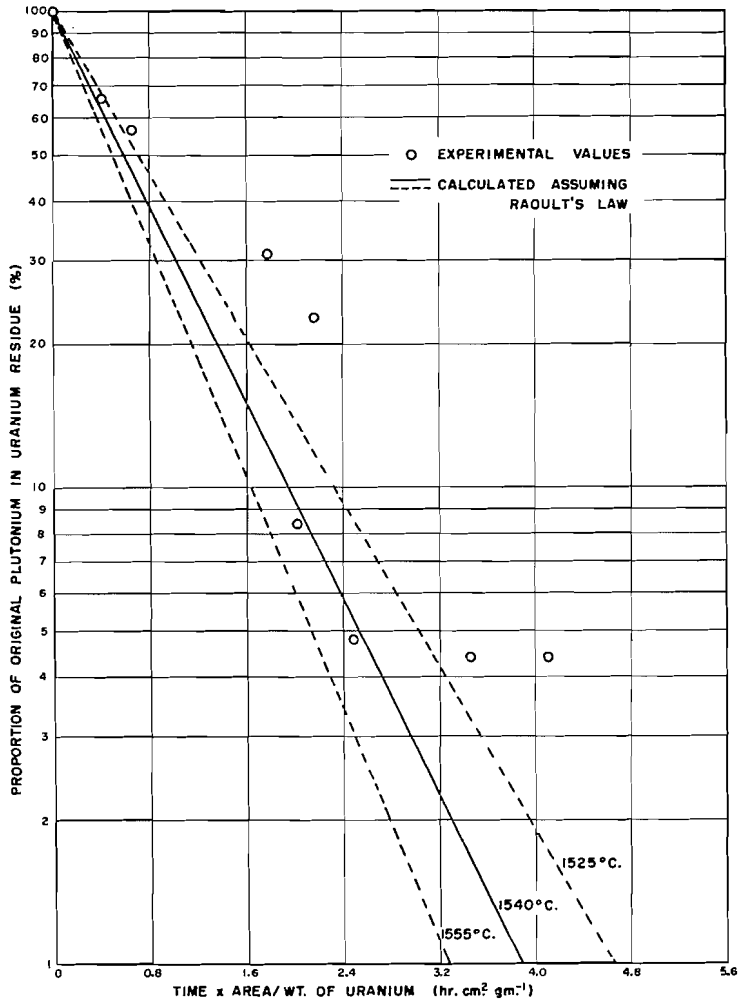

FIG. 2. Comparison of calculated and experimental results for runs at 1540°C. The dotted lines indicate the effect, on the calculations, of an error of ± 15°C. in temperature.

The quantity k' is the activity coefficient of plutonium in neutron-irradiated uranium. Its variation with temperature can be related to the heat of solution of plutonium in this material. However, the estimated error in the values of k' obtained by the present procedures is about $\pm 25\%$ (the uncertainty in temperature alone results in an error of $\pm 17\%$). The average value of k' for each temperature deviates from unity by less than this experimental error.

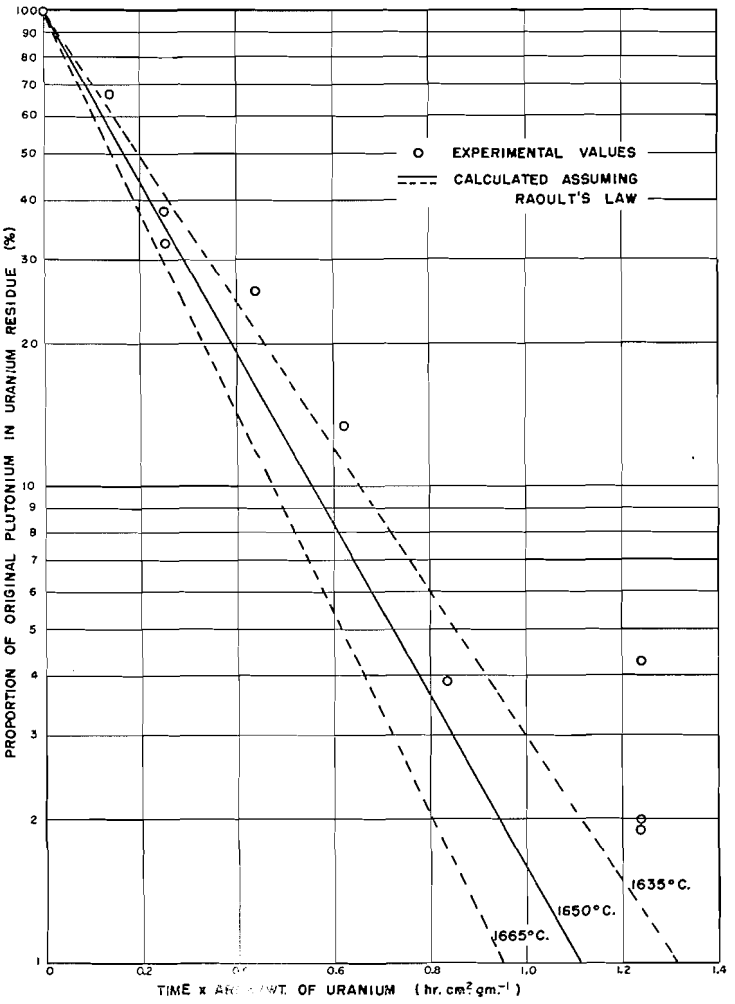

FIG. 3. Comparison of calculated and experimental results for runs at 1650°C.

In addition, no effect due to varying plutonium concentrations is observed. Thus, for these temperatures and concentrations, it is concluded that plutonium in neutron-irradiated uranium forms essentially an ideal solution.

This conclusion might have been predicted from the proximity of plutonium to uranium in the actinide series. Deviations of k' from unity, if real, are probably associated with assumptions made in the treatment of the data. Uranium, since it is an excellent "getter" for oxygen, would not be expected to have a clean evaporating surface. Also plutonium may form high melting point compounds with one or more of the fission products. Both of these effects would lower the evaporation rate from that predicted from the Langmuir equation and Raoult's law.

THE ELUCIDATION OF THE STRUCTURE OF HYOCHOLIC ACID[1]

By P. Ziegler

ABSTRACT

Hyocholic acid, a new bile acid isolated from hog bile, was identified as 3(α), 6(α),7(α)-trihydroxycholanic acid.

The bile acids are the main constituents of animal bile where they are usually found in conjugation with amino acids. In the past it has been the practice to saponify bile under rigorous alkaline conditions prior to isolation of the constituent bile acids and, in this manner, the compositions of the bile acid mixtures from a large number of animals were determined. Hog bile proved to be an exception despite a considerable amount of effort, and the greater portion of the saponified hog bile solids could never be accounted for in the form of identifiable bile acids or their derivatives (7, 8). This has prompted a careful investigation of hog bile in these laboratories resulting in the isolation of a hitherto unknown acid which, according to established terminology, will be named hyocholic acid.

By the procedure of isolation (to be reported in more detail at a later date) hyocholic acid was obtained as the methylated and acetylated derivative which gave satisfactory analyses for I and also was found, by acetate determination, to contain three moles of acetate per mole of steroid. This compound was transparent to ultraviolet from 220 to 400 mμ, failed to react with tetranitromethane or ketone reagents, and, on infrared examination, exhibited the characteristic bands of the carbomethoxy and acetate groups. Saponification of I afforded hyocholic acid (II) which analyzed correctly for a trihydroxycholanic acid; it was not identical with the widely distributed cholic acid and a literature survey failed to reveal any bile acid with properties similar to II. It was later found that the methyl ester of hyocholic acid gave a positive Malaprade test, indicating that at least two of the three hydroxyl groups were adjacent to each other, an arrangement unknown in the natural bile acids.

Hyocholic acid (II) was then oxidized with chromic acid to give, after methylation, 3-ketothilobilianic acid trimethyl ester (III), not previously described. This compound gave a positive Zimmermann reaction and analyzed correctly for three methoxyl groups. Obviously the carbon–carbon bond of the vicinal glycol was ruptured giving rise to two new carboxyl groups, while the third hydroxyl function was oxidized to a ketone. This proved that all three hydroxyl groups were secondary alcohols and that one of these was isolated from the glycol structure and not adjacent to it. The positive Zimmermann reaction showed that the ketone was not located at positions 6, 7, or 12 of the nucleus. It now remained to determine which of the rings had broken during the oxidation; this would locate at once the positions of the two vicinal

[1]*Manuscript received December 8, 1955.*
Contribution from the Research and Development Laboratories of Canada Packers Ltd., Toronto, Ont.

hydroxyl groups. It was then assumed that the isolated hydroxyl group in hyocholic acid (II) was present at C-3, because all naturally occurring bile acids have this characteristic grouping and because the positive Zimmermann test exhibited by III lent further evidence for that, although this did not

constitute a rigid proof. That assumption at once eliminated ring A as the site of the glycol which previously was shown to be removed by at least two carbon atoms from the third hydroxyl group. Ring C also could be excluded because all possible isomers of 3(α),11,12-trihydroxycholanic acid are synthetic products described in the literature (2, 11) and none of these compounds had the physical properties of hyocholic acid. That left rings B and D as the only possible locations for the vicinal hydroxy groups. Ring D seemed an unlikely prospect since hydroxylation in that ring is not known to occur in bile acids. Clearly then ring B was suspected and circumstantial evidence could be derived from the fact that hog bile contains 20% of 3(α),6(α)-dihydroxycholanic acid and an appreciable quantity of 3(α),7(α)-dihydroxycholanic acid. These acids (hyo- and cheno-desoxycholic acid respectively) are produced in the liver from cholesterol and it seemed reasonable to think that the enzymes responsible for hydroxylation at C-6 and C-7 could also produce compounds that are doubly hydroxylated, giving rise to the 6,7-vicinal glycol.

Definite proof for this was then obtained from two products derived from 3-ketothilobilianic acid trimethyl ester (III). This compound was reduced by Huang-Minlon's modification of the Wolff–Kishner reduction (4) to give, after methylation, IV which was found to be identical with the thilobilianic acid trimethyl ester prepared by Wieland (10). Sodium borohydride reduction of III and subsequent esterification gave V which was found to contain only two methoxyl groups. Infrared examinations showed conclusively the presence of a five-membered lactone ring by the very characteristic absorption bands at 940 and 1775 cm.$^{-1}$ (3, 5). This lactone (V) has also been prepared by Japanese workers (13) by nitric acid oxidation of 3(α)-acetoxy-6(or 7)-ketocholanic acid.

The above experiments furnished proof for the location of the hydroxyl groups at positions 3, 6, and 7. It now remained to determine the stereochemical configuration of these groups. It was found that hyocholic acid did not give an insoluble digitonide, which indicated that the hydroxyl group at C-3 was in the α-position. Conclusive evidence for this was also obtained from V which was identical with the lactone obtained by the Japanese investigators (13) whose starting material contained the 3(α)-hydroxy group; during their sequence of reactions no change took place involving in any way the stereochemistry of the alcohol group. In our hands, V was obtained by sodium borohydride reduction of the ketone III and it is well known (6) that such reductions yield predominantly 3(α)-hydroxy compounds in the A/B *cis* series and 3(β)-hydroxy analogues in the A/B *trans* series. Furthermore, the presence of the lactone in V is also excellent proof not only for the α-configuration of the 3-hydroxy group but also for the A/B *cis* junction. Five-membered lactones are planar and as such require that their two bonds, which are the links to ring A, be in the same plane, either both α or both β. There is however a difference between the two as regards ease of formation. Lactones of the α-type such as V form spontaneously from the corresponding hydroxy acids which cannot be isolated (3, 13); on the other hand, 3(β)-hydroxy-5(β)-carbohydroxy steroids exist as such and lactonize only after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

treatment with hot acetic anhydride or under similar conditions (12). In our work the hydroxy compound was not isolated but only the lactone which must have formed during acidification in the cold of the alkaline sodium borohydride reaction mixture. Clearly this represents ample support for the α-configuration of the lactone in V.

The hydroxyl groups at C-6 and C-7 can exist in four different stereochemical positions in two of which they are in the same plane ($6\alpha,7\alpha$ or $6\beta,7\beta$). It is known that only those vicinal glycols in which the alcoholic functions are in the same plane form acetonides (9). The methyl ester of hyocholic acid (II) was therefore treated with acetone and *p*-toluenesulphonic acid, but no crystalline substance could be obtained. The residue was then acetylated and the products chromatographed on alumina. Nearly all the material was eluted with benzene but again no crystals could be isolated. The benzene fraction was found to contain only one acetate group per mole of steroid. Another portion of the benzene eluate was then examined in the infrared and no trace of a free hydroxyl group could be detected. Therefore the acetonides VI and VII must have been formed and the hydroxyl groups in II are in the same plane. Additional support for acetonide formation was also obtained by refluxing VII with acetic acid which decomposed the acetonide to give acetone. After dilution with water, the mixture was distilled and the distillate gave a positive iodoform test.

The above experiments then left only two possibilities for the structure of hyocholic acid, the one having the glycol at $6(\alpha),7(\alpha)$, the other at $6(\beta),7(\beta)$. A differentiation between these two can be made on the basis of molecular rotation data which have recently been very useful in structure elucidation of steroids. The fundamental concept consists of the usually valid claim that a given functional group at a given location and configuration will always contribute the same amount to the molecular rotation of the whole molecule; or, in other words, the molecular rotation of a compound is the algebraic sum of the rotatory contributions of the constituent parts of the molecule. This holds true only if there are no "vicinal effects" which result from the interaction of functional groups which are situated close to each other in space.

From the data of Barton and Klyne (1) and from our own work, we have determined the individual rotatory contributions (all values in alcohol) of hydroxyl groups in ring B of the normal bile acid series. Lithocholic acid was found to have $[M]_D$ +121 and from these values the approximate molecular rotations of the two alternative structures for hyocholic acid should be as given below:

$[M]_D$ of $3(\alpha),6(\alpha),7(\alpha)$-trihydroxycholanic acid $= +121-62-72 = -13$,

$[M]_D$ of $3(\alpha),6(\beta),7(\beta)$-trihydroxycholanic acid $= +121+24+103 = +248$.

Hyocholic acid was found to have $[M]_D$ +19, which agrees more closely with the $6(\alpha),7(\alpha)$-structure, though the approximation is not nearly as satisfactory as would be expected if there were no "vicinal effects". But it must be realized immediately that such "vicinal effects" are operative in hyocholic acid because of the interaction within the glycol grouping. An examination of the above data reveals that both the $6(\alpha)$- and the $7(\alpha)$-hydroxy contributions are

negative, while the opposite configurations give positive increments. It is reasonable to predict that, where "vicinal effects" exist, the numerical value of a rotatory contribution will be smaller than the calculated "non-vicinal" value, provided the latter has a numerical value which is not close to zero. If this is applied to the 6(α),7(α)-structure, the $[M]_D$ value would come close to +19 which was determined experimentally for hyocholic acid. At the same time the vicinal contributions of the two hydroxyl groups, though numerically reduced, would not change in sign (negative). On the other hand, in the 6(β), 7(β)-structure, the combined "non-vicinal" contributions are +127 which would have to change to −102 to accommodate the experimentally determined value of $[M]_D$ +19. This is extremely unlikely.

Besides the above evidence obtained from rotation data, there is also available some biogenetic indication for the α-configuration of the hydroxyl groups in ring B. An examination of the known constituents of hog bile shows that some compounds have hydroxyl groups at 6(α) or 7(α), but not a single hog bile acid has a hydroxyl group in the β-configuration in ring B.

From the data presented it was concluded that hyocholic acid is 3(α),6(α), 7(α)-trihydroxycholanic acid.

EXPERIMENTAL[2,3,4]

The Isolation of Methyl Hyocholate Triacetate (I)

Hog bile (1 liter) was refluxed with sodium hydroxide (100 gm.) for 60 hr. The solution was then acidified, extracted with ethyl acetate, and the solvent extract evaporated to a small volume. After cooling, the resulting precipitate was filtered off to yield 55 gm. of material, m.p. 150–160°C. This was treated with ethereal diazomethane and the crude methyl esters were crystallized from benzene to provide methyl hyodesoxycholate – benzene complex (23 gm.). The filtrate was evaporated *in vacuo* and the dry residue was then refluxed with pyridine (50 ml.) and acetic anhydride (250 ml.) for four hours. Evaporation of the solvents, extraction with ether, washing, and crystallization from hexane or iso-octane afforded crude I (15 gm.), m.p. 173–176°C. This was recrystallized several times from ether–hexane to give transparent, irregular plates, m.p. 188–190°C. and $[\alpha]_D^{20}$ +20.95° (*c*, 1.22, dioxane). Infrared absorption bands at 1040, 1165, 1225–1250, 1362, 1735–1740, and 2950 $cm.^{-1}$. This compound was found to contain 33.1% of acetate (calculated value = 32.27%). Analysis: Calcd. for $C_{31}H_{48}O_8$: C, 67.85; H, 8.82; O, 23.33. Found: C, 67.85, 67.81; H, 8.90, 8.88; O, 23.24, 23.34.

Hyocholic Acid (II)

Refluxing I with 4% methanolic potassium hydroxide for two hours provided, after several recrystallizations from ethyl acetate, prismatic needles of II, m.p. 183–185°C. and $[\alpha]_D^{24}$ +4.59° (*c*, 1.18, dioxane) and $[\alpha]_D^{25}$ +4.59° (*c*, 1.10, ethanol). Analysis: Calcd. for $C_{24}H_{40}O_5$: C, 70.55; H, 9.87; O, 19.58. Found: C, 70.78, 70.79; H, 9.75, 9.84; O, 19.64, 19.48.

[2]*The microanalyses were kindly performed by Mr. E. Thommen, Basel, Switzerland; the acetate determinations by Mr. C. K. Cross in our laboratories.*

[3]*The infrared examinations were made through the courtesy of Dr. G. D. Laubach of Ch. Pfizer & Co., Brooklyn, N.Y., and Miss Kirby of the Ontario Research Foundation, Toronto.*

[4]*The procedure for the isolation of I was developed in collaboration with Mrs. G. C. Buckley and Mr. A. A. Amos.*

3-Ketothilobilianic Acid Trimethyl Ester (III) from II

Compound II (2 gm.) was dissolved in acetic acid (25 ml.) and there was then added over a period of one hour a solution of chromic acid (1.8 gm.) in water (1 ml.) and acetic acid (25 ml.). The temperature was kept at 15–20°C. during the addition and for 14 hr. thereafter. The excess oxidizing agent was destroyed by sodium bisulphite and the solvents were then removed *in vacuo* at 30°C. The residue was taken up in dilute sulphuric acid and ether, the aqueous phase was extracted two more times with ether, the combined ether extracts were washed with dilute acid, then with water, and finally dried and evaporated to dryness. After methylation with ethereal diazomethane, the residue was crystallized from ether–hexane to afford 854 mgm. of material, m.p. 130–137°C. Several recrystallizations from ether–hexane yielded prismatic needles, m.p. 140–142°C. and $[\alpha]_D^{25}$ −5.05° (*c*, 0.29, dioxane). This compound (III) gave a positive Zimmermann reaction, failed to give a coloration with alcoholic ferric chloride, tetranitromethane, or triphenyltetrazolium, and did not absorb in the ultraviolet region. Infrared examination revealed strong bands at 1165, 1220, 1445, 1730, and 2930 $cm.^{-1}$ and several weaker bands in the region of 1100 to 1400 $cm.^{-1}$. Analysis: Calcd. for $C_{27}H_{42}O_7$: C, 67.75; H, 8.85; OCH_3, 19.45. Found: C, 67.81, 67.93; H, 8.82, 8.93; OCH_3, 19.33, 19.35.

Thilobilianic Acid Trimethyl Ester (IV) from III

Compound III (250 mgm.) was dissolved in diethylene glycol (8 ml.), then a hot solution of potassium hydroxide (2 gm.) in the same solvent (12 ml.) was added. After addition of 85% hydrazine hydrate (3 ml.), the solution was refluxed for one hour, the condenser was then set downwards, and the solution distilled until the internal temperature had reached 200°C. The solution was then refluxed for two hours, cooled, diluted with water, acidified with hydrochloric acid, and extracted three times with ether. The solvent extracts were washed first with dilute acid, then with water, and subsequently dried over sodium sulphate and evaporated to dryness to yield an amorphous residue (162 mgm.). This was methylated with diazomethane, then crystallized from aqueous methanol to give 82 mgm. of impure IV, m.p. 95–100°C. Two recrystallizations from iso-octane furnished IV, m.p. 108–109°C. and $[\alpha]_D^{24}$ −13.6° (*c*, 0.695, dioxane). Wieland (10) cites m.p. 109°C. Analysis: Calcd. for $C_{27}H_{44}O_6$: C, 69.79; H, 9.55; O, 20.66; OCH_3, 20.03. Found: C, 69.92; H, 9.36; O, 21.39; OCH_3, 19.84.

3(α)-Hydroxythilobilianic Acid – 3,5-Lactone Dimethyl Ester (V) from III

Compound III (100 mgm.) was dissolved in methanol (15 ml.) and the solution was cooled to 5°C. There was then added, in five portions, sodium borohydride (60 mgm.). The solution was kept at 20°C. overnight; it was then diluted and acidified and the products extracted with ether several times. Working up in the usual way, methylating, and crystallizing from ether–hexane afforded 47 mgm. of substance, m.p. 152–153°C. This was dissolved in ether–hexane, the solution heated to remove the ether and cooled; in this manner, irregular, transparent plates, m.p. 157–159°C. and $[\alpha]_D^{24}$ −18.9° (*c*, 0.61, dioxane), were obtained. Infrared examination showed the typical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

five-membered lactone absorption at 940 and 1775 cm.$^{-1}$ as well as bands at 1725 and 1750 cm.$^{-1}$. This compound did not give a color reaction in the Zimmermann test. Analysis: Calcd. for $C_{26}H_{40}O_6$: C, 69.61; H, 8.99; O, 21.40; OCH_3, 13.84. Found: C, 69.82; H, 9.08; O, 21.57; OCH_3, 13.52.

Acetonide Formation (VI and VII)

Hyocholic acid (250 mgm.) was methylated with diazomethane and the excess reagent was removed *in vacuo*. After thorough drying, the residue was dissolved in dry acetone (20 ml.), *p*-toluenesulphonic acid (50 mgm.) was added, and the stoppered flask kept at 20–25°C. for 20 hr. The solution was neutralized with sodium bicarbonate, diluted with water, and exhaustively extracted with ether. The solvent extracts were washed, dried, and evaporated to dryness to give a residue (284 mgm.) which could not be induced to crystallize, despite chromatography on alumina.

This residue (VI) was then acetylated at 20°C. with pyridine (3 ml.) and acetic anhydride (5 ml.) for 17 hr. The solvents were removed *in vacuo* at 30°C. and again the residue did not crystallize. It was dissolved in benzene (25 ml.), poured over a column of alumina (10 gm.) and the adsorbent washed with benzene (100 ml.). The combined benzene eluates were evaporated to dryness to give the residue (223 mgm.) which was used for the subsequent tests.

(*a*) Infrared analysis showed that the material did not contain any free hydroxyl groups. The main bands were at 880, 1040, 1050, 1260, 1370, 1385, 1465, 1740, and 2875 cm.$^{-1}$.

(*b*) 45.8 mgm. of the residue required 4.03 ml. of 0.02438 *N* sodium hydroxide in the acetate determination; this indicates the presence of 12.7% acetate in VII. The calculated value (for one mole of acetate) is 11.7%.

(*c*) *Iodoform test.*—Approximately 100 mgm. of amorphous VII was dissolved in acetic acid (10 ml.) and the solution refluxed for one-half hour. The solution was diluted with water (40 ml.) and the resulting mixture distilled until 10 ml. of distillate was collected. The distillate was made strongly alkaline by addition of 10% sodium hydroxide and then the potassium iodide – iodine reagent was added. An immediate precipitation of yellow iodoform resulted. A blank did not produce any precipitate.

SYNTHESES AND ABSORPTION SPECTRA OF 1-CHLOROPHENYL-3-PHENYL-4-ALKYL-5-PYRAZOLONES AND PYRAZOLONES-4-C^{14} [1]

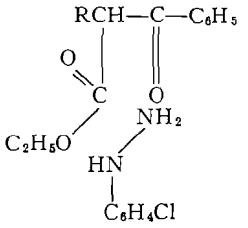
By Paul E. Gagnon, Jean L. Boivin,[2] and Yvon Laflamme[3]

ABSTRACT

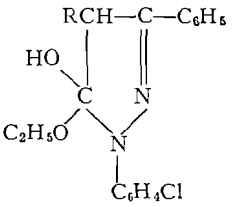
Monosubstituted benzoylacetic esters $C_6H_5COCH(R)CO_2C_2H_5$ (R = H, C_nH_{2n+1} (n = 1 to 9), and $C_6H_5CH_2$) obtained by the condensation of n-alkyl halides with ethyl benzoylacetate were reacted with o-, m-, and p-chlorophenylhydrazines to give 1-chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones. Pyrazolones-4-C^{14} were prepared by the action of the same hydrazines on ethyl benzoylacetate-α-C^{14} obtained from benzoyl chloride and ethyl malonate-2-C^{14}. Their activities were 801, 894, and 847 c./min. respectively. The ultraviolet and infrared absorption spectra of all the pyrazolones were determined and the most probable structures ascribed to the compounds.

INTRODUCTION

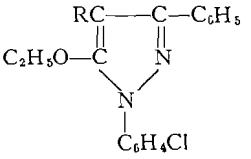
The condensation of hydrazine and its monosubstituted derivatives with β-keto esters (I) gives by elimination of water a hydrazone (II) which, by elimination of another molecule of water, produces an alkoxypyrazole (III) or a pyrazolone (IV) by elimination of alcohol.



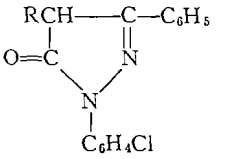
I



II



III



IV

The main product is an ethoxypyrazole when the reagents are heated in acid media and a pyrazolone when they are heated alone.

One of the objects of the present investigation was to synthesize and to determine the structure of 1-chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones. Another object was to prepare pyrazolones-4-C^{14}.

The starting esters used in the present work, the ethyl-α-monosubstituted-α-benzoylacetates, were prepared (9) by alkylation of ethyl benzoylacetate. The *o*-, *m*-, and *p*-chlorophenylhydrazines were prepared by diazotation of their respective anilines followed by reduction with sodium sulphite. The ethyl benzoylacetate-α-C^{14} was obtained by the condensation of benzoyl chloride with ethyl malonate-2-C^{14} and decarboxylation (1, 8).

The individual properties and analyses of all pyrazolones prepared are listed in Tables I, II, and III.

Ultraviolet Absorption Spectra

The ultraviolet absorption spectra of all pyrazolones were determined in alcohol solution. The results obtained are given in Tables I, II, and III and shown graphically in Figs. 1, 2, and 3.

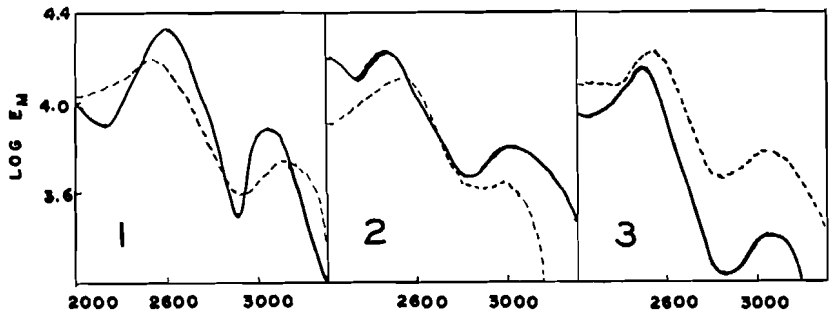

FIG. 1. Ultraviolet absorption spectra of 1-*o*-chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones; ——— 4-methyl, --- 4-amyl.
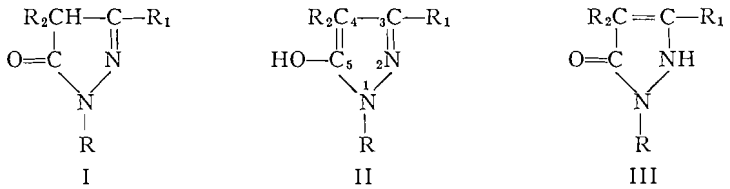
FIG. 2. Ultraviolet absorption spectra of 1-*m*-chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones; ——— 4-amyl, ---- 4-benzyl.
FIG. 3. Ultraviolet absorption spectra of 1-*p*-chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones; ——— 4-propyl, ---- 4-butyl.

The pyrazolones have a tendency towards tautomerism and three structures may be postulated for the pyrazolones prepared.



The 4,4-dialkyl-pyrazolones as well as the pyrazolone dyes are derived from formula I. Formula II is invoked to explain the formation of alkoxypyrazoles and the formation of sodium salt. Formula III explains the easy methylation of the nitrogen atom 2.

The spectra exhibited by many pyrazolones have been studied intensively by many workers (2, 3, 4, 5, 6). These authors related the wavelength of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

absorption band and its intensity to the position of the double bond in the ring. It was found that a high intensity maximum at short wavelength was indicative of a double bond between two carbon atoms while a low intensity maximum at longer wavelength corresponded to a double bond between the nitrogen atom 2 and the carbon atom 3. The presence of two maxima for the same compound was attributed to the presence of two tautomeric forms (7).

The spectra of the *o*-, *m*-, and *p*-chlorophenylpyrazolones prepared are quite similar in their characteristics. In neutral solution these pyrazolones exhibit two maxima, one of high intensity at short wavelength and one of low intensity at longer wavelength. These results indicate that during the spectra determination in alcoholic solution the pyrazolones existed in at least two tautomeric forms; one with a carbon nitrogen double bond, formula I or II, and the other with the carbon carbon double bond as shown in formulas II and III.

Infrared Absorption Spectra

The infrared absorption spectra of the pyrazolones were determined with a Perkin-Elmer spectrometer. The results obtained are given in Tables IV, V, and VI and some data are plotted in Figs. 4, 5, and 6.

Because of the three tautomeric structures theoretically possible for the 1,3,4-trisubstituted pyrazolones, they may be expected to give rise to very complicated infrared spectra. The problem of interpretation of those spectra

is difficult since few reference spectra for pyrazolones are available in the literature. The absorption spectrum of the 3-methyl-5-pyrazolone has been reported by Randall and his co-workers (10) and he only gave an assignment for a cyclic C=N band. The infrared spectra of several 4-monosubstituted-1,3-diphenyl-5-pyrazolones were determined by Gagnon, Boivin, and Paquin (6). Bond assignments were made tentatively for the C=O group at 1700 cm.$^{-1}$ and the C=N group at 1600 cm.$^{-1}$. Gagnon, Boivin, MacDonald, and Yaffe (5) have studied the absorption spectra of 2-substituted-3-hydroxy-5-pyrazolones and assigned a band in the region of 3300 cm.$^{-1}$ to an OH group. The presence of

that group was also proved by chemical methods. Another band occurring in the region of 1670–1700 cm.$^{-1}$ was attributed to a C=O group. A third band in the region of 1590–1680 was attributed to a C=N band as suggested by Randall (10) after studying many cyclic nitrogen compounds such as thiazolidines, imidazolines, and pyridines.

In the present investigation band assignments can be made for two functional groups. An absorption band of high intensity occurring in the region of 1630–1710 cm.$^{-1}$ is attributed to a C=O group. Randall and his co-workers have assigned an absorption band in this region to the carbonyl group for the lactams; therefore it is reasonable to do the same for pyrazolones. Furthermore the absence of a band in the region of 3300 cm.$^{-1}$ characteristic of an OH group is another proof for the presence of a carbonyl group.

A second band occurs in the double band region and absorbs in the range of 1565–1610 cm.$^{-1}$. This band is attributed to a C=N group as suggested by Randall after having studied many cyclic nitrogen compounds.

From those results, one might conclude that in the solid state the pyrazolones prepared have the form CH—C=N while in alcoholic solution this form is in equilibrium with its tautomer C=C—NH.

EXPERIMENTAL PART*

1-o-Chlorophenyl-3-phenyl-4-alkyl-5-pyrazolones

A mixture of ethyl-α-monosubstituted-α-benzoylacetate (0.02 mole) and *o*-chlorophenylhydrazine hydrochloride (0.02 mole) was heated under reduced pressure for three hours at 110–120° C. The red viscous liquid obtained was cooled and dissolved in sodium hydroxide (5%, 200 ml.). The solution was filtered and washed with ether until the extracts were no longer colored. The alkaline solution was cooled and acidified with acetic acid (50%). The precipitate obtained was recrystallized from alcohol or petroleum ether. The pyrazolones are listed together with their melting points, analyses, and ultraviolet absorption spectra in Table I and the infrared data are given in Table IV. Typical ultraviolet absorption curves are plotted in Fig. 1 while some infrared data are plotted in Fig. 4.

1-m-Chlorophenyl- and 1-p-Chlorophenyl-3-phenyl-4-monosubstituted-5-pyrazolones

A mixture of ethyl-α-monosubstituted-α-benzoylacetate (0.02 mole) and *m*-chlorophenyl- or *p*-chlorophenyl-hydrazine was heated under reduced pressure for three hours at 110–120° C. and then for one hour at 170–180° C. The red viscous liquid was treated in a manner similar to that used to obtain the 1-*o*-chlorophenylpyrazolones. The melting points, analyses, and ultraviolet absorption maxima are given in Tables II and III. The infrared absorption bands are given in Tables V and VI and some data are plotted in Figs. 5 and 6.

Preparation of Ethyl Benzoylacetate-α-C^{14}

Magnesium (5.6 gm., 0.23 mole) was placed in a flask equipped with a condenser and a mechanical stirrer. Ethyl malonate (32 gm., 0.20 mole) and

**All melting points are uncorrected.*

ethyl malonate-2-C^{14} (10 mgm. containing 0.1 mc. of activity) were added. The reaction was initiated with a few drops of carbon tetrachloride and when it subsided, dried ether (75 ml.) was introduced. After all the magnesium had reacted, benzoyl chloride (31 gm., 0.22 mole) was added dropwise while the mixture was refluxed and stirred. When the reaction was completed the solution was cooled and diluted with water (100 ml.). The compound $C_6H_5COCH(CO_2C_2H_5)_2.3H_2O$ crystallized from ether. That substance was decomposed with dilute sulphuric acid. The product was extracted with ether, dried, and distilled. B.p.: 185–190° C. at 12 mm. The benzoyl malonate-2-C^{14} was decarboxylated by steam distillation in dilute sulphuric acid solution. The distillate was neutralized with sodium bicarbonate, extracted with ether, dried, and distilled. B.p.: 113–116° C. at 2 mm.

1-o-Chlorophenyl-3-phenyl-5-pyrazolone-4-C^{14}

Ethyl benzoylacetate-α-C^{14} (3.84 gm., 0.02 mole) was heated with *o*-chlorophenylhydrazine hydrochloride (3.58 gm., 0.02 mole) during three hours at 110–120° C. The product of the reaction was dissolved in sodium hydroxide solution and purified by several extractions with ethyl ether. Acidification with acetic acid (50%) gave the labelled pyrazolone, which was crystallized from ethyl alcohol. Yield, 3.3 gm., 61%.

1-m-Chlorophenyl- and 1-p-Chlorophenyl-3-phenyl-5-pyrazolones-4-C^{14}

A mixture of ethyl benzoylacetate-α-C^{14} (1.92 gm., 0.01 mole) and *m*-chlorophenyl- or *p*-chlorophenyl-hydrazine (1.43 gm., 0.01 mole) was heated under reduced pressure for three hours at 110–120° C. and then for one hour at 170–180° C. The product obtained was treated in a manner similar to that used to obtain the 1-*o*-chlorophenylpyrazolone. The chemical yields varied from 60 to 70%, after purification from ethyl alcohol.

Combustion of C^{14} Products, Plating, and Counting

Samples weighing about fifteen milligrams were completely transformed into carbon dioxide by burning them in a closed system in the presence of oxygen. The carbon dioxide evolved was absorbed in two traps containing carbonate-free sodium hydroxide. After some ammonium chloride was added, the carbonate was precipitated with barium chloride. The barium carbonate was transferred to an aluminum counting plate by centrifuging. Sufficient barium carbonate was added to each plate to ensure "infinite thickness". When dry, the samples were counted using an end window Geiger-Müller counter. The results obtained are given in Table VII.

TABLE VII

COUNTING DATA OF 1-CHLOROPHENYL-3-PHENYL-5-PYRAZOLONES-4-C^{14}

1-Chloro	Weight, mgm.	Total count	Time, min.	Thickness, mgm./cm.^{2}	Net activity, c./min.
Ortho	13.1	20758	25	30.4	801
Meta	13.6	23082	25	30.8	894
Para	13.9	21896	25	31.0	847

Ultraviolet Absorption Spectra

The ultraviolet absorption spectra of the pyrazolones were taken on a Beckman Spectrophotometer Model DU. The method has been previously described (4). The solvent used was ethanol (95%). The results are listed in Tables I, II, and III and some of the data are plotted in Figs. 1, 2, and 3.

Infrared Absorption Spectra

All the infrared absorption spectra of the pyrazolones were obtained with a Perkin-Elmer Model 21 double-beam null principle recording spectrophotometer. The method has been described in the literature (6). The spectra covering the range 5000–1100 cm.$^{-1}$ only are given in Figs. 4, 5, and 6. The curves all show the four specific bands of nujol. The other absorption bands are listed in Tables IV, V, and VI, and have been discussed in the theoretical part.

ACKNOWLEDGMENTS

The authors are grateful to Mr. M. Bedard of the Canadian Armament Research and Development Establishment for assistance with the infrared spectra measurements.

REACTION OF ALDOSES AND KETOSES WITH LEAD TETRAACETATE[1]

By A. S. Perlin and Carol Brice

ABSTRACT

Lead tetraacetate is highly selective for oxidation of α-hydroxy-hemiacetal groups and hence most readily attacks cyclic forms of the sugars. The reaction proceeds stepwise; the hemiacetal α-glycol being cleaved and the monoester of a correspondingly shorter-chained sugar formed. After cyclization the new sugar in turn is oxidized at the hemiacetal α-glycol group to yield a diester of a still-lower-order member of the series. In this manner D-glucose first yields mono-*O*-formyl-D-arabinose and then di-*O*-formyl-D-erythrose. Similarly, D-fructose is degraded to a glycolate ester of D-erythrose and finally to a formate–glycolate diester of D-glyceraldehyde. Some relatively rare sugars thus may conveniently be prepared directly from abundant higher-order members of the series. The reactions appear to involve preferential attack of the furanose form of a sugar rather than of the normally-predominant pyranose form, or possibly migration of ester groups towards the reducing end of the sugars.

Criegee noted that D-glucose rapidly consumes about three moles of lead tetraacetate in warm acetic acid without concurrent production of formaldehyde (5). He suggested that the apparent failure of the oxidant to attack the 5,6-glycol group was due to the presence of the 1,5-hemiacetal oxygen bridge, and that the sugar must therefore be oxidized as a ring, rather than in the open-chain form. According to Hockett and Zief (14) D-glucose at 20°C. quickly consumes only two moles of lead tetraacetate and further oxidation is very slow. If the sugar exists in solution predominantly as D-glucopyranose (I) it would be expected to consume at least three moles of oxidant, as had been found by Criegee, and possibly yield 2-*O*-formyl-D-glyceraldehyde (II). For the related oxidant, periodic acid, this possibility has been verified recently by Schöpf and Wild (28) who isolated D-glyceraldehyde monoformate by treating D-glucose with a limited quantity of periodate. In contrast to these results, Abraham (1) reported that D-glucose in warm aqueous acetic acid is completely but slowly degraded by lead tetraacetate to five moles of formic acid and one mole of formaldehyde, the reaction being recommended for radioactive-carbon assay. Hence the literature records at least three different sets of data for the reaction of D-glucose with lead tetraacetate. These variations are attributable most probably to the differences in the oxidation conditions employed but they invited further examination of the reaction.

The results of Hockett and Zief were of particular interest since the consumption of only two moles of oxidant would be expected to afford a derivative of a tetrose, rather than of a triose. Accordingly, D-glucose, in glacial acetic acid or in acetic acid containing 1–2% of water (2), was treated at room temperature with excess lead tetraacetate. Two moles of oxidant were consumed within three minutes and oxidation proceeded subsequently at a

Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan. Issued as Paper No. 217 on the Uses of Plant Products and as N.R.C. No. 3897. Presented before the 11th Annual Meeting of the Chemical Institute of Canada, Quebec City, 1955.

markedly slower rate reaching a value of 2.1 moles in one hour; the rapidity of the reaction may be contrasted with the relatively slow oxidation rates of polyols (12) and glycosides (13). The product of the initial rapid oxidation, isolated as a sirup in 95% yield, was strongly reducing, very soluble in ethyl acetate, and it absorbed strongly in the infrared region at about 1170 cm.$^{-1}$, characteristic of formate esters (31). In agreement with the latter result two moles of formic acid were liberated when the compound was hydrolyzed with acid or alkali. Acid hydrolysis afforded D-erythrose as the sole sugar (23), characterized by hydrogenation to give erythritol, by oxidation to give D-erythrono-γ-lactone, by formation of a 2,5-dichlorophenylhydrazone, and by comparison of its specific rotation, infrared absorption spectrum, and paper chromatographic behavior with those of authentic D-erythrose. The product of the oxidation of D-glucose with lead tetraacetate is therefore a diformate ester of D-erythrose.

The position of the formate substituents has not been definitely established, in part because of the groups' high instability. For example, formic acid is released spontaneously when the compound is dissolved in water, and the ester groups are removed when the compound is hydrogenated in alcohol at room temperature with platinum oxide (23). This instability thus adds to the difficulty so often encountered in attempting to determine the position of acyl substituents. Because the compound is so very slowly oxidized by lead tetra-

acetate one formate group is most likely at the 2-position; the second ester group, however, could be on either carbon 3 or 4.

Degradation of D-glucose to a 2,3- or 2,4-diformate ester of D-erythrose may occur in one or both of at least two different ways. According to one of these possibilities (Fig. 1) D-glucopyranose (I) is oxidatively cleaved at the hemiacetal α-glycol group to yield 4-*O*-formyl-D-arabinose (II). Acyl-migration of the formate group to the 3-position (IV) then takes place, perhaps via the orthoacid (III). The newly-formed hemiacetal α-glycol of the pentose consumes a second mole of oxidant to yield 2,4-di-*O*-formyl-D-erythrose, or, if a second acyl-migration follows to permit ring closure, 2,3-di-*O*-formyl-D-erythrose (V). Several known instances of acyl-migration (see 30) provide precedence for this suggested route. However, little is known of the behavior of formate groups because very few sugar formates have been prepared and characterized. The great rapidity of the oxidation as compared with the rates of reaction of, for example, polyols or glycosides may be accommodated by this route if the oxidation proceeds by an ionic mechanism (4, 18) since the hemiacetal α-glycol would be the prime site of carbonium-ion formation.

An alternative route could be depicted by assuming that α-D-glucofuranose (VI), although present perhaps in small proportion, is oxidized preferentially. Thus oxidation of the α-hydroxy-hemiacetal group, accompanied by displacement of the pyranose–furanose equilibrium, would yield 3-*O*-formyl-D-arabinose (IV) directly, which as a furanose sugar in turn would be degraded to (V). The possibility that the furanoid form of the sugar is oxidized preferentially finds support in the fact that the five-membered furan ring is nearly planar and the hemiacetal α-glycol group of α-D-glucofuranose is therefore more nearly able to assume a true *cis* (0°) position. Reeves (26) has shown that compounds having true *cis*-α-glycols, such as 2,3-dihydroxy tetrahydrofuran, react extremely rapidly with lead tetraacetate and may, in fact, be titrated with the reagent in the presence of ethylene glycol or methyl glycopyranosides containing a *cis*-α-glycol group. He noted, further, that reducing sugars can interfere with the titration since they presumably may form furanose rings containing true *cis*-α-glycol groups. The lead tetraacetate – glycol reaction possesses second order kinetics (6, 25) and therefore should require a relatively high concentration of the furanose modification to account for the observed rate of oxidation of D-glucose. However, the position of the pyranose–furanose equilibrium in acetic acid solution is not known, but the great rapidity of the interconversion between the two forms (17) might be sufficient to accommodate displacement of the equilibrium in favor of the latter as oxidation proceeds. This may be true particularly for acetic acid, in which mutarotation is extremely rapid. Thus, it was not possible to observe the changes in rotation when α- or β-D-glucose, dissolved quickly in a minimum quantity of water, was taken up in acetic acid; the specific rotation in each solution had reached an equilibrium value of $[\alpha]_D$ +70° before the polarimeter reading could be made.

From Reeves' data (26) it may be inferred that reducing sugars are titratable in the presence of substances such as ethylene glycol. If, then, α-D-gluco-

furanose is the species oxidized, the hemiacetal α-glycol should be preferred as the point of attack rather than the 5,6-glycol group. Once D-arabinose formate is produced the new hemiacetal ring, either pyranose or furanose, could in turn prevent oxidation of the terminal glycol group. The failure of methyl α-D-mannofuranoside to yield formaldehyde when oxidized with lead tetraacetate was explained in a similar manner (5). On the other hand, absence of oxidation at the 5,6-glycol group of D-glucose could be regarded as evidence favoring the interpretation that D-glucopyranose is the form involved in the reaction, with the hemiacetal ring at carbon-5 preventing attack.

Considering these possibilities further the oxidation behavior of D-*glycero*-D-*gulo*heptose and D-*erythro*-D-*gala*octose was examined. Even in the pyranose form the heptose contains a free terminal 1,2-glycol group and the octose, a 1,2,3-triol group. Thus if a pyranose ring in glucose is required to explain the results just discussed, cleavage of the terminal groups of the higher sugars would be expected. Like D-glucose, the heptose and octose also rapidly consumed two moles of lead tetraacetate and a relatively slow reaction then followed (Fig. 2). When two moles of oxidant had been consumed by the heptose, arabinose was the only product detected chromatographically and the amount (colorimetrically determined) was one mole per mole of heptose. These results corresponded to quantitative removal of carbon atoms 1 and 2 without simultaneous attack at carbons 6 and 7. In 24 hr. reaction time the consumption of oxidant had increased to 3.4 moles per mole but arabinose was still the only product detectable on the chromatogram and the quantity present was now 0.65 moles per mole. The 0.35 moles of pentose formate which appeared to have been completely oxidized in the interim accounted for the extra 1.4 moles of oxidant consumed (i.e., 4 moles per mole of pentose $\times 0.35$). Similarly, the octose yielded the expected glucose on oxidation with two moles of lead tetraacetate and glucose was still present when consumption of oxidant reached four moles per mole. Therefore, it was evident that the terminal glycol groups did not require protection from the original pyranose ring in order to escape oxidation, and the reactions could be depicted in the same general manner as already indicated for D-glucose (Fig. 1). Accordingly the product from the heptose would be 2,3- or 2,4-di-*O*-formyl-D-arabinose and from the octose, 2,3- or 2,4-di-*O*-formyl-D-glucose and further oxidation could result from ring opening and slow hydrolysis of ester groups followed by complete oxidation of the compounds.

In addition to D-glucose other aldoses also rapidly consume two moles of lead tetraacetate (Fig. 3), although a further relatively fast oxidation occurs with some of the compounds. The reaction rates illustrated in Fig. 3 have been greatly reduced relative to those in Fig. 2 by employing a reaction temperature of 0°C. in a mixture of acetic and propionic acids, so that the early portion of the reaction could be examined; the consumption of oxidant by each sugar at room temperature in acetic acid reaches approximately the same level as at the lower temperature. In no instance is a consumption of three moles, expected of a pyranose sugar, attained. Moreover, there is a wide diversity in

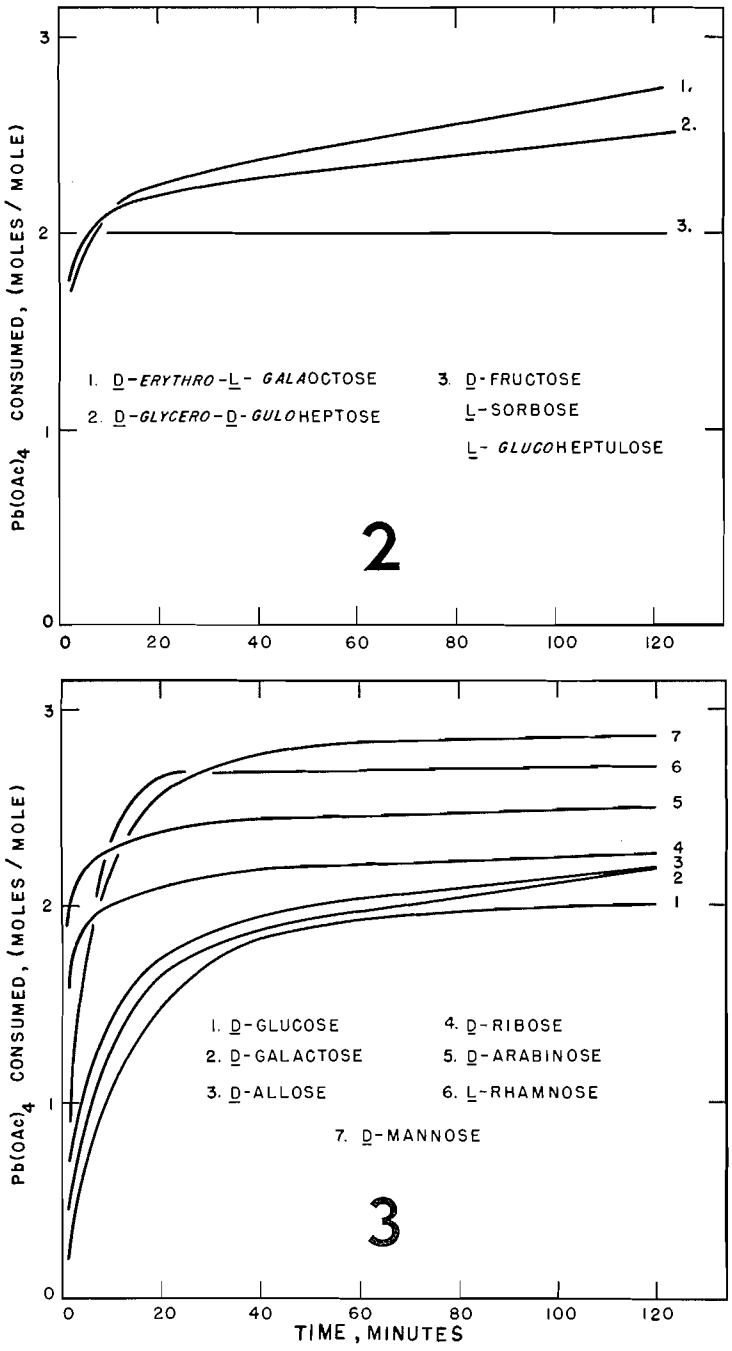

FIG. 2. Rates of lead tetraacetate consumption at room temperature (*ca.* 25°C.).

FIG. 3. Rates of lead tetraacetate consumption for aldoses at 0°C.

the rates of oxidation. These differences have shown no obvious correlation with structural differences between the compounds nor with the predicted stabilities from Reeves' measurements of fixed pyranose rings of the sugar glycosides (27).

Despite these variations the oxidations in general appear to follow a pattern similar to that already described for D-glucose with departures occurring in differing degree. For example, the oxidation of L-arabinose with two moles of lead tetraacetate affords a 90% yield of a sirupy product which from analysis appears to be a triose containing approximately 1.5 formate ester groups, and which on hydrolysis gives L-glyceraldehyde (23), characterized as the dimedon derivative. This triose formate again indicates a cleavage of carbon atoms 1 and 2 from the reducing end of the parent aldose and its production, in part, may be described by the same type of reaction sequences as presented above. The oxidation of D-galactose even more closely resembles the reaction with D-glucose. Treatment with two moles of lead tetraacetate gives a product which contains approximately 1.8 ester groups and which on hydrolysis yields D-threose, characterized as tri-*O*-acetyl-α-D-threose, by hydrogenation to D-threitol, and as a 2,5-dichlorophenylhydrazone. The specific rotation of the D-threose is about $[\alpha]$ $-12°$, which is also the value assigned by Hockett and co-workers (10, 11), who prepared the compound by other methods, but different from Freudenberg's value of $+19°$ (7). By consuming 2.7 moles of lead tetraacetate, D-mannose appears to differ most markedly from D-glucose. It will be seen, however, that in some respects the oxidations of these two compounds are closely similar.

To account for the conversion of a hexose to a tetrose containing two formate ester groups it has been necessary to assume that the oxidation proceeds *via* a pentose monoformate. It was expected therefore that on treatment with somewhat less than two moles of lead tetraacetate a hexose should yield the related pentose, which would constitute a new procedure for the stepwise shortening of the carbon chain of sugars. Accordingly, when D-glucose-1-C^{14} was oxidized with one mole of lead tetraacetate (21) the products found on paper chromatograms after precipitation of lead as the oxalate were unoxidized D-glucose (radioactive by radioautography), a compound which gave color tests for pentoses but which travelled more rapidly than the pentoses (radioactive), and a third compound which travelled at a rate similar to that of D-erythrose diformate (radioactive). After acid hydrolysis to remove ester groups the latter two compounds were no longer radioactive and travelled on the paper chromatogram at the same rate as arabinose and erythrose, respectively. The pentose, subsequently isolated and characterized as D-arabinose, was undoubtedly therefore the expected monoformate ester but the yield was only about 15%. Possibly this low yield is obtained because D-arabinose is much more rapidly oxidized than is D-glucose (Fig. 3) and hence is converted to D-erythrose instead of being accumulated. Application of this reaction to studies employing C^{14}-labelled sugars has been suggested (21).

D-Mannose is oxidized much more rapidly than glucose and since, like D-glucose, it also is degraded to D-arabinose the amount of the pentose oxidized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12

For personal use only.

further to D-erythrose is proportionately less (Fig. 2). When treated with 0.8 moles of lead tetraacetate, for example, D-mannose gave D-arabinose in about 35% yield; since 35% of the D-mannose remained unoxidized the actual conversion of hexose to pentose was greater than 50%. A 35% yield of pentose was also obtained in the degradation of D-galactose to D-lyxose. On oxidation with one mole of lead tetraacetate D-altrose and D-allose are degraded to D-ribose, the yields being approximately 70% and 20%, respectively. The difference between these two hexose epimers appears again to be related to differences in oxidation rates; D-altrose consumes lead tetraacetate at a rate close to that of D-mannose, attaining an oxidation level of 2.6 moles per mole, but D-allose is oxidized much more slowly (Fig. 3). These results support the suggestion that the lead tetraacetate reaction involves an initial attack at the α-hydroxy-hemiacetal group, but also indicate that the conformation of the rest of the molecule markedly affects the rate of oxidation.

According to Hockett and co-workers (14, 13) D-fructose also consumes only two moles of lead tetraacetate and at a rate close to that for D-glucose. In the present investigation this result was confirmed and similar results were also obtained with L-sorbose and L-*gluco*heptulose (Fig. 3). The product from the oxidation of D-fructose with two moles of lead tetraacetate, isolated in 95% yield, gave on hydrolysis approximately one mole each of formic acid, glycolic acid, and D-glyceraldehyde (24). Similarly, the oxidation of L-sorbose produced a formic acid – glycolic acid diester of L-glyceraldehyde (24). The formation of these diesters from ketohexoses may be described by reaction sequences (Fig. 4) similar to those considered earlier for aldose oxidations. Assuming β-D-fructofuranose (VII) to be the species chiefly concerned in the

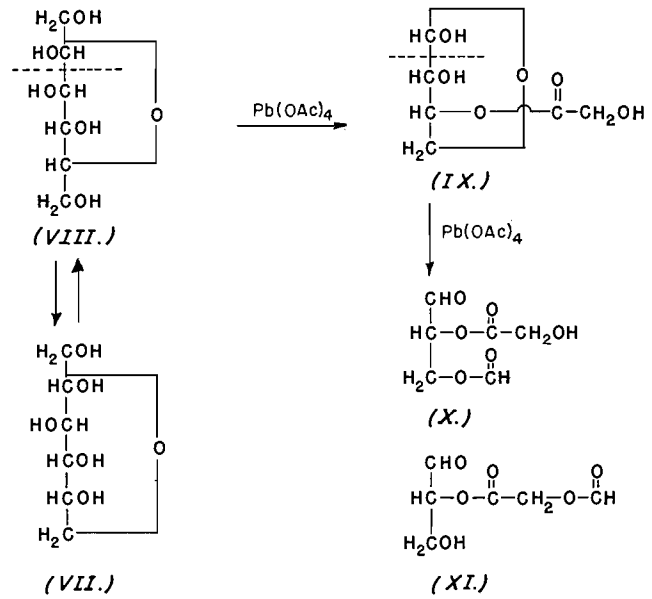

FIG. 4. Oxidative degradation of D-fructose to a formate–glycolate diester of D-glyceraldehyde.

reaction, the initial attack cleaves the hemiacetal α-glycol group to yield 3-*O*-glycolyl-D-erythrose (VIII), which in turn is degraded to 3-*O*-formyl-2-*O*-glycolyl-D-glyceraldehyde (IX). Alternatively compounds VIII and IX may be produced from D-fructopyranose by an initial acyl-migration of the glycolic acid ester group from carbon atom 4 of D-erythrose to carbon atom 3. Since the glycolate ester group itself contains a primary hydroxyl the latter conceivably could also accommodate the formate ester group, as in X.

A mechanism for the reaction of aldoses and ketoses with lead tetraacetate cannot be described at present with certainty. It is seen, however, that the oxidation is highly selective for α-hydroxy-hemiacetal groups, and hence involves cyclic forms of the sugars almost exclusively as first proposed by Criegee (5). The reaction proceeds stepwise with cleavage of the hemiacetal α-glycol group and formation of a monoester of a new sugar having a shorter carbon-chain. After cyclization the new sugar in turn is attacked oxidatively at the hemiacetal α-glycol group to yield a diester of a still-lower-order member. No racemization appears to be involved in these reactions. With aldoses the oxidation tends to stop after the consecutive scission of carbons 1 and 2, and to yield a diformate ester of the corresponding sugar with two carbon atoms less. The initial oxidation of ketoses involves cleavage of carbons 1 and 2 together as glycolic acid and the reaction then stops after carbon 3 is converted to formic acid, the final product being a formate–glycolate diester of the corresponding sugar having three carbon atoms less. Because of these characteristics the reaction constitutes a means for the stepwise degradation of sugars and thus provides a simple method for preparing some relatively rare carbohydrates directly from higher-order members of the series.

EXPERIMENTAL

Lead tetraacetate was prepared according to the procedure recommended by Vogel (32), or was obtained commercially (Matheson Co., Inc.), and was kept moist with acetic acid during storage. The weight taken for a reaction was based on the predetermined oxidant content of the wet material. If the lead tetraacetate was dark it was recrystallized from acetic acid before use, or it was dissolved in acetic acid and the solution was filtered and added directly to the aqueous acetic acid solution of the sugar.

Cellulose chromatography was carried out according to Hough *et al.* (16) using butanol, half-saturated with water, as the developing solvent. The eluate was first passed through a Seitz bacterial filter and after distillation of the solvent the sugar sirup was extracted with water and clarified with charcoal.

Pentose was estimated colorimetrically by the orcinol method (20). The lead was precipitated with excess oxalic acid, the acetic acid was distilled, and the residue was taken up in water and its pentose content estimated. The values obtained were not corrected for possible interference by other sugars present.

Solutions were concentrated *in vacuo* at 35–40°C.

Measurement of Oxidation Rates

Measurements were made both at room temperature (about 25°C.) and at 0°C. In experiments carried out at room temperature the sugar (25–30 mgm.), dissolved in 0.4 ml. of water (2), was taken up in 20 ml. of acetic acid. At zero reaction time 400 mgm. of lead tetraacetate in 20 ml. of acetic acid was added to the sugar solution, a reagent blank being run simultaneously. Five-milliliter aliquots of the reaction mixture were withdrawn at desired intervals and treated with 10 ml. of stopping solution (10 gm. of potassium iodide and 50 gm. of sodium acetate in 100 ml. of water (4)), and the iodine released was titrated with sodium thiosulphate. Some reactions were carried out in glacial acetic acid, the sugar being first finely ground and dissolved directly.

*Di-O-formyl-*D*-erythrose*

D-Glucose (1.5 gm., 8.3 mM.) dissolved in 3 ml. of water was taken up in 150 ml. of acetic acid. Lead tetraacetate (7.7 gm., 17.4 mM.) was added to the rapidly stirred sugar solution over a period of three to four minutes. When the oxidant had dissolved, oxalic acid dihydrate (1.9 gm.) dissolved in acetic acid was added, and the suspension was stirred for an additional 30 min. The precipitate was filtered and washed with acetic acid and the filtrate was concentrated to a volume of a few milliliters. Ethyl acetate was added and the precipitate which formed was triturated with several portions of ethyl acetate. The extracts were combined, filtered, and concentrated to a sirup which was further purified twice by extraction into ethyl acetate. The product (1.3 gm.) was a clear, pale yellow oil, $[\alpha]_D^{25}$ +20° (*c*, 3, water) dropping slowly owing to hydrolysis of the ester groups. The infrared absorption spectrum showed very strong absorption at 1725 cm.$^{-1}$ and at 1170 cm.$^{-1}$, characteristic of formate esters (31). A sample of the oil (7.4 mgm.) required 8.35 ml. of 0.010 *N* sodium hydroxide in 10 min. reaction time at room temperature, equivalent to 2.0 formate ester groups per mole. Another sample (21.5 mgm.) was slowly titrated with 0.05 *N* sodium hydroxide to a phenolphthalein end point. The solution was then acidified with sulphuric acid and extracted continuously with ether for four hours; the ether extract required 5.20 ml. of 0.048 *N* sodium hydroxide, equivalent to 2.0 formate ester groups per mole. The formic acid content of the ether extract was determined by lead tetraacetate – potassium acetate titration (22) to be equivalent to 2.0 moles per mole. On hydrolysis with dilute acid the compound gave D-erythrose in 90% yield (23).

One sample of the ester which had been kept at 3°C. for several months partially crystallized but the crystalline material could not adequately be separated from the sirup. The infrared absorption spectrum of a specimen from which the majority of sirup had been separated by tiling was similar to that of the sirup but the absorption bands were sharper and now appeared as doublets. The crystalline material failed to induce crystallization of other preparations of the diester and may possibly have been a monoester formed by slow hydrolysis during storage.

For personal use only.

D-*Threose Formate Ester*

D-Galactose was treated with 2.05 molar equivalents of lead tetraacetate and the reaction mixture was worked up as described above for the preparation of di-*O*-formyl-D-erythrose; 1.5 gm. of D-galactose yielded 1.2 gm. of sirup, $[\alpha]_D^{27}$ +15° (*c*, 3, water) dropping slowly owing to hydrolysis of the ester groups. Alkaline hydrolysis indicated that the compound contained 1.8 formate groups per mole. The infrared absorption spectrum was very similar to that of D-erythrose diformate.

D-*Threose*

Crude D-threose formate, obtained by distillation of the acetic acid but without purification by extraction into ethyl acetate, was taken up in 0.05 *N* sulphuric acid and heated at 45°C. for 18 hr. to hydrolyze the ester groups. The hydrolyzate was neutralized with Dowex-1 resin (bicarbonate form) and was concentrated to a sirup. Weight, 1.68 gm. from 3.0 gm. of D-galactose. Chromatographic examination with the methyl ethyl ketone solvent (3) showed a major component which travelled slightly faster than D-erythrose, and which gave a yellow-brown color and a bright fluorescence under ultraviolet light with aniline oxalate spray (15); a small quantity of a pentose which corresponded on the paper to D-lyxose was also present. A portion of the sirup (1.1 gm.) was chromatographed on a cellulose column and the tetrose fraction was recovered. Weight 0.70 gm., $[\alpha]_D^{25}$ −12.9° (*c*, 2.3, water). Hockett (10) reports $[\alpha]_D$ −12° for D-threose.

D-*Threitol*

D-Threose formate ester (0.79 gm.) was dissolved in 15 ml. of water and was carefully saponified with 1 *N* sodium hydroxide. Sodium borohydride (0.20 gm.) dissolved in 10 ml. of water was added. A negative Fehling's test was obtained in 90 min. reaction time and acetic acid was then added to decompose excess borohydride. Cations were removed with Amberlite IR-120 resin and boric acid by repeated distillation of the sirup with methanol. The product was recrystallized from ethanol. Weight 0.27 gm., m.p. 76–83°C. After two further recrystallizations, m.p. 86–88°C.; $[\alpha]_D^{25}$ −10.6° (*c*, 1, ethanol), $[\alpha]_D^{25}$ +4.2° (*c*, 1, water) in agreement with literature values (8). Calculated for $C_4H_{10}O_4$: C, 39.34%; H, 8.25%; found: C, 39.62%; H, 8.15%.

Dibenzylidene D-threitol, m.p. 225–226°C., was prepared from the compound according to Haskins and co-workers (8).

*Tri-O-acetyl-α-*D-*threose*

D-Threose sirup (300 mgm.) was heated at 100°C. for one hour with 15 ml. of acetic anhydride and 0.5 gm. of sodium acetate. The acetic anhydride was distilled *in vacuo*, the residue was extracted with chloroform, and the chloroform extract washed with water. After evaporation of the chloroform the product was recrystallized from alcohol. Weight 115 mgm., m.p. 115–118°C. Two further recrystallizations raised the melting point to 118–120°C., $[\alpha]_D^{25}$ +34.4° (*c*, 2, chloroform). Hockett (10) reports m.p. 117–118°C. and $[\alpha]_D$ +35.5° for D-threose triacetate. Calculated for $C_{10}H_{14}O_7$: C, 48.78%; H, 5.73%; acetyl, 52.4%; found: C, 48.90%; H, 5.69%; acetyl, 52.2%.

D-*Threose 2,5-Dichlorophenylhydrazone*

D-Threose sirup (0.51 gm.), prepared by concentrating an aliquot of the neutral hydrolyzate described above, was dissolved in 20 ml. of methanol in an evaporating dish. 2,5-Dichlorophenylhydrazine (0.75 gm.) was added and the methanol was rapidly evaporated off on the steam bath (procedure of Mandl and Neuberg (19)). The product was taken up in ether, filtered, and the ether was distilled. The residue was dissolved in ethyl acetate, treated with charcoal, and an equal volume of benzene was added. The product (0.60 gm.) had m.p. 103–106°C. Recrystallized twice, m.p. 108–110°C.; $[\alpha]_D^{25}$ +14.4°. A mixed m.p. with D-erythrose 2,5-dichlorophenylhydrazone (m.p. 110–112°C. (23)) was depressed. Calculated for $C_{10}H_{29}O_3N_2Cl_2$: C, 43.03%; H, 4.33%; found: C, 43.08%; H, 4.28%.

Regeneration of D-*Threose from the Hydrazone*

D-Threose 2,5-dichlorophenylhydrazone was treated with benzaldehyde according to the procedure described by Sowden and Fischer (29). The product had $[\alpha]_D$ +21.2° (*c*, 1.5, water) and in addition to the free sugar appeared to contain a glycoside formed presumably during the reflux with alcoholic benzaldehyde. An aqueous solution of the product was acidified with dilute hydrochloric acid and heated on the steam bath for 5–10 min. which effected a sharp decrease in rotation and an increase in reducing power. D-Threose (91 mgm.) was obtained from 280 mgm. of the hydrazone, $[\alpha]_D^{25}$ −11.4° (*c*, 1.8, water). On the paper chromatogram the regenerated D-threose exactly corresponded to the compound isolated by column chromatography.

L-*Glyceraldehyde Formate Ester*

L-Arabinose was treated with 2.1 molar equivalents of lead tetraacetate and the reaction was worked up as described above for the preparation of di-*O*-formyl-D-erythrose. A clear, yellow oil was obtained, 1.2 gm. from 1.5 gm. of L-arabinose. The infrared absorption spectrum of this compound showed strong absorption characteristic of formate ester groups. On saponification the compound consumed alkali equivalent to approximately 1.5 formate ester groups per mole. Hydrolysis of the ester groups in 60% acetic acid afforded L-glyceraldehyde in 83% yield (23).

D-*Arabinose*

D-Mannose (1.0 gm., 5.56 mM.), dissolved in 2 ml. of water, was taken up in 250 ml. of acetic acid. Lead tetraacetate (2.1 gm., 4.73 mM.) was added to the stirred solution; a negative potassium iodide – starch test was obtained within two minutes reaction time. Oxalic acid dihydrate (0.59 gm. in 6 ml. of acetic acid) was added, stirring was continued for an additional 30 min., and the suspension was filtered. The filtrate was evaporated to a sirup which was chromatographed on a cellulose column. Separation of the arabinose from the unoxidized mannose, sometimes difficult by chromatography, was readily achieved in the present instance because the pentose was present in the mixture as the formate ester. Its rate of travel was thus greatly enhanced and it was completely eluted from the column within 24 hr. A fraction containing the D-erythrose formate ester (0.17 gm.) was eluted just ahead of the pentose

and the unoxidized D-mannose (0.34 gm.) was recovered by prolonged elution. In passage through the column the pentose ester was partially hydrolyzed and the product was therefore a mixture of esterified and free sugar. The ester remaining was hydrolyzed by heating in water for three hours on the boiling-water bath, and the final sirup obtained crystallized completely in one to two days. Weight 0.32 gm. Recrystallized from alcohol the product had m.p. 150–152°C., raised by a second recrystallization to 156.5–157.5°C., undepressed by admixture with authentic D-arabinose (m.p. 157°C.). $[\alpha]_D^{27}$ −102.0°. The X-ray diffraction pattern of the compound was identical with that of D-arabinose.

D-Arabinose was prepared also from D-glucose by partial oxidation as described above for D-mannose. The yield of pentose estimated colorimetrically was about 15%, and the product was isolated by chromatography and characterized as the benzoylhydrazone (9), m.p. 185–186°C. The X-ray diffraction pattern was identical with that of D-arabinose benzoylhydrazone.

D-Lyxose

D-Galactose (1.0 gm., 5.56 mM.) was oxidized with 3.4 gm. (7.68 mM.) of lead tetraacetate and the product was worked up as described above under D-arabinose. Prior to chromatography on the cellulose column the formate ester groups were hydrolyzed by heating an aqueous solution of the oxidation products on the boiling-water bath for three hours. D-Threose (0.31 gm.) was eluted first, and 0.19 gm. of unoxidized D-galactose was recovered from the column following the pentose fraction. The middle fraction (0.37 gm.) crystallized completely when seeded with D-lyxose. Recrystallized from alcohol it had m.p. 113–116°C., and mixed m.p. 114–115°C. with authentic D-lyxose (m.p. 116.5°C.). $[\alpha]_D^{25}$ −13.9° (*c*, 2, water).

On acetylation by refluxing with acetic anhydride and sodium acetate the sugar yielded α-D-lyxose tetraacetate, m.p. 94–96°C., undepressed by admixture with an authentic specimen.

3-O-Formyl-2-O-glycolyl-D-glyceraldehyde

D-Fructose was treated with 2.1 molar equivalents of lead tetraacetate as described above for the preparation of di-*O*-formyl-D-erythrose. The ethyl acetate extract afforded a clear, pale yellow sirup, 1.47 gm. from 1.5 gm. of D-fructose. $[\alpha]_D^{25}$ +5.1° (*c*, 1, water) dropping slowly owing to hydrolysis of the ester groups. The infrared absorption spectrum of the compound was similar to that of the formate esters described above, but the carbonyl bands were broader, presumably owing to the contribution of the glycolate ester group. On complete hydrolysis of the ester groups with dilute acid the product gave D-glyceraldehyde in 90% yield (24).

The hydrolyzate obtained from 0.26 gm. of the diester was neutralized by slow addition of Dowex-1 resin (200–400 mesh; bicarbonate form) to the stirred solution and the resin was filtered off and washed. The resin was then shaken with 20 ml. of 1 *N* sulphuric acid for 90 min., filtered and washed well on the filter, and the acid eluate was concentrated to dryness using a dry ice – acetone trap as condenser. Water was added and the distillation resumed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

and the procedure was repeated four times. The formic acid content of the distillate was determined by lead tetraacetate – potassium acetate oxidation (22) to be 1.1 mM.; requires 1.5 mM. After distillation of the formic acid the residue was three times extracted under reflux with ether. Concentration of the ether extract gave glycolic acid, 0.083 gm. (1.09 mM.; requires 1.5 mM.), m.p. 67–72°C. Recrystallized from ether m.p. 72–75°C., undepressed by admixture with authentic glycolic acid.

ACKNOWLEDGMENTS

The technical assistance of Mr. J. Giroux is gratefully acknowledged. The authors express their gratitude to Dr. A. C. Neish for the gift of sugar samples, to Mr. J. A. Baignee for analyses, to Miss A. Epp for preparation of infrared spectra, and to Dr. W. H. Barnes for X-ray diffraction analyses.

EFFECT OF COMPLEXING ON THE HOMOGENEOUS CATALYTIC ACTIVATION OF HYDROGEN BY CUPRIC SALTS[1]

By E. Peters[2] and J. Halpern

ABSTRACT

The effects of various organic and inorganic complex-forming reagents on the homogeneous catalytic activation of H_2 by Cu^{++} in aqueous solution have been determined. The catalytic activities of the cupric complexes decrease in the order: butyrate, propionate > acetate > $SO_4^=$ > Cl^- > H_2O (i.e. the uncomplexed Cu^{++} ion) > glycine, ethylenediamine. The mechanism of the activation process is discussed.

INTRODUCTION

Detailed kinetic studies of the homogeneous catalytic activation of molecular hydrogen in aqueous perchlorate (11) and acetate (4, 2, 10) solutions were described earlier. In view of the fact that the catalytic activity of the undissociated cupric acetate complex was found to be about 120 times greater than that of the uncomplexed cupric ion, it seemed of interest to examine the effect of other complexing agents. In the present paper kinetic studies on the catalytic activation of hydrogen by a number of organic and inorganic cupric complexes are described.

EXPERIMENTAL

Glycine and ethylenediamine were Eastman white label grade products. All other chemicals were of reagent grade. Hydrogen and nitrogen gases were supplied by Canadian Liquid Air Co.

As in previous investigations (10, 11) the rate of hydrogenation of $Cr_2O_7^=$ was used as a measure of the rate of catalytic activation of H_2. The equipment and experimental procedure have been described earlier (10, 11). When the solutions contained chloride, a titanium liner was placed in the autoclave and the stainless steel stirrer, thermocouple well, and sampling tube were replaced by titanium counterparts to avoid corrosion.

To follow the reaction, the solution was sampled periodically and analyzed for $Cr_2O_7^=$, usually by measuring the optical density at 3500 Å with a Beckman DU spectrophotometer. This procedure was not suitable for chloride-containing solutions because of interference from cupric chloride complexes which absorb light of this wave length. $Cr_2O_7^=$ was determined in such solutions by a volumetric method based on adding an excess of $FeSO_4$ and back-titrating with $KMnO_4$. The cupric content of the solutions was determined electrolytically.

In each experiment, prior to introduction of the H_2, the solution was allowed to remain in the autoclave under N_2 for a period of time comparable with the duration of the subsequent reaction. The rate at which $Cr_2O_7^=$ was consumed under these conditions, by side reactions with the complexing reagent or with the metal reaction vessel, was determined and subtracted from the subse-

[2]*Holder of a National Research Council Studentship, 1954–55.*

quently measured rate of consumption in the presence of H_2 to obtain the rate of reaction with H_2. This correction was usually small, in most cases less than five per cent of the latter rate. Exceptions to this rule were encountered with solutions containing formate and glycine, whose rates of reaction with $Cr_2O_7^=$ under certain conditions were of the same order as that of H_2. The estimation of the latter rate in these systems was therefore subject to appreciable error.

RESULTS AND DISCUSSION

In all the experiments for which results are reported, the rate of disappearance of $Cr_2O_7^=$ was found to be of zero order in the concentration of the latter. Typical rate plots, obtained for various solutions, are shown in Fig. 1 and are

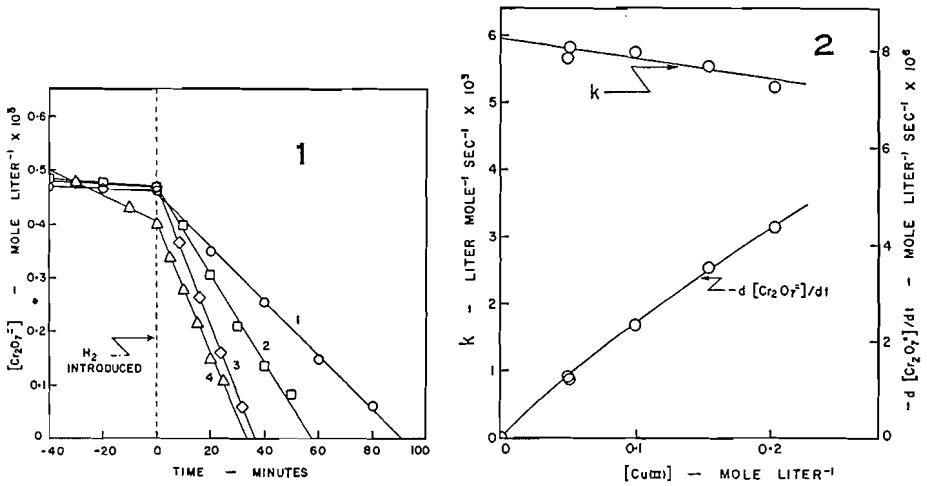

FIG. 1. Typical rate plots for reaction of H_2 with $Cr_2O_7^=$ in presence of various cupric complexes. H_2 partial pressure, 20 atm. 1. Ethylenediamine (0.05 *M* Cu^{++}, 0.20 *M* EDA, pH 4.0, 130° C.). 2. Chloride (0.10 *M* Cu^{++}, 1.0 *M* Cl^-, 110° C.). 3. Sulphate (0.10 *M* Cu^{++}, 0.10 *M* $SO_4^=$, 110° C.). 4. Glycine (0.05 *M* Cu^{++}, 0.05 *M* Gl, pH 3.5, 130° C.).
FIG. 2. Dependence of rate on cupric propionate concentration. 100° C. 20 atm. H_2.

of the same form as those reported earlier for cupric perchlorate (11) and cupric acetate (10).

The reaction between $Cr_2O_7^=$ and H_2 is represented by:

$$Cr_2O_7^= + 3H_2 + 8H^+ \rightarrow 2Cr^{+++} + 7H_2O. \qquad [1]$$

Using this stoichiometric relation, the rate of consumption of H_2 ($-d[H_2]/dt$) was determined from the measured rate of disappearance of $Cr_2O_7^=$ and expressed in terms of an apparent rate constant, k, defined by:

$$-d[H_2]/dt = -3d[Cr_2O_7^=]/dt = k[\text{Cu (II)}]\,[H_2] \qquad [2]$$

where [Cu (II)] is the total cupric ion concentration (including simple and complex forms) in the solution.

A kinetic relation of this form was shown earlier (10, 11) to apply to solutions of cupric perchlorate and cupric acetate. With solutions containing more than one cupric species, k, determined in this manner, obviously represents a weighted average of the rate constants for all the species.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

The solution concentration of hydrogen, $[H_2]$, was estimated from the measured partial pressure using available data for the solubility of H_2 in water (12, 14).

Cupric Carboxylate Complexes

Measurements of the rate of reduction of $Cr_2O_7^=$ by H_2 in the presence of various cupric carboxylate salts are reported in Table I.

The results for cupric propionate ($CuPr_2$)* parallel those obtained earlier for $CuAc_2$ suggesting that the mechanism of activation of H_2 in the two systems is essentially the same. Fig. 2 shows that the rate is nearly proportional to the $CuPr_2$ concentration, a slight tendency being apparent for the rate constant, k, to decrease at higher $CuPr_2$ concentrations. A similar effect in the $CuAc_2$ system (10) was attributed to a lowering of the solubility of H_2. The fact that the rate is essentially independent of the concentrations of NaPr and HPr, over a wide range, suggests that the catalytic activity is associated with a fully complexed cupric species. In the case of cupric acetate it has been suggested that the principal active species is the undissociated $CuAc_2$ molecule. By analogy, the active species in the present case is probably $CuPr_2$, although the possibility of participation of other complexes with catalytic activities of the same order as $CuPr_2$ is not excluded.

At 100° C., the catalytic activity of $CuPr_2$ in propionate-buffered solutions ($k \approx 6.0\times10^{-3}$ liter mole^{-1} sec.$^{-1}$) was found to be about 20% higher than that determined earlier for $CuAc_2$ ($k = 5.0\times10^{-3}$ liter mole^{-1} sec.$^{-1}$) and about

**The following abbreviations are used in this paper: Pr–propionate; Bu–butyrate; Ac–acetate; Fo–formate; Su–succinate; Ma–maleate; Fu–fumarate; Gl–glycinate; EDA–ethylenediamine.*

For personal use only.

150 times as great as that for the uncomplexed Cu^{++} ion ($k = 4.1\times10^{-5}$ liter mole^{-1} sec.$^{-1}$). Rate measurements for $CuPr_2$ at temperatures between 80° and 120° C. gave a good Arrhenius plot from which an apparent activation energy of 24.8±0.8 kcal./mole and a frequency factor of 2×10^{12} liter mole^{-1} sec.$^{-1}$ ($\Delta S^{\ddagger} = -4.7$ e.u. at 100° C.) were calculated. These values are in good agreement with those reported earlier for $CuAc_2$ (10).

Two experiments with $CuBu_2$ in butyrate-buffered solutions yielded rates identical with those for $CuPr_2$.

Measurements of the rate of activation of H_2 in formate-buffered solutions were subject to large errors because of complications arising from side reactions between formate and $Cr_2O_7^{=}$. The rate at 100° C. ($k = 1.8\times10^{-3}$ liter mole^{-1} sec.$^{-1}$) was about one third that for $CuAc_2$ and the higher carboxylate complexes. This may reflect the fact that complexing between Fo^{-} and Cu^{++} is incomplete, consistent with the higher dissociation constant of formic acid. Similar considerations apply to cupric fumarate and cupric maleate.

The catalytic activity of succinate-buffered cupric solutions ($k \approx 2.5\times10^{-3}$ liter mole^{-1} sec.$^{-1}$ at 100° C.) was about one half that for $CuAc_2$. It is probable that the CuSu complex has a chelate structure.

Cupric Sulphate

The results for cupric sulphate are summarized in Figs. 3 and 4. It is seen that addition of Na_2SO_4 was found to increase the catalytic activity of Cu^{++}, presumably the result of complex formation.* It has been suggested that only the first stage of association, i.e.

$$Cu^{++} + SO_4^{=} \rightleftharpoons CuSO_4, \qquad [3]$$

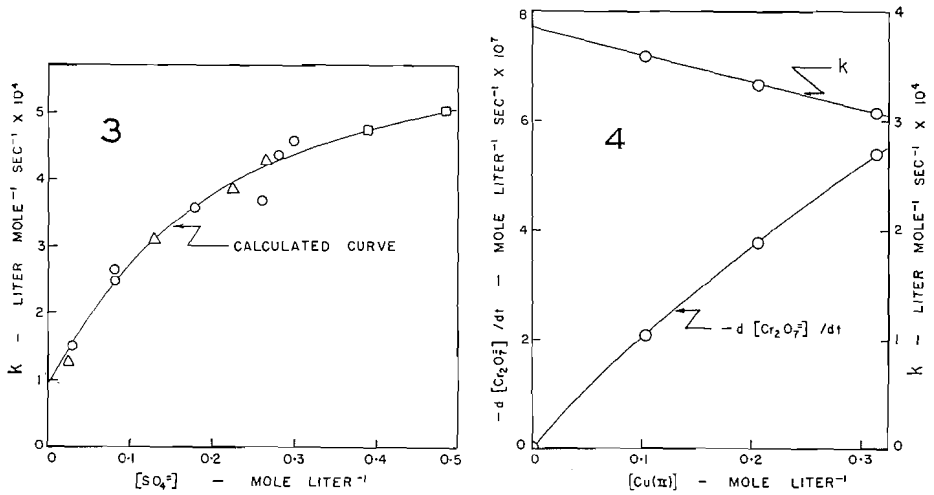

FIG. 3. Dependence of rate on $SO_4^{=}$ concentration. 0.10 *M* Cu^{++}, 20 atm. H_2. 110° C. Experimental points: ○ Total ionic strength held constant at 1.0; $[HSO_4^{-}] = 0$. □ Total ionic strength variable (>1); $[HSO_4^{-}] = 0$. △ $[HSO_4^{-}] + [SO_4^{=}] = 0.32$ *M*.

FIG. 4. Dependence of rate on cupric ion concentration in sulphate solution. 0.25 *M* $SO_4^{=}$, 0.10 *M* HSO_4^{-}, 20 atm.H_2, 110° C.

**Since sodium perchlorate was found to be without effect on the rate of catalytic activation of H_2 by cupric perchlorate, it seems reasonable to interpret the effects obtained on adding other sodium salts in terms of complexing of the anions with Cu^{++}.*

is important (7, 9), and that higher cupric sulphate complexes are not formed to an appreciable extent. The failure of the curve in Fig. 3 to level off suggests that complexing is incomplete at $SO_4^=$ concentration as high as 0.5 M./liter.

Consistent with the above interpretation, it was found that the experimental results could be fitted by a relation of the form:

$$k = (k_1[Cu^{++}] + k_2[CuSO_4])/[Cu\ (II)] \quad [4]$$

where k_1 and k_2 represent the specific rate constants for the activation of H_2 by Cu^{++} and $CuSO_4$ respectively. k_1 is known from measurements in perchlorate solution (11) and has a value of 1.0×10^{-4} liter mole^{-1} sec.$^{-1}$ at 110° C.

From equation [3], Cu^{++} and $CuSO_4$ are related by

$$[CuSO_4]/[Cu^{++}]\,[SO_4^=] = K \quad [5]$$

while

$$[Cu^{++}] + [CuSO_4] = [Cu\ (II)]. \quad [6]$$

The best correspondence between a curve for k, calculated from equations [4], [5], and [6], and the experimental points (shown in Fig. 3) was obtained using the following values: $k_2 = 6.5\times10^{-4}$ liter mole^{-1} sec.$^{-1}$ at 110° C. (i.e. about six times as great as k_1) and $K = 6.7$ liter mole^{-1}. The excellent fit lends support to these values. However, some uncertainty arises through neglect of activity coefficients and of the effect of variable salt concentration on the solubility of H_2. It is of interest that the above value of K, derived from the kinetic results at 110° C., is of the same order as the room temperature value ($\approx$4.5 liter mole^{-1} for ionic strength of unity) estimated by a spectrophotometric method (9).

Cupric Chloride Complexes

The promoting influence of Cl^- on the catalytic activity of Cu^{++} at 110° C. (Fig. 5) is attributed to the formation of cupric chloride complexes. It is probable that in the region above 1 M./liter Cl^-, where the rate levels off, the cupric ion is fully complexed, i.e. exists as $CuCl_4^=$. Hence it seems reasonable

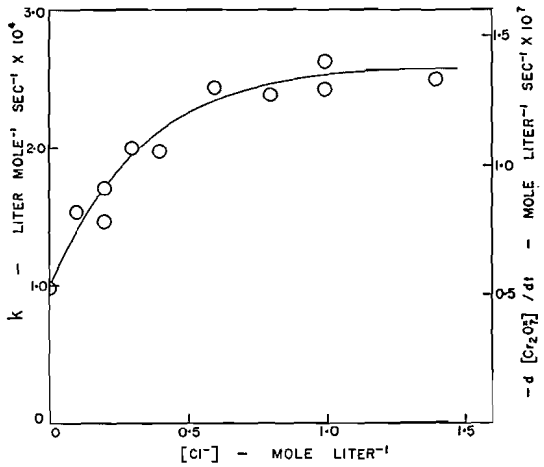

FIG. 5. Dependence of rate on Cl^- concentration. 0.10 M Cu^{++}, 20 atm. H_2, 110° C.

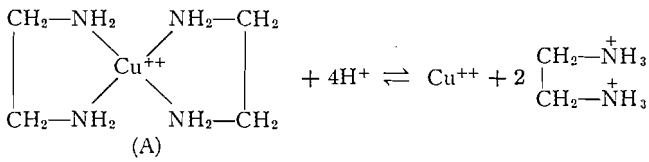
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

to attribute the measured value of k in this region to this complex.* This value (2.5×10^{-4} liter mole^{-1} sec.$^{-1}$) is about 2.6 times as great as for the uncomplexed Cu^{++} ion.

At constant Cl^- concentrations the rate was found to be directly proportional to the total Cu (II) concentration confirming that the catalytic activity is associated with the cupric species.

Cupric Ethylenediamine Complexes

The extent of complexing between Cu^{++} and EDA is a function of the H^+ concentration, i.e.



(A) [7]

The variation of k with pH, shown in Fig. 6, thus reflects a variation in the extent of complexing of the Cu^{++} ion.

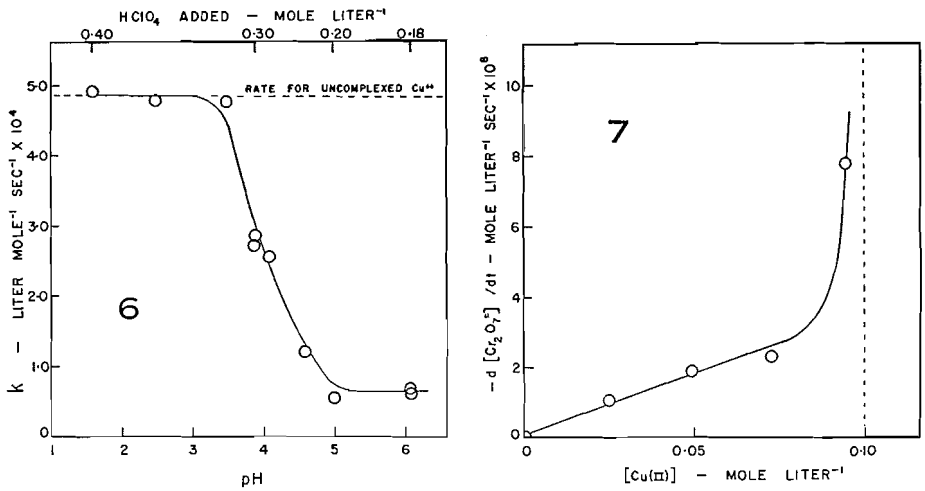


FIG. 6. Effect of pH on rate in cupric ethylenediamine solutions. 0.05 M Cu^{++}, 0.20 M EDA, 20 atm. H_2, 130° C. (pH measured at room temperature).

FIG. 7. Dependence of rate on cupric ion concentration in ethylenediamine solution. 0.20 M EDA, 20 atm. H_2, 130° C., pH 6 (measured at room temperature).

At low pH (<3, measured at room temperature) dissociation of the complex is apparently complete and the observed value of k approaches that for the uncomplexed Cu^{++} ion. Increasing the pH (by decreasing the amount of added $HClO_4$) results in a lowering of the rate, presumably reflecting the lower

**Spectrophotometrically determined values of the complexity constants of cupric chloride complexes at room temperature (8) suggest that higher Cl^- concentrations would be required to achieve complete complexing. However, it has been pointed out that these values probably increase with temperature (13).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

catalytic activity of the $Cu(EDA)_2^{++}$ complex (A). At high pH (>5) the rate levels off at a value ($k \approx 0.6\times10^{-4}$ liter mole^{-1} sec.$^{-1}$ at 130° C.), which is about one eighth that for the uncomplexed Cu^{++} ion at the same temperature. Room temperature values of the complexity constants (6) suggest that in this region complexing is essentially complete, all the Cu (II) being present as the $Cu(EDA)_2^{++}$ complex; hence it seems reasonable to associate the measured value of the k with this complex.

This interpretation is consistent with the results shown in Fig. 7. In a series of experiments in which the Cu (II) concentration was increased while the total EDA concentration was held constant, the rate (and the apparent value of k) rose sharply as the ratio [Cu (II)]: [EDA] approached the value 0.5.

Cupric Glycinate Complexes

Figs. 8 and 9 depict the effect of Gl on the rate of catalytic activation of H_2 by Cu^{++} in solutions of different pH.

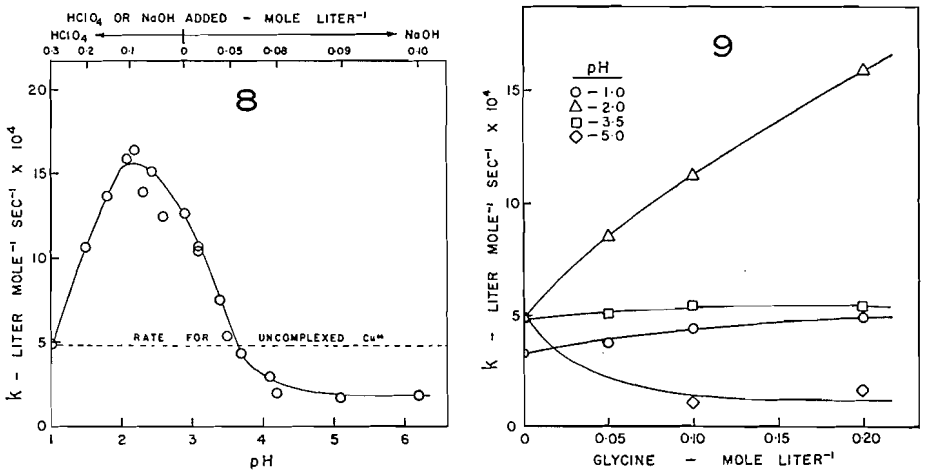

FIG. 8. Effect of pH on rate in cupric glycine solution. 0.05 *M* Cu^{++}, 0.20 *M* Gl, 20 atm. H_2, 130° C. (pH measured at room temperature).

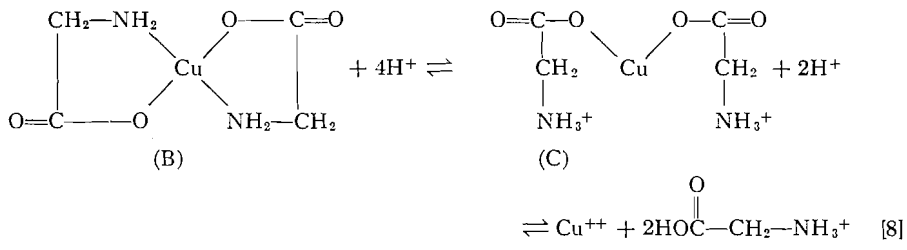
FIG. 9. Dependence of rate on glycine concentration. 0.05 *M* Cu^{++}, 20 atm. H_2, 130° C. (pH adjusted with NaOH or $HClO_4$ and measured at room temperature).

In basic solutions complexing the Cu^{++} with Gl (involving formation of the $CuGl_2$ chelate complex) is essentially complete (6). However, with decreasing pH it is probable that the complex undergoes dissociation, passing through a number of intermediate stages including the following:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

Consistent with this it was found that at low pH (≈ 1), the value of k approaches that for the undissociated Cu^{++} ion (Fig. 8) and is essentially independent of the Gl concentration (Fig. 9).

In the region of high pH (>3.5), k decreases with increasing pH (Fig. 8) and with increasing Gl concentration (Fig. 9) approaching a value ($\approx 1.5 \times 10^{-4}$ liter $mole^{-1}$ $sec.^{-1}$ at 130° C.) about one third that of the uncomplexed Cu^{++} ion. This value, which presumably reflects the catalytic activity of the $CuGl_2$ complex (B), is subject to considerable uncertainty because of the competing side reactions between $Cr_2O_7^=$ and Gl (see Fig. 1).

In the region of intermediate pH (1–3.5) the measured value of k is greater than that for Cu^{++} and increases with the Gl concentration, presumably reflecting the presence of cupric carboxylate complexes such as (C). In common with the other cupric carboxylate complexes discussed earlier, the catalytic activity of this complex is apparently greater than that of the uncomplexed Cu^{++} ion.

CONCLUSIONS

The data obtained in this work have been used to compile Table II in which the various complexes, for which values of k have been determined, are arranged in order of decreasing catalytic activity. The listed values of the relative catalytic activities (that of the uncomplexed Cu^{++} ion being taken as unity) are only approximate since they are based on rate measurements at different temperatures (ranging from 100° to 130° C.) and of varying precision. Of particular interest is the fact that negative ions (such as Ac^-, $SO_4^=$, Cl^-) enhance the catalytic activity of Cu^{++} while chelating reagents containing amine groups reduce it.

TABLE II

RELATIVE CATALYTIC ACTIVITIES OF VARIOUS CUPRIC COMPLEXES

Complex	Catalytic activity*
$CuBu_2$	150
$CuPr_2$	150
$CuAc_2$	120
$CuSO_4$	6.5
$CuCl_4^=$	2.5
Cu^{++}	1
$CuGl_2$	<0.5
$Cu(EDA)_2^{++}$	0.1

**Relative to that of Cu^{++}.*

The similarity of the pattern of kinetic behavior for the different cupric complexes suggests that they all activate H_2 by a common mechanism. As proposed earlier (10, 11), the reduction of $Cr_2O_7^=$ may be depicted in each case as occurring through the following sequence of steps:

$$Cu\ (II) + H_2 \xrightarrow[\text{slow}]{k} X \qquad [9]$$

$$X + Cr_2O_7^= \xrightarrow[\text{fast}]{} Cu\ (II) + \text{products}. \qquad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

The detailed configuration of the active reducing intermediate (X) has not been definitely resolved, but it has been suggested (5) that the activation process may involve electron displacement from the H_2 molecule to the catalytic Cu (II) species. Support for this suggestion is provided by the fact that the effects of the various complexing agents on the catalytic activity, noted above, follow the same general pattern as has been observed for other reactions between metal ions (such as isotopic electron exchange) which are believed to occur by electron transfer mechanisms. Such reactions are commonly catalyzed by complexing anions (1, 3, 15).

UNIT CELL, SPACE GROUP, AND INDEXED X-RAY DIFFRACTION POWDER DATA FOR POTASSIUM HYDROGEN MALONATE, $KHC_3H_2O_4$[1]

By M. P. Gupta[2] and W. H. Barnes

The crystal structure of malonic acid has been the subject of two investigations (1, 2) but the configuration of the malonate group has not been determined in detail. In the hope that the introduction of a heavy atom may assist in the establishment of phase angles, a study of potassium hydrogen malonate has now been undertaken. Considerable delay, however, is anticipated before the work on the structure can be completed. The unit cell constants, space group, and X-ray diffraction powder data, therefore, are given in the present note as an aid to the identification of the acid salt, and the opportunity is taken of recording an interesting observation regarding the preparation of dipotassium malonate.

According to Groth (3), crystals of potassium hydrogen malonate, $KHC_3H_2O_4$, are monoclinic prismatic with $a:b:c = 1.1981:1:0.8121$, $\beta = 136°52'$, and show the forms {110}, {001}, {011}, {010}. In this laboratory the acid salt has been prepared by mixing aqueous solutions containing the appropriate stoichiometric proportions of malonic acid and potassium hydroxide, respectively, and allowing crystallization to proceed by evaporation of the solvent at room temperature. The crystals thus obtained have predominant forms corresponding to those designated {001} and {110} by Groth.

Zero-level precession photographs, taken with Mo K_α radiation ($\lambda = 0.7107$Å), along all three principal axes show that the diffraction symmetry is $2/mC-/-$. The unit cell constants are $a = 13.75$, $b = 11.61$, $c = 4.79$ Å, $\beta = 136°12'$. The axial ratio, $a:b:c = 1.184:1:0.4125$, is in reasonable agreement with that given by Groth if the latter's c/b ratio is divided by two. The density, measured at ~22°C. by flotation in mixtures of methylene iodide and toluene, is 1.81 gm./ml. There are, therefore, four molecules of $KHC_3H_2O_4$ in the unit cell; calculated density, 1.79 gm./ml.

Three space groups are compatible with the observed diffraction symmetry. Of these, $C2/m$, with eight general positions, may be eliminated from further consideration on the grounds that there are only four molecules of $KOOC.CH_2.COOH$ in the unit cell and each of these obviously must be asymmetric. Although no response was obtained from the crystals in a piezoelectric test, definite significance cannot be attached to this observation. An attempt was made to distinguish between the two other possible space groups $C2$ and Cm, on the basis of the statistical distribution of reflection intensities (4) in the $\{h0l\}$ zone. In the plot of $N(z)\%$ against $z\%$(2) the points at $z\% = 20$, 30, 40, 50, 90, 100 lie very close to the acentric curve, that at $z\% = 10$ is midway

[1]*Issued as N.R.C. No. 3870.*
[2]*National Research Laboratories Postdoctorate Fellow.*

between the acentric and centric curves, while those at $z\% = 60, 70, 80$ agree better with the centric curve. These results are not completely free of ambiguity but they do strongly suggest an acentric distribution in the $\{h0l\}$ zone, and hence the space group Cm for the crystal structure. Wilson's ratio (5), $\rho = \langle|F|\rangle^2/\langle I\rangle = 0.716$, unfortunately is almost exactly the mean of the theoretical values for centric (0.637) and acentric (0.785) distributions. The forms observed on the crystals are too few for definite conclusions from the crystal morphology but the crystal class appears to be m, again suggesting Cm (rather than $C2$) as the space group.

A better choice of the unit cell (with $c < a < b$ and β closer to 90°) than that corresponding with Groth's orientation is obtained by application of the transformation matrix 102/010/001. The dimensions of the new cell are $a = 9.52$, $b = 11.61$, $c = 4.79$ Å, with $\beta = 92°6'$. There are four molecules in this unit cell, and the probable space group, as before, is Cm.

A powder photograph of potassium hydrogen malonate is reproduced in Fig. 1. It was obtained with Co K_α radiation ($\lambda = 1.790$Å) in a cylindrical

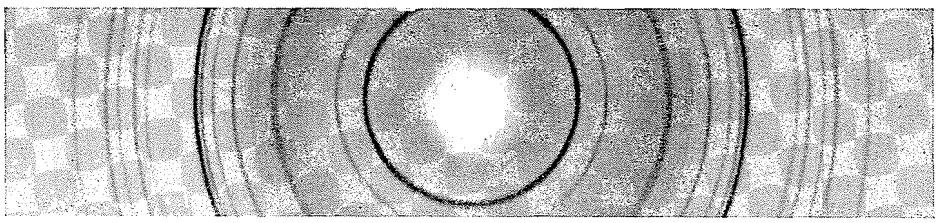

FIG. 1. X-ray diffraction powder photograph of potassium hydrogen malonate, $KHC_3H_2O_4$. (Camera diameter: 114.6 mm.; radiation: Co K_α, $\lambda = 1.790$Å.)

camera (114.6 cm. diameter), Straumanis film mounting, apparatus "cut-off" 20Å. Only the transmission section of the film is shown although the pattern extends almost to the limit of the back-reflection region. The measured spacings (d) and the visually-estimated relative intensities (I/I_1) of the lines of the powder pattern are recorded in Table I, where B identifies lines that were broader than the average, and an asterisk (in the column d(Obs.)) indicates the possible presence of a line the intensity of which was too low ($I/I_1 < 1$) for accurate determination of d. The lines of the pattern have been indexed for $d > 2.00$Å on the basis of the unit cell constants given in the preceding paragraph.

In case it should be observed in other laboratories, a very weak line of $d = 4.56$Å, which cannot be indexed, appeared in the powder photographs of two samples from the same preparation of potassium hydrogen malonate. Because this line is of significantly different relative intensity in the two films it was presumed to be due to the presence of an impurity; this was confirmed by its absence from a powder photograph of comparable density obtained from a second specimen of the salt. The spurious line cannot be due to potassium hydroxide, potassium carbonate, or malonic acid because the

For personal use only.

powder patterns of none of these compounds have a strong line in the appropriate 2θ region. It was considered, therefore, that it might perhaps indicate the presence of a trace of the neutral salt.

Two attempts were made to prepare dipotassium malonate by mixing solutions containing the base and the acid in the proportions of two moles of potassium hydroxide to one mole of malonic acid. In each case the resulting solution was boiled and set aside at room temperature. Both preparations yielded poorly-formed crystals from an oily, viscous liquid which had the usual appearance of a concentrated solution of potassium hydroxide. Both batches of crystals gave powder photographs identical with that obtained from potassium hydrogen malonate. Solutions of potassium hydroxide and malonic acid containing the base and the acid in the molar proportions of 3: 1 (i.e., 50% excess KOH) then were mixed and the solvent was evaporated by boiling until crystallization commenced. When cooled to room temperature the mixture had the same appearance as the previous preparations, but, upon stirring vigorously, almost instantaneous conversion to a solid mass occurred. The solid was brought back into solution by the addition of distilled water, and the volume was reduced by boiling until it was estimated that crystallization would not take place until the temperature was reduced almost to that of the room. No solid phase appeared, however, on cooling to about 22°C., but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

crystallization was initiated by storage for a short time at 5°C. These crystals grew very rapidly at 22°C. into short, thick prisms of about 3 mm. cross-section, and the supernatant liquid was water-like in appearance. The crystals were reduced to powder and taken up in a capillary tube in a dry box because they proved to be somewhat deliquescent. The powder pattern of this material is not the same as that of the acid salt, nor does it have a strong line corresponding to $d = 4.56$Å.

The powder photograph of this new solid phase is not reproduced in the present note because, although it presumably represents that of dipotassium malonate, the composition of the crystals and the degree of possible hydration have not been determined. The large excess of KOH required for the formation of the neutral salt, and the tendency of the solution to supersaturation, suggest that a study of the reaction between potassium hydroxide and malonic acid, and a crystal structure determination of dipotassium malonate, might be of considerable interest. In order not to delay the investigation of the structure of potassium hydrogen malonate, however, the examination of the neutral salt has been discontinued for the present, and it has not been considered worth while to make further attempts to identify the impurity giving rise to the extraneous line of $d = 4.56$Å in the powder patterns of one of the two preparations of the acid salt.

Mr. B. J. Cowick assisted with the powder investigations.

APPLICATION OF THE WISHAW–STOKES EQUATION TO THE CONDUCTANCES OF POTASSIUM CHLORIDE SOLUTIONS AT 25° C.

By A. N. Campbell and L. Ross

We have determined the conductances, densities, and viscosities of 2, 3, and 4 normal potassium chloride solutions; the latter concentration is almost the highest that can be attained at 25°. Campbell and Kartzmark (2) had previously calculated the conductances of potassium chloride solutions, using the equation of Wishaw and Stokes (5):

$$\Lambda = \left(\Lambda^\circ - \frac{B_2\sqrt{C}}{1+B\mathring{a}\sqrt{C}}\right)\left(1 - \frac{B_1\sqrt{C}.F}{1+B\mathring{a}\sqrt{C}}\right)\frac{\eta^\circ}{\eta}.$$

APPLICATION OF THE WISHAW–STOKES EQUATION TO THE CONDUCTANCES OF POTASSIUM CHLORIDE SOLUTIONS AT 25° C.

By A. N. Campbell and L. Ross

We have determined the conductances, densities, and viscosities of 2, 3, and 4 normal potassium chloride solutions; the latter concentration is almost the highest that can be attained at 25°. Campbell and Kartzmark (2) had previously calculated the conductances of potassium chloride solutions, using the equation of Wishaw and Stokes (5):

$$\Lambda = \left(\Lambda^\circ - \frac{B_2\sqrt{C}}{1+B\mathring{a}\sqrt{C}}\right)\left(1 - \frac{B_1\sqrt{C}.F}{1+B\mathring{a}\sqrt{C}}\right)\frac{\eta^\circ}{\eta}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

The meanings of the symbols in the above equation are given in the original paper. Campbell and Kartzmark obtained very good agreement between the observed and calculated conductances, up to a concentration of 1 normal, using the experimental values of the International Critical Tables, and an å value (distance of closest approach) of 4.6 Å.

In the present note, we have recalculated the results, using for Λ° the very accurate figure of Gunning and Gordon (3) (Λ° = 149.88 mhos) and using two different values of å, viz. 3.3 Å and 4.6 Å. The value 3.3 Å is recommended by Stokes himself (4) for dilute solutions, but we consider that the value 4.6 Å is just as good in the dilute region and reproduces the results for concentrated solutions much better than the lower value. In our recalculation, for dilute solutions, we have used the results of Gunning and Gordon (3) wherever they were applicable. Our technique has often been described. The complete results, both our own and the literature values, are contained in the table.

TABLE I

OBSERVED AND CALCULATED EQUIVALENT CONDUCTANCES OF KCl SOLUTIONS
t = 25.0° C.

C, moles per liter	Density, gm. per ml.	Relative viscosity (H_2O = 1.000)	Λ_{exp}, mhos	Λ_{calc}		α	
				å = 3.3	å = 4.6	å = 3.3	å = 4.6
0.0000	Viscosity and density as in literature		149.88	149.91	149.86	0.999	1.000
0.0005			147.79	147.82	147.78	0.999	1.000
0.0010			146.95	146.99	146.91	0.999	1.000
0.0020			145.79	145.86	145.90	0.999	0.999
0.0050			143.59	143.70	143.71	0.999	0.999
0.0100			141.30	141.41	141.68	0.999	0.997
0.0200			138.34	138.39	138.91	0.999	0.996
0.0500			133.37	133.09	134.19	1.002	0.994
0.1000			128.96	127.98	129.88	1.008	0.993
0.2000			123.90	121.95	125.00	1.016	0.991
0.5000			117.20	112.83	117.29	1.039	0.999
1.0000			111.90	105.30	111.96	1.063	0.999
2.0050	1.087	1.005	105.81	96.95	104.53	1.091	1.012
3.0000	1.130	1.030	100.38	89.99	98.04	1.115	1.024
3.9590	1.169	1.069	94.59	83.55	91.77	1.132	1.031

The table is almost self-explanatory. The values of $\alpha = \Lambda_{obs}/\Lambda_{calc}$ have no theoretical significance; they merely represent the discrepancy between observed and calculated results. The figures for observed and calculated conductances are plotted in the diagram (Fig. 1).

It is difficult to see why so "normal" a substance as potassium chloride fails to agree with the Wishaw–Stokes equation, as contrasted with the remarkable agreement for lithium nitrate (1). For potassium chloride the discrepancy amounts to 3% at 3.96 N (using å = 4.6 Å) and this is certainly much better than is given by any other conductance equation but we had hoped for something better. It may be that the weakness lies in using the bulk viscosity instead of some related function, the bulk viscosity being somewhat too great a dividing factor. We still think, however, that the Wishaw–Stokes extension of the Debye–Hückel equation is by far the most significant contribution to

A NEW METHOD FOR PREPARING HYDROXYETHYL ETHERS OF GLUCOSE[1]

BY W. P. SHYLUK[2] AND T. E. TIMELL

ABSTRACT

Three monosubstituted hydroxyethyl ethers of D-glucose have been synthesized by a novel method involving reduction of the corresponding carboxymethyl derivatives with lithium aluminum hydride. This technique also allowed introduction for the first time of hydroxyethyl substituents containing polyethylene oxide chains of a definite length in the glucose molecule, as exemplified by the synthesis of 3-*O*-hydroxyethoxyethyl-D-glucose.

The quantitative paper chromatographic technique has recently been applied to distribution studies on hydroxyethylcellulose (1). In order to obtain the hydroxyethyl derivatives of glucose which were needed as reference compounds, a glucose derivative with the appropriate hydroxyl groups unsubstituted was reacted with ethylene oxide in the presence of alkali. This method of preparation was, however, hampered by the fact that further reaction of the hydroxyethyl group to give polyethylene oxide substituents could not be controlled.

$$ROCH_2CH_2OH + n\overset{O}{\diagup\diagdown}CH_2{-}CH_2 \rightarrow RO(CH_2CH_2O)_nCH_2CH_2OH$$

The synthesis of some carboxymethyl derivatives of glucose has recently been described (3). It has been found that the intermediates which were used for this purpose can be converted by reduction with lithium aluminum hydride into the corresponding hydroxyethyl derivatives of glucose. By repeated carboxymethylation and reduction of the latter, polyethylene oxide substituents of definite length can also be introduced.

$$ROCH_2\overset{O}{\overset{\|}{C}}OCH_3 \xrightarrow{LiAlH_4} ROCH_2CH_2OH \xrightarrow[2.\ BrCH_2\overset{O}{\overset{\|}{C}}OCH_3]{1.\quad Na} ROCH_2CH_2OCH_2\overset{O}{\overset{\|}{C}}OCH_3$$

$$\xrightarrow{LiAlH_4} ROCH_2CH_2OCH_2CH_2OH \quad \text{etc.}$$

Thus, reduction of 3-*O*-carboxymethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose methyl ester (3) with lithium aluminum hydride in ethyl ether gave the corresponding hydroxyethyl derivative as a sirup. The latter was hydro-

[1]*Manuscript received December 27, 1955.*

lyzed to give 3-*O*-hydroxyethyl-D-glucose which gave only one spot on a paper chromatogram, corresponding to that for Creamer's (2) 3-*O*-hydroxyethyl-D-glucose. The seeds required for crystallizing the sirupy product were obtained by purification on a paper chromatogram.

Reaction of 3-*O*-hydroxyethyl-1,2;5,6-di-*O*-isopropylidene-D-glucose with sodium and methyl bromoacetate in the manner described before (3), followed by reduction, yielded 3-*O*-hydroxyethoxyethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose as a sirup. This compound was hydrolyzed to give a sirupy 3-*O*-hydroxyethoxyethyl-D-glucose which moved slightly faster on a paper chromatogram than a trace of unreacted 3-*O*-hydroxyethyl-D-glucose, no complete separation being effected, however.

A sirupy sample of methyl 3,5,6-tri-*O*-benzyl-2-*O*-carboxymethyl-α,β-D-glucofuranoside methyl ester (3) was reduced in the same manner. The corresponding hydroxyethyl derivative thus obtained was hydrogenated for removal of the benzyl groups and subsequently hydrolyzed to give 2-*O*-hydroxyethyl-D-glucose as a sirup, which, after fermentation, showed only one spot on a paper chromatogram.

Reduction of 6-*O*-carboxymethyl-1,2;3,5-di-*O*-methylene-D-glucofuranose methyl ester and subsequent hydrolysis yielded 6-*O*-hydroxyethyl-D-glucose as a sirup which gave only one spot on a paper chromatogram. This material was crystallized by means of seeds which were obtained after purification by paper chromatography. Brownell (1) had prepared this derivative by a different method, but was unable to crystallize the product.

As is shown in Fig. 1, the three *O*-hydroxyethyl-D-glucoses could be completely separated by paper chromatography, the best solvent system being a mixture of ethyl acetate, acetic acid, and water in the (v/v) ratio of 9:2:2.

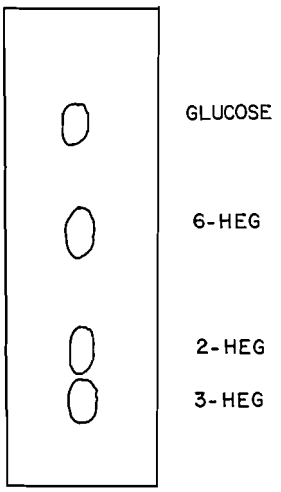

FIG. 1. Paper chromatogram of D-glucose and three *O*-hydroxyethyl-D-glucoses (HEG).

EXPERIMENTAL

Chromatograms were run by the descending method using (1) *n*-butanol saturated with water; (2) ethyl acetate, pyridine, and water, 5:2:5; and (3) ethyl acetate, acetic acid, and water, 9:2:2. Aniline phosphate was used as the spraying reagent. Melting points were determined as referred to earlier (3).

*3-O-Hydroxyethyl-*D*-glucose*

To a solution of 3 gm. of 3-*O*-carboxymethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose methyl ester (3) in 50 ml. of absolute ethyl ether, an ether solution of lithium aluminum hydride was added dropwise with stirring in an atmosphere of nitrogen. After three hours at room temperature, anhydrous ethyl acetate was slowly added to decompose the excess of the hydride. Wet ethyl ether was slowly added until a coarse crystalline mass separated, after which approximately 0.5 ml. of water was added. The mixture was dried with sodium sulphate and filtered. Evaporation of the ether solution gave 2.1 gm. of a sirup, which was hydrolyzed with 2% sulphuric acid and deionized with Amberlite IR-120 and IR-4B exchange resins. Evaporation of the neutral solution *in vacuo* yielded a sirup which was found by paper chromatography (solvents No. 1 and 2) to give as the only spot one which corresponded to Creamer's sample of 3-*O*-hydroxyethyl-D-glucose.

Approximately 70 mgm. of the above sirup was applied to a sheet of 3MM paper in spots of 0.005 ml. each, after which the sheet was irrigated with solvent No. 1 for two days. Guide strips were cut from the ends, sprayed, and then used for locating the band on the remainder of the sheet, which was cut out and eluted with water. The aqueous solution was concentrated *in vacuo* to a white residue which was extracted with 2 ml. of absolute ethanol. The latter solution was evaporated to dryness, giving a sirup which crystallized when rubbed with ethanol. Further crystallization with the aid of these crystals as seeds gave 0.78 gm. of crystalline material, m.p. 122–124° C., corresponding to a yield of 50% based on the weight of the sirup hydrolyzed. Recrystallization from ethanol gave 0.40 gm. of a product, m.p. 125–126° C., $[\alpha]_D$ after 3 min., 82.8°, and at equilibrium, 51.8° (*c*, 1.4 in water). Brownell (1) reported an extrapolated initial value of 93° and an equilibrium value of 51.4° for $[\alpha]_D$.

*3-O-Hydroxyethoxyethyl-*D*-glucose*

A dry sirup of 3-*O*-hydroxyethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose, 1.4 gm., prepared as described above, was dissolved in 50 ml. of absolute ethyl ether and stirred with 2 ml. of dispersed sodium for 15 hr. at room temperature in an atmosphere of nitrogen. Methyl bromoacetate, 4 ml., was added, the color turning green with evolution of heat, after which the mixture was stirred for six hours at room temperature. Water, 50 ml., and ethyl ether, 50 ml., were added. The ether layer was washed twice with 25-ml. portions of water, dried over sodium sulphate, and evaporated *in vacuo* to a sirup weighing 2 gm., which was subsequently reduced with lithium aluminum hydride in absolute ethyl ether as described above. The sirupy product was hydrolyzed with 4 gm. of Amberlite IR-120 exchange resin and 8 ml. of water at reflux temperature for 12 hr. The aqueous filtrate obtained after removal of the resin

was concentrated to 1.5 ml. Paper chromatography (solvent No. 3) indicated a strong spot which was not completely separated from a weaker, slower moving spot, corresponding to that of 3-*O*-hydroxyethyl-D-glucose. When the latter compound was applied together with the reaction product, the slower moving spot became stronger while the intensity of the faster moving one appeared unchanged.

2-O-Hydroxyethyl-D-glucose

Crude, sirupy methyl 3,5,6-tri-*O*-benzyl-2-*O*-carboxymethyl-α,β-D-glucofuranoside methyl ester (3), 1.0 gm., was dissolved in 10 ml. of absolute tetrahydrofuran and an excess of lithium aluminum hydride was added. After the mixture had been refluxed for 3.5 hr., 0.8 gm. of material was isolated as described for the 3-*O*-hydroxyethyl derivative. The sirup obtained was hydrogenated at a pressure of slightly more than 1 atm. of hydrogen in 20 ml. of tetrahydrofuran in the presence of 0.3 gm. of palladium black at room temperature. The catalyst was removed by filtration and the filtrate was concentrated *in vacuo* to a sirup which was hydrolyzed in the usual way with Amberlite IR-120 exchange resin. Paper chromatography (solvent No. 3) indicated a strong spot which was assigned to 2-*O*-hydroxyethyl-D-glucose and a medium spot for glucose, which disappeared after fermentation of the aqueous solution. No attempt was made to purify this glucose derivative.

6-O-Hydroxyethyl-D-glucose

An excess of ethyl ether solution of lithium aluminum hydride was added to a solution of 1.8 gm. of 6-*O*-carboxymethyl-1,2;3,5-di-*O*-methylene-D-glucofuranose methyl ester in 50 ml. of absolute tetrahydrofuran and the mixture was refluxed for two hours under dry nitrogen. The reaction product was isolated as described for 3-*O*-hydroxyethyl-D-glucose. The sirup obtained, 1.2 gm., was refluxed with 20 ml. of 2.5% hydrochloric acid for 12 hr. The yellow solution was deionized with Amberlite IR-120 and IR-4B exchange resins, treated with Darco G-60, and evaporated *in vacuo* at 45° C. to a sirup. Crystals were obtained by applying 90 mgm. of the latter to a sheet of Whatman No. 3MM paper and by following the chromatographic procedure described above. The remaining sirup was dissolved in 0.5 ml. of ethanol, seeded, and allowed to crystallize at room temperature, resulting in 0.47 gm. of material in 32% yield, m.p. 94–101° C. Recrystallization from ethanol gave 0.16 gm. of a product, m.p. 106–107° C., $[\alpha]_D$ after 4 min., 83.5°, at equilibrium, 48.7° (*c*, 1.5 in water). Calc. for $C_8H_{16}O_7$: C, 42.8; H, 7.14%. Found: C, 42.8; H, 7.09%.

ACKNOWLEDGMENTS

The authors are very thankful to Professor C. B. Purves for his kind interest in the present study. One of them (W.P.S.) also wishes to express his gratitude to The American Viscose Corporation for two fellowships.

SYNTHESIS OF FOUR CARBOXYMETHYL ETHERS OF GLUCOSE[1]

By W. P. Shyluk[2] and T. E. Timell

ABSTRACT

The 2-, 3-, and 6-*O*-carboxymethyl-D-glucoses and the 2,3-di-*O*-carboxymethyl-D-glucose have been synthesized. A solvent system was found which gave complete paper chromatographic separation of these derivatives as well as of those obtained upon hydrolysis of a carboxymethylcellulose.

The physical and chemical properties of partially substituted cellulose derivatives cannot be explained only in terms of molecular weight, polymolecularity, and degree of substitution, the distribution of the substituents along the chain molecules of cellulose also having to be considered. Various approaches in such distribution studies have been used, the most direct of which involves quantitative paper chromatography. Brownell (3) appears to have come the closest to a successful application of such a method in his work on hydroxyethylcellulose. However, in this study, as well as in similar work on methylcellulose (1, 8, 11), most of the isomeric mono- and di-substituted derivatives of glucose could not be separated.

Previous investigations on carboxymethylcellulose (6, 12, 15, 16) have indicated the desirability of a more direct approach and this study was undertaken to develop the quantitative paper chromatographic technique for this purpose. Three stages had to be considered in this connection, namely hydrolysis of the carboxymethylcellulose, separation and identification of the various carboxymethylated glucoses in the hydrolyzate, and the quantitative determination of these glucose derivatives.

The hydrolysis of carboxymethylcellulose and the stability of the carboxymethyl group to the conditions of acid hydrolysis have been previously investigated (15). For separation and identification of the seven possible carboxymethyl derivatives of glucose which conceivably could be formed by hydrolysis of a partially substituted carboxymethylcellulose, it was necessary to have these seven compounds available. The present study deals with the synthesis and separation of the 2-, 3-, and 6-*O*-carboxymethyl-D-glucoses and the 2,3-di-*O*-carboxymethyl-D-glucose.

RESULTS AND DISCUSSION

The general procedure used for introducing the carboxymethyl groups in the desired positions was to allow methyl bromoacetate to react with the sodio compound, prepared by the reaction of metallic sodium with a glucose derivative having the appropriate hydroxyl groups unsubstituted. For the preparation of the sodio derivative, advantage was taken of the greater chemical reactivity of sodium dispersions (2). Such dispersions consist of a stable sus-

[1]*Manuscript received December 27, 1955.*

[2]*Present address: Hercules Powder Company, Wilmington, Del., U.S.A.*

pension of microscopic particles of sodium in an inert medium which has almost the same fluidity as the latter, the handling of metallic sodium thus being greatly simplified as a burette or pipette can be used. A microcrystalline semi-dispersion of sodium hydride in oil was also used for the same purpose. This reagent was very similar in its handling and chemical reactivity to the sodium dispersions, having the added advantage of being available commercially.

The following sequence of reactions was used to prepare 3-*O*-carboxymethyl-D-glucose. Reaction of 1,2;5,6-di-*O*-isopropylidene-D-glucofuranose with dispersed sodium in ethyl ether gave the corresponding sodio derivative. The latter was not isolated and an excess of methyl bromoacetate was added to the reaction mixture. Crystalline 3-*O*-carboxymethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose methyl ester was isolated in 61% yield. The same crystalline derivative was also obtained in a somewhat improved yield by the use of sodium hydride in oil. Hydrolysis gave 3-*O*-carboxymethyl-D-glucose as a sirup which was pure as indicated by paper chromatography.

Various analyses of the sirupy 3-*O*-carboxymethyl-D-glucose indicated that it was reasonably pure and the product obtained by treatment of this derivative with methanolic hydrogen chloride also had the correct analysis. The sample could not be induced to crystallize, however, although various techniques were tried. It seemed probable that the main factor preventing its crystallization was to be found in the complex equilibrium mixture existing in its aqueous solution, involving the α- and β-modifications of the furanose and pyranose forms in equilibrium with the *aldehydo* form as well as the two δ-lactones in the 2- and 4-positions.

For the synthesis of 2-*O*-carboxymethyl-D-glucose, a series of reactions similar to that applied by Weygand and Trauth (18) for the preparation of 2-*O*-methyl-D-glucose was used. Treatment of methyl 3,5,6-tri-*O*-benzyl-α,β-D-glucofuranoside with dispersed sodium in ethyl ether resulted in the sodio derivative, which was treated with methyl bromoacetate to give sirupy methyl 3,5,6-tri-*O*-benzyl-2-*O*-carboxymethyl-α,β-D-glucofuranoside methyl ester. Sirupy 2-*O*-carboxymethyl-D-glucose was obtained after hydrogenolysis of the latter compound, followed by acid hydrolysis and purification by adsorption on Amberlite IR-4B exchange resin and thorough washing with water. The regenerated sugar acid contained only a trace of glucose but failed to crystallize. Crystalline methyl 4,6-*O*-ethylidene-β-D-glucopyranoside 3-nitrate was also prepared in the hope that it might be used for obtaining the corresponding 2-*O*-carboxymethyl methyl ester derivative in the crystalline form. The nitrate group, however, was found to be unstable to metallic sodium.

Dimethylene glucose, the structure of which has recently been shown to be 1,2;3,5-di-*O*-methylene-D-glucofuranose (13, 14), has been used for the introduction of substituents in the 6-position of glucose (3, 9). Treatment of this derivative with dispersed sodium in dioxane gave the corresponding sodio derivative which, upon reaction with methyl bromoacetate, yielded 6-*O*-carboxymethyl-1,2;3,5-di-*O*-methylene-D-glucofuranose methyl ester in the crystalline form. Hydrolysis of the latter compound produced a chromatographically pure 6-*O*-carboxymethyl-D-glucose, which could not, however, be induced to crystallize.

For personal use only.

In an attempt to establish whether the Purdie reaction could be applied in the synthesis of carboxymethyl derivatives of glucose, dimethylene glucose was treated twice with methyl bromoacetate and silver oxide. A paper chromatogram showed two spots of equal intensity for 6-*O*-carboxymethyl-D-glucose and glucose after hydrolysis, thus indicating the feasibility of the procedure.

For preparation of 2,3-di-*O*-carboxymethyl-D-glucose the following reactions were used. Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside was treated with dispersed sodium to give the disodio derivative which was subsequently allowed to react with methyl bromoacetate to yield methyl 4,6-*O*-benzylidene-2,3-di-*O*-carboxymethyl-α-D-glucopyranoside methyl ester as a sirup. A paper chromatogram of the hydrolyzed material exhibited weak spots for 2-*O*-carboxymethyl-D-glucose and glucose, and an additional strong spot which was assumed to represent 2,3-di-*O*-carboxymethyl-D-glucose. Better results were obtained with sodium hydride but the Purdie reaction gave only a trace of disubstituted compound.

As shown in Fig. 1, a complete separation of the *O*-carboxymethyl-D-glucoses by paper chromatography was accomplished. As far as is known, this appears

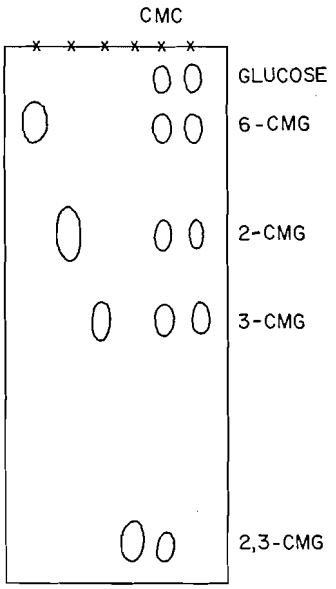

FIG. 1. Paper chromatogram of D-glucose, four *O*-carboxymethly-D-glucoses (CMG), and hydrolyzate of a carboxymethylcellulose (CMC).

to be the first instance when three isomeric monosubstituted glucose derivatives have been unambiguously separated on a paper chromatogram. The solvent system which gave this separation was composed of ethyl acetate, formic acid (87–90%), and water in the (v/v) ratio of 12: 1: 12.

The carboxymethylcellulose referred to in Fig. 1 was a specimen averaging 1.11 carboxymethyl groups per anhydroglucose unit of the chain molecules. This compound, when hydrolyzed and subjected to paper chromatography,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

gave the spots indicated, the intensity of which suggested the correctness of a previous, indirect analysis of the same sample (16). With only one disubstituted carboxymethyl glucose available nothing, of course, could be stated yet concerning the presence and nature of the disubstituted sugars present in the hydrolyzate.

EXPERIMENTAL

Although two samples of dispersed sodium were kindly supplied by U.S. Industrial Chemical Company, New York, N.Y., most of the dispersed sodium was prepared shortly before use with the aid of a Waring Blendor with a modified Pyrex jar (2). A 20% microcrystalline semidispersion of sodium hydride in Bayol 85 was obtained as a sample through the courtesy of Metal Hydrides Inc., Beverly, Mass.

For paper chromatography, the descending flow technique was applied throughout and the solvent system was the mixture mentioned above. The chromatograms were made on Whatman No. 3MM paper and aniline phosphate (4) was used to locate the spots. The thermometer employed for determining the melting points was checked against pure compounds as suggested by Bunce (5) and all values were corrected accordingly.

3-O-Carboxymethyl-1,2;5,6-di-O-isopropylidene-D-glucofuranose Methyl Ester

A. Method Using Sodium Dispersed in Toluene

An excess of dispersed sodium was added with constant stirring and in an atmosphere of nitrogen to 60 gm. of 1,2;5,6-di-*O*-isopropylidene-D-glucofuranose (17) dissolved in 575 ml. of absolute ethyl ether. After six hours at room temperature, 35.6 ml. of methyl bromoacetate was added dropwise from a burette and a vigorous exothermic reaction was observed, after which the mixture was refluxed for two hours. Water, 100 ml., was added and the resulting red aqueous layer was separated. After the ether layer had been washed with four 50-ml. portions of water, it was dried over anhydrous sodium sulphate and concentrated *in vacuo* at 50° and 75° C. to give 73.0 gm. of a crystalline product. Hydrolysis and paper chromatography showed a strong spot which was assigned to 3-*O*-carboxymethyl-D-glucose and a weak spot for glucose. Recrystallization of the crude product from isopropyl ether gave 46.7 gm. of material in 61% yield, m.p. 100–101.5° C. Four more recrystallizations from isopropyl ether removed the unreacted diacetone glucose and gave fine needles of 3-*O*-carboxymethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose methyl ester, m.p. 104–105° C., $[\alpha]_D$ −3.5° (*c*, 1.5 in chloroform). Calc. for $C_{15}H_{24}O_8$: C, 54.2; H, 7.28; (OCH_3), 9.34%. Found: C, 54.4; H, 7.31; (OCH_3), 9.35%.

B. Method Using Sodium Hydride in Oil

Dispersed sodium hydride, 4 ml., was added to 5 gm. of 1,2;5,6-di-*O*-isopropylidene-D-glucofuranose in 75 ml. of absolute ethyl ether. The mixture was stirred in an atmosphere of dry nitrogen at room temperature for 18 hr. Methyl bromoacetate, 5 ml., was added, causing an immediate reaction with evolution of heat. Another 5 ml. of methyl bromoacetate was added after the mixture had been stirred at room temperature for 12 hr. After additional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

stirring for 28 hr., 2 ml. of absolute methanol was added to decompose any excess of hydride, very little of which appeared to be left. Ethyl ether, 75 ml., and 50 ml. of water were added to the reaction mixture. The dark red aqueous layer formed was discarded and the ether layer was washed with four 25-ml. portions of water. The pale yellow ether solution was treated as above and yielded 8.3 gm. of a partially crystalline product (including 2.5 gm. of Bayol 85). Recrystallization from isopropyl ether gave 5.0 gm. in 78% yield of slightly colored needles, m.p. 103–104.5° C. Two more recrystallizations from the same solvent resulted in 4.2 gm. of a pure product with the same melting point and mixed melting point as the material referred to above.

*Methyl 3-O-Carboxymethyl-α-*D*-glucopyranoside Methyl Ester*

A sirup of 3-*O*-carboxymethyl-D-glucose (pure as indicated by paper chromatography), 0.93 gm., was dissolved in 75 ml. of 2.5% methanolic hydrogen chloride and 5 gm. of Drierite was added. The reaction mixture was kept at reflux temperature in a dry atmosphere for three days. The pale yellow solution was neutralized with silver carbonate and the cloudy filtrate obtained was clarified by saturating with hydrogen sulphide and heating. After filtering, the solution was concentrated *in vacuo* at 50° C. to a sirup, which was decolorized and clarified by dissolving in a small volume of methanol and treating with Darco G-60, three such treatments being necessary. The resulting sirup was dried *in vacuo* at 55° C. for two days and was found to weigh 0.82 gm. Although the product had the correct methoxyl analysis of 23.5% (theoretical 23.3%), it failed to crystallize after several months.

*3-O-Carboxymethyl-*D*-glucose*

A mixture of 7 gm. of 3-*O*-carboxymethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose methyl ester and 25 gm. of Amberlite IR-120 exchange resin in 25 ml. of water was stirred on a steam bath for 12 hr. The resin was filtered off and washed thoroughly with water. The combined filtrate and washings was treated with Darco G-60 and evaporated to approximately 50 ml. Freeze-drying of this solution gave 5.0 gm. of a friable resin-like material, $[\alpha]_D$ 51.2° (*c*, 1.5 in water), which was very hygroscopic. This product was chromatographically pure with regard to several solvent systems and several spraying agents. Other solutions of 3-*O*-carboxymethyl-D-glucose were evaporated to sirups which all failed to crystallize when subjected to various techniques used to induce crystallization. Calc. for $C_8H_{14}O_8$: C, 40.3; H, 5.9%. Found: C, 39.2; H, 6.0%. Titration of 64.0 mgm. in 5 ml. of water under nitrogen with 0.0222 *N* barium hydroxide and with methyl red as indicator resulted in the consumption of 12.66 ml. of barium hydroxide. This titer was equivalent to 66.9 mgm. of 3-*O*-carboxymethyl-D-glucose. Various techniques were applied to obtain sirups free of lactones, all of which, however, failed to produce the desired crystallization.

*Methyl 3,5,6-Tri-O-benzyl-2-O-carboxymethyl-α,β-*D*-glucofuranoside Methyl Ester*

Sirupy 3,5,6-tri-*O*-benzyl-α,β-D-glucofuranoside, 34 gm., was dissolved in 125 ml. of absolute ethyl ether. Dispersed sodium, 15 ml., was added dropwise

over a two-hour period with stirring and in an atmosphere of dry nitrogen, after which stirring was continued for six hours at room temperature. Methyl bromoacetate, 25 ml., was added dropwise and an exothermic reaction was observed. The mixture was stirred at room temperature for 12 hr. Water, 100 ml., and ethyl ether, 200 ml., were added to the gray reaction mixture, the color changing to red. The ether layer was washed with five 100-ml. portions of water, dried over sodium sulphate, and evaporated to 34 gm. of a light red sirup.

The product was dissolved in 100 ml. of tetrahydrofuran in a stainless steel bomb and 3 gm. of palladium black was added. Hydrogenation was effected at a pressure of 600 p.s.i. of hydrogen over a five-hour period and at 100° C. After the catalyst had been removed, 17.3 gm. of a brown sirup was obtained upon evaporation *in vacuo* of the filtrate. This material was stirred in 200 ml. of 2% sulphuric acid on a steam bath for eight hours. The hydrolyzate was extracted with eight 50-ml. portions of ethyl ether, evaporation of which yielded 4 gm. of a red, optically inactive sirup. The acid was neutralized with barium hydroxide and the barium sulphate digested on a steam bath for two hours. After centrifuging, the supernatant aqueous solution was slowly passed through a column of Amberlite IR-120 exchange resin and the latter washed with water until the effluent was neutral. Evaporation of the pale-yellow aqueous effluent *in vacuo* at 60° C. gave 9.0 gm. of a brown sirup. Paper chromatography showed a strong spot which was assigned to 2-*O*-carboxymethyl-D-glucose and a medium spot for glucose. After further purification with the aid of the same exchange resin, the final product contained only a trace of glucose.

Attempted Preparation of 2-O-Carboxymethyl-4,6-O-ethylidene-β-D-glucopyranoside 3-Nitrate Methyl Ester

Methyl 4,6-*O*-ethylidene-β-D-glucopyranoside 3-nitrate (7, 10), 1.6 gm., was stirred at room temperature under dry nitrogen with 2 ml. of dispersed sodium in 50 ml. of absolute ethyl ether for 20 hr. The orange-brown reaction mixture was cooled in an ice-bath and 10 ml. of methyl bromoacetate was added. The mixture was stirred at room temperature for one and one-half hours and at reflux for eight hours. Ethyl ether, 50 ml., was added and the ether solution was washed with three 50-ml. portions of water. The light yellow solution was dried over sodium sulphate and evaporated *in vacuo* at 40° and 90° C. to a yellow sirup weighing 0.6 gm. A spot test for organic nitrate with diphenylamine and sulphuric acid on the sirup was negative. Hydrolysis of a small amount of this material and paper chromatography indicated a strong spot for glucose and medium spots for the 2- and 3-*O*-carboxymethyl-D-glucoses and the 2,3-di-*O*-carboxymethyl-D-glucose.

6-O-Carboxymethyl-1,2;3,5-di-O-methylene-D-glucofuranose Methyl Ester

A. Method Involving Sodium Dispersed in Toluene

A solution of 1 gm. of 1,2;3,5-di-*O*-methylene-D-glucofuranose, prepared as described previously (14), in 25 ml. of absolute dioxane was treated with 2 ml. of dispersed sodium. The mixture was stirred in an atmosphere of nitrogen for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

17 hr. and was then cooled in an ice-bath, after which 0.81 ml. of absolute methanol was added. The brown, gelatinous mixture was stirred for one hour at room temperature, methyl bromoacetate, 4.5 ml., was slowly added, and the resulting reaction mixture stirred for an additional four hours. Dioxane, 50 ml., was added and the mixture was centrifuged. The dioxane solution was concentrated *in vacuo* at 50° and 90° C. to a light red sirup, which was dissolved in benzene and applied to a column of 5: 1 Magnesol–Celite. The latter was washed with 100: 1 benzene–ethanol and the slightly yellow filtrate concentrated to a sirup weighing 1.15 gm. Hydrolysis and paper chromatography of a small amount of this material indicated a strong spot which was assigned to 6-*O*-carboxymethyl-D-glucose and a weak spot for glucose. The remainder of the sirup was rubbed on a watch glass with methanol and ethyl ether, crystallization occurring after 12 hr. A solution of 1.0 gm. of the sirup in 2 ml. of methanol was cooled, seeded, and allowed to crystallize at 5° C. A crystalline material in the form of long flat rods, 0.66 gm., corresponding to a yield of 49%, was obtained. The product had a melting point of 46.5–47.5° C. and $[\alpha]_D$ 32.7° (*c*, 1.3 in chloroform) after three recrystallizations from methanol at 5° C. Calc. for $C_{11}H_{16}O_8$: C, 47.8; H, 5.84; (OCH_3), 11.2%. Found: C, 47.7; H, 5.52; (OCH_3), 11.4%.

B. Method Involving Sodium Hydride

Dispersed sodium hydride, 2 ml., was added to a solution of 1,2;3,5-di-*O*-methylene-D-glucofuranose, 1.0 gm., in 25 ml. of absolute dioxane and the mixture was stirred under nitrogen for 25 hr. at room temperature. Methyl bromoacetate, 5 ml., was added and stirring continued for another 12 hr. After addition of 50 ml. of dioxane and centrifuging, the dioxane solution was evaporated to a sirup which was rinsed once with petroleum ether. Crystallization from methanol yielded 0.35 gm. in 26% yield of crystals with a melting point of 47–48° C. Paper chromatography after hydrolysis of the crude product showed a strong spot for 6-*O*-carboxymethyl-D-glucose and a weak spot for glucose.

C. Purdie Method

A mixture of 1.0 gm. of 1,2;3,5-di-*O*-methylene-D-glucofuranose, 2 ml. of methyl bromoacetate, 1.16 gm. of silver oxide, and a small amount of Drierite was stirred at 100° C. for two hours with exclusion of moisture. Another 0.5 gm. of silver oxide was added and the reaction was continued for another hour. Chloroform was added to the cooled mixture, followed by filtration. Evaporation of the filtrate *in vacuo* gave a sirup which was treated once more with the same reagents. The product was hydrolyzed and paper chromatography indicated spots of equal intensity for 6-*O*-carboxymethyl-D-glucose and glucose.

6-O-Carboxymethyl-D-glucose

A mixture of 2.8 gm. of 6-*O*-carboxymethyl-1,2;3,5-di-*O*-methylene-D-glucofuranose methyl ester and 6 gm. of Amberlite IR-120 exchange resin in 12 ml. of water was stirred at reflux temperature for 24 hr. The resin was removed by filtration and the filtrate clarified with Darco G-60. The sirup obtained after

evaporation *in vacuo* was carefully dried over phosphorus pentoxide and failed to crystallize after one month. The material was dissolved in water for easier handling and freeze-dried to a friable, resin-like material. Paper chromatography suggested the presence of only 6-*O*-carboxymethyl-D-glucose.

Methyl 4,6-O-Benzylidene-2,3-di-O-carboxymethyl-α-D-glucopyranoside Methyl Ester

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (7), 3.0 gm., and 5 ml. of dispersed sodium hydride were stirred in 50 ml. of anhydrous dioxane at room temperature in an atmosphere of nitrogen for 13½ hr. The thick, gray, gelatinous reaction mixture was shaken with an additional 2 ml. of sodium hydride for another 61½ hr. Methyl bromoacetate, 10 ml., was added and the mixture stirred for 46 hr. After addition of 50 ml. of chloroform and centrifuging, the supernatant solution was evaporated *in vacuo* at 60° and 75° C. to a sirup, the Bayol was poured off, and the remaining material washed with petroleum ether to yield 7.8 gm. of a sirup. Hydrolysis of a small amount of the latter and paper chromatography indicated weak spots for glucose and 2-*O*-carboxymethyl-D-glucose and an additional, strong, faster moving spot which was assigned to 2,3-di-*O*-carboxymethyl-D-glucose. The sirup failed to crystallize after several weeks during which time it was subjected to various techniques for inducing crystallization.

A similar synthesis involving sodium dispersed in toluene yielded a product which, after hydrolysis and paper chromatography, showed strong spots for glucose and 2,3-di-*O*-carboxymethyl-D-glucose and somewhat weaker spots for the 2- and 3-*O*-carboxymethyl-D-glucoses.

ACKNOWLEDGMENTS

One of the authors (W.P.S.) wishes to express his gratitude to the American Viscose Corporation for two fellowships. The authors are also very thankful to Drs. L. F. McBurney and H. M. Spurlin of the Hercules Powder Company for their kind interest in the present investigation.

THE HEATS OF CRYSTALLIZATION OF VACUUM DEHYDRATED MAGNESIUM SULPHATE HEPTAHYDRATE AND COBALTOUS CHLORIDE HEXAHYDRATE[1]

By J. W. S. Jamieson[2] and G. B. Frost

ABSTRACT

Magnesium sulphate monohydrate prepared by vacuum dehydration of the heptahydrate does not yield a pattern of X-ray diffraction lines, and in this sense may be said to have an amorphous character. By measurement of the heats of solution of the "X-ray amorphous" and crystalline monohydrates, the heat of transition has been found to be 6550 cal. mole^{-1}. Cobaltous chloride monohydrate prepared by vacuum dehydration appears to be microcrystalline. The heat of transition to the normal crystalline form is 1390 cal. mole^{-1}. These values are related to the surface areas of the vacuum dehydrated products.

INTRODUCTION

Kohlschütter and Nitschmann (5) have shown that when copper sulphate pentahydrate is dehydrated under vacuum, a product of monohydrate composition is obtained which does not yield a pattern of diffraction lines on X-ray examination. Hammel (3) obtained similar results for other dimetal sulphates, and Volmer and Seydel (8) for manganous oxalate dihydrate. For convenience, the term "X-ray amorphous" will be used to designate such products. These products have high energy contents with reference to the corresponding crystalline salts. From measurements of heats of solution, Frost, Moon, and Tompkins (1) found values of the order of 7000 cal. mole^{-1} for the heats of transition from the "X-ray amorphous" to the crystalline forms of copper sulphate monohydrate and zinc sulphate monohydrate.

Wheeler and Frost (9) have shown that the vacuum dehydration of magnesium sulphate heptahydrate results in the gradual loss of water to the monohydrate stage, the product showing no X-ray diffraction lines. This product is very stable, the characteristic monohydrate (kieserite) lines being formed only when the product is heated for two days at 130° C. They also found that on vacuum dehydration of cobaltous chloride hexahydrate, a gradual loss in weight occurred, the rate being rapid to the dihydrate stage followed by a much slower rate. It was not possible to characterize the final product by X-ray diffraction using the radiation available.

In the course of a more comprehensive study of the dehydration kinetics of these salts, and of other studies, it became desirable to have reasonably accurate information concerning the energetic character of the products of monohydrate composition obtained by vacuum dehydration, in reference to the normally occurring crystalline monohydrates. The purpose of this paper is to report the results obtained.

EXPERIMENTAL

The experimental method involved the comparison of the heats of solution of the crystalline monohydrates with those of the products of stoichiometric

[1]*Manuscript received November 18, 1955.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ont.
[2]*Present address: Graduate student in Chemistry, McGill University, Montreal, Que.*

monohydrate composition obtained by vacuum dehydration. The calorimeter and general procedures were identical with those described in detail in the earlier work on copper and zinc sulphates (1).

Magnesium sulphate heptahydrate and cobaltous chloride hexahydrate, both of reagent grade, were recrystallized twice at room temperature, air dried, and screened, the "through 60 on 80 mesh" fractions being retained.

A series of mixtures of crystalline hydrates were prepared by dehydrating small weighed samples for various times at 100° C. in an Abderhalden apparatus containing fused calcium chloride as a desiccant. The percentage of water in each sample was calculated from the loss in weight. The heats of solution of these samples were determined and plotted against the water content, the value corresponding to the monohydrate composition being determined by extrapolation.

Vacuum dehydration to various water contents was carried out as follows. A weighing thimble containing a small weighed sample was placed in a tube which was connected to a vacuum line by means of a ground joint. The system was then evacuated (usually at 40° C.) for a sufficient time to give a product of the approximate composition desired. At the end of the evacuation, the pump was shut off, and dry air admitted to the system. The sample container was then quickly removed, capped, and weighed, the water content being determined by the weight loss. The heats of solution of the samples were determined, plotted against water content, and the value corresponding to the stoichiometric monohydrate composition determined by interpolation.

Samples of the magnesium salt were characterized by X-ray diffraction as required. It was not possible to obtain suitable diffraction patterns with the cobalt salt using the copper K_α radiation available.

RESULTS

Magnesium Sulphate

The results of determinations of the heats of solution of pure magnesium sulphate heptahydrate and of crystalline mixtures of hydrates, prepared by the dehydration of the heptahydrate in the Abderhalden apparatus, are given in Table I. In this, and the following tables, the percentage of water in a given

TABLE I

For personal use only.

sample is denoted by c and the heat of solution to infinite dilution by J. Heats of dilution were obtained from the data of Lange and Streeck (6). The last column gives the temperature of the calorimeter at the instant of the salt addition. The results are plotted in Fig. 1, from which it will be seen that the

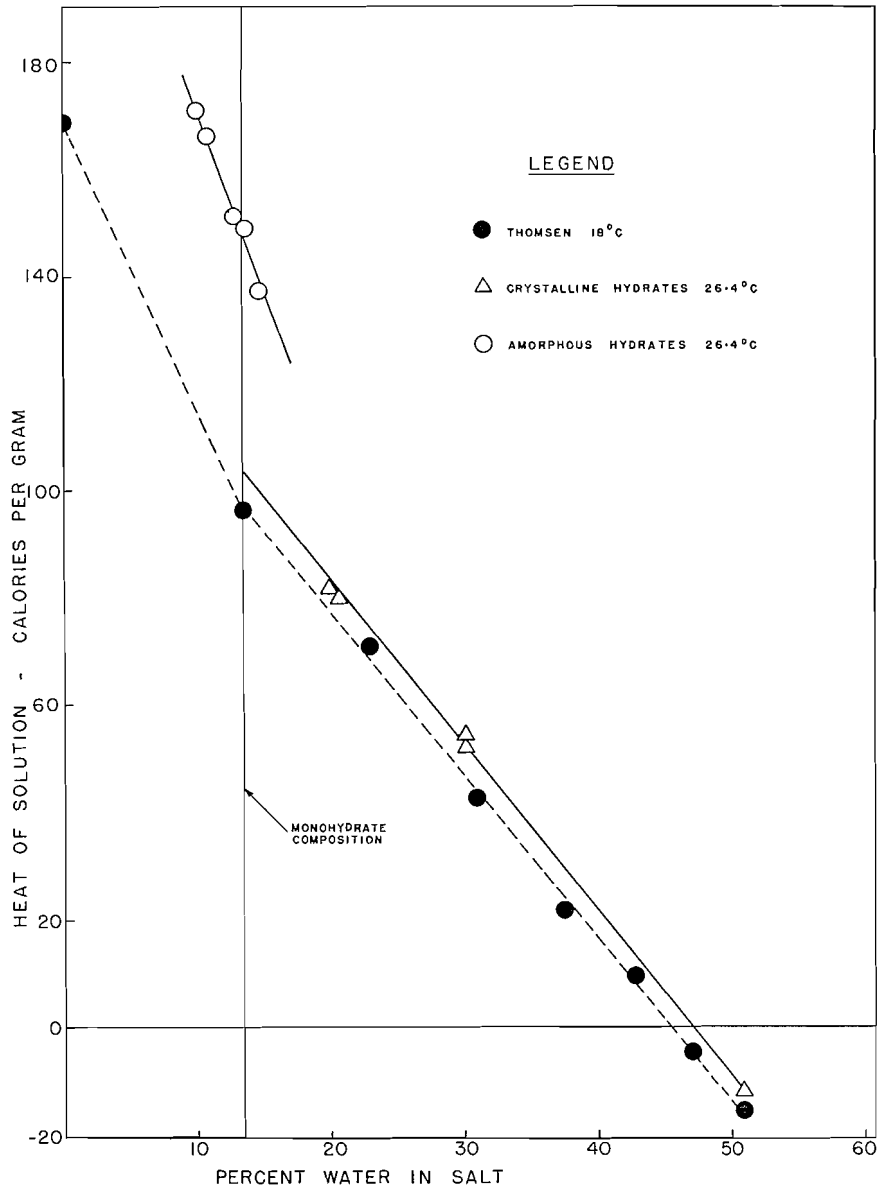

FIG. 1. Heats of solution to infinite dilution of crystalline and X-ray amorphous hydrates of magnesium sulphate.

heat of solution values for samples of water content between the heptahydrate and the monohydrate lie on a straight line.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

The equation of the best straight line, fitted to the points obtained by the method of least squares, is

$$J = 142.8 - 3.012\,c \quad (13.02 < c < 51.16)$$

from which the value of J corresponding to the percentage of water in the crystalline monohydrate ($c = 13.02\%$) is 103.6 cal. gm.$^{-1}$.

The results for the determinations of the heats of solution of samples dehydrated under vacuum are given in Table II and are also plotted in Fig. 1.

TABLE II

HEATS OF SOLUTION OF AMORPHOUS HYDRATES OF MAGNESIUM SULPHATE

Expt. No.	Per cent water = c	Heat evolved, cal. gm.$^{-1}$	Heat of dilution, cal. gm.$^{-1}$ hydrated salt	J, cal. gm.$^{-1}$ hydrated salt	Temp., ° C.
8	14.68	132.7	3.78	136.5	26.53
9	13.69	144.5	3.45	148.0	26.31
10	12.79	147.4	3.35	150.8	26.23
11	10.81	162.4	3.38	165.7	26.84
12	10.04	167.4	3.21	170.7	25.97

Although these samples varied somewhat in water content, none showed an X-ray diffraction pattern. It will be observed that the values lie on a straight line cutting the vertical line corresponding to the stoichiometric monohydrate composition.

The equation of the best straight line fitted to these values is

$$J = 243.1 - 7.077\,c \quad (10.04 < c < 13.69)$$

from which J is 150.9 cal. gm.$^{-1}$ for the dehydration product having the stoichiometric monohydrate composition.

For personal use only.

of dilution data are available for this salt. It has been thought desirable, therefore, to tabulate the sample weights used. The amount of water in the calorimeter in each determination was 591.6 ± 0.2 gm.

The results obtained in Expt. 20 refer to the crystalline hexahydrate. In Expt. 21 dehydration was carried out to the crystalline monohydrate stage. Expt. 23 is a vacuum dehydration in which nearly six hours elapsed between the end of dehydration and the introduction of the sample into the calorimeter. It was observed that the heat of solution value for this vacuum dehydrated product fell on the straight line joining the values obtained for the crystalline hexahydrate and the crystalline monohydrate. In view of this result, it was first thought that a high energy intermediate was not formed on vacuum dehydration. It was then considered possible that the product had reverted to the normal crystalline form during the period which elapsed between the end of the dehydration process and the introduction of the sample into the calorimeter. Accordingly Expts. 24 and 25 were carried out in which the heat of solution determinations were made as soon as possible after evacuation. These were found to give slightly higher values than Expts. 26 and 27 in which dehydration was carried out to approximately the same water content as before, but a considerable time allowed to elapse between the dehydration and calorimetric procedures.

Expts. 29, 30, and 32 are vacuum dehydrations carried to lower water contents, the samples being introduced into the calorimeter within 10 min. after dehydration. The heat of solution values lie on the upper straight line of Fig. 2. It is interesting to note that the heat of solution value obtained in Expt. 30 is the same as that obtained from a sample of the same product taken two hours later, reported as Expt. 31. This indicates that the high energy intermediate is more stable for samples having a percentage of water less than that corresponding to the monohydrate. Expt. 28 is of interest in that, although the dehydration was carried out under vacuum and the sample transferred to the calorimeter quickly, the heat of solution value lies slightly below the line drawn through the values obtained for the crystalline samples. This result cannot be accounted for by experimental error and suggests that some phase transition occurs just prior to the formation of the monohydrate phase. Further exploration of this region would be of interest.

The best straight line, calculated by the method of least squares, for the crystalline hydrates, from the data of Expts. 20, 21, 23, 26, and 27 is:

$$J' = 130.1 - 3.048\,c \quad (11.99 < c < 45.43)$$

where J' is the experimental value of the heat of solution uncorrected for the heat of dilution. The value of J' corresponding to the percentage of water in the monohydrate ($c = 12.18\%$) is 93.0 cal. gm.$^{-1}$.

The equation of the best straight line for the heats of solution of the vacuum dehydrated products of Expts. 24, 25, 29, 30, and 32 was found to be

$$J' = 161.5 - 4.848\,c \quad (3.09 < c < 18.50)$$

from which the value of J' corresponding to the monohydrate composition is 102.4 cal. gm.$^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

The difference in heat of solution between the vacuum dehydrated and crystalline monohydrates is therefore 9.4 cal. gm.$^{-1}$, or for the change in state,

$$CoCl_2.H_2O(\text{vacuum dehydrated}) \rightarrow CoCl_2.H_2O(\text{crystalline}),$$
$$\Delta H_{300°K.} = -1390 \text{ cal. mole}^{-1}.$$

This value is to be regarded as somewhat approximate in that the interval between evacuation and placing the sample in the calorimeter (during which some crystallization may have occurred in samples of higher water content) is arbitrary.

COMMENT

The value obtained in the foregoing for the heat of transition of X-ray amorphous magnesium sulphate monohydrate to the corresponding crystalline form is comparable to those previously reported for the copper and zinc sulphate monohydrates (1). The value obtained for the cobalt salt is significantly lower. It is unfortunate that characterization of the product obtained on vacuum dehydration could not be made by X-ray diffraction. However, such results would be of doubtful value in view of the rapidity of crystallization, unless a technique could be devised whereby dehydration could be carried out in the X-ray camera itself.

The surface area of magnesium sulphate monohydrate prepared by vacuum dehydration is approximately 8 meters^2 gm.$^{-1}$; that of cobalt chloride monohydrate is 35.9 meters^2 gm.$^{-1}$. Both of these values were determined by argon adsorption at 78° K. (7). The ratio of the heat of transition per gram to the surface area of the vacuum dehydrated product is 5.9 cal. meters^{-2} for the magnesium salt, and 0.26 cal. meters^{-2} for the cobalt salt.

Giauque (2) has reported a value of 22.2 cal. gm.$^{-1}$ for the heat of transition of magnesium oxide from a finely divided crystalline to the normal macrocrystalline form. Jura and Garland (4) have reported the surface area of finely divided magnesium oxide prepared in a similar manner to that of Giauque to be 86 meters^2 gm.$^{-1}$. The experimental evidence indicates that the heat of transition is wholly due to the difference in surface area between the finely divided and normal crystalline forms. The ratio of the heat of transition to surface area is 0.26 cal. meters^{-2}.

The identical agreement of this value with the ratio obtained for cobalt chloride is undoubtedly fortuitous in view of the uncertainties involved. Nevertheless, the values of these ratios are comparable, and suggest that the product of vacuum dehydration of cobaltous chloride hexahydrate is microcrystalline and that the difference in heat of solution between the normal crystalline monohydrate and that formed by vacuum dehydration results, as with magnesium oxide, from the difference in crystal dimensions only. If this view is correct, it must be assumed that the microcrystals are accessible to the gas used in determining the surface area by the usual adsorption methods, or, in other words, that the surface area values have the same significance for cobaltous chloride monohydrate as for magnesium oxide.

The vacuum dehydration products of both cobaltous chloride hexahydrate and magnesium sulphate heptahydrate have large internal surfaces resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

from capillary formation (7). It is probable that these capillaries are formed as the lattice contracts with the movement of the dehydration interfaces along preferred planes. In terms of the foregoing interpretation, it must be assumed that, for the cobalt salt, this lattice contraction is associated with the formation of loosely packed aggregates of microcrystals differing from crystals of the normal monohydrate in dimensions only.

For magnesium sulphate monohydrate, prepared by vacuum dehydration, the ratio of heat of transition to surface area is very much higher. It is possible that this material also consists of microcrystals. If this is so, however, the dimensions of these must be below the limit required for X-ray diffraction (about 100 Å). It is possible that these crystallites are packed in localized regions and that the adsorption surface area gives, not the area of the microcrystals, but the area resulting from the internal capillary structure. Consequently, the ratio of heat of transition to surface area would have a very different meaning than that just considered.

It is of interest, however, to point out another aspect of the magnesium sulphate dehydration. The crystalline monohydrate (kieserite) is known to be very stable and does not lose water at temperatures below about 200° C. under atmospheric pressure. It has been suggested, on this basis, that the water molecule does not exist as an entity in the kieserite lattice. However, the data given in Table II show that a loss in weight, corresponding to water contents well below the monohydrate stage, takes place quite readily during vacuum dehydration at 40° C.

These products have been found to give the characteristic kieserite diffraction lines when heated for two or three days at about 130° C. It is possible, therefore, that vacuum dehydration of the heptahydrate results in the formation of an intermediate, which under proper conditions crystallizes into the kieserite lattice. The measured heat of transition would therefore be the energy release accompanying crystallization from the intermediate, and not that associated solely with change in surface.

It is intended to present other data pertinent to the nature of X-ray amorphous dehydration products in a later paper.

THE LOW PRESSURE DEHYDRATION OF MAGNESIUM SULPHATE HEPTAHYDRATE AND COBALTOUS CHLORIDE HEXAHYDRATE[1]

By R. W. Ford[2] and G. B. Frost

ABSTRACT

Rates of dehydration under vacuum, and at a series of controlled water vapor pressures, have been carried out for powdered samples of magnesium sulphate heptahydrate and of cobaltous chloride hexahydrate. It has been found for the magnesium salt that as the pressures are increased, the rate at first drops rapidly, this decrease being followed by a period of acceleration which is followed in turn by a decline. The curves are similar to those previously reported for copper sulphate pentahydrate, but the changes occur over a much wider range of water vapor pressures. In the dehydration of cobaltous chloride hexahydrate the initial drop in rate with increase in water vapor pressure is not observed. The results are interpreted in terms of the crystallization of intermediate products in the presence of adsorbed water.

INTRODUCTION

Recently, Wheeler and Frost (8) have reported the results of a survey of the dehydration kinetics of a number of hydrated salts. It has been shown that the rate of dehydration is markedly affected by the pressure of water vapor at the reaction interface, acceleration in rate being frequently observed over certain pressure ranges. Some hydrated salts on low pressure dehydration yield products which do not give diffraction lines on X-ray examination and therefore have no evident crystalline structure. For others the end products are crystalline. A more detailed study of the rates of dehydration at a series of water vapor pressures of magnesium sulphate heptahydrate, and of cobaltous chloride hexahydrate, has revealed some interesting points, both of similarity and contrast, in these respects. The purpose of the present paper is to report these findings.

EXPERIMENTAL METHOD

Determinations of rates of dehydration under vacuum, and also at externally controlled and constant pressures of water vapor, have been carried out. The apparatus and experimental method differed in no important respect from that used by Frost and Campbell (2) in a comparable study of the dehydration kinetics of copper sulphate pentahydrate. Rates of dehydration were measured by reading the extension of a quartz spiral from which small powdered samples were suspended. Water vapor, at pressures below 4.58 mm., was obtained by maintaining ice crystals, deposited on glass wool, at suitable low temperatures. Water vapor at higher pressures was obtained by first evacuating the system containing ice crystals at low temperatures, and then allowing these to melt by surrounding the container with a temperature-controlled water bath through which cold water could be circulated as needed. It was found that the temperature could be controlled to $\pm 0.02°$ C.

In rate experiments carried out in the presence of water vapor, samples were nucleated by dehydrating under vacuum for two or three minutes during which period readings were taken. The spiral case was then shut off from the vacuum system and exposed to water vapor at the desired pressure, readings of spiral extensions being continued for the duration of the experiment. X-ray powder photographs were made of the dehydration products of magnesium sulphate heptahydrate. Unfortunately this was not possible for the cobalt salt since the copper K_α radiation used was strongly absorbed, resulting in fluorescent radiation.

RESULTS

Magnesium Sulphate Heptahydrate

The dehydration of magnesium sulphate heptahydrate was studied at 40°, 50°, and 60° C. and over a range of water vapor pressures from zero to approximately 18 mm. Hg at each temperature. At 40° C., eight experiments were conducted, curves showing loss in weight in milligrams versus time in minutes being shown in Fig. 1.

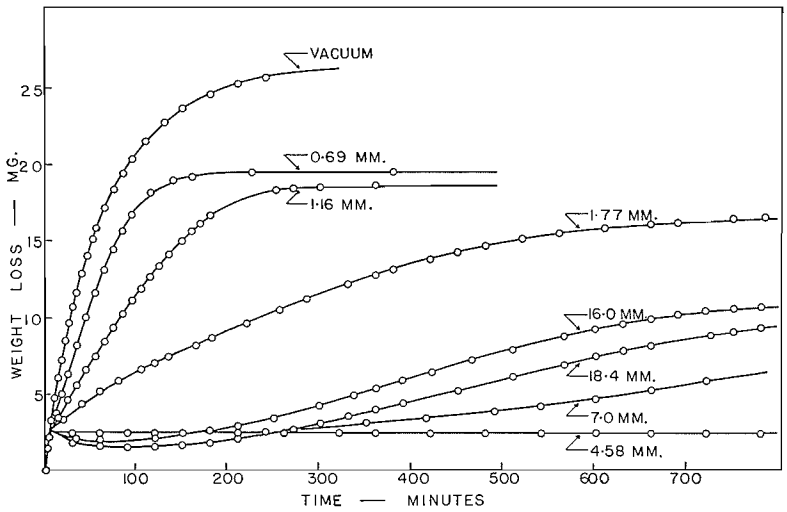

FIG. 1. The change in weight loss of fine crystal aggregates of magnesium sulphate heptahydrate at a series of constant water vapor pressures at 40° C.

These curves fall into three groups. Under vacuum, and at water vapor pressures of 0.69, 1.16, and 1.77 mm., the curves show a smooth and gradual decrease in rate as the dehydration progresses. Also the initial slope of each curve decreases with increasing pressure. The composition of the products varied from the monohydrate in the vacuum dehydration to approximately the tetrahydrate stage in the dehydration at 1.77 mm. None of these products diffracted X-rays.

The curve obtained at 4.58 mm. was unique in that no decomposition was apparent after the initial nucleation period.

All of the experiments at pressures of 7 mm., or higher, gave curves of a sigmoid character; that is, following nucleation, an induction period set in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

during which no weight loss was observed. During this period, a slight gain in weight was sometimes noted, which was probably due to the adsorption of water on the outer dehydrated layer. This period was followed by another during which the rate of decomposition was almost constant with time, before gradually decreasing as the reaction neared completion. It will be seen that for the curves obtained at 7.0 mm., 16.0 mm., and 18.4 mm., the slopes of these nearly linear portions first increase with increasing pressure and then decline. The end products corresponding to these sigmoid type curves were crystalline, clearly defined diffraction patterns of tetrahydrate lines being obtained.

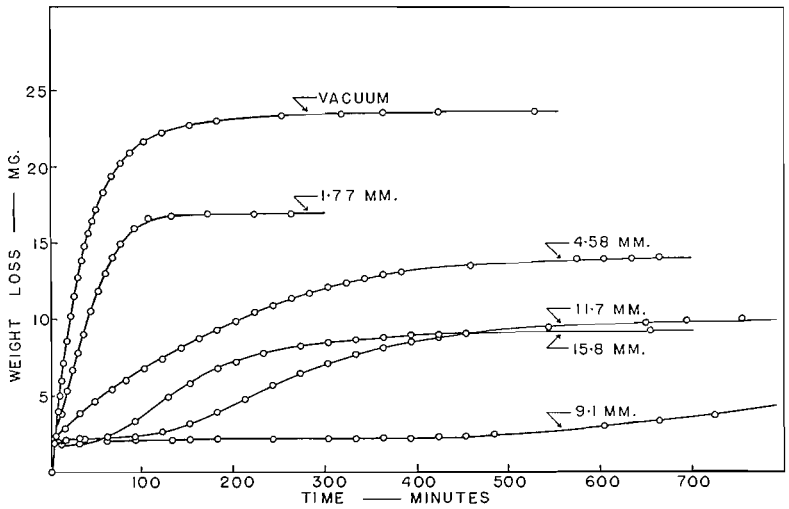

FIG. 2. The change in weight loss of fine crystal aggregates of magnesium sulphate heptahydrate at a series of constant water vapor pressures at 50° C.

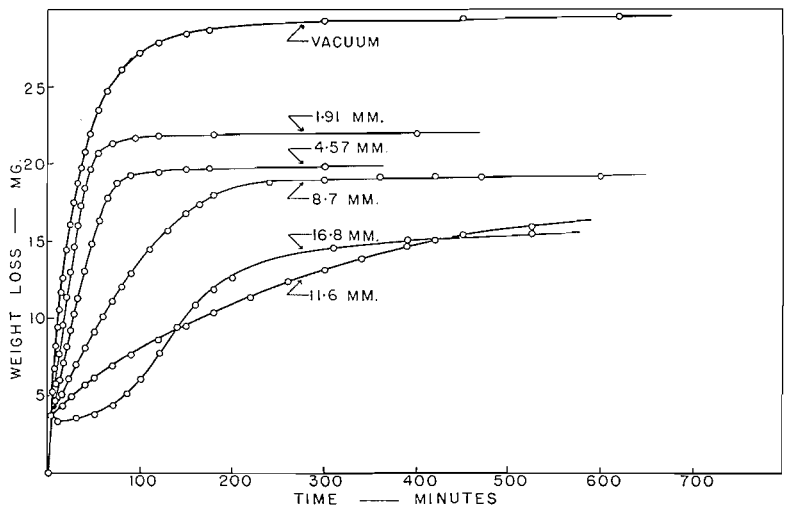

FIG. 3. The change in weight loss of fine crystal aggregates of magnesium sulphate heptahydrate at a series of constant water vapor pressures at 60° C.

For personal use only.

Curves obtained from dehydrations carried out at 50° C. and 60° C. are shown in Figs. 2 and 3 and are similar in character to those just described.

It is evident from all of these plots that the duration of the induction periods decreases as either the pressure or the temperature is increased. This effect of pressure is shown most clearly in the group of curves obtained at 50° C.

The change in rate of dehydration with water vapor pressure per decigram of material is shown in Fig. 4. These rates have been obtained by the method used by Frost and Campbell (2) in their study of the dehydration of copper

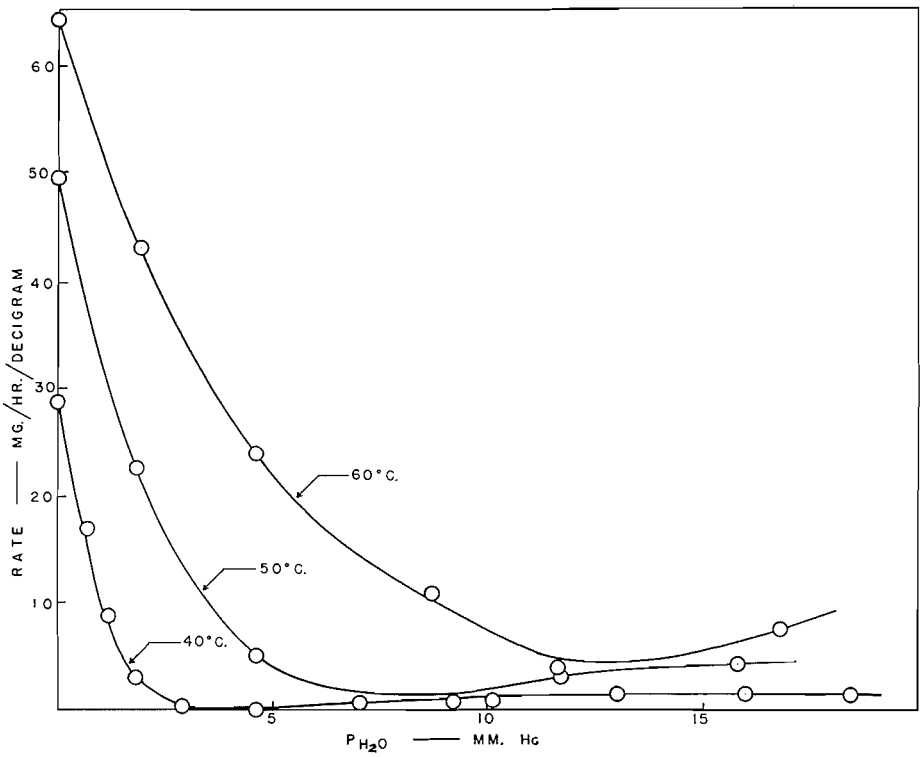

FIG. 4. The dependence of over-all dehydration rate upon water vapor pressure for magnesium sulphate heptahydrate.

sulphate pentahydrate. Essentially, the rates compared correspond to the slopes of the initial (nearly linear) portions of the curves showing a gradual decline in rate at low pressures, and to the slopes of the nearly linear portions following the induction period for the curves which are sigmoid in character.

At each of the three temperatures, the rate is seen to decrease fairly rapidly with increasing water vapor pressure until a minimum is reached, after which the rate increases. At 40° C., and 50° C., the rates decline again at higher pressure. This decline could not be observed at 60° C. since sufficiently high pressures could not be conveniently obtained by the experimental method used.

The curves shown in Fig. 4 are very similar to these reported by Frost and Campbell for copper sulphate pentahydrate, and by Topley and Smith (5) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

by Volmer and Seydel (6) for manganous oxalate dihydrate, except that the pressure at which the minimum in rate occurs is very much higher. The minimum occurs at higher pressures as the temperature is increased.

Cobaltous Chloride Hexahydrate

Studies of the rate of dehydration of this salt were carried out at 30° C. and 40° C. at water vapor pressures ranging from zero to approximately 18 mm. Hg.

The dehydration curves obtained at these two temperatures are shown in Figs. 5 and 6 respectively. The end product of the vacuum dehydrations, which were carried out for 30 hr., was a product of somewhat lower water content

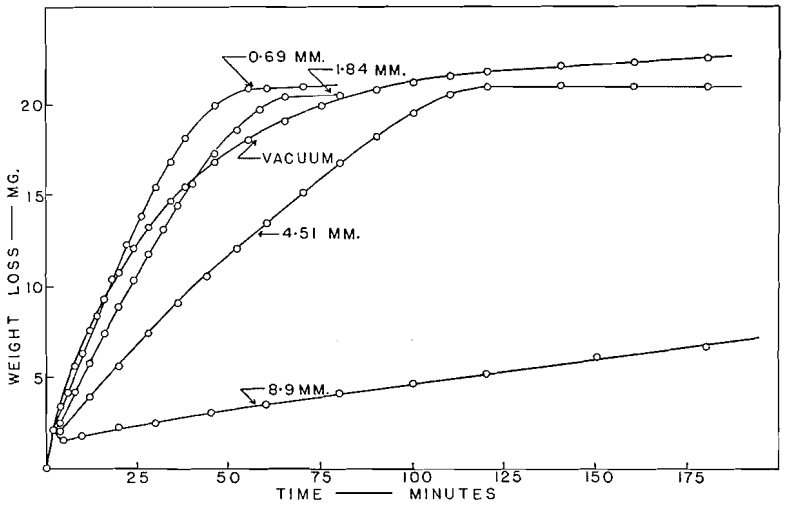

FIG. 5. The change in weight loss of cobalt chloride hexahydrate at a series of constant water vapor pressures at 30° C.

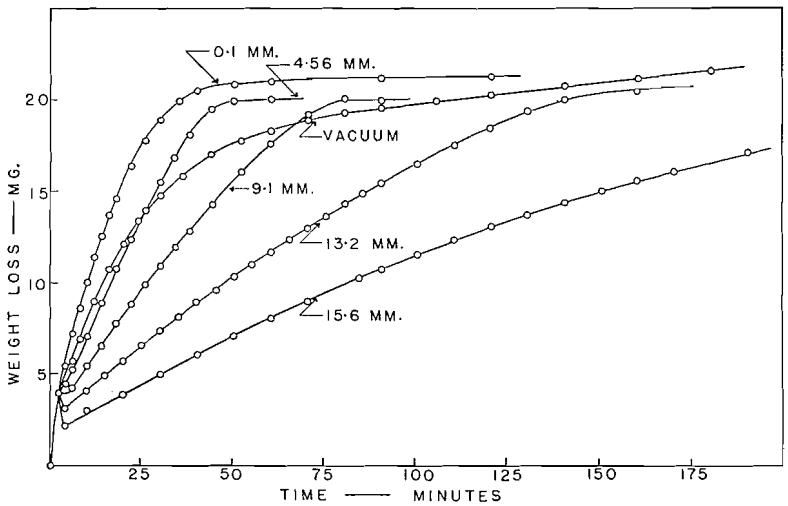

FIG. 6. The change in weight loss of cobalt chloride hexahydrate at a series of constant water vapor pressures at 40° C.

For personal use only.

than the stoichiometric monohydrate composition. For the other determinations, the rate of decomposition became very slow when the dihydrate stage was reached. Control experiments showed that no significant amount of hydrogen chloride was formed in any of these dehydrations (4).

These curves show several interesting features in comparison with those obtained for magnesium sulphate heptahydrate. The curves obtained for vacuum dehydrations are somewhat similar. However, when water vapor at low pressure is admitted to the system, the cobalt salt shows quite different properties. Whereas with the magnesium salt, the initial slopes of the weight-loss curves decrease with increasing pressure, the slopes of the curves obtained with cobalt chloride hexahydrate initially increase with increasing pressure up to a limiting value, after which the slopes decrease, and then only gradually. Curves of a sigmoid character were not obtained at any pressure. At higher pressures, a slight gain in weight was observed following the nucleation period, but this effect was probably due to the adsorption of water vapor on the dehydrated surface and bore no resemblance to the induction periods observed for magnesium sulphate heptahydrate.

Rate values, calculated per decigram of sample, and obtained from the nearly linear portions of the weight-loss curves, are shown plotted against water vapor pressure in Fig. 7.

DISCUSSION

The dependence of the rate of dehydration of magnesium sulphate heptahydrate upon water vapor pressure has been found to be similar to that which has been reported for copper sulphate pentahydrate except that the minimum in rate occurs in a very much higher range of pressure. It would appear reasonable therefore to give the same interpretation of these curves as has been done for the copper sulphate pentahydrate dehydration (2). Under vacuum, the parent lattice breaks down into a state of monohydrate composition which does not yield a pattern of X-ray diffraction lines. It has been shown elsewhere that this material is very stable, and that the heat of crystallization is approximately 6500 cal. per formula wt. (3). Data regarding its surface area and capillary structure have been reported (4). At water vapor pressures below those corresponding to the minima in rates shown in Fig. 4, a material is formed which likewise does not diffract X-rays, but the rate of dehydration becomes very slow after the approximate stoichiometric composition of the tetrahydrate is reached.

At pressures higher than those corresponding to the minima in rates (or therefore those for which the weight loss curves show induction periods) the end product of dehydration is crystalline tetrahydrate. In these experiments a layer of amorphous material is formed in the nucleation stage of dehydration. Upon exposure to water vapor the induction period immediately sets in, which may be interpreted as a period during which crystallization of the X-ray amorphous transition layer takes place under the influence of adsorbed water. This effect occurs over small ranges of pressure and appears to be specifically due to water. Experiments have been carried out in order to ascertain if methyl or ethyl alcohol have any effect in accelerating the rate of these dehydrations, but with negative results. Upon the occurrence of crystallization the escape of water molecules is facilitated, giving rise to the nearly linear increase in the loss-in-weight curves following the induction periods. The final decline in rate may be ascribed to the impedance of this crystalline layer. The occurrence of a zero rate at approximately 4.58 mm. in the dehydration at 40° C. is of interest. It is probable that this is a very long induction period, and if carried farther would resemble the dehydration of 9.1 mm. at 50° C. shown in Fig. 2.

The relatively high pressure at which the minimum in rate occurs has been related elsewhere to the low adsorptive capacity and the capillary structure of the X-ray amorphous material (4). The observed shift of the minimum toward higher pressures by increase in temperature would be expected if it is assumed that a definite quantity of adsorbed water is required to induce crystallization of the amorphous material. Since the adsorption of water will be lowered by rise in temperature, it follows that as the temperature is increased, a higher water vapor pressure external to the interface will be required to provide the necessary quantity of water in the reaction zone.

The dependence of the rate of dehydration of cobaltous chloride hexahydrate upon water vapor pressure is very similar to that observed for the dehydration of chrome alum by Cooper and Garner (1) who made microscopic measurements on the rate of growth of nuclei on single crystals. They assumed the

formation of a transition layer (probably microcrystalline) at the reaction interface and explained the maximum in rate observed at low pressure as being due to a decrease in the thickness of this transition layer as a consequence of the development of macrocrystals of the product. X-ray powder photographs, made in this laboratory, of the vacuum dehydration product of chrome alum show a definite diffraction pattern. Although X-ray diffraction data for the cobalt salt are lacking, observations reported by Jamieson and Frost (3) during determinations of the heat of solution of the vacuum dehydrated product indicate that vacuum dehydration results in a microcrystalline product of high internal surface, the formation of macrocrystals occurring readily.

The group of loss-in-weight versus time curves obtained for this salt are similar to the group of curves following the long induction periods observed in the dehydration of magnesium sulphate heptahydrate or copper sulphate pentahydrate, in that the over-all dehydration rate at first increases with water vapor pressure, and then declines. The absence of observable induction periods in the dehydration of cobalt chloride hexahydrate suggests that the processes assumed to occur during them (i.e. crystallization of amorphous material) either do not occur at all, or take place at extremely low pressures.

It is possible that a state corresponding to the X-ray amorphous state of magnesium sulphate monohydrate is formed as a transitory step as the primary lattice breaks down, but that crystallization occurs immediately. If the presence of water is a necessary factor, this crystallization must take place merely as water molecules from the reaction zone pass through the transition layer. There will result a mesh of microcrystals interspersed with capillaries formed by lattice contraction, the surface properties of which have been described elsewhere (4).

With increase in water vapor pressure external to the reaction zone, further adsorption will occur, resulting in crystal growth, and further contraction in volume, resulting in larger capillaries. In consequence, the more rapid escape of water molecules from the reaction interface will be facilitated, and the observed increase in rate accounted for. The decline in rate following the observed maximum may, as before, be ascribed to the impedance of the growing crystalline layer. This crystalline layer appears to have the composition of the dihydrate. It has been pointed out elsewhere (8) that the rate of dehydration under vacuum proceeds fairly rapidly to the dihydrate stage, followed by monohydrate formation at a slower rate. It appears that this second rate becomes very much slower in the presence of water vapor at low pressures.

It should be noted that the maximum in rate is displaced in the direction of lower pressure with temperature increase, whereas the reverse is true for magnesium sulphate heptahydrate. It has been pointed out that if water plays any significant role in the formation of crystalline dehydration products of cobalt chloride hexahydrate, the quantities required are very small. Any slight adsorption of water will of course decrease with temperature rise. However, it has been shown (3) that the product formed on vacuum dehydration forms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

macrocrystals very readily. It is probable that this crystallization rate increases with temperature and is therefore more significant than the adsorption factor.

In this study, and in other studies of the rates of dehydration of hydrated salts which have been reported, there seems to be a common over-all pattern of the sequence of changes occurring. The point of real interest is the mechanism whereby these changes occur in the presence of adsorbed water, and the variation in the range of pressures of water vapor over which this sequence of changes is observed for different salts. It would be of interest to attempt to correlate these findings with data concerning the crystallographic changes involved. Although some suggestive information is available concerning these crystal structures (7), our knowledge is not as yet sufficiently comprehensive for this purpose.

THE INFLUENCE OF ALKALI ON THE OXIDATION OF TETRALIN[1]

By K. U. Ingold

ABSTRACT

Strong alkalies are powerful catalysts for the initial oxidation of tetralin but their catalytic activity is rapidly replaced by an inhibiting action which makes oxidation of more than 5% of the tetralin an exceedingly slow process. Inhibition is due to the base catalyzed enolization and oxidation of the initial product, 1-tetralone, to various naphtholic compounds. Ring scission yields β-2-carboxyphenylpropionic acid. The rate shows a certain periodicity which may be due to the reaction proceeding by a series of consecutive autocatalytic steps.

INTRODUCTION

Not much is known about the influence of alkali on the oxidation of liquid hydrocarbons (4) but some recent work in these laboratories has shown that the rate of oxidative discoloration of lubricating oils is markedly reduced by the addition of alkali (17). The present work was started in the hope of elucidating this effect by the examination of a less complex system.

Tetralin was chosen for study as a large amount of work has been done on its catalyzed, uncatalyzed, and inhibited oxidation (1, 6–10, 13, 15, 16). The general features of its oxidation are now fairly well understood. In the uncatalyzed reaction tetralin is autoxidized first to a fairly stable hydroperoxide which subsequently breaks down to give a variety of products (16).

EXPERIMENTAL

The general design of the apparatus was the same as that described by Cooper and Melville (3). The manostat, which was used to follow the oxygen uptake at constant pressure, was immersed in a water bath at 34.0° C. The pyrex reaction vessel was connected to the manostat by way of a silicone greased cone and socket and a flexible glass spiral. The cone had a short projection on it that prevented any tetralin which distilled up to the grease during the course of a reaction from returning to the reactants. The reaction vessel was immersed in an oil bath at 119.0° C. and was shaken at 250 cycles/min. Tetralin was added to it from a constant volume pipette (3) which delivered 2.5 ml. The reaction vessel was cleaned by washing with benzene, alcohol, and distilled water, followed by heating to the softening point of glass in a stream of dry air in order to burn out any insoluble residue.

Infrared spectra were taken with a Model 21 Perkin–Elmer infrared spectrophotometer.

PURIFICATION OF TETRALIN

Commercial tetralin was shaken repeatedly with concentrated sulphuric acid until there was no discoloration. It was then washed with water, dilute alkali, and again with water. After being dried with $CaSO_4$ it was run through

[1]*Manuscript received January 20, 1956.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3919.

an alumina column and distilled twice under vacuum from sodium through a 2 ft. column packed with Dixon gauze rings (2). It was stored under an atmosphere of pure nitrogen.

Infrared analysis showed the purified tetralin to contain less than 0.05% of hydroperoxide, less than 0.1% of ketone, and only a very small amount of 1,2-dihydronaphthalene. The refractive index was 1.538_8 (n_{25}^{D}).

RESULTS

Kinetic Data

All the work reported in this paper was done at 119.0° C. with 2.5 ml. samples of tetralin.

Table I gives some data on the effect of various alkaline additives on the maximum rate of oxidation of tetralin (r_{max}, given in ml. O_2 at S.T.P./liter

TABLE I

EFFECT OF ALKALI ON THE OXIDATION OF TETRALIN

Additive	r_{max}	t_{max}	t_1	t_3	t_5	t_6	t_{10}	t_{20}

tetralin/sec.), on the time at which the maximum rate is reached (t_{max}, sec.), and on the times to various percentages of oxidation (t_1, t_3, etc., calculated for 1 mole O_2/mole tetralin). All data given are averages of at least two experiments. The run without additives, called hereafter the "normal" run, was an average of about 20 runs, none of which differed by more than 5% from the mean. In the presence of strong alkali, although the time taken to reach a given amount of oxidation was reproducible to within 5 or 10%, the maximum rate was of such short duration that it may be in error by 20%. Within the experimental error the same rates and times were obtained with 0.1–0.5 gm. NaOH, 0.5 gm. of sodium metal, and 0.5 gm. of a 10% Na – 90% Pb alloy. These runs with strong alkali are called hereafter "alkali" runs. For contrast the "normal" and "alkali" oxidation curves are shown in Fig. 1. It can be seen that the initial catalytic activity of the alkali is rapidly replaced by a strong inhibiting action. In addition to the very sharp maximum at 275 sec., there are two or more subsidiary maxima, the most noticeable of which occur at about 650 and 1300 sec.

The "normal" reaction went through the color sequence from light yellow (10% oxidation) to canary yellow (35%) and finally to a viscous reddish-orange oil. Oxidation in the presence of strong alkali gave a fine suspension of solid particles which went through a large range of colors. At 5% oxidation the color was yellow, at 7% brown, then greenish-brown, green (9%), dirty green, yellow,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

and finally reddish-orange (10–12%). If the suspension was removed by centrifuging or by extraction with water, the liquid remained colorless until about 10% oxidation; it then showed a faint reddish-yellow color.

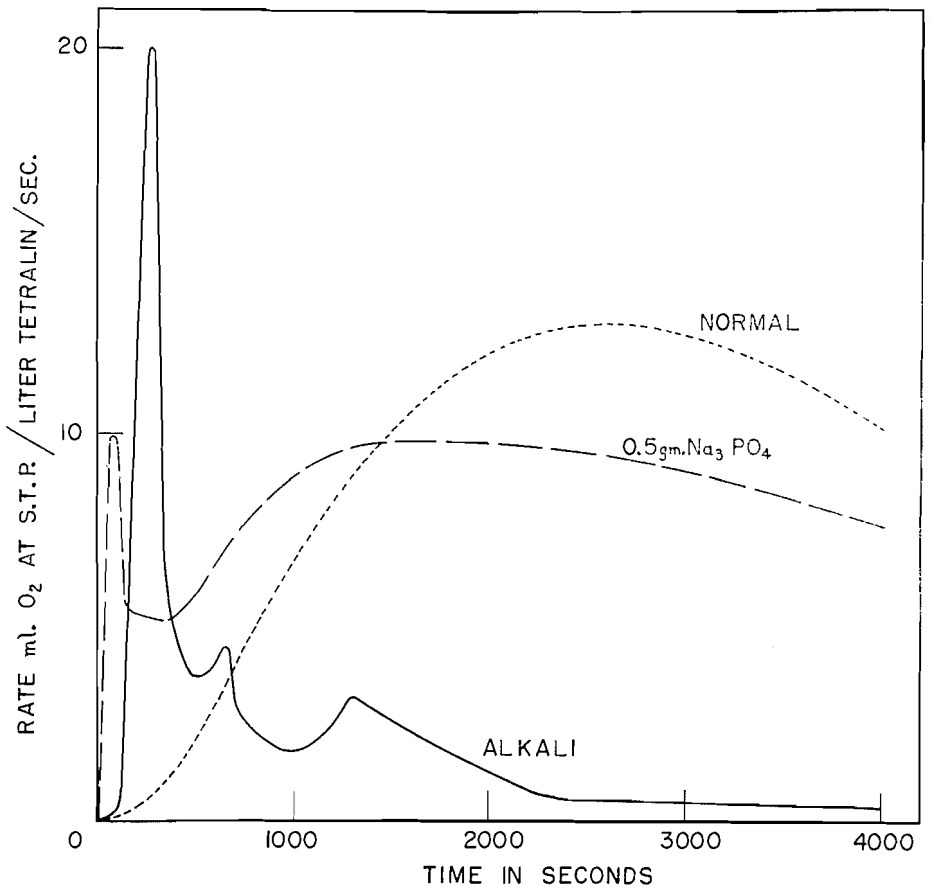

FIG. 1. The rates of oxidation of tetralin for "normal", "alkali", and Na_3PO_4 reaction.

The effect of moderate amounts of weak alkali, e.g. 0.5 gm. of dehydrated Na_3PO_4, was to give a combination of the "normal" and the "alkali" oxidation curves. The curve showed two maxima, the first near the beginning of the reaction and the second at about 12% oxidation (see Table I and Fig. 1). The liquid was a faint reddish-yellow at 30% oxidation.

Small amounts of weak alkali, e.g. 0.1 gm. of Na_3PO_4, or larger amounts of very weak alkali, e.g. 1.0 gm. of dipotassium phthalate, merely lowered the maximum rate of an otherwise "normal" reaction. The liquid was canary yellow at 25% oxidation.

Large amounts of weak alkali, e.g. 2 gm. of Na_3PO_4, gave an oxidation curve of the "alkali" type. However, the rate after 6% oxidation did not decrease sharply, but steadied down to a value of about 3.0 after 600 sec. The liquid was reddish-yellow at 25% oxidation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

A 5% oxidized "alkali" run (rate = 0.4) was centrifuged and all the solids removed. Measurements were then made on the further oxidation of the clear liquid (Table I). The reaction was of the "normal" type with only slight inhibition. The liquid became light yellow in color. The solid portion of the "alkali" run was washed with tetralin, dried, and then added to a fresh sample of tetralin. The rate remained low (0.38) and fairly constant to 12,000 sec. (t_1 = 4,800, t_3 = 11,700 sec.). The liquid remained colorless.

The addition of 0.3 gm. NaOH to a "normal" run after 1500 sec. (rate = 10.0) produced for the first 50 sec. an apparent negative rate due to the evolution of steam. After 400 sec. the rate reached its maximum value (3.9) and then fell rapidly to a low value characteristic of an "alkali" reaction. The pale yellow color of the "normal" run was changed to a pale pink. Na_3PO_4 would also convert the yellow color of a "normal" run to the pale pink color characteristic of an "alkali" run.

It is known from the work of Hock and Susemihl (11) that 1-tetralone is a major product of the "alkali" reaction. The influence of pure 1-tetralone on the oxidation of tetralin was therefore studied.

The addition of 0.2 ml. of 1-tetralone had only a slight effect on the reaction. The oxidation times were the same as those of a "normal" run but the maximum rate was a little lower (Table II). A rather larger inhibition was obtained by the addition of 0.2 ml. of a sample of 1-tetralone which had been 3% oxidized.

TABLE II

EFFECT OF KETONES ON THE OXIDATION OF TETRALIN

Additive	r_{max}	t_{max}	t_1	t_3	t_5	t_{10}	t_{20}
0.2 ml. 1-tetralone	12.2	2600	555	980	1285	1895	2950
As above, 3% oxidized	10.1	3900	590	1190	1625	2430	3760
0.5 ml. 1-tetralone + 0.3 gm. NaOH	4.6	2250	950	1630	2190	3740	—
0.2 ml. *n*-valerophenone	12.6	150	110	330	540	1045	2105

1-Tetralone autoxidized very slowly compared with tetralin, but in the presence of alkali it was oxidized to a dark viscous oil with extreme rapidity, the rate reaching 78.0 in 300 sec. A large amount of water was evolved and the reaction mixture went rapidly through the color sequence blue-green, brown-green, brown, purple, cherry red, and finally black and opaque. In contrast a mixture of 1-tetralone, tetralin, and alkali gave a "normal" type oxidation curve with a very low maximum rate (Table II). The liquid became cherry red in color.

For comparison with the effects produced by 1-tetralone some experiments were done adding other compounds containing a carbonyl group adjacent to a benzene ring.

The addition of 0.1 ml. of acetophenone gave a slightly lower maximum rate than a "normal" reaction, but the same amount had no effect on the reaction in the presence of strong alkali.

The addition of 0.2 ml. of *n*-valerophenone ($C_6H_5.CO(CH_2)_3CH_3$) strongly catalyzed the oxidation of tetralin (Table II). Within the first 200 sec. the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

rate rose to the maximum value characteristic of the "normal" rate of oxidation. It then decreased in accordance with first order kinetics until 20% of the tetralin had been oxidized. Beyond 20% the rate decreased more rapidly.

n-Valerophenone autoxidized very slowly ($r = 0.4$ after one hour, 0.45% oxidized); its rate of oxidation at 119° C. was unaffected by alkali. The addition of *n*-valerophenone and alkali to tetralin (Table III) gave an "alkali" type

TABLE III

EFFECT OF *n*-VALEROPHENONE (V) AND ALKALI ON THE OXIDATION OF TETRALIN

Additive	r_{max}	t_{max}	t_1	t_3	t_5
0.1 ml. V + 0.1 gm. NaOH	18.8	180	210	670	1325
2.0 ml. V + 0.1 gm. NaOH	15.0	310	230	400	1190
2.0 ml. V + 0.2 gm. NaOH	10.5	230	250	555	1170

2.0 ml. V + 0.5 gm. NaOH	8.9	225	350	6000	—

curve but with the maximum rate dependent on the amount of alkali and to a lesser extent on the amount of ketone. The addition of a partially oxidized (0.2%) mixture of 2 ml. of *n*-valerophenone and 0.2 gm. NaOH to tetralin gave a strongly inhibited "alkali" curve (Table III).

A few experiments were also done on the oxidation of tetralin in the presence of *n*-valerophenone and weak acids (Table IV).

TABLE IV

EFFECT OF *n*-VALEROPHENONE (V) AND ACID ON THE OXIDATION OF TETRALIN

Additive	r_{max}	t_{max}	t_1	t_3	t_5	t_{10}	t_{20}
0.5 gm. $C_6H_4(CO_2)_2KH$	12.4	2300	510	900	1190	1775	2840
0.5 gm. $C_6H_4(CO_2)_2KH$ + 0.2 ml. V	11.5	2050	260	575	830	1410	2535
0.5 gm. $C_6H_4(CO_2)_2H_2$	11.2	2450	570	1005	1320	1940	3120
0.5 gm. $C_6H_4(CO_2)_2H_2$ + 0.2 ml. V	11.6	2300	740	1150	1435	2010	3170

The addition of 0.1 ml. of commercial benzaldehyde increased the rate of the "normal" oxidation, but it decreased the rate of the "alkali" reaction. Benzyl alcohol reduced the rate of both "normal" and "alkali" reactions.

The addition, at the beginning of a run, of phenolic compounds such as 2-naphthol, sodium salicylate, γ-2-hydroxyphenylbutyric acid and its sodium salt almost completely inhibited the oxidation of tetralin. Their addition in the middle of a run caused a marked reduction of rate, e.g. 0.1 gm. of γ-2-hydroxyphenylbutyric acid when added to a "normal" run after 1300 sec. caused the rate to drop from 8.8 to 1.1 (cf. 16).

Dehydrating agents such as $CaSO_4$, P_2O_5, and conc. H_2SO_4 completely inhibited the oxidation of tetralin for at least 5000 sec.

Analysis for Products

The infrared spectrum of pure tetralin was compared with the spectra of the products of the "normal" and "alkali" reactions. The "normal" runs showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

one strong new band at 3470 cm.$^{-1}$ due to O—H stretching in the hydroperoxide. With increasing oxidation hydrogen bonding caused this band to become broader and its maximum to shift to lower wave numbers. There were also some new but weaker bands at lower wave numbers (830, 880, and 912 cm.$^{-1}$) which can also presumably be associated with the hydroperoxide group.

The "alkali" runs showed a number of weak bands and one strong new band at 1683 cm.$^{-1}$ due to C=O stretching. There were no bands due to hydroperoxide, but instead a weak band appeared at 3550 cm.$^{-1}$ which may be due to a naphtholic OH group.

The spectrum of pure 1-tetralone gave a strong band at 1683 cm.$^{-1}$ and a number of weaker bands at lower wave numbers which accounted for most of the differences between the tetralin and "alkali" spectra. For runs lasting less than 6000 sec., i.e. less than about 8% oxidation, the intensity of the 1683 cm.$^{-1}$ band was roughly proportional to the amount of oxidation, but for longer runs its intensity was very much reduced. At 12% oxidation (23,000 sec.) the 1683 band corresponded to only about 2% oxidation, i.e. to about one sixth of the products; since no other new bands appeared the end products of the "alkali" reaction must be rather insoluble in tetralin. Acidification of an "alkali" run eliminated a weak band at 1560 cm.$^{-1}$, but two new bands appeared at 1728 cm.$^{-1}$ and 1715 cm.$^{-1}$. This represents the change from ionized to non-ionized carboxylic acids. The reverse of this process was observed when alkali was added to the products of a "normal" run, i.e. two weak bands at 1728 cm.$^{-1}$ and 1715 cm.$^{-1}$ were replaced by a band at 1560 cm.$^{-1}$. β-2-Carboxyphenylpropionic acid (see below) gave a strong band at 1728 cm.$^{-1}$. The carboxylic acid band at 1715 cm.$^{-1}$ was not characterized.

When alkali was added to the end product of a "normal" run the hydroperoxide was destroyed. Its addition at 6% oxidation gave only 1-tetralone but at 12% a weak new band appeared at 1670 cm.$^{-1}$ which became stronger than the 1683 cm.$^{-1}$ band at 35% oxidation. This band did not appear in the "alkali" reaction. It is probably due to a naphthoquinone.

No other differences of any magnitude were noted in the spectra.

The orange suspension from a 12% oxidized "alkali" run dissolved in water to give a red solution. On acidification the solution turned faint yellow and an acidic, slightly soluble orange oil was obtained. This oil was recrystallized twice from methyl alcohol and identified as 2-hydroxy-1,4-naphthoquinone (m.p. 189° C. (decomp.) (18)).

The green compound was not isolated from an "alkali" run. It was obtained by adding sodium hydroxide to a 12% oxidized "normal" run and heating the mixture at 119° C. for 15 min. The sodium hydroxide pellets turned green; extraction with water followed by acidification gave a dark blue precipitate, m.p. 250° C. (decomp.), identified as 1-(3′,4′-dihydroxy-1′-naphthyl)-3,4-naphthoquinone (m.p. 245° C. (sinters), 255° C. (decomp.) (18)).

A white crystalline compound was obtained from a 7% oxidized "alkali" run by extraction with water and acidification. Recrystallization from boiling water gave β-2-carboxyphenylpropionic acid (m.p. and mixed m.p. 164° C.).

DISCUSSION

The results given in Fig. 1 and Table I show that the initial catalysis by alkali is soon replaced by a strong inhibition. Although nearly all phenols act as inhibitors in the initial stages of the autoxidation of hydrocarbons, only certain easily oxidized ones such as the naphthols are also effective once the reaction has started (15). The oxidation of tetralin in the presence of strong alkali must therefore produce some powerful inhibitors.

It is clear from the experiments with the solid and liquid phases of a sodium hydroxide run that the inhibitor is only slightly soluble in tetralin, which suggests that the inhibitor is acidic and forms a salt with the alkali.

The very rapid conversion of tetralin hydroperoxide to 1-tetralone by hot alkali (11) was confirmed by infrared analysis. When alkali was added in the middle of a "normal" run the subsequent course of the reaction was of the "alkali" type, but the maximum rate (3.9) was only about one fifth of the rate reached when alkali was added at the start of a run (20.0). This indicates that inhibition depends on the reaction of alkali with 1-tetralone. An "alkali" run has to proceed to just over 1% oxidation before the rate starts to decrease, but when alkali is added in the middle of a "normal" run, the immediate conversion of tetralin hydroperoxide to 1-tetralone almost eliminates the catalytic effect of the alkali. The strong inhibition of the reaction by 1-tetralone and alkali (Table II) is therefore not unexpected; it is probably due in part to a base catalyzed enolization of 1-tetralone to 1-hydroxy-3,4-dihydronaphthalene on the surface of the alkali, and in part to the further oxidation products of 1-tetralone (see below).

The spectrum of colors through which the "alkali" reaction proceeds is very suggestive when compared with the results of Strauss, Bernouilly, and Mautner (18). These workers oxidized 2-hydroxy-1-tetralone in alkaline solution. The solution went through the color changes yellow, brown, greenish-brown, pure green, dirty green, and finally to a permanent orange. They identified the various colored compounds as 1,2-dihydroxynaphthalene (yellow); 3,4;3′,4′-tetrahydroxy-1,1′-dinaphthyl (brown in alkaline solution, pinkish-yellow in acid); 1-(3′,4′-dihydroxy-1′-naphthyl)-3,4-naphthoquinone (dark green in alkali, dark blue in acid); 2-hydroxy-1,4-naphthoquinone (orange in alkali, sodium salt red, yellow in acid). The last named compound was the end product of the reaction and did not further absorb oxygen under their experimental conditions. These substituted naphthols are all acidic and form insoluble salts; they are powerful oxidation inhibitors. While complete reliance can rarely be placed on color reactions alone, the identification in the present work of the last two compounds, and the fact that the "alkali" reaction goes through an almost identical color sequence, would seem to indicate that the first two products are probably also formed.

In agreement with the results of Robertson and Waters (16), no γ-2-hydroxyphenylbutyric acid was detected. These workers found that although this acid was produced by the autoxidation of tetralin and by the decomposition of tetralin hydroperoxide, it was not produced by the autoxidation of 1-tetralone. They concluded that it was formed by an ionic mechanism involving 1-tetra-

lone and tetralin hydroperoxide. In the "alkali" reaction there is of course little or no hydroperoxide present and therefore no γ-2-hydroxyphenylbutyric acid would be expected. Ring scission yields instead β-2-carboxyphenylpropionic acid. The formation of this acid instead of the phenolic acid can be compared with the action of acids and bases on the decomposition of cumene hydroperoxide (12). In the presence of acids this hydroperoxide breaks between the ring and the α carbon atom to yield phenol and acetone, but in the presence of alkali it is the bond between the α and β carbon atoms which breaks to give acetophenone and methane.

No 1-tetralol was detected in the alkaline oxidation of tetralin.

The effect of weak alkali on the oxidation of tetralin was intermediate between "normal" and "alkali" oxidations. This supports the belief that inhibition is due in part to a base catalyzed enolization of 1-tetralone. The amount of enolization, and hence the inhibition, depends both on the strength of the alkali and on its concentration, or more probably on its surface area.

The slight reduction in the rate of oxidation of tetralin by 1-tetralone is in agreement with earlier work (9, 13). Acetophenone behaves in the same way. The greater inhibition produced by partly oxidized 1-tetralone is due to the presence of the inhibitor 3,4-dihydro-1,2-naphthoquinone or its isomer 1-keto-2-hydroxy-1,4-dihydronaphthalene (16). The elimination of the normal induction period by the addition of *n*-valerophenone is similar to the technical use of ketones in promoting the autoxidation of hydrocarbons (19).

The results given in Table III indicate that inhibition by *n*-valerophenone and alkali is probably also due to a base catalyzed enolization on the surface of the alkali. The greater inhibition produced by a partially oxidized *n*-valerophenone and alkali mixture is similar to the increased inhibition produced by oxidized 1-tetralone.

The results in Table IV present some slight evidence that inhibition can also be produced by an acid catalyzed enolization of *n*-valerophenone, although the effect is much less marked than that produced by alkali. The effect shows up most clearly where the catalysis by *n*-valerophenone is compensated for, i.e. in a comparison of the times required to reach a given percentage oxidation for ketone plus potassium hydrogen phthalate and for ketone plus phthalic acid. The latter is a much slower reaction.

Alcohols have been reported both to decrease (15) and to increase (5) the rate of oxidation of tetralin. In the present work benzyl alcohol was found to act as a weak inhibitor.

The complete inhibition brought about by the addition of dehydrating agents at the start of the reaction is probably due to the dehydration of the hydroperoxide directly to 1-tetralone. This prevents chain branching which is normally brought about by scission of the O—O bond of the hydroperoxide.

The very sharp maximum in the "alkali" rate curve could be due to the build-up of sufficient inhibitor to reverse the initial catalyses. However two or more consecutive autocatalytic reactions can lead to periodicity in the reaction rate (14), and a close examination of the rate curves reveals that there are probably at least two subsidiary maxima. The whole course of the "alkali"

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

reaction might therefore also be explained as a consecutive series of autocatalytic reactions, the formation of inhibitors accounting for the decrease in height of successive maxima.

CONCLUSION

The usual method of reducing the rate of oxidative deterioration of hydrocarbons is by the addition of certain strong inhibitors such as aromatic amines and naphthols. These inhibitors are, however, gradually oxidized and therefore lose their effectiveness. Inhibition by alkali of the oxidation of tetralin, and presumably of many other hydrocarbons, offers certain advantages in that the concentration of inhibitors is maintained by the oxidation process. The most effective stabilization would probably be obtained by the use of both methods.

ACKNOWLEDGMENTS

The author wishes to thank Dr. I. E. Puddington for his continuing interest and advice throughout the course of this work. Thanks are also due to Dr. A. M. Eastham and Mr. G. Latremouille for the preparation of 1-tetralone and γ-2-hydroxyphenylbutyric acid, and to Mr. R. Ironside and Mr. E. C. Goodhue for running the infrared spectra. Acknowledgment is also made of some preliminary work on this subject by Dr. L. Young.

MYRISTIC ACID MONOLAYER AT LOW SURFACE PRESSURES[1]

By G. P. Semeluk,[2] J. W. V. Hahn,[3] and John L. Morrison[4]

ABSTRACT

The surface pressure–area relationships of gaseous myristic acid films at the air–aqueous interface have been measured at very low surface pressures. The acid was spread from petroleum ether solutions. The molecular cohesion was found to be about six times that of gaseous butane under comparable conditions. Some explanation of Moss and Rideal's "double molecule" phenomenon is given.

A number of studies have already been made of myristic acid monolayers on water surfaces (2, 3, 4, 7, 8). Different types of apparatus have yielded concurring results (2, 3, 4) as well as anomalous ones (7, 8). Often insufficient data has been given concerning the methods of spreading, the concentration of the spreading solutions, and the time allowed for evaporation of the solvent, all of which are very important for monolayer studies at the low pressures of gaseous films. It is still correct to say that "Further work on gaseous films, with very sensitive instruments at areas over 1,000 sq. A., is desirable." (1, p. 43).

EXPERIMENTAL

Apparatus

A horizontal film balance of the Langmuir–Adam type (1) was used with an original modification which permitted a sweeping of the whole surface at one time (5). In this modification the head and mica float were vertically moved by a cam. Small stirrups held gold foil ribbons against the bakelized aluminum trough during film measurements. The other ends of the S-shaped ribbons were attached to the mica float to prevent leaks. On raising the head, the small stirrups raised the gold ribbons, and aluminum wire stirrups raised the float. Fragile parts of the head were specially clamped during these operations. The trough had a total area of 960 cm.^{2} and a film dispersing area of 687 cm.^{2}

The forces on the float were measured by phosphor bronze torsion wires. The 5 mil diameter wire measured forces from 0.01 to 1 dyne cm.$^{-1}$. The 3 mil wire measured forces from 0.010 to 0.1 dyne cm.$^{-1}$ to an accuracy of about 0.001 dyne.

Forces were registered by float movements which were transferred through a lever to a mirror pivoted on a torsion wire axle. The balance was used as a null instrument, readings being made on a calibrated dial.

Surface potential measurements were made with a polonium-coated air electrode and a calomel half cell. The potential was amplified by a Dubridge and Brown circuit using an FP 54 electron tube (10). The polonium electrode was mounted on a movable frame to explore the whole surface.

The surface balance was completely enclosed in a double wall copper box which was thermostatted at $20 \pm 0.1°$ C. A small door in a double wall plexiglass front face provided entry to the balance.

Materials

Myristic acid from Eastman Kodak Co. was recrystallized three times from absolute ethanol with norite treatment before each crystallization. The product melted sharply at 58° C.

The spreading solvents were petroleum ether (b.p. 30–35° C.) and benzene (thiophene-free). They were refluxed for 12 hr. over phosphorus pentoxide and then slowly fractionated in a combined reflux and fractionating column.

Solutions of myristic acid in each of the solvents were prepared and used immediately. Concentrations ranged from 0.0011 mgm. myristic acid per ml. to 0.0172 mgm. $ml.^{-1}$ in the case of petroleum ether which was the better solvent.

Procedure

The trough was filled to its brim with 0.01 *N* HCl in conductivity water. The solution had been previously treated with norite to remove surface active impurities. The surface was swept 10 times, the balance head lowered, and the zero point allowed to come to rest.

Each film was spread drop by drop over different parts of the surface from a 0.0878 ml. micropipette. A standard 10 min., determined from a preliminary study of spreading times, was allowed for solvent evaporation and spreading of the film.

Two types of experiments were made. For all areas below 7000 $Å^2$ $molecule^{-1}$, the 5 mil wire was used and the conventional procedure of successively decreasing the surface area was followed. The interval between successive force readings was from 6 to 10 min. For areas above 7000 $Å^2$, the 3 mil wire was used and a single determination of force and area was made. The surface was then swept clean and a new film was spread on a different area. Although the latter method was laborious, each reading taking about 45 min., it avoided any vibrations which cause zero point changes.

Surface potential measurements were determined only on the less dilute films. In very dilute films too few molecules were under the electrode (1 $cm.^2$ in area) to cause a potential change.

Complete details of the great precautions necessary to ensure cleanliness and stability are given elsewhere (9).

RESULTS AND DISCUSSION

The results for myristic acid dispersed from petroleum ether and from benzene are plotted in Fig. 1 as the surface pressure, F dyne $cm.^{-1}$, against the area, A, Angstrom^2 per molecule, following the notation of Adam (1). They are also plotted in Fig. 2 as the product FA against F. In this figure the results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

of Adam and Jessop (2), Guastalla (4), and Allan and Alexander (3) are given for comparison with the present results. The present results, particularly for the single value experiments, are at lower pressures than any reported in the literature.

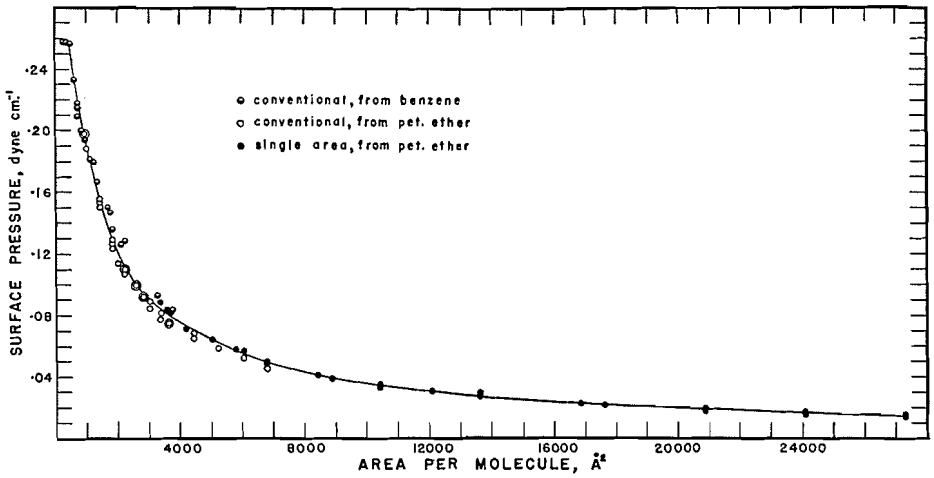

FIG. 1. Surface pressures corresponding to various surface areas occupied by myristic acid molecules on 0.01 *N* HCl aqueous solution.

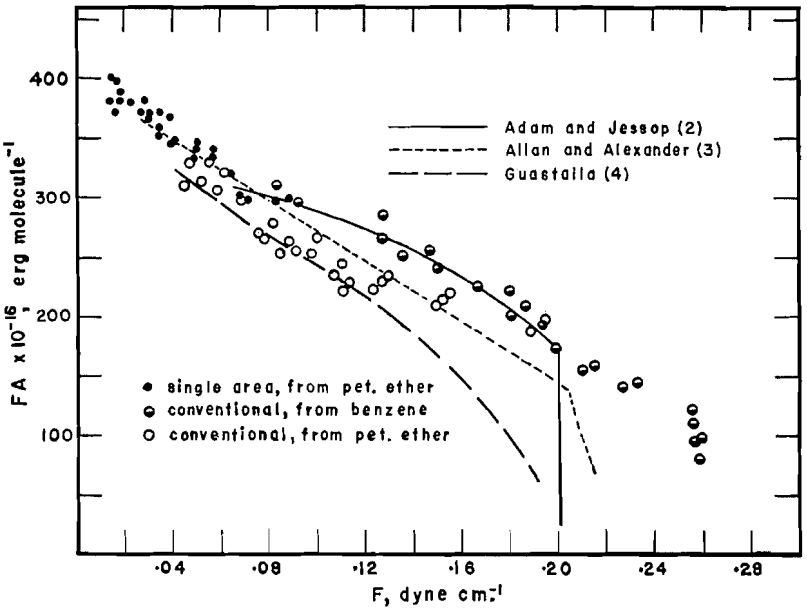

FIG. 2. Comparisons of *FA* versus *F* plots.

Although our results do not agree with those of Moss and Rideal (8), some experimental evidence will be given which may account for their observations. Also, an explanation will be suggested for the observations of Kalousek (7).

Cohesive Force

Corresponding to van der Waals equation for three dimensions, an equation for two-dimensional surface films (1, p. 120) would be

$$[1] \qquad (F+\alpha/A^2)(A-\beta) = kT$$

where F and A are the same as above, α/A^2 is the cohesive force, β is the "excluded area" of the molecules, k is Boltzmann's constant, and T the absolute temperature. In the present case, at very low surface pressures (<0.1 dyne cm.$^{-1}$), β becomes negligible compared with A and the equation reduces to

$$[2] \qquad FA = kT-\alpha/A.$$

This equation was applied to the single point determinations (29 in number) made on the 3 mil wire. By plotting FA against $1/A$ and using the method of least squares to obtain the straight line, we obtained the equation

$$FA = 402-4.02\times10^5/A.$$

The theoretical value of kT at 293° K. is 404 ergs per molecule when the area is expressed in Å^2.

Arbitrarily choosing an area of 12,000 Å^2 per molecule, we calculate the cohesive force α/A^2 to be 2.80×10^{-3} dyne cm.$^{-1}$ molecule^{-1}. If the film thickness is assumed to be 4.5 Å (1, p. 45), then α/A^2 is equivalent to 6.1×10^{-2} atm. cm.$^{-2}$ in three dimensions.

This cohesive force may be compared with that of butane under similar conditions. Thus, at $A = 12{,}000$ Å^2 per myristic acid molecule, F is equal to 0.03 dyne cm.$^{-1}$. The equivalent pressure in three dimensions at 20° C. is 0.66 atm. (1, p. 45). Under the same conditions, and for ideal behavior, the molar volume of butane is 36.4 liters. The van der Waals constant for butane, a, is 14.5 liter^2 atm. Thus, the cohesive forces are $a/V^2 = 1.1\times10^{-2}$ atm. for butane and $\alpha/V^2 = 6.1\times10^{-2}$ atm. for myristic acid. This is a very reasonable value for myristic acid in the gaseous film state.

Equation [2] was applied to the results of the conventional force–area experiments, which cover a somewhat higher pressure range than the single experiments. Low values for FA at zero pressure were obtained. For example, for benzene solutions FA was equal to 335. This is not surprising as the range of pressure is from 0.08 to 0.22 dyne, the latter being quite close to the "vapor pressure" of the "liquid" myristic acid film.

However, when extrapolations were made on FA versus F straight lines, the least square values at zero surface pressure were 410, 405, and 419 respectively for single runs, and for conventional runs from petroleum ether and from benzene. There is no theoretical justification for this type of *linear* extrapolation. At the same time, it is apparent that measurements must be made well below the "vapor pressure" of the "liquid" film in order that the van der Waals type of extrapolation be valid.

Latent Heat of Vaporization

Adam and Jessop (2), using the Clapeyron equation, have calculated the latent heat of vaporization of myristic acid liquid monolayer to be 3200 cal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

mole^{-1} at 14.5° C. The latent heat can also be estimated by combining their vapor pressure measurements at 14.5° (0.203 dyne) with ours at 20° (0.258 dyne from Fig. 2) in the Clausius–Clapeyron equation. By making the approximation that the latent heat is constant over this temperature range, we obtain the value of 730 cal. mole^{-1}. Two comments may be made concerning this value: (1) one would expect the latent heat to fall off rapidly with temperature near the "critical temperature" of the gaseous film (est. 30–35° (2)); (2) the present calculation takes more account of the effect of the substrate than does the method using the areas of the liquid and gaseous films at the terminal points of the liquid–gas equilibrium line.

The Island Phenomenon

For areas less than 6000 Å^2 per molecule, force readings taken at successively smaller areas, in each case 10 min. after spreading, exhibited an erratic behavior. A typical experiment is given in Table I. The surface potential apparatus showed that the film was not homogeneous. Wherever a drop of spreading

solution had been placed, the potential was 5 to 10 mv. more positive. Other parts of the surface showed no change from the potential of a clean surface. These observations suggest the presence of islands of unspread myristic acid. Since the islands did not disperse in a convenient length of time, a procedure was devised to disperse them. The film was compressed to one-seventh of its original area to merge the islands, then it was expanded very slowly (10–15 min.). Surface potentials varied over the surface to a smaller extent (2–6 mv.) and no clean surface potentials were found. After complete decompression, the compression was repeated with much more consistent results. It was found that the increased time did not accumulate much contamination.

The island phenomenon was observed for both benzene and petroleum ether solvents. It was also found to depend on the concentration of the dis-

For personal use only.

persing solution. For example, when measurements were made at the lowest pressure range with the 3 mil torsion wire, solutions more dilute than 0.0043 mgm. per ml. spread completely in 10 min.

Further observations help to account for the island phenomenon. Immediately after placing the dispersing solution on the surface, the pressure increased momentarily to a fairly high value (approx. 0.3 dyne), then rapidly decreased practically to zero within a minute, and finally increased slowly for the next few minutes. Each drop of solution formed a lens of from 2 to 3 cm. diam. According to Harkins' theory of spreading (6), there is a monomolecular layer of hydrocarbon in equilibrium with a visible liquid lens. This would account for the high initial pressure. Apparently this monomolecular layer (5–10 Å thick) is not able to drag many myristic acid molecules with it. Most of them remain at the site of the lens, and the lens decreases largely by spreading as a monolayer and *then* evaporating.

The erratic force measurements can be explained[5] by the suggestion that each island of myristic acid will exert a dynamic vapor pressure in excess of the final static pressure of the homogeneous film. The mica float would pick up these dynamic pressures when islands floated near to it. Conversely, the absence of islands near the float would be similar to a two-dimensional vacuum. It is to be noted that this phenomenon is not the same as the incomplete spreading caused by contamination. In the latter case, the surface pressure is uniform over the whole surface.

Double Molecules

Moss and Rideal (8) determined the force–area relations of myristic acid films within the molecular area range of 1000 to 15,000 Å^2. They found a nearly constant value for FA of about 200 over the whole gaseous range. They concluded that the film consists of extremely stable double molecules, and that these follow the two-dimensional ideal gas law.

Moss and Rideal's spreading method differed from the one used here. Instead of obtaining successively smaller areas by moving a barrier towards the float, they used a fixed area. They spread a film from one drop of a solution, then they made a force measurement. Another drop was placed on top of the existing film to obtain a smaller molecular area and again a force measurement was taken. A series of such measurements on films spread one on top of the other comprised their experiment.

We duplicated the results of Moss and Rideal to a large extent by repeating their method of spreading on a fixed area. Initially 0.0878 ml. of a petroleum ether solution containing 0.0021 mgm. myristic acid per ml. solution was placed on a surface area of 662 sq. cm. After complete spreading of the film, duplicate amounts were placed successively on top of each film. The results are given in Fig. 3. In view of the fact that the first film spread on a clean surface did not give a FA value near 200 and the further fact that the island phenomenon disappeared as the initial areas became much greater than

[5]*The first referee has observed even* negative *pressures under conditions similar to the above and suggests that the observations may be accounted for by a cooling caused by the evaporating volatile solvent.*

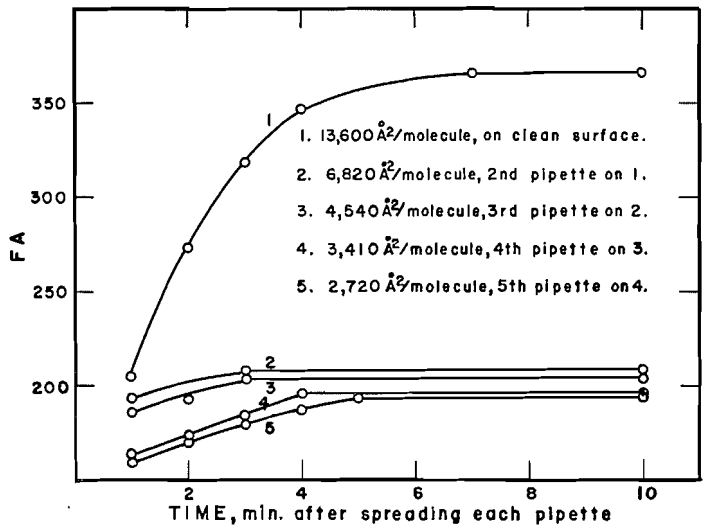

FIG. 3. The changes of surface pressure with time after adding one spreading solution on top of another at constant surface area.

7000 Å² per molecule, it is possible that a critical concentration of the spreading solution exists above which there is spontaneous double molecule formation.[6,7]

As the island phenomenon was most pronounced with solutions of concentration 0.0043 mgm. ml.$^{-1}$ and greater, it is believed that this is near the critical concentration. Unfortunately, Moss and Rideal, in common with most workers in this field, did not report their spreading solution concentrations. Moreover their experimental temperature (17°) would be more favorable to double molecule formation than ours.

The time of spreading is very important. In our case, the one minute reading for each pipette (Fig. 3) is obtained *after* the rise caused by the petroleum ether has fallen off. Adam (1, p. 31) suggests taking readings within one minute. Moss and Rideal allowed "a few minutes" between readings. It is apparent from our results that even for such a volatile solvent as petroleum ether (b.p. 30–35°) at least six minutes are required to obtain a steady force reading.

It may be possible to explain Kalousek's anomalous results for myristic acid (7). His results for the ester ethyl hexadecanedicarboxylate are normal, extrapolating to an *FA* value of about 400. However, his myristic acid *FA* values only reach about 65 at 0.014 dyne cm.$^{-1}$. Although he gives no data on the concentrations of his spreading solutions, a clue to their magnitude may be given in his statement—"This condition is fulfilled with light petroleum (b.p. 70°) which in amounts of 1 mm.^{3}/100 cm.^{2} evaporates in about 1 minute." If he used this volume for his spreading solutions, then his concentrations would be of the order of 10 times the present ones. Such high concentrations

[6]*The significance of the concentration of the spreading solution was not fully realized at the time these measurements were made so that other initial spreading concentrations were not tested.*

[7]*The first referee has suggested that Moss and Rideal* may *have used water as a substrate* and *an uncoated metal trough for their balance. Either or both these differences in method may account for their anomalous results.*

would be very conducive to the occurrence of islands and double molecules. In his efforts to overcome the effect of residual solvent on the surface pressure, Kalousek may have become involved in a more serious error in the spreading of myristic acid films.

Solvents

Each of the solvents, benzene and petroleum ether, has its disadvantages. Our low boiling petroleum ether evaporated too quickly, which was conducive to island formation. Benzene leaves a significant residual pressure and increases the rate of contamination of the surface.

Because of residual pressure, measurements made on benzene solutions at areas greater than 2750 $Å^2$ were not reliable. At surface pressures greater than 0.2 dyne, where the residual pressure was less than one-tenth of the total pressure, the benzene and petroleum ether results coincided. The surface vapor pressure of myristic acid was the same from both solvents.

The change in surface potential for the residual benzene, compared with the clean surface, was about −3 mv. at 10 min. Myristic acid changes the potential in the opposite direction. Petroleum ether evaporated completely in 10 min. to leave the surface potential unchanged. Thus, the latter is the more suitable solvent for surface potential measurements.

APPLICATION OF THE VIBRATIONAL SUM RULE TO HALOGENATED ETHYLENES[1]

By H. J. Bernstein

ABSTRACT

The vibrational sum rule has been applied to the fluoro-chloro-bromo-ethylenes and good agreement obtained between observed frequency sums and those calculated on the basis of additivity considerations. Two unobserved frequencies for *trans* dibromoethylene have been calculated and the in-plane and out-of-plane sums for some molecules not yet investigated. Several ambiguities with regard to some halogenated ethylenes have been resolved and several assignments which merit reinvestigation have been indicated.

Considering the zero-point energy in a homologous series of molecules to be an additive property, analogous to the heat of atomization for example, indicated that the sum of the frequencies of the fundamental modes of vibration could be treated as an additive property (2). The additivity scheme describing these properties was one in which contributions from bonds, interactions between neighboring bonds and/or atoms, and interactions between next neighboring bonds, etc., were taken into account (1).

New vibrational data for several halogenated ethylenes have been reported recently and it seems worth while at this time to show the kind of agreement that can be obtained between observed frequency sums and those calculated on the basis of the additivity model. On the strength of this agreement it is then possible to predict some frequency sums for molecules which as yet have not been investigated spectroscopically and also disclose existing assignments which merit reinvestigation.

The relations derived (1) for the substituted ethylenes $C_2X_{4-n}Y_n$ are given in Table I. In making use of the sum rule* it is often required to estimate two

represent frequency sums used to evaluate the parameters. Comparison of the observed and calculated value for the sixth sum indicates agreement to within ± 50 cm.$^{-1}$. The average of the calculated values of the unobserved *trans* sum has an average deviation from the mean of 41 cm.$^{-1}$.

Since the potential energy function for the nine in-plane and three out-of-plane vibrations of a substituted ethylene may be separated, one might expect that the relations of Table I are valid both for the in-plane and for the out-of-plane frequency sums as well as for the total sums. This has already been verified for the chloroethylenes (2).

In Tables III and IV the calculated frequency sums for the in-plane and out-of-plane modes for the bromoethylenes are given, corresponding to the calculations shown in Table II for the total sums.

C_2Br_4	775[e]	—	—	—	729

All footnotes are the same as for Table II.

From Table III it is seen that the calculated sum for *trans* $C_2H_2Br_2$ is very nearly the same for all solutions and that the agreement for the sixth sum is quite good. Since all but one of the in-plane fundamentals are known (3) for *trans* $C_2H_2Br_2$ the unobserved fundamental may be estimated from the sum in Table III to be 149 ± 6 cm.$^{-1}$. Similarly the unobserved out-of-plane mode (3) for *trans* $C_2H_2Br_2$ may be estimated at 170 ± 50 cm.$^{-1}$. Applying the above method to the recent data (7) for the fluorochloroethylenes gives the results shown in Tables V and VI.

It is evident from Table I that the average of the frequency sums for *cis*, *trans*, and *asym* disubstituted ethylenes lies on a parabola passing through the sums for the other molecules when the frequency sum is plotted against the number of substituents n. Thus the X, Y, Z substituted ethylenes may be treated as the X, X, Z substituted methanes and the relations between their sums expressed in terms of the six parameters of Table III in Reference (1) and shown again for convenience in Tables VII and VIII. In Table VII the sums calculated with the least squares values of the parameters are compared with the observed sums for the chloro- and fluoro-ethylenes. In all cases the value for the disubstituted molecule is asterisked and is the average of the sums for the isomeric disubstituted molecules. The agreement between observed and calculated sums is rather good, being within ± 25 cm.$^{-1}$ for the in-plane modes and ± 10 cm.$^{-1}$ for the out-of-plane. The asterisked sum is only roughly

[k]*Same as i of Table VII.*

equal to the sum for each isomer so that observed sums for CF_2=CHCl are given for comparison to indicate only that no gross error in assignment has been made. This is the case also for $C_2H_2Br_2$ and $C_2H_2F_2$ given in Table VIII. In Table VIII the least squares values of the parameters were not obtained since there is only one equation for evaluating γ. However, the same values of P, β, and Δ_2 were used as for the molecules in Table VII and α and Δ_1 obtained from the observed sums for C_2HBr_3, C_2H_3Br, and C_2Br_4 by averaging the solutions from the three pairs of equations thus provided. The value for γ was then obtained from the observed sums for C_2F_3Br. The estimated error in the calculated sums for the bromofluoroethylenes is about ± 50 cm.$^{-1}$ for the in-plane sums and about ± 25 cm.$^{-1}$ for the out-of-plane sums.

Several ambiguities with regard to the assignments of some halogenated ethylenes can be resolved by comparison of the observed and calculated sums. Also several assignments which require reinvestigation are indicated. In C_2H_3Br the assignment (Ref. *b* in Table VII) for the out-of-plane modes is consistent with the sum rule whereas that given by Kohlrausch (4) and that given in Ref. *d* of Table VII are not. In C_2H_3F the assignment given in Ref. *d* of Table VII for the out-of-plane modes is not consistent with the sum rule. For C_2F_3Cl the assignment of Mann *et al.* (5) for the in-plane modes is con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

sistent with the sum rule. For C_2F_3Cl the assignment of Mann *et al.* (5) for the in-plane modes is consistent with the sum rule but that of Smith *et al.* (Ref. *f* of Table VII) is not. For C_2FCl_3 the assignments of Mann and Plyler (6) and Nielsen *et al.* (Ref. *f* of Table VII) for the in-plane modes are not consistent with the sum rule. All recent assignments for the fluorochloroethylenes of Mann and Plyler (7) are consistent with the sum rule.

As shown in Ref. (2) the theory predicts the following relationship between the frequency sum of the molecules and their deuterated analogues:

$$\sum\nu_{C_2H_{4-n}X_n} - \sum\nu_{C_2D_{4-n}X_n} = (1-n/4)\left\{\sum\nu_{C_2H_4} - \sum\nu_{C_2D_4}\right\}.$$

This equation is valid also for each of the isomeric disubstituted ethylenes. Using this equation for the in-plane and out-of-plane sums, the sums shown in Table IX have been calculated for some deuterated fluoro- and bromo-

ethylenes. The sums for C_2D_4 are given in Ref. *a* of Table II. The corresponding calculations for the frequency sum of the deuterated chloroethylenes have been given elsewhere (2).

Graphical Methods

If the frequency sums for two homologous series of substituted ethylenes are quadratic functions of the number of substituents, then there is a quadratic relationship between the frequency sums for the molecules of one series and those of the corresponding molecules of the other series (3). It has been discussed previously (3) under what conditions this relationship between the two sets of frequency sums becomes nearly linear, namely, if the ranges of frequency sums for both series are large and of the same order of magnitude and/or the deviation from linearity of the frequency sum as a function of the number of substituents is small. These conditions are fulfilled approximately for the chloro-, fluoro-, and bromo-ethylenes and the linear plots for the in-plane sums are shown in Fig. 1. To form the average of the sums of the isomeric disubstituted molecules the calculated sum for the molecule whose spectrum is unknown has been used (see Tables II to VIII). In Fig. 2 the corresponding

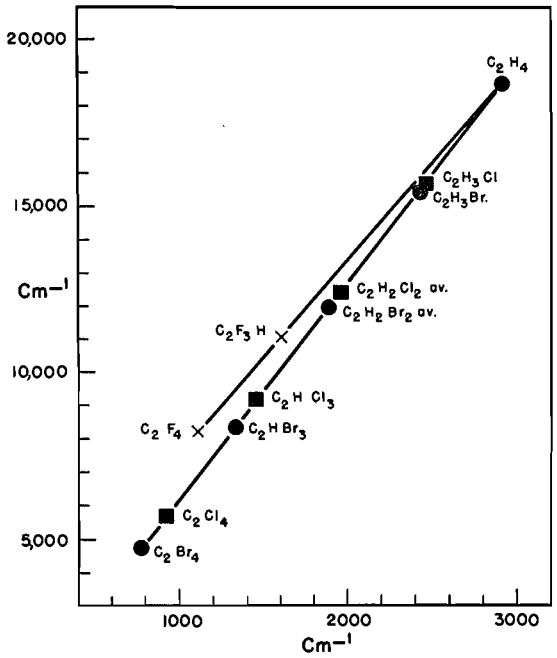

FIG. 3. The in-plane vs. out-of-plane sums for the fluoro-, chloro-, and bromo-ethylenes.

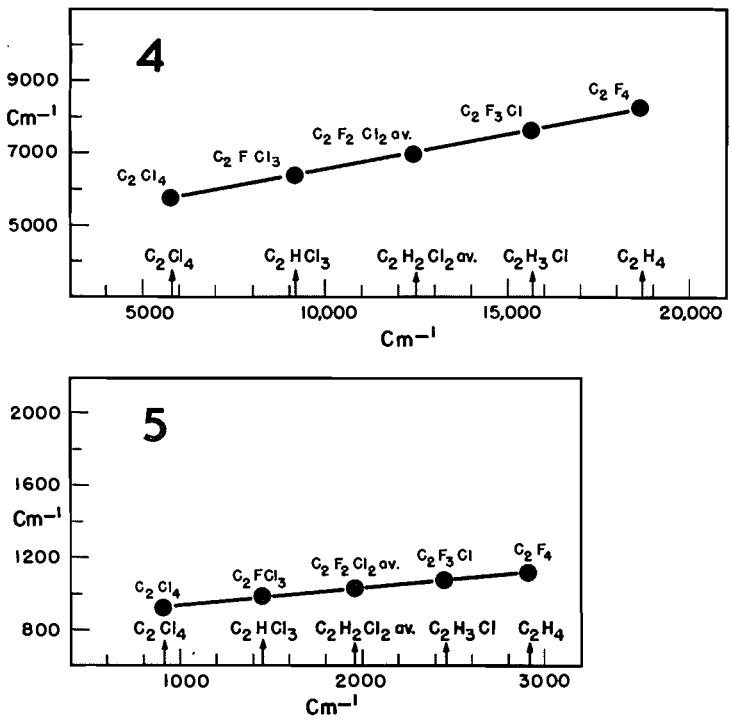

FIG. 4. The in-plane sums for the fluorochloroethylenes vs. the in-plane sums for the chloroethylenes.

FIG. 5. The out-of-plane sums for the fluorochloroethylenes vs. the out-of-plane sums for the chloroethylenes.

plots are given for the out-of-plane sums. It is apparent that a good internal check in the assignments for such a series is to plot the frequency sum for the in-plane modes against that for the out-of-plane modes. The resulting straight lines for the chloro-, bromo-, and fluoro-ethylenes are shown in Fig. 3. It is fortuitous that the points for the chloro- and bromo-ethylenes lie on the same straight line in Fig. 3. In Fig. 4 the in-plane sums for the fluorochloroethylenes are plotted against those for the chloroethylenes on the same scale and Fig. 5 shows the corresponding plot for the out-of-plane sums. The chlorofluoroethylenes and chlorobromoethylenes also fulfill approximately the conditions for obtaining linear plots so that the frequency sums for the chlorobromoethylenes may be estimated from the straight line given by the end members of the two series and reading off these sums from the values for the corresponding chlorofluoroethylenes. These estimates are given in Table X.

A SYSTEM OF MOLECULAR THERMOCHEMISTRY FOR ORGANIC GASES AND LIQUIDS[1]

By Keith J. Laidler

ABSTRACT

An analysis has been made of the heats of formation and combustion of organic gases and liquids, and of the heats of vaporization of liquids. The work has been done as far as possible with homologous series, in order to discover systematic effects. The data are converted into heats of atomization, i.e., the heats required to convert the gases or liquids into their constituent atoms. It is shown that the heats of atomization of the gaseous aliphatic hydrocarbons (paraffins, olefins, and acetylenes) can be accurately represented by a scheme in which a distinction is made between primary, secondary, and tertiary carbon–hydrogen bonds, and between bonds that are next to, and next but one to, multiple bonds. For aromatic molecules an appropriate correction for resonance is proposed. For other types of compound it is found that suitable values for the various bonds (e.g., C–CHO, C–OH) will give rise to good agreement with experiment.

It is shown that to a reliable approximation heats of vaporization are also amenable to the same treatment. Since this is so it is possible to assign bond values on the basis of which it is possible to make predictions about heats of formation of liquids.

A system of coefficients is worked out by means of which the numbers of atoms of various kinds in a molecule can be expressed in terms of the numbers of the different kinds of bonds. On the basis of these it is shown how bond contributions to heats of formation and heats of combustion can be calculated. A table (Table X) gives the contributions proposed for the heats of atomization, heats of formation, and heats of combustion for both gases and liquids.

INTRODUCTION

Various attempts have been made from time to time to devise systems that will enable reliable values of heats of formation and of heats of combustion to be deduced on the basis of chemical structure. Very approximate values can be calculated assuming strict bond additivity, using bond strengths such as those listed by Pauling (26) and by Syrkin (37); however such a procedure can lead to considerable errors in organic molecules of even only moderate complexity. Various schemes for the inclusion of terms for interactions (27) between bonds or between atoms have been proposed, notably those of Taylor, Pignocco, and Rossini (42), Tatevskii (38, 39, 40), and Bernstein (4). Of these workers Taylor, Pignocco, and Rossini did not specifically consider heats of formation, but Tatevskii showed that reliable predictions could be made for paraffins by recognizing three different types of carbon–hydrogen bonds and 10 different types of carbon–carbon bonds. Bernstein later showed that equally good agreement could be obtained with fewer types. In the present paper it is shown that satisfactory agreement for the lower paraffins is obtained by treating all carbon–carbon bonds as the same and recognizing three different types of carbon–hydrogen bonds. For olefins and acetylenes six additional types of bonds are required, and in most cases it is shown that the scheme is equivalent to, but much simpler than, a scheme of near-neighbor interactions.

The present paper is restricted to organic compounds containing carbon, hydrogen, oxygen, and nitrogen only, but the methods are readily extended to

other substances. Bond contributions are arrived at that will allow heats of atomization, formation, and combustion of gaseous and liquid substances to be estimated in a reasonably reliable manner. The procedures employed are necessarily empirical ones, but as far as possible an attempt has been made to provide some theoretical basis for the method; this has been done by taking the heats of atomization as the fundamental quantities to be analyzed. The method differs in this respect from certain others, such as the very useful one of Andersen, Beyes, and Watson (3, 19) in which the conventional heats of formation are the basic quantities employed.

Heats of Formation, Atomization, and Combustion

Thermochemical data are generally quoted in terms of heats of formation, Q_f, which are the heats liberated when one mole of the substance is produced from the elements in their standard states, viz., gaseous hydrogen, oxygen, and nitrogen, and carbon in the form of graphite. The data at 25°C. are considerably more extensive than those at any other temperature (including 0°K.), and in the present paper data at this temperature will always be used.

For the present purposes the most convenient procedure, and certainly the most fundamental, is to make use of heats of atomization, Q_a, instead of the heats of formation. By the heat of atomization (which will again always be referred to 25°C.) is meant the work required to dissociate one mole of the substance into its constituent atoms in their ground states. In the present paper heats of atomization have been calculated from heats of formation by making use of the following thermochemical relationships, which apply at 25°C.:

$$C_{graphite} = C_{gaseous}(^3P) - 171.7 \text{ kcal.},$$
$$\tfrac{1}{2}H_2 = H - 52.09 \text{ kcal.},$$
$$\tfrac{1}{2}O_2 = O - 59.16 \text{ kcal.},$$
$$\tfrac{1}{2}N_2 = N - 113.0 \text{ kcal.}$$

Of these values all except the last are taken from the National Bureau of Standards tables (46), which are the source of most of the thermochemical data employed here. The second and third values are well established on the basis of spectroscopic and other results, but the first and last have been the subject of considerable controversy and can still not be said to have been firmly established. On the whole, in the author's opinion, the evidence seems to point fairly strongly to the values quoted. The value given for graphite is consistent with the direct determination of the heat of sublimation of graphite by Brewer, Gilles, and Jenkins (8), and with some more recent work (10, 18). Springall (33) (see also Laidler and Casey (23)) has reviewed the evidence and favors this value. The nitrogen value given above was first proposed by Gaydon (14), and has been supported by much later work (13, 17, 21, 43).

On the basis of the above relationships it is easily seen that heats of atomization are related to heats of formation by the formula

$$[1] \qquad Q_a = Q_f + 171.7n_C + 52.09n_H + 59.16n_O + 113.0n_N$$

where n_C, n_H, n_O, and n_N are the numbers of carbon, hydrogen, oxygen, and

nitrogen atoms in the molecule. Heats of formation are frequently calculated from heats of combustion, Q_c, the two being related (for a compound containing only C, H, O, and N) by

[2] $$Q_f = -Q_c+94.05n_C+34.16n_H.$$

This formula assumes the combustion to give rise to carbon dioxide and nitrogen, and water in the liquid state. It is consistent with the thermochemical values given in the N. B. S. tables, namely

$$Q_c(\text{graphite}) = 94.05, \qquad Q_c(H_2\ \text{gas}) = 68.32.$$

The above two relationships give rise to

[3] $$Q_a = -Q_c+265.75n_C+86.25n_H+59.16n_O+113.0n_N.$$

The Bond Strength

The bond strength is a measure of the strength of the bond as it exists in the molecule, and its value is assigned in a purely empirical manner so that the sum of the various bond strengths in a molecule is equal to the heat of atomization. The present paper is concerned with the problem of assigning bond strengths in a self-consistent manner.

With diatomic molecules the bond strength is equal to the dissociation energy. In a polyatomic molecule containing only one type of bond, such as methane, there is again no difficulty; the bond strength is simply the heat of atomization divided by the number of bonds. For molecules containing more than one type of bond, on the other hand, the bond strengths cannot be defined with such precision. The procedure in such cases is to devise a scheme of classifying bonds that will give rise to a self-consistent scheme for all the molecules for which there are adequate data; a value is assigned to each type of bond in such a manner that the sum of the bond strengths is equal to the heat of atomization in every case. In the simplest schemes, such as those of Pauling (26) and Syrkin (37), all bonds connecting the same pair of atoms are considered to be the same. By taking into account all sorts of interactions it is apparent that very complicated schemes can be developed. From the most practical point of view it is evident that the most useful scheme is one that combines simplicity with accuracy. The system proposed in the present paper is a very simple one in that a differentiation between bonds connecting the same pair of atoms is only made in the case of carbon–hydrogen bonds, which are classified into different types which are readily recognized. In the present state of thermochemical data (which as far as homologous series are concerned are very incomplete except for the hydrocarbons) it is doubtful whether a more elaborate scheme would be justified or would give more satisfactory agreement with the data. As additional data accumulate, however, it will doubtless be advantageous to differentiate between bonds connecting other pairs of atoms; a scheme for doing this is in fact outlined below.

HEATS OF ATOMIZATION OF GASES

The N. B. S. tables (46) include values for heats of formation of a considerable number of paraffins, olefins, acetylenes, and aromatic compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

With other classes of compounds, however, such as alcohols and nitrates, data for only a few scattered compounds are generally available. A more complete analysis can obviously be made for the former groups of compounds, and the bond strengths derived from these will be the backbone of the present system. The homologous series will be considered first, after which some values will be derived for bonds such as C–OH and C–ONO_2. The latter values will be subject to revision as more reliable and complete data become available.

The Paraffins

The inadequacy of the simple additive scheme for the paraffins, with all C–H bonds considered as the same, is readily demonstrated. Thus the bond strength in CH_4 is 398.0/4 = 99.5 kcal., and the assumption that this remains the same in ethane gives a C–C strength of 79.1 kcal. These values lead to a heat of atomization for *n*-hexane of 1788.5 kcal., whereas the observed value is 1799.5 kcal. The errors become greater as the size of the molecule increases.

The simplest way to effect some improvement is to classify carbon–hydrogen bonds as primary, secondary, and tertiary bonds. A primary bond is one that involves a carbon atom in common with two other C–H bonds (i.e. that appears in the structure $-CH_3$); a secondary bond is one that has a carbon atom in common with only one other C–H bond (in $>CH_2$); a tertiary bond is one that is alone (in $\gtrless CH$). A clue to how to improve the systems of bond additivities is provided by comparing, from this point of view, the heats of atomization of isomers. Thus in neopentane, in which all the C–H bonds are primary bonds, the heat of atomization is appreciably greater than that in the normal and iso compounds, and this suggests that primary bonds are stronger than secondary and tertiary ones; a similar conclusion can be drawn from the results for the two butanes.

In the light of this conclusion it is possible to proceed in a more quantitative manner and to arrive at a scheme which represents the heats to a considerably better approximation than does the simple procedure. This improved scheme will be built up on the basis of the following assumptions:

1. The strength of the C–C bond is the same in all of the paraffins; it may be denoted by c_1.

2. The strengths of all primary C–H bonds are the same; the strength may be denoted by p. Similarly the secondary and tertiary bond strengths, s and t, are constants.

There are four quantities, c_1, p, s, and t, to be determined from the data, and four Q_a values are therefore required to determine them. The success of the method depends upon what choice is made, and after the trial of a number of possibilities it was found that the most satisfactory agreement was obtained by using the values for 2,2-dimethylbutane, 3-methylhexane, 2,2-dimethylpentane, and 2,3-dimethylpentane. The data for these compounds give rise to the following equations:

$$5c_1+12p+2s = 1803.9, \quad [4]$$

$$6c_1+9p+6s+t = 2081.3, \quad [5]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

[6] $$6c_1+12p+4s = 2084.6,$$

[7] $$6c_1+12p+2s+t = 2082.9.$$

The solution of these equations gives

$$c_1 = 85.40 \text{ kcal.}, \qquad s = 97.650 \text{ kcal.},$$

$$p = 98.467 \text{ kcal.}, \qquad t = 96.797 \text{ kcal.}$$

Calculated Q_a values derived on the basis of these figures are shown in the fourth column of Table I, and the agreement is seen to be very satisfactory,

the errors* being in no case higher than 0.05%. Methane is not included, the C–H bond strength in it, 99.5 kcal., being greater again than that of a primary C–H bond.

In addition to the agreement with the observed Q_a values, the c_1–p–s–t scheme obtained in this way shows a number of other satisfactory and interesting features, as follows.

1. *Regularity of Values*

In the first place, the values for C–H (methane), C–H (p), C–H (s), and C–H (t) diminish in a more or less regular manner. A similar type of decrease in dissociation energies has frequently been invoked to explain the fact that in hydrocarbon chemistry the reactivity of C–H bonds decreases in the order

$$\text{tertiary} > \text{secondary} > \text{primary}.$$

Rice (28), for example, found the relative rates of attack of alkyl radicals on

Greater errors are, however, found with the octanes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

primary, secondary, and tertiary hydrogen atoms to be 1:3:33 at 300°C. A similar conclusion has been reached from studies of the oxidation of hydrocarbons (48).

2. *Relationship with Heats of Dissociation*

The value obtained in the above manner for the C–C bond strength is consistent with that obtained by entirely independent methods for the *dissociation energy* of C–C bonds. Kistiakowsky and co-workers (1, 2, 22, 47) have shown that at 25°C. the heat of dissociation of methane into CH_3+H is ~102 kcal., and from this together with the thermochemical relationships

$$H_2 + C_2H_6 = 2CH_4 + 15.6 \text{ kcal.},$$

$$2H = H_2 + 104.2 \text{ kcal.},$$

it follows that

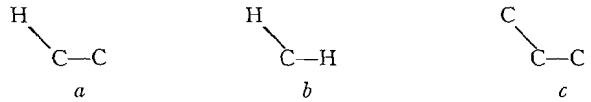
$$C_2H_6 = 2CH_3 - 84.4 \text{ kcal.}$$

This value, which is independent of the value for the heat of sublimation of carbon, is very close to the C–C bond strength obtained above ($c_1 = 85.40$). It is of interest that the c_1 value *is* dependent on the value assumed for the heat of sublimation of carbon; if the value of 125 kcal. were taken for this value, as proposed by some, c_1 would be 55.8 and therefore in considerable disagreement with the value for the heat of dissociation.

An interesting result is obtained when one derives from the present work a value for the heat of sublimation of diamond. Diamond can be considered to be an extended paraffin hydrocarbon, containing only C–C bonds, and the heat of sublimation of a mole should be the sum of the bond strengths for all of the bonds contained in a mole of carbon atoms. The number of bonds in a mole of diamond is twice the number of carbon atoms, so that the energy of sublimation should be $2\times85.40 = 170.8$ kcal. The experimental value is 171.2 kcal., in excellent agreement. No such agreement is obtained if bond strengths are calculated on the basis of other values for the heat of sublimation of graphite. Thus if the heats of atomization of all the paraffins had been calculated using the 125 kcal. value, the C–C bond strength (c_1) would have been 55.8 kcal. This leads to a heat of sublimation of diamond of $2\times55.8 = 111.6$ kcal., to be compared with the value for diamond of about 125 kcal. which must be assumed if the 125 value is taken for graphite.* This argument would appear to provide some evidence in favor of the 171 kcal. value.

3. *The Scheme of Near-neighbor Interactions*

It is now of interest to see how the scheme proposed is related to an alternative scheme that has some quantum-mechanical justification (9, 12), namely a scheme that takes into account interactions between bonds that spring from a common carbon atom. In the paraffins there are three different kinds of such interactions, and these may be denoted by *a*, *b*, and *c* as follows:

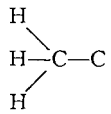


**The heat of sublimation of graphite is actually 0.45 kcal. greater than that of diamond.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

It would clearly be possible to attempt a scheme of bond strengths by assigning basic values g and h to the C–C and C–H bonds, respectively, and adding correction terms according to the numbers of interactions of the types a, b, and c. Such a scheme will be referred to as the g–h–a–b–c system.

Now it is readily seen that whenever there is a triplet of primary bonds, i.e. whenever the structure



exists, there are three interaction terms of type a, three of type b, and none of type c. Thus we have

$$3p = 3h+3a+3b. \quad [8]$$

In a similar manner it can be seen that

$$2s = 2h+4a+b+c \quad [9]$$

and

$$t = h+3a+3c. \quad [10]$$

These equations can be used to relate the c_1–s–p–t system to the g–h–a–b–c system. For example 3-methylpentane may be represented by either

$$5c_1+9p+4s+t$$

or

$$5g+14h+20a+11b+5c,$$

these alternative formulations being rendered equivalent by equations [8], [9], and [10].

It follows that there is no real difference between the two schemes, and that the c_1–s–p–t one is entirely consistent with the hypothesis that near-neighbor interactions are the only ones that need be considered. For practical purposes the c_1–s–p–t system is to be preferred, for various reasons. It is simpler to use, not only because it has one fewer parameter (four instead of five), but because it is easier to count bond types than bond interactions. Furthermore, if the g–h–a–b–c system is used one of the values must be assigned entirely arbitrarily. That this is so may be seen by inserting into eqs. [8], [9], and [10] the p, s, and t values obtained earlier, and attempting to solve for h, a, b, and c. Since there are three equations and four unknowns this cannot be done, but one can arrive at the solutions

$$c = -0.018,$$

$$2a-b = -1.616.$$

One may assign a purely arbitrary value to either a or b, after which it is possible to proceed. Suppose that b is arbitrarily given the value zero; it follows that

$$a = -0.808.$$

One finds that

$$h = 99.275.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

The conclusion is that a g–h–a–b–c scheme with the values

$$g = 85.40, \quad a = -0.808,$$
$$h = 99.275, \quad b = 0,$$
$$c = -0.018$$

(or indeed an infinite number of other schemes with a or b chosen arbitrarily) is equivalent to the c_1–p–s–t scheme proposed above, and will give exactly the same predictions for the heats of atomization of the paraffins.

The Olefins

The unsaturated hydrocarbons can be treated in a somewhat similar manner. After trials of various possibilities it has been found that the most satisfactory procedure for the olefins is to classify carbon–hydrogen bonds as follows:

(1) Bonds that are neither next to, nor next but one to, a double bond; these are considered to be ordinary primary, secondary, and tertiary bonds and to have the bond strengths calculated above for the paraffins.

(2) Bonds that are next but one to a double bond; these may be primary, secondary, or tertiary bonds, and their strengths are denoted as p', s', and t'.

(3) Bonds that are next to a double bond; these may be secondary or tertiary and their strengths will be denoted as s_2 and t_2. The carbon–carbon single bond strength (c_1) is assumed to be the same as previously determined; the carbon–carbon double-bond strength will be denoted as c_2.

In order to determine the additional bond strengths c_2, p', s', t', s_2, and t_2, the following heats of atomization were chosen:

(1) 3-Methyl-1-butene
$3c_1+c_2+6p+2s_2+t_2+t' = 1386.3$

(2) 2-Methyl-2-butene
$3c_1+c_2+t_2+9p' = 1389.6$

(3) 2-Methyl-1-butene
$3c_1+c_2+3p+2s_2+3p'+2s' = 1388.1$

(4) 4-Methyl-1-pentene
$4c_1+c_2+6p+t+2s_2+t_2+2s' = 1667.0$

(5) 2-Ethyl-1-butene
$4c_1+c_2+6p+2s_2+4s' = 1668.2$

(6) 3,3-Dimethyl-1-butene
$4c_1+c_2+9p+2s_2+t_2 = 1669.6$

With the values obtained earlier for c_1, p, s, and t, these equations give rise to the figures given in Table II. In Table III are shown calculated and observed values for a large number of olefins; the agreement is seen to be very satisfactory.

TABLE II

BOND STRENGTHS FOR C—C AND C—H BONDS

$c_1 = 85.40$	$p = 98.467$	$p' = 98.902$	
$c_2 = 145.275$	$s = 97.650$	$s' = 98.002$	$s_2 = 99.2575$
	$t = 96.797$	$t' = 97.483$	$t_2 = 98.007$

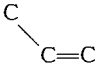
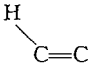
It may be seen that one source of minor error in the treatment arises from the neglect of forces between non-bonded atoms. That these forces are significant is illustrated by the differences in heats of atomization between *cis* and *trans* isomers; thus *cis*-2-pentene and *trans*-2-pentene, although having identical bond systems, have heats differing by 0.9 kcal. Generally the *trans* compound has the higher value, but the 3-methyl-2-pentenes (see Table III) constitute an exception.

Relationship to a Scheme of Interactions

It is now of interest to see how the scheme proposed is related to an interaction scheme. The double bond introduces the two following additional neighboring-bond interactions:

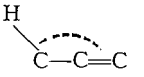


d



e

Since, moreover, bonds next but one to a double bond are found to be slightly different from *p*, *s*, and *t* bonds, it is clear that the interaction



f

is also involved. The following relationships are then obtained:

[11] $$t_2 = h+a+e+d,$$

[12] $$2s_2 = 2h+b+2e,$$

[13] $$3p' = 3h+3a+3b+3f,$$

[14] $$2s' = 2h+4a+b+c+2f,$$

[15] $$t' = h+3a+3c+f.$$

Insertion into eqs. [11] and [12] of the known values of t_2, s_2, h, a, and b gives rise to

$$d = -0.4425, \qquad e = -0.0175.$$

Insertion into eq. [13] of the values of p', h, a, and b gives rise to

$$f = 0.435.$$

A similar treatment of eqs. [14] and [15] gives values for f of 0.343 and 0.632. Equations [13], [14], and [15] are not exactly compatible, but are nearly so, and a slightly different set of values for p', s', and t' would lead to equal values of f. The scheme proposed is therefore very closely similar to (but is much simpler than) an interaction scheme of the type indicated.

It is of interest that whereas the interactions c, d, and e (and perhaps a and b also) are all negative, the f interaction is positive; this is of course related to the fact that C–H bonds are slightly strengthened by being next but one to double bonds.

The Acetylenes

Column 2 of Table IV lists heats of formation for a number of acetylenes, and these have been converted into heats of atomization in column 3.

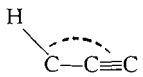
The best agreement was obtained by using the following values:

$$c_3 \text{ (the C}\equiv\text{C bond strength)} = 202.3 \text{ kcal.},$$

t_3 (the strength of a C–H bond adjacent to a triple bond) = 96.3 kcal.

The Q_a values calculated on this basis are shown in the fourth column. It was found that no advantage was gained by employing special values for C–H bonds next but one to the triple bond; the regular p, s, and t values are used for these.

This scheme is evidently equivalent to one of neighboring-bond interactions, the next-near-neighbor interaction



being taken to be zero. The interaction term corresponding to

$$\text{H—C}\equiv\text{C}$$

is $96.3 - 99.275 = -2.975$ kcal.

Aromatic Compounds

Observed heats of formation and of atomization of aromatic compounds are shown in Table V. In the fourth column are given heats of atomization

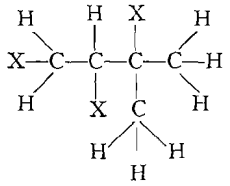
For personal use only.

calculated without regard to resonance energy, i.e., by treating the double bonds in the benzene ring as ordinary double bonds. The differences between the observed and calculated values are listed in the last column, and are seen to be quite constant. The average value of these differences is 42.2 kcal., and this can be taken to be the resonance energy, the value of which should be subtracted when it is desired to estimate the heats of atomization or formation of benzene derivatives.

Compounds Containing Specific Groups

It is now necessary to consider the situation when hydrogen atoms in the hydrocarbons are replaced by specific groups, such as aldehyde, alcohol, and nitrate groups. This type of compound cannot, in principle, be treated in as simple a manner as previously, and unfortunately a completely satisfactory system of bond energies cannot as yet be worked out. This is because there do not exist, in the case of compounds containing specific groups, data for a sufficient number of homologous compounds. It is, however, of interest to consider a general type of treatment that it will ultimately be possible to test using adequate data. Two situations may be considered; the one in which there is no more than one of the specific groups X on any carbon atom, and the one in which more than one group is present. The latter situation is more complex in that interactions of the type X—C—X must be considered.

1. When there is never more than one X on each carbon atom, as in the compound



it may be seen that as far as neighbor interactions are concerned all possible structural features of the compound are included in a scheme that recognizes three different types of C–X bonds:

(*a*) bonds in which X replaces a primary hydrogen atom; these may be designated x^p bonds;

(*b*) x^s bonds, in which a secondary hydrogen atom is replaced; and

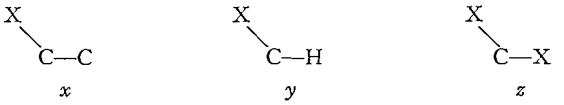
(*c*) x^t bonds, involving a tertiary hydrogen.

Since the values of c_1, p, s, t, etc., have been determined from the hydrocarbon data, it would be possible to evaluate x^p, x^s, and x^t from the data for those members of a homologous series of this type, and to test the system on additional members of the series. For an adequate test it would be desirable to have data for at least 10 compounds, and the data should be accurate to within 0.2 kcal. or so. Neither of these conditions can as yet be satisfied for any group X.

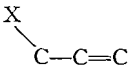
2. When more than one X can be on a carbon atom the simplest scheme taking into account neighbor interactions would be one in which they are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

treated explicitly. A theory of this type would proceed as follows. The additional interaction terms are



with more being necessary if there are double or triple bonds; in the former case it would probably be desirable to add terms for the next-near-neighbor interaction



The interaction terms a, b, c, d, and e have already been calculated from the hydrocarbon data, and results for these compounds containing C–X bonds would enable x, y, and z to be determined. Again this cannot as yet be done for lack of adequate data.

In view of the fact that data do not permit a treatment equivalent to that for the hydrocarbons the best that can at present be done is to treat all C–X bonds as equivalent, and be content with bond strengths that are an average of values showing some scatter. For most practical purposes this procedure is in fact adequate, since most compounds of interest contain only a few C–X bonds; the errors therefore do not tend to accumulate in the way they do with C–H bonds.

This procedure has been applied to a number of different groups, and the contributions of various groups to the energy of atomization have been evaluated. Since the data for substances other than the hydrocarbons are not very accurate or extensive the details will not be given here. A note on the sources of the thermochemical values is given in the Appendix, and the final group contributions are shown in Table VI. The procedure used in

TABLE VI

RECOMMENDED CONTRIBUTIONS FOR SPECIFIC GROUPS

Bond	Contribution to heat of atomization, kcal.
C—OH (alcohol)	198.1
C—O—C (ether)	172.0
C—CHO (aldehyde)	355.4
C—CO—C (ketone)	350.1
C—COOH (acid)	480.1
C—NH_2 (amine)	256.6
C—NO_2 (nitro)	285.2
C—ONO_2 (nitrate)	354.5

deciding the type of a C–H bond is to treat the substituent as if it were a carbon atom; in ethyl alcohol, for example, it is considered that there are three primary C–H bonds and two secondaries. An alternative procedure would be to consider all five to be primaries, since the molecule is derived from ethane, which has six primaries. The procedure employed seems to give a smaller spread of values.

There is a great need for additional work on series of homologous compounds, and the values given in Table VI will require revision as new data accumulate.

HEATS OF VAPORIZATION

The bond contributions arrived at in the previous section enable an estimate to be made of the heats of atomization of gases and, by an extension to be discussed later, of the heats of formation and combustion of gases. It is clearly of some practical importance to be able to extend this system to liquids and solids. In the present section a start has been made on this problem for the case of liquids; for solids a satisfactory solution will probably have to await further experimental results.

The procedure that has been adopted is to analyze data for heats of vaporization and to arrive at a scheme of bond energies of the same type as that used for heats of atomization. It is then a simple matter to combine the two systems and so obtain a scheme of bond energies for liquids; this is done in the section that follows.

It is actually found that heats of vaporization are not strictly additive in terms of bonds, and that for best agreement the presence of certain structural features (such as five–carbon structures of the neopentane type) should be taken into account. However the simple system of bond energies is, as will be seen, very satisfactory, and is certainly adequate for present purposes. Since heats of vaporization are relatively small compared with heats of atomization and combustion (and sometimes with heats of formation) a large percentage error in a heat of vaporization will lead to only small errors in the final estimated values.

Paraffins

Accurate values for a number of paraffins are given in the N. B. S. tables (46), and some of them are shown in the second column of figures in Table VII. Analysis of these values reveals the fact that it is possible to make

TABLE VII

CALCULATED AND OBSERVED HEATS OF VAPORIZATION FOR PARAFFINS

Paraffin	Heat of vaporization (kcal. per mole)		Difference (calc. − obs.)
	Obs.	Calc.	
n-Hexane	7.540	7.596	0.056
2-Methylpropane	4.570	4.967	0.397
2-Methylbutane	5.878	6.125	0.247
2-Methylpentane	7.138	7.186	0.048
2-Methylhexane	8.318	8.444	0.126
2-Methylheptane	9.483	9.602	0.119
2-Methyloctane	10.670	10.760	0.090
3-Ethylpentane	8.419	8.441	0.022
3-Ethylhexane	9.475	9.599	0.124
3-Ethylheptane	10.710	10.757	0.047

2,2-Dimethylbutane	6.617	7.080	0.363
2,2-Dimethylpentane	7.751	8.238	0.487
2,2-Dimethylhexane	8.912	9.396	0.484
2,2-Dimethylheptane	10.100	10.554	0.454

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

reasonable estimates of them using the following values for the contributions of the various bonds:

$$c_1 = 0 \text{ kcal.}, \qquad s = 0.579 \text{ kcal.},$$

$$p = 0.494 \text{ kcal.}, \qquad t = 0.518 \text{ kcal.}$$

Table VII shows calculated values and the differences between calculated and observed. The agreement is seen to be reasonably satisfactory in most cases, but is least so in hydrocarbons having the neopentane type of structure; such compounds have heats of vaporization that are significantly lower than the predicted ones, a fact that may be related to their high degree of symmetry. In estimating the values for compounds containing this structural feature it would be well to subtract a value of about 0.5.

The data for unsaturated hydrocarbons are unfortunately not adequate to allow a similar treatment to be applied to them.

Compounds Containing Specific Groups

Heat of vaporization data for compounds such as alcohols, ethers, and acids are not extensive and not of great accuracy. Application of the same type of treatment as the above, however, leads to the conclusion that to a useful approximation the values are additive. This is illustrated by the results shown in Table VIII for the nitrates; the data for these are fairly reliable (see Appendix). The details for other groups will not be given, but the thermochemical data employed are discussed in the Appendix and the final group contributions are summarized in Table IX.

TABLE VIII

HEATS OF VAPORIZATION OF NITRATES

Nitrate	Q_s (obs.)	C—ONO_2
CH_3ONO_2	8.2	6.72
$C_2H_5ONO_2$	8.7	6.06
CH_2ONO_2 | CH_2ONO_2	15.7	6.69
CH_2ONO_2 | $CHONO_2$ | CH_2ONO_2	21.7	6.29
		Av. 6.44

Improvement for all of these compounds could no doubt be achieved by employing a procedure such as that used by Wiener (50), who introduces parameters that take some account of the general shape of the molecule. However for present purposes it is more useful to have a system that is of the same type as that used for heats of atomization—i.e. involving only bond contributions. With such a system for heats of vaporization it is then possible,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

as will now be explained, to arrive at a scheme for making predictions of the thermochemical values for liquids.

TABLE IX

BOND CONTRIBUTIONS TO HEATS OF VAPORIZATION

Bonds	Contribution (kcal. per mole)
C—C	0
C—H (*p*)	0.494
C—H (*s*)	0.579
C—H (*t*)	0.518
C—OH	6.76
C—CHO	5.21*
C—CO—C	6.76
C—O—C	1.25
C—COOH	18.8*
C—ONO_2	6.44
C—NO_2	7.04

**Based on one heat of vaporization only; data from Ref. (35).*

TABLE X

BOND CONTRIBUTIONS FOR HEATS OF ATOMIZATION, FORMATION, AND COMBUSTION OF GASES AND LIQUIDS

Bond	Symbol	Heat of atomization		Heat of formation		Heat of combustion	
		Gas	Liquid	Gas	Liquid	Gas	Liquid
C—C	c_1	85.4	85.4	−0.45	−0.45	47.48	47.48
C=C	c_2	145.3	(145.3)	30.2	(30.2)	32.5	(32.5)
C≡C	c_3	202.3	(202.3)	−55.3	(−55.3)	196.3	(196.3)
C—H	p	98.47	98.96	3.45	3.95	54.22	53.73
C—H	s	97.65	98.23	2.64	3.21	55.04	54.46
C—H	t	96.80	97.32	1.78	2.30	55.89	55.37
C—H	p'	98.90	(99.40)	3.89	(4.38)	53.79	(53.29)
C—H	s'	98.00	(97.58)	2.99	(3.57)	54.69	(54.11)
C—H	t'	97.48	(98.00)	2.47	(2.99)	55.20	(54.69)
C—H	s_2	99.26	(99.84)	−10.07	(−9.49)	75.58	(75.00)
C—H	t_2	98.01	(98.53)	−25.62	(−24.11)	98.97	(98.45)
C—H	t_3	96.30	(96.82)	1.29	(1.80)	56.39	(55.87)
C—OH	a_{lc}	198.1	204.9	49.93	50.69	13.75	6.99
C—O—C	e	172.0	173.3	27.0	28.3	20.0	18.7
C—CHO	a_{ld}	355.4	360.6	29.5	34.7	122.2	117.0
C—CO—C	k	350.1	356.9	33.4	40.2	107.7	100.9
C—COOH	a_c	480.1	498.6	95.1	113.9	56.7	37.9
C—NH_2	a_m	256.6	—	−3.5	—	95.3	—
C—NO_2	n_i	285.2	292.2	11.0	18.0	12.6	5.5
C—ONO_2	n_a	354.5	361.0	21.1	27.5	2.4	−4.0
C—$NHNO_2$	n_{m1}	—	440.2	—	0.9	—	56.8
C>NNO_2 C	n_{m2}	—	421.3	—	−8.9	—	55.9

The values in brackets are based on the assumption that the contributions for the heats of vaporization of C—H are the same irrespective of the proximity of double and triple bonds.

HEATS OF FORMATION AND COMBUSTION OF GASES AND LIQUIDS

In the present section the results of the previous work will be consolidated and an outline will be given of a complete set of procedures for estimating heats of atomization, formation, and combustion of both gases and liquids.

Table X shows the final bond contributions that have been arrived at. The methods used in obtaining them will now be discussed.

Heats of Atomization

The first column of numbers in the table consists of the values obtained earlier. The second shows the corresponding values for liquids. Since both the heats of atomization and the heats of vaporization are given additively in terms of bond contributions it is necessary simply to add together the two contributions in order to obtain that for the heat of atomization of a liquid. For example, the value 361.0 for the nitrate group is the sum of 354.5, the gas contribution, and 6.5, that for the heat of vaporization.

Heats of Formation

The conventional heat of formation is related to the heat of atomization by eq. [1], which involves n_C, n_H, n_O, and n_N, the numbers of the various atoms in the molecule. In order to relate the contributions for heats of formation to those for heats of atomization it is necessary to relate n_C, n_H, n_O, and n_N to the numbers of the various bonds in the molecule.

The following example will illustrate the type of procedure that may be employed for doing this. Consider a molecule containing C_1 carbon–carbon single bonds, C_2 carbon–carbon double bonds, P primary (p) C–H bonds, S secondary (s) C–H bonds, S_2 bonds of type s_2 (next to a double bond), T_2 bonds of type t_2 (next to a double bond), S' bonds of type s', N_a nitrate groups, and A_{ld} aldehyde groups. According to the previous work (see column 1 of Table X) the heat of atomization of such a compound in the gas phase will be

$$[16]\quad Q_a = 85.4\ C_1+145.28\ C_2+98.47\ P+97.65\ S+99.26\ S_2 +98.00\ S' +354.5\ N_a+355.4\ A_{ld}.$$

If n_C, n_H, n_O, and n_N can be expressed in terms of C_1, C_2, P, etc., it will then be possible to express Q_f as a linear function of C_1, C_2, P, etc., with explicit coefficients that will be the relevant bond contributions for the various atoms and groups.

Consider first the number of carbon atoms, n_C, in the molecule under consideration. The presence of a primary C–H bond implies the existence of a carbon atom, but since the carbon atom is tetravalent the bond actually only has a one-fourth share in it;* for each primary C–H one must therefore count only a quarter of a carbon atom. The same argument applies to secondary (and tertiary) C–H bonds, and to bonds next but one to a double bond. We thus find that

$$[17]\quad n_C = \tfrac{1}{4}(P+S+S')+ \ldots .$$

**This is no longer true if the C—C bond is next to a double or triple bond; the correction required for this is considered later.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

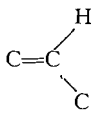
Each C–C single bond has a fourth share in two carbon atoms, so that

[18] $$n_C = \tfrac{1}{4}(P+S+S')+\tfrac{1}{2}C_1+ \ldots .$$

Each C–ONO_2 bond has a fourth share in a carbon atom, while each aldehyde group has a fourth share in one carbon atom and a full share in another; thus

[19] $$n_C = \tfrac{1}{4}(P+S+S')+\tfrac{1}{2}C_1+\tfrac{1}{4}N_a+\tfrac{5}{4}A_{1d}+ \ldots .$$

A slight complication arises from the presence of double (and triple) bonds. Each C=C double bond has one-third share in two carbon atoms, so that the contribution is $\frac{2}{3}C_2$ (for a triple bond it is C_3). An S_2 bond has one-third share in a carbon atom, so that the contribution is $\frac{1}{3}S_2$. Similarly a t_2 bond has a one-third share in a carbon atom, so that a contribution of $\frac{1}{3}T_2$ is indicated. However this result neglects one factor. The existence of a t_2 bond implies the structure*



and this means that an error has been made in treating the C–C single bond, since one end of this is a carbon atom that is only attached to three different atoms. The contribution at one end of the carbon atom is therefore $\frac{1}{3}$ rather than $\frac{1}{4}$, and the estimated number of carbon atoms is therefore too low by $\frac{1}{3}-\frac{1}{4} = \frac{1}{12}$ for every time this structure appears. The easiest way to make the correction is to add a term $\frac{1}{12}T_2$. The final expression for the number of carbon atoms in the molecule is therefore

[20] $$n_c = \tfrac{1}{4}(P+S+S')+\tfrac{1}{2}C_1+\tfrac{2}{3}C_2+\tfrac{1}{3}S_2+(\tfrac{1}{3}+\tfrac{1}{12})T_2+\tfrac{1}{4}N_a+\tfrac{5}{4}A_{1d}.$$

Proceeding in a similar manner for the various bonds it is possible to arrive at the coefficients shown in the first column of Table XI. The procedure for the remaining bonds is straightforward except when triple bonds are present. Here again the contributions from C–C single bonds will be wrongly counted unless a correction is made. The number of times the structure

C—C≡C

appears in a molecule is $2C_3-T_3$, and every time it appears the number of carbon atoms is in error by $\frac{1}{4}$; the term $\frac{1}{4}(2C_3-T_3)$ must therefore be added. The expression for n_C for a molecule containing triple bonds therefore contains the terms

[21] $$n_C = C_3+\tfrac{1}{2}T_3+\tfrac{1}{4}(2C_3-T_3)+ \ldots .$$

The second column of figures in Table XI shows the corresponding coefficients in the expression for n_H, while the third and fourth are for n_O and n_N. These are obtained in a similar way to the coefficients for n_C.

A special treatment is required if one of the substituent groups is next to the double bond. There are, however, few data for this type of compound.

TABLE XI

MATRIX OF COEFFICIENTS WHICH RELATE n_C, n_H, n_O, AND n_N TO THE NUMBERS OF BONDS

Bond	n_C	n_H	n_O	n_N
C_1	$\frac{1}{2}$	0	0	0
C_2	$\frac{2}{3}$	0	0	0
C_3	2	0	0	0
P	$\frac{1}{4}$	1	0	0
S	$\frac{1}{4}$	1	0	0
T	$\frac{1}{4}$	1	0	0
P'	$\frac{1}{4}$	1	0	0
S'	$\frac{1}{4}$	1	0	0
T'	$\frac{1}{4}$	1	0	0
S_2	$\frac{1}{3}$	1	0	0
T_2	$\frac{5}{12}$	1	0	0
T_3	$\frac{1}{4}$	1	0	0
A_{1c}	$\frac{1}{4}$	1	1	0
E	$\frac{1}{2}$	0	1	0
A_{1d}	$\frac{5}{4}$	1	1	0
K	$\frac{3}{2}$	0	1	0
A_c	$\frac{5}{4}$	1	2	0
A_m	$\frac{1}{4}$	2	0	1
N_i	$\frac{1}{4}$	0	2	1
N_a	$\frac{1}{4}$	0	3	1
N_{m1}	$\frac{1}{4}$	1	2	2
N_{m2}	$\frac{1}{2}$	0	2	2

In order to obtain the bond contribution to the heat of formation one proceeds as follows. The expression for Q_f contains a number of terms, that for the nitrate group, for example, being as follows:

$$[22] \quad Q_f = Q_a - 171.7\ n_C - 52.09\ n_H - 59.16\ n_O + 113.0\ n_N$$

$$[23] \quad = 354.5\ N_a + \ldots - 171.7\ (\tfrac{1}{4}N_a + \ldots) - 52.09(0 + \ldots) - 59.16(3N_a + \ldots) - 113.0(N_a + \ldots)$$

$$[24] \quad = 21.10\ N_a + \ldots .$$

The entry in the third column of numbers in Table X for the nitrate group is therefore 21.10. The remaining figures are obtained in a similar way.

The values for the liquid state are obtained in the same manner as for the heats of atomization, making use of the heat of vaporization contributions.

Heats of Combustion

The heat of combustion is related to the heat of formation by eq. [2]. The bond contributions to the heats of combustion can therefore be calculated from those for the heats of formation by making use of the appropriate coefficients in Table XI, the procedure being similar to the above. The heat of vaporization contributions must now be *subtracted* from the gas values to obtain those for the liquids.

The resulting contributions are shown in the last two columns of Table X.

SOME EXAMPLES

In order to illustrate the method, and to give some indication of its reliability, typical calculations will now be carried out.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

Ethyl Nitrate

The calculation of the heat of combustion of liquid ethyl nitrate is as follows:

$$\begin{aligned} 1 \times c_l &= 47.48 \\ 3 \times p &= 161.19 \\ 2 \times s &= 108.92 \\ 1 \times n_a &= -4.0 \end{aligned}$$

$$Q_c = 313.59 \text{ kcal.}$$

The observed value, derived from Berthelot's heat of esterification of ethyl nitrate and from Gray's treatment of Wheeler, Whittaker, and Pike's explosion data, is 313.2 kcal.

The heat of formation calculation is, for the liquid:

$$\begin{aligned} 1 \times c_l &= -0.45 \\ 3 \times p &= 11.85 \\ 2 \times s &= 6.42 \\ 1 \times n_a &= 27.5 \end{aligned}$$

$$Q_f = 45.32 \text{ kcal.}$$

The observed value, based on the data referred to above, is 45.7 kcal.

Diethyl Nitramine

The heat of combustion of liquid diethyl nitramine is calculated as follows:

$$\begin{aligned} 2 \times c_l &= 94.96 \\ 6 \times p &= 322.38 \\ 4 \times s &= 217.84 \\ 1 \times n_{m2} &= 55.9 \end{aligned}$$

$$Q_c = 691.08 \text{ kcal.}$$

The observed value is 692.2 ± 0.9 kcal.

ACKNOWLEDGMENTS

The author is grateful to Dr. Peter Gray and Mr. Harold Hurwitz for discussions relative to the thermochemistry of the nitrates, and to Dr. Theodore Austin for work on the heats of vaporization. He is also indebted to Miss Susan Pyatt and Mrs. O. Kracek for help with the computations and for valuable suggestions.

APPENDIX. SOURCES OF THERMOCHEMICAL DATA

Hydrocarbons

Q_f and Q_v data were obtained in all cases from the N. B. S. tables (46).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

Alcohols

Q_f values for *n*-alcohols up to C_{10} from Rossini (31); other values quoted by Bischowsky and Rossini (6) and by Roberts and Skinner (30).

Q_v values from Landolt-Börnstein (24).

Ethers

Q_f values from Bischowsky and Rossini (6), Kharasch (20), and Stohmann (34). Q_v values calculated from vapor pressure data of Stull (35).

Aldehydes

Q_f values for formaldehyde and acetaldehyde only (46). Q_v values calculated from vapor pressure data of Stull (35).

Ketones

Roberts and Skinner (30) quote Q_f values for CH_3COCH_3, $C_2H_5COCH_3$, *n*-$C_3H_7COCH_3$, and *sec*-$C_3H_7COCH_3$. Q_v values for the first three were calculated from Stull's vapor pressure data (35); Q_f(gas) for the last was obtained using an estimated Q_v. The four Q_f values employed were 51.8, 58.2, 65.1, and 66.8 kcal., respectively.

Acids

Q_f values for HCOOH, CH_3COOH, $CH_2ClCOOH$, and $CHCl_2COOH$ are given by Bischowsky and Rossini (6). A C–Cl value of 80.5 was assumed. Q_v's calculated from Stull's data (35).

Amines

Reliable Q_f data appear to be available only for methylamine and ethylamine (46). No reliable Q_v values.

Nitro Compounds

Thermochemical data for nitro compounds are not of high reliability. Some Q_f values for liquids are given in the Landolt-Börnstein tables (24) and were converted into gaseous values using either experimental heats of vaporization (6) or values estimated using the methods of this paper. Bischowsky and Rossini (6) give Q_v values for nitromethane and nitroethane.

Nitrates

Some of the data for the nitrates are contradictory; discussion of the individual compounds is therefore necessary.

Methyl Nitrate

The value of 29.0 kcal. for Q_f(gas) is based upon a value of Q_f(liquid) = 37.2 kcal. calculated by Gray and Smith (16) from heat of explosion data of Wheeler, Whittaker, and Pike (49), and a heat of vaporization of 8.2 kcal. calculated from vapor pressure measurements of McKinley-McKee and Moelwyn-Hughes (25).

Other sources of data are as follows. Swientoslawski (36) quotes Berthelot as having obtained Q_c(gas) = 166.2, presumably on the basis of the heat of esterification. Using modern thermochemical data this leads to Q_f(liquid) = 39.1. In view of the uncertain origin of this value, however, that of Gray seems

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

preferable. An alternative determination of Q_v is due to Thompson and Purkis (44), whose results lead to 7.8 kcal. On the whole the McKinley-McKee and Moelwyn-Hughes value seems more reliable; the vapor pressures were measured over a wider temperature range, and the results were fitted to the Antoine equation (Thompson and Purkis report their results only as the equation of a straight line on a log p vs. $1/T$ graph).

Ethyl Nitrate

A value for Q_f(liquid) of 45.7 was calculated by Gray (15) from Wheeler, Whittaker, and Pike's heat of explosion data (49), and the same value is obtained by applying modern auxiliary data to Berthelot's heat of esterification value (5). Thomsen (45) obtained different results by measuring Q_c directly, but the error in this type of investigation is intrinsically greater than in heat of esterification measurements. In view of this, and of the agreement between Berthelot and Gray, their value seems preferable (16*a*).

The vapor pressure of ethyl nitrate was measured by Goodeve (14*a*) over a range of temperature, and a reanalysis of her data leads to a value of $Q_v = 8.7$ at 25°C.

These values lead to Q_f(gas) = 37.0.

Glycol Dinitrate

Rinkenbach (29) and Schmidt (32) give Q_c(liquid) values that both lead to Q_f(liquid) = 58.2. A value of $Q_v = 15.7$ comes from vapor pressure results of Brandner (7); when fitted to the Antoine equation they lead to 15.7 at 25°C. Crater (11) carried out a similar study, but his data lead to a higher Q_v. For various reasons Brandner's results seem more reliable.

Nitroglycerine

A Q_f(liquid) value of 89.0 is calculated from Taylor and Hall's value (41) of 364 for Q_c(liquid). A variety of earlier values have been given in the literature, and Taylor and Hall list objections to these, based mainly on defects in experimental procedures or on absence of information.

THE FORMATION OF SUPERCOOLED LIQUID SOLUTIONS IN SIMPLE-EUTECTIC TYPE ORGANIC SYSTEMS BY THE SUBLIMATION OF SOLID MIXTURES[1]

By Ralph H. Petrucci[2] and C. H. Sorum[3]

ABSTRACT

A process is described for the formation of supercooled liquid solutions by the sublimation of solid mixtures—the liquids formed being supercooled in the sense that they can be condensed from the vapor phase above solid mixtures at temperatures below the eutectic values. The process can be thought of as proceeding, solids → mixed vapor → supercooled liquid solutions. The general nature of this phenomenon in organic systems of the simple-eutectic type is established as a result of the microscopic and macroscopic experiments performed in this investigation. A $P/T/c$ space-model of a typical binary, eutectic-type, organic system, *o*-nitrophenol–naphthalene, is presented. A physical picture of the process under consideration is made possible on the basis of this model.

INTRODUCTION

In an earlier contribution from this laboratory, Sorum and Durand (4) reported the fact that individual crystals, maintained out of physical contact, could melt at temperatures just slightly above their eutectic temperature as a result of the condensation of the vapor phase above them. Forty-five organic, binary, eutectic-type systems were studied at that time and this phenomenon was observed in every case.

In the present work it was noted that condensation to liquids occurred even when solids were maintained at temperatures below their eutectics. In order that liquids might condense it was necessary to have the collecting surfaces at temperatures below those of the solids; the entire systems therefore were at temperatures below the eutectic values. The liquids formed under these conditions were supercooled solutions of the two components; the evidence of supercooling was the fact that these liquids persisted at temperatures below the eutectics. The present paper is concerned with some of the factors involved in the formation of supercooled liquids by this process.

EXPERIMENTAL

A. Materials

All the chemicals used in this investigation were organic compounds of relatively low melting points and high vapor pressures (*ca.* 10^{-4} to 10^{-1} mm.). The compounds were recrystallized twice from suitable solvents, dried for one to two days over appropriate desiccants in a vacuum desiccator, and then further dried at elevated temperatures and reduced pressures in an Abderhalden Drying Apparatus. The melting points and melting point ranges of the final products were used as criteria of purity.

B. Apparatus for Microscopic Experiments

A Bausch and Lomb crystallographic microscope, equipped with 8 and 16 mm. objectives and 7.5 and 10× eyepieces, was used for all the microscopic work. Heating and thermostating of samples were accomplished by the use of a water-heated microscope hot-stage fabricated from aluminum metal. A small water bath equipped with heaters, cooling coils, bimetallic thermoregulator, and circulating pump served as a source of water. The stage could be thermostated with a precision of a few tenths °C. By continuously varying the temperature of the external bath, heating and cooling rates from 0.1° to 1.0°C. per minute could be established. Accurately calibrated mercury-in-glass thermometers inserted through a re-entrant thermometer well were used for making temperature measurements in the stage. A set of inserts fitting into the central light orifice made the stage adaptable for all of the various microscopic measurements—melting points, eutectic temperatures, refractive indices, sublimation temperatures, etc.

C. Macroscopic Sublimation Apparatus

Macroscopic studies on the condensation of liquid sublimate from the vapor phase above solid mixtures were carried out in an all-glass sublimation apparatus. The essential features of this apparatus were sublimation wells to hold the solid samples and "cold-thumb" condensers (maintained at a short distance above the solids) upon which sublimate could condense.

Macroscopic sublimation studies were performed on the system *o*-nitrophenol–naphthalene. Solid mechanical mixtures of the two components were placed in the sublimation wells of the sublimation apparatus and thermostated at one temperature. By maintaining the "cold-thumb" condensers of the apparatus at some lower temperature, liquid condensates were collected on the condensers. Collection of the condensates was allowed to continue for a few days and when sufficient amounts of liquid had deposited (*ca.* 0.01–0.05 ml.) these liquids were analyzed by a microscopic refractometric method.

D. Determination of Eutectic Temperatures

The eutectic temperature for a multicomponent system is the equilibrium temperature at which all the phases, solid, liquid, and vapor, are present in bulk. In practice to initiate and maintain a finite rate of freezing the temperature of a system must be somewhat below the eutectic temperature. To initiate and maintain melting the temperature must be slightly above the eutectic. The true eutectic temperature is somewhere between these upper and lower limits. For the purposes of this paper the melting temperature has been taken as essentially equal to the equilibrium temperature.

Two microscopic methods were used in establishing eutectic temperatures. One was the "contact-method" developed by the Koflers (2). The second method simply involved crystallizing liquid samples between 12- and 25-mm. microscope cover glasses and then observing the lowest temperature at which fusion occurred when these samples were slowly reheated. In contrast to the "contact-method" where eutectic fusion occurred only in a limited "zone-of-mixing" of the components, with the "fusion-preparations" eutectic fusion

could take place anywhere in the crystalline area. The latter method proved to be particularly applicable to studies on ternary and quaternary systems where "zones-of-mixing" of all the components were difficult to establish.

E. Refractive Index Measurements

Mixtures of *o*-nitrophenol and naphthalene were analyzed by determining the refractive indices of solutions of the two components. A series of "working-curves" was established, giving the temperatures at which mixtures of fixed composition had specified refractive indices. Compositions of unknown mixtures were obtained by referring to these standard curves. This method is described in detail by the Koflers (2). Refractive index curves for the system *o*-nitrophenol–naphthalene are presented in Fig. 1.

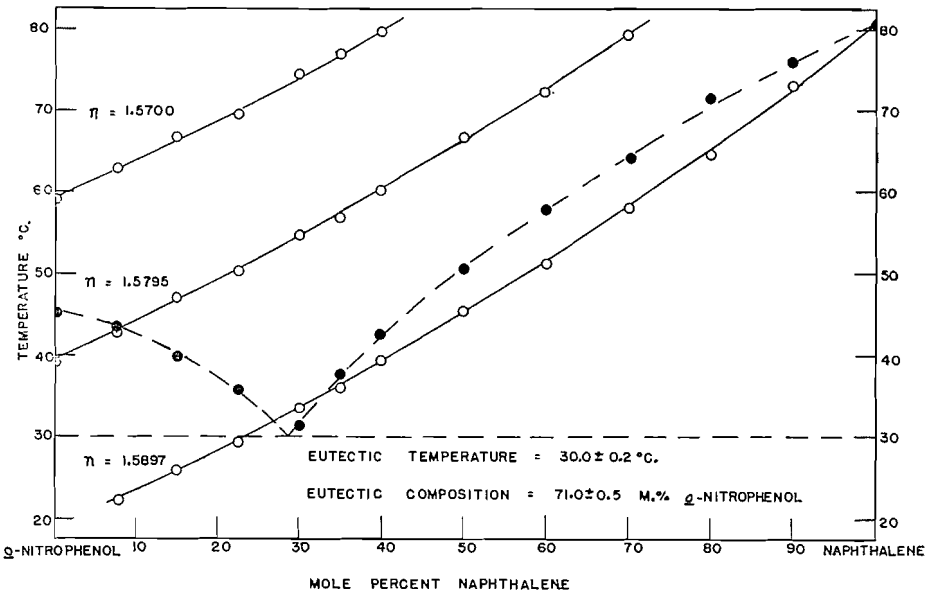

FIG. 1. Equilibrium diagram (closed circles) and refractive index curves (open circles) for the system *o*-nitrophenol–naphthalene.

STUDIES ON THE SYSTEM *o*-NITROPHENOL–NAPHTHALENE

A. Determination of the Equilibrium Diagram

The equilibrium diagram for the system, *o*-nitrophenol–naphthalene, was determined by a combination of macroscopic and microscopic methods. The macroscopic method used was essentially the "thaw-point" method of Rheinboldt (3). In this procedure synthetic solid mixtures are prepared and the melting of such samples followed in a conventional capillary melting-point type of apparatus. The pertinent data are the "beginning melting point" and the "end melting point". In this system the "beginning melting point" for every sample was the eutectic temperature. The "end melting point" corresponded to the primary crystallization temperature in a cooling curve study on a binary system. The synthetic mixtures required were obtained by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

melting together weighed amounts of the two components sufficient to give a solution of a few milliliters volume. These solutions were then crystallized and carefully pulverized in a cold mortar. The resulting solid mixtures were used for the melting point determinations. Microscopic melting points were also determined on samples prepared in this same manner.

The equilibrium diagram for the system, *o*-nitrophenol–naphthalene, based on macroscopic melting points is presented in Fig. 1. Equilibrium relationships are shown by dashed lines. Refractive index curves for the system, plotted on the same temperature and composition scales, are given as solid lines.

B. Subeutectic Region of the P/T/c Space-model

The space-model (see Fig. 2) for this system was calculated principally from literature data, although two items of experimental information from this investigation, the eutectic temperature and eutectic composition, were also required. In Fig. 2 the curve *LK* is the vapor pressure curve for pure solid naphthalene and *JI* the vapor pressure curve for pure solid *o*-nitrophenol. The curves *HN* and *GM* define the sum of the vapor pressures of the two

solids as a function of temperature. The surface *GMNH* is a ruled surface generated by an infinite collection of isobaric, isothermal tie lines. The mole ratio of the two components in the vapor phase above solid mixtures at any temperature is equal to the ratio of the vapor pressures of the pure solids at that temperature, if the vapors are assumed ideal. Variation of vapor composition with temperature is given by the curve *FS*.

Because no vapor pressure data for solid *o*-nitrophenol could be found in the literature and because the existing vapor pressure data for solid naphthalene were not altogether consistent, vapor pressure values for the solid components were calculated from a knowledge of liquid vapor pressures. Liquid vapor pressures were obtained from Stull's compilation (5). The heat of vaporization of each pure liquid was calculated from a conventional log p vs. $1/T$ plot. Heats of fusion of the two solids were available in the literature (1). The sum of the heat of vaporization and the heat of fusion for each component at its triple point was taken as the heat of sublimation for that component. By extrapolating the liquid vapor pressure data to temperatures below the melting points of the respective components, a value of the vapor pressure for each supercooled liquid at the eutectic temperature was obtained. An assumption was then made that Raoult's law was obeyed by the eutectic liquid, and from this law a value for the vapor pressure was derived for each pure solid at 30°C. Substituting these vapor pressures and the previously derived heats of sublimation into the Clausius–Clapeyron equation, a vapor pressure equation for each solid component was established. The vapor pressure equations employed were: for solid *o*-nitrophenol, $\log p(\text{mm.}) = -3634/T+11.32$ (*a*) and for solid naphthalene, $\log p(\text{mm.}) = -3516/T+10.71$ (*b*).

The variation of vapor pressure with temperature for supercooled liquid naphthalene is shown in Fig. 2 by the curve *CD*. *AB* is the vapor pressure curve for supercooled liquid *o*-nitrophenol. The supercooled liquid–vapor equilibrium surface was obtained by again assuming the validity of Raoult's law for solutions of *o*-nitrophenol and naphthalene.

C. Discussion

The process by which vapors generated above solid mixtures condense to yield supercooled liquid solutions can be illustrated with reference to the space-model. If we consider a simple experiment in which a mixture of the solids *o*-nitrophenol and naphthalene is held at one temperature in a sublimation well of the sublimation apparatus and a "cold-thumb" condenser at some lower temperature, the following phenomena can occur: First of all the mixed vapor arising from the solids at the higher temperature can simply condense to give a mixture of solids. It is also possible, however, for the vapor, as it is cooled, to pass from the solid–vapor surface without condensing into solids. If this vapor is cooled to a sufficient extent, the point in space representing the variables of state of the vapor phase will strike the vaporous surface of the supercooled liquid–vapor loop and at this point a liquid can condense. With reference to Fig. 2 these steps are represented by the points *a*, *b*, and *c*. A solid mixture vaporized at the temperature of point *a* yields a vapor phase whose composition is also fixed by point *a*. (The point *a* lies on the dashed line

FS.) This vapor then cools in some fashion (pressure may decrease in this cooling process because of the existence of a temperature gradient between condenser and solids) until its representative point in space strikes the vaporous surface of the supercooled liquid–vapor loop at point *b*. At this point vapor may condense yielding a liquid condensate of composition *c*.

If such an experiment is performed where the solid mixture is held at the eutectic temperature and the condenser at a temperature only very slightly below this, then the model shows that eutectic vapor, *F*, will condense to give essentially the eutectic liquid, *E*.

The model of Fig. 2 is strictly applicable only to systems where *o*-nitrophenol and naphthalene are the sole substances present. However as the effect of external pressure on equilibrium between condensed phases is usually quite small, the exertion of an additional atmosphere of pressure on these solids would leave their vapor pressures essentially unchanged. This means that the vapor composition and total vapor pressure above a solid mixture in a system open to the atmosphere should be practically identical to the corresponding quantities in a closed system with air excluded. In all the experimental work solid mixtures were maintained at atmospheric pressure. Preliminary experiments were performed which showed that the composition of the liquid collected in the process, solids → mixed vapor → supercooled liquid solutions, was unaffected by external pressure in the range from *ca.* 1 to 760 mm.

Other preliminary experiments were conducted to test the effect of the composition of the solid mixtures on the composition of the supercooled solutions condensed from the vapor phase. As might be expected for a system of the simple-eutectic type, a type of system characterized by complete immiscibility of the solid components, the compositions of the liquid condensates were independent of the compositions of the solid mixtures from which they were ultimately derived.

Studies on the effect of the temperature variable consisted in thermostating the condensers of the sublimation apparatus at a particular set of temperatures and then determining, to within a few tenths of a degree, the temperatures to which solid mixtures had to be heated in order for the first liquid sublimate to form on the condensers. A period of a few hours was allowed at each temperature before a higher temperature was tried. The results of these studies are tabulated in Table I.

TABLE I

LIQUID SUBLIMATE FORMATION AS A FUNCTION OF TEMPERATURE IN THE SYSTEM *o*-NITROPHENOL–NAPHTHALENE

Temperature of solid mixture, °C.	Temperature of condenser, °C.	Composition of the liquid sublimate, mole % *o*-np
29.0	28.4	71.0
28.5	27.5	71.0
27.0	25.5	71.0
25.5	23.5	71.5
24.0	21.5	72.5
23.0	19.5	73

Eutectic composition for this system: 71.0 mole % o-nitrophenol. Precision of the analyses: 0.5–1 mole % o-nitrophenol.

The first feature that can be brought out from Table I is arrived at by comparing the first and second columns in that table. It is seen that at the higher solid temperatures only small temperature differences had to be maintained between the sublimation wells and condensers in order for liquid sublimate to form. At lower temperatures the required temperature differences became progressively greater. These temperature differences, considered as a function of temperature, indicate the manner in which the two surfaces, solid–vapor and liquid–vapor, are oriented with respect to each other in the composition region along the dashed line *FS* of Fig. 2.

The variation of the composition of liquid sublimate with the temperatures of generation and condensation of mixed vapors is seen in the third column of Table I. It is noted that at higher temperatures eutectic liquid was formed and that at lower temperatures a trend was established in the direction of somewhat higher concentrations of *o*-nitrophenol in the liquid sublimate. Though the difference in composition of the liquid at the highest and lowest temperatures was slight, it was still felt to be outside the range of experimental error.

Calculations stemming from equations (*a*) and (*b*) indicate that at the eutectic temperature the composition of the vapor in equilibrium with solid *o*-nitrophenol and naphthalene should be about 60 M.% *o*-nitrophenol and should increase to about 62–63 M.% *o*-nitrophenol at temperatures of 5° or 10°C. Constant-temperature cross-sections of the space-model for the temperature range from 30° to 10°C. were constructed and from these cross-sections the compositions of the liquid in equilibrium with a vapor containing 60 M.% *o*-nitrophenol were estimated. For example, the estimated liquid composition at 30°C. was 71 M.% *o*-nitrophenol; at 10°C., 74 M.% *o*-nitrophenol.

From these considerations we can see that even if vapor composition in this system did not change with temperature, we should expect a slight change in liquid composition, increasing percentages of *o*-nitrophenol in the liquid at the lower temperatures. Add to this effect the possibility of a slight enrichment of the vapor phase in *o*-nitrophenol content at lower temperatures and it is all the more to be expected that some change in liquid composition should occur with decreasing temperature of liquid formation.

MICROSCOPIC STUDIES

In order to investigate a large number of systems and thus to prove the general nature of the phenomenon, solids → mixed vapor → supercooled liquid solution, rapid semiquantitative microscopic methods were employed. The microscopic studies served to show that supercooled liquids could be condensed from the vapor phase in a number of systems of the unary, binary, ternary, and quaternary types.

In the microscopic sublimation studies mixtures containing approximately equal weights of all the components of a system of a given type were first prepared. Samples of these mixtures were placed on a 12-mm. cover glass maintained at one level in the sublimation chamber insert of the microscopic hot-stage. At a level about 3 to 4 mm. above the solids a 25-mm. cover glass was supported. The stage was heated at a rate of 0.2°C. per minute and the

lower surface of the upper cover glass was observed microscopically during the heating process. The lowest temperature at which a microscopically visible liquid deposit appeared was recorded; this temperature was called the liquid sublimation temperature. Also for each system a number of experiments were performed in which the solid components at the lower level were maintained out of physical contact. In some cases, after a liquid sublimate had started to form, the temperature of the stage was maintained at a constant value for a period of time and larger quantities of supercooled liquids were thereby collected. These liquids were crystallized at dry ice temperatures and the resulting crystallized samples observed upon reheating.

DISCUSSION

Representative data obtained in these microscopic studies are compiled in Table II. A number of interesting observations can be drawn from these data. It is noted first of all that in every case liquid was obtained at tempera-

**The temperature of the surroundings of the microscope stage was maintained at about 10° to 15°C. below the eutectic temperature for each sublimation study.*

tures below the lowest eutectic temperature. This observation was made both in the case of mixtures and for the "non-contact" studies. Except for small differences in liquid sublimation temperatures the phenomenon of condensation of supercooled liquid solutions above solids did not depend upon whether the solids were in physical contact.

The fact that in every case liquid formation in a binary system took place at a lower temperature than in either unary indicates that both components were present in the supercooled liquid in the binary system, since at these temperatures the vapor phase could not have been saturated with respect to either of the pure components. A similar situation existed in the ternary and quaternary systems.

In a number of experiments (see footnotes to Table II) a sufficient amount of liquid was collected to allow for a subsequent melting point determination on a crystallized sample. The fact that all preparations began to melt at or near the appropriate eutectic temperatures shows that each liquid sublimate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

must have contained all the components present in the original solid samples. (It is noted that in a few instances the "beginning melting point" for a recrystallized sample was somewhat below the indicated eutectic temperature. Here it is probable that crystallization was incomplete at dry ice temperatures. The "beginning melting point" simply signifies the temperature at which a solid phase began to disappear rapidly.)

HYDROGEN OVERPOTENTIAL ON ALUMINUM[1]

By D. J. Hansen[2] and F. E. W. Wetmore

ABSTRACT

The hydrogen overpotential of pure and impure aluminum in 0.1 N H_2SO_4 at 25° has been studied. The effect of the autocorrosion of the metal has been interpreted and the role of impurities in determining the overpotential and the rest potential has been shown. As well, the build-up and decay of the overpotential has been studied; the behavior is much more complicated than that of noble metals.

Studies of hydrogen overpotential on aluminum have been few (2, 3, 5, 6, 7, 8) and in most cases details of procedure and the degree of purity of the metal are lacking or there is indication that proper experimental precautions (1) have not been taken. In no case was the rate of corrosion reported, although it may have been substantial. The investigation reported here was an exploration at low current densities, for which there are no serious doubts about the homogeneity of current density distribution.

EXPERIMENTAL

The electrolyte used for all experiments was 0.1 N H_2SO_4, a concentration selected as a compromise between the desires for high conductivity and low rate of corrosion. The water was of "conductivity" grade, $k = 8\times10^{-7}$ ohm^{-1} $cm.^{-1}$, the acid redistilled reagent quality. The electrolyte was purged with purified hydrogen and subjected to lengthy pre-electrolysis, according to the method recommended by Bockris and co-workers (1).

The aluminum cathode and platinum anode of the cell were in separate compartments connected through closed ungreased stopcocks wet with solution. Hydrogen was bubbled continuously about both electrodes. An auxiliary cathode of platinum was available for pre-electrolysis. A capillary probe near the cathode surface led to a reference electrode, 0.1 N H_2SO_4/Hg_2SO_4, Hg. Four types of cathode material were selected for study: (I) rolled sheet, 99.995% pure, (II) cast polycrystalline, 99.995% pure, (III) single crystal, 99.995% pure, and (IV) "commercially pure" ingot, 99.5% pure. The cathodes were electropolished in a perchloric acid bath, then mounted in a Teflon box which exposed only one flat face. Unless stated otherwise, current densities mentioned refer to the apparent area of this face.

The currents used were electronically regulated. The potential difference between the probe and cathode was passed to a direct-coupled amplifier of very high impedance (about 10^{13} ohms) and thence to a torsion string galvanometer (Model TSB-A29, Kipp en Zonen, Delft). The deflection of the galvanometer could be recorded on film in a drum camera. Alternatively, a potentiometer was used for steady state readings. Rates of corrosion were determined by measurement of the weight loss of the sample; a resistance–capacitance bridge

[1]*Manuscript received December 30, 1955.*

was used to show that the resistance, and hence the thickness, of the oxide film did not change sufficiently to cause appreciable error in the weight loss measurements.

RESULTS AND DISCUSSION

In the following description the overpotential will be defined as the potential of the reversible hydrogen electrode in the electrolyte less the potential of the cathode, and will therefore be positive.

Figure 1A shows the overpotential plotted against the logarithm of the applied current density, i_x, for sample I; the curves for samples II and III

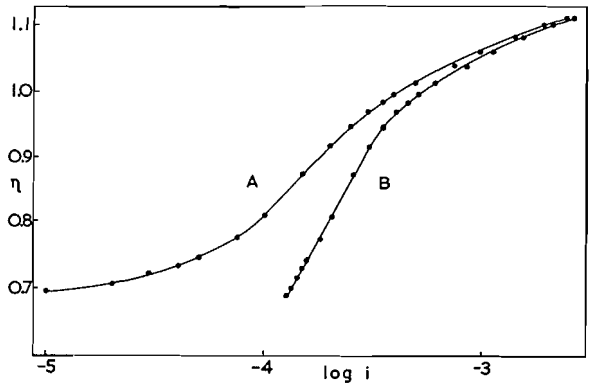

FIG. 1. Overpotential of sample I as a function of the applied current density (A) and the total current density (B).

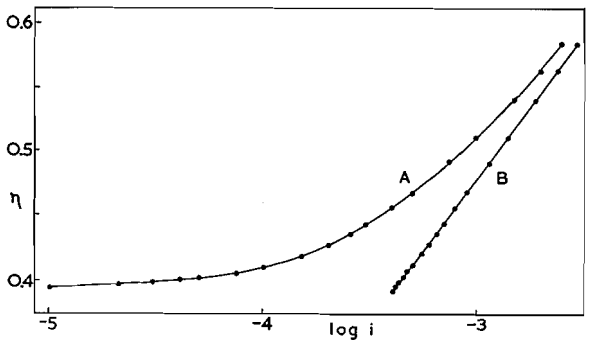

FIG. 2. Overpotential of sample IV as a function of the applied current density (A) and the total current density (B).

are similar. Figure 2A shows the curve for sample IV; it differs from the others in not exhibiting a bend to lower slope at the higher current densities. All of these curves show a distinct deviation from the linearity frequently found for unreactive metals, expressed by Tafel's relation

$$\eta = b \ln(i/i_0). \qquad [1]$$

Even when there is no applied current there is a cathodic current due to the autocorrosion of the sample. Under this condition the cathodic current I is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

identical with the corrosion current I_a. With application of an electrolyzing current I_x, the total cathodic current I equals I_a+I_x. Table I gives corrosion

**Second series, one month after first.*

current densities from weight loss determinations through Faraday's law. These data were obtained without applied current. Weight loss measurements made with electrolyzing current flowing showed that the corrosion current is enhanced by current densities above some 75 μa. cm.$^{-2}$. These corrosion rates were not as reproducible as those taken without electrolyzing current. Fortunately this is not a serious concern in determining $\log(i_a+i_x)$. For typical example, at $i_x = 267$ with $i_a = 50$, a deviation of 10 in i_a would represent only 0.015 in $\log(i_a+i_x)$. The curves B of Figs. 1 and 2 are plotted with $\log(i_a+i_x)$ as the abscissae. These curves show that at the lower current densities the overpotential is indeed linear in the logarithm of the *total* cathodic current density.

It was found that the rest potentials of the samples (E_r at $I_x = 0$) were diverse and were decreased after prolonged electrolysis. There exists, however, a relationship between the corrosion current density and the rest potential. This is shown in Table I; the rest potentials recorded were taken before prolonged electrolysis.

With the exception of sample IV, the cathodes showed a decrease in the slope of the "Tafel curve" at the higher current densities. Such a change in slope is sometimes attributed to a change in the mechanism of the discharge process. In this case an explanation of more direct appeal is to attribute the change to an alteration in the nature of the active cathodes. It will be assumed that both the aluminum and the traces of impurities present can act as cathodes. The total cathodic current I can then be visualized as consisting of two terms, I_1 for that part of the current accepted by the aluminum, and I_2 for that accommodated by the impurities. Thus

$$[2] \qquad I_a+I_x = I_1+I_2.$$

Spectroscopic analysis showed iron and copper to be the major part of the 0.005% of impurity present in samples I, II, and III. From earlier work (3) iron and copper are known to have low overpotentials at low current densities with marked rise at very high current densities. It is possible that these impurities can accommodate the greater part of the current at low current densities, even though their exposed areas are extremely minute, since the overpotential of the aluminum at very low current density may be greater than the overpotential of the impurities at the relatively high current densities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

corresponding to their small exposed areas. This, and the variation in the slope of curve B of Fig. 1, can be explained more formally in terms of the behavior of mixed cathodes.

Let b_1 denote the slope of the curve of overpotential of aluminum plotted against ln I_1. Then $b_1 = I_1(d\eta/dI_1)$. Similarly for the impurities, $b_2 = I_2(d\eta/dI_2)$. Further, let b^* denote the slope of the curve for the mixed cathodes (the actual experimental curve). Then $b^* = (I_1+I_2)[d\eta/d(I_1+I_2)]$. It follows that

$$[3] \qquad 1/b^* = I_1/b_1(I_1+I_2)+I_2/b_2(I_1+I_2) = \phi_1/b_1+\phi_2/b_2,$$

in which ϕ_1 is the fraction of the total cathodic current flowing to the aluminum and ϕ_2 that to the impurities. Thus it is seen that b^* becomes identical with b_1 only as ϕ_1 becomes much greater than ϕ_2. From the form of the curves B of Figs. 1 and 2, the impurities appear to be the predominant cathodes at the low current densities and b^* can be expected to approach b_1 only for high current density on very pure metal. Some confirmation of this viewpoint can be obtained from examination of the rest potentials of the samples (Table I). Sample IV contains one hundred times as much impurity as the other three; the ratio of the exposed areas of impurities will be about the same number. The current density of autocorrosion is therefore much less on the impurities of sample IV than on those of the other three; this is reflected in the much lower rest potential of sample IV. It is consistent with this observation to say that the rest potential is simply the overpotential on the impurities at the particular current density defined by the corrosion current and the area of the impurities exposed. This concept is supported by calculation of the value of the quotient: the difference between the rest potential of sample IV and that of another sample, divided by the natural logarithm of their current density ratio (taking into account the 100:1 ratio of areas of impurities). From Table I the values of the quotients range from 0.074 to 0.100, in agreement with those for iron and copper, but much too high for aluminum.

It is now clear why the rest potential varies without apparent change of conditions, why it varies with the proportion and kind of impurity, why it is affected by prolonged electrolysis, and why the overpotential decreases slightly with prolonged electrolysis. The rest potential is very sensitive to the area of impurites exposed, which can vary as aluminum is dissolved away. Even minute traces of ions of more noble metals present in the electrolyte, whether initially or by dissolution, can change the effective area of active cathode by plating out as the sample is driven cathodically. This emphasizes the need for high purity in both the aluminum and the electrolyte.

Although definite values for the parameters of the overpotential of aluminum cannot be stated from this work, it is evident that both b and i_0 of equation [1] must have very small values, even smaller than those previously reported. The determination of precise values will require the use of extremely pure metal at current densities as high as can be consistent with homogeneous distribution of the current. Work with zone-crystallized metal is proposed.

Both build-up and decay of overpotential as functions of time were determined with the galvanometer and drum camera. For noble metals the initial and greater part of the potential-coulomb curve of build-up is linear; with aluminum cathodes the curve is not linear in any part, in agreement with the following considerations. The generally accepted theory of overpotential leads to an expression for the rise of potential with time of the form (4)

$$[4] \qquad dE/dt = I/C - K.\exp(E/b),$$

in which C is a constant with the dimensions of capacitance, K is a constant, and b is the slope of the "Tafel curve" (equation [1]). Before an electrolyzing current is applied there exists the steady state of rest potential, E_r, and the corrosion current, I_a. Equation [4] then becomes

$$[5] \qquad 0 = dE/dt = I_a/C - K.\exp(E_r/b).$$

With application of an electrolyzing current, I_x, equation [4] becomes

$$[6] \qquad dE/dt = (I_a + I_x)/C - K.\exp(E/b).$$

The initial slope of the build-up curve is given by equation [6] with equation [5] valid at $t = 0$:

$$[7] \qquad (dE/dt)_{t=0} = (I_a + I_x)/C - K.\exp(E_r/b) = I_x/C.$$

For noble metals the value of E_r is small and the exponential term remains small over a considerable portion of the build-up. With aluminum the condition is quite different. The rest potential represented from 50 to 85% of the ultimate overpotential in the range of conditions used here. Therefore the exponential term was appreciable at all stages of the build-up and not even the initial part of the build-up curve was linear. The initial slope was determined by extrapolation to zero time of the secants from the rest potential to the first several points on the build-up curve. Table II gives the data for cathode III, for example.

TABLE II

C FROM SLOPES OF BUILD-UP CURVES

i_x, μa.cm.$^{-2}$	55	91	127	215	273	364	545	727
C, μf.cm.$^{-2}$	28	25	26	26	22	22	24	17

Potential decay curves also showed complication not found with noble metal. The curves were not superimposable by a simple time shift, θ, as found for silver (4), but a value of Δt could be found such that E was linear in $\log(t + \Delta t)$ over the first 90% of the decay curve. With the assumption that Δt corresponds to θ, C was calculated as $(I_a + I_x).\Delta t/k$; the value of k was determined from the slope of the curve of E against $\ln(t + \Delta t)$. Values of C were also calculated by a method similar to that used for the build-up curves. After a build-up of potential there exists a steady state of overpotential and a steady state of cathodic current. Equation [4] then takes the form

$$[8] \qquad 0 = dE/dt = (I_a + I_x)/C - K.\exp(\eta/b).$$

When the electrolyzing current is removed, $I_x = 0$ and equation [4] takes the form appropriate to decay

$$[9] \qquad (dE/dt)_{t=0} = I_a/C - K.\exp(\eta/b) = -I_x/C.$$

Table III shows values of C calculated by the two methods, for sample III.

SKELETAL SILVER CATALYSTS FOR THE OXIDATION OF ETHYLENE TO ETHYLENE OXIDE[1]

By A. Cambron[2] and W. A. Alexander

ABSTRACT

Skeletal silver catalysts of high specific activity have been prepared by the removal of calcium from calcium–silver alloys. The activity of these catalysts in the oxidation of ethylene to ethylene oxide has been investigated. Catalysts prepared by the removal of the other alkaline earth metals from their alloys with silver have also been studied. It has been found that catalysts prepared from calcium–silver alloys show a higher specific activity and are more stable and more conveniently prepared than the catalysts from the other silver alloys investigated.

INTRODUCTION

The increasing interest in ethylene oxide as a starting material in organic syntheses is shown by the numerous references in the recent current and patent literature not only to improved methods of producing this versatile chemical, but also to its use in the preparation of other aliphatic chemicals and derivatives. A survey of the literature was included in a recent communication (7).

Considerably more work has been done on the direct oxidation of ethylene to ethylene oxide than on the older chlorohydrin method since the specific activity of silver as a catalyst in that reaction was first reported by Francon (4). The reason for this is that the direct catalytic oxidation offers a more attractive method provided the complete oxidation of ethylene, which is also promoted by the silver catalyst, is limited.

Metallic silver is the only substance which has been found to have a specific catalytic effect on the oxidation of ethylene to ethylene oxide. The methods described in the literature for the preparation of silver catalysts have been almost exclusively by the precipitation of the finely divided metal or of the oxide, from solutions of a silver salt or by the thermal decomposition of a silver salt. The use of numerous oxides or metals as promoters has also been mentioned in the literature (8, 11, 13), but in all cases the oxides are added as a distinct solid phase, or the added metal remains in the catalyst.

The preparation of an active catalyst by the thermal decomposition of silver oxalate in the presence of water under pressure was described in a previous paper (7). It was found that the activity of the latter catalyst could be increased by the use of lime and stannous oxide as promoters. The pronounced action of calcium oxide as a promoter even when present in very small amounts suggested that a reduction of the calcium oxide by silver might take place locally on the surface of the catalyst, resulting in alteration in the surface of the catalyst by the momentary formation of a calcium silver compound, followed by the regeneration of calcium oxide and of metallic silver by the action of the oxygen in the reacting gases. Dowden (3) in a recent paper has

[2]*Deceased February, 1952.*

pointed out the possibility that irreducible oxides in the presence of a reducing metal such as copper, and one would expect silver to behave similarly, may lead to the formation of a metallic surface phase. Even if this only resulted in the formation of a chemisorbed layer of the added metal, it would be expected to have a strong influence on the activity of the surface.

In the previous work on the use of calcium oxide as a silver catalyst promoter, it was observed that this oxide, in addition to promoting the oxidation of ethylene to ethylene oxide, also strongly promoted the complete oxidation of ethylene to carbon dioxide and water. In order to study the effect of calcium on the catalyst surface in the absence of calcium oxide a calcium–silver alloy was prepared and the activity of the surface was determined after removing the calcium metal with a suitable reagent. In this manner a very active and very stable skeletal silver catalyst was obtained which possessed an appreciably higher selectivity than finely divided silver catalysts prepared by known methods.

EXPERIMENTAL

In order to determine the effect of the removal of the calcium component of the alloy on the structure of the remaining silver skeleton, an X-ray examination of the alloy was made. This gave a spectrum different from that of silver owing to the presence of the calcium–silver compound and of a eutectic. After removal of the calcium the characteristic silver lines corresponding to the face-centered cubic arrangement of crystalline silver reappear and the sharpness of these lines indicates that the silver crystal units must form particles of the order of 1000 Å in size.

The first calcium–silver alloys were prepared with a calcium content of 5–7%. It was found, however, that complete removal of the calcium required prolonged treatment of the alloy with steam after grinding to 20–30 mesh. Alloys were therefore prepared with a higher calcium content, in the range 7–12% calcium. These are considerably more brittle and could be ground conveniently to the required size for complete removal of the calcium. It is interesting to note that the calcium–silver alloys themselves possess no specific activity in the oxidation of ethylene and that maximum specific activity is obtained by as complete a removal as possible of the calcium.

In the course of the work done on the preparation of skeletal silver catalysts from silver alloys a number of other alloying elements from groups one to four have been studied, namely lithium, magnesium, strontium, barium, zinc, aluminum, lanthanum, cerium, and tin. Although a few of these alloys showed some activity after complete or partial removal of the alloying elements, with the possible exception of barium none showed as high a specific activity as the catalysts prepared from calcium–silver alloys. This may in part be due to the fact that the removal of calcium from the calcium–silver alloy can be done more readily and under less drastic conditions than is the case with the other metals.

Preparation of Silver–Calcium Alloys

The calcium–silver alloys were prepared by melting the required amount of silver in a crucible made from a stainless steel or iron tube, fitted with a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12

$\frac{1}{4}$ in. iron thermocouple tube which also served as a hand stirrer and was so arranged that an argon atmosphere would be maintained in the crucible. A slight excess of freshly cleaned calcium metal was then added to the molten silver. After the molten mass was kept above the melting point of the alloy for about one minute with stirring, the alloy was allowed to cool, or was quenched, and the solid ingot obtained was recovered by stripping off the metal tube. By a later procedure, especially with large melts, the silver was first allowed to solidify and then dissolved slowly by alloying with the calcium at 750° to 850°C., to decrease the rate of gas evolution and to eliminate the danger of a mild explosion.

Silver alloys of other alkali and alkaline earth metals were prepared by the same procedure.

Activation of Silver Catalysts

Several methods were tried for removing the added metal from the silver alloys. Simple refluxing in acetic acid with or without diluted oxidizing agents such as hydrogen peroxide or potassium permanganate did not produce a highly active catalyst. Since the present work was concerned mainly with alloys of silver with metals of groups II and III, many of which react with steam at temperatures below 350°C., the usual initial step in the activation procedure was the treatment of the alloys, ground to about 20–30 mesh, with steam at 300–450°C. for about six to eight hours, or with water in an autoclave at 200–250°C. for about four hours. Control of temperature in the activation treatments is necessary and is aided by use of only small amounts of powder in one place to prevent accumulation of heat of reaction. With silver alloys containing magnesium, strontium, and barium, it was found difficult if not impossible to react the added element completely. Tests carried out with other than calcium alloys were therefore qualitative in character, but did indicate that the calcium alloy was the most convenient to use.

Variations in the activation procedure which were successful included the heating of the alloy in a moist air stream or in the off-gas from a reactor for long periods at about 400°C. followed by leaching with warm acetic acid. Refluxing in acetic acid with repeated additions of 5% hydrogen peroxide, treatment with 15% nitric acid, and variations of the autoclaving such as addition of alcohol, hydrogen peroxide, dioxane, phenol, borax, and ethylene glycol to the water resulted in only normally active catalysts.

After conversion of the added element to the hydroxide by steam, the latter was leached out by refluxing with 20% acetic acid for one hour followed by washing the residue with distilled water and sometimes alcohol. Formic and citric acids may also be used to dissolve the calcium hydroxide.

Apparatus and Materials

The test apparatus arrangement was similar to that described before (7) except that the ethylene was taken directly from the cylinder and the reaction tubes now consisted of $\frac{1}{2}$ in. diameter holes in an aluminum block. The bottom of each reaction hole was closed by a bed of coarse silver granules which served as a preheater for the reactants. Most alloys were crushed to 20–35 mesh,

and weighed lots placed on top. The temperature was measured by a chromel alumel thermocouple with a silver strip about $\frac{1}{4}$ in. $\times$ 1 in. $\times$ 0.020 in. brazed to the junction, which was covered by the catalyst. The products were normally vented to a water tower and the solution discarded, or passed to the analytical part of the apparatus. No change was made in the analytical procedures.

Ethylene of U.S.P. grade was obtained from the Ohio Chemical Co. and produced by the dehydration of alcohol. It was used without further purification. The air supply was passed through an activated charcoal bed and, in later tests, through a tube containing heated silver catalyst as well. Both reactant streams were measured by calibrated flowmeters. The silver was mint grade granules and the calcium, magnesium, strontium, and barium probably distilled products of the Dominion Magnesium Company.

Some attempts were made to modify the disposition of the catalyst bed, for better temperature control on a larger scale. Pressing of the silver granules into pellets using various pressures showed that the activated catalyst could not be deformed without loss of activity. However, further tests with alloys having some plasticity showed that active catalysts could be prepared from pellets or disks of alloy granules. Mixing the alloy granules with other metal powders to improve the bonding showed that aluminum, brass, iron, and monel decreased the activity severely, while pure silver was neutral.

RESULTS

As mentioned above, calcium–silver alloys produced the most stable catalysts with the highest activity. Usually catalysts from these alloys exhibited an increase in activity, as measured by selectivity, to a maximum at about 10–20 days with a subsequent slow decrease. This decline was normally very

slow as numerous tests were carried on for periods of up to about 12 months, with a high level of activity at the end of the test. One such experiment is summarized in Table I. This catalyst was activated by treating with steam for one-half hour, at 150°C. initially and gradually raising the temperature to 350°C., followed by one hour at 340–355°C. The lime was removed by 20% acetic acid followed by water and methanol washings. This test was carried on for more than a year, the catalyst being poisoned by unknown substances three times with subsequent recovery to normal activity levels. Results with a number of calcium–silver alloy catalysts are shown in Table II. Activation of

these alloys was by heating in a current of steam at 300° to 400°C., followed by leaching with acetic acid and with water. As complete removal of calcium as possible from an 8 to 11% alloy is the preferred procedure, since a high residual calcium content apparently decreases the stability of the catalyst.

Catalysts prepared from magnesium and strontium alloys showed a lower selectivity at comparable total reaction levels than calcium–silver. Barium apparently approached the activity of calcium, but for economic reasons and because of its reactivity it was not extensively tested. Results obtained with these alloys are shown in Table III, from which it will be noted that the yields are considerably lower than with the calcium alloys of Table II.

Mg 2.5 Ca 11.6	0.0 0.4	259	271	43	98	44	11	16

Experiments with the ternary magnesium–calcium–silver alloys are summarized in Table IV. These were activated by steaming at 350° to 375°C. and leaching with acetic acid followed by washing with water and drying. As mentioned earlier, the removal of a large excess of magnesium is difficult, and the yields or selectivities of the resulting catalysts tend to be considerably lower than with calcium–silver alloys. Catalysts prepared from alloys with an excess of calcium apparently show activities similar to the binary calcium–silver alloys.

Several metals from groups I to IV of the periodic table were tried as substitutes for calcium. In some cases the added element could not be removed readily while in others the residual silver showed no enhanced catalytic effect. The possible exceptions are tin and lanthanum, which were, however, inferior to the alkaline earth metals. Other elements tested were sodium, lithium, mercury, and aluminum.

The effects of many promoters, of preconditioning procedures, and of anticatalysts were also investigated. As promoters, many metals were added in minor amounts, some being partially removed during the activation procedure. In no case was any reproducible increase in yield of ethylene oxide observed. The metals tested were copper, manganese, platinum, nickel, zinc, cadmium, mercury, tin, cerium, lanthanum, as well as calcium oxide and calcium carbonate.

As will be noted in Table I the selectivity of the catalyst is usually low for the first 10 to 20 days. This induction period may be reduced to as little as two to three days by heating at the reaction temperature for about one week in an atmosphere of carbon dioxide, oxygen, steam, air, ethylene, and probably other gases. The catalyst then shows normal reactivity in other respects.

The efficiency of halogen compounds (1, 2, 5, 6, 14) and halides (12, 19) as anticatalysts in the suppression of the reaction to carbon dioxide and water has been mentioned frequently in the literature. The use of organic halogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/04/12
For personal use only.

compounds has also been suggested in the reactivation of a poisoned catalyst or in the regeneration of an old one with low activity (20). McKim and Cambron (7) found no anticatalytic activity with an organic halogen, but a definite poisoning. The effect of inorganic halide solutions was investigated in the course of the present experiments. In only three instances were moderate increases in activity observed which might be attributed to the sodium chloride and to the hydrogen chloride treatments, the latter apparently being the more effective. Large amounts of halides acted as poisons. There was, however, some indication that this treatment would decrease the induction period in the same way as preheating. The halides tested were hydrogen chloride, potassium chloride, sodium chloride, sodium fluoride, magnesium chloride, and magnesium fluoride. Silver chromate in large amounts also acted as a poison.

On adding ethane to the feed gas, a decrease in selectivity was again observed (7). In seven experiments, 10% ethane was mixed with the ethylene and in only one was an increase in yield observed, amounting to only about 3%. In the remainder decreases of up to about 15% occurred. An additional test with 5% ethane showed a decrease of about 20%. The presence of ethane in these amounts might thus be considered undesirable.

Several papers (9, 10, 15, 16, 17, 18) have discussed the kinetics and reaction mechanisms and nothing can be added from this work. Various engineering developments in the use of these catalysts have been made in these laboratories, such as the means of disposal of the catalyst in the reactant stream to maintain close temperature control and achieve optimum reactivity. These will undoubtedly be discussed in future publications.

ACKNOWLEDGMENT

The assistance of many members of the staff of the National Research Council who contributed directly or indirectly to this work while in progress is gratefully acknowledged. Thanks are also due to Dr. I. E. Puddington for reading the manuscript.

THE SYSTEM LiCl–NaCl–KCl–H_2O AT 25° C.[1]

By A. N. Campbell and E. M. Kartzmark

ABSTRACT

Of the component ternary systems of the quaternary system LiCl–NaCl–KCl–H_2O, the system LiCl–KCl–H_2O has not previously been investigated. This has now been done and it is shown to be very similar to the system LiCl–NaCl–H_2O investigated by Smits, Elgersma, and Hardenberg (4). In both systems, the strongly hydrated lithium ion reduces the content of second salt to a low value at the (isothermal) invariant point.

The quaternary system of the title has been investigated, using a new method of analysis which involves the determination of total chloride and of density. The quaternary invariant composition is similar to that of the ternary invariant in the system LiCl–KCl–H_2O. In none of these systems is there formation of double salt or solid solutions and the only hydrate occurring as a solid phase is LiCl.H_2O.

The study of this system was undertaken as the first part of a comprehensive study of the five-component system containing the radicals Li_2, Na_2, K_2, Cl_2, and SO_4, and water. A similar comprehensive study on the ions of sea-water was made by van't Hoff (5) but his investigation did not extend to lithium. The present study includes, in addition to the system now described, the ternary systems (1) Li_2Cl_2–Li_2SO_4–H_2O, (2) Na_2Cl_2–Na_2SO_4–H_2O, (3) K_2Cl_2–K_2SO_4–H_2O; the quaternary system Li_2SO_4–Na_2SO_4–K_2SO_4–H_2O; and the reciprocal salt pairs (1) $Li_2Cl_2 + Na_2SO_4 = Na_2Cl_2 + Li_2SO_4$, (2) $Na_2Cl_2 + K_2SO_4 = K_2Cl_2 + Na_2SO_4$, (3) $Li_2Cl_2 + K_2SO_4 = K_2Cl_2 + Li_2SO_4$; as well as the quinquenary system mentioned above. Much of the experimental work involved has already been done but not all of it. The method of graphical representation chosen was that of Jänecke (3), the only one of reasonable simplicity. The axes of representation for Jänecke's system are the edges of a regular equal-sided triangular prism. On this model, the six vertices represent single salts and water, the edges ternary systems, the triangular surfaces quaternary systems, the rectangular surfaces reciprocal salt pairs, and the interior of the model the quinquenary system.

On reviewing the literature of the present study, we found that of the component ternary systems, viz. (1) LiCl–NaCl–H_2O, (2) LiCl–KCl–H_2O, and (3) NaCl–KCl–H_2O, system (3) was well known, and system (1) had been done by Smits, Elgersma, and Hardenberg (4); system (2) was unknown. In view of our own results for system (2) we see no reason to doubt the results of Smits, Elgersma, and Hardenberg for the analogous system (1); it appears that the highly hydrated lithium ion acts very powerfully in displacing other salts from solution, so that the isothermal invariants: LiCl.H_2O, NaCl, solution and LiCl.H_2O, KCl, solution, respectively, contain in solution very little salt other than lithium chloride. Our first task then was to carry out an investigation of the system LiCl–KCl–H_2O, at 25° C., preparatory to a study of the quaternary system named in the title.

EXPERIMENTAL

The technique of preparing and filtering saturated solutions is too well known to merit description. For the investigation of the ternary system we used Schreinmakers' method of the 'wet rest'. No such method is available for the quaternary system, neither is it necessary since the nature of all solid phases is known. The chemicals used were all either B.D.H. 'Analar' or Merck's 'reagent' grade. They were used without further purification since very slight traces of impurity are without effect on studies of this kind.

The great difficulty in studies involving mixtures of alkali cations is a method of analysis. Any chemical method would be laborious and too inaccurate for the present purpose. It is possible in theory, however, to analyze any three-component mixture by determining any two physical properties for all proportions of the three components. One of us used the method, very successfully, for the analysis of liquid mixtures of benzene – ethyl alcohol – carbon tetrachloride (2), but here the problem is simpler, since the amount of water does not enter as a fourth variable. To overcome this difficulty we proceeded in the following way: after determining total solubility in the usual manner, exactly 10 gm. of the anhydrous solid mixture was dissolved in water and diluted to exactly 100 ml. and the density and total chloride content determined. Because of the very hygroscopic nature of lithium chloride, it was not advisable to weigh exactly 10 gm. of the mixture and therefore the total weight of solid mixture was dissolved in water, the solution weighed, such an aliquot taken as corresponded to 10 gm., and this then made up to 100 ml. In their study of the system LiCl–NaCl–H_2O, Smits, Elgersma, and Hardenberg (4) used the viscosity of mixtures of constant total composition as the analytical method. When the chloride contents and densities, or rather the density minus one, of all possible mixtures of LiCl, NaCl, and KCl, are plotted on two separate triangular diagrams, and points of equal density and of equal chloride content respectively are joined by curves, the method of analysis is complete. The density of an unknown mixture places it on a curve of density and its chloride content on a curve of chloride content. Since fortunately these two curves always intersect sharply, the point of intersection represents the composition of the mixture. On previous occasions, we had adopted the method of placing one diagram exactly above the other and illuminating strongly from below. In the present instance, we found it better to plot both sets of results on one diagram, as shown in Fig. 1.

The densities were determined in a 25 ml. specific-gravity bottle. In order to obtain an accuracy of one per cent in the analysis, the density must be determined to two units in the fourth decimal place. Since we were able to obtain a reproducibility of one in the fourth decimal place, we feel we attained an analytical accuracy of $\pm 1.0\%$, as far as the density determinations are concerned. Since, however, the analysis of a ternary mixture depends also on the chloride determination, we feel that the over-all accuracy is somewhat less than this, but it is much better than any chemical method.

In preparing the calibration curves, the chloride content was simply calculated from the formulae of the chlorides, for all possible mixtures. In de-

termining the chloride content of unknowns, we titrated conductimetrically with silver nitrate. In the analysis of the simple ternary system LiCl–KCl–H_2O, it was of course unnecessary to determine both chloride content and density, and we used chloride content alone for this purpose.

EXPERIMENTAL RESULTS

Table I contains our density determinations, which were used in the calibration; the chloride content is also included. When plotted against composition, either as binary or ternary mixture, the density curves are straight lines, as are those of chloride content.

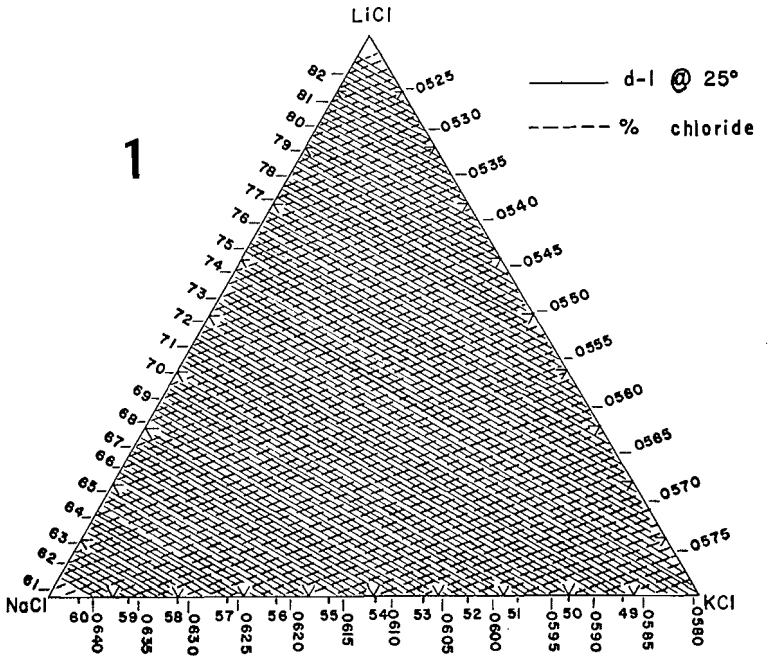

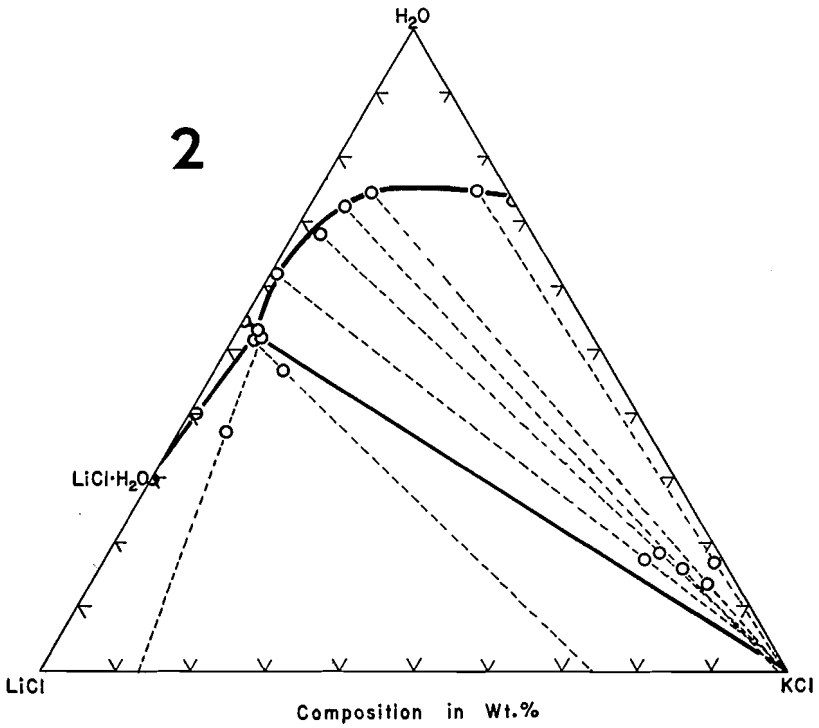

FIG. 1. Density and per cent chloride curves for the analytical method.
FIG. 2. The system LiCl–KCl–H_2O at 25°C.

In order to investigate the quaternary system, LiCl–NaCl–KCl–H_2O, we started with the only ternary isothermal invariant which contains appreciable quantities of two salts, viz. the invariant: KCl, NaCl, saturated solution, and, while keeping potassium chloride and sodium chloride present in excess, we added increasing quantities of lithium chloride, established equilibrium at 25°, and analyzed both liquid and solid phases. The system is of such a simple kind, as we knew from the component ternary systems, that only one quaternary (isothermal) invariant was to be expected, viz. LiCl.H_2O, KCl, NaCl, saturated solution. Moreover, since the ternary invariants with LiCl.H_2O as one solid phase contained very little potassium chloride or sodium chloride respectively in solution, we expected that the quaternary invariant would likewise contain little other than lithium chloride in solution. The point of analyzing the solid phase was that, so long as LiCl.H_2O was not a solid phase, the lithium chloride content of the solid phase would be entirely due to adhering mother liquor but, as soon as LiCl.H_2O appeared as a solid phase, the lithium chloride content would increase sharply. Our results are contained in Table III.

TABLE III

COMPOSITION OF EQUILIBRIUM SOLUTIONS AND OF SOLID PHASES IN THE SYSTEM LiCl–NaCl–KCl–H_2O

Composition						Nature of solid phase
Liquid phase			'Wet' solid phase			
% LiCl	% KCl	% NaCl	% LiCl	% KCl	% NaCl	
—	10.4	21.1	—	27.0	56.7	KCl + NaCl
8.2	7.6	10.7	0.8	17.9	62.5	KCl + NaCl
8.1	8.8	12.5	2.0	13.8	63.3	KCl + NaCl
32.9	1.3	2.2	7.3	29.5	43.2	KCl + NaCl
4.5	9.9	15.7	Trace	40.6	43.1	KCl + NaCl
41.5	3.1	0.2	34.05	12.2	20.8	KCl + NaCl + LiCl.H_2O

In Table IV the results are calculated in accordance with Jänecke's system of notation, viz.: $m$$H_2O$, aLiCl, bKCl, $(1-a-b)$NaCl, where a, b, and $(1-a-b)$ are the mole fractions of LiCl, KCl, and NaCl respectively, and m is the number of moles of water to one total mole of salt in solution.

TABLE IV

THE SYSTEM LiCl–NaCl–KCl–H_2O AT 25° C., CALCULATED BY THE JÄNECKE SYSTEM OF NOTATION

a	b	m	Nature of solid phase
0.00	0.388	7.60	NaCl + KCl
0.405	0.212	8.52	NaCl + KCl
0.649	0.402	7.49	NaCl + KCl

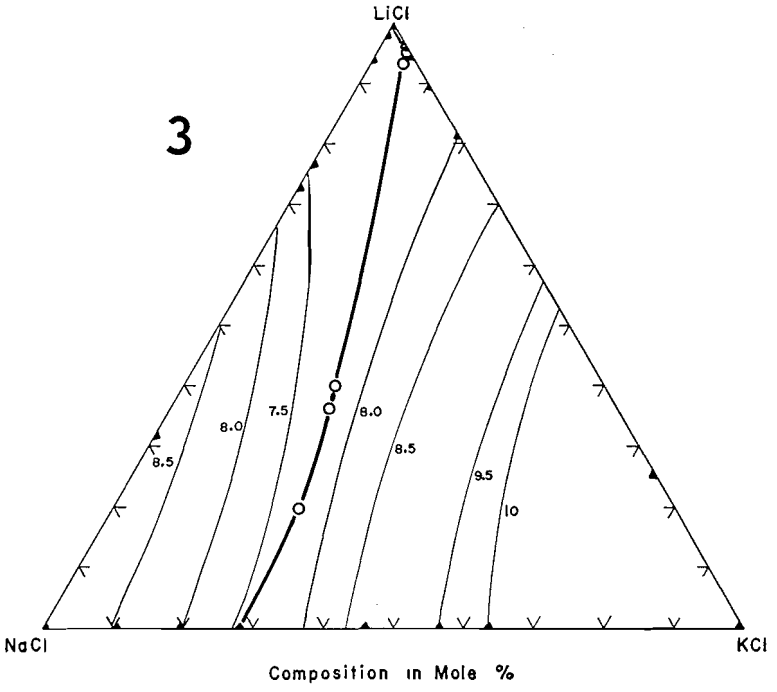

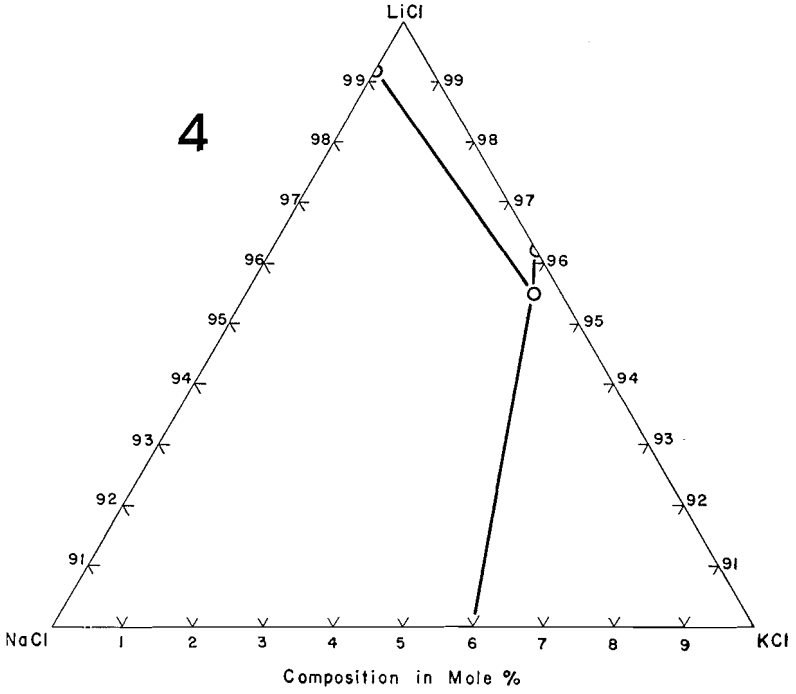

FIG. 3. The system LiCl–NaCl–KCl–H_2O at 25° in Jänecke representation.
FIG. 4. Enlargement of the quaternary invariant area.

The equilibrium diagram is given as Fig. 3, while Fig. 4 gives an enlarged picture of the lithium chloride corner of the diagram, showing two ternary invariants and the quaternary invariant. In Fig. 3, the isohydrores (lines of equal water content) are drawn in as faint lines.

DISCUSSION

No great discussion is called for, since neither double salts nor solid solutions form, but one or two points of interest emerge. First, the tremendous salting-out effect of the lithium ion is evident in the new system, LiCl–KCl–H_2O, as it was in the system LiCl–NaCl–H_2O, investigated by Smits, Elgersma, and Hardenberg. In the system containing sodium chloride, however, the sodium chloride content is reduced to 0.5 weight per cent at the invariant point, while the corresponding invariant in the potassium chloride system contains 3.2% potassium chloride. Otherwise, the two systems are very similar; for instance, in both there is a range of solutions which contain less sodium chloride or potassium chloride than the invariant solution. Attention has been drawn elsewhere (1) to the tenacity with which the lithium ion holds its water of hydration.

The composition of the isothermal invariant solution in the quaternary system is very similar to that in the ternary system LiCl–KCl–H_2O. The lithium chloride solid phase is always the monohydrate, $LiCl.H_2O$.

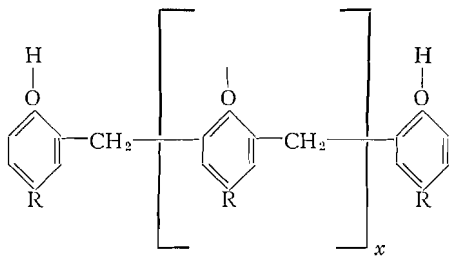
INFLUENCE OF THE NUMBER OF CARBON ATOMS OF THE ALKYL GROUP ON POLYMERIZATION AND PROPERTIES OF PARA-ALKYLPHENOL–FORMALDEHYDE POLYMERS[1]

By A. Rosenthal, F. Lederer, and K. Gilson

ABSTRACT

The polymerization (in organic media) of *p*-cresol–formaldehyde has been investigated in sealed tubes and in open systems. A series of almost colorless *p*-alkylphenol–formaldehyde polymers, prepared in sealed tubes, was studied to determine the influence of the number of carbon atoms of the substituting alkyl group on the polymerization process and on the properties of the polymers. Infrared spectra and chemical analyses of the original and heat-treated polymers were correlated with the structures of the polymers.

Para-alkylphenol–formaldehyde polymers have been little investigated. In 1930 the first completely oil-soluble phenolic resin was reported (3). Turkington and Allen (20) published the first comprehensive review of the properties and general preparation in open systems of oil-soluble phenolic resins, including a rather general evaluation of the varnishes made from these resins. Shreve and Golding (18) attempted to evaluate what they believed to be the best of the phenolic compounds for making varnishes. In work connected with a structural determination of Koresin, Marvel and co-workers (13) prepared and studied a few *p*-alkylphenol–formaldehyde resins. Although there is an extensive patent literature on oil-soluble resins, almost all of the preparative techniques involve the use of open systems and inorganic substances, in aqueous media, as catalysts. Considerable fundamental information on the condensation of formaldehyde with substituted phenols has been obtained from the model studies of Zinke (22, 24), Hultzsch (10), and others (6). Individual members of a polymer homologous series from *p-tert*-butylphenol and formaldehyde (I) were prepared by Zinke and co-workers (23).



I; $x = 0$ to 6

It was the first objective of the work herein reported to prepare, under carefully controlled conditions, a homologous series of *p*-alkylphenol–formaldehyde polymers having structure I (R = alkyl group), and to study in a quanti-

[1]*Manuscript received January 31, 1956.*
Contribution from the Department of Chemistry, The University of British Columbia, Vancouver, B.C.

tative way the effect of the aliphatic side chain on the polymerization process. A second objective was to study the structures and properties of these polymers.

The *p*-alkylphenol–formaldehyde polymers were prepared at 130° in sealed Carius tubes using bis-(2-ethoxyethyl) ether as solvent, *s*-trioxane as a source of formaldehyde, and *p*-toluenesulphonic acid monohydrate as catalyst. The crude resins were freed of insoluble material and reprecipitated from water. Almost completely colorless solid resins, which were soluble in N,N-dimethylformamide or pyridine, were obtained. The use of a closed system rather than an open one permitted an excellent control of conditions as evidenced by the fact that agreement in specific viscosities of the resins obtained in repeat runs was ±3%. Polymerization of *p*-cresol with formaldehyde under a closed system led to the production of a resin having approximately twice the specific viscosity of one obtained under similar experimental conditions except for that of carrying out the polymerization under reflux in an open system (Table I, polymers 4 and 14).

The effects of varying temperature, reaction time, volume of solvent, and tube length on the polymerization of *p*-cresol–formaldehyde polymers (as revealed by specific viscosities) are shown in Table I. An increase of 1 to 3% molar excess of formaldehyde over *p*-cresol resulted in no significant increase in specific viscosities of the polymers when the condensation was carried out at 110° (polymers 1 and 2). When the polymerization was carried out at 130°, a 2% molar increase in formaldehyde gave approximately a 10% increase in specific viscosity (polymers 4 and 5). Although use of equimolar quantities of

reactants at a temperature of 150° might be expected to yield a much higher molecular weight polymer than was obtained at 130°, such a result was not attained as seen in polymer 6.

At constant molar ratios of reactants an increase in polymerization temperature from 110° to 130° led to an increase in specific viscosities of the polymers from 0.037 to 0.091 and also a 20% increase in the amounts of insoluble material (Table I, polymers 1 and 4). Previous workers (1, 8, 23) have suggested reasons for the partial insolubility of some *p*-alkylphenol–formaldehyde polymers. Infrared studies did not reveal any significant difference in the structures (as shown by the spectra) of the soluble and insoluble fractions of the *p*-cresol–formaldehyde polymers (Fig. 1, polymer 1 and Fig. 2, 4*d*).

It was surprising to discover that a less soluble phenol–formaldehyde polymer was obtained when the Carius tube length was decreased from 40 to 10 cm. (other conditions being the same), although the specific viscosities of the soluble portions of the polymers were essentially the same (Table I, polymers 11 and 12).

The effect of the *p*-alkyl group on the degree of polymerization of *p*-alkylphenol–formaldehyde polymers is shown in Table II. It is interesting to note

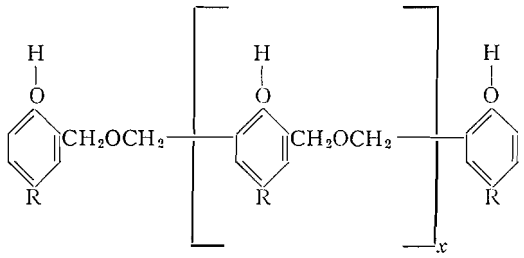
that as the straight chain alkyl group increased in size from methyl to *n*-hexyl the specific viscosities of the polymers decreased from 0.091 to 0.042 (polymers 4, 16, 18, 22, and 26). Polymers obtained from *p-sec*-butylphenol and *p-sec*-

amylphenol had more than double the specific viscosities of those obtained from the isomeric branched-chain or straight-chain *p*-alkylphenols (polymers 19 to 25). Other workers (18, 14), who have studied the properties of the varnishes from resins of several *p*-alkylphenols, have found that the alkyl group has an effect on the time of resinification.

A surprising and interesting finding was the wider divergence of the experimental per cent carbon from the theoretical of polymers prepared from *p*-cresol than of those prepared from the other *p*-alkylphenols (Table II, Analytical). It might have been expected that the reverse would have been the case, since the *p*-cresol–formaldehyde polymer had a higher specific viscosity than most of the other *p*-alkylphenol polymers. A *p*-cresol–formaldehyde condensate having three benzene nuclei has a carbon content of 79.2% and as a result, the low per cent carbon found can not be fully explained on the basis of a high concentration of low molecular weight fractions. Zinke (22) has proposed that benzyl ether linkages (as shown in II) and methylene bridges are formed at



II

temperatures up to 170°, and above these temperatures formaldehyde is evolved leaving a polymer having structure I. If the structure of the *p*-cresol–formaldehyde polymer is more accurately represented by II than by I, the theoretical per cent carbon would be 72% instead of 80%. The fact that the carbon found was 76.4% indicates that more than half of the linkages which bound the phenolic nuclei were methylene bridges. In an attempt to study this problem further, purified *p*-cresol– and *p-sec*-amylphenol–formaldehyde

polymers having high specific viscosities were heated at 182° for three hours under an atmosphere of dry nitrogen. The *p*-cresol–formaldehyde polymer evolved formaldehyde. When the latter polymer was heated at about 250° for about one minute, a rapid evolution of bubbles accompanied the change in state of the polymer from solid to liquid. Analytical studies (Table III) of the *p*-cresol–formaldehyde polymer heated at 182° showed that the carbon content of the polymer had increased by 2.4% and the hydrogen content remained about the same. There was a decrease in the specific viscosities of the polymers from 0.091 to 0.019. The *p-sec*-amylphenol polymer when heated under the same conditions had approximately the same carbon content and a 30% decrease in specific viscosity (Table III). Infrared studies showed that the band at 1095 cm.$^{-1}$, present in the spectra of both original polymers, was not present in those of the corresponding heat-treated polymers (Fig. 1, polymers 4 to 4*c* and Figs. 4 and 5, polymers 24 to 24*c*). Evidence that the band at 1095 cm.$^{-1}$ is characteristic of a benzyl ether linkage is provided by the fact that the spectrum of dibenzyl ether has a band at 1095 cm.$^{-1}$ whereas that of 4,4′-dihydroxydiphenylmethane does not (16). Zinke (23) and Hultzsch (10) have suggested that the fission of the ether bridge results in the production of phenol aldehydes together with *o*-quinone methides. The presence of the latter degradation products would account for the fact that the polymers darkened after

prolonged heating at 182°. Present studies do not permit a correlation of polymer structure with the band at 1670 cm.$^{-1}$ which was present in the spectrum of the original polymer but absent in that of the heat-treated *p*-cresol–formaldehyde polymer.

The softening points of the *p*-cresol–formaldehyde polymers were essentially the same for polymers having specific viscosities ranging from 0.057 to 0.091. A slightly lower value (230–235°) was obtained with a *p*-cresol polymer having a specific viscosity of 0.037 (Table I). The fact that the melting points were found to be essentially independent of the molecular weights of these polymers lends support to the assumption that the polymers being dealt with were of high molecular weight (4). Attempts to obtain molecular weights of the polymers by the Rast method or by the use of benzil as solvent were unsuccessful.

The effect of the alkyl groups upon the softening points of linear phenoplasts is strikingly brought out by the fact that the softening point of *p-sec*-amylphenol–formaldehyde polymer ($\eta_{sp} = 0.112$) was 105–110°, whereas that of the *p*-cresol–formaldehyde polymer ($\eta_{sp} = 0.091$) was 240–245° (Table II, polymers 4 and 24). In this connection it is interesting to note that other workers (4, 9) have recently found that the size and flexibility of alkyl groups have a marked effect on the melting points of linear polyesters. For polymers of approximately the same molecular weight (Table II, polymers 21 and 25), an increase in the size and bulkiness of the alkyl group from *tert*-butyl to *tert*-amyl resulted in approximately a 30° lowering in the softening points of the polymers. Surprisingly, the *p-sec*-amylphenol polymer (polymer 24) which had the highest specific viscosity of all the isomeric amylphenol polymers had a softening point 60° lower than that of the *tert*-amylphenol polymer. From a consideration of molecular dimensions and bond angles, Megson (15) deduced that a Novolak resin must consist of highly kinked, asymmetrical molecules. He pointed out that a hardened resin has a sponge-like structure which can explain, partially, certain physical and chemical properties of the resin.

The infrared spectra of the *p*-alkylphenol–formaldehyde polymers are presented in Figs. 1 to 5. Compounds containing alkyl hydrocarbon groups usually exhibit absorption from 3130 to 2800 cm.$^{-1}$, which is the region attributed to the (C–H) stretching vibrations. Richards and Thompson (16) and Bender (2) have ascribed a weak absorption band at about 12.2 μ (820 cm.$^{-1}$) to 2,4-substitution of the phenolic ring. They suggest that a band at about 11.50 μ (870 cm.$^{-1}$) is characteristic of a 2,4,6-substituted phenol residue. On the basis of their work, one can conclude that most of the polymers studied having an alkyl side chain equal to or greater than four carbons had 2,4-substitution. All polymers which had a specific viscosity greater than 0.069 showed no band at 820 cm.$^{-1}$. It is interesting to note, however, that the *p*-cresol–formaldehyde polymer 1, which had a specific viscosity of 0.037, exhibited no band at 820 cm.$^{-1}$, whereas the *p*-isopropylphenol–formaldehyde polymer (No. 17), which had a specific viscosity of 0.069, absorbed in this region. This would indicate that one can not always correlate molecular size with 2,4-substitution, although it might be expected that polymers belonging to the series I which have the lowest molecular weight should have the highest concentration

of 2,4-disubstituted end groups. It has been pointed out by Thompson and Torkington (19) that the characteristic frequencies shown by the substituted benzenes in the range of 715 to 880 cm.$^{-1}$ vary with the position of the substituents and are largely independent of their exact nature. The pronounced band at 860 to 875 cm.$^{-1}$ exhibited by all *p*-alkylphenol–formaldehyde polymers is attributed to 2,4,6-trisubstitution (16, 2). Absorption in the region of 3100 to 3300 cm.$^{-1}$ is characteristic of associated phenolic hydroxyl groups (16).

EXPERIMENTAL

1. Reagents

Bis-(2-ethoxyethyl) ether was purified and dried according to the procedure outlined in Vogel (21).

p-Cresol was distilled in vacuum and the middle fraction used.

p-Ethylphenol and *p*-*n*-propylphenol were prepared by the Martin modification (12, 21) of the Clemmensen reduction of purified *p*-hydroxyacetophenone and *p*-hydroxypropiophenone, respectively.

p-*n*-Butylphenol was prepared by sulphonating the pure hydrocarbon (21).

p-*n*-Hexylphenol was prepared according to the method of Sandulesco and Girard (17). The ester was first formed and then rearranged.

p-Isoamylphenol was prepared according to a modification of the procedure of Klages (11, 5).

The remaining chemicals used were obtained from Eastman Organic Chemicals, New York, and from Bios Laboratories, Inc., 17 West 60th Street, New York 23. They were checked for purity.

p-tert-Octylphenol was kindly donated by Rohm and Haas Company, Philadelphia 5, Pennsylvania, and was used without further purification.

2. Preparation of Polymers

Polymerizations of the p-alkylphenols and formaldehyde were carried out in pyrex combustion tubes having an inside diameter of 19 mm. The following procedure is representative of that used in all polymerizations.

To a mixture of purified *p*-cresol (10.813 gm., 0.100 mole) and *s*-trioxane (3.026 gm., 0.101 mole as formaldehyde) there was added a solution of 5 ml. of bis-(2-ethoxyethyl) ether containing 0.20 gm. of *p*-toluenesulphonic acid monohydrate. The reaction mixture (in the presence of nitrogen) contained in a sealed Carius tube was thoroughly mixed and heated in a Carius bomb furnace for 20 hr. at 130°.

After the *p*-alkylphenol–formaldehyde polymer was removed from the tube, it was air-dried and then finely pulverized. An amount of 4 gm. of the crude polymer (slightly colored) was added to 100 ml. of N,N-dimethylformamide and the mixture then heated at 80–90° for about 10 min. Undissolved polymer was removed by filtration with a coarse sintered glass funnel or filter paper. The clear filtrate was added dropwise with rapid stirring to 2 liters of water containing 5 ml. of concentrated hydrochloric acid (to cause settling of the polymer). The almost completely colorless polymer, removed by filtration, was then washed with water until free of chloride and dried at 60° under vacuum over phosphorus pentoxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/04/12
For personal use only.

3. Viscosity Determinations of Polymers

All viscosities were carried out using a Fenske (A.S.T.M. No. 50) viscometer. The specific viscosity of 0.500 gm. of each dried polymer in 100 ml. of N,N-dimethylformamide at 25° (±0.05°) was taken.

4. Softening Points of Polymers

The softening points of the polymers were taken in capillary tubes which were heated in a copper melting point block fitted with a light and lens for illumination and observation (7). The approximate softening point of each polymer was determined by raising the temperature of the melting point block by 5° intervals and noting the temperature interval in which a new sample softened in one minute. The softening points recorded are those at which all of each polymer fully underwent a change in physical state. Part of the polymer usually softened at a temperature considerably lower than that reported. When the polymers were heated gradually, no softening points could be obtained. No claim to quantitative accuracy of the softening points of the polymers is made.

5. Infrared Spectrophotometric Analyses

A Perkin-Elmer Model 21 double-beam recording spectrophotometer with a sodium chloride prism was used to obtain the spectra presented in Figs. 1 to 5. Most of the samples were run as 5% solutions in chloroform. Any polymer samples which were partially soluble in chloroform were also run as Nujol mulls and are so noted on the spectra concerned.

The authors are indebted to the British Columbia Research Council for the infrared analyses.

SUMMARY

Polymerization of *p*-cresol with formaldehyde in sealed tubes resulted in polymers having almost double the molecular weight of those obtained in open systems. In closed systems higher molecular weight polymers were obtained from *p-sec*-butylphenol and *p-sec*-amyphenol than from *p*-cresol. A polymer obtained from *p-sec*-amyphenol and formaldehyde (η_{sp} 0.112) was found to be much more stable to heat than one from *p*-cresol–formaldehyde (η_{sp} 0.091). Infrared studies of the polymers showed that two of the absorption bands present in the original *p*-cresol–formaldehyde polymer (at 1095 and 1670 $cm.^{-1}$) were not present in the spectrum of the same polymer subsequently heated at 182° for three hours. The spectra of the original and heat-treated *p-sec*-amylphenol–formaldehyde polymers were essentially the same.

ACKNOWLEDGMENT

The authors wish to thank the National Research Council of Canada for a grant in support of this research.

NOTE

SUR LE SPECTRE ULTRAVIOLET DE L'ACIDE PERACÉTIQUE ET L'HYDROLYSE DES PERACÉTATES

PAR PAUL A. GIGUÈRE ET A. W. OLMOS[1]

Il ne semble pas exister dans la littérature de données précises sur l'absorption ultraviolette de l'acide peracétique. Egerton et ses collaborateurs (2) rapportent avoir mesuré l'absorption d'une solution à 75% et l'avoir trouvée à peu près égale à celle de l'acide acétique, ce qui paraît surprenant a priori étant donné la grande opacité du groupement peroxydique dans l'ultraviolet. Comme nous avions déjà préparé ce composé à un assez haut degré de pureté afin d'étudier sa structure moléculaire au moyen de l'infrarouge (4) nous avons jugé bon de mesurer en même temps son spectre ultraviolet.

La préparation de l'acide peracétique à 97% a déjà été décrite en détail. La soude qui servit à neutraliser les solutions fut préparée à partir de sodium métallique et d'alcool éthylique absolu; le produit de l'hydrolyse était ensuite dosé par l'acide phtalique solide. En général les solutions semblaient parfaitement stables, même sous l'action de l'ultraviolet dans le spectrophotomètre (Modèle DU de Beckman). L'apparition occasionnelle de bulles d'oxygène sur les parois de la cuvette d'absorption entrainait inévitablement le rejet de l'échantillon. Toutes les mesures furent faites avec des solutions fraîchement préparées et chaque spectre fut enregistré deux fois afin de s'assurer qu'il ne se produisait aucune décomposition appréciable.

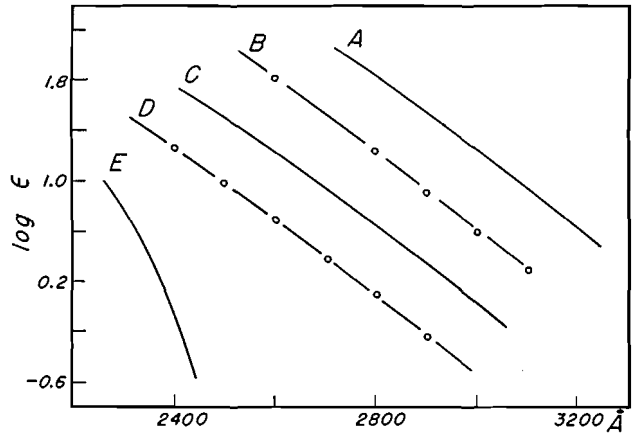

FIG. 1. Absorption ultraviolette de solutions d'acide peracétique et de peracétates. A. Ion perhydroxyle. B. Ion peracétate. C. Peroxyde d'hydrogène. D. Acide peracétique. E. Acide acétique.

[1]*Boursier Cominco. Adresse actuelle*: *St. Francis Xavier University, Antigonish, N.S.*

Les courbes de la figure 1 donnent les coefficients d'extinction d'après la loi de Beer, $\log I/I_0 = -\epsilon\, c\, d$, où les concentrations, c, sont en moles par litre et l'épaisseur de l'échantillon, d, est en cm. Comme pour le peroxyde d'hydrogène, dont le spectre bien connu (6) est reproduit ici pour fin de comparaison, l'absorption ultraviolette de l'acide peracétique ne présente qu'un seuil continu sans aucune indication de maximum. Il en est de même des ions correspondants, O_2H^- et CH_3COOO^-, dont l'absorption est toutefois beaucoup plus forte que celle des molécules non dissociées. On sait par ailleurs que les solutions de soude sont transparentes jusqu'à 2300 Å environ.

L'acide peracétique dissous dans un solvant indifférent (iso-octane) absorbe presque de la même façon qu'en solution aqueuse, ce qui confirme bien que les peracides sont des acides assez faibles. En effet, Everett et Minkoff (3) ont trouvé récemment par titration potentiométrique une valeur de 8.2 pour le pK de l'acide peracétique. Ce résultat est en tout point conforme aux nôtres, comme le montrent les données du tableau I, où les pH de solutions partiellement neutralisées ont été calculés à partir de l'équation de Henderson, d'abord d'après la composition,

TABLEAU I

pH DES SOLUTIONS DE PERACÉTATES ALCALINS

Base / Acide	pH, d'après la composition	ϵ	pH, d'après l'absorption
0	4.7	2.58	—
0.05	6.9	3.75	6.9
0.1	7.2	4.97	7.1_5
0.2	7.6	6.97	7.4
0.3	7.8	10.8	7.7_5
0.5	8.2	17.0	8.2_5
0.7	8.5_5	23.1	8.5
1.0	10.4	33.6	—

$$\mathrm{pH} = \mathrm{p}K + \log([\mathrm{sel}]/[\mathrm{acide}]) \qquad [1]$$

puis d'après les coefficients d'extinction ϵ à 2700 Å,

$$\mathrm{pH} = \mathrm{p}K + \log[(\epsilon - \epsilon_{HA})/(\epsilon_{A^-} - \epsilon)], \qquad [2]$$

ϵ_{HA} étant le coefficient correspondant de l'acide pur (en solution environ 0.08 molale) et ϵ_{A^-}, celui du mélange équimoléculaire soude-acide.

A la suite de leurs travaux sur la vitesse d'oxydation de l'acide *O*-iodobenzoique par l'acide peracétique Boëseken et Wicherlink (1) ont conclu que la décomposition de ce dernier par un excès de base caustique procède en deux étapes:

$$CH_3COOOH + NaOH \rightarrow CH_3COONa + H_2O_2 \qquad [3]$$

et

$$H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2. \qquad [4]$$

Dans les conditions de leurs expériences, soit par addition de 5 à 10 cc. de soude (variant de 20 à 50%) à 1 cc. d'acide peracétique à 10%, l'hydrolyse

[3] semblait complète en quelques minutes tandis que la décomposition du peroxyde d'hydrogène était alléatoire. Leur conclusion était basée sur le fait que ces solutions ne libéraient pas d'iode lors de l'addition d'une solution acide de KI, réaction connue sous le nom de Riesenfeld-Liebhafsky (6). Il est maintenant évident qu'une telle conclusion est erronée. En effet, si l'hydrolyse était aussi rapide que prétendu, les courbes d'absorption de solutions de peracide partiellement neutralisées ne devraient pas dépasser celles du peroxyde d'hydrogène (courbe C, Fig. 1). Bien plus, nous avons trouvé que l'addition d'un grand excès de soude (6:1) à l'acide peracétique n'augmente pas le coefficient d'absorption au delà de la courbe C alors que dans l'hypothèse de l'hydrolyse [3] l'absorption devrait tendre vers celle de l'ion O_2H^- (courbe A). Récemment, Partington et Fathallah (5) ont prouvé qu'un test de Riesenfeld-Liebhafsky *négatif* n'est pas valide dans le cas des perborates et des percarbonates; nos résultats confirment bien qu'il en est de même pour les peracétates.

THE PREPARATION OF D-*ARABO*PENTURONIC ACID AND D-*THREO*- AND D-*ERYTHRO*-TETRURONIC ACIDS[1]

BY P. A. J. GORIN[2] AND A. S. PERLIN

ABSTRACT

D-Glucurono-γ-lactone, D-galacturonic acid, and potassium D-glucuronate have been degraded in good yield to D-*arabo*penturonic, D-*threo*tetruronic, and D-*erythro*tetruronic acids, respectively, using lead tetraacetate in acetic acid solvent as the reagent.

INTRODUCTION

Earlier papers (11, 12) have described lead tetraacetate as a reagent useful for the stepwise degradation of sugars. It has been shown, for example, that D-glucose and L-sorbose may be degraded respectively to D-erythrose and L-glyceraldehyde in excellent yield. In the present paper it is shown that a similar reaction can be utilized as a convenient method for preparing D-*arabo*-penturonic acid and D-*erythro*- and D-*threo*-tetruronic acids from the related higher-order member of the series. D-*Arabo*penturonic acid and its barium salt have been prepared by Machida (8) from 2,3-*O*-isopropylidene-D-mannono-γ-lactone by lead tetraacetate oxidation followed by acid hydrolysis. D-*Erythro*-tetruronic acid (3) and L-*threo*tetruronic acid (4) have been shown to be present in the ozonolysis products of the enol of 5-keto-4-deoxy-D-mannosaccharo-3,6-γ-lactone and the corresponding D-gluco-derivative, respectively. The 2,3-di-*O*-acetyl methyl ester of the latter uronic acid has also been reported (7).

Trial experiments showed that D-glucurone in acetic acid containing a little water (1) rapidly consumed one mole of lead tetraacetate oxidant. Under similar conditions D-galacturonic acid took up 2.2 moles and potassium D-glucuronate 1.9 moles of oxidant; thereafter the uptakes of the oxidizing agent were relatively slow. These amounts of lead tetraacetate consumed during the initial rapid stage of the reaction were consistent with virtually stoichiometric conversion of the compounds to penturonic and tetruronic acids. Accordingly, the oxidations were repeated on a preparative scale.

The product from D-glucurone (I), after oxidation with one mole of lead tetraacetate followed by hydrolysis of the formate ester group, was shown

[1]*Manuscript received February 3, 1956.*
Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan, Canada. Issued as Paper No. 219 on the Uses of Plant Products and as N.R.C. No. 3942.

to contain both D-*arabo*penturono-lactone (II) and D-*arabo*penturonic acid (III). This mixture was characterized as follows: reaction of the mixture with diazomethane in ethereal methanol gave a sirupy mixture of methoxyl content 6.9%, corresponding to 0.35 equivalents of free acid and 0.65 equivalents of lactone in the original oxidation product. Also, reduction of the lactone–acid mixture gave mainly crystalline D-arabitol (13) and a trace of D-lyxono-γ-lactone (detected on a paper chromatogram). Treatment of the oxidation product with acetone containing a little sulphuric acid followed by methylation with diazomethane in methanol–ether gave, in small yield, a crystalline material which was identified as 1,2-*O*-isopropylidene-D-*arabo*-penturonic acid methyl ester. The above mixture with hot methanolic hydrogen chloride gave methyl-D-*arabo*pentofururonoside methyl ester which was purified by distillation. Sirupy D-*arabo*penturonic acid could be obtained from this substance by hydrolysis with hot aqueous formic acid and was characterized by conversion with aqueous sodium borohydride to crystalline D-lyxono-γ-lactone (2). The structure of the methyl ester fururonoside was confirmed by reduction with aqueous sodium borohydride to methyl-αβ-D-arabofuranoside which was hydrolyzed in hot aqueous formic acid to D-arabinose, characterized as its crystalline toluene-*p*-sulphonylhydrazone (6).

D-Galacturonic acid (IV) was oxidized with two moles of lead tetraacetate. The product appeared to be a monoformate ester from its characteristic infrared spectrum, with strong peaks at 1725^{-1} and 1170^{-1} cm. (15), and from alkaline saponification data. Since hydrolysis of the formate ester derivative occurred on standing, it is possible that the oxidation product originally

For personal use only.

contained more than one formate group and partly hydrolyzed before the reaction mixture could be worked up. A separate oxidation under similar conditions, followed by hydrolysis of the formate esters, furnished in very good yield D-*threo*tetruronic acid (V) which gave a single spot on a paper chromatogram with the *p*-anisidine hydrochloride spray (5). Its R_F value was less than D-*arabo*penturonic acid, thus suggesting that the tetruronic acid exists in solution as the dimer. The uronic acid was characterized as its crystalline 2,4-dinitrophenylhydrazone and by conversion on sodium borohydride reduction to D-threonolactone which gave crystalline D-threonic acid phenylhydrazide after treatment with ethanolic phenylhydrazine (9). Methanolic hydrogen chloride reacted with D-*threo*tetruronic acid to give the methyl ester dimethyl acetal, which was purified by distillation.

Oxidation of potassium D-glucuronate (VI) in acetic acid with two moles of lead tetraacetate afforded, in about 50% yield, a product which contained mainly D-*erythro*tetruronic acid (VII). On a paper chromatogram the tetruronic acid moved at practically the same speed as D-*threo*tetruronic acid and thus also appears to be dimeric in solution. A small proportion of a faster moving compound, probably due to overoxidation, was shown to be present. The uronic acid was characterized by reduction with aqueous sodium borohydride, to give crystalline L-erythrono-γ-lactone (14). Also, cold methanolic hydrogen chloride converted the tetruronic acid to the methyl ester dimethyl acetal which could be purified by distillation.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper using *n*-butanol–ethanol–water (40:11:19 v/v) and ethyl acetate – acetic acid – formic acid – water (18:3:1:4 v/v) as solvents. The terms R_{gal}, R_{rh} are used to denote distances travelled on the paper chromatogram by a compound relative to galactose and rhamnose, respectively. Evaporations were carried out under reduced pressure at 40°C. Optical rotations were measured at 27°C.

Oxidation of D-*Glucurono-γ-lactone with Lead Tetraacetate*

D-Glucurone (25 mgm.) was dissolved in water (0.2 cc.) and added to acetic acid (25 cc.). The solution was treated with a 1% solution of lead tetraacetate in acetic acid (25 cc.). At intervals aliquots (3 cc.) of the mixture were removed and added to an aqueous solution (10 cc.) containing potassium iodide (0.7 gm.) and sodium acetate (4 gm.). The iodine liberated was titrated with 0.1 *N* sodium thiosulphate. A blank determination was also carried out. The following results were obtained:

Oxidation time (min.)	2	5	10	30	60	131
Molar uptake of lead tetraacetate	0.99	1.01	1.04	1.08	1.18	1.40

On a preparative scale finely powdered D-glucurone (3.56 gm.) was stirred vigorously in a solution of lead tetraacetate (12.6 gm.; 1.4 equivalents) in acetic acid (350 cc.). After six minutes the suspension had dissolved and 10%

oxalic acid in acetic acid (30 cc.) was added to decompose excess oxidant. After it was stirred for 30 min. the solution was filtered and the filtrate evaporated to a sirup which was dissolved in water (50 cc.). After 18 hr. the solution was treated with Amberlite IR-120 and evaporated to a sirup (3.23 gm.). The product, detected by the *p*-anisidine hydrochloride spray (5) after running on a paper chromatogram in the acidic solvent, gave much streaking, perhaps because of the ready conversion of the lactonic material to the free D-*arabo*-penturonic acid. The sirup had, on successive days, $[\alpha]_D$ +57°, +55°, +52°, +51°, and +49° (*c*, 3.43, water).

To determine the proportion of lactone to free acid in the mixture the sirup (293 mgm.) was dissolved in methanol (30 cc.) and ethereal diazomethane added until the yellow color persisted. The solution was evaporated to a sirup which was dissolved in acetone. A little insoluble material was filtered off and the filtrate was evaporated to a sirup (282 mgm.) which had –OMe 6.9%. This value corresponds to 0.35 equivalents of free acid and 0.65 equivalents of lactone in the starting material. When the sirup was run on a paper chromatogram using the neutral solvent two spots with R_{rh} 1.26 and R_{rh} 1.48 of roughly equal intensity were detected by spraying with ammoniacal silver nitrate (10).

D-*Arabitol*

The lead tetraacetate oxidation product from D-glucurone (264 mgm.) in water (10 cc.) was treated dropwise with a solution of sodium borohydride (150 mgm.) in water (10 cc.). After 18 hr. excess reductant was destroyed with acetic acid, the solution was passed through a column of Amberlite IR-120 and evaporated to dryness. The residue was dissolved in methanol and the solution evaporated to a sirup, the process being repeated six times in order to remove boric acid as volatile methyl borate. The product (245 mgm.) gave, on a paper chromatogram run with the ethyl acetate – acetic acid – water (9:2:2 v/v) solvent, a strong spot (R_{gal} 1.4) corresponding to arabitol and a small one (R_{gal} 2.0) corresponding to lyxono-γ-lactone (ammoniacal silver nitrate spray). It crystallized and was recrystallized twice from ethyl acetate – methanol and then from ethanol. The crystals (72 mgm.), m.p. 99–101°C., $[\alpha]_D$ +7° (*c*, 11.0, saturated aqueous borax), undepressed on admixture with authentic D-arabitol, gave the same X-ray powder diagram as D-arabitol. Calculated for $C_5H_{12}O_5$: C, 39.47%, H, 7.95%; found: C, 39.43%, H, 7.99%.

*1,2-O-Isopropylidene-*D*-arabopenturonic Acid Methyl Ester*

The *arabo*penturonic acid – lactone mixture (145 mgm.) was shaken for 18 hr. in acetone (20 cc.) containing sulphuric acid (0.1 cc.). The solution was neutralized with barium carbonate, filtered, and evaporated to a white solid. The residue was dissolved in water, treated with Amberlite IR-120, and the solution evaporated to a sirup (178 mgm.). The product was dissolved in methanol and treated with ethereal diazomethane until the yellow color persisted. The solvents were evaporated off and the resulting sirup (192 mgm.) partly crystallized. The crystals were isolated and recrystallized from ether–pentane to give long colorless prisms (26 mgm.), m.p. 133–134°C., $[\alpha]_D$ +67°

(*c*, 1.0, ethanol); non-reducing to Fehling's solution. Calculated for $C_9H_{14}O_6$: C, 49.54%, H, 6.47%; found: C, 49.62%, H, 6.36%. The poor yield is probably accounted for by the small proportion of free D-*arabo*penturonic acid present in the starting material.

Methyl D-*Arabopentofururonoside Methyl Ester*

The sirup containing D-*arabo*penturonic acid and its lactone (291 mgm.) was dissolved in 0.5% methanolic hydrogen chloride (5 cc.) and refluxed for five minutes. The solution was neutralized (Ag_2CO_3) and evaporated to a sirup (339 mgm.), which did not reduce Fehling's solution. Distillation (bath temperature 140°C. at 1 mm.) gave the methyl ester glycoside as a sirup (83% of sirup distilled), n_D^{21} 1.4723, $[\alpha]_D$ +19° (*c*, 2.9, ethanol). Calculated for $C_7H_{12}O_6$: C, 43.75%, H, 6.29%, –OMe, 32.3%; found: C, 44.10%, H, 6.23%, –OMe, 33.3%.

D-*Arabopenturonic Acid*

The methyl ester methyl fururonoside (127 mgm.) was converted to D-*arabo*penturonic acid by heating at 100°C. for 10 hr. in water (2 cc.) containing formic acid (0.2 cc.). The solution was evaporated to a sirup (105 mgm.), $[\alpha]_D$ +22° (*c*, 2.6, water), which gave on a paper chromatogram (acid solvent) a gray-brown spot with R_{rh} 0.42 using the *p*-anisidine hydrochloride spray.

D-*Lyxono-γ-lactone*

D-*Arabo*penturonic acid obtained by acid hydrolysis of its methyl ester methyl fururonoside (134 mgm.) was dissolved in water (10 cc.) and added to an aqueous solution (10 cc.) of sodium borohydride (250 mgm.). After 18 hr. the reaction mixture was worked up as in the preparation of arabitol (above) and the final sirup was heated at 100°C. for six hours to promote lactonization. On a paper chromatogram (neutral solvent; ammoniacal silver nitrate spray) the product showed mainly lyxono-γ-lactone and a trace of material corresponding to arabitol. The sirup crystallized and it was recrystallized thrice from ethyl acetate. Yield 23 mgm., m.p. and mixed m.p. 108–110°C., and $[\alpha]_D$ +70° (*c*, 4.0, water). The product gave an X-ray diffraction pattern similar to that of D-lyxono-γ-lactone. Calculated for $C_5H_8O_5$: C, 40.54%, H, 5.44%; found: C, 40.67%, H, 5.49%.

D-*Arabinose*

The distilled methyl ester of methyl-D-*arabo*pentofururonic acid (158 mgm.) in ice cold water (10 cc.) was added during 10 min. to ice cold aqueous sodium borohydride (200 mgm. in 10 cc.). After 18 hr. at 0°C. and 10 hr. at 27°C. the reduction product was isolated as in the preparation of arabitol and the free carboxyl groups were esterified with ethereal diazomethane. A second treatment of the methyl ester with sodium borohydride was then carried out. The final product was dissolved in water, passed through IR4B to remove the unchanged acid, and evaporated to a sirup (116 mgm.). On a paper chromatogram (neutral solvent) it moved with R_{rh} 1.2 (spray: ammoniacal silver nitrate). On detection with the *p*-anisidine hydrochloride spray a pink spot of similar speed was observed. It corresponded to methyl-αβ-arabofuranoside.

The methyl-$\alpha\beta$-D-arabofuranoside (116 mgm.) was hydrolyzed in water (4 cc.) containing formic acid (1 cc.) at 100°C. for two hours. The solution was evaporated to a sirup which was dissolved in water and kept at 100°C. for two hours to hydrolyze formate esters. On evaporation the sirup obtained (105 mgm.) was found by paper chromatography to contain only arabinose (neutral solvent; sprays: *p*-anisidine hydrochloride and ammoniacal silver nitrate). The sirup crystallized and the material was twice recrystallized from ethanol. Yield 30 mgm., m.p. *ca.* 147°C.

Since the melting point of the D-arabinose was low, it (16 mgm.) was refluxed for 30 min. in methanol (10 cc.) containing toluene-*p*-sulphonylhydrazine (1.2 equivalents; 24 mgm.). The product was recrystallized from methanol. Yield 10 mgm., m.p. and mixed m.p. 150–152°C. Calculated for $C_{12}H_{18}O_6N_2S$: C, 45.28%, H, 5.70%; found: C, 45.27%, H, 5.705%. The crystals gave an X-ray powder diagram which was identical with that of authentic D-arabinose toluene-*p*-sulphonylhydrazone.

D-Threotetruronic Acid

The rate of reaction of lead tetraacetate with D-galacturonic acid in acetic acid was followed in the manner described for the oxidation of D-glucurone. The following results were obtained:

Oxidation time (min.)	2	5	10	30	60	131
Molar uptake of lead tetraacetate	2.22	2.26	2.33	2.49	2.88	3.53

On a larger scale, D-galacturonic acid monohydrate (860 mgm.) in water (2 cc.) and acetic acid (100 cc.) was stirred vigorously with lead tetraacetate (3.6 gm.; 2 equivalents). After two minutes the solution had cleared and no oxidant remained. Water (100 cc.) was added followed by 10% oxalic acid in acetic acid (8.2 cc.). The precipitate which formed was filtered off with the aid of Celite and the filtrate was evaporated to a sirup which was dissolved in water (25 cc.). After 18 hr. the solution was passed through Amberlite IR-120 and the eluate evaporated to a friable light yellow solid (530 mgm.) with $[\alpha]_D$ $-11° \rightarrow +3°$ (18 hr.; constant value; *c*, 2.3, water). On a paper chromatogram (acidic solvent; spray: *p*-anisidine hydrochloride) a yellow-brown spot of R_{gal} 1.3 was obtained.

Formate Ester of D-Threotetruronic Acid

D-Galacturonic acid was oxidized with lead tetraacetate using the same amounts and conditions as above. Remaining excess lead was removed from the acetic acid solution by stirring with Amberlite IR-120 until no precipitate was produced on addition of oxalic acid in acetic acid. The mixture was evaporated to a sirup which was dissolved in ethyl acetate. A little insoluble material was separated by filtration and the filtrate was evaporated to a sirup which was kept overnight at 1 mm. pressure over potassium hydroxide. The product (497 mgm.) absorbed strongly in the infrared region at 1725 cm.$^{-1}$ and 1170 cm.$^{-1}$, characteristic of formate esters (1723 cm.$^{-1}$ and 1170–1200 cm.$^{-1}$) and was shown by saponification with alkali to contain 1.0 formate ester group, assuming a molecular weight of 162.

D-*Threotetruronic Acid 2,4-Dinitrophenylhydrazone*

The tetruronic acid (138 mgm.) was refluxed for 18 hr. in ethanol (40 cc.) containing 2,4-dinitrophenylhydrazine (204 mgm.; 1 equivalent) and acetic acid (1 cc.) and the solution was then evaporated to dryness. The residue was dissolved in warm aqueous ethanol from which crystals separated on cooling. Recrystallization from the same solvent gave ochre crystals (116 mgm.), m.p. 111–113°C. Calculated for $C_{10}H_{10}O_8N_4$: C, 38.22%, H, 3.21%; found: C, 37.99%, H, 3.165%.

D-*Threonic Acid Phenylhydrazide*

The tetruronic acid (140 mgm.) in water (10 cc.) was added to a solution of sodium borohydride (250 mgm.) in water (10 cc.). After 18 hr. reaction time the sirupy product (117 mgm.), isolated by the procedure described in the preparation of arabitol, was heated at 100°C. for eight hours in order to promote lactonization; it did not crystallize. On a paper chromatogram (neutral solvent; ammoniacal silver nitrate spray) the major spot had R_{rh} 1.3, and a fainter spot with R_{gal} <1, corresponding to unchanged acid, was also present. A portion of the sirup (58 mgm.) was refluxed for two minutes in ethanol (0.2 cc.) containing phenylhydrazine (36 mgm.) and then kept for 24 hr. at room temperature. The solution deposited crystals which were recrystallized from ethanol. Yield 15 mgm., m.p. 156–157.5°C. (D-erythronic acid phenylhydrazide (14) has m.p. 128°C.), and $[\alpha]_D$ −35° (*c*, 4.2, ethanol). Calculated for $C_{10}H_{14}O_4N_2$: C, 52.93%, H, 6.21%; found: C, 53.09%, H, 6.24%.

D-*Threotetruronic Acid Methyl Ester Dimethyl Acetal*

The tetruronic acid (201 mgm.) was refluxed for two minutes in 1% methanolic hydrogen chloride (10 cc.) and allowed to stand at room temperature for 18 hr. The solution was neutralized (Ag_2CO_3), filtered, and evaporated to a sirup which was distilled (bath temperature 120°C. at 1 mm.). The resulting sirup (177 mgm.) had $[\alpha]_D$ −27° (*c*, 2.3, ethanol) and n_D^{21} 1.4501. Calculated for $C_7H_{14}O_6$: C, 43.29%, H, 7.27%, $-OCH_3$, 46.9%; found: C, 43.42%, H, 7.25%, $-OCH_3$, 46.2%.

D-*Erythrotetruronic Acid*

The rate of oxidation of potassium D-glucuronate with $Pb(OAc)_4$ in acetic acid was followed using the method described for the oxidation of D-glucurone. The following results were obtained:

Oxidation time (min.)	2	4	7	15	22
Molar uptake of lead tetraacetate	1.92	2.16	2.37	2.53	2.62

Potassium D-glucuronate (1.76 gm.) in water (2 cc.) was mixed with acetic acid (200 cc.), and lead tetraacetate (7.4 gm.; 2.2 equivalents) added with vigorous stirring. When the lead tetraacetate had dissolved, water (200 cc.) was added followed by 10% oxalic acid in acetic acid (17.6 cc.). The precipitate was filtered off, and the filtrate evaporated to a sirup which was dissolved in water (25 cc.). After 18 hr. the solution was passed through Amberlite IR-120 and the eluate evaporated to a sirup (516 mgm.), $[\alpha]_D$ +16° → +18° (18 hr.;

constant value; *c*, 2.32, water). On a paper chromatogram (acidic solvent; *p*-anisidine hydrochloride spray) the main spot was yellow-brown, with R_{gal} 1.4 and also there was a reddish brown spot of R_{rh} 1.3.

D-*Erythrono-γ-lactone*

The tetruronic acid (106 mgm.) was reduced with aqueous sodium borohydride as described for the preparation of D-threonolactone from D-*threo*-tetruronic acid. The sirupy product (93 mgm.) crystallized after distillation (1 mm. pressure). The distillate, on a paper chromatogram (neutral solvent; ammoniacal silver nitrate spray), gave a single spot corresponding to erythrono-γ-lactone. The crystals were separated by tiling and were recrystallized twice from benzene–ethanol. Yield 7 mgm., m.p. 99–102°C., $[\alpha]_D$ +73° (*c*, 1.3, water). Calculated for $C_4H_6O_4$: C, 40.68%, H, 5.12%; found: C, 40.73%, H, 5.19%. The X-ray diffraction pattern of the product was identical with that of D-erythrono-γ-lactone.

D-*Erythrotetruronic Acid Methyl Ester Dimethyl Acetal*

The sirupy tetruronic acid (230 mgm.) was dissolved in 1% methanolic hydrogen chloride (5 cc.) which was then refluxed for a few seconds and left at 27°C. for 24 hr. The solution was neutralized (Ag_2CO_3), filtered, and evaporated to a sirup which was distilled at 1 mm. pressure (bath temperature 120°C.) to give a sirup (175 mgm.), n_D^{21} 1.4557 and $[\alpha]_D$ +40° (*c*, 2.7, ethanol). Calculated for $C_7H_{14}O_6$: C, 43.29%, H, 7.27%, $-OCH_3$, 46.9%; found: C, 43.27%, H, 7.23%, $-OCH_3$, 46.9%.

ACKNOWLEDGMENT

The authors thank Mr. J. A. Baignee for carbon and hydrogen microdeterminations, Miss A. Epp for preparation of infrared spectra, and Mr. T. M. Mallard for obtaining X-ray diffraction patterns.

FREE RADICALS BY MASS SPECTROMETRY

XI. THE MERCURY PHOTOSENSITIZED DECOMPOSITION OF C_2–C_4 OLEFINS[1]

By F. P. Lossing, D. G. H. Marsden,[2] and J. B. Farmer[2]

ABSTRACT

The mercury photosensitized (Hg^3P_1) decomposition of olefins has been examined using a reactor coupled directly to a mass spectrometer. The primary split of ethylene has been shown to be predominantly molecular, and that of propylene mainly into an allyl radical and a hydrogen atom. With 1-butene the split is predominantly at a C–C bond giving allyl and methyl radicals, although a rupture of a C–H bond occurs as well. With 2-butene and isobutene a C–H bond is broken. It is concluded that the allyl and methallyl radicals produced have large cross sections for reaction with excited mercury atoms.

INTRODUCTION

The use of mass spectrometers to detect free radicals in reacting systems has been described by a number of authors and has been reviewed in some detail in two recent publications (24, 26). The radicals have been produced by various means: pyrolysis in furnaces and on hot filaments, by reactions of hydrogen atoms, and in combustion flames. Although some 25 free radicals have been detected in pyrolytic reactions, the temperatures used in the production of the radicals are usually so high that only radicals with considerable thermal stability can be studied. In addition, the reactions of such radicals that are stable enough to be investigated are those corresponding to much higher temperatures than are customary in kinetic studies. It would be a great advantage if a means of producing radicals at lower temperatures could be employed.

NH_2 radicals and CN radicals have been detected in a continuously irradiated flow system by photographing the absorption spectrum (23). The absorption coefficients of most organic compounds are so small, however, that at low pressures very little energy is absorbed by a reactant which is flowing rapidly through an illuminated zone of reasonable proportions. The use of external reflectors to increase the path length is of little advantage at these pressures since the wall of the reaction vessel absorbs much more radiation than the reactant.

This difficulty could be overcome in part by taking advantage of the large absorption coefficient of mercury vapor for radiation of 2537 Å, as has been done in studies of photosensitized reactions. Preliminary work (8) has shown that mercury photosensitization permits the absorption of sufficient quanta to dissociate acetone in a fast flow system. At a partial pressure of a few microns in a stream of helium at 8 mm., acetone was dissociated to the extent of 50–80% in 0.002 sec. The detection of CH_3CO radicals as well as CH_3 radicals showed that relatively unstable radicals could be produced in appreciable amounts.

[2]*National Research Council of Canada Postdoctorate Fellow.*

In the present work an attempt has been made to use this technique to determine the primary products of dissociation of C_2–C_4 olefins upon collision with $Hg(^3P_1)$ atoms. The reaction conditions are much different from those ordinarily used in photosensitized studies, the partial pressure of reactant being only a few microns and the partial pressure of mercury much higher. The incident flux is greater than is customary. A large excess of helium is present. These factors make conditions more favorable for determining the primary step, but the subsequent reaction products may be quite different from those found at higher pressures and lower intensities.

Previous work on the photosensitized decomposition of olefins has been reviewed in detail (17, 26) and only a brief summary will be given here.

For ethylene a molecular split has been suggested (28) and a mechanism involving an excited ethylene molecule has been proposed (18):

$$C_2H_4 + Hg(^3P_1) \rightarrow C_2H_4^* + Hg(^1S_0) \quad [1]$$

$$C_2H_4^* \rightarrow C_2H_2 + H_2 \quad [2]$$

$$C_2H_4^* + C_2H_4 \rightarrow 2C_2H_4. \quad [3]$$

An alternative primary split is one leading to a vinyl radical and H atom (16):

$$C_2H_4 + Hg(^3P_1) \rightarrow C_2H_3 + H + Hg(^1S_0). \quad [4]$$

Evidence for the occurrence of reaction [4] has been found at 300°C. (19) but at lower temperatures the evidence supports the split by reactions [1] and [2]. The predominance of reactions [1] and [2] over reaction [4] has been recently demonstrated quite convincingly using mixtures of C_2H_4 and C_2D_4 (2, 4). There is evidence that the detailed reaction is more complex than written above (5, 2, 3).

The mercury photosensitized decomposition of propylene appears to proceed by the following mechanism (10):

$$C_3H_6 + Hg(^3P_1) \rightarrow C_3H_6^* + Hg(^1S_0) \quad [5]$$

$$C_3H_6^* \rightarrow C_3H_5 + H \quad [6]$$

$$C_3H_6^* + C_3H_6 \rightarrow 2C_3H_6. \quad [7]$$

The absence of an initial pressure rise led these authors to the conclusion that reaction [6] predominated over the analogue of reaction [2], presumably as a result of the weaker C–H bond in propylene. Although the quenching cross-section for propylene is slightly larger than for ethylene (6) the quantum yield is only about one-half that of ethylene (26).

The mercury photosensitized decompositions of the butenes have not been studied in as much detail. The main products of the reaction of 1-butene were 2-butene and a liquid polymer (12). At low pressures other products were found and the following mechanism was proposed:

$$1\text{-}C_4H_8 + Hg(^3P_1) \rightarrow 1\text{-}C_4H_8^* + Hg(^1S_0) \quad [8]$$

$$1\text{-}C_4H_8^* \rightarrow C_4H_7 + H \quad [9]$$

$$1\text{-}C_4H_8^* + 1\text{-}C_4H_8 \rightarrow 2\text{-}C_4H_8 + 1\text{-}C_4H_8. \quad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

The reaction of $Hg(^3P_1)$ atoms with 2-butene was found to be similar except that no isomerization to 1-C_4H_8 occurred (12). In the mercury photosensitized reaction of isobutene, a complex mixture of products was found (11, 1) and the following mechanism was suggested:

$$\text{iso-}C_4H_8 + Hg(^3P_1) \rightarrow \text{iso-}C_4H_8^* + Hg(^1S_0) \quad [11]$$

$$\text{iso-}C_4H_8^* \rightarrow \text{products} \quad [12]$$

$$\text{iso-}C_4H_8^* + \text{iso-}C_4H_8 \rightarrow 2\ \text{iso-}C_4H_8. \quad [13]$$

The nature of the products of reaction [12] could not be determined. A liquid polymer was found and was attributed to the following reaction:

$$\text{iso-}C_4H_8^* + \text{iso-}C_4H_8 \rightarrow C_8H_{16}. \quad [14]$$

EXPERIMENTAL

The Reactor

A diagram of the reaction system used is given in Fig. 1. It consisted of a mercury saturator, a reaction zone, and a low pressure mercury lamp. The

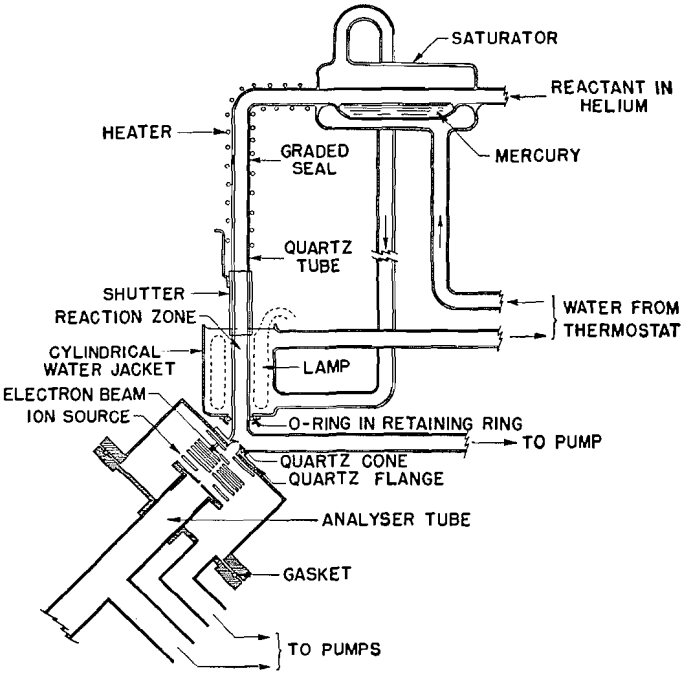

FIG. 1. The reaction system.

reactant gas, at a partial pressure of a few microns, was carried in a stream of helium at about 8 mm. pressure through the mercury saturator into the reaction zone. Just beyond the reaction zone the gas stream passed over a quartz cone containing a small orifice opening into the ionization chamber of a mass spectrometer. A suitable rate of flow was obtained by a pump of large capacity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

The reactor itself was constructed of a length of quartz tubing of 7 mm. inside diameter bent into a right angle. At the elbow thus formed a larger tube of quartz, suitably drawn down, was sealed. This tube was cut off and flared out to form a flange with a central hole, into which was sealed a quartz cone of the type described previously (21). The tip of this cone, which had been pierced by a spark to form a circular hole 28μ in diameter, projected about 2 mm. into the reactor tubing. By means of the flange, the reactor was cemented to the top of the vacuum jacket of the mass spectrometer tube with Apiezon W wax. This seal was sufficiently soft to prevent breakage of the quartz by differential expansion. A copper cooling coil (not shown in Fig. 1) soldered to the top of the vacuum jacket prevented the wax from becoming too soft during outgassing of the tube, or as a result of heating by the mercury lamp.

The Mercury Lamp

Since a high intensity of unreversed 2537 Å radiation was required to produce sufficient decomposition of reactant in a contact time of a millisecond, special consideration was given to the design of the low pressure mercury lamp. A number of designs, consisting of helices of quartz of various internal diameters, were tried, but all were inferior to the design shown in Fig. 2.

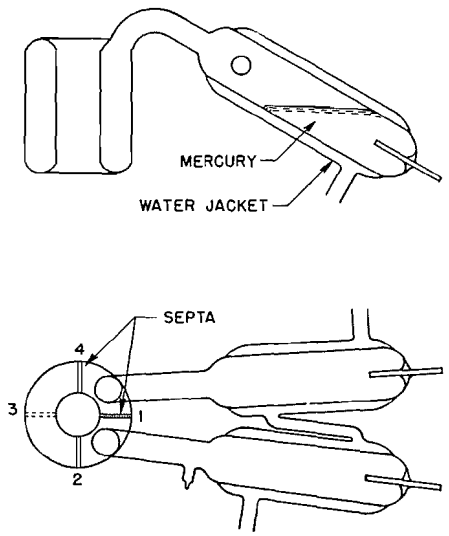

FIG. 2. The mercury lamp.

The body of the lamp consisted of two concentric cylinders of quartz tubing with internal diameters of 13 mm. and 23 mm. These were sealed together at the top and bottom to form an annular cell 36 mm. long. Four longitudinal septa were provided as shown in Fig. 2, the septa numbered 2 and 4 having a space at the bottom and that numbered 3 having a space at the top. Septum No. 1 extended the full length of the cell. The discharge was in this way forced to proceed in a zigzag path which filled the cell almost completely. The electrodes were water-cooled mercury pools. After being thoroughly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

outgassed by heating, the lamp was filled with neon at a pressure of 1.5 mm. When operated from a source of 220 v. d-c. through a series resistor the lamp was started by being touched with a Tesla coil. At a current of 4–5 amp. the voltage drop across the lamp was 90 v. To prevent self-reversal the body of the lamp and the electrodes required water cooling. Conditions for the maximum output of unreversed 2537 Å radiation could be rapidly determined by observing the extent of decomposition of ethylene flowing through the reactor. The maximum output was found to occur with the electrodes at about 10°C. and the body of the lamp at 55–60°C. It was found, rather surprisingly, that the partial pressure of mercury in the lamp was not determined by the temperature of the mercury pool electrodes. Even with the electrodes at 10°C. and the body of the lamp at 60°C., mercury slowly condensed in the latter. Evidently the pumping action of the current was able to overcome the rate of diffusion. It is interesting to note that the temperature of optimum output agrees quite well with that of 50°C. found for a low pressure lamp with iron electrodes (14) although the criterion for maximum output was not the same. In the present work only the unreversed 2537 Å line was effective, while in the work of Heidt and Boyles the output was measured by uranyl oxalate actinometry, which would respond to the wings of the line as well.

The vapor pressure of mercury at 60°C. is 25.2μ and with this partial pressure in the reactor the absorption of the 2537 Å line was probably complete in the 7 mm. diameter of the reactor tube. Owing to the rapid deposit of polymeric layers on the reactor at high reactant pressures it was not possible to measure the amount of ethylene decomposed under conditions of complete quenching. It was found, however, that a quantity of ethylene greater than that equivalent to 1.39 cc. (the illuminated volume) at 0.010 mm. could be decomposed in 0.001 sec., i.e. about 5×10^{17} molecules/sec. It is probable that the output of unreversed 2537 Å radiation falling on the reaction volume of 1.39 cc. was in excess of 10^{18} photons/sec., an amount roughly the same as that found by Heidt and Boyles.

The Water Circulating System

The arrangement shown in Fig. 1 for maintaining the body of the lamp and the reactor at 60°C. was found to be convenient. A cylindrical Pyrex water jacket was made with a hole in the bottom slightly larger than the outside diameter of the reactor tubing. A Pyrex retaining ring cemented over the hole served to hold a rubber O-ring, making a watertight seal around the reactor tube. This allowed the lamp and water jacket to be slid upward along the reactor tube so that the reactor could be cleaned by heating with a torch when polymeric deposits in the reactor reduced the transparency. Flowing oxygen through the reactor while flaming removed the most stubborn deposits.

Water connections to the mercury saturator and the thermostat were made by means of ball and socket ground joints which could be removed to allow the water jacket to be moved. It was found that contact of the cooling water with metal parts caused an opaque deposit to be formed on the lamp. Consequently distilled water was used, and the thermostat and connecting tubing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

were also made of glass. A glass centrifugal pump provided sufficient pressure to pump water through the jacket of the mercury saturator to the water jacket. The overflow from the latter returned to the thermostat. When the lamp was operating, the temperature of the reactor was a degree or so higher than that of the saturator. This served to prevent condensation of mercury in the reactor.

The Gas Flow System

The control of the helium flow and the addition of reactants at a constant proportion was the same as that described previously (20). Using a mechanical pump with a free air capacity of 140 liters/min., a flow through the reactor of 50–60 meters/sec. could be obtained with helium pressures of from 7 to 13 mm. The rate of flow was adjusted over the range of 10–60 meters/sec. by means of taps of various size in the pumping lead.

The Mass Spectrometer and Operation

The mass spectrometer has been described in earlier papers of this series (21, 20). The identification of the free radicals was done by the low electron energy method of Eltenton (7). In some cases the long periods of illumination required for the complete scanning of spectra at 50 v. resulted in the formation of sufficient polymer in the reactor to change the fraction of reactant decomposed during the time of scanning. This frequently interfered with the measurement of the spectra of the reaction products.

It has been assumed throughout this work that the appearance of a given ion at an electron energy appreciably less than that required to produce the ion from any identifiable stable compound present indicated the presence of a free radical with this mass. Where possible the identification was supplemented by a search for the corresponding dimerization product. It is, of course, possible that the appearance potential of a given ion from an excited molecule such as $C_3H_6^*$ or $C_4H_8^*$ might be lower than the normal appearance potential. It seems reasonable to suppose that in such an excited molecule the appearance potentials of all ions would be lowered by a similar amount. If this were detectable by the present apparatus it would lead to the spurious detection of "free radicals" of a mass number corresponding to each ionic species formed by electron impact on the excited molecule. No such effect was found in the present apparatus. The lifetimes of such excited molecules are short compared to those of free radicals, and an insignificant fraction would survive long enough to be struck by an electron.

Detection of H Atoms

A difficulty arose in the detection of hydrogen atoms produced in some of the reactions studied. In experiments in which hydrogen was reacted with Hg ($^3P_1$) atoms, the amount of reaction was much less than expected, H atoms being detected only in small amounts. It was concluded that the combination of H atoms to H_2 occurred rapidly, most probably on the walls of the ionization chamber. Consequently, a failure to detect H atoms among the products of decomposition of a compound was not a proof that they were not formed. On the other hand the formation of H_2 by reactions such as

$$H + RH \rightarrow H_2 + R \qquad [15]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

is undoubtedly too slow at 60°C. to form appreciable quantities of H_2 under the reaction conditions used. In earlier work with CH_3 radicals (15) it was found that even at 850°C. a small amount of methane found among the products of decomposition of mercury dimethyl did not arise from reactions such as

$$CH_3 + RH \rightarrow CH_4 + R \qquad [16]$$

but rather from reactions in the ion source. For this reason the formation of H_2 by reaction [15] at 60°C. was considered to be negligible.

Contact Times

In almost all the experiments described a standard pressure of helium of 7.8 mm. was used. The contact time was varied either by changing the pumping speed, or more conveniently by reducing the length of the illuminated zone by a cylindrical shutter of tantalum (Fig. 1).

RESULTS AND DISCUSSION

Ethylene

In the photosensitized decomposition of ethylene the only products of any importance were acetylene and hydrogen. No other products were found in the mass range 2–100 except for small peaks (~0.5% of C_2H_2 peaks) at mass 52 and 50. No radicals could be detected at mass 27 and no butadiene was formed. The extent of decomposition and the yields of hydrogen and acetylene for a typical experiment are given in Table I. The carbon balance has an

TABLE I

PHOTOSENSITIZED DECOMPOSITION OF ETHYLENE

C_2H_4 pressure (μ)		C_2H_4 reacted		Contact time	C_2H_2 found		H_2 found	
Lamp off	Lamp on	μ	%	(millisec.)	μ	Yield (%)	μ	Yield (%)
3.03	1.78	1.25	41.3	1.4	1.27	102	1.06	85

estimated error of 5% and the hydrogen balance is considerably more uncertain. It may be concluded that vinyl radical production, if it occurred, amounted to less than 3% of the total reaction. Experiments with higher pressures of ethylene also showed no sign of vinyl radical production. In a separate experiment in which acetylene was irradiated it was found to decompose hardly at all in the same contact time, so that no secondary reactions would be expected. These results constitute good evidence for a molecular process for the decomposition of ethylene at 60°C., and are in agreement with the recent experiments of Cvetanović and Callear (2, 4) in this respect.

Propylene

Under the same experimental conditions as with ethylene, the decomposition of propylene led to the formation of allyl radicals in considerable amounts as shown by a search at low electron energies. The dimer of allyl, 1,5-hexadiene, was also produced. Other products were allene in appreciable quantity, and traces of ethylene and acetylene. Since the mass spectrum of the allyl radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

in the mass 40 range was not determined, a quantitative measurement of the amount of allene could not be made and a carbon balance was not obtained. The extent of decomposition and the yield of hydrogen (presumably from H atom combination) are shown in Table II. It was possible to show in the following way that allene was produced mainly by a secondary reaction. At an electron energy of about 10 v., the mass 40 (allene) and 41 (allyl) peaks were free from contributions from other compounds and the ratio of their heights was proportional (but not equal) to the ratio of allene and allyl present. As the contact time was shortened by using the shutter, it was observed that the amount of allene decreased greatly while the amount of allyl decreased only slightly (Table II). A large decrease in allene production

TABLE II

PHOTOSENSITIZED DECOMPOSITION OF PROPYLENE

C_3H_6 pressure (μ)		C_3H_6 reacted		Contact time	H_2 found		Mass	Mass	Ratio
Lamp off	Lamp on	μ	%	(millisec.)	μ	Yield (%)	40	41	40/41
1.40	1.16	0.24	17.1	1.4	0.21	88	—	—	—
1.36	1.22	0.14	10.3	0.7	0.11	79	—	—	—
Low electron energy experiments				0.7	—	—	0.40	0.70	0.57
				0.4	—	—	0.10	0.62	0.16
				0.2	—	—	0.05	0.55	0.09

would be expected if it were produced from allyl by a secondary process, but not if it were produced in a primary molecular split of propylene. The relatively small decrease in the amount of allyl shows that the decrease in production resulting from the shorter contact time was nearly balanced by the decrease in reactions removing allyl. The high yield of hydrogen (Table II) indicates that the fate of most of the allyl radicals was to give a hydrogen atom. This also supports the view that allyl radicals were disappearing rapidly to form allene and an H atom. Three reactions by which this could occur may be considered:

$$CH_2{:}CH{\cdot}\dot{C}H_2 + H \rightarrow CH_2{:}C{:}CH_2 + H_2 \quad [17]$$

$$CH_2{:}CH{\cdot}\dot{C}H_2{}^* \rightarrow CH_2{:}C{:}CH_2 + H \quad [18]$$

$$CH_2{:}CH{\cdot}\dot{C}H_2 + Hg(^3P_1) \rightarrow CH_2{:}C{:}CH_2 + H + Hg(^1S_0). \quad [19]$$
$$\text{(or HgH)}$$

Reaction [17] is undoubtedly too slow at 60°C. to be effective. Such abstraction reactions are several orders of magnitude slower than dimerizations, and only a small proportion of allyl radicals had time to dimerize. The second reaction is improbable on energetic grounds. Of the 112 kcal. imparted by a $Hg(^3P_1)$ atom, about 77 kcal. (27) are required to break the $CH_2{:}CH{\cdot}CH_2$–H bond. The allyl radicals could have a maximum excitational energy of 35 kcal., neglecting the translational energy imparted to the H atom. From the heat of formation of allene, 45.9 kcal./mole at 25°C. (25), and of allyl, 32 kcal./mole (22), a dissociation energy of 65 kcal./mole can be derived for the C_3H_4–H bond in allyl. Even if this value were in error by more than a few kilocalories there is not sufficient energy available for a "hot" allyl to dissociate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12

For personal use only.

The third possibility, reaction [19], is generally not considered in conventional photosensitized reaction experiments because of the relatively low concentrations of radicals and excited mercury atoms. In the present work, however, the high intensity of radiation and the low pressure of olefin results in relatively large concentrations of radicals and excited mercury atoms, and collisions between these are not statistically negligible. It should be noted from the reactions given below that if reaction [19] did not occur, the yield of H_2 would be 50%, and if all allyl radicals were removed by this reaction, the yield would be 100%. A yield of 79%, as found, indicates that some $2\times(79-50)$ or 58% of the radicals had decomposed in this way. Since propylene itself was decomposed to the extent of 10.3% in a somewhat greater contact time, it would appear, if this interpretation is correct, that allyl radicals have a cross section for reaction with $Hg(^3P_1)$ atoms about five times larger than has propylene. This could arise from a larger collision cross section for quenching or a larger quantum yield, or from a combination of both.

On this basis the following reactions would account for the products found:

$$CH_2{:}CH\cdot CH_3 + Hg(^3P_1) \rightarrow CH_2{:}CH\cdot\dot{C}H_2 + H + Hg(^1S_0) \quad [20]$$

$$CH_2{:}CH\cdot\dot{C}H_2 + Hg(^3P_1) \rightarrow CH_2{:}C{:}CH_2 + H + Hg(^1S_0) \quad [19]$$

$$2CH_2{:}CH\cdot\dot{C}H_2 \rightarrow \text{1,5-hexadiene} \quad [21]$$

$$H + H + M \rightarrow H_2 + M. \quad [22]$$

The present work gives no direct indication as to whether reactions [20] and [19] proceed by formation of HgH or by excited molecule formation. As mentioned above, a large part of reaction [22] must proceed in the ion source.

Isobutene

The extent of decomposition of isobutene under the same experimental conditions as used with propylene and ethylene is given in Table III, along

TABLE III

PHOTOSENSITIZED DECOMPOSITION OF ISOBUTENE

Isobutene pressure (μ)		Isobutene decomposed		Contact time (millisec.)	H_2 found	
Lamp off	Lamp on	μ	%		μ	Yield (%)
1.75	1.57	0.18	10.4	1.4	0.10_1	56.0
1.72	1.61	0.11	6.5	0.7	0.05_6	50.0

with the yield of H_2 based on the isobutene decomposed. A search for radicals at low electron energy showed that a radical of mass 55 was produced in considerable amounts, and that methyl radicals were present in small amounts. Allene, an octadiene, and a pentene were also produced. The spectrum of the octadiene was similar to that of 2,5-dimethyl-1,5-hexadiene, the dimer of the β-methallyl radical (22). Of the two possible radicals of mass 55 which could be formed from isobutene

$$\dot{C}H{:}C\cdot CH_3 \quad \text{and} \quad CH_2{:}C\cdot\dot{C}H_2$$
$$\dot{C}H_3 \qquad\qquad\qquad\quad \dot{C}H_3$$

the second (β-methallyl) is capable of resonance stabilization because of its allylic structure, and the β-methallyl–H bond is correspondingly weak, 76 ± 3 kcal./mole (22). From this consideration and from the identity of the dimer, it is almost certain that the radical formed is β-methallyl. Considering the structure of isobutene, neither methyl radicals nor allene appear to be likely products of a primary split. They have, however, been identified as the products of thermal decomposition of β-methallyl radicals (22). In view of this it is reasonable to believe that they arise from the reaction of a β-methallyl radical with a $Hg(^3P_1)$ atom, in a manner analogous to reaction [19]. As with propylene, the decomposition of a radical carrying excitation energy left over from the primary split is unlikely on energetic grounds. From the heat of formation of allene, 45.9 kcal./mole (25), and that of β-methallyl radical, 21.3 ± 3 kcal./mole (22), and methyl radical, 32.6 kcal./mole (13), the dissociation energy of the C_3H_4–CH_3 bond in β-methallyl radical is 57 kcal./mole. From ΔH_f(isobutene) $= -3.3$ kcal./mole (25) and ΔH_f(β-methallyl) as above, D(β-methallyl–H) $= 76$ kcal./mole. Consequently the maximum excitation of a "hot" β-methallyl would be only 36 kcal.

The reactions which would account for the products found are then:

$$CH_2{:}C(CH_3)CH_3 + Hg(^3P_1) \rightarrow CH_2{:}C(CH_3)\dot{C}H_2 + H + Hg(^1S_0) \quad [23]$$

$$CH_2{:}C(CH_3)\dot{C}H_2 + Hg(^3P_1) \rightarrow CH_2{:}C{:}CH_2 + CH_3 + Hg(^1S_0) \quad [24]$$

$$2CH_2{:}C(CH_3)\dot{C}H_2 \rightarrow \text{2,5-dimethyl-1,5-hexadiene} \quad [25]$$

$$CH_3 + CH_2{:}C(CH_3)\dot{C}H_2 \rightarrow C_5H_{10} \quad [26]$$

$$H + H + M \rightarrow H_2 + M. \quad [22]$$

These reactions would lead to a yield of H_2 of 50%, in good agreement with that found (Table III). In addition to these products small amounts of propylene and a substance of mass 54 were found. It is difficult to understand how either of these products could be produced either as a primary reaction or by secondary reactions among the species identified. The formation of butadiene (mass 54) appears improbable since an extensive rearrangement would be required. One possible origin of a substance of mass 54 would be the removal of a hydrogen from β-methallyl to form methylene cyclopropane:

$$CH_2{:}\underset{\displaystyle CH_3}{\overset{|}{C}}\!-\!\dot{C}H_2 + Hg(^3P_1) \rightarrow CH_2{:}C\!<\!\begin{matrix}CH_2\\ CH_2\end{matrix} + H + Hg(^1S_0). \quad [27]$$

The preparation of methylene cyclopropane has been carried out (9) by removal of chlorine as follows:

$$CH_2{:}\underset{\displaystyle CH_2Cl}{\overset{|}{C}}\!-\!CH_2Cl \xrightarrow{Mg} CH_2{:}C\!<\!\begin{matrix}CH_2\\ CH_2\end{matrix} \quad [28]$$

This reaction is essentially similar to reaction [27].

The primary split, reaction [23], is the same as that suggested by previous workers (11) although the final products of the reaction are quite different.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

The products also differ from those found by Allen and Gunning (1). This is to be expected in view of the great difference in the isobutene pressure in the two experiments. The latter authors found evidence for excited molecule formation and it is probable that reaction [23] proceeds by this means. The dimer found by these authors may have been at least partly 2,5-dimethyl-1,5-hexadiene rather than a dimer of isobutene as they suggested.

2-Butene

In the photosensitized decomposition of 2-butene, a radical of mass 55, presumably the γ-methallyl radical $CH_3 \cdot CH{:}CH \cdot \dot{C}H_2$, was produced in considerable amounts. Other products were butadiene, hydrogen, some propylene, and possibly some allene. A dimer was also produced, whose spectrum was similar to the spectrum of 2,6-octadiene produced from γ-methallyl radicals previously (22). As no pure sample of 2,6-octadiene was available,

TABLE IV

PHOTOSENSITIZED DECOMPOSITION OF 2-BUTENE

2-Butene pressure (μ)		2-Butene decomposed		Contact time	H_2 found		Mass 54	Mass 55	Ratio
Lamp off	Lamp on	μ	%	(millisec.)	μ	Yield (%)	(low *E*)	(low *E*)	54/55
1.68	1.48	0.20	11.9	1.4	0.17	85.0	1.9	1.10	1.70
1.68	1.59	0.11	6.5	0.7	0.09_2	83.6	1.0	0.90	1.10

this identification was not completely certain. In order to establish whether butadiene was a primary product, the ratio of the 54 to 55 peaks at low electron energy was examined at different contact times. The ratio decreased but not as greatly as in the similar experiments with propylene. There is a possibility that some butadiene may be formed from 2-butene by a molecular process as well as by the decomposition of γ-methallyl radicals. As in the case of isobutene, the further decomposition of a "hot" radical can be ruled out. The dissociation energy of the γ-methallyl–H bond has been given as 80±3 kcal./mole (22) and the maximum excitation of the radical could be 32 kcal. From ΔH_f(butadiene) = 26.3 kcal./mole (25) and ΔH_f(γ-methallyl radical) = 26±3 kcal./mole (22), the butadiene–H bond in γ-methallyl radical would be 52 kcal./mole. Insufficient energy would be available for a "hot" radical to decompose spontaneously.

1-Butene

The extent of decomposition of 1-butene and the yield of hydrogen are shown for two contact times in Table V. A search at low electron energy showed that allyl and methyl radicals were present in abundance and a radical of mass 55 in moderate amounts. Other products were allene, 1,5-hexadiene, ethane, hydrogen, and small amounts of pentene, butadiene, and propylene. With higher pressures peaks at mass 91, 95, and 96 appeared, suggesting the presence of a heptadiene. Experiments using the shutter indicated that allyl,

TABLE V

PHOTOSENSITIZED DECOMPOSITION OF 1-BUTENE

1-Butene pressure (μ)		1-Butene decomposed		Contact time (millisec.)	H_2 found	
Lamp off	Lamp on	μ	%		μ	Yield (%)
2.42	1.87	0.55	22.7	1.4	0.17	31
2.43	2.08	0.35	14.4	0.7	0.10	29

methyl, and the radical of mass 55 were primary products. The latter was undoubtedly a methallyl radical, the two forms $CH_2{:}CH\cdot\dot{C}H\cdot CH_3$ (α) and $\dot{C}H_2\cdot CH{:}CH\cdot CH_3$ (γ) being resonance hybrids.

The spectra given in Fig. 3 illustrate the detection of the allyl and methallyl radicals formed from 1-butene. Fig. 3A shows a portion of the low electron energy spectrum of 1-butene with the lamp off. With the lamp on and the shutter completely withdrawn (Fig. 3B) the increase in the mass 40, 41, and 42 peaks shows the presence of allene, allyl, and propylene. With the shutter halfway in, as in Fig. 3C, the contact time was halved, and the propylene and allene peaks were greatly reduced, while the allyl peak remained almost unchanged. This shows that allene and propylene were products of secondary reactions. In Fig. 3D the spectrum was obtained at an electron energy low enough to avoid the formation of the $C_4H_7^+$ ion (mass 55) by electron impact. With the lamp on (Fig. 3E) and the shutter withdrawn, the increase in the mass 54 and 55 peaks indicates the presence of butadiene and methallyl radicals. With the shutter halfway in (Fig. 3F), the butadiene peak was considerably reduced, while the methallyl peak was only slightly changed. Fig. 3G shows the 50 v. spectrum of the dimers 1,5-hexadiene at mass 82, 81, and 67; pentene at mass 70; and peaks at 96, 95, and 91, possibly heptadiene, barely visible.

The formation of the methyl, allyl, and methallyl radicals as primary products indicates that two modes of splitting must occur as primary steps:

$$CH_2{:}CH\cdot CH_2\cdot CH_3 + Hg(^3P_1) \rightarrow CH_2{:}CH\cdot\dot{C}H_2 + CH_3 + Hg(^1S_0) \quad [29]$$

$$CH_2{:}CH\cdot CH_2\cdot CH_3 + Hg(^3P_1) \rightarrow CH_2{:}CH\cdot\dot{C}H\cdot CH_3 + H + Hg(^1S_0). \quad [30]$$

The other products can be accounted for by the following reactions:

$$CH_2{:}CH\cdot\dot{C}H_2 + Hg(^3P_1) \rightarrow CH_2{:}C{:}CH_2 + H + Hg(^1S_0) \quad [31]$$

$$CH_2{:}CH\cdot\dot{C}H\cdot CH_3 + Hg(^3P_1) \rightarrow CH_2{:}CH\cdot CH{:}CH_2 + H + Hg(^1S_0) \quad [32]$$

$$2CH_3 \rightarrow C_2H_6 \quad [33]$$

$$2CH_2{:}CH\cdot\dot{C}H_2 \rightarrow \text{1,5-hexadiene} \quad [34]$$

$$CH_3 + CH_2{:}CH\cdot\dot{C}H\cdot CH_3 \rightarrow \text{pentene} \quad [35]$$

$$CH_2{:}CH\cdot CH_2 + CH_2{:}CH\cdot\dot{C}H\cdot CH_3 \rightarrow \text{heptadiene} \quad [36]$$

$$CH_2{:}CH\cdot\dot{C}H_2 + H \rightarrow \text{propylene} \quad [37]$$

$$H + H + M \rightarrow H_2 + M. \quad [22]$$

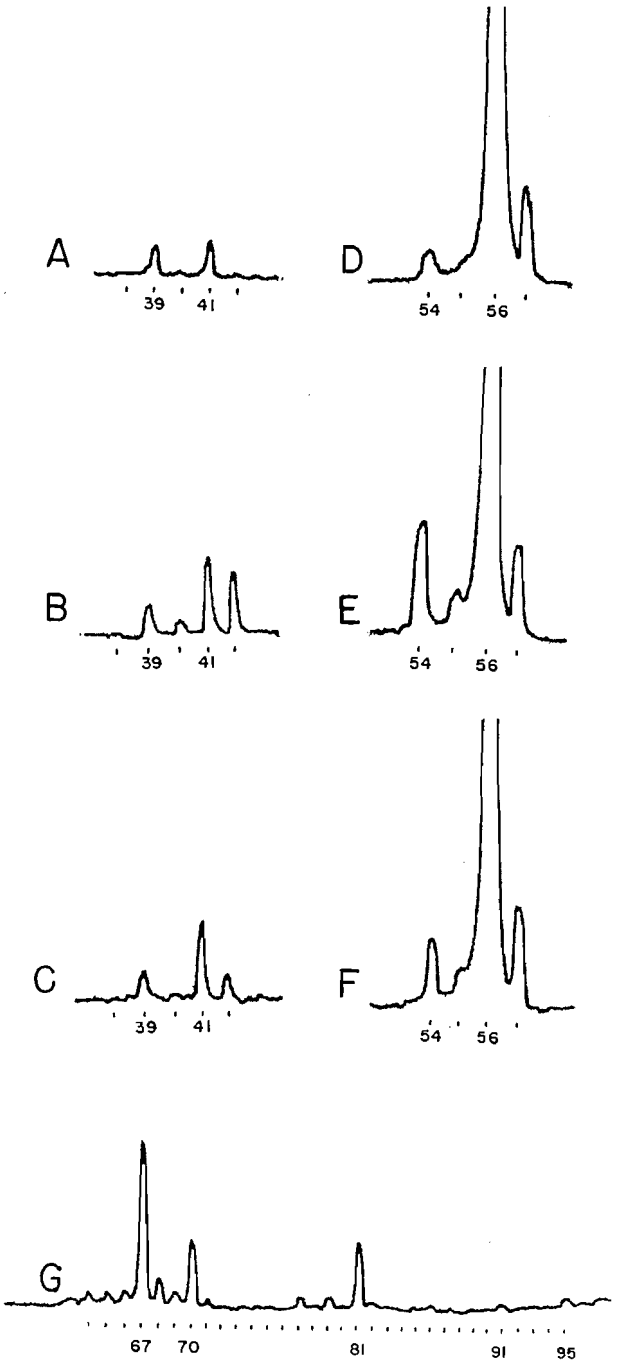

FIG. 3. Portions of mass spectra illustrating the detection of allyl and methallyl radicals in the decomposition of 1-butene. As described in the section on 1-butene, the propylene and butadiene are formed as secondary products.

It is interesting to compare the energies required for the two primary steps given above. From ΔH_f(allyl) = 32 kcal./mole (22), $\Delta H_f(CH_3)$ = 32.6 kcal./mole (13), ΔH_f(γ-methallyl) = 26 kcal./mole (22), ΔH_f(1-butene) = 0.280 kcal./mole (25), and ΔH_f(H) = 51.5 kcal./mole, the following bond dissociation energies can be derived:

$$D(\text{allyl–}CH_3) = 64 \text{ kcal./mole},$$

$$D(\text{methallyl–H}) = 77 \text{ kcal./mole}.$$

If the decomposition of 1-butene proceeds, as seems probable, by the formation of an excited molecule (26), then this molecule would suffer bond rupture after the time interval required for sufficient vibrational energy to become associated with a particular bond. Although the C–H bond is stronger than the C–C, the difference is only about 13 kcal., and it is not surprising that a molecule with 112 kcal. of excitation energy should be able to decompose by either mode. It is not possible from the present data to establish the relative probabilities of reactions [29] and [30], but the greater abundance of the ethane and hexadiene over the pentene and heptadiene, as well as the relative size of the radical peaks, indicates that the C–C split predominates. The low yield of H_2 compared with that found for propylene and 2-butene is also consistent with a smaller probability for the C–H split. The proportion of H_2 found is not much greater than was estimated above to result from the reaction of excited mercury atoms with the allyl radicals from propylene.

ACKNOWLEDGMENT

The authors wish to thank Dr. E. W. R. Steacie and Dr. R. J. Cvetanović for their interest and advice during the course of this work. The mercury lamp, the reactor, and many other components were constructed by Mr. George Ensell, to whose skill and experience the authors are greatly indebted.

RADIOIODINE EXCHANGE BETWEEN IODOSTEARIC ACID MONOLAYERS AND SUBSTRATE IODIDE[1]

By R. F. Robertson, C. A. Winkler, and S. G. Mason

ABSTRACT

Velocities of exchange of iodine between monolayers at the air/water interface of α-iodostearic acid and potassium iodide in the substrate have been measured over a range of monolayer and substrate concentrations and temperatures using a radioactive tracer technique. The pressure–area isotherms were also determined. The process was followed by measuring the decrease in counting rate immediately above the surface. It is shown theoretically that ions released to the substrate diffuse rapidly and do not contribute appreciably to the counting rate. The velocity of exchange was found to be first order in concentration of the surface phase and of higher but indeterminate order in concentration of potassium iodide. In the region of 18°C., where a transition from liquid-condensed to liquid-expanded film occurs, the reaction velocity constant undergoes a discontinuous increase. Activation energies of 8.0 and 10.8 kcal./mole were found for exchange in the condensed and expanded films respectively.

INTRODUCTION

The kinetics of chemical reactions occurring in monolayers at air/water interfaces have been studied by following changes in the surface potential (22), or in the area per molecule at constant pressure in the film (5). The reactions studied thus far have been limited to oxidation (4, 18, 22, 26), hydrolysis (5, 3, 16, 6, 27, 13, 28), and lactonization processes (12, 24). Both experimental methods involve indirect measurement of the changes in concentration of the reactants in the surface films from which the reaction velocity is computed. A more direct method of following such reactions is to use monolayers containing radioactively tagged groups which on reaction pass into the substrate. Such a method could also be used to study exchange reactions between films and substrates.

Tracer techniques have already been used in the study of soluble films (14). Carbon-14 tagged films deposited by the method of Blodgett (9) on various surfaces have been used to measure backscattering and chemical reactions in adsorbed films (7), to investigate lubrication problems (10), and to study surface diffusion phenomena (15). Deposited radioactive monolayers have been proposed as standard β-ray sources because of their stability and ease of reproduction and negligible self-absorption (8).

To the present, however, no investigations of insoluble monolayers at the air/water interfaces have been reported in which the tracer technique has been employed. In this paper a successful application of the method to the study of halogen exchange between a tagged monolayer molecule and a reactant in the substrate is described. Results are presented for iodine-exchange between monolayers of α-iodostearic acid and potassium iodide substrates at various surface and substrate concentrations over a range of temperatures.

EXPERIMENTAL PART

Materials

Radioiodine was incorporated by an exchange reaction into α-iodostearic acid which was prepared from the corresponding bromo acid. Iodine-131 was selected as the tracer element because it is a β-emitter of intermediate energy (0.6 Mev.), has a convenient half life (8.0 days), and is readily available in carrier-free form.

α-Bromostearic Acid

This acid, prepared from purified stearic acid by the method of Hell and Sadomsky (21), was recrystallized 10 times from petroleum ether (40°–60°C. boiling range) and three additional times from 95% ethanol at −13°C. The pure α-bromostearic acid crystallized as white needles and plates. Melting point 60.1–60.5°C. (Hell and Sadomsky 60°C.).

α-Iodostearic Acid

This acid was prepared essentially by the method of Frewing (17). α-Bromostearic acid (0.058 mole) was refluxed with KI (0.116 mole) in 300 ml. of 95% ethanol for three hours. The ethanol was then removed *in vacuo* and the α-iodostearic acid dissolved in hot benzene. After eight recrystallizations at +8°C. from benzene, the acid was recrystallized three additional times from 95% ethanol at −13°C. The crystals were similar in appearance to those of the α-bromostearic acid. Melting point 67.0–67.3°C. (Frewing 67°C.).

Radioactively Tagged α-Iodostearic Acid

The exchange was carried out in a 250 ml. erlenmeyer flask with a rounded bottom. One ground-glass joint was attached to the neck of the flask, and a second to the side just above the rounded bottom.

Ten millicuries of aqueous carrier-free and buffered NaI^{131} solution (AECL grade) was placed in the flask and the water removed by freeze-drying. A weighed sample of 0.01 to 0.02 gm. of inactive α-iodostearic acid was dissolved in 4 ml. of 95% ethanol and added to the reaction flask over the freeze-dried residue (largely buffer). The resulting solution was gently refluxed for two to three hours to allow the exchange reaction to occur, and then allowed to cool to room temperature.

A sintered-glass filter tube was inserted in place of the stopper in the ground-glass joint on the side, the flask was tipped until the filter was elevated somewhat above the body of the flask, and 200 ml. of 1 *N* HCl solution was added. An emulsion of fatty acid in HCl solution formed initially, but after the flask had been left for two to three hours or sometimes overnight, fairly large aggregates of fatty acid appeared. The aqueous layer was then filtered off, the fatty acid being retained on the flask walls and on the filter. Two consecutive 50 ml. portions of 0.1 *N* HCl were then added to the flask and the precipitate of fatty acid washed as completely as possible on to the filter where it was again washed twice with 25 ml. portions of distilled water. The flask was again connected to the freeze-drying apparatus and the water completely removed from the flask and filter tube.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

The dry I^{131} α-iodostearic acid on the sides of the flask and on the filter was dissolved by washing with warm benzene. The resulting solution was then made up to volume with benzene in a 25 ml. volumetric flask. The benzene solution of I^{131} α-iodostearic acid was stored in the stoppered volumetric flask away from light, behind a lead shield. The concentration of α-iodostearic acid in the benzene solution was determined, when necessary, from the measured pressure–area relation of a known volume of the fatty acid solution, spread to form a monolayer.

The relative quantities of NaI^{131} and α-iodostearic acid used in the above preparations were chosen by calculation to give an experimentally convenient initial radioactive counting rate of about 5000 counts per cm.^{2} per min. when the acid is spread on a surface area of about 40 Å^2 per molecule. In the calculation it was assumed that 50% exchange represented complete reaction and that the over-all counting efficiency was 50%. The counting rates found experimentally were surprisingly close to the expected values.

Other Materials

All the materials used in the experiments and preparations, including the paraffin used in coating the monolayer trough, were purified to ensure the absence of surface-active contaminants. Routine checks were made by spreading pressure measurements in the conventional way.

Apparatus

The general arrangement of the monolayer trough and accessory equipment is shown in Fig. 1. The stainless steel trough (carefully coated with paraffin

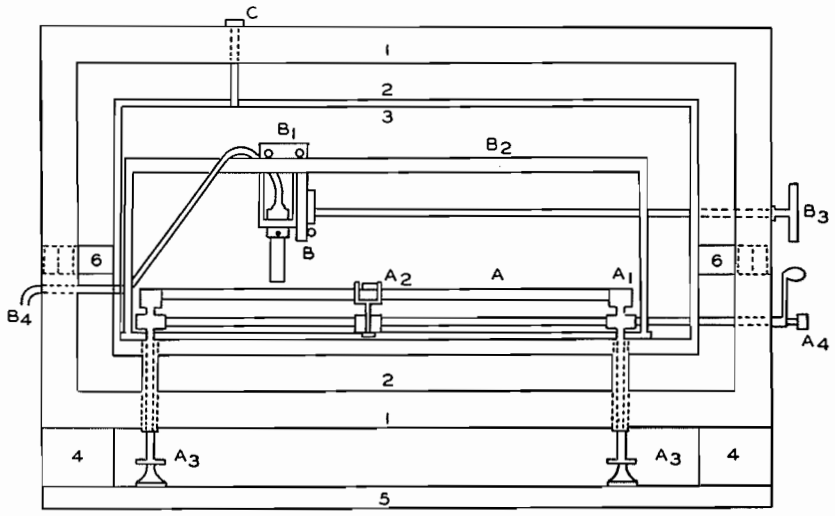

FIG. 1. Monolayer trough arrangement (schematic).

Air bath: 1, insulation; 2, chamber containing copper coils; 3, air chamber; 4, cork supports; 5, stone pedestal; 6, windows (triple glass).

before use) was enclosed in an air bath, the temperature of which was held constant by pumping water from external thermostats (not shown) through copper coils in the air bath. The water in the trough was also held to constant temperature by circulation of water from the thermostats. The temperature of the solution in the trough could be controlled manually to within ±0.2°C. of the temperature of the air bath. A reservoir of water, into which filter paper hung and which was similarly held at constant temperature, maintained a saturated atmosphere within the air bath. After temperature equilibration the temperature of the air bath could be held within ±0.1°C. for periods of 15 hr. in the range of 10°C. to 40°C.

The surface balance was the Harkins vertical pull type (20). An image of a hairline was reflected from a small mirror mounted at the main knife edge of the balance, and projected on a curved scale. The balance had a sensitivity of 0.48 dyne per cm. per scale division of the optical lever.

The barrier of the trough could be operated by remote control from outside the box and its position in the trough could be determined from the reading on an externally mounted revolution counter. The Geiger tube mounting was also remote-control-operated from outside the box. The Geiger tube, which had an effective window area of 2 cm.^{2}, could be moved to scan any region of the film surface when the tube was fixed in its carrier.

The counting equipment consisted of an Electronics Associates type 1725 Ratemeter used in conjunction with an Esterline-Angus 10 milliamp. recording milliammeter. The counting rate could be recorded as a function of time on the chart of the milliammeter. The Geiger tube was a mica end-window counter (Nuclear Instrument Corp. type D 34). The fused mica/glass seal eliminated tube failures experienced with cemented mica-end-window tubes in the saturated atmosphere.

Experimental Procedure

All substrates used in the present work were allowed to come to constant temperature overnight. The technique used to obtain the pressure–area isotherms was essentially that of Adam (2). The substrate was 0.01 *N* HCl solution. Before the film was spread the surface was repeatedly swept by the barriers until a decrease in area to one-third of the original caused less than 0.05 dyne/cm. increase in surface pressure.

To spread a film, a measured volume of benzene solution of α-iodostearic acid was added dropwise at many points on the surface from an Agla micrometer syringe. Fifteen minutes were allowed for the evaporation of the benzene, the initial pressure was noted, and the film was compressed in steps every three to four minutes. Since the surface balance did not permit accurate measurements of decreases in surface pressure, only compression curves were obtained.

The same spreading technique was used in the exchange experiments except that the Agla syringe was replaced with a microliter syringe-pipette. Sufficient acid was added to the surface during spreading to bring the surface pressure to a value just below that desired for the exchange experiment. The final pressure adjustment was made by compression of the film.

The slide of the surface balance was removed after each pressure measurement during an exchange reaction to prevent undue contamination with substrate solution and film molecules, and was cleaned between each measurement. At the end of an exchange experiment the active film was removed by suction through a capillary pipette to a suction flask.

Directly after the trough was filled with KI solution the Geiger tube was mounted in position with the end window 3 mm. above the surface to allow passage of the barrier and left inside the air bath during the period of thermal equilibration. The background counts were about 60 per min.; since the counting rates obtained with the films were of the order of 10^4 per min., no correction for background was necessary.

Standard radiochemical techniques and precautions were used at all stages of preparation and use of the radioactive fatty acid.

RESULTS

Pressure–Area Isotherms

To characterize the various types of monolayer, pressure–area isotherms were determined over 0.01 *N* HCl substrates. Because of rapid contamination

of the slide of the surface balance when salts were present in the substrate solution, it was not possible to measure the isotherms over substrates containing potassium iodide at the relatively high concentrations used in the monolayer/substrate exchange experiments.

The isotherms between 9° and 27.4°C. are presented in Fig. 2 and are typical of fatty acids. The curves indicate the existence of three distinct types of film which may be illustrated by reference to the 17.4°C. isotherm:

1. From very low pressures up to a pressure 5.5 dynes/cm. and an area 38.95 Å^2/molecule, the film is "liquid-expanded" in the nomenclature of Adam (2). The coefficient of compressibility $K = 1/A\ (\partial A/\partial \pi)$, where π is the surface pressure and A is the area per molecule, is 2.9×10^{-2} cm./dyne, which may be compared with values of 2×10^{-2} to 7×10^{-2} cm./dyne given by Harkins (19) for this type of film.

2. Above the pressure 5.5 dynes/cm. the film is "intermediate-liquid", the initial K being 1.1×10^{-1} cm./dyne.

3. As the pressure is further increased the isotherm shows a gradual transition to a "liquid-condensed" film. At 28.45 Å^2/molecule, $K = 9\times10^{-3}$ cm./dyne.

Above 19.8°C. the films are of the liquid-expanded type. Below this temperature an intermediate-liquid film exists down to about 12°C. Between 12°C. and 19.8°C., the films are liquid-expanded at low pressures up to a transition pressure, which increases with increasing temperature, when condensation to an intermediate-liquid film occurs. As the pressure is increased the intermediate-liquid film passes gradually to the liquid-condensed film.

The isotherms yield an area at zero compression of about 30.2 Å^2/molecule. This value lies between 27.8 Å^2/molecule and 32.8 Å^2/molecule for the C_{16}–C_{17} and C_{18}–C_{21} α-bromo acids respectively (1). The marked tendency to collapse exhibited by α-iodostearic acid monolayers at temperatures below 12°C. as the surface pressure was increased above about 10 dynes/cm. made it impossible to determine the pressure–area isotherms over a large range of pressures in this condensed state. The area at zero compression may consequently be in error by as much as +1 Å^2/molecule.

Preliminary Exchange Experiments

When a monolayer of the tagged acid was deposited on a substrate containing 0.01 N HCl and potassium iodide, the counting rate decreased with time. A series of preliminary experiments showed that the rate of the process, as measured by the rate of change of counting rate, increased with increased KI concentration. From these experiments it was concluded that 1.0 M KI was the most convenient concentration for temperature coefficient measurements. Measurements at concentrations in excess of 1.5 M KI were found impractical because of crystallization of the salt on the barriers.

In the experiments, condensation of water on the end window of the Geiger tube could conceivably occur and thus cause an apparent decrease in counting rate. It was shown however that this had a negligible effect on the counting rate. In further experiments it was shown that when the film was swept off

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

at any time the counting rate dropped to the normal background value of about 60 per min. so that the activity transferred from the monolayer to the substrate has a negligible influence on the background count.

The possibility that the decrease in counting rate was due to hydrolysis of the α-halogen compound to the corresponding α-hydroxy compound was investigated in a series of experiments using active films spread on 0.01 N HCl, and 0.01 N HCl substrates containing 1.0 M and 2.0 M KCl. In no case did any significant decrease in counting rate with time occur. Some films spread on 0.01 N NaOH substrates to favor hydrolysis also showed no decrease in counting rate with time.

All the foregoing experiments were made at constant total area; in all instances, including those over the KI substrates, the surface pressure remained constant, which indicated a constant chemical composition of the film. These experiments also left little doubt that the decrease in counting rate of the film on a KI substrate was associated with the presence of I^- ion in the substrate and that the observed decrease in counting rate was due to iodine exchange between the alkyl halide in the monolayer and inorganic iodide in the substrate.

Exchange Reaction

The rate of the exchange reaction was studied at various values of the surface pressure, temperature, and concentration of potassium iodide in the 0.01 N HCl substrate. The rate was computed in the following manner:

Let V moles cm.$^{-2}$ min.$^{-1}$ be the velocity (forward and reverse) of the exchange reaction

$$CH_3(CH_2)_{15}CHI^*COOH + KI \rightarrow CH_3(CH_2)_{15}CHICOOH + KI^*.$$

Let n moles/cm.^{2} be the total concentration of fatty acid in the film, and $f(t)$ be the fraction of fatty acid molecules containing radioactive atoms at time t. Assuming that the radioactive atoms are homogeneously distributed in the surface film, the rate of disappearance of radioactive atoms from the surface film is $Vf(t)$, i.e.

$$[1] \qquad -d(nf(t))/dt = Vf(t),$$

which, on integration, yields

$$[2] \qquad \log_e[f(0)/f(t)] = Vt/n.$$

If it is further assumed that the recorded counting rate $c(t)$ is proportional to $f(t)$, i.e radioactive atoms passing into the substrate do not register on the counter, Eq. [2] becomes

$$[3] \qquad \log_e[c(0)/c(t)] = kt,$$

where $k = V/n$.

Semilogarithmic plots of $c(t)$ against t in most cases yielded straight lines from which the rate constant k could be readily determined. Typical examples are illustrated in Fig. 3 for films at 25°C. and 35°C. Exceptions occurred at 18°C. as shown in Fig. 4, where the plot became linear only after approximately two hours of exchange.

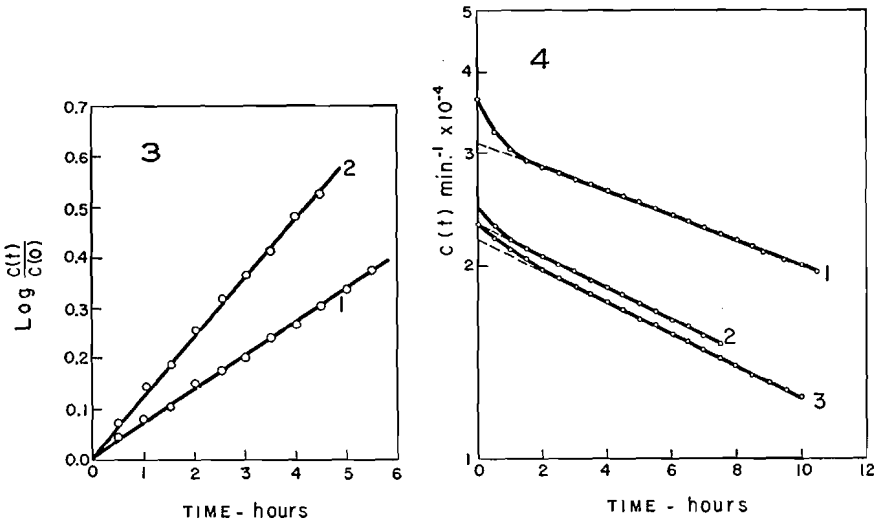

FIG. 3. Counting rate vs. time plots at 25°C., 15.5 dynes/cm. (curve 1) and 35°C., 14.6 dynes/cm. (curve 2).
FIG. 4. Semilogarithmic plots of counting rate vs. time at 18°C. at surface pressures of 14.8 dynes/cm. (curve 1) 4.3 dynes/cm. (curve 2), and 3.9 dynes/cm. (curve 3).

Values of k at various temperatures between 10°C. and 37°C. and at various surface pressures over 1.0 M KI+0.01 N HCl substrates are summarized in Table I. It will be noted from Table I that at a given temperature k is independent of surface pressure and hence surface concentration. This is also approximately true for the linear portion of the 18°C. plots.

The Arrhenius plot for the temperature coefficient of k is given in Fig. 5 and shows two linear portions separated by a discontinuity between 14°C. and 22.5°C. The calculated activation energies are 10.8 kcal./mole in the higher and 8 kcal./mole in the lower temperature range.

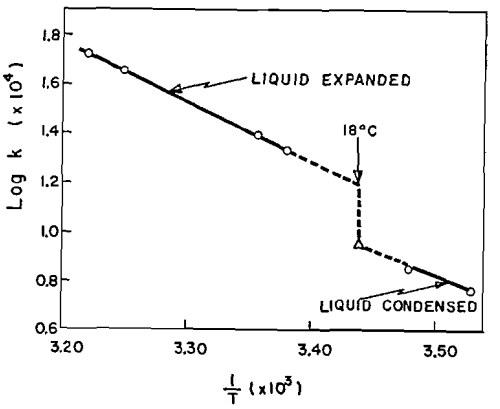

FIG. 5. Arrhenius plot of k for 1.0 M KI+0.01 N HCl substrates.

The variation of k with concentration of KI in the substrate was measured at a surface pressure of 7.7 dynes/cm. and at a temperature of 22.5°C. The experimental values are given in Table II. The rate constant k increases rapidly

TABLE II

1.5	24.9

with increase in KI concentration, particularly between 0.5 and 1.0 M, but the order of the reaction in concentration of KI could not be determined.

DISCUSSION

In computing the exchange velocity it is not strictly correct to assume, as above, that the counter detects the radioactive atoms in the surface film but not in the substrate. Time is required for the I^- ions released from the surface to diffuse to a distance beyond which, because of β-particle absorption by the water, they make a negligible contribution to the counting rate. However, if the rate of exchange is much less than the rate of diffusion of I^- ions into the substrate, the method of calculation is acceptable. That this condition prevails can be demonstrated by the following argument.

If it is assumed that the exchange occurs instantaneously, it is possible to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

calculate the decrease with time of the radioactive counting rate that results from diffusion of the radioactive ions away from the surface. The basic equation for diffusion in the substrate may be written

$$\partial C/\partial t = D\partial^2 C/\partial x^2, \quad [4]$$

where C is the volume concentration of radioactive ions at time t at a distance x below the surface, and D is the self-diffusion coefficient of the ions.

If at time $t = 0$, $C = 0$ for all values of x', the solution of Eq. [4] corresponds to that of a one-dimensional diffusion in a semi-infinite system having an instantaneous plane source at $x = 0$ and is given by (23)

$$C = (s/\sqrt{\pi Dt}) \cdot e^{-x^2/4Dt}, \quad [5]$$

where s is the amount of radioactive iodine instantaneously released per unit area of surface.

For simplicity an exponential absorption may be assumed for the β-radiation passing through the substrate to the counter. Then the contribution to the counting rate due to a layer of thickness dx at x is

$$dc(t) = \alpha C \cdot e^{-\mu x} dx, \quad [6]$$

where μ is the absorption coefficient of the substrate and α is a proportionality constant related to counter efficiency and the disintegration constant of the radioactive species.

Combining Eqs. [5] and [6] and integrating yields the total counting rate of the diffusing ions as

$$c(t) = \frac{s}{\sqrt{\pi Dt}} \int_0^\infty \exp\left[-\left(\frac{x^2}{4Dt} + \mu x\right)\right] dx, \quad [7]$$

for which the solution is readily shown to be the remarkably simple relation

$$c(t) = c(0) \cdot e^{-D\mu^2 t}. \quad [8]$$

Eq. [8] is identical with Eq. [3] when $k = D\mu^2$. Taking $D = 1.7 \times 10^{-5}$ cm.^{2}/sec., which is the mean experimental value for I^- in NaI (31), and $\mu = 26.6$ cm.$^{-1}$, which is assumed identical with that of aluminum for the β-radiation of iodine-131 (32), $k = D\mu^2 = 7200 \times 10^{-4}$ min.$^{-1}$. This is several orders of magnitude greater than the values given in Tables I and II. Furthermore D, and therefore $D\mu^2$, is for all practical purposes constant, whereas the experimental values of k increase rapidly with increase in I^- concentration.

It may therefore be safely concluded that exchange rather than diffusion is the rate-controlling step in the process measured.

The values of k $(= V/n)$ in Table I appear to be independent of surface pressure, and hence surface concentration, over the range studied at the indicated temperatures. The exchange reaction is therefore first order in concentration of monolayer molecules.

As noted previously the Arrhenius plot was discontinuous between 14°C. and 22.5°C. (Fig. 5) and the exchange reaction at 18°C. failed to show first

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

order behavior over the initial one and one-half to two hours of exchange (Fig. 4). The "critical temperature" for the disappearance of the intermediate-liquid film occurred near this temperature (Fig. 2). The failure of the 18°C. experiments to show the same first order behavior as shown at other temperatures might arise from the simultaneous presence of condensed and expanded liquid films under non-equilibrium conditions on the surface. The over-all exchange velocity would then result from two simultaneous reactions with different rates and associated with the two types of film present.

The discontinuous increase in reaction velocity and activation energy near 18°C. is probably a direct result of the change in surface phase from liquid-condensed to liquid-expanded which occurs in the region of 18°C. Similar discontinuities have been observed by Rideal and others (5, 12, 16, 26) in hydrolysis and oxidation studies in monolayers. The differences in the activation energies were considered by Rideal to arise from changes in the configuration and orientation of monolayer molecules in the surface and hence were attributed to a change in the steric factor of the collision theory treatment of reaction kinetics. The same might apply to the present systems.

Activation energies for homogeneous isotopic halogen exchange in bulk of halogenated acids similar to α-iodostearic acid have been determined. Values of 16 kcal./mole for free α-iodoacetic acid and 17 kcal./mole for the methyl ester have been reported for isotopic iodine exchange with I^- in aqueous solution (29). The value of the activation energy of isotopic bromine exchange between Br^- and α-bromopropionic acid in H_2SO_4 was found to be 20.9 kcal./mole (25). The value of 10.8 kcal./mole found in the present exchange for the expanded film is thus between 5 and 6 kcal./mole lower than the activation energy for similar iodine exchanges in solution. This decrease in activation energy may be associated with a small steric factor for the monolayer exchange in terms of collision theory treatment. In other kinetic studies of monolayer reactions the steric or accessibility factor was found to be essentially unity for reactions involving the α position (22).

Aliphatic halogen exchange reactions are considered to proceed through the mechanism of the Walden inversion (11, 30). The entering halogen ion has been shown to have the greatest probability of substitution if it approaches the carbon atom holding the exchangeable atom from a direction normal to the face of the carbon tetrahedron opposite the atom to be replaced. In monolayers the poor accessibility of this tetrahedron face to the I^- ions might be the cause of the apparent low steric factor in the exchange kinetics, and the change of activation energy observed might be the result of a change in accessibility in going from the condensed to the expanded liquid film.

To obtain the specific rate constant k_s for the exchange reaction the true order of the reaction in monolayer concentration and substrate I^- concentration must be known. Since the reaction is first order in monolayer concentration, the relationship between the over-all velocity and the specific rate constant is given by

$$V = k_s n\, m^y,$$

where m is the concentration of I^- in the substrate and y the order of the reaction with respect to I^-.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/04/12
For personal use only.

To obtain k_s, the value of y must be determined. In the present investigation it was not possible to determine the true order of dependence on KI concentration. The values of k in Table II do not fit any simple order when the concentration of the substrate solution is used as the effective surface phase concentration. The apparently anomalous dependence of reaction velocity on KI concentration might be resolved if it were possible to calculate the change in concentration in the solution as the monolayer is approached. At present no method exists for calculating the concentration of I^- at the surface; this concentration will depend, among other factors, upon the structure of the electrical double layer existing at the interface.

The behavior of the film itself as the substrate KI concentration is increased must not be overlooked as a possible cause of the anomalous concentration dependence of the exchange. No pressure–area curves could be obtained on KI substrates, and it was assumed that the film characteristics were not greatly changed with increasing KI concentration. This requires experimental confirmation.

While the experimental findings of this investigation are of a preliminary nature and must be extended before further conclusions regarding the detailed mechanism of exchange can be drawn, it is nevertheless considered that these results demonstrate the value of the radioactive tracer method in monolayer systems.

ACKNOWLEDGMENTS

The authors wish to express their indebtedness to Dr. L. G. Yaffe for advice and assistance in the radiochemical procedures, to Mr. W. Rabinovitch for assistance in performing some of the experiments, and to the Defence Research Board of Canada for generous financial assistance.

THE SURFACE ENERGIES OF CALCIUM OXIDE AND CALCIUM HYDROXIDE[1]

By Stephen Brunauer, D. L. Kantro, and C. H. Weise

ABSTRACT

The total surface energies (or surface enthalpies) of calcium oxide and calcium hydroxide were determined by measuring the heats of solution in 2 *N* nitric acid of calcium oxide and calcium hydroxide having high and low specific surface areas, and by determining the surface areas by the B.E.T. method, using nitrogen as adsorbate. The molecular area of nitrogen was taken to be 16.2 Å^2 at 77.3°K. Precision determinations of the lattice parameters indicated that the high and low surface substances had the same unit cell dimensions, and X-ray line broadening measurements indicated that the crystals were perfect or nearly perfect. The surface energy of calcium oxide at 23°C. was found to be 1310±200 erg/cm.^{2}, which compares well with the theoretical value of 1100 erg/cm.^{2} The surface energy of calcium hydroxide at 23°C. was found to be 1180±100 erg/cm.^{2} The heat of the reaction CaO (*c*, 23°)+H_2O (*l*, 23°) = $Ca(OH)_2$ (*c*, 23°), for crystals having negligible specific surface areas, was found to be −15,620 cal.

INTRODUCTION

In 1927 and 1928, Lipsett, Johnson, and Maass (18) published three papers on the surface energy of sodium chloride. They determined the heats of solution of coarsely crystalline and finely divided sodium chloride, measured the surface area microscopically, and obtained the surface energy from the ratio of the energy difference to the difference in surface area. The quantity thus measured is really the surface heat content or enthalpy; however, since Gibbs, it has been customary not to make a distinction between surface enthalpy and total surface energy (or, briefly, surface energy). The investigators concluded, ". . . the surface energy of sodium chloride is found to be about 400 ergs per sq. cm. The errors involved in these measurements are of necessity rather large, and this figure can be regarded as only approximate. It will serve to show, however, the practical applicability of this method to the determination of the surface energy of solids, for which experimental data, so far, are sadly lacking."

The largest error in the above work was in the determination of the surface area of sodium chloride. Only the geometrical surface is visible in the microscope; surface roughnesses of a molecular scale are not visible even in an electron microscope. If the "roughness factor" of the sodium chloride was, let us say, 1.33, the surface area was 33% larger than that measured with the microscope, and the surface energy was only 300 erg/cm.^{2}

Twenty-seven years have passed since 1928, and experimental data on the surface energies of solids are still "sadly lacking". Meanwhile, reliable methods of surface area determination were developed and widely used, yet the problem of the surface energy of sodium chloride is not fully solved to date. The most recent information on the subject is found in a paper of Benson and Benson (1), who prepared sodium chloride samples of widely differing surface areas and determined the surface areas by the B.E.T. method (3), using

[1]*Manuscript received February 2, 1956.*
Contribution from the Portland Cement Association Research and Development Laboratories, Chicago, Illinois.

nitrogen as the adsorbate. Because of slight quantities of impurities, the effects of which on the surface energy the authors were unable to estimate, they regarded their surface energy value of 305 erg/cm.^{2} as "provisional". If the effects of impurities on the heats of solution were additive, the value of Benson and Benson must be close to the true surface energy of sodium chloride.

The only other reliable experimental surface energy value published so far is that of Jura and Garland (14) for magnesium oxide. In this case, also, the authors pointed out that their surface energy value may have been in error; and in the light of the results reported in this paper, their value for magnesium oxide does appear to be somewhat too low.

Theoretical evaluations of the surface energies of certain ionic crystals, crystallizing in cubic lattices, were made by a number of investigators, but these are only rough approximations. The scarcity of data on surface energies is so much the more surprising, since the interest in surface chemistry in general, and in adsorption in particular, has tremendously increased in the last decade and a half. Energy changes occurring in adsorption were widely investigated, but the investigators usually interpreted the changes as being due to a change in state of the adsorbate and assumed, for convenience, that the change in state of the surface of the adsorbent was negligible. The theoretical arguments advanced in favor of this assumption were inadequate, and experimental data were wholly lacking. It seems that a systematic investigation of the energy contents of a variety of surfaces could throw some light on this problem. It could, probably, also furnish some useful information as to the validities of various theories advanced for the structures of solid surfaces, such as, for example, the theory developed by Weyl (30).

In the present investigations, the surface energies of calcium oxide and calcium hydroxide were obtained by determining the heats of solution in 2 *N* nitric acid of samples having different surface areas, and measuring the surface areas by the B.E.T. method (3), using nitrogen as the adsorbate.

EXPERIMENTAL

Calcium Oxide

The low surface calcium oxide, Batch A-40, was prepared from Fisher's certified reagent grade calcium carbonate. The calcium carbonate was ignited at 1050°C. for four hours, cooled, and pressed into pellets, $\frac{1}{4}$ in. in diameter and $\frac{1}{4}$ in. to $\frac{3}{8}$ in. long, by a Parr pellet press. The pellets were then ignited at 1300°C. for 64 hr., and cooled and stored in a desiccator containing phosphorus pentoxide. Prior to use, each sample was ignited at 1050°C. for 30 min., cooled in a phosphorus pentoxide desiccator, weighed, and then introduced immediately into the calorimeter or the adsorption apparatus.

The high surface calcium oxide, Batch A-39, was prepared from calcium hydroxide, Batch E-4. Each sample was separately prepared before use. The calcium hydroxide was ignited at 1050°C. for 30 min., cooled for 15 min. over fresh phosphorus pentoxide in a desiccator, weighed, reignited at 1050°C. for 15 min., again cooled for 15 min., then immediately introduced into the calorimeter or the adsorption apparatus. The samples were not weighed after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

the second ignition. The first ignition always gave the correct ignition loss, and it was assumed that the weight after the second ignition was the same as after the first ignition. A single ignition, with subsequent weighing, gave far less reproducible results.

In handling both calcium oxide and calcium hydroxide, extreme precautions were taken to avoid contamination of the materials by atmospheric moisture and carbon dioxide. To the extent possible, all operations, including pelleting, were carried out in a controlled-atmosphere cabinet.

All samples of calcium oxide and calcium hydroxide were exposed to the atmosphere only while they were being dropped into the calorimeter, which period never exceeded five seconds. To ascertain the amount of moisture picked up in this short time, the following experiment was performed. (1) A 1 gm. sample of calcium oxide, A-39, was prepared as described above. (2) After the final cooling period, the covered platinum crucible with the sample was transferred from the desiccator into a weighing bottle inside the controlled-atmosphere cabinet. (3) The weighing bottle, with its contents, was weighed. (4) The sample was exposed to the atmosphere over the calorimeter bath for five seconds. The crucible was then covered, returned to the weighing bottle, the weighing bottle was covered, and the weight was determined. (5) The procedure of step (4) was repeated three times, except that each exposure interval was 20 sec.

The experiment was performed on three separately prepared samples, with the result that the amount of moisture picked up in five seconds was *at most* 0.13 mgm./gm. Actually, no gain in weight occurred in the first five seconds, probably because time was needed for the moisture to reach the sample after the opening of the crucible. It is possible that a shorter time delay would have occurred if the sample had been dropped into the calorimeter funnel. The moisture gain was very close to linear with time between 5 sec. and 45 sec., with a slope of 0.13 mgm./gm. per 5 sec.

Calcium Hydroxide

The coarsely crystalline calcium hydroxide, Batch E-4, was prepared in a manner similar to that employed at the National Bureau of Standards (20). A 100 ml. beaker, filled with saturated sodium hydroxide solution, and a 150 ml. beaker, filled with saturated calcium nitrate solution, were placed in a large jar. Both chemicals were Baker's analyzed reagent grade, and deionized water was used. Water was then added to the jar until the liquid level was about one inch above the level of the taller beaker. Care was taken to avoid mixing. The jar was covered, and was left standing undisturbed for about two weeks, by which time a growth of calcium hydroxide crystals practically filled the mouth of the beaker containing the calcium nitrate solution. The calcium hydroxide crystals were removed from the beaker in the controlled-atmosphere cabinet, washed several times with water, and dried overnight at a water vapor pressure of 0.5 μ of mercury. The dry calcium hydroxide was sieved in the cabinet; the fraction passing a U.S. Standard No. 30 sieve was discarded, and the rest was stored in paraffin-sealed weighing bottles until used.

The high surface calcium hydroxide, Batch E-8, was prepared by vapor phase hydration of calcium oxide in a manner similar to that described by Thorvaldson and Brown (26). Fisher's certified reagent grade calcium carbonate was ignited at 1050°C. for four hours, cooled in a desiccator containing phosphorus pentoxide, and crushed in the controlled-atmosphere cabinet to pass a U.S. Standard No. 100 sieve. The calcium oxide was then distributed among several tared polyethylene weighing bottles, which were placed over water in a desiccator jar. The bottles were weighed periodically. When the water content had risen to a value 35% in excess of the stoichiometric quantity, the material was removed and dried at a water vapor pressure of 0.5 μ of mercury. The dry calcium hydroxide was pressed into pellets, $\frac{1}{4}$ in. in diameter and $\frac{1}{4}$ in. to $\frac{3}{8}$ in. long, in a Parr pellet press inside the controlled-atmosphere cabinet, and the pellets were stored in paraffin-sealed weighing bottles until used.

After vacuum drying and pelleting, Batch E-8 contained 0.76% excess water. This corresponded approximately to a quantity of water sufficient to cover the entire surface of the calcium hydroxide with an adsorbed monolayer of water. To obtain a sample with less excess water, half of Batch E-8 was heated at 180° to 200°C. for 16 hr. in a vacuum of the order of 10^{-6} mm. of mercury. The batch, E-8A, contained only 0.12% excess water, but the heating resulted in some sintering. The pellets were stored in paraffin-sealed weighing bottles until used.

An experiment similar to that performed on calcium oxide, and described in the previous section, was made on calcium hydroxide, Batch E-8A, to ascertain the water pickup during the five seconds of introduction of the sample into the calorimeter. The amount of water picked up was less than 0.1 mgm./gm.

X-Ray Measurements

X-Ray powder diffraction patterns were obtained by means of a North American Philips wide range Geiger counter diffractometer. The basic unit was operated at 40 kv. and 20 ma. Copper K_α radiation was used; the K_β component was removed by a nickel filter. For precision determinations of the lattice parameters, the goniometer scanning rate was $\frac{1}{4}$°/min. and the chart speed was 1 in./min., so that readings could be made to the nearest 0.02°2θ.

For each calcium oxide sample six lines and for each calcium hydroxide sample seven lines were recorded in the back-reflection region. Relative intensities (I/I_1) and (hkl) assignments were taken from the data of Swanson and Tatge (25). It was found that the calcium hydroxide reflection corresponding to a d spacing of 0.8140 Å was incorrectly assigned. The (hkl) values should be (312) rather than (006).

For calcium oxide, plots of a_0 vs. $\frac{1}{2}\left(\frac{\cos^2\theta}{\sin\theta}+\frac{\cos^2\theta}{\theta}\right)$ (15) gave good straight lines, regardless of specific surface area and crystallite size. In the case of calcium hydroxide, there were not enough ($hk0$) and no ($00l$) reflections to permit single parameter evaluations. All unambiguous reflections in the range

d = 1.13 to 0.814 were, therefore, used, and a_0 and c_0 were obtained by least squares calculations (16). Statistical weights were assigned proportional to $(I/I_1)\tan^2\theta/d^2$, and the systematic errors were assumed to have the same angular dependence as those found for calcium oxide.

For the line broadening investigations, a scanning rate of $\frac{1}{8}$°/min. was used. The broadening of the calcium oxide line at 2.405 Å (100) and of the calcium hydroxide lines at 3.11 Å (100) and 4.91 Å (001) was measured. The crystallite dimensions were calculated by means of Scherrer's equation (22).

Other Operations

Ignition loss and carbon dioxide content were determined and chemical analyses were performed according to the methods described by Brunauer, Hayes, and Hass (4).

The calorimeter was essentially the same as that of Verbeck and Foster (28), with the modifications described by Brunauer, Kantro, and Weise (5). The acid solvent was 420 gm. of 2 N nitric acid.

Surface areas were measured by the B.E.T. method (3), using nitrogen at 77.3°K. Corrections for deviations from the perfect-gas law were taken from Emmett and Brunauer (8).

RESULTS

The experimental calorimetric results for calcium oxide and calcium hydroxide are shown in Table I. These results were then corrected for impurities.

Only impurities amounting to 0.01% or more were considered. Both batches of calcium oxide contained 0.01% sodium oxide; in addition, calcium oxide, Batch A-40, contained 0.05% magnesium oxide. The following impurities were found in the three batches of calcium hydroxide: in E-4, 0.01% sodium hydroxide and 0.13% calcium carbonate; in E-8, 0.01% sodium hydroxide, 0.07% magnesium hydroxide, 0.36% calcium carbonate, and 0.76% water; in E-8A, 0.01% sodium hydroxide, 0.07% magnesium hydroxide, 0.27% calcium carbonate, and 0.12% water. The following values were used for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

heats of solution of the impurities, in cal./gm.: sodium oxide, 1346; sodium hydroxide, 590; magnesium oxide, 865; magnesium hydroxide, 446; and calcium carbonate, 86. The corrections for water in calcium hydroxide, Batches E-8 and E-8A, will be discussed later.

Corrected values of the heats of solution, in cal./gm., exclusive of the heat evolved in the uptake of excess water, were as follows: calcium oxide, Batch A-40, 844.67; calcium oxide, Batch A-39, 847.03; calcium hydroxide, Batch E-4, 428.44; calcium hydroxide, Batch E-8, 432.64; and calcium hydroxide, Batch E-8A, 434.05.

Surface areas of the five substances, in meters^2/gm., were as follows: calcium oxide, Batch A-40, 0.3; calcium oxide, Batch A-39, 7.8; calcium hydroxide, Batch E-4, 0.1; calcium hydroxide, Batch E-8, 26.1; and calcium hydroxide, Batch E-8A, 21.8. It was assumed that one nitrogen molecule covered an area of 16.2 Å^2.

The two batches of calcium oxide gave identical values for the lattice parameter a, the edge of the unit cube, the value being 4.8108 ± 0.0002 Å. For the three batches of calcium hydroxide, the parameters of the hexagonal lattice were: Batch E-4, $a = 3.5933\pm0.0003$ Å, $c = 4.9086\pm0.0021$ Å; Batch E-8, $a = 3.5929\pm0.0006$ Å, $c = 4.9078\pm0.0046$ Å; and Batch E-8A, $a = 3.5926\pm0.0003$ Å, $c = 4.9082\pm0.0026$ Å. The determinations were made at 26°C.

The X-ray line broadening measurements gave the following results: On the basis of the half-intensity width of the 2.405 Å line of calcium oxide, Batch A-40, as standard, the broadening of that line of Batch A-39 was $0.030°2\theta$. With the half-intensity widths of the 3.11 and 4.91 Å lines of calcium hydroxide, Batch E-4, as standards, the broadening of the 3.11 Å lines of Batches E-8 and E-8A were 0.085 and $0.070°2\theta$, respectively; and the broadening of the 4.91 Å lines of E-8 and E-8A were 0.105 and $0.1325°2\theta$, respectively.

DISCUSSION

The Surface Energy of Calcium Oxide

1. In order to be reasonably certain that the energy difference between the two batches of calcium oxide was due to the difference between the specific surface areas *alone*, it had to be ascertained whether the bodies of the crystals had identical structures. This was accomplished (1) by precision determinations of the lattice parameter and (2) by X-ray line broadening measurements. The former showed that the lattice parameters a of the high and low surface calcium oxide were identical to the fifth significant figure. The identity is subject to an uncertainty of only 2×10^{-12} cm. in each determination, or one part in 24,000. Thus, the spacings of the ions in both batches of calcium oxide were found to be identical. The X-ray line broadening measurements, to be discussed in detail later, indicated that the crystals of both batches were either almost perfect, or, if not, the imperfections were of the same kind and extent.

2. The two batches of calcium oxide were prepared by widely differing methods: A-40 was "hard burned" lime, obtained by igniting calcium carbonate at 1300°C. for 64 hr., whereas A-39 was soft burned lime, obtained by igniting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

For personal use only.

calcium hydroxide at 1050°C. for 45 min. It is a well-known fact that hard burned lime reacts with water very slowly. The two batches of calcium oxide showed a marked disparity in their rates of reaction with 2 *N* nitric acid. It is clear from the X-ray results that this could not have been caused by differences in crystal densities (and, by implication, by differences in bond strengths), nor by crystalline imperfections. Very probably, the disparity in rate was caused by the difference between the specific surface areas of A-39 and A-40.

3. The corrected heat of solution of A-39 was 847.03 cal./gm., with a standard error of 0.17 cal./gm.; that of A-40 was 844.67 cal./gm., with a standard error of 0.29 cal./gm. The difference between the heats of solution was 2.36 cal./gm., with a standard error of 0.34 cal./gm. The surface area of A-39 was 7.8 meters^2/gm.; that of A-40 was 0.3 meters^2/gm. The difference was 7.5 meters^2/gm., and the uncertainty in the difference was 0.1 meters^2/gm. *The calculated surface energy of calcium oxide at 296°K. was 1310±200 erg/cm.*^{2}

In addition to the errors mentioned above, there are two other possible sources of error to be considered. The molecular area of nitrogen at 77.3°K. was assumed to be 16.2 Å^2. Livingston (19) proposed an area of 15.4 Å^2. If Livingston's figure is correct, the surface energy of calcium oxide is 70 erg/cm.^{2} *higher* than the value given above. The area of 16.2 Å^2 was used by Brunauer, Emmett, and Teller (3), and it was confirmed by Harkins and Jura (12) by means of a totally different approach.

A second source of error may have come from an uptake of water by calcium oxide, Batch A-39, during the introduction of the sample into the calorimeter. In the experimental part, the method used to estimate the magnitude of this effect was described. It is possible that no water was picked up during the less than five seconds of addition; if there was any uptake, it was at most about 0.13 mgm./gm. (A monolayer of water would correspond to 2.20 mgm./gm., using a molecular area of 10.6 Å^2.) Jura and Garland (14) found that when magnesium oxide sorbed an amount of water sufficient to form half a monolayer, the heat evolved per mole of water was about equal to the heat of hydration of magnesium oxide. If it is assumed that the same is true for calcium oxide, the heat evolved in the sorption of 0.13 mgm. of water would be 0.11 cal. A correction for this effect would *raise* the surface energy of calcium oxide by 60 erg/cm.^{2}

The above errors may or may not exist, but even if they do, they are relatively small. If both were present, the surface energy would be raised by a *maximum* of 130 erg/cm.^{2} Not knowing whether or not these errors were present, no attempt was made to correct for them. It is clear, however, that a more cautious estimate of the surface energy of calcium oxide would be 1375± 250 erg/cm.^{2}

4. Lennard-Jones and Taylor (17) calculated the surface energy of the (100) face of calcium oxide at 0°K. and obtained 1032 erg/cm.^{2} Jura and Garland found experimentally that the surface energy of magnesium oxide increased by 50 erg/cm.^{2} in the temperature range from 0° to 298°K. Because of the similarity between calcium oxide and magnesium oxide, it may safely be

assumed that the surface energy of calcium oxide at room temperature is also larger than the 0°K. value by the same amount. Thus, the theoretical surface energy of calcium oxide at 23° would be about 1100 erg/cm.^{2} The experimental value is 1310±200 erg/cm.^{2} The agreement between theory and experiment is, therefore, quite good.

The agreement between the experimental and theoretical surface energy of magnesium oxide is reasonably good. Jura and Garland obtained 1100 erg/cm.^{2} for the former, and Lennard-Jones and Taylor obtained 1362 erg/cm.^{2} for the latter. The value of Jura and Garland is probably too low. Since the surface energy of even calcium hydroxide appears to be greater than 1100 erg/cm.^{2}, it seems improbable that that of calcium oxide should be less than this value. On the basis of theory, the surface energy of magnesium oxide should be about 300 erg/cm.^{2} larger than that of calcium oxide, or at least 1400 erg/cm.^{2} Jura and Garland pointed out that they were unable to estimate the amount of water picked up by the magnesium oxide samples in the course of introducing them into the calorimeter. It is possible that their high surface magnesium oxide picked up enough water and carbon dioxide from the atmosphere to account for the somewhat low result.

The agreement between the theoretical and experimental surface energies of calcium oxide and magnesium oxide is so much the more surprising, since the experimental surface energy obtained for sodium chloride is twice as large as the best theoretical value, calculated by Shuttleworth (23).* Recently, van der Hoff and Benson (13) calculated the surface energy of lithium fluoride on the basis of a quantum mechanical model, instead of the "classical" model used by earlier investigators. They obtained a surface energy value almost three times as large as that based on the classical model. It seems that it would be desirable to recalculate the surface energies of calcium oxide and magnesium oxide on the basis of quantum mechanical models.

The Surface Energy of Calcium Hydroxide

1. The lattice parameters of the three batches of calcium hydroxide were given under "Results". The precision attained in the evaluation of the two parameters was somewhat smaller than that obtained for the single lattice parameter of calcium oxide. Since the differences are not statistically significant, it can be concluded that all three batches of calcium hydroxide had the same a and the same c parameters, indicating the same spacings of the ions in the crystals. The X-ray line broadening measurements, to be discussed in detail later, indicated that the crystals of all three batches were either almost perfect or, if not, the imperfections were of the same kind and extent.

In spite of the above facts, the differences between the heats of solution of E-4 and E-8 on the one hand, and between E-4 and E-8A on the other, were not caused by differences in surface energy *alone*. Both E-8 and E-8A contained some excess water, and the differences between the heats of solution were

*G. C. Benson and R. McIntosh (*Can. J. Chem. 33: 1677. 1955*) recently pointed out that the agreement between the theoretical value of Lennard-Jones and Taylor and the experimental value of Jura and Garland for the surface energy of magnesium oxide is probably fortuitous. In the theoretical calculations, the van der Waals term was neglected and the repulsive term was calculated in a questionable manner. The same criticism applies to the theoretical calculation of the surface energy of calcium oxide.*

partly caused by the heat of sorption of water. It is possible that the water was occluded in the lattice, and it is possible that it was adsorbed on the surface. Corrections for the water were attempted both ways and, as will be seen, both types of correction led to the same result.

2. Calcium hydroxide, Batch E-4, contained no excess water, Batch E-8A contained 0.12%, and Batch E-8 contained 0.76% excess water. The fact that the lattice parameters of the three batches were the same made it unlikely that the water was dissolved in the lattice. Nevertheless, it is possible that some water can be dissolved in the calcium hydroxide lattice without changing its dimensions, and it is also possible that the dimensions of the three batches were actually slightly different, even though in the present experiments the differences could not be detected. At any rate, calculations were made on the basis of the assumption that the water was dissolved in the lattices of E-8 and E-8A.

The corrected heat of solution of E-4 was 428.44 cal./gm.; the heats of solution of E-8 and E-8A, corrected for all impurities but uncorrected for the heat of sorption of excess water, were 432.64 and 434.05 cal./gm., respectively. The surface areas of E-4, E-8, and E-8A were 0.1, 26.1, and 21.8 meters^2/gm., respectively. By assuming that the heat evolved in the solution of water in the calcium hydroxide lattice is proportional to the amount of water dissolved, one can calculate from the above data both the heat of solution of water and the surface energy. The heat evolved in the solution was found to be 412 cal./gm. of water (or 7420 cal./mole of water), and the surface energy of calcium hydroxide was 1180 erg/cm.^{2}

3. It seems more likely that the excess water in Batches E-8 and E-8A was adsorbed water. Since there are no data available on the heats of adsorption of water on calcium hydroxide, the values were estimated on the basis of the fact that the heats of physical adsorption of water on a variety of surfaces show striking similarities.

The amount of excess water in Batch E-8 corresponded to a monolayer of adsorbed water, provided the area of a water molecule is assumed to be 10.3 Å^2. Although this value is somewhat smaller than the 10.6 Å^2 obtained from the density of liquid water, such a close packing on the surface does not seem unreasonable. Harkins and Jura (11) found that the integral net heat of adsorption of water on anatase (titanium dioxide), at an amount of water adsorbed equal to a monolayer, was 6550 cal./mole of water. Copeland (6) found in this laboratory that the integral net heat of adsorption of water on *hydrated* portland cement under the same condition was 6640 cal./mole. If one takes the average, 6600 cal./mole, as a reasonable value for the integral net heat of adsorption of water on calcium hydroxide at an adsorption equal to a monolayer, the water correction of the heat of solution of Batch E-8 is 2.78 cal./gm. This value is to be added to the difference between the heats of solution of E-8 and E-4, 4.20 cal./gm. The difference between the surface areas of E-4 and E-8 was 26.0 meters^2/gm. The calculated surface energy of calcium hydroxide was 1120 erg/cm.^{2}

As stated earlier, the heating of E-8 resulted in some sintering, the surface area decreasing from 26.1 to 21.8 meters^2/gm. If one assumes a molecular

area of 10.3 Å^2 for water, 6.33 mgm. of water would cover 1 gm. of E-8A with an adsorbed monolayer. The water content of E-8A was 1.2 mgm. per gm., corresponding to a surface coverage of 19%. The heat of adsorption of this water was estimated in the following manner. The integral net heat of adsorption of water on various surfaces was plotted against θ, the fraction of the surface covered. The data of Harkins and Jura (11) for anatase, those of Powers and Brownyard (21) and Copeland (6) for hydrated portland cement, and some data by the authors of this paper for hydrated tricalcium silicate fell on a single curve. The integral net heat of adsorption at $\theta = 0.19$ was 12,500 cal./mole. Assuming that this is a reasonable value for a calcium hydroxide surface as well, the water correction of the heat of solution of Batch E-8A is 0.83 cal./gm. This value is to be added to the difference between the heats of solution of E-8A and E-4, 5.61 cal./gm. The difference between the surface areas of E-8A and E-4 was 21.7 meters^2/gm. The calculated surface energy of calcium hydroxide was 1240 erg/cm.^{2}

The surface energy obtained from the data on E-4 and E-8 was found to be 1120 erg/cm.^{2}, and that obtained from the data on E-4 and E-8A was 1240 erg/cm.^{2} The average of the two is 1180 erg/cm.^{2} The value obtained on the basis of the assumption that the excess water was dissolved in the lattice of calcium hydroxide was also 1180 erg/cm.^{2}

4. Whether the excess water was dissolved or adsorbed, the conclusion is that *the surface energy of calcium hydroxide at 296°K. is 1180 erg/cm.^{2} The uncertainty, estimated below, is ±100 erg/cm.^{2}*

The standard errors of the average heats of solution for the three batches of calcium hydroxide were given in Table I. The standard error in the surface area of Batches E-8 and E-8A is ±0.2 meters^2/gm. These errors lead to an uncertainty of ±50 erg/cm.^{2} in the surface energy. Uncertainties in the corrections for impurities other than water introduce an additional error of ±15 erg/cm.^{2} The error in the water correction may be as high as 40 erg/cm.^{2} For the heat of adsorption of water on E-8A the value of 12,500 cal./mole was assumed. The heat of adsorption of water on calcium hydroxide is probably not as high as the heat of reaction of calcium oxide with water; nevertheless, if the value of 15,600 cal./mole is used for the heat of adsorption, the surface energy of calcium hydroxide calculated from the data of E-8A would be raised by 40 erg/cm.^{2}

The above errors together amount to an uncertainty of about 100 erg/cm.^{2} This does not take into account the uncertainty in the molecular area of nitrogen, discussed before. If Livingston's (19) value is correct, the surface energy of calcium hydroxide would be raised by 5%, or about 60 erg/cm.^{2} Nor does the 100 erg/cm.^{2} error include the possible error caused by an uptake of water during the introduction of the calcium hydroxide into the calorimeter. This error may amount to as much as 15 erg/cm.^{2} A cautious estimate of the surface energy of calcium hydroxide would be 1220±150 erg/cm.^{2}

5. The only surface energy value in the literature with which the present value for calcium hydroxide can be compared is that obtained by Fricke, Schnabel, and Beck (9) for magnesium hydroxide. Their value of 330 erg/cm.^{2}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12

For personal use only.

seems to be too low by a factor of 3, at least. They estimated the specific surface areas of their magnesium hydroxide samples by means of X-ray line broadening measurements, and the greatest part of the line broadening may have been caused by crystalline imperfections, rather than by dimensions. This point will be further discussed later.

One would intuitively expect that the surface energy of calcium hydroxide should be somewhere between the surface energies of calcium oxide, 1310 erg/cm.^{2}, and water, 118.5 erg/cm.^{2} (11). (There is no surface energy value available for ice.) The value of 1180 erg/cm.^{2} is actually between those limits, and it is quite close to the surface energy of calcium oxide. Perhaps this result is not too surprising. The non-specificity that one finds in physical adsorption is primarily due to the fact that the predominating factor is the change in the state of the adsorbate. Nevertheless, when one encounters such a *high degree* of non-specificity as found, for example, in the already discussed heats of adsorption of water on *anhydrous* and *hydrated* surfaces, the cause is probably to be found not merely in the identity of the adsorbate but also in the similarities between the surface energies of the adsorbents. Likewise, such dissimilarities as were found, for example, by Harkins and Boyd (10) in the heats of wetting of various ionic surfaces by water were probably caused by dissimilarities in the energies (both free and total) of those surfaces.

6. Jura and Garland (14) found that the free surface energy of magnesium oxide was 90 erg/cm.^{2} less than its total surface energy at room temperature. Because of the similarity of calcium oxide to magnesium oxide, it is probable that the free surface energy of calcium oxide is also about 100 erg/cm.^{2} less than its surface energy, or about 1200 erg/cm.^{2} In general, the entropies of solid surfaces seem to be low; thus, at room temperature the free surface energy differs only slightly from the total surface energy. A value of 1100 erg/cm.^{2} for the free surface energy of calcium hydroxide is probably close to the true value.

X-Ray Line Broadening and Surface Area

1. The broadening of X-ray diffraction lines is caused either by crystalline imperfections, such as, for example, mosaic structure (7), or by small dimensions of the crystals. Scherrer (22) was the first to show how mean dimensions of the crystallites can be calculated from line broadening. Naturally, this can be done only if the broadening caused by imperfections is negligible compared to the broadening caused by crystal size. This appeared to be true or nearly true for the calcium oxide and calcium hydroxide crystals used in the present investigations, since the surface areas calculated from line broadening measurements were, within the errors involved, about the same as those obtained from nitrogen adsorption.

2. The 2.405 Å line of calcium oxide is the (100) reflection; the dimension calculated from the broadening of this line is, therefore, that of the edge of the average cube. It follows from Scherrer's formula that

$$\frac{B}{93.11} = \frac{1}{D_{A\text{-}39}} - \frac{1}{D_{A\text{-}40}}$$

where B is the difference between the half intensity widths of the 2.405 Å lines of A-39 and A-40 in degrees of 2θ, and $D_{A\text{-}39}$ and $D_{A\text{-}40}$ are the lengths of the edges of the average cubes of A-39 and A-40 in Ångstrom units, respectively.

Using 3.345 gm./cc. for the density of calcium oxide and 0.3 meters^2/gm. for the specific surface area of A-40, one obtains the value of 5.98 μ for $D_{A\text{-}40}$. Since $B = 0.030°$ (see "Results"), $D_{A\text{-}39} = 2950$ Å. If it is assumed that A-39 was composed of cubes of equal sizes, calculation leads to the results that (*a*) 1 gm. of A-39 contained 1.16×10^{13} cubes, and (*b*) the specific surface area was 6.1 meters^2/gm. The surface area obtained by nitrogen adsorption was 7.8 meters^2/gm. Thus, line broadening indicated a surface area 22% *smaller* than nitrogen adsorption did.

3. Similar calculations were made for the two high-surface calcium hydroxide batches, E-8 and E-8A. In this case, it was assumed that the calcium hydroxide crystallites were hexagonal prisms, and the height of the average prism was obtained from the broadening of the 4.91 Å line (001), and the side of the hexagon was calculated from the broadening of the 3.11 Å line (100). The density of calcium hydroxide was taken to be 2.241 gm./cc., and the specific surface area of E-4 (used as standard), 0.1 meters^2/gm. The height of the average prism was found to be 845 Å for E-8 and 670 Å for E-8A, and the side of the average hexagon 1230 Å for E-8 and 1495 Å for E-8A. If it is assumed that E-8 was composed of hexagonal plates of equal sizes, and a similar assumption is made for E-8A, calculations lead to the results that (*a*) 1 gm. of E-8 contained 1.34×10^{14} and 1 gm. of E-8A, 1.15×10^{14} plates, and (*b*) the specific surface area of E-8 was 18.9 and that of E-8A, 20.2 meters^2/gm. The specific surface areas thus obtained for E-8 and E-8A are *smaller* than the nitrogen adsorption areas by 28 and 7%, respectively.

4. It is to be noted that in all three instances line broadening gave smaller surface areas than nitrogen adsorption did. The reason for this is found in the fact, experimentally demonstrated by Birks and Friedman (2), that line broadening gives greater weights to the large particles than to the small ones. It seems clear from their results, as well as from the present data, that the surface area calculated from the average dimensions, obtained from X-ray line broadening, will, in general, be smaller than the true surface area for polydisperse systems, *provided that the line broadening is caused by the dimensions of the crystals alone*. Line broadening can give an accurate value for the surface area only for monodisperse systems, just as nitrogen adsorption can give the correct particle size only for monodisperse systems.

In the majority of cases published in the literature, the surface areas calculated from line broadening were *larger* than those determined by nitrogen adsorption. It is very likely that in these instances the broadening was not caused by crystal size alone but by a combination of size and crystalline imperfections.

5. It follows from the above considerations that care must be exercised in calculating surface areas from line broadening. For example, the large apparent surface area value obtained by Fricke, Schnabel, and Beck (9) for magnesium hydroxide, discussed earlier, was probably caused by imperfections in the

crystals. Another example is found in some of the results obtained for calcium hydroxide, Batches E-8 and E-8A. The latter was obtained by heating the former at 180° to 200° for 16 hr. The nitrogen adsorption clearly indicated sintering, the surface area having decreased from 26.1 to 21.8 meters²/gm. However, the surface area calculated from line broadening showed a reverse effect; it increased on heating from 18.9 to 20.2 meters²/gm. This is, obviously, a false result.

6. Nevertheless, some interesting speculations can be made on the basis of the line broadening measurements. Heating resulted in a decrease in the number of crystallites per gram of calcium hydroxide by about 14%. This is an indication of sintering. The crystallites that disappeared must have been the smallest ones. The resulting material must have been more nearly monodisperse than the initial material, from which it follows that there should be a better agreement between the X-ray surface and the nitrogen surface for E-8A than for E-8. This was actually true; the X-ray surface of E-8 was 28% smaller than the nitrogen surface, whereas the X-ray surface of E-8A was only 7% smaller. The agreement between the X-ray surface and the nitrogen surface obtained for E-8A is quite striking. It would become even more striking if one would use Livingston's (19) value for the adsorption area of a nitrogen molecule. In that case the two would differ only by 2%.

The slight sintering resulted in some flow of the material. Line broadening showed that the flat plates had become thinner; the average height of the hexagonal plates of E-8 was 845 Å, that of E-8A was 670 Å.

7. All dimensions in this section were calculated by means of Scherrer's formula (22). Warren (29) also proposed a formula for the calculation of crystal dimensions from line broadening. For calcium oxide, Batch A-39, Scherrer's formula led to a value of 2950 Å for the edge of the average cube, whereas Warren's formula led to 860 Å. The former value gave a surface area 22% smaller than the nitrogen adsorption area, the latter gave an area 2.8 times larger. It seems, therefore, that for the types of systems investigated, Warren's formula is not applicable. No attempt was made to use the method of Stokes (24).

The Heat of Hydration of Calcium Oxide

A by-product of the present investigations was a value for the heat of the reaction

$$CaO\ (c, 23°) + H_2O(l, 23°) = Ca\ (OH)_2\ (c, 23°)$$

for the case when both the calcium oxide and calcium hydroxide crystals have negligible surface areas. The heat of solution of calcium oxide, Batch A-40, was 844.67 cal./gm. The surface area of this batch was 0.3 meters²/gm. Correcting to zero surface gave a heat of solution of 844.58 cal./gm. The heat of solution of calcium hydroxide, Batch E-4, was 428.44 cal./gm., and the surface area was 0.1 meters²/gm. Correcting to zero surface gave a heat of solution of 428.42 cal./gm. From these values, it follows that

$$\Delta H_{296} = -15{,}620 \text{ cal.}$$

The estimated uncertainty is ±20 cal. Thorvaldson, Brown, and Peaker (27) obtained the value of −15,640 cal. for ΔH_{293} by determining the heats of solution of calcium oxide and calcium hydroxide in hydrochloric acid, and −15,490 cal., by measuring directly the heat evolved in the hydration of calcium oxide. They gave preference to the former value, and the present result confirms the correctness of their choice.

ACKNOWLEDGMENTS

The authors are greatly indebted to Mr. R. H. Bragg for obtaining all the X-ray data published in this paper and for helping in their interpretation. They also wish to express their thanks to Miss Edith Turtle, who assisted Mr. Bragg in the X-ray work, to Messrs. C. L. Ford, E. E. Pressler, and E. LaBonde for the analytical data, and to Mr. T. C. Powers and Dr. L. E. Copeland for helpful discussions.

AMINO ACIDS

III. CYCLIC GUANIDINO ACIDS AND THEIR DERIVATIVES[1]

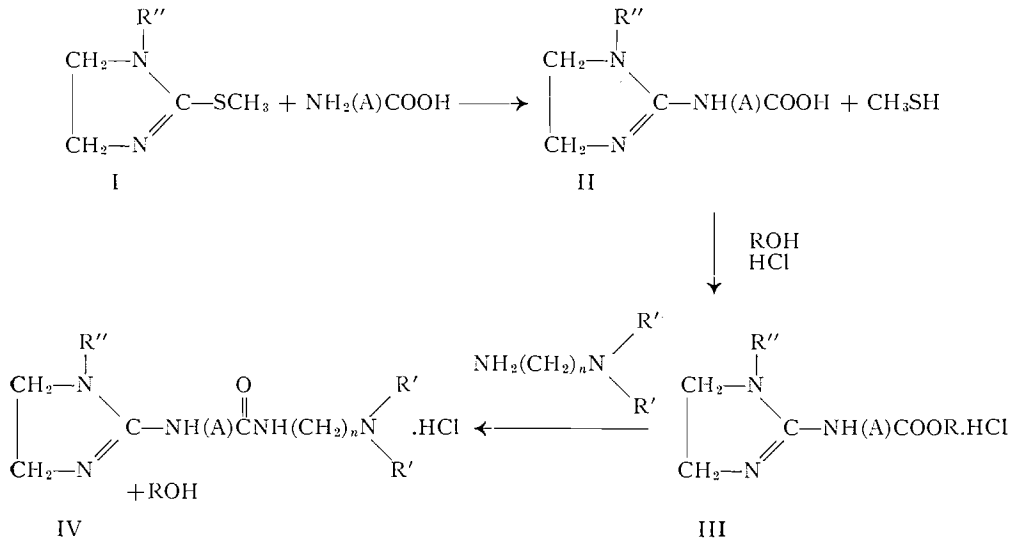
By D. L. Garmaise,[2] S. O. Winthrop,[3] Gordon A. Grant,[3] and A. F. McKay[2]

ABSTRACT

Several new cyclic guanidino acids have been prepared by the reaction of cyclic isothioureas with amino acids. The ethyl esters of some of these acids have been converted into dialkylaminoalkylamides by refluxing with dialkylaminoalkylamines in the presence of an inert solvent. A series of dialkylaminoethyl esters of the 2-(carboxyalkylamino)-2-imidazolines also have been prepared.

The reaction (3) of amino acids with cyclic isothioureas (I) provides a convenient method for the preparation of 2-(carboxyalkylamino)-2-imidazolines (II) (or the tautomeric 2-(carboxyalkylimino)-imidazolidines). These imidazoline derivatives are prepared most conveniently in the laboratory by refluxing the free base of a 2-methylmercapto-2-imidazoline and an amino acid in the presence on an inert solvent such as methanol or benzene. In this manner, the products have been obtained in yields as high as 96%.

Some difficulty has been experienced with the esterification of the 2-(carboxyalkylamino)-2-imidazolines (II). The yields of ester hydrochlorides (III) vary considerably although yields as high as 83% have been obtained. A



A = alkylene group R = alkyl or dialkylaminoethyl R′ = alkyl R″ = H or $-CH_2CH_2OH$

number of dialkylaminoethyl esters of the 2-(carboxyalkylamino)-2-imidazolines also have been prepared. These are described fully in the Experimental section.

The ethyl esters of the 2-(carboxyalkylamino)-2-imidazolines are converted into the corresponding amides (IV) by refluxing with amines in the presence of inert solvents. The amides are very difficult to purify as free bases. They are generally waxy light brown solids, so their dipicrates have been prepared for identification.

EXPERIMENTAL[4]

γ-Aminobutyric Acid

A solution of 2-pyrrolidone[5] (212.5 gm., 2.50 mole) and anhydrous barium hydroxide (223.3 gm., 1.30 mole) in 1 liter of water was heated at 100°C. for two hours. The solution was cooled, a few drops of concentrated hydrochloric acid added, and the solution was neutralized with 2.3 *N* sulphuric acid (1129 cc.). The suspension was boiled for 30 min. and then allowed to stand overnight. The barium sulphate was filtered (with the aid of Celite) and the filtrate, on evaporation, gave 200 gm. (78%) of crude product. One crystallization from ethyl alcohol (2 liters) yielded 170 gm. (68%) of product melting at 198–198.5°C.

ε-Aminocaproic Acid

A solution of ε-caprolactam[6] (113 gm., 1.0 mole) and anhydrous barium hydroxide (95.0 gm., 0.55 mole) in 1500 cc. water was heated at 100°C. for two hours. The solution was cooled, a few drops of concentrated hydrochloric acid were added, and the solution was neutralized by dropwise addition of 3 *N* sulphuric acid (370 cc.). The suspension of barium sulphate was boiled for 10 min., and then allowed to settle overnight. The precipitate was removed by filtration and the filtrate was evaporated, yield 120 gm. (92%). This crude residue was crystallized from ethyl alcohol (1 liter) to give 100 gm. (76.5%) of material melting at 200–202°C.

2-(γ-Carboxypropylamino)-2-imidazoline

Method A

A solution of 2-methylmercapto-2-imidazolinium iodide (1) (244 gm., 1.0 mole), γ-aminobutyric acid (98.0 gm., 0.95 mole), and sodium hydroxide (80 gm., 2.0 mole) in 2 liters of water was allowed to stand at room temperature for three days. The evolved methyl mercaptan was absorbed in 20% sodium hydroxide solution. At the end of the reaction period, the solution was diluted to a volume of 6 liters with water and it was passed through a column of mixed-bed resin (2 liters of Amberlite IRA–400[7] activated resin and 2 liters of Amberlite IRC-50 resin[7]) at a rate of 20 cc. per min. The column was washed with water and the combined eluate and washings were evaporataed *in vacuo*. The semicrystalline residue weighed 130 gm. (80% yield). Crystallization from methanol (300 cc.) gave 100 gm. of white crystals melting at 185–224°C.

Another crystallization from methanol raised the melting point to a constant value of 224–225°C. Calc. for $C_7H_{13}N_3O_2$: C, 49.10; H, 7.65; N, 24.52%. Found: C, 48.78; H, 7.99; N, 24.75%. Its picrate, which was formed in aqueous solution, melted at 171–172°C. after crystallization from alcohol. Calc. for $C_{13}H_{16}N_6O_9$: C, 38.99; H, 4.03; N, 21.00%. Found: C, 38.79; H, 3.88; N, 21.18%.

Method B

A solution of 2-methylmercapto-2-imidazolinium iodide (122 gm., 0.5 mole) in 500 cc. of water was passed through a column of Amberlite IRA–400 resin (1 liter) at a rate of 7 cc. per min. and then the column was washed with 2 liters of water. γ-Aminobutyric acid (50.0 gm., 0.49 mole) was added to the total eluate and the solution was allowed to stand in the fume-hood at room temperature for 60 hr. An amorphous residue (79 gm., 95% yield)was obtained from evaporation of this solution *in vacuo*. One crystallization from methanol (200 cc.) gave pure 2-(γ-carboxypropylamino)-2-imidazoline (m.p. 224–225°C.). This product did not depress the melting point of a sample of the acid prepared by method A. The methanolic mother liquor on evaporation gave 12 gm. of oily residue. This oil has not been identified.

Method C

2-Methylmercapto-2-imidazolinium iodide (24.4 gm., 0.10 mole) was added to a solution of potassium hydroxide (11.4 gm., 0.20 mole) in 12 cc. of water. This solution was extracted with ether (4×50 cc.) and the ethereal solution was evaporated. Nine grams (77.5%) of the free base, 2-methylmercapto-2-imidazoline, was obtained. The 2-methylmercapto-2-imidazoline and γ-aminobutyric acid (7.5 gm., 0.073 mole) in methanol (100 cc.) were refluxed for two hours until the evolution of methylmercaptan had ceased. When the solution was concentrated *in vacuo*, 12 gm. (96% yield based on γ-aminobutyric acid) of 2-(γ-carboxypropylamino)-2-imidazoline (m.p. 223–225°C.) was obtained.

1-(β-Hydroxyethyl)-2-(γ-carboxypropylamino)-2-imidazoline

γ-Aminobutyric acid (64.3 gm., 0.62 mole), 1-(β-hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (4) (179.4 gm., 0.60 mole), and sodium hydroxide (25.0 gm., 0.62 mole) were dissolved in 3 liters of water and this solution was allowed to stand at room temperature for three days. After the reaction was complete, the solution was processed as described in method A above for 2-(γ-carboxypropyl)-2-imidazoline. The crude product (94 gm., 77% yield) was purified to constant melting point of 204.5–205.5°C. by crystallization from methanol, yield 36.0 gm. Calc. for $C_9H_{17}N_3O_3$: C, 50.22; H, 7.97; N, 19.53%. Found: C, 50.21; H, 8.12; N, 19.80%.

1-(β-Hydroxyethyl)-2-(ε-carboxypentylamino)-2-imidazoline

1-(β-Hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (115.2 gm., 0.40 mole) in 62 cc. of absolute ethanol was added to a 2.42 *N* absolute ethanolic potassium hydroxide solution at 0°C. Ether (680 cc.) was added and the precipitated potassium iodide (65.3 gm., 98.2% yield) was removed by filtration. ε-Aminocaproic acid (46 gm., 0.35 mole) was added to the filtrate and the ether was removed by distillation. The residual alcoholic solution was refluxed for six hours until the evolution of methylmercaptan ceased. The alcoholic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/04/12
For personal use only.

solution on cooling gave 66.2 gm. (78%) of crude product which melted at 188–195°C. Crystallization from methanol (6 cc. per gm.) raised the melting point to a constant value of 209–210°C. Calc. for $C_{11}H_{21}N_3O_3$: C, 54.20; H, 8.70; N, 17.28%. Found: C, 54.25; H, 8.76; N, 16.80%.

2-(γ-Carbethoxypropylamino)-2-imidazoline

A solution of 2-(γ-carboxypropylamino)-2-imidazoline (17.1 gm., 0.1 mole) in ethanol (150 cc.) containing 0.3 mole of hydrogen chloride was refluxed for two hours. Benzene (50 cc.) was added and the refluxing was continued another hour. The benzene was distilled from the solution to remove water as the benzene–water–alcohol azeotrope. This procedure was repeated twice more and then the solution was taken to dryness, yield 21.0 gm. (89.5%). A sample of this product in aqueous solution was converted into its picrate. Its melting point was raised from 104–108°C. to 114–115°C. by three crystallizations from 50% aqueous ethanol. Calc. for $C_{15}H_{20}N_6O_9$: C, 42.02; H, 4.71; N, 19.62%. Found: C, 42.19; H, 4.65; N, 19.9%.

2-(N-γ-Dimethylaminopropyl-γ-carbamylpropylamino)-2-imidazoline

The above-described 2-(γ-carbethoxypropylamino)-2-imidazolinium chloride (20.5 gm., 0.087 mole) and γ-dimethylaminopropylamine (10.4 gm., 0.1 mole) were dissolved in absolute ethanol (200 cc.) and this solution was refluxed for four hours. Then the solution was evaporated to dryness and the residue was dissolved in 300 cc. of water. This aqueous solution was passed through a column of activated Amberlite IRA-400 resin (400 cc.) and the column was washed with water (1 liter). On evaporation the eluate gave 5.5 gm. (24.7%) of a brown gummy solid. This solid, its mono- and its di-hydrochlorides, could not be purified by crystallization. Its picrate formed from aqueous solution melted at 155–155.5°C. Calc. for $C_{24}H_{31}N_{11}O_{15}$: C, 40.38; H, 4.38; N, 21.6%. Found: C, 40.37; H, 4.56; N, 21.82%.

β-Diethylaminoethylamine

N,N-Diethyl ethylenediamine (b.p. 146–150°C. at 760 mm.; $n_D^{25} = 1.4345$) was obtained in 41% yield by the method of Braz and Skorodumov (2). This reaction also gave a 21.8% yield of N,N-diethyl-N′-(2-aminoethyl) ethylenediamine ($n_D^{27} = 1.4572$) as well as higher addition products.

2-(N-β-Diethylaminoethyl-γ-carbamylpropylamino)-2-imidazoline

A solution of 2-(β-carbethoxyethylamino)-2-imidazolinium chloride (7.34 gm., 0.029 mole) and β-diethylaminoethylamine (3.4 gm., 0.029 mole) in 60 cc. of absolute ethanol was refluxed for four hours. After evaporation, this solution gave 9.0 gm. (95%) of amorphous material. The residue was dissolved in methanol (100 cc.) and the methanolic solution was passed through a column of Amberlite IRA-400 resin (150 cc.). After the column was washed with methanol (450 cc.), the total eluate was evaporated. The oily residue weighed 3.2 gm. (35.6%). It could be crystallized from ethyl acetate (8 cc.) to give a gummy reddish solid. A picrate formed from this solid melted at 135–135.5°C. Calc. for $C_{25}H_{33}N_{11}O_{15}$: C, 41.26; H, 4.57; N, 21.2%. Found: C, 41.11; H, 4.36; N, 21.28%.

2-(N-γ-Dimethylaminopropylcarbamylmethylamino)-2-imidazoline (VI)

2-(Carbethoxymethylamino)-Δ^2-1,3-diazacyclopentene hydrochloride (3) (4.23 gm., 0.02 mole) and 2.08 gm. (0.02 mole) of N,N-dimethylaminopropylamine were refluxed in the presence of 40 cc. of absolute ethanol for four hours. On cooling in the refrigerator, a white solid separated, yield 0.658 gm. (22.5%). This solid melted at 280°C. with decomposition. It was identified as the free acid 2-(carboxymethylamino)-Δ^2-1,3-diazacyclopentene, by a comparison of their infrared absorption spectra. The ethanolic filtrate from the free acid was taken to dryness *in vacuo*. The residue was a viscous oil, which crystallized on standing, yield 4.09 gm. (74.8% as the monohydrochloride). A small sample of this solid was precipitated as its picrate from its aqueous solution. Two crystallizations from water raised the melting point from 167°C. to 189.5–191°C. Anal. Calc. for dipicrate $C_{22}H_{27}N_{11}O_{15}$: C, 38.52; H, 3.97; N, 22.48%. Found: C, 38.11; H, 4.14; N, 22.25%.

Dimethylaminoethyl Ester of 2-(ε-Carboxypentylamino)-2-imidazolinium Chloride Monopicrate

2-(ε-Carboxypentylamino)-2-imidazoline (3) (9.9 gm., 0.05 mole) and dimethylaminoethanol (4.5 gm., 0.05 mole) were suspended in 150 cc. of toluene and heated at 140°C. for 10 hr. During the heating period dry hydrogen chloride was bubbled through the solution and toluene was distilled over slowly. Fresh toluene was added at intervals as required. On cooling, the toluene was decanted and the oily residue was converted into its picrate in aqueous solution, yield 17 gm. (63.5%). The melting point of this picrate was raised from 183–185°C. to 186–187.5°C. by one crystallization from ethanol. Calc. for $C_{19}H_{30}ClN_7O_9$: C, 42.65; H, 5.63; Cl, 6.62; N, 18.30%. Found: C, 43.02; H, 5.57; Cl, 6.75; N, 18.28%.

Dimethylaminoethyl Ester of 2-(γ-Carboxypropylamino)-2-imidazolinium Chloride Monopicrate

The dimethylaminoethyl ester of 2-(γ-carboxypropylamino)-2-imidazoline chloride monopicrate (m.p. 183–185°C.) was prepared in 46.3% yield by the above procedure. One crystallization from acetonitrile raised the melting point to a constant value of 188–189°C. Calc. for $C_{17}H_{26}ClN_7O_9$: C, 40.25; H, 5.16; Cl, 6.98; N, 19.35%. Found: C, 40.44; H, 5.15; Cl, 6.73; N, 19.25%.

Dimethylaminoethyl Ester of 2-(Carboxymethylamino)-2-imidazoline Dipicrate

The above esterification procedure gave the dipicrate of the dimethylaminoethyl ester of 2-(carboxymethylamino)-2-imidazoline (m.p. 152–156°C.) in 48.0% yield. Two crystallizations from acetonitrile raised the melting point to 161.5–165.5°C. Calc. for $C_{21}H_{24}N_{10}O_{16}$: C, 37.55; H, 3.37; N, 20.85%. Found: C, 37.85; H, 3.46; N, 20.57%.

In a similar manner the following dialkylaminoalkyl esters of 2-(ε-carboxypentylamino)-2-imidazoline were prepared.

Diisopropylaminoethyl Ester of 2-(ε-Carboxypentylamino)-2-imidazoline Dipicrate

M.p. 127–130°C.; yield 86.6%. Calc. for $C_{29}H_{40}N_{10}O_{16}$: C, 44.35; H, 5.14; N, 17.85%. Found: C, 44.76; H, 5.08; N, 17.78%.

Diethylaminoethyl Ester of 2-(ε-Carboxypentylamino)-2-imidazoline Dipicrate

M.p. 120–123°C.; yield 68.8%. Calc. for $C_{27}H_{36}N_{10}O_{16}$: C, 42.85; H, 4.79; N, 18.51%. Found: C, 43.15; H, 4.51; N, 18.49%.

ACKNOWLEDGMENT

The authors are grateful to Dr. A. Halasz for the preparation of the β-diethylaminoethylamine and to Miss E. Laycock for skillful technical assistance.

THE DISTRIBUTION OF PLUTONIUM IN THE SYSTEMS URANIUM–SILVER AND URANIUM–SILVER–GOLD[1]

By D. E. McKenzie

ABSTRACT

An expression due to Hildebrand and Scott has been used to select silver as a possible extractant for plutonium from neutron-irradiated uranium. The distribution of plutonium between molten silver and molten neutron-irradiated uranium has been examined in small-scale experiments. The fraction of plutonium in the silver layer increases with increasing temperature. For equal weights of silver and uranium containing 0.1% plutonium, 88% of the total plutonium is distributed to the silver phase at 1350°C. Greater proportions of plutonium are found in the silver phase in experiments with uranium of lower initial plutonium concentration. On the addition of gold to the system plutonium extraction is increased and passes through a maximum. This maximum appears to be associated with a particular concentration of gold in silver and of gold in uranium.

INTRODUCTION

A cheap and simple method for the separation of plutonium from neutron-irradiated uranium may be important to the development of cheap nuclear power. One approach of some promise for metallic uranium fuels is to achieve the separation while retaining the uranium as metal. The volatilization of plutonium from neutron-irradiated uranium was described in a previous paper (3) as an example of this approach. A second possible technique makes use of the principle of molten metal extraction. In this method plutonium is extracted from molten uranium into a metal which is essentially immiscible with uranium. As the extracting metal, silver has shown considerable promise. The theoretical background used for the selection of silver and some of the results obtained with this metal are described in this paper. The use of silver has also been considered by Dr. F. H. Spedding and co-workers at the Ames laboratory of the United States Atomic Energy Commission. Recent work by this group was reported at Geneva, Switzerland, in August, 1955 (7).

SELECTION OF AN EXTRACTING METAL

For the extraction of plutonium from uranium, a metal was required which dissolved plutonium but which was essentially immiscible with uranium. Although uranium phase diagrams were available, a theoretical method was required to predict which metals would dissolve plutonium.

A method due to Hildebrand and Scott (2, p. 333) was used. They deduced as a criterion for the complete miscibility of two liquid metals the expression

$$\tfrac{1}{2}(V_1+V_2)(\delta_1-\delta_2)^2 < 2RT,$$

where V_1 and V_2 are the atomic volumes of metals 1 and 2,

δ_1 and δ_2 are the solubility parameters of 1 and 2,

R is the gas constant and T is the absolute temperature.

[1]*Manuscript received February 21, 1956.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 308.

The solubility parameter δ is given by the expression $\delta = (\Delta E_v/V)^{\frac{1}{2}}$ where ΔE_v is the energy of vaporization of the metal. Hildebrand and Scott have calculated the solubility parameters of most metals (2, p. 323). For plutonium a value for δ of 84 at room temperature was determined from the available data.

The miscibility criterion was used to compile a group of metals whose liquids should be miscible with liquid plutonium. From this group were chosen those metals which were immiscible with liquid uranium and which would exist as liquids under one atmosphere pressure in the temperature range 1132° to 1400°C. In this manner silver and the rare earth metals were predicted as possible extracting agents. Of these, silver appeared the most promising because its physical and chemical properties are so markedly different from those of plutonium.

EXPERIMENTAL

Materials and Apparatus

The neutron-irradiated uranium was cut from rods which had been irradiated in the NRX reactor and allowed to decay for three years. For each experiment the uranium was washed immediately before use in dilute nitric acid, water, and then acetone. The silver with a fineness of 999.7 was obtained from the Royal Canadian Mint. Beryllia crucibles were purchased from the Brush Beryllium Co.

Molten uranium and molten silver were contacted in a bell jar type of apparatus which is illustrated in Fig. 1. Cooling water was circulated through a copper coil soldered around the mild steel bell and through a compartment

in the fixed bottom plate. Heat was supplied by a 15 kva. Lepel sparkgap induction furnace. The chamber was evacuated by a Welch Duo-seal mechanical pump and welding grade argon was used as an inert atmosphere. The bell jar resided in a lead-shielded dry box and was viewed through high density glass.

Temperatures were determined with an optical pyrometer. The pyrometer was calibrated from observations of the melting of various solids of known melting point in the apparatus. A rough check of the calibration was obtained by observing the melting point of silver in each run. The temperatures have a probable error of ±25°C.

A different apparatus which will be described in a later communication was used to determine the temperature coefficient of plutonium distribution. The charge was resistance heated and its temperature measured by a thermocouple. The temperatures cited for these measurements are accurate to ±5°C.

Procedures and Analyses

For an experiment weighed amounts of silver and neutron-irradiated uranium in a beryllia crucible were placed in the graphite holder, the bell bolted to the bottom plate, and the chamber evacuated to a pressure of 1 to 10 microns of Hg. The pump was then diverted and the chamber filled to atmospheric pressure with argon. The evacuation and argon filling were repeated three times before heating. The charge was held at temperature for 20 min., which was found to be ample time to establish equilibrium.

After cooling in argon, the metal billet was removed from the crucible and placed in dilute hydrochloric acid to remove the uranium phase. The silver phase which remained was washed thoroughly with water, dried, and weighed. It contained substantially all of the original silver and about 5% by weight of uranium, in approximate agreement with published solubility data (1). This phase was dissolved in dilute nitric acid. In runs in which gold was added, a fluffy black residue, containing most of the gold in the silver layer, remained and was dissolved in aqua regia.

The solutions were analyzed for plutonium by standard radiochemical procedures and the distribution coefficient K_{Pu} calculated where K_{Pu} = mole fraction of plutonium in silver/mole fraction of plutonium in uranium. Gold analyses were performed using the iodide method (5) and K_{Au} calculated from K_{Au} = mole fraction of gold in silver/mole fraction of gold in uranium.

RESULTS AND DISCUSSION

Variation of K_{Pu} with Temperature

The temperature range of interest in this system lies between 1132°C., the melting point of uranium, and 1350°C., above which temperature silver begins to distill at an appreciable rate in one atmosphere of argon. K_{Pu} increases with temperature in this range. The results are summarized in Table I and plotted as log K_{Pu} vs. $1/T$ in Fig. 2.

the slope of this line. (The uncertainties in a single determination of K_{Pu} are equivalent to an error of ± 0.5 kcal. in ΔH.) This ΔH represents the heat of transfer of one gram-atom of plutonium from liquid uranium to liquid silver and, hence, is the sum of a total or integral heat of solution of plutonium in silver and a heat of dilution of plutonium in neutron-irradiated uranium. From investigations of the volatilization of plutonium from uranium fuel (3, 4) it was concluded that plutonium behaves essentially ideally in molten neutron-irradiated uranium in the temperature range 1540–1770°C. This conclusion implies a zero heat effect associated with the removal of plutonium from this material at such temperatures. Assuming the validity of this conclusion and that ideal behavior extends to the lower temperatures encountered in the present work, the measured heat of transfer is a total heat of solution, per gram-atom of plutonium, of liquid plutonium in liquid silver. Recognizing that the equilibrium concentration of plutonium in silver is about 0.05 atom %, 12.5 kcal. may be considered as $\bar{L}^{\circ}_{Pu}$, the limiting partial molal heat content, relative to liquid plutonium, of plutonium in liquid silver, or "the partial molar heat of mixing of plutonium in silver" (6).

Variation of K_{Pu} with Plutonium Concentration

Plutonium concentrations were varied by choosing uranium of suitable irradiation history and also by adding natural uranium as required. K_{Pu} was found to increase with decreasing plutonium concentration. The data are given in Table II and plotted as log K_{Pu} vs. log(Pu concentration) in Fig. 3. Included in the data is a value for K_{Pu} at 1325°C. and an initial plutonium concentration of 0.1%, calculated from the equation derived in the preceding section.

TABLE II

VARIATION OF K_{Pu} WITH PLUTONIUM CONCENTRATION
U/Ag weight ratio = 1/1, temperature = 1325±25°C.

Run No.	Wt. U (gm.)	Initial Pu conc. in U (%)	K_{Pu}
61	8.823	3.63×10^{-4}	7.48
72	5.852	5.08×10^{-4}	6.87
60	4.631	8.29×10^{-4}	5.93
71	5.642	2.21×10^{-3}	6.58
70	4.113	5.22×10^{-3}	5.16
79	3.847	8.50×10^{-3}	5.31
119	5.408	4.24×10^{-2}	4.20
—	—	1.0×10^{-1}	3.16

The equation $\log K_{Pu} = 0.47 - 0.11 \log(\text{initial \% Pu in U})$ describes approximately the increase in plutonium extraction with decreasing plutonium concentration. In the recent work with silver at the Ames laboratory (7) a similar effect was observed in extractions from uranium/chromium alloy but the opposite effect, i.e. a decrease in extraction with decreasing plutonium concentration, was obtained for extractions from uranium. The latter results, which were obtained at 1200 °C. using samples of uranium of two different plutonium concentrations, are also plotted in Fig. 3.

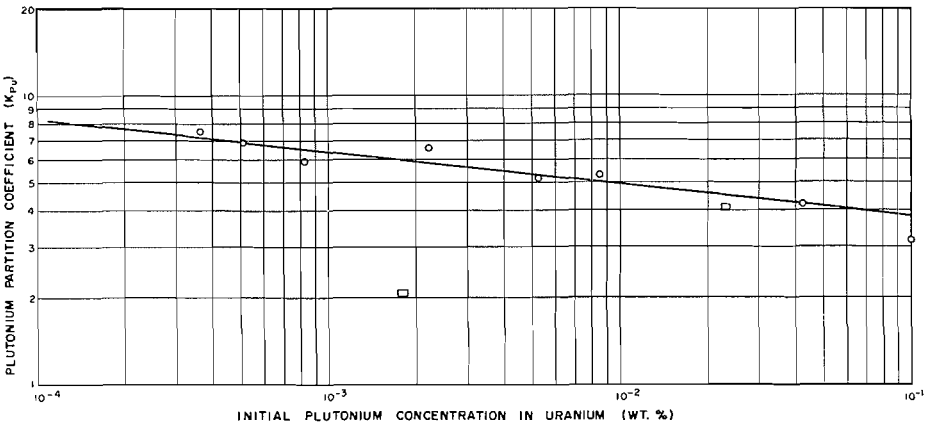

FIG. 3. The variation of K_{Pu} with plutonium concentration.
○ This work. U/Ag weight ratio = 1/1. Temperature 1325±25°C.
□ Voigt's (7) results. U/Ag weight ratio = 1.8/1. Temperature = 1200°C.

Variation of K_{Pu} with the Addition of Gold to the Uranium/Silver System

The effect, on plutonium distribution, of adding other metals to the uranium/silver system was examined for effects analogous to those of complexing or salting-out agents in water/organic solvent systems. The metal was added to a silver and uranium charge and then the melting and contacting operations performed. The metals cerium, tin, gold, copper, magnesium, lead, bismuth, aluminum, lithium, and gallium were considered but all, except gold, showed an adverse effect on plutonium extraction. In each case the weight of the added metal was less than 4% of the weight of uranium in the run.

The extraction of plutonium by silver/gold alloys was studied in greater detail. The extraction exhibits a dependence on gold concentration whereby K_{Pu} passes through a maximum. Also, the distribution of gold between uran-

ium and silver has been determined and K_{Au}, for a given uranium to silver ratio, appears to be independent of the amount of gold added. A typical set of data is shown in Table III which summarizes the results for a uranium to silver ratio of 1/1. These results are plotted as K_{Pu} vs. Au concentration in Fig. 4. For this ratio a maximum value for K_{Pu} of about 13.5 is obtained, corresponding to a gold addition of 3.5 wt. % of the uranium present.

Similar studies have been made for uranium to silver weight ratios of 2/1, 4/1, and 8/1 at the same temperature (1325°C.) and using uranium of the same initial plutonium concentration (0.01%). The maximum values of K_{Pu} were essentially the same as that found for a 1/1 ratio of uranium to silver. However, maximum plutonium extraction occurs at a different amount of added gold

for each ratio. The gold addition corresponding to maximum K_{Pu} and the average K_{Au} for each ratio are presented in columns 2 and 3 of Table IV. By combining these data, the concentration of gold in silver and in uranium may be calculated for the condition of maximum K_{Pu}. The results of the calculations are shown in columns 5 and 7 of Table IV. It appears that, within the precision of the data, maximum plutonium extraction is achieved at essentially a uniform concentration of gold in silver and also a uniform concentration of gold in uranium independent of the uranium to silver ratio.

THE PREPARATION AND SOME CLEAVAGE REACTIONS OF ALKYL AND SUBSTITUTED ALKYL METHANESULPHONATES

THE SYNTHESIS OF FLUORIDES, IODIDES, AND THIOCYANATES[1,2]

By F. L. M. Pattison and J. E. Millington

ABSTRACT

Representative esters of methanesulphonic acid were synthesized, and cleaved to form the corresponding fluorides, iodides, and thiocyanates. From this work was developed a convenient laboratory procedure for converting alcohols to fluorides.

The preparation and uses of simple alkyl sulphonates, $ROSO_2R'$, have received considerable attention (7, 8, 9, 10, 26, 27, 30), but little information is available on the reactions of those alkyl sulphonates in which R contains a second functional group. The work described in this paper was undertaken with two objectives: (*a*) to develop a new method of preparing ω-fluoroalkyl compounds, which in turn were required for toxicity studies (20, 21), and (*b*) to examine the reactivity of the sulphonate group relative to that of other functional groups in the same molecule. Methanesulphonates were investigated in most detail, but some benzenesulphonates and *p*-toluenesulphonates were prepared and used for comparison studies on the relative reactivities of the sulphonate moieties.

The sulphonates were prepared by three methods. (1) Esterification of alcohols with the appropriate sulphonyl chloride (19, 26) or fluoride (21) was found to be convenient and economical. Results are summarized in Table I. (2) Occasionally, treatment of iodides or bromides with silver methanesulphonate in acetonitrile (10) proved to be satisfactory, particularly in those instances in which the corresponding hydroxyl compounds were unstable or inaccessible. Results are summarized in Table II. (3) Early in the work, a new method was developed for the preparation of ω-chloroalkyl methanesulphonates by opening of cyclic ethers with methanesulphonyl chloride; an analogous method has subsequently been reported for the preparation of 4-chlorobutyl *p*-toluenesulphonate (11). Conditions and yields are summarized in Table III. One reaction using benzenesulphonyl chloride was carried out: the acid chloride, ethylene oxide, and a trace of zinc chloride were sealed in a glass ampoule and allowed to stand at room temperature for 70 days; 2-chloroethyl benzenesulphonate was obtained in 82% yield.

Reactions of Sulphonates with Potassium Fluoride (8, 21)

$$ROMs + KF \rightarrow RF + MsOK$$

Initially, replacement of the sulphonoxy group (CH_3SO_2O–) by fluoride was attempted in methanol; however, the isolation of a relatively large proportion

of hexyl methyl ether from a mixture of potassium fluoride and hexyl methanesulphonate indicated the unfavorable properties of this solvent. Dimethyl formamide, dimethyl sulphoxide, and diethyl cellosolve were found to be unsuitable. Ethylene glycol gave results analogous to those obtained with methanol, but diethylene, triethylene, and tetraethylene glycols did not exhibit the same tendency for ether formation. Diethylene glycol was finally selected as the solvent for this study because of its availability and ease of purification. The product was continuously removed as the reaction proceeded. Conditions and yields are summarized in Table V.

The main side reactions were: (*a*) dehydration of diethylene glycol in the presence of potassium fluoride to give dioxane; and (*b*) replacement of halide by fluoride to give ω,ω'-difluoroalkanes. In all the cleavage reactions, appreciable quantities of dioxane were formed, and when temperatures higher than those listed in Table V were used, difluoroalkanes were obtained from ω-haloalkyl methanesulphonates in 40–60% yield.

Attempts were then made to combine the two stages—esterification and cleavage—in order to devise a continuous one-step process for conversion of hydroxyl to fluoride. For satisfactory yields in the potassium fluoride cleavage, it is advantageous to exclude all traces of sulphonyl chlorides and of ionic chloride, the latter competing with the fluoride during the cleavage. Consequently a modified preparation of sulphonates was developed in this laboratory[3](21); this involved treatment of the alcohol with a sulphonyl fluoride, in the presence of an excess of anhydrous potassium fluoride to remove the liberated hydrogen fluoride as potassium bifluoride:

$$X(CH_2)_nOH + MsF + KF \rightarrow X(CH_2)_nOMs + KFHF.$$

The cleavage of the resultant sulphonate was then effected by the excess potassium fluoride. The over-all reaction may be represented thus:

$$X(CH_2)_nOH + MsF + 2KF \rightarrow X(CH_2)_nF + MsOK + KFHF.$$

A limited number of alcohols were converted to the corresponding fluorides by this method; yields are shown in Table VII. When applied to unsubstituted alcohols this method failed at the esterification stage. From the gradation in yields obtained (Table VII: $Cl(CH_2)_2- > Cl(CH_2)_3- > Cl(CH_2)_5-$; Cl– > Br–; Cl– > MeO– > EtO–), it seems probable that a fundamental requirement is the presence in the alcohol of an electronegative group capable of exerting an inductive effect; hence the method is of very limited applicability.

TABLE VII

CONVERSION OF ALCOHOL TO FLUORIDE BY CONTINUOUS METHOD

Alcohol	Yield of fluoride, %
$Cl(CH_2)_2OH$	53[a]
	60[b]
$Cl(CH_2)_3OH$	10[a]
$Cl(CH_2)_5OH$	0[a]
$Br(CH_2)_2OH$	35[a]
$MeO(CH_2)_2OH$	43[a]
$EtO(CH_2)_2OH$	27[a]
	29[b]

[a] *Via methanesulphonate.*
[b] *Via benzenesulphonate.*

To circumvent this difficulty, a semicontinuous method was examined. Adapted from the previously reported procedure of Edgell and Parts (8), this involved the preparation of the sulphonate using the appropriate sulphonyl chloride, followed by isolation and azeotropic drying, but not purification; cleavage with potassium fluoride was then effected in the usual way. Results are summarized in Table VIII. This method affords a convenient and simple means of converting alcohols to the corresponding fluorides.

[3] *Originally developed by S. B. D. Hunt.*

TABLE VIII

CONVERSION OF ALCOHOL TO FLUORIDE BY "SEMICONTINUOUS" METHOD

Alcohol	Sulphonate intermediate	Yield of fluoride, %
$CH_3(CH_2)_5OH$	$CH_3(CH_2)_5OMs$	54
	$CH_3(CH_2)_5OBs$	54
	$CH_3(CH_2)_5OTs$	47
$CH_3(CH_2)_9OH$	$CH_3(CH_2)_9OMs$	48
	$CH_3(CH_2)_9OBs$	35

Physical constants of the fluorides prepared by the above methods are listed in Table IX.

Reactions of Chloroalkyl Sulphonates with Sodium Iodide

$$Cl(CH_2)_nOMs + NaI \rightarrow Cl(CH_2)_nI + MsONa$$

The preparations listed in Table X were studied for various reasons: (*a*) to obtain samples of the chloroiodides for other work; (*b*) to devise an improved procedure for preparing 2-chloroethyl iodide, which is inconvenient to obtain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

by other means; (*c*) to compare the procedure with the well-known half-iodination of dichloroalkanes; and (*d*) to obtain information regarding the relative reactivities of the chloride and sulphonoxy groupings in a typical S_N2 reaction.

The chloroalkyl sulphonates were allowed to react at room temperature with an equimolar quantity of sodium iodide in acetone. Yields of the corresponding chloroalkyl iodides are shown in Table X. It can be seen that the reaction is as efficient as the half-iodination procedure for which yields of 50–70% are reported (1, 13), and that 2-chloroethyl iodide can be obtained in satisfactory yield. The sulphonoxy grouping is preferentially replaced under the conditions employed.

TABLE X

Preparation of Methanesulphonates

The following are representative examples of the procedures employed in the preparation of methanesulphonates.

Method (1). The reaction of an Alcohol with a Sulphonyl Halide

2-Chloroethyl methanesulphonate

A mixture of 2-chloroethanol (80.5 gm., 1.0 mole) and methanesulphonyl fluoride (21.7 gm., 0.22 mole) was stirred at −15°, and powdered sodium hydroxide (8.8 gm., 0.22 mole) was added in small portions. Stirring was continued at 25° for five and one-half hours. The product was diluted with water and extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulphate. The ether was removed and fractionation of the residue gave 2-chloroethyl methanesulphonate (26.2 gm., 75%).

2-Chloroethyl methanesulphonate

A mixture of 2-chloroethanol (40.5 gm., 0.5 mole), methanesulphonyl fluoride (9.8 gm., 0.1 mole), and anhydrous potassium fluoride (17.4 gm., 0.3 mole) was vigorously stirred at room temperature for six hours and then allowed to stand overnight. It was diluted with water and extracted with ether. The extract was dried over anhydrous sodium sulphate, the ether removed, and the residue fractionated to give 2-chloroethyl methanesulphonate (14 gm., 88%).

3-Chloropropyl methanesulphonate

A mixture of 3-chloropropanol (71 gm., 0.75 mole) and pyridine (79 gm., 1.0 mole) was stirred in a flask cooled in an ice–salt bath, and methanesulphonyl chloride (86 gm., 0.75 mole) was added slowly over a period of one

[4]*The microanalyses were performed by Mr. J. F. Alicino, Metuchen, N.J. Results are shown in Table XII.*
Boiling points are uncorrected.
Physical constants are listed in the appropriate tables.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

and one-half hours. Stirring was continued for a further three hours. The reaction product was diluted with water and 6 *N* hydrochloric acid until there was no pyridine odor, and then extracted with ether. The extracts were washed successively with water, aqueous sodium carbonate, and water again. After drying over anhydrous calcium chloride and removal of the ether, fractionation of the residue gave 3-chloropropyl methanesulphonate (106.5 gm., 83%).

Method (2). The Reaction of a Halide with Silver Methanesulphonate

Ethyl 4-methanesulphonoxycrotonate

A mixture of ethyl 4-bromocrotonate (58 gm., 0.3 mole), silver methanesulphonate (61 gm., 0.3 mole), and acetonitrile (200 ml.) was heated under reflux on a water bath for one hour. After cooling, the precipitated silver bromide was removed by filtration and the filtrate concentrated. After a further amount of precipitate had been removed, the filtrate was taken up in ether, washed successively with water, aqueous sodium carbonate, and water again, and dried over anhydrous sodium sulphate. After removal of the ether, fractionation of the residue gave ethyl 4-methanesulphonoxycrotonate (37.3 gm., 60%).

Method (3). The Reaction of a Cyclic Ether with a Sulphonyl Halide

2-Chloroethyl methanesulphonate

Ethylene oxide (66 gm., 1.5 moles), methanesulphonyl chloride (58 gm., 0.51 mole), freshly fused zinc chloride (2 gm.), and ether (100 ml.) were placed in a stainless steel bomb, and heated at 40° for 32 hr. with constant agitation. On cooling, the solid material was removed by filtration, and the filtrate fractionated to give methanesulphonyl chloride (23.2 gm.) of b.p. 52° at 12 mm., and 2-chloroethyl methanesulphonate (27.8 gm.). This represents a yield of 50% based on reacted starting material.

2-Chloroethyl benzenesulphonate

A mixture of ethylene oxide (21 gm., 0.48 mole), benzenesulphonyl chloride (26.5 gm., 0.15 mole), and zinc chloride (0.5 gm.) was sealed in a glass ampoule and allowed to stand at room temperature (*ca.* 22°) for 70 days. The mixture was filtered to remove solid material, and the filtrate on fractionation yielded 2-chloroethyl benzenesulphonate (27 gm., 82%).

4-Chlorobutyl methanesulphonate

Tetrahydrofuran (24.6 gm., 0.33 mole), methanesulphonyl chloride (39 gm., 0.33 mole), anhydrous zinc chloride (1.0 gm.), and ether (100 ml.) were heated in a stainless steel bomb at 80° with constant agitation for four hours. On cooling, the product was filtered to remove solid material, and the filtrate fractionated to give methanesulphonyl chloride (25 gm.) of b.p. 52° at 12 mm., and 4-chlorobutyl methanesulphonate (15.7 gm.). This represents a yield of 69% based on reacted starting material.

Preparation of Fluorides

The following procedures illustrate the methods employed for the preparation of fluorides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/04/12
For personal use only.

2-Fluoroethyl Chloride

A mixture of 2-chloroethyl methanesulphonate (15.9 gm., 0.1 mole), potassium fluoride (11.6 gm., 0.2 mole), and methanol (200 ml.) was heated under reflux with intermittent stirring for $11\frac{1}{2}$ hr. On cooling, it was diluted with water and extracted with di-*n*-butyl ether. The extracts were dried over anhydrous sodium sulphate and on fractionation gave 2-fluoroethyl chloride (4 gm., 49%).

3-Fluoropropyl Chloride

A mixture of 3-chloropropyl methanesulphonate (17.3 gm., 0.1 mole), anhydrous potassium fluoride (11.6 gm., 0.2 mole), and diethylene glycol (200 gm.) was placed in a three-necked flask equipped with a thermometer, precision-bore stirrer, and a short still head carrying a condenser and ice-cooled receiver. The stirrer was started, the pressure in the system reduced to 320 mm., and the temperature maintained at 100°. The distillate was collected over a period of four hours, and on fractionation gave 3-fluoropropyl chloride (6.3 gm., 65%).

Ethyl 4-Fluorocrotonate

A mixture of ethyl 4-methanesulphonoxycrotonate (21 gm., 0.1 mole), anhydrous potassium fluoride (11.6 gm., 0.2 mole), and diethylene glycol (200 gm.) was placed in a flask fitted with a thermometer, precision-bore stirrer, and a still head carrying a condenser and ice-cooled receiver. The flask was heated to 100°, and the distillate was collected at a pressure of 13 mm. over a period of three hours. This was dissolved in ether, washed with water, and dried over anhydrous sodium sulphate. After removal of the ether, the residue on fractionation through a modified Podbielniak column gave ethyl 4-fluorocrotonate (6.6 gm., 50%).

2-Fluoroethyl Chloride (Continuous Method)

In the equipment described above, a mixture of 2-chloroethanol (24.1 gm., 0.3 mole), methanesulphonyl fluoride (29.4 gm., 0.3 mole), and anhydrous potassium fluoride (34.8 gm., 0.6 mole) was stirred at room temperature for 24 hr. Diethylene glycol (250 gm.) and anhydrous potassium fluoride (11.6 gm., 0.2 mole) were added, the pressure in the system was reduced to 300 mm., and the temperature raised to 100°. The distillate (16.6 gm.), collected over four hours, gave on fractionation 2-fluoroethyl chloride (13.1 gm., 53%).

n-Hexyl Fluoride (Semicontinuous Method)

n-Hexyl alcohol (15.3 gm., 0.15 mole) and pyridine (30 gm., 0.38 mole) were stirred at −15°, and to the mixture methanesulphonyl chloride (17.1 gm., 0.15 mole) was slowly added. The mixture was stirred for a further four hours and diluted with water and 6 *N* hydrochloric acid until there was no pyridine odor. The aqueous layer was extracted with methylene chloride, and the combined organic layer and extracts were washed with water. These were then transferred to the three-necked flask described above. The water – methylene chloride azeotrope was distilled, and any residual low-boiling material removed under aspirator pressure. Diethylene glycol (250 gm.) and anhydrous

potassium fluoride (17.4 gm., 0.3 mole) were added, the temperature was raised to 100°, and the distillate collected over one and one-half hours at a pressure of 300 mm. Fractionation of this yielded *n*-hexyl fluoride (8.8 gm., 54%).

Preparation of Chloroalkyl Iodides

The preparation of 3-chloropropyl iodide is representative.

3-Chloropropyl Iodide

A mixture of 3-chloropropyl methanesulphonate (17.3 gm., 0.1 mole), sodium iodide (15.0 gm., 0.1 mole), and anhydrous acetone (100 ml.) was allowed to stand at room temperature, with occasional shaking, for 72 hr. It was diluted with water and extracted with ether. The extracts were washed successively with aqueous sodium thiosulphate and with water, and dried over anhydrous sodium sulphate. Removal of the ether and fractionation of the residue gave 3-chloropropyl iodide (10.5 gm.) and 3-chloropropyl methanesulphonate (4.5 gm.). This represents a yield of 70% based on reacted starting material.

Preparation of Chloroalkyl Thiocyanates

The preparation of 3-chloropropyl thiocyanate is representative.

3-Chloropropyl Thiocyanate

A mixture of 3-chloropropyl methanesulphonate (17.3 gm., 0.1 mole), potassium thiocyanate (9.7 gm., 0.1 mole), and 80% ethanol (25 ml.) was heated under reflux on a water bath for 16 hr. The mixture was diluted with water and extracted with ether. The extract was dried over anhydrous sodium sulphate and fractionated, yielding 3-chloropropyl thiocyanate (10 gm., 62%).

THE ADSORPTION OF NITROGEN BY CARBON BLACK AND GRAPHITE[1]

By H. L. McDermot and B. E. Lawton

ABSTRACT

The adsorption of nitrogen by a carbon black designated as Spheron 9 has been measured at 78°K. and 71°K. The second type of hysteresis previously reported for three Acheson graphites has also been observed for the adsorption of nitrogen by Spheron 9 at both temperatures. Unlike the graphite isotherms, it was possible to scan the hysteresis loop of the Spheron isotherm. The adsorption of nitrogen has been measured for an artificial graphite in which the ash had been leached out by treatment with hydrofluoric acid. The results were compared with those obtained previously for a sample of the unleached graphite. It was found that although the surface area was altered by this treatment, the hysteresis effects remained unchanged.

INTRODUCTION

In an earlier communication (3), two hysteresis effects were reported for the adsorption of nitrogen, oxygen, and argon on three Acheson graphites at liquid nitrogen temperatures. The first of these was attributed to the porous structure of the graphite and the second to swelling of the graphite crystallites. The second type of hysteresis took the form of an initial isotherm which lay below subsequent isotherms. Except for the region of the isotherm which exhibited "pore" hysteresis, the isotherms after the first were observed to be reversible provided the sample was not fully desorbed. The upper or reversible isotherm could only be reached after a certain relative pressure had been exceeded. At relative pressures below this value, the initial isotherm was observed to be reversible, or very nearly so. By analogy with known cases of swelling hysteresis, it was postulated that this second type of hysteresis was caused by intercrystalline swelling. In the course of the work with these graphites it was found necessary for purposes of comparison to introduce an isotherm for a non-porous carbon. The adsorption isotherm of nitrogen on a non-porous carbon black (Spheron 9) was chosen. More detailed measurements on this system since publication of the earlier paper have revealed hysteresis effects similar to the second type of hysteresis observed with the graphite systems. The new work presented here includes scanning runs and an isotherm at another temperature.

In the work referred to above (3), the adsorption of gases was studied on three Acheson graphites which were used as they were received from the manufacturers. One of these graphites, which was designated by the symbol G-3, was selected for a study of the effect of ash removal. This graphite was chosen because it had a high ash content and displayed "swelling" hysteresis to the greatest extent. It will be shown that although removal of the ash displaces the isotherm downwards, it does not alter the amount of hysteresis.

EXPERIMENTAL AND RESULTS

The carbon black employed in these studies was a non-porous material

designated as Spheron 9. It was supplied to us by the Godfrey L. Cabot Co., Cambridge, Mass.

The graphite used was a sample of G-3 in which the ash content was reduced from 0.77% to 0.09% by leaching with hydrofluoric acid. This ash-free graphite will be designated as GF-3.

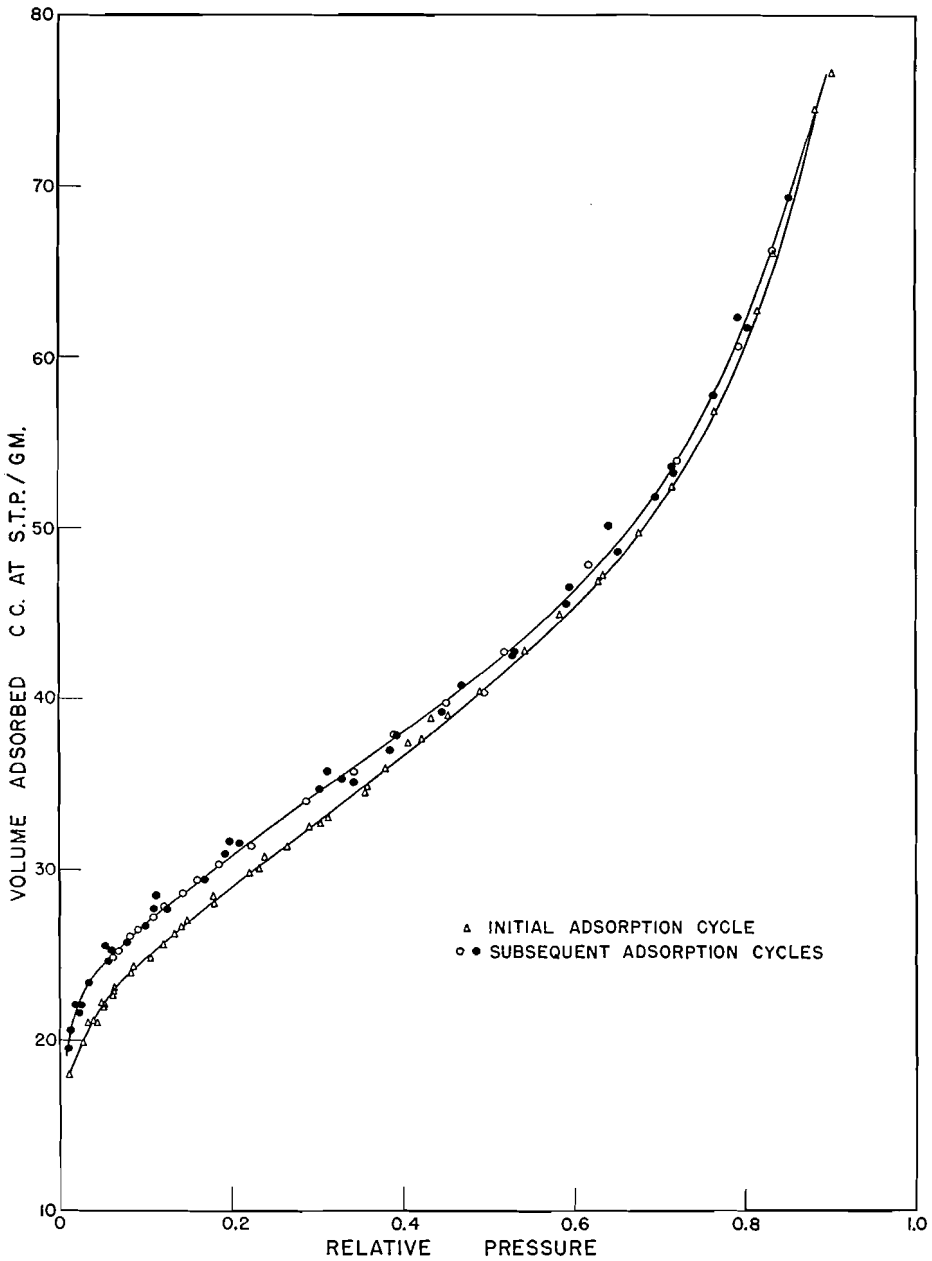

FIG. 1. Isotherm of nitrogen adsorbed by Spheron 9 at 78°K. Desorption points from the initial adsorption cycle and from subsequent cycles are represented by inked-in circles.

Nitrogen was supplied by the Canadian Liquid Air Co. It was stated to be 99.5% nitrogen and was used without further purification.

The apparatus and procedure was exactly as described previously (3).

The adsorption isotherm of nitrogen on Spheron 9 at 78°K. is shown in Fig. 1. The triangles represent the initial adsorption curve after outgassing. The circles represent the first desorption curve as well as points taken on subsequent adsorption cycles. It will be noted that the upper curve is reversible. Scanning runs were made in which desorption was first carried out from a relative pressure of 0.356 followed by readsorption from $p/p_0 = 0.039$ to $p/p_0 = 0.514$. Desorption from this latter pressure resulted in a curve which was well within the hysteresis loop. The scanning curves along with a desorption curve from a high relative pressure are displayed in Fig. 2. In contrast

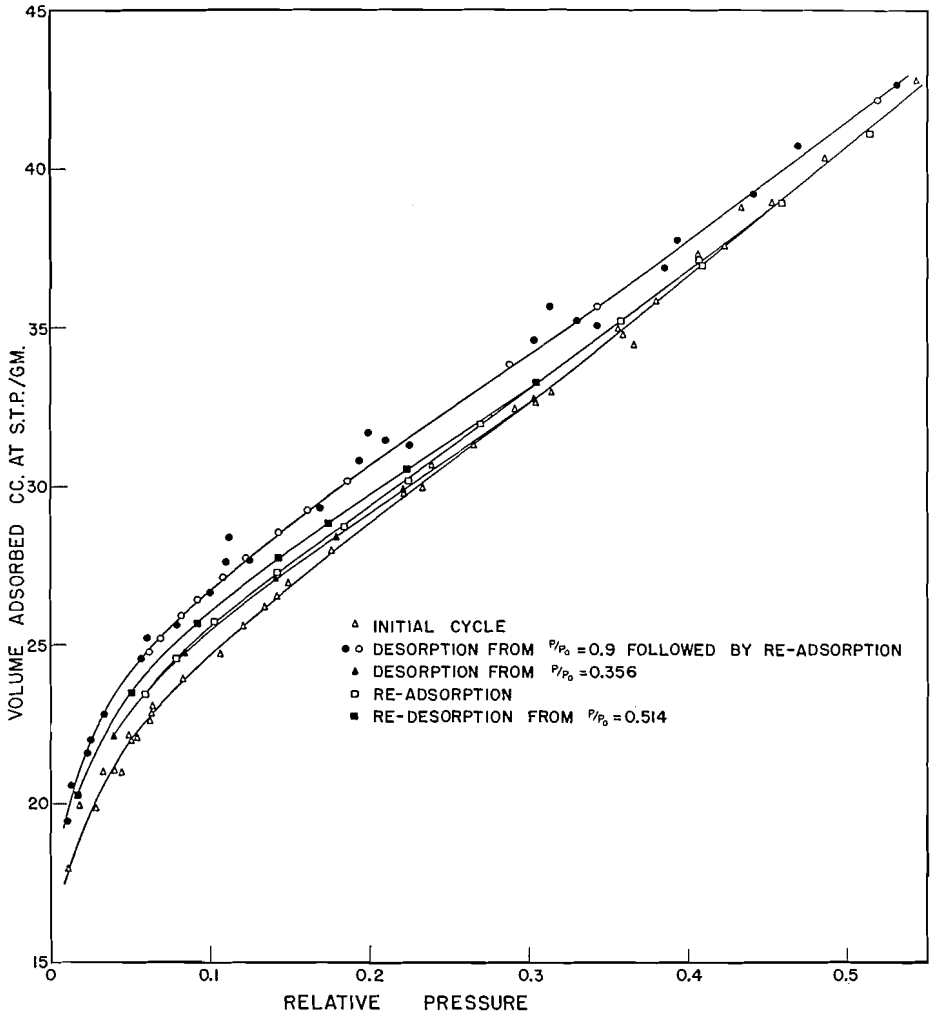

FIG. 2. Isotherm of nitrogen adsorbed by Spheron 9 at 78°K. showing the scanning runs. Desorption points are represented by inked-in symbols.

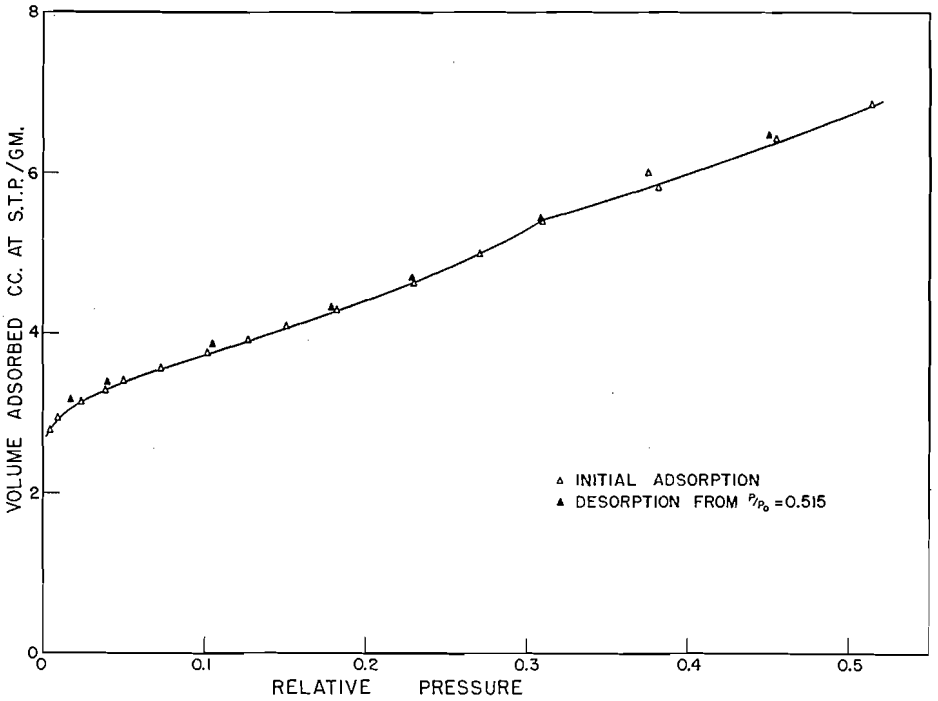

FIG. 3. Isotherm of nitrogen adsorbed by GF-3 at 71°K. illustrating desorption from moderate relative pressures. Desorption points are represented by inked-in triangles.

to the case of Spheron 9, the initial curve for graphite is very nearly reversible at moderate relative pressures. For example the isotherm shown in Fig. 3 for the adsorption of nitrogen on GF-3 at 71°K. exhibits only slight hysteresis. The adsorption of nitrogen by Spheron 9 was also measured at 71°K. The isotherm was identical in shape to the one shown in Fig. 1; therefore, it is not reproduced here. The monolayer volumes were calculated from the B.E.T. equation for the isotherms at both temperatures. They are presented in Table I along with the corresponding surface areas. The swelling process is seen to increase the surface area over its initial value by approximately 5%.

TABLE I

Temperature, °K.	Lower curve		Upper curve	
	V_m, cc. at S.T.P./gm.	S, m.²/gm.	V_m, cc. at S.T.P./gm.	S, m.²/gm.
78	23.81	104.3	25.45	111.5
71	24.96	106.1	25.89	110.0

The isotherms of nitrogen on GF-3 are presented in Figs. 3 and 4. The isotherm depicted in Fig. 3 shows that hysteresis is virtually absent when desorption occurs from moderate relative pressures (less than $p/p_0 = 0.6$). Hysteresis effects are evident in the isotherm shown in Fig. 4 when desorption

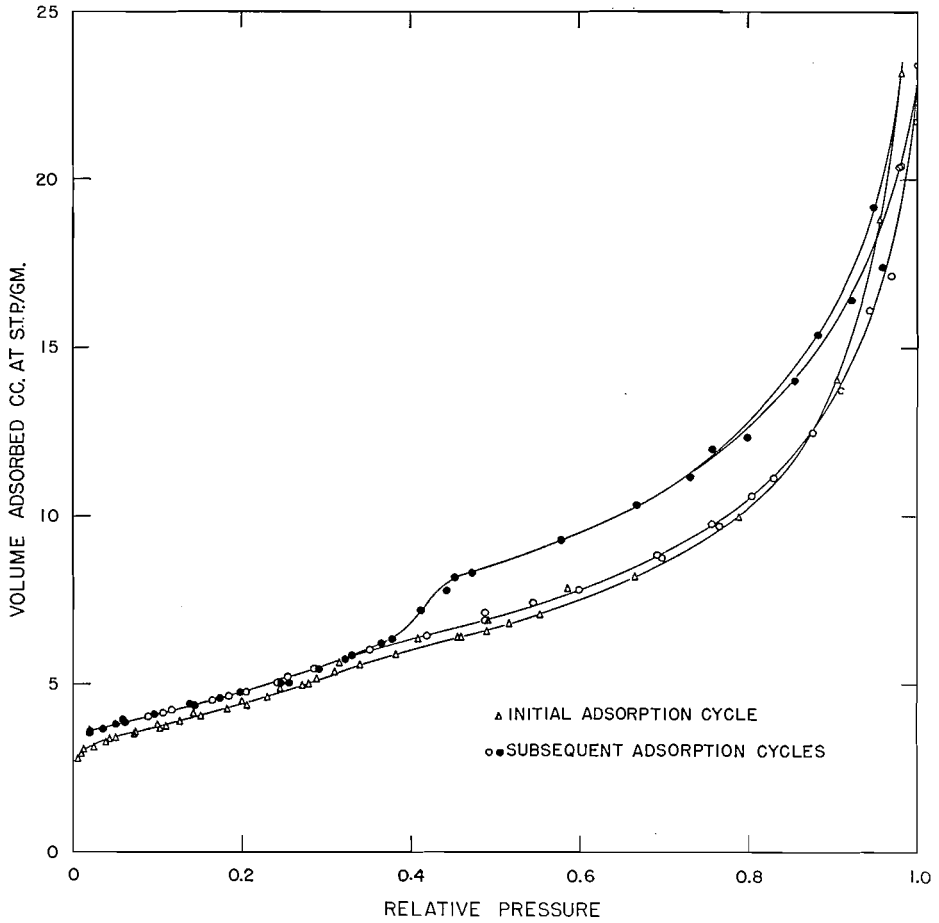

FIG. 4. Isotherm of nitrogen adsorbed by GF-3 at 71°K. Desorption points from the initial adsorption cycle and from subsequent cycles are represented by inked-in circles.

was carried out from relative pressures close to one. The quantity of nitrogen adsorbed by GF-3 is less than that adsorbed by G-3, but the hysteresis effects and the shape of the isotherm have not been changed by removal of most of the ash originally present in G-3. The monolayer volumes and corresponding surface areas for G-3 and GF-3 measured at 71°K. are compared in Table II. The difference between the volumes for upper and lower curves is the same for both graphites.

DISCUSSION

It is evident from the foregoing results that Spheron 9 displays hysteresis effects similar to the second type of hysteresis shown by the Acheson graphites. This type of hysteresis has been ascribed to intercrystalline swelling (3). However, the Spheron results differ from those of graphite in one important respect. It was found possible to scan the hysteresis loop of the Spheron isotherm at moderate relative pressures. In contrast the initial adsorption curve for graphite was observed to be more or less reversible at moderate relative pressures (up to $p/p_0 = 0.5$). It was suggested in the earlier paper that the behavior of the graphite system could be explained if the swelling occurred irreversibly at a high relative pressure. Below this relative pressure the initial isotherm would be reversible or nearly so. By the same reasoning one would deduce that the Spheron swells continuously over the whole course of the isotherm. However, even in the case of Spheron the swelling does seem to become irreversible at a high enough relative pressure because the desorption curve from a high relative pressure lies on a reversible isotherm. Arnell and Barss (1) have measured the specific surface of the crystallites of Spheron 9 by X-ray diffraction methods and obtained a value of 1180 m.^{2}/gm. Comparing this value with the surface area of the particle as measured by nitrogen adsorption it can be estimated that each particle is an aggregate of about a thousand crystallites. Biscoe and Warren (2) have shown that the crystallites (or more correctly parallel layer groups) of Spheron 6 (a closely related carbon black) are composed of two-dimensional plane hexagonal nets of carbon atoms separated by essentially the same spacing as in graphite but randomly oriented about a normal to the layers. On the other hand, X-ray diffraction patterns of the Acheson graphites display the sharp lines characteristic of a regular three-dimensional graphite structure. It is logical to attribute the continuous swelling shown by Spheron to the imperfection of the crystallites. It might be expected that the adhesion would be less between the crystallites of Spheron than between those of graphite and consequently swelling occurs continuously from the very onset of adsorption. In the case of graphite a certain reduction of the surface free energy must be attained before any swelling occurs.

The work with GF-3 was undertaken to show that the hysteresis effects were not the result of inhomogeneities in the graphite structure due to the presence of inorganic matter. The isotherm in Fig. 4 demonstrates that neither the shape of the isotherm nor the amount of hysteresis is affected by the amount of ash. However, the quantity of gas adsorbed was found to be somewhat less for the ashless sample.

ACKNOWLEDGMENT

The authors wish to express their indebtedness to Dr. J. C. Arnell of the Defence Research Board for many helpful discussions and for assistance in preparing the manuscript.

REACTION OF OXYGEN ATOMS WITH ACETALDEHYDE[1]

By R. J. Cvetanović

ABSTRACT

Reaction of oxygen atoms, produced by mercury photosensitized decomposition of nitrous oxide, with acetaldehyde has been studied at room temperature. The major products of the reaction are water and biacetyl and the only primary process appears to be

$$CH_3CHO + O \rightarrow CH_3CO + OH \quad [1]$$

followed by

$$CH_3CHO + OH \rightarrow CH_3CO + H_2O \quad [2]$$

and

$$CH_3CO + CH_3CO \rightarrow (CH_3CO)_2. \quad [3]$$

At room temperature oxygen atoms react with acetaldehyde 0.7 ± 0.1 times as fast as with ethylene, so that the activation energy of reaction [1] is likely to be close to 3 kcal./mole.

INTRODUCTION

The present work is the second in a series of investigations of the reactions of oxygen atoms with different organic compounds. In a previous publication (6) the reaction of oxygen atoms with ethylene has been described.

Oxygen atoms are produced by mercury photosensitized decomposition of nitrous oxide. It has been shown (7) that the primary step in this reaction is the formation of an atom of oxygen and a molecule of nitrogen and the rate of nitrogen production serves as a measure of oxygen atoms participating in the process. The important advantage of the use of nitrous oxide, in addition to the presence of an internal actinometer, is the absence of molecular oxygen, which by its rapid reaction with free radicals normally obscures the primary reactions of the atoms.
