BIOGENESIS OF ALKALOIDS

XVIII. THE FORMATION OF HORDENINE FROM PHENYLALANINE IN BARLEY¹

JACQUES MASSICOT² AND LÉO MARION

ABSTRACT

When phenylalanine-2-C¹⁴ was fed to sprouting barley the hordenine isolated from the plant was radioactive. The activity in the hordenine was shown by degradation of the alkaloid to be located on the carbon of the side chain β to the aromatic ring. A fraction of the fatty acids present in the roots was more strongly radioactive than the hordenine and must have arisen by the breakdown of the amino acid. The gramine isolated from the shoots was inert. Phenylalanine does not take part in the synthesis of gramine, but it is a precursor of hordenine and, hence, must be converted to tyrosine in barley. This conclusion is supported by the simultaneous synthesis of a radioactive aliphatic acid.

It has already been shown that in barley tyrosine is decarboxylated to tyramine, which is methylated by methionine first to N-methyltyramine and then to hordenine (5, 6, 7). It is known that in animals phenylalanine is transformed into tyrosine (8, 12) and if this were to occur in barley, then phenylalanine would be a precursor of hordenine. Since the metabolism of phenylalanine can follow other pathways (10) it was of interest to investigate its fate in barley.

When D,L-phenylalanine-2-C¹⁴ was fed to sprouting barley, the N-methyltyramine and hordenine isolated from the roots were radioactive. Hordenine was converted to O-methylhordenine methiodide, which was subjected to the Hofmann degradation and oxidized to radioactive anisic acid as previously described (5).

It has been shown previously that *p*-vinylanisole containing a C¹⁴ in the β -position to the vinyl group gives, on oxidation with potassium permanganate, inert anisic acid. If, on the other hand, it is oxidized first with mercuric oxide and iodine, and the oxime of the product further oxidized with potassium permanganate, radioactive anisic acid is obtained (5). This anomaly is due to a well-known rearrangement taking place under the conditions of the mercuric oxide oxidation (5). It can be concluded, therefore, that the C¹⁴ was present in the side chain of the hordenine in the β -position to the aromatic ring.³

The N-methyltyramine isolated with the hordenine was not further examined.

The fraction of the root extract containing the non-nitrogenous acids was much more

²National Research Council of Canada Postdoctorate Fellow, 1955-1956. Attaché de Recherches, C.N.R.S., Lyon, France, on leave of absence.

³Because of the definite proof of the location of C¹⁴ in hordenine derived from tyrosine (6) and from tyramine (5), it has been assumed that the label in the present instance would be similarly located, although the proof offered is not as rigorous as previously.

radioactive than the alkaloids. By chromatography on silica gel, this yielded a fraction eluted by chloroform which had an equivalent weight of 442. It seems to contain a carbonyl as well as one or more carboxyl. It was readily converted to a methyl ester with diazomethane but could not be crystallized nor properly characterized, since it gradually decomposed on standing. Its activity was 6×10^3 d.p.m. per mg.

It has been shown that, in barley, tryptophan is the precursor of gramine (1), and it is known that in *Neurospora*, tryptophan is synthesized from indole and serine (11, 13). Gramine was therefore isolated from the extract of the shoots of the barley to ascertain whether phenylalanine could be a precursor of the indole nucleus. The gramine, however, was inert.

EXPERIMENTAL

Administration of D,L-Phenylalanine-2-C¹⁴ to the Barley

Barley (Charlottetown No. 80, 720 g.) was evenly divided among 12 Pyrex trays containing glass wool and grown as previously described (4). On the 6th day of sprouting, a solution of D,L-phenylalanine-2-C¹⁴ (110 mg.) in distilled water (600 ml.) containing hydrochloric acid (0.1 ml.) was fed to the barley. The amino acid administered had a total activity of 1.1×10^8 disintegrations per minute, or a specific activity of 1.6×10^8 d.p.m. per millimole.⁴

Isolation of the Alkaloids from the Roots

The barley was harvested on the 11th day of sprouting, the roots separated from the shoots and extracted with methanol for 48 hours. The evaporated extract was dissolved in 2 N sulphuric acid, the solution filtered, extracted with ether (Extract A), and treated as previously described for the isolation of the alkaloids (5). The N-methyltyramine separated from the hordenine by chromatography was not further examined. The hordenine (254 mg., m.p. 117°) was diluted with inactive hordenine, methylated, and subjected to the Hofmann degradation, and the resulting *p*-vinylanisole oxidized with mercuric oxide and iodine, all as previously described (6). The oxime of the homoanisaldehyde produced (m.p. 116–118°) was oxidized with potassium permanganate to radioactive anisic acid (5). Anisic acid was characterized by comparison with an authentic specimen and by preparation of its *p*-toluidide, which was identical with a sample prepared from authentic anisic acid. The activities of the various products are listed in Table I.

TABLE I
ACTIVITIES OF DERIVATIVES AND DEGRADATION PRODUCTS
OF HORDENINE

Compound	D.p.m. per millimole
Hordenine	1.78×10^4
O-Methylhordenine methiodide	1.75×10^4
Trimethylamine chloroplatinate	0
Homoanisaldehyde oxime	1.53×10^4
Anisic acid	1.47×10^4
Anisic acid <i>p</i> -toluidide	1.50×10^4

Isolation of Acids

Extract A, which had been obtained in the course of the isolation of the alkaloids, yielded on evaporation a black resin soluble in ethanol, but only partially soluble in

⁴D,L-Phenylalanine-2-C¹⁴ was purchased from Tracerlab, Inc.

benzene. The resinous residue contained no nitrogen, and was strongly radioactive. It was triturated with benzene at room temperature and the benzene-soluble fraction was chromatographed on a column of silica. The column was eluted by being washed first with carbon tetrachloride and then with chloroform. The carbon tetrachloride eluate consisted of a very small fraction containing little activity and was discarded. The main fraction with the highest radioactivity per milligram was eluted by chloroform. It consisted of a clear yellow product with an activity about forty times that of the purified hordenine. It contained no nitrogen and decomposed on standing, becoming after a few days only partially soluble in benzene. Its equivalent weight, determined by electrometric titration with alkali, was 442. The acid could not be induced to crystallize and, because of its instability, could not be characterized. Methylation with diazomethane gave rise to a methyl ester which remained oily. Found: C, 70.10; H, 10.03%. The acid discolored potassium permanganate rapidly and with 2,4-dinitrophenylhydrazine gave rise to an amorphous, insoluble product. The ultraviolet spectrum of the acid contained a maximum at $289\text{ m}\mu$ as well as one at $< 215\text{ m}\mu$ attributable to the carboxylic group. The acid is probably a long-chain unsaturated acid containing a carbonyl group but, because of paucity of material could not be further identified.

The activities of the various fractions obtained from the root extract are given in Table II. The only two fractions studied were the alkaloids and non-nitrogenous acids.

TABLE II
ACTIVITIES OF FRACTIONS OF ROOT EXTRACT

Compound	Weight, mg.	Total activity, d.p.m.	Activity per mg., d.p.m.
Crude amines	818	2.64×10^5	320
Hordenine	254	3.4×10^4	134
Crude acids	470	1.3×10^6	2700
Main acid fraction	95	5.7×10^5	6000
Phenols	895	Not determined	
Lipids, sterols, etc.	1200	3.6×10^5	285

Gramine

The shoots of the plants, which had been separated from the roots, were extracted with methanol and the gramine was isolated from the extract by the procedure already described (1). The gramine was inactive.

DISCUSSION

In barley, phenylalanine, just like tyrosine (6) and tyramine (5), is a precursor of hordenine. It is known that in animals phenylalanine is converted to tyrosine (8, 12) and, further, it has been shown that tyrosine is decarboxylated in the plant and that the resulting tyramine is methylated by methionine first to N-methyltyramine and then to hordenine (5, 6, 7). It can be presumed, therefore, that, in barley, phenylalanine is first converted to tyrosine.

Gramine isolated from the shoots of the barley was not radioactive and it can be concluded that phenylalanine is not a precursor of the indole nucleus in barley or at least of the tryptophan since it is known that tryptophan is the precursor of gramine (1).

Phenylalanine is the precursor of a long-chain acid in barley. Although the identity of this acid has not been established, it appears to be an unsaturated keto acid in which

no aromatic groups seem to be present. Phenylalanine can be metabolized via tyrosine with scission of the aromatic ring to produce the intermediates homogentisic acid and fumarylacetoacetic acid, which finally give rise to acetoacetic acid (3, 9). Acetoacetic acid derived from phenylalanine could then be a precursor of the long-chain acid. Indeed, it has been shown that acetoacetic acid can give rise to fatty acids without going through acetic acid (2). In the absence of more exact knowledge of the identity of the radioactive acid, any suggestion as to the intermediate steps between it and phenylalanine or tyrosine is mere speculation. The relatively high radioactivity of the acid, however, seems to indicate that it is very actively synthesized during the early growth of the plant. The formation of the aliphatic acid supports the conclusion derived from the biosynthesis of hordenine that in barley phenylalanine is converted to tyrosine.

ACKNOWLEDGMENT

The authors are indebted to Mr. R. B. MacLaren of the Experimental Station, Charlottetown, P.E.I., for supplying the barley used in these experiments.

THE SOLUBILITY OF URANIUM(IV) HYDROXIDE IN SOLUTIONS OF SODIUM HYDROXIDE AND PERCHLORIC ACID AT 25° C.¹

K. H. GAYER AND H. LEIDER

ABSTRACT

The solubility of uranium(IV) hydroxide has been measured in sodium hydroxide, water, and perchloric acid solutions. A possible reaction in sodium hydroxide solutions is evaluated.

The purpose of this investigation was to measure the solubility of uranium(IV) hydroxide in dilute basic and dilute acidic media. Information pertaining to this subject is not available at this time in the literature except for the following:

Kraus and Nelson (3) investigated the hydrolytic behavior of uranium(IV) ions in excess perchloric acid (above 0.2 *M*) and in solutions of constant ionic strength ($\mu = 0.5$). They concluded that the simple ion U^{+4} exists in excess acid and is associated with eight water molecules, $U(H_2O)_8^{+4}$, and that the principal hydrolysis reaction is

$$pK = 1.44$$

where $pK = -\log [IV]_1$, and $[IV]_1 = [UOH^{+3}][H^+]/[U^{+4}]$.

Their results did not indicate an ion type such as UO^{++} .

They also found that uranium(IV) ions show a tendency to form rather stable polymeric solutions on hydrolysis, where the polymeric form has an approximate composition of $U(OH)_4$. When uranium(IV) hydroxide is dissolved in a non-complexing acid, such as perchloric, solutions containing polymeric products result. The difference in color between the simple solution and the polymeric form is very marked, being bright green for the former and almost black for the latter.

PROCEDURE

The general procedure is similar to that described by Garrett and Heiks (2). An all glass apparatus was used.

Water.—Conductivity water was prepared in a Barnstead conductivity still, degassed by being boiled with nitrogen bubbling through it, and then stored under nitrogen.

Perchloric acid solutions.—Approximately 1 molar acid was prepared from 70% G. F. Smith purified perchloric acid with degassed conductivity water and stored under nitrogen. Standard acid solutions were also made with conductivity water and standardized against standard sodium hydroxide.

Sodium hydroxide solutions.—Approximately 1 molar solutions of base were prepared under nitrogen by dissolving Baker and Adamson reagent pellets in degassed conductivity water in a paraffined flask. Barium hydroxide was added to just precipitate any carbonate, and the solutions were stored under nitrogen. Standard base solutions were also prepared with conductivity water and standardized against potassium acid phthalate using phenolphthalein indicator.

¹Manuscript received July 16, 1956.

Uranium(IV) sulphate.—Crystalline uranium(IV) sulphate was prepared by the reduction of acid solutions of uranyl sulphate with Eastman Kodak sodium dithionite (1). The precipitated sulphur was filtered off and uranium(IV) hydroxide was precipitated with excess sodium hydroxide. The product was washed with distilled water until the absence of a sodium flame test, and then dissolved in Baker and Adamson A. C. S. standard sulphuric acid, and filtered. The sulphate solution was evaporated until crystals of $\text{U}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$ deposited. The crystals were filtered, dried, analyzed for uranium by 8-hydroxyquinoline precipitation, and ignited to U_3O_8 . Calculated % uranium is 47.4; found % uranium equals 47.6. Solutions of the sulphate were made by dissolving the crystals in degassed conductivity water and then stored under nitrogen.

Colorimetric reagents.—A standard uranium solution was prepared by dissolving stoichiometric $\text{UO}_3 \cdot \text{H}_2\text{O}$ (prepared from hydrolysis of uranyl acetate by boiling) in perchloric acid. Aliquot portions of this solution were used to prepare the color standards. A 10% sodium hydroxide solution was prepared from Baker and Adamson reagent pellets and distilled water. A 20% sodium carbonate solution was prepared with Baker and Adamson anhydrous reagent and distilled water. Baker and Adamson 30% hydrogen peroxide was used in preparing colorimetric solutions.

Uranium(IV) hydroxide.—The hydroxide used in making samples for the acid series was precipitated from the sulphate solution with sodium hydroxide and washed with degassed conductivity water. Absence of a sodium flame test indicated completed washing.

Uranium(IV) hydroxide used in preparing basic samples was made by reacting sodium hydroxide with crystalline $\text{U}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$. In all other respects the treatment was the same as that just described. Such a preparation was necessary because the gelatinous hydroxide precipitated from solution was extremely sensitive to oxidation in alkaline medium. The dense hydroxide prepared from crystalline sulphate proved much more stable to oxidation and could be handled more easily. In order to eliminate any possibility of oxidation the system was kept under a nitrogen pressure of 4 to 5 lb. above that of the atmosphere.

Analysis showed that the solid phase was unchanged after equilibration with acid or base.

Equilibration.—Pairs of 100 ml. samples of the hydroxide in acid or base were collected in 125 ml. sample flasks under nitrogen. One of each pair was agitated in a 35° thermostat for 5 to 7 days, followed by agitation in a 25° thermostat for 5 to 7 days. The other member of each pair was directly agitated in the 25° thermostat for 5 to 7 days. After the agitation in the 25° C. thermostat, the samples were allowed to settle for 3 to 5 days.

Uranium analyses.—The uranium analyses was made with a Beckman Model B spectrophotometer using the $\text{NaOH}-\text{Na}_2\text{CO}_3-\text{H}_2\text{O}_2$ method described in *Analytical Chemistry of the Manhattan Project* (4).

THE DATA

The data are collected in Tables I and II. Owing to the polymeric nature of the acid solubility products no definite reactions or ionic species can be evaluated and proved to occur.

Assuming that the formula for solid uranium(IV) hydroxide can be represented by

$\text{U}(\text{OH})_4$, we believe that the reaction in basic solution over the range studied (0.1 molal to 0.5 molal) can be written as follows:

Evidence for this reaction comes from (1) the fair constancy of the equilibrium constant, (2) the extremely low solubility of the oxide, and (3) the high equilibrium sodium hydroxide concentrations.

In calculating the equilibrium constant it was assumed

(1) that

$$\gamma_{\text{H}_3\text{UO}_4^-} / \gamma_{\text{OH}^-} = 1,$$

(2) that the dissolved uranium all occurred as H_3UO_4^- . This latter assumption is not improbable since the solubility is very low.

A NEW SYNTHESIS OF 1-SUBSTITUTED-2,3,5,6-TETRAHYDRO-1-IMIDAZ(1,2-a)IMIDAZOLES¹

A. F. MCKAY AND D. L. GARMAISE

ABSTRACT

A number of 1-(β -hydroxyethyl)-2-(substituted amino)-2-imidazolines have been prepared by the reaction of amines with 1-(β -hydroxyethyl)-2-methylmercapto-2-imidazoline. These intermediates on chlorination and dehydrochlorination give the corresponding 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles.

Recently (2) the preparations of 1-benzyl- and 1- β -diisopropylaminoethyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles by the reaction of benzylamine and β -diisopropylaminoethylamine with 1-(β -chloroethyl)-2-nitriminoimidazolidine were described. This work presents another new method of preparing 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles (IV) which involves the reaction of an amine with 1-(β -hydroxyethyl)-2-methylmercapto-2-imidazoline (I) (1, 3).

1-(β -Hydroxyethyl)-2-methylmercapto-2-imidazoline (I) or its hydroiodide salt condenses with amines with the liberation of methyl mercaptan. This reaction proceeds smoothly to give good yields of the 1-(β -hydroxyethyl)-2-(substituted amino)-2-imidazolines (II). The properties of some of these intermediates and/or their derivatives are described in Table I. Some of the 1-(β -hydroxyethyl)-2-(substituted amino)-2-imidazolines could be distilled *in vacuo* without decomposition to give good yields of purified products whereas others such as 1-(β -hydroxyethyl)-2-(β -dimethylaminoethylamino)-2-imidazoline and 1-(β -hydroxyethyl)-2-(β -di-*n*-propylaminoethylamino)-2-imidazoline partially cyclized and partially decomposed. The water liberated during the cyclization reaction is thought to be responsible for the observed degradation. The crude or purified 1-(β -hydroxyethyl)-2-(substituted-amino)-imidazolines were converted into their cor-

R = alkyl, aralkyl, or dialkylaminoalkyl

responding 1-(β -chloroethyl)-2-(substituted amino)-2-imidazolinium chlorides by chlorination with thionyl chloride. These chloro derivatives, with the exception of 1-(β -chloroethyl)-2-benzylamino-2-imidazoline, were used for the next stage of synthesis without further purification. They were dehydrochlorinated to give the 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles (IV). Some of the yields reported in Table II are low because of the partial degradation encountered in the distillation of the intermediates. It was observed that the over-all yields of the bicyclic compounds (IV) were much higher when the intermediate 1-(β -hydroxyethyl)-2-(substituted amino)-2-imidazolines were used directly without preliminary distillation. The properties of the 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles and their picrates are given in Tables II and III respectively.

1-(β -Dimethylaminoethyl)- and 1-(β -diethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles were methylated with methyl iodide. These compounds combined with 2 mole equivalents of methyl iodide to give derivatives whose analytical values are in good agreement with those calculated for structure (V).

EXPERIMENTAL²

1-(β -Hydroxyethyl)-2-methylmercapto-2-imidazolinium Iodide

1-(β -Hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (m.p. 120–121° C.) was prepared in 95% yield as previously (3) described.

1-Substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles

The procedures for the preparations of the 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles are very similar and only three variations in procedure are described below in detail. Tables II and III list the physical properties of the 1-substituted-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazoles and their picrates respectively.

1-Benzyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

A solution of 1-(β -hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (144 g., 0.50 mole) and benzylamine (55.0 g., 0.52 mole) in 240 cc. of methanol was refluxed for 1½ hours. The methanol was removed by evaporation and the residue in water (2% solution) was passed through a column of IRA-400 (1 liter) resin. This column was washed with water and the washings and eluate were combined and acidified with hydrochloric acid solution. On evaporation of the aqueous solution 1-(β -hydroxyethyl)-2-benzylamino-2-imidazolinium chloride (m.p. 142–147° C.) was obtained in quantitative yield. A sample was prepared for analysis by crystallization twice from a methanol –

²All melting points are uncorrected. Microanalyses were performed by Micro Tech Laboratories, Skokie, Illinois.

ethyl acetate solution. The final melting point was 147–148° C. Its picrate prepared in the usual manner melted at 124° C. (3).

1-(β -Hydroxyethyl)-2-benzylamino-2-imidazolinium chloride (16.0 g., 0.062 mole) and thionyl chloride (14.0 g., 0.118 mole) in 50 cc. of chloroform were refluxed together for 3 hours. After the excess thionyl chloride and chloroform were removed by distillation, a reddish oil was obtained in quantitative yield. A portion (0.3 g.) of this oil was converted into its picrate melting at 137–138° C. This melting point was not increased on further crystallization. Calc. for $C_{18}H_{19}ClN_6O_7$: C, 46.30; H, 4.11; Cl, 7.59; N, 18.24%. Found: C, 46.35; H, 4.30; Cl, 7.89; N, 18.00%.

The remainder of the reddish oil, 1-(β -chloroethyl)-2-benzylamino-2-imidazolinium chloride, was refluxed for 2 hours in a solution of potassium hydroxide (10.0 g., 0.178 mole) in absolute methanol (150 cc.). The precipitated potassium chloride was removed by filtration and the filtrate was evaporated to dryness. The residue was extracted with ether (2 $\times$ 50 cc.) and the ethereal solution on evaporation gave 8.8 gm. (70%) of oil. This oil (b.p. 124–126° C. at 0.1 mm.) was distilled *in vacuo* using a Vigreux column. Its picrate melted at 123–124° C. The picrate of 1-benzyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole was previously reported (2) to melt at 109–109.5° C. A mixture melting point determination with these two picrates gave a melting point of 123° C. When the low melting picrate was dissolved in water and then seeded with the high melting form, it gave the picrate melting at 123–124° C. It appears that this picrate is dimorphous. Both picrates gave good analytical values for the monopicrate of 1-benzyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole.

1-n-Tetradecyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

1-(β -Hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (86.4 g., 0.30 mole) and *n*-tetradecylamine (63.9 g., 0.30 mole) were refluxed for 3 hours in 200 cc. of methanol. This solution was diluted with 600 cc. of methanol and then it was passed through a column of IRA-400 resin (1000 cc., previously washed with 800 cc. of methanol) at a rate of 8 cc. per minute. The column was washed with methanol (1200 cc.) until the eluate gave no further positive test with picric acid solution. The eluate and washing were combined and evaporated to dryness, yield 97.5 g. (100%). Part (65 g., 0.20 mole) of this residue was converted into its hydrochloride. The dry hydrochloride was dissolved in 200 cc. of dry benzene and thionyl chloride (47.6 g., 0.4 mole). After this solution had refluxed for 2 hours, the excess thionyl chloride and solvent were removed by evaporation. This procedure gave a quantitative yield of the intermediate 1-(β -chloroethyl)-2-*n*-tetradecylamino-2-imidazolinium chloride.

1-(β -Chloroethyl)-2-*n*-tetradecylamino-2-imidazolinium chloride in a solution of potassium hydroxide (24.7 g., 0.442 mole) in 425 cc. of absolute alcohol was refluxed for 3 hours. The resulting mixture was worked up as described in the procedure above for 1-benzyl-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole. A black oily residue was obtained, yield 50.5 g. (82.4%). Fractional distillation using a Vigreux column setup yielded 27.4 g. of colorless oil (b.p. 172–173° C. at 0.08 mm.). Its picrate melted at 75–76° C. after two crystallizations from ether.

1-(Di-n-propylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

1-(β -Hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide (40.0 g., 0.115 mole) was condensed with *N,N'*-di-*n*-propyl ethylenediamine (17.3 g., 0.12 mole) under the conditions described above for the preparation of 1-(β -hydroxyethyl)-2-benzylamino-2-imidazoline and the condensation product was dissolved in 100 cc. of water. This aqueous

solution was passed through a column of highly active IRA-400 resin (450 cc.) at a rate of 25 cc. per minute. After the column was washed with water (2000 cc.), the combined washings and eluate were evaporated to dryness, yield 29.0 g. (98%). This oily product on distillation *in vacuo* underwent extensive decomposition giving 5 g. of di-*n*-propylaminoethylamine. One fraction (b.p. 114–123° C. at 0.05 mm.) gave a picrate melting at 169–170° C., which was identified as the picrate of the bicyclic product, 1-(di-*n*-propylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole, yield 1.2 g.

Another fraction (b.p. > 123° C. at 0.05 mm.) (6 g.), which appeared to be a mixture of 1-(β-hydroxyethyl)-2-(di-*n*-propylaminoethylamino)-2-imidazoline and the bicyclic product, was converted into the bicyclic product by the procedure described in the above examples. The oily product (b.p. 106–108° C. at 0.05 mm.) was obtained in 44.8% yield based on the over-all conversion of 1-(β-hydroxyethyl)-2-methylmercapto-2-imidazolinium iodide into 1-(di-*n*-propylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole. The picrate of the latter compound formed in the usual manner melted at 169–170° C. It was purified by crystallization from ethanol.

Methylation of 1-(β-Dimethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

A solution of 4.8 g. (0.0247 mole) of 1-(β-dimethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole and 14.2 g. (0.10 mole) of methyl iodide in 50 cc. of absolute alcohol was refluxed for 1 hour. This solution on evaporation of solvent and excess methyl iodide gave 11.5 g. (93.5%) of a crystalline solid (m.p. 160–170° C.). Several crystallizations from various solvents always gave crystals melting over a range (m.p. 155–170° C.). However, after drying at 64° C. *in vacuo*, the crystals had a melting point of 234–236° C. Anal. Calc. for C₁₁H₂₄I₂N₄: C, 28.33; H, 5.19; I, 54.45; N, 12.02%. Found: C, 28.36; H, 5.16; I, 54.29; N, 11.99%.

The dipicrate (m.p. 205–206° C.) of the dimethiodide of 1-(β-dimethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole was prepared in the usual manner. Anal. Calc. for C₂₃H₂₈N₁₀O₁₄: C, 41.31; H, 4.22; N, 20.95%. Found: C, 41.03; H, 4.01; N, 21.39%.

Dimethiodide of 1-(β-Diethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-a)imidazole

The dimethiodide of 1-(β-diethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole (m.p. 180–200° C.) was prepared in 97% yield by the procedure described above for preparing the dimethiodide of 1-(β-dimethylaminoethyl)-2,3,5,6-tetrahydro-1-imidaz(1,2-*a*)imidazole. Four recrystallizations from methanol–ethyl acetate (1:3) solution raised the melting point to a constant value of 228–230° C. Anal. Calc. for C₁₃H₂₈I₂N₄: C, 31.59; H, 5.71; I, 51.37; N, 11.34%. Found: C, 31.71; H, 5.83; I, 51.15; N, 11.31%.

The dipicrate formed in the usual manner melted at 190–191° C. after two crystallizations from alcohol. Anal. Calc. for C₂₅H₃₂N₁₀O₁₄: C, 43.09; H, 4.63; N, 20.11%. Found: C, 43.12; H, 4.48; N, 19.83%.

ACKNOWLEDGMENT

The authors are pleased to acknowledge the skillful technical assistance of Miss E. Laycock of these laboratories.

THE STRUCTURE OF ARTIFICIAL GRAPHITES AS REVEALED BY X-RAY, ELECTRON MICROSCOPE, AND ADSORPTION STUDIES¹

L. G. WILSON AND H. L. McDERMOT

ABSTRACT

Three artificial graphites have been studied by X-ray, electron microscope, and adsorption techniques. Surface areas were calculated from the adsorption isotherms and from the X-ray spectra. The two sets of areas were of the same order of magnitude and varied from 18 m.²/g. for the graphite of smallest surface area to 385 m.²/g. for the graphite of largest surface area. The appearance of the graphites under the electron microscope was in qualitative agreement with the adsorption and X-ray data.

INTRODUCTION

Two previous papers (4, 5) on the adsorption of gases by graphite have shown that the artificial graphites studied were porous adsorbents which displayed Type II isotherms in the B.E.T. classification. It was also found that the graphites displayed two types of hysteresis. The first type, which was observed at high relative pressures (above $p/p_0 = 0.5$), was associated with the porous structure of the graphite. The second type, seen at relative pressures below $p/p_0 = 0.5$, was attributed to intercrystalline swelling. In every case, the isotherms were smooth Type II isotherms without any of the humps which have become associated with homogeneous surfaces (1). Hence, it was concluded that these graphites presented heterogeneous surfaces to gases at liquid nitrogen temperatures. These effects were observed with graphites varying in area from 20 m.²/g. to approximately 100 m.²/g. Finally, it was shown that the above phenomena were associated solely with the graphite and were not caused by traces of inorganic material present in the graphites.

Early X-ray studies of graphite (7) showed the crystal to be composed of layers of coplanar carbon atoms arranged in hexagons. The layers were separated by distances which were large compared with the interatomic distances within each layer. This classical structure was termed hexagonal holohedral. Atoms within the plane were 1.42 Å apart and the planes were separated by 3.34 Å.

The unit cell was hexagonal with

$a = 2.456 \text{ Å}$, $c = 6.696 \text{ Å}$, and the four atoms in the following two sets of special positions of $C6mc$:

(a) $0, 0, u; 0, 0, u + \frac{1}{2}$,

(b) $1/3, 2/3, v; 2/3, 1/3, v + \frac{1}{2}$ with $u \simeq 0$ and $v \gtrsim 0.05$.

The packing in the crystal is such that half the carbon atoms in adjacent layers lie over one another (*A* atoms) while the other half (*B* atoms) lie over empty hexagon centers. This packing is designated *ABAB*

Further work revealed a second structure which could coexist with the classical hexagonal one above. This structure was composed of the same hexagonal nets of carbon atoms, but the planes were stacked differently than in the structure just described. The sequence was such that the fourth plane was identically placed to the first, i.e. *ABCABC* When this structure was indexed on the unit cell given above, fractional

¹Manuscript received September 21, 1956.

Contribution from the Defence Research Chemical Laboratories, Ottawa, Canada. Also issued as D.R.C.L. Report No. 224.

indices were obtained, which accounted for the extra lines observed on some graphite spectra. These indices, which contain a multiple of $2/3$, are most simply explained by postulating a graphite structure with a c axis $3/2$ as long as the usual one, i.e. $a = 2.456 \text{ \AA}$ and $c = 3/2 \times 6.696 = 10.044 \text{ \AA}$ with atoms in positions $0, 0, 0; 1/3, 2/3, 0; 0, 0, 1/3; 2/3, 1/3, 1/3; 1/3, 2/3, 2/3$; and $2/3, 1/3, 2/3$. This structure is rhombohedral with $a = 3.635 \text{ \AA}$, $\alpha = 39.49^\circ$, atoms at $\pm u, u, u$ ($u = 1/6$), and space group $R\bar{3}M$. This second form occurs widely in natural and artificial graphites, sometimes to as much as 15%.

It was thought to be of interest to study some of the artificial graphites by means of the X-ray camera and electron microscope and to attempt to correlate the results with adsorption data. For this purpose, graphites of widely different surface area were chosen so that differences between them would be readily discernible. The spectra of these graphites showed no evidence of the rhombohedral form and are indexed below on a hexagonal lattice.

EXPERIMENTAL AND RESULTS

Three graphites manufactured by Acheson Colloids Ltd. were used in these studies. They were designated as G-3, G-5, and GF-5. G-3 has been described in two previous papers (4, 5). G-5 was an Acheson graphite of high surface area. GF-5 was prepared by treatment of a sample of G-5 with strong hydrofluoric acid followed by washing with copious quantities of distilled water. This treatment has been found to remove effectively small quantities of inorganic ash from the graphite. The experimental work is presented under the following three headings: Adsorption, X-ray Spectroscopy, and Electron Microscopy.

Adsorption

The apparatus and procedures are exactly as described previously (4).

Isotherms for the adsorption of nitrogen by G-3, G-5, and GF-5 are presented in Fig. 1. The isotherm for G-3 has been published previously (4), but is reproduced for purposes of comparison with those of G-5 and GF-5. It is immediately obvious that G-5 and GF-5 have about the same surface area and that the surface area of G-3 is very much less than those of the other two graphites. This point is also demonstrated by the data of Table I, which gives the surface areas calculated by the B.E.T. equation (2).

TABLE I

Graphite	Surface area, m. ² /g.
G-3	18
G-5	380
GF-5	385

X-ray Spectroscopy

G-3, G-5, and GF-5 were already fine powders and were therefore used without pretreatment. Each powder was coated on to a glass fiber 0.09 mm. in diameter using a thin layer of white vaseline as an adhesive. The layer of carbon was formed into a uniform cylinder by means of a needle under a stereomicroscope. The specimen was then mounted in the camera. The over-all diameter of such a specimen was about 0.15 mm.

FIG. 1.

The powder spectrum was photographed using a Unicam S25 camera (30.0 mm. radius). Exposures were usually about 5 hours, and were made with both cobalt and copper radiations appropriately filtered. After the spectrum had been exposed, a density scale was printed on each negative by exposing clear parts of the film to suitable radiation intensities for a known series of times. All films were developed in a standard manner. Spectra for G-3, G-5, and GF-5 are given in Fig. 3.

After development the film was photometered using a visual split-beam photometer. Both spectrum and density scale curves were then obtained enabling relative intensities for each line to be measured. The curves were then plotted and corrected for background intensity. Finally, a curve was obtained for each graphite showing the relative intensity of each line versus its position on the film.

In order to determine the true line broadening due to particle size, the above curves had to be corrected for the doublet nature of the radiations and the broadening due to the experimental arrangement. Both of these corrections were made by taking photographs of finely-ground pure sodium chloride. This compound gave a set of clearly

resolved lines spaced at suitable intervals. From its spectrum, the natural broadening due to the experimental arrangement was measured for all values of the diffraction angle θ .

A curve was calculated for the camera used giving the peak separation to be expected for the K_{α_1} and K_{α_2} lines for each type of radiation. This curve showed that a maximum separation of 0.12 mm. was to be anticipated for the lines used. Inasmuch as the limit of resolution of the photometer was 0.1 mm. and since the above correction includes most of the doublet corrections, no further correction for K_{α_1} and K_{α_2} was made. The corrected curves are given in Fig. 2 for all three graphites. It is obvious that the lines for

FIG. 2.

G-3 are much sharper than those for G-5, consistent with its much smaller surface area as demonstrated by its lower nitrogen adsorption. The lines for GF-5 are quite different in profile from those of G-5. They are shorter and broader indicating crystallites of different shape. This must be reconciled with the fact that both graphites have the same area as measured by nitrogen adsorption.

The procedure outlined above gives a linear measure of the true line broadening due to particle size. This broadening was converted to particle size measurements by a set of graphs relating ϵ , the particle dimension normal to the crystal planes giving a spectrum line at angle θ , and β , the angular broadening. The equation used was

$$\epsilon = \tau / \beta \cos \theta$$

where τ is the wave length.

The values of ϵ were read from these graphs corresponding to various values of τ .

The accuracy with which ϵ can be measured depends on the two factors involved in the determination of β . These factors are B , the width of the broadened line in the graphite spectrum, and b , the width of the unbroadened line in the salt spectrum. The errors inherent in determining B and b vary with the line width and angular position. The ratio b/B was converted to β/B by means of the Jones Curve (3), which has been reported to give reasonable accuracy in the case of graphite. The quantity β is obtained in linear measure from β/B and B . Conversion of β to angular measure and hence to ϵ does not introduce inaccuracies of more than a few per cent. It is obvious that the greater the broadening the less important are the instrumental errors, hence the smaller values

G-5	112	45	165
GF-5	195	85	67

Electron Microscopy

The three graphites were photographed by means of a Philips electron microscope with a resolving power of about 20 Å. The specimens of graphite were prepared in two ways both of which gave substantially the same results. In the first method, some of the dry powder was placed on a Formvar-coated Athene specimen grid under a stereomicroscope. The second method consisted of dispersing some of the powder in water and then placing a drop of the resulting suspension on a grid. After drying, the specimen was ready for observation. The microscope field was calibrated by means of a grating replica of 1000 lines per mm.

Many photographs were taken in order to ensure that they were representative of the graphites. Three typical photographs are shown in Figs. 4, 5, and 6. It is immediately apparent that the graphite of smallest surface area (G-3) was composed of crystallites which were flatter and more regular than those of the graphites of high surface area (G-5 and GF-5). The crystallites of G-5 and GF-5 were made up of crumpled sheets with a granular appearance on a scale of about 30 Å. The particles of G-3 are very much more massive than those of G-5 and GF-5, in agreement with the X-ray data for G-3, which shows sharp $hk0$ and $00l$ lines. The particles of G-5 and GF-5 are wispy and in many cases, almost transparent to the electron beam. This is in line with the X-ray data which display broad $00l$ lines of low intensity. The particles of all the graphites are broken up and are composed of small crystallites piled in an irregular way, hence it is impossible to calculate surface areas from the photographs. However, it is clear that the observations are qualitatively in agreement with the X-ray and adsorption data.

It can be seen from the photographs that the adsorbing surfaces would contain many cracks, crevices, and wrinkles caused by crumpled-up graphite sheets. This would lead to a variety of energy states depending on the degree to which adjacent sheets of carbons gave rise to co-operative effects. Hence, it would be expected that these graphites would be energetically heterogeneous owing to the topography of the surface. This idea is supported by the adsorption isotherms which are smooth curves without the humps characteristic of homogeneous surfaces. Graphitic carbons prepared from carbon blacks may show homogeneous surfaces (1) because they presumably retain the fairly smooth topography of the parent carbon. McDermot and Lawton (6) have shown that these graphites are relatively free of chemisorbed oxygen hence the heterogeneity is likely to be exclusively of the topographic type. In this connection it was pointed out in the Introduction that removal of any ash present in the graphite left the shape of the isotherms unaffected.

DISCUSSION

The three graphites studied differ principally in degree of subdivision. The differences in surface area have been broadly indicated by all three of the methods used to study the graphites. The electron microscope photographs, while qualitatively in agreement with information from the other two methods, are not amenable to quantitative treatment. Accordingly, the following discussion will be limited to the X-ray and adsorption work.

It was impossible to calculate accurate values for the surface areas of the graphites from the X-ray data because no information was available on the distribution of particle sizes. For example, according to the method of stacking the crystallites, different 0004 profiles would be obtained for a given mass of graphite, but the $11\bar{2}2$ profile would be the same. Calculations such as the ones used, which employ dimensions calculated from the 0004 line, would tend to neglect this size distribution effect. However, as a first approximation surface areas were calculated from dimensions derived from the 0004 and the $11\bar{2}0$ lines. These are presented in Table III along with areas calculated from the adsorption data.

TABLE III

Graphite	Surface area m. ² /g.	
	Nitrogen adsorption	X-ray spectroscopy
G-3	18	55
G-5	380	220
GF-5	385	230

The areas calculated from the X-ray patterns are of the same order as those calculated from the adsorption data by means of the B.E.T. equation. In view of the approximations involved the agreement reached is considered to be good. It is of particular interest to note that the areas for G-5 and GF-5 derived from the X-ray data are in good agreement despite the differences in these spectra as illustrated in Fig. 2. In other words, although the crystallites are shaped differently, their surface areas are the same. This is in agreement with the fact that the B.E.T. areas are also equal, and their appearances in the electron microscope are similar.

PYRROLE CHEMISTRY

I. SUBSTITUTION REACTIONS OF 1-METHYLPYRROLE¹

HUGH J. ANDERSON

ABSTRACT

An investigation of some substitution reactions of 1-methylpyrrole has indicated that the α -directing effect of the hetero nitrogen during nitration is even less than it is in pyrrole. 3-Nitro-1-methylpyrrole has been prepared together with the 2-isomer by direct nitration of 1-methylpyrrole as well as indirectly. These two compounds have been found to undergo Friedel-Crafts acylation, a reaction not previously reported among simple nitro compounds of the 5-membered heterocycles. It has been found, contrary to the results of previous workers, that direct nitration of pyrrole itself yields a mononitro product containing about 7% of the 3-isomer.

INTRODUCTION

The reactions of pyrrole and its derivatives, while generally similar to those of the corresponding furan and thiophene compounds, show a number of differences. Some of these differences are of course due to the presence in pyrrole of the acidic imino hydrogen and some are inherent in the ring system itself. We have been interested in preparing simple pyrrole derivatives that have not yet been investigated and, in order to avoid the reactions due to the imino hydrogen as well as to stabilize somewhat the compounds being prepared, we have focused our attention on 1-methylpyrrole (I) the simplest homologue not possessing the reactive hydrogen.

1-Methylpyrrole shows more similarity in physical properties to toluene and the methylthiophenes than pyrrole with its imino hydrogen does to benzene and thiophene. For instance the boiling point of pyrrole is some 40–50° higher than expected probably owing to hydrogen bonding, while that of 1-methylpyrrole is where one might predict it to be. Like thiophene, 1-methylpyrrole may be C-metalated with *n*-butyllithium (13); it undergoes Friedel-Crafts acylation (4), forms the aldehyde with phosphorus oxychloride and dimethylformamide (15), and takes part in many other reactions all leading, with the exception of nitration as reported below, to a 2-substituted product when no other functional group is present in the molecule. In all its reactions it is much more reactive than thiophene.

Thiophene, furan, and pyrrole are well known to undergo substitution primarily or exclusively in an α -position if one is open in the ring. The presence of a meta-directing group in one α -position may, however, alter this situation substantially. Thus it has been found that nitration of 2-nitrothiophene leads to 2,4-dinitrothiophene predominantly and much less of the 2,5-dinitro compound (11, 16). From 2-nitrofuran only 2,5-dinitrofuran is obtained (8), indicating the overwhelming α -directing influence of the hetero oxygen in furan. The nitration of 2-acetylthiophene gives 4- and 5-nitro-2-acetyl isomers in roughly equal amounts (11) but again with the corresponding furan compound only 2-acetyl-5-nitrofuran is isolated (10).

The situation with pyrrole, on the other hand, is somewhat different. Further nitration of 2-nitropyrrole is reported by Rinkes (12) to give about four parts of 2,4-dinitropyrrole to one of 2,5-dinitropyrrole. Similarly he found that the nitration of 2-acetylpyrrole (XI) gave more of the 2,4-isomer (IX) than of the 2,5- one (X) while with the less strongly

¹Manuscript received September 24, 1956.

Contribution from the Chemistry Department, Memorial University of Newfoundland, St. John's, Nfld.

meta-directing carbomethoxy group in the 2-position roughly equal amounts of the 2,4- and 2,5-isomers were obtained on nitration. Many similar results indicate that the α -directing effect of the hetero nitrogen in pyrrole during nitration is less than that of the sulphur in thiophene, which, in turn, is much less than that of the oxygen in furan.

It was of interest to see first how the replacement of the imino hydrogen with a methyl group would change the directive influences of the pyrrole ring either through electronic or steric effects. It has now been found that nitration of 2-acetyl-1-methylpyrrole (II) following a procedure parallel to that of Rinkes (12) leads to about six parts of 2-acetyl-4-nitro-1-methylpyrrole (III) to one of the 5-nitro isomer (IV). This is a distinct change from the results for 2-acetylpyrrole where Rinkes found a ratio of roughly 2:1 in favor of the 4-isomer. The structures of III and IV have been established by repeating Rinkes' preparation of the corresponding pyrrole compounds IX and X and then methylating these two compounds on the nitrogen using sodium ethoxide and methyl sulphate in a modification of the method of Corwin and Quattlebaum (2). Formation of the sodium salt using sodium metal was found to be extremely slow even at the boiling point of toluene; however sodium ethoxide gave reasonable yields quite rapidly with these two compounds.

The synthesis of 3-nitro-1-methylpyrrole was then accomplished by subjecting the now proved 2-acetyl-4-nitro-1-methylpyrrole to a haloform reaction with alkaline sodium hypochlorite which formed the corresponding 4-nitro-1-methyl-2-pyrrole-carboxylic acid (VII). This acid was then decarboxylated to give the desired 3-nitro-1-methylpyrrole (VI), which was identical with that obtained by direct nitration as reported below and consequently proved the structure of that product. The success of the haloform reaction is an example of the stability increase caused by the N-methyl group. With simple pyrrole derivatives, alkaline hypochlorite or hypobromite causes the formation of halogenated maleimides (14). Thus it was not surprising to find that alkaline sodium hypochlorite solution gave none of the desired acid in a reaction with 2-acetyl-4-nitropyrrole, while, as reported, the 1-methyl compound gave about 40% yield of VII. With simpler N-methyl compounds there seems to be a simultaneous nuclear halogenation and this reaction is being investigated further.

Although acylation of a nitro compound has not hitherto been reported for thiophene, furan, or pyrrole, it has been found possible to acetylate 2-nitro-1-methylpyrrole (V) and the 3-nitro isomer (VI) using boron fluoride etherate as a catalyst. As might be expected from the combined meta-directing influence of the nitro group and the α -directing influence of the hetero nitrogen, only one product, 2-acetyl-4-nitro-1-methylpyrrole (III), was obtained from compound VI. With 2-nitro-1-methylpyrrole a single compound was again isolated which would be expected to be 4-acetyl-2-nitro-1-methylpyrrole (VIII). It is not the 2,5-isomer (IV) obtained above and, although we have not proved its structure, there seems little doubt of its identity.

An even more striking indication of the less intense α -directing influence in 1-methylpyrrole was found in the results of direct nitration. When furan is nitrated with acetic anhydride - nitric acid, only the 2-isomer is obtained (8) but in the nitration of thiophene roughly 5% of the 3-isomer is formed along with the 2-isomer (16). Rinkes found only 2-nitropyrrole in the mononitration product from pyrrole under these conditions (12). Following the standard procedure, nitration of 1-methylpyrrole yielded roughly two parts of 2-nitro-1-methylpyrrole (V) to one of the 3-isomer (VI). This is similar to the

EXPERIMENTAL

1-Methylpyrrole (I)

This compound was kindly donated by the Electrochemicals Department of E. I. du Pont de Nemours and Company, Inc.

2-Acetylpyrrole (XI)

This compound was prepared by the method of Oddo and Dainotti (9). Crystallized from water, m.p. 89–89.5°. Literature 90°.

2-Acetyl-4-nitropyrrole (IX) and 2-Acetyl-5-nitropyrrole (X)

These compounds were prepared by the nitration of 2-acetylpyrrole following the procedure of Rinkes (12). 2-Acetyl-4-nitropyrrole (IX) was crystallized from aqueous ethanol as pale yellow prisms, m.p. 195–196°. Literature 197°. Calc. for $C_6H_6N_2O_3$: C, 46.76; H, 3.92; N, 18.18. Found: C, 46.54; H, 4.03; N, 18.15. 2-Acetyl-5-nitropyrrole (X) was crystallized from water as fibrous needles, m.p. 154.5–155°. Literature 156°. Calc. for $C_6H_6N_2O_3$: C, 46.76; H, 3.92; N, 18.18. Found: C, 46.98; H, 3.96; N, 18.09.

*2-Acetyl-1-methylpyrrole (II)**Method A*

Following the procedure used by Hartough and Kosak (5) for the acetylation of furan and thiophene, 1-methylpyrrole (16.2 g., 0.2 M.), acetic anhydride (20.4 g., 0.2 M.), and freshly fused and powdered zinc chloride (27.3 g., 0.2 M.) were stirred together in 250 ml. dry ether for 1 hour and hydrolyzed in 600 ml. cold water overnight. The two layers were separated and, after saturation with salt, the aqueous layer was extracted twice with ether. The ether was dried over magnesium sulphate and removed to give an oil which was distilled at 88–91° at 22 mm. Yield 9.8 g. (40%). Hess and Wissing (7) report b.p. 75–76° at 15 mm.

Method B

In a manner similar to that used by Heid and Levine (6) to acetylate furan and thiophene, there was added to a previously chilled mixture of 1-methylpyrrole (4.0 g., 0.05 M.) and acetic anhydride (6.0 g., 0.05 M.) 0.5 ml. of practical boron fluoride–ethyl ether. The heat evolved was not great and the mixture was warmed to about 80° and allowed to cool over 30 minutes; it was then poured into 200 ml. cold water. Several hours later the solution was steam distilled. After being neutralized with sodium carbonate and saturated with salt the distillate was extracted with ether and the product recovered as in Method A. The yield was 1.85 g. (30%).

Nitration of 2-Acetyl-1-methylpyrrole

2-Acetyl-1-methylpyrrole (6.2 g., 0.05 M.) was dissolved in 35 ml. acetic anhydride and chilled to –10°. To this was added a cold mixture of fuming nitric acid (5.6 g., 0.09 M.) in 15 ml. acetic anhydride at such a rate as to prevent the temperature from rising above 0°. The dark purple solution was poured into 300 ml. ice water and extracted three times with ether. The extract was evaporated to dryness in a vacuum and the solid taken up in benzene, washed once with 10% sodium carbonate solution, and dried. The benzene solution was concentrated twice, producing a total of roughly 3.6 g. of crude material, m.p. 120–130°. The residue after all solvent was removed was a red oil, which on steam distillation produced 0.6 g. of crude solid, m.p. 90–95°.

The first substance, 2-acetyl-4-nitro-1-methylpyrrole (III), was recrystallized from

aqueous ethanol to give needles, m.p. 141–141.5°. Calc. for $C_7H_8N_2O_3$: C, 50.00; H, 4.79; N, 16.66. Found: C, 50.23; H, 4.93; N, 16.38.

The second isomer, 2-acetyl-5-nitro-1-methylpyrrole (IV), was recrystallized from aqueous ethanol to give pale yellow prisms, m.p. 95.5–96°. Calc. for $C_7H_8N_2O_3$: C, 50.00; H, 4.79; N, 16.66. Found: C, 50.12; H, 4.83; N, 16.93. This compound is very sensitive to light.

Preparation of Compounds III and IV by N-Methylation

To a solution of 2-acetyl-5-nitropyrrole (X) (0.30 g., 0.002 M.) in 20 ml. dry toluene was added 0.5 ml. ethanol in which metallic sodium (0.05 g., 0.002 M.) had been dissolved. After the mixture had been heated for 15 minutes all the salt had precipitated; methyl sulphate (0.25 g., 0.002 M.) was then added and the solution heated at 100° for about 30 minutes. After the solution was cooled 20 ml. of 6 N sodium hydroxide was added and the mixture shaken vigorously; then the layers were separated. The toluene solution was dried with magnesium sulphate and evaporated to dryness under vacuum. The residue was vacuum sublimed at 3 mm., then recrystallized from water to give 0.15 g. (44%) of 2-acetyl-5-nitro-1-methylpyrrole, m.p. 94–95° and mixed m.p. with compound IV from direct nitration 94–95°.

In a similar manner 2-acetyl-4-nitropyrrole (IX) was converted to 2-acetyl-4-nitro-1-methylpyrrole, m.p. 139–140° and mixed m.p. with compound III from direct nitration 139–140°.

Haloform Reaction with 2-Acetyl-4-nitro-1-methylpyrrole

An alkaline solution of sodium hypochlorite was prepared by passing chlorine into a solution of sodium hydroxide (4.4 g., 0.11 M.) in 4 ml. water chilled by 40 g. ice until 3.6 g. (0.10 M.) had been absorbed. Then after 2 g. sodium hydroxide was added in 8 ml. water, the solution was warmed to 65° and compound III (1.8 g., 0.10 M.) was added slowly with vigorous shaking while the temperature rose to nearly 90°. When the solution had cooled to room temperature a small amount of sodium bisulphite solution was added until there was no reaction with starch-iodide paper. After an ether extraction to remove any neutral material the solution was carefully acidified with dilute hydrochloric acid solution and extracted three times with ether. The product, 4-nitro-1-methyl-2-pyrrole-carboxylic acid (VII), weighed 0.65 g. (38%) and after recrystallization from water gave thick prisms, m.p. 199–199.5°. Calc. for $C_6H_6N_2O_4$: C, 42.36; H, 3.55; N, 16.47. Found: C, 42.57; H, 3.58; N, 16.37.

Decarboxylation of Acid VII

4-Nitro-1-methyl-2-pyrrolecarboxylic acid (50 mg.) and copper powder (25 mg.) were mixed intimately and added to 3.5 ml. quinoline in a 10 ml. pear-shaped flask. The mixture was heated in an oil bath to 175°; at this temperature bubbles were evolved. After 10 minutes the temperature had reached 190° and all reaction was over. When the reaction mixture had cooled to room temperature, an excess of ether was added and the quinoline removed by washing the mixture with dilute hydrochloric acid solution. The ether extract was washed once with water, dried, and the ether removed. The dark oily residue was crystallized from petroleum hexane to give 30 mg. (80%) of 3-nitro-1-methylpyrrole (VI) as long needles, m.p. 60–62°. Another recrystallization from water gave very pale cream prisms, m.p. 62–62.5°. Calc. for $C_5H_6N_2O_2$: C, 47.62; H, 4.79; N, 22.21. Found: C, 47.25; H, 4.74; N, 21.86.

Nitration of 1-Methylpyrrole

1-Methylpyrrole (12 g., 0.15 M.) was dissolved in 60 ml. acetic anhydride and cooled to -10° , then treated slowly with a solution of fuming nitric acid (12 g., 0.19 M.) in 20 ml. acetic anhydride, the temperature being kept below 5° during the addition. After being poured into ice water and extracted with ether the extract was washed with sodium carbonate solution until no longer acidic, then dried. When the ether had been removed, the residual oil was vacuum distilled to give 5.5 g. of a yellow oil, b.p. $90-95^{\circ}$ at 5 mm., and 4.5 g. of dark residue.

The yellow oil crystallized when cooled and, after being pressed dry on unglazed porcelain and recrystallized from petroleum pentane, yielded 4.6 g. of 2-nitro-1-methylpyrrole (V), m.p. $28-28.5^{\circ}$. Calc. for $C_5H_6N_2O_2$: C, 47.62; H, 4.79; N, 22.21. Found: C, 47.30; H, 4.93; N, 21.88.

The dark residue was repeatedly extracted with petroleum hexane and the crystalline solid recrystallized from water to give 2.6 g. of a compound, m.p. $62-62.5^{\circ}$. Mixed m.p. with 3-nitro-1-methylpyrrole (VI) from the decarboxylation was $62-62.5^{\circ}$.

Friedel-Crafts Acetylation of Compounds V and VI

To a solution of 3-nitro-1-methylpyrrole (VI) (0.2 g.) in 4 ml. acetic anhydride was added 0.1 ml. practical boron fluoride-ethyl ether. The solution was warmed slowly to 100° and allowed to cool again. After hydrolysis and neutralization with sodium carbonate solution the product, which was not very soluble in ether, was extracted with chloroform, dried over magnesium sulphate, and the solvent evaporated. The residue was crystallized from aqueous ethanol to give 0.16 g. of a compound, m.p. $140-141^{\circ}$. Mixed m.p. with 2-acetyl-4-nitro-1-methylpyrrole (III) was $140-141^{\circ}$.

Similarly 2-nitro-1-methylpyrrole (0.5 g.) was acetylated to give 0.35 g. of needles from water, m.p. $113.5-114^{\circ}$. Calc. for $C_7H_8N_2O_3$: C, 50.00; H, 4.79; N, 16.66. Found: C, 50.18; H, 4.87; N, 16.22. This compound is almost certainly 4-acetyl-2-nitro-1-methylpyrrole (VIII).

Nitration of Pyrrole

This reaction was carried out following the procedure of Rinkes but on twice the scale. To pyrrole (10 g., 0.15 M.) in 80 ml. acetic anhydride was added fuming nitric acid (11.3 g., 0.18 M.) in 40 ml. acetic anhydride, the temperature being kept below 5° . The crude solid isolated weighed 9.8 g. Attempts to recrystallize small portions led first to crude material of wide melting range and then to pure 2-nitropyrrole, m.p. $55-56^{\circ}$. Literature 56° .

After a preliminary trial, 1.00 g. of crude was dissolved in 8 ml. benzene-ethanol (9:1 by volume) and chromatographed on a column consisting of a mixture of Magnesol and Celite (3:1 by weight) weighing 50 g. Elution was carried out with the same solvent. The first solid-containing fraction was evaporated to dryness leaving 0.18 g. solid. This was extracted repeatedly with small amounts of petroleum pentane and first 0.10 g. of 2-nitropyrrole, m.p. $50-52^{\circ}$, was obtained. Then 65 mg. of 3-nitropyrrole, m.p. $63-64^{\circ}$ (literature 63°), was recovered. Fraction two contained only 2-nitropyrrole so, allowing for small losses, it appears that roughly 7% of the crude nitration product from pyrrole is 3-nitropyrrole.

To confirm its identity the 3-nitropyrrole was recrystallized from water, m.p. $100-101^{\circ}$. Literature 101° . Calc. for $C_4H_4N_2O_2$: C, 42.86; H, 3.60; N, 24.99. Found: C, 42.78; H, 3.62; N, 25.08.

SELECTIVE SUBSTITUTION IN SUCROSE

I. THE SYNTHESIS OF 1',4,6'-TRI-*O*-METHYL SUCROSE¹G. G. McKEOWN, R. S. E. SERENIUS,² AND L. D. HAYWARD

ABSTRACT

Sucrose was tritylated and acetylated to give a crystalline tri-*O*-trityl-penta-*O*-acetyl sucrose derivative, and detritylation of this product by graded hydrolysis with acetic acid followed by methylation and deacetylation yielded 1',4,6'-tri-*O*-methyl sucrose. The structure of the tri-*O*-methyl sucrose was established by periodate oxidation and by hydrolysis to the corresponding *O*-methyl ethers of glucose and fructose. Acetyl group migration from C₄ to C₆ in the glucose moiety of sucrose probably occurred during the methylation reaction.

Some aspects of syntheses involving sucrose are discussed.

INTRODUCTION

Although the molecular structure of sucrose has been carefully established (3, 21, 22, 34) and it is one of the cheapest and most abundant of the available fine organic chemicals (9), the satisfactorily characterized sucrose derivatives appear to be limited to the octa-*O*-substituted compounds which carry in each case one kind of ester or ether group (Table I). An exception is 1',6,6'-tri-*O*-methyl sucrose, which was prepared and character-

ized as the penta-*O*-acetyl compound by Percival (28). Other partially *O*-substituted sucrose derivatives and sucrose compounds with mixed *O*-substituents have been reported frequently but without proof of structure (4, 15, 19).

The scant attention that sucrose derivatives have received may in some degree be attributed to the molecular structure of sucrose itself. The presence in the polyol molecule of five secondary and three primary hydroxyl groups each with a unique structural environment makes theoretically possible the synthesis of an enormous number of sucrose derivatives. Substitution of just one kind of R group for hydroxyl hydrogen could theoretically give some 255 different compounds and with mixed R groups the

¹Manuscript received September 4, 1956.

Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C. Presented in part at the second Western Regional Conference, the Chemical Institute of Canada, Vancouver, September, 1954.

²Present address: Research and Development Department, Powell River Company Limited, Powell River, B.C.

number becomes astronomical (for example 1.6×10^7 possible octa-*O*-R derivatives for eight different R groups). Synthetic preparations from sucrose are hampered by the very easy acid hydrolysis of the double glycosidic linkage (25, 32), which limits the application to sucrose of synthetic procedures commonly used with the less acid-sensitive mono- and di-saccharide compounds. Furthermore, the steric hindrance imposed on some of the hydroxyl groups as a consequence of the size and preferred conformations of the sucrose molecule makes complete substitution difficult as, for example, in the well-known case of methylation of sucrose (6).

The objective of the present work was the synthesis of a sucrose derivative with the five secondary hydroxyl groups "blocked" with acetyl groups in preparation for a study of the comparative reactivity of the free primary alcohol groups. The structure of the penta-*O*-acetyl sucrose was to be established by methylation and hydrolysis to mono-saccharide derivatives. The series of preparations is outlined in Fig. 1.

FIG. 1.

Josephson in 1929 (19) reported the synthesis of a crystalline "tritrityl sucrose" by treatment of sucrose with 3 moles of triphenylchloromethane in pyridine for 2 hours on the steam bath. The constants reported were m.p. 127–129° C. and $[\alpha]_D^{23} +43.4^\circ$ ($c = 2.4$ in ethanol) and the product was analyzed for carbon and hydrogen but not for trityl content. In our attempts to reproduce these results we obtained in each case a colorless glass with a softening point of about 125–130° C. which was a mixture of tri-*O*-trityl sucrose, products with lower trityl content, reducing sugar fragments, and tritanol. We were unable to prepare pure tri-*O*-trityl sucrose by this route and also were unable to obtain a compound corresponding to the one reported by Josephson as resulting from acetylation of his tritritylsucrose.

We found that tri-*O*-trityl-penta-*O*-acetyl sucrose was conveniently prepared in crystalline form by tritylation of sucrose in pyridine solution at room temperature followed by acetylation in the same solution (29). Tritylation at higher temperatures gave a less pure product and no substantial increase in yield. The crude yield did not exceed 50% in any of the preparations and the mother liquors were strongly reducing toward Fehling's solution, indicating that a considerable degree of hydrolysis had occurred. Our tritylated and acetylated sucrose derivative could be recrystallized from methanol in admixture with chloroform or from chloroform-petroleum ether (b.p. 30–60° C.) as beautiful six-sided prisms which melted sharply at 235–236° C. (corr.), had $[\alpha]_D^{17} +68.9^\circ$ ($c = 2.45$ in chloroform), and reduced Fehling's solution only after acid hydrolysis; the composition was confirmed by the determination of the trityl and acetyl contents and the molecular weight and by the carbon and hydrogen analysis.

To effect the selective removal of the trityl groups from the tri-*O*-trityl-penta-*O*-acetyl sucrose, three methods were investigated: (a) the use of a hydrogen halide in an organic solvent (7, 13), (b) catalytic hydrogenation (24, 33), and (c) graded hydrolysis with aqueous acetic acid (20). Since the trityl ether and the glycosidic linkage of sucrose are both notably sensitive to acid hydrolysis (10) it was expected that competition would occur in methods (a) and (c), and indeed method (a) caused extensive inversion of the starting material and none of the desired product could be isolated. In method (b) catalyst poisoning was troublesome and the yields of penta-*O*-acetyl sucrose were low. Method (c) gave the acetate conveniently (43–60% yield) when optimum conditions had been established. The penta-*O*-acetyl sucrose was obtained in crystalline form (m.p. 155–156° C.; $[\alpha]_D^{22} +22.0^\circ$ ($c = 3.1$ in chloroform)) and analysis indicated the compound to be a dihydrate. Acetylation of this compound gave the known octa-*O*-acetyl sucrose in 61% yield.

The progress of the methylation of the penta-*O*-acetyl sucrose with Purdie's reagents was followed by deacetylating samples with a strongly basic ion exchange resin and chromatographing the mixed sucrose ethers on paper (Table II). After five methylations

the chromatograms indicated that substitution was essentially complete and the product was isolated as a colorless glass with the correct methoxyl and acetyl analyses. The crude tri-*O*-methyl-penta-*O*-acetyl sucrose, which did not crystallize during 6 months' standing, was deacetylated in 90% aqueous methanol solution on a column of strongly basic ion exchange resin which had previously been tested with sucrose octa-*O*-

acetate, in which case pure crystalline sucrose was obtained in better than 90% yield. The eluate from the column yielded nearly the theoretical amount of sirupy partially methylated sucrose; paper chromatography showed this product to be about 75% tri- and 25% di-*O*-methyl sucrose accompanied by a trace of mono-*O*-methyl sucrose. Pure tri-*O*-methyl sucrose was isolated from the mixture by means of a cellulose column.

When treated with an aqueous sodium metaperiodate solution the tri-*O*-methyl sucrose used up 1.8 moles of oxidant in 6 hours at room temperature and no further consumption occurred during the next 18 hours; no formic acid could be detected in the reaction mixture. Examination of the formulas of the 56 possible tri-*O*-methyl sucrose derivatives revealed that the 1',6,6'-isomer could be expected to consume 3 moles of periodate ion and form 1 mole of formic acid while the 1',2,6-, 2,6,6'-, 1',2,6'-, 1',4,6-, 4,6,6'-, and 1',4,6'-isomers would consume 2 moles of periodate and produce no formic acid. Nine of the other isomers would consume 2 moles of periodate and produce 1 mole of formic acid and the remaining 40 isomers would consume either 1 mole or no periodate and form no formic acid. The results obtained in the periodate oxidation of our tri-*O*-methyl sucrose therefore clearly ruled out the 1',6,6'-tri-*O*-methyl structure and pointed to one of the six compounds which carry secondary methoxyl groups on C₂ or C₄ of the glucose moiety and two other primary methoxyls.

Acid hydrolysis of the tri-*O*-methyl sucrose and chromatography of the hydrolyzate on a cellulose column yielded one mono-*O*-methyl hexose and one di-*O*-methyl hexose. The mono-*O*-methyl hexose was identified as 4-*O*-methyl-D-glucose by the optical rotation, analysis, behavior on paper chromatograms, and by its conversion to the known, crystalline 4-*O*-methyl-D-glucose phenylosazone.

The di-*O*-methyl hexose (with correct methoxyl content) was a colorless liquid with $[\alpha]_D^{24} + 17.4^\circ$ (equilibrium value) ($c = 1.84$ in water). It consumed 3.2 moles of periodate (constant value after 24 hours) and produced 1.71 moles of acid and no formaldehyde in 58 hours at room temperature. The R_f and R_{TG} values for this compound on paper chromatograms developed with butanol-ethanol-water (5:1:4 v/v) were larger than the corresponding values reported for the di-*O*-methyl glucose derivatives and for the known 3,4-di-*O*-methyl fructose (14). The bright yellow U.V.-fluorescent spot formed by spraying the chromatogram with *p*-anisidine hydrochloride reagent was characteristic of a ketose (17). Examination of the formulas of the possible di-*O*-methyl fructoses and their theoretical behavior toward periodate oxidation clearly indicated that our di-*O*-methyl hexose was 1,6-di-*O*-methyl fructose, which has not previously been reported (2). This conclusion was supported by the chromatographic evidence and by the equilibrium specific rotation observed, which was in good agreement with the values reported or calculated for D-fructofuranose and its *O*-methyl ethers and distinctly different from the large negative rotation given by the *O*-methyl-D-fructopyranoses (2, 22, 28, 34). The source and quantitative yield of the di-*O*-methyl hexose were also compatible with the assigned structure.

The actual isolation and identification of 4-*O*-methyl-D-glucose and 1,6-di-*O*-methyl-D-fructose established the structure of the original tri-*O*-methyl sucrose as the 1',4,6'-tri-*O*-methyl derivative (I). Satisfactory support to this formula was given by the results of the periodate oxidation study of the tri-*O*-methyl sucrose.

If the original trityl substitution was assumed to have been at the three primary alcohol groups in the sucrose molecule (Helferich's Rule (10)), it followed that acetyl migration from C₄ to C₆ occurred in the glucose moiety during the detritylation or

methylation reactions. The latter event appeared the more probable, since several cases of such migrations in monosaccharide derivatives during methylation with Purdie's reagents have previously been reported (31). The question of the original locations of the trityl groups in the tri-*O*-trityl-penta-*O*-acetyl sucrose will be examined in Part II of this series.

EXPERIMENTAL

Tri-O-trityl-penta-O-acetyl Sucrose

Commercial granulated sucrose (m.p. variable 162–177° C., $[\alpha]_D^{23} +65.57^\circ$ ($c = 26$ in water)) (5.0 g.) and freshly prepared triphenylmethyl chloride (14.3 g.) (m.p. 110–111° C. (1)) were treated with 100 ml. of dry pyridine and the mixture was allowed to stand with occasional shaking at room temperature for 48 hours. Acetic anhydride (20 ml.) was then added and the pale yellow solution was stored overnight in the refrigerator. The next day a crop of colorless, hygroscopic, crystals was recovered on a filter (6.7 g., m.p. 175–177° C.). The crystalline material gave a positive test for chloride ion, an acid reaction, yielded triphenyl carbinol on hydrolysis with water, and was presumably pyridinium triphenylmethyl chloride (11, 12). The filtrate was poured in a fine stream with stirring into 1500 ml. of ice water causing the precipitation of a white amorphous solid which was recovered by filtration, washed thoroughly with water, and dried *in vacuo*. The product crystallized from solution in 20 ml. of chloroform diluted with 50 ml. of methanol (yield 8.5 g., 45%) as colorless hexagonal plates which, after repeated recrystallizations from chloroform-methanol or tetrahydrofuran-methanol, melted sharply at 235–236° C.; $[\alpha]_D^{17} +68.9^\circ$ ($c, 2.45$ in chloroform). Analysis: Calc. for $C_{79}H_{74}O_{16}$: C, 74.2%; H, 5.84%; acetyl, 16.8%; trityl, 57.1%; mol. wt., 1279.5. Found: C, 73.7%; H, 5.9%;* acetyl, 16.8%; trityl, 56.4%; mol. wt., 1270 (Rast method; the lactam of *cis-p*-aminohexahydrobenzoic acid was used as solvent (30)).

The tri-*O*-trityl-penta-*O*-acetyl sucrose was soluble in acetone, chloroform, ethyl ether, and tetrahydrofuran; insoluble in water, ethanol, methanol, and petroleum ether; and reduced Fehling's solution only after acid hydrolysis.

Penta-O-acetyl Sucrose

(a) A solution of tri-*O*-trityl-penta-*O*-acetyl sucrose (2.0 g.) in glacial acetic acid (50 ml.) was heated to boiling and 1 ml. of water was introduced. After refluxing for 30 minutes the solution was cooled, the solvent evaporated under reduced pressure at 50° C., and the partially crystalline residue was dried *in vacuo*. Recrystallization from

*Carbon and hydrogen analyses by W. Manser, Zurich, Switzerland.

chloroform and petroleum ether acidified with acetic acid yielded colorless, needle-like crystals of penta-*O*-acetyl sucrose dihydrate (504 mg., 55%). Tritanol was recovered from the mother liquor. The penta-*O*-acetyl sucrose dihydrate was recrystallized to a constant melting point (155–156° C.) and had $[\alpha]_D^{22} +22.0$ ($c = 3.1$ in chloroform). Analysis: Calc. for $C_{22}H_{32}O_{16} \cdot 2H_2O$: acetyl, 36.6%. Found: acetyl, 36.6%. The dihydrate was soluble in methanol, acetone, chloroform; was insoluble in water and petroleum ether; gave a positive Molisch test; and reduced Fehling's solution only after acid hydrolysis. Acetylation of the compound gave octa-*O*-acetyl sucrose in 61% yield; m.p. 86–88° (23), not depressed on admixture with an authentic sample.

Some hydrolysis of the glycosidic linkage occurred during the detritylation since the reaction mixtures showed reducing action toward Fehling's solution. The effect of variation of time of reaction on the yield of penta-*O*-acetyl sucrose was as follows: 15 minutes, 23–31%; 30 minutes, 43–60%; 60 minutes, 35%; 120 minutes, 0%. Variation of the amount of water added to the glacial acetic acid solution did not greatly influence the yield: 0.25 ml., 23%; 1.0 ml., 31%; 2.0 ml., 26% (reaction time, 15 minutes).

(b) Catalytic hydrogenation was found to cause complete detritylation of only extremely pure samples of tri-*O*-trityl-penta-*O*-acetyl sucrose; less pure samples yielded a mixture of mono- and di-*O*-trityl sucrose derivatives (with palladized charcoal catalyst) or these compounds together with sucrose derivatives substituted with tricyclohexylmethyl groups (platinum oxide catalyst).

A 5.0 g. sample of tri-*O*-trityl-penta-*O*-acetyl sucrose which had been recrystallized 18 times alternately from chloroform-methanol and chloroform-petroleum ether (b.p. 30–60° C.) was dissolved in glacial acetic acid and hydrogenated under 4 atm. pressure in the presence of platinum oxide at 40–50° C. After 34 hours 2.55 g. of crystalline tricyclohexylmethane (83% of theor.) was recovered by filtration. Evaporation of the filtrate and crystallization of the residue yielded 0.60 g. (27%) of nearly pure penta-*O*-acetyl sucrose. In subsequent runs the yields obtained were 20, 38, 16, and 23%. Using palladized charcoal as catalyst a sample of the very pure tri-*O*-trityl compound also gave a 20% yield of the penta-*O*-acetyl sucrose accompanied in this case by triphenylmethane.

(c) A solution of tri-*O*-trityl-penta-*O*-acetyl sucrose (3.0 g.) in glacial acetic acid (80 ml.) was treated with 20 ml. of acetic acid saturated with hydrogen bromide (7, 13). Trityl bromide (1.7 g., m.p. 150–152° C.) precipitated immediately and was removed by filtration. The filtrate was diluted with chloroform, washed free of acid, and dried over anhydrous sodium sulphate. Evaporation of the solvent yielded a brown sirup which could not be induced to crystallize and was found to be strongly reducing toward Fehling's solution. Modifications of the procedure were applied, including the use of propionic acid or benzene as solvent, the use of hydrogen chloride as detritylating agent, and the use of buffered solutions for washing, but a non-reducing carbohydrate fraction could not be isolated from any of the reaction mixtures.

Methylation of Penta-O-acetyl Sucrose

Penta-*O*-acetyl sucrose dihydrate (1.579 g.) was dissolved in dry acetone (25 ml.) and freshly distilled methyl iodide (15 ml.), silver oxide (5 g.), and Drierite (2 g.) were added. The mixture was refluxed for 15 hours and filtered, and the filtrate was evaporated to give a viscous colorless sirup. A sample of the partially methylated sirup

was dissolved in methanol and deacetylated by heating with Dowex I strongly basic ion exchange resin for about 2 hours. The solution was then chromatographed on paper using butanol-ethanol-water (5 : 1 : 4 v/v) as developer. Treatment of the developed chromatograms with *p*-anisidine hydrochloride spray reagent (17) showed bright yellow spots for sucrose and sucrose *O*-methyl ethers which fluoresced strongly under an ultra-violet lamp. The R_f values for these compounds are given in Table II. The methylation procedure was repeated five times essentially as described above and the course of the reaction was followed by the chromatographic method as shown in Table II. After the second methylation the partially methylated sirup dissolved completely in methyl iodide, and acetone was then omitted from the reaction mixture. The final product was a colorless glass (1.55 g.) which did not crystallize during 6 months' standing; $[\alpha]_D^{17} + 57.7^\circ$ ($c = 3.72$ in chloroform). Analysis: Calc. for tri-*O*-methyl-penta-*O*-acetyl sucrose, $C_{25}H_{38}O_{16}$: OCH_3 , 15.7%; acetyl, 36.2%. Found: OCH_3 , 15.5, 15.8%; acetyl, 36.2, 36.0%.

Tri-O-methyl Sucrose

A solution of the methylated penta-*O*-acetyl sucrose (1.30 g.) in 90% aqueous methanol was run onto a column of Dowex I strongly basic ion exchange resin (20×1.8 cm. diam.). After standing 24 hours the column was washed with 600 ml. of the same solvent, and the eluate was evaporated to a colorless viscous sirup (835 mg., 99%). The sirup failed to crystallize after being left for several months and a paper chromatogram showed it to consist of *ca.* 75% tri-*O*-methyl, 25% di-*O*-methyl, and 1% mono-*O*-methyl sucrose. About 650 mg. of the sirup was chromatographed on a cellulose column (30×2.6 cm. diam.) using butanol-water as developer. The di-*O*-methyl sucrose fractions on evaporation yielded 193 mg. of a colorless glass and the tri-*O*-methyl sucrose fractions yielded 472 mg. of a colorless viscous sirup which had $[\alpha]_D^{24} + 67.6^\circ$ ($c = 1.74$ in water). Analysis: Calc. for tri-*O*-methyl sucrose, $C_{15}H_{28}O_{11}$: OCH_3 , 24.2%. Found: OCH_3 , 24.9, 24.3%.

Periodate Oxidation of the Tri-O-methyl Sucrose

A sample of the chromatographically pure tri-*O*-methyl sucrose (19.2 mg.) was dissolved in 10 ml. of 0.02 *M* sodium metaperiodate solution at 25° C. and the course of the reaction was followed by titration of aliquots of the solution for periodate ion consumed and for acid formed. Found: at 3 hours, 1.7 moles periodate consumed, 0.025 moles acid formed; at 6 hours, 1.8 moles and 0.025 moles; at 24 hours, 1.8 moles and 0.025 moles. Sucrose under the same conditions gave the following results: at 1 hour, 2.3 moles periodate consumed and 0.26 moles of formic acid formed; at 3 hours, 2.7 and 0.35 moles; at 6 hours, 2.9 and 0.47 moles; at 24 hours, 3.1 and 0.61 moles. Fleury and Courtois (8) reported a consumption of 3.0 moles of periodate and production of 0.70 moles of formic acid for sucrose after 24 hours.

Acid Hydrolysis of the Tri-O-methyl Sucrose

Tri-*O*-methyl sucrose (358 mg.) was hydrolyzed in 10 ml. of 1% acetic acid at reflux temperature during 5 hours. The hydrolyzate was filtered through Celite and evaporated under reduced pressure to a colorless sirup (342 mg.). A paper chromatogram of a sample of the sirup was run on the same sheet with authentic specimens of 2-, 3-, 4-, and 6-*O*-methyl-D-glucose under the conditions described for the chromatography of partially

methylated sucrose derivatives. The hydrolyzate showed a brown-yellow, U.V.-fluorescent spot, R_f 0.29, which agreed in color and R_f value with that from 4-*O*-methyl-D-glucose. 2-*O*-Methyl- and 6-*O*-methyl-D-glucose gave brown spots which did not fluoresce under U.V. light. A bright yellow, U.V.-fluorescent spot, R_f 0.57 (R_{TG} 0.69), was the only other present on the chromatogram of the hydrolyzate and was tentatively assigned to 1,6-di-*O*-methyl-D-fructofuranose; 3,4-di-*O*-methyl-D-fructose has been reported to have a considerably lower R_f value (0.51 (R_{TG} 0.61)) as have di-*O*-methyl glucose derivatives, under these conditions (14). The hydrolyzate was chromatographed on the cellulose column and the appropriate fractions gave on evaporation 161 mg. of the di-*O*-methyl hexose and 148 mg. of the mono-*O*-methyl hexose.

The mono-*O*-methyl hexose was a colorless viscous sirup, $[\alpha]_D^{24} +61.2^\circ$ ($c = 1.43$ in water), which did not crystallize after nucleation with 2-, 3-, or 6-*O*-methyl glucose. Analysis: Calc. for mono-*O*-methyl hexose, $C_7H_{14}O_6 : OCH_3$, 16.0%. Found: OCH_3 , 15.5, 15.9%. A phenylosazone was prepared in 40% yield which crystallized from aqueous acetone as fine yellow needles, m.p. 156–158° C. The melting point was not depressed on admixture with an authentic sample of 4-*O*-methyl-D-glucose phenylosazone (5).

The di-*O*-methyl hexose was a colorless liquid, $[\alpha]_D^{24} +17.4^\circ$ (equilibrium value) ($c = 1.84$ in water). Analysis: Calc. for $C_8H_{16}O_6 : OCH_3$, 29.8%. Found: OCH_3 , 29.8, 29.3%. Twenty-two milligrams of the liquid was treated with 20 ml. of 0.02 *M* sodium metaperiodate solution at 25° C. and the oxidation solution was analyzed at intervals for the amounts of periodate consumed and of acid and formaldehyde produced. Found: at 4 hours, 3.1 moles periodate consumed, 1.26 moles of acid formed; at 24 hours, 3.2 and 1.58 moles and no formaldehyde; at 58 hours, 3.2 and 1.71 moles.

THE PAPILIONACEOUS ALKALOIDS

XXIII. THE STRUCTURE OF BAPTIFOLINE¹

M. MARTIN-SMITH² AND LÉO MARION

ABSTRACT

Baptifoline ($C_{15}H_{20}O_2N_2$) has been found on spectroscopic evidence to contain a hydroxyl group and an α -pyridone ring. On catalytic hydrogenation it gives rise to tetrahydrobaptifoline, which has been identified as *l*-hydroxylupanine. Baptifoline is, therefore, *l*-13-hydroxylanagryne.

Baptifoline ($C_{15}H_{20}O_2N_2$), also designated as alkaloid P3, is a base occurring in *Baptisia perfoliata* (L.) R. Br. (9) and *Baptisia minor* Lehm. (10). It is a crystalline, monoacidic alkaloid, $[\alpha]_D -147.7^\circ$, forming easily crystallizable salts (10).

It contains a free hydroxyl group detected by a strong band at 3260 cm^{-1} in its infrared absorption spectrum, and at 3340 cm^{-1} in that of its perchlorate. There is strong spectroscopic evidence for the presence in the base of an α -pyridone ring. The infrared spectrum of the base shows an absorption band at 1650 cm^{-1} and one at 1555 cm^{-1} with a shoulder at 1567 cm^{-1} , while that of its perchlorate shows three bands at 1652, 1576, and 1552 cm^{-1} . The frequencies of these three bands are almost identical with those observed in each of the spectra of cytisine, N-methylcytisine, rhombifoline, anagryne, and thermopsine (3, 4), the only other members of the series in which the lactam group is part of an α -pyridone ring.

In the series of the C_{15} lupine alkaloids all those containing an α -pyridone ring such as anagryne ($[\alpha]_D = -165.3^\circ$), thermopsine ($[\alpha]_D = -159.6^\circ$), and rhombifoline ($[\alpha]_D = -232.4^\circ$) have numerically high optical rotations whereas those containing an α -piperidone ring, such as lupanine ($[\alpha]_D = +61.4^\circ$), hydroxylupanine ($[\alpha]_D = +64.2^\circ$), and α -isolupanine ($[\alpha]_D = +65.9^\circ$), have optical rotations that are numerically relatively low. Hence the high optical rotation of baptifoline ($[\alpha]_D = -147.7^\circ$) supplies contributory evidence of the presence in the base of an α -pyridone ring.

It was therefore decided, owing to the small amount of material available, that the most promising line of attack in attempting to elucidate the structure of baptifoline would be to hydrogenate the double bonds and endeavor to relate the product to the known hydroxylupanine alkaloids containing an α -piperidone ring, such as hydroxylupanine (2) and lupilaxine (12).

Accordingly, baptifoline was reduced catalytically under the conditions employed for the conversion of thermopsine to α -isolupanine (3). The reaction was rapid and at the end of 20 minutes the uptake of 2 moles of hydrogen was complete. Such catalytic reduction of the α -pyridone ring in the C_{15} lupine alkaloids is known to be stereospecific and to cause the hydrogen entering at C-6 to assume a *cis* position with respect to the methylene bridge (11). Hence the resulting tetrahydrobaptifoline could only be either an hydroxy- α -isolupanine or an hydroxylupanine, depending upon whether baptifoline was a thermopsine or an anagryne derivative, i.e., whether the hydrogen at C-11 was *cis* or *trans* relative to the methylene bridge (cf. Ref. 11).

Since it was not possible to obtain the hydrogenated product in crystalline form, it was converted to its crystalline hydrochloride. The behavior of the hydrochloride on heating was identical with that of a specimen of hydroxylupanine hydrochloride.³ Loss of solvent was apparent at *ca.* 100° and a change of phase occurred at 180–230°. The prisms resulting from this change then melted at 272–273°, whereas the final melting point of hydroxylupanine hydrochloride was 274–276°. A search of the literature revealed that a wide range of melting points has been reported for the hydrochloride of hydroxylupanine, i.e., 273° (2), 275° (6), 283° (1), 288–289° (5), and 296–298° (7).

The infrared spectra of the hydrochlorides in chloroform solution (because of low solubility) were of little value; in nujol mulls they were weak and although they appeared identical were not too satisfactory. The samples were therefore sublimed (220–230° at 10^{−3} mm.) and the infrared spectra of the hydrochlorides taken by the potassium chloride disk method. These were undisputedly identical. Consequently, tetrahydrobaptifoline is either *d*- or *l*-hydroxylupanine and, therefore, must contain a hydrogen at C-6 which is *cis* and a hydrogen at C-11 which is *trans* relative to the methylene bridge.

As an additional confirmation, tetrahydrobaptifoline liberated from its salt was chromatographed on paper using butanol saturated with water and glacial acetic acid as the solvent phase, and developed with Munier–Dragendorff reagent (13). Its *R_F* value (0.40) was identical with that of hydroxylupanine chromatographed under the same conditions.

The optical rotations of tetrahydrobaptifoline hydrochloride and of hydroxylupanine hydrochloride were measured in water solutions. Because the quantity of material available was so small, the error involved in the determination was rather large. The literature records $[\alpha]_D = +45.2^\circ$ for hydroxylupanine hydrochloride (1) and we found $[\alpha]_D^{23} = +55^\circ$, whereas the rotation of tetrahydrobaptifoline was $[\alpha]_D^{23} = -72^\circ$. There is no doubt, therefore, that whereas the naturally occurring hydroxylupanine is known to be dextro-rotatory, tetrahydrobaptifoline is levorotatory and, hence, must be *l*-hydroxylupanine.

It has been established by Galinovsky, Pöhm, and Riedl (8) that hydroxylupanine is 13-hydroxylupanine and, therefore, because of the established relationship between anagryne and lupanine (11), it can be concluded that baptifoline is *l*-13-hydroxyanagryne, represented by the above formula.

EXPERIMENTAL

The infrared absorption spectra were taken with a Perkin–Elmer double beam spectrometer, model 21B, using a sodium chloride prism. Unless otherwise stated they were taken on nujol mulls.

Tetrahydrobaptifoline

Baptifoline (50 mg.) dissolved in glacial acetic acid (7 ml.) was hydrogenated at room temperature and atmospheric pressure in the presence of Adams' catalyst (30 mg.). At

³Prepared from a specimen of hydroxylupanine given by Professor V. Deulofeu, whose courtesy is acknowledged.

the end of 20 minutes the compound had adsorbed 2 moles of hydrogen. The solution was filtered, the catalyst washed several times with acetic acid, and the combined filtrate and washings evaporated to dryness under diminished pressure. The residual colorless oil was soluble in acetone, methanol, chloroform, and ethanol, but could not be induced to crystallize. Addition of ether to the various solutions caused oiling out.

The product was converted to the hydrochloride by adding one drop of hydrochloric acid to a methanolic solution of the base and diluting the solution with acetone. The crystalline salt was recrystallized twice from methanol-acetone from which it separated as colorless plates. On being heated the salt lost solvent at *ca.* 100°, showed a change of phase at 180–230°, and melted at 272–273°. $[\alpha]_D^{23} = -72^\circ \pm 10^\circ$ (*c.* 0.179 in water).

Authentic hydroxylupanine hydrochloride when heated showed the same behavior, and the final melting point was 274–276°. $[\alpha]_D^{23} = +55^\circ$ (*c.* 0.19 in water).

Tetrahydrobaptifoline hydrochloride was sublimed (220–230° at 10^{-3} mm.) and the infrared spectrum taken by the potassium chloride disk method. The spectrum was superimposable on that of hydroxylupanine hydrochloride taken under the same conditions.

Both tetrahydrobaptifoline liberated from its hydrochloride and hydroxylupanine were spotted on paper and butanol saturated with water (10 ml.) and glacial acetic acid (0.5 ml.) used as the solvent phase. The chromatogram was developed with Munier-Drageendorff reagent (13). For both the R_F was 0.40.

ACKNOWLEDGMENT

We are indebted to Mr. R. Lauzon of these laboratories for taking the infrared absorption spectra.

TRIARYLMETHANE COMPOUNDS AS REDOX INDICATORS IN THE SCHOENEMANN REACTION

I. MECHANISM OF THE SCHOENEMANN REACTION¹

G. A. GRANT, R. BLANCHFIELD, AND D. MORISON SMITH

ABSTRACT

A method is outlined for the detection of anticholinesterase agents similar to sarin (isopropyl methylphosphonofluoridate) in aqueous solution at concentrations as low as 0.1 p.p.m. in 10 ml. of solution by the use of the Schoenemann reaction. A new series of indicators, 4,4'-(2-thenylidene)bis[N,N-dimethylaniline] variously substituted in the thiophene ring, was used in the investigation. The dependence of color formation on pH, chloride ion concentration, and other factors led to an explanation of the mechanism of the reaction involved. Chloride ion is necessary for the reaction and, in the absence of the indicator, free chlorine can be detected in acid solution. Presumably, then, during acidification perphosphonate ion reacts with chloride ion to give hypochlorous acid, which oxidizes the mono ion of the leuco compound to a dye.

Ions such as cyanide ion, with a lower oxidation-reduction potential than the leuco compounds, interfere with the test. Oxidation of the leuco compound by hypochlorous acid is bypassed in the method described for the detection of sarin in the presence of hypochlorous acid.

INTRODUCTION

In the search for a sensitive method for the detection, in aqueous solution, of anticholinesterase agents known as nerve gases, a number of reactions were explored. The Schoenemann reaction, which showed the most promise, has been described by Wilson, Gehauf, and Rueggeberg (8) and by Epstein and Bauer (1). It involves the formation of a perphosphonate ion by the interaction of hydrogen peroxide with phosphonofluoridate ester in basic solution as given in equation 1.

The perphosphonate ion is capable of producing colored oxidation products from certain organic compounds. In this respect *o*-dianisidine has been extensively investigated as an indicator by Epstein and Bauer (1) and by Thomas and Grant (2). By extraction of the orange oxidized form with organic solvents, as little as 0.1 p.p.m. of agent can be detected without interference from a number of substances which are colored in aqueous solution. It would be preferable to avoid the use of organic solvents and to have a purple or blue indicator of equal or better sensitivity. Certain leuco triarylmethane compounds, for example 4,4'-(2-thenylidene)bis[N,N-dimethylaniline], were found to give blue colors on oxidation in the Schoenemann reaction. A number of these leuco compounds, variously substituted in the thiophene ring, were synthesized and tested (7). The syntheses and properties of the leuco compounds, the results of the tests, and the spectra of the dyes will be described in detail in later papers in this series.

Contribution from Defence Research Board, Defence Research Chemical Laboratories, Ottawa, Ontario. Issued as D.R.C.L. Report 135A.

It was previously assumed that the perphosphonate ion oxidizes the reduced indicator to the colored compound in acid solution. Preliminary investigation has, however, shown that this is not the correct reaction mechanism when the triarylmethanes are employed as the redox indicators. Indeed, because of the results of the present investigation in which the principal factors involved in the Schoenemann reaction are studied, an alternative reaction mechanism must be postulated to account for the oxidation of the leuco triarylmethane compounds.

EXPERIMENTAL AND RESULTS

Testing Procedure

A procedure was adopted for the determination of the variables affecting color formation. One milliliter of a 4% aqueous solution of sodium pyrophosphate peroxide ($\text{Na}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}_2$) was added to 10 ml. of an aqueous solution of sarin (isopropyl methylphosphonofluoridate) whose concentration (0 to 10 p.p.m.) had been accurately determined by the Schoenemann reaction using *o*-dianisidine as the redox indicator, the calibration data for this indicator having previously been obtained with solutions of sarin made up by weight (3). The solutions of sarin and sodium pyrophosphate peroxide were mixed and (optimum within 30 seconds) 1 ml. of a 0.1% solution of the redox indicator in dilute hydrochloric acid (1:16) was added. The optimum concentration of hydrochloric acid was found to be a 1/16 *N* solution, which gave a final chloride ion concentration of approximately 6.5×10^{-2} gram-ions/liter. The same procedure was followed in making the blank solution except that 10 ml. of distilled water was used instead of the sarin solution. Optical density readings of the sarin solution against the blank were taken at the wavelength of the absorption maximum (*ca.* 625 $\text{m}\mu$) using a Beckman Model DU spectrophotometer and 2 cm. Corex Cells. The optimum time for this measurement was found to be 7 minutes after the addition of the leuco compound.

Redox Measurements

Attempts were made to determine polarographically the oxidation-reduction potential for the leuco compounds in solutions of optimum pH and chloride ion concentration, using the method of Julian and Ruby (4). The rate of change of voltage was 160 mv./minute instead of the recommended 20 to 40 mv./minute because of the limitations of the Leeds and Northrup Electrochemograph, Type E. Consequently the results were inaccurate and indicated only that the redox potential for transformation of leuco compound to dye was from -0.9 to -1.0 volts while the potential at which destructive oxidation occurred was between -1.0 and -1.1 volts.

Previously, attempts had been made to determine the oxidation potential using a redox titration according to the method of Meyer and Treadwell (6). The buffers of pH 1.7 which were tried were Clark and Lubs potassium chloride-hydrochloric acid, Sorensen citrate buffer, and a solution of 0.1 *N* potassium bisulphate and 0.1 *M* potassium sulphate. Oxidizing agents tried were 0.1 *N* potassium dichromate and 0.1 *N* and 0.001 *N* ceric sulphate. For agitation, either nitrogen bubbling or magnetic stirring was used. From these measurements it was impossible to obtain accurate data, for destructive oxidation occurred near the oxidation potential.

Factors Affecting Color Development

In studying these factors use was made of only a few representative triarylmethane leuco dyes, namely 4,4'-(2-thenylidene)bis[*N,N*-dimethylaniline] (*I(a)*); 4,4'-(5-methyl-

2-thenylidene)bis[N,N-dimethylaniline] (I(b)); 4,4'-(4,5-dimethyl-2-thenylidene)bis[N,N-dimethyl-
[N,N-dimethylaniline] (I(c)); 4,4'-(5-ethyl-4-methyl-2-thenylidene)bis[N,N-dimethyl-
aniline] (I(d)).

Unless otherwise stated, compound I(c) was used.

Duration of Time after Initial Color Formation

The solutions were mixed as described and placed in the spectrophotometer. Density measurements were made at the absorption maximum at various times. Compounds I(a), I(b), I(c), and I(d) were used and the results are plotted in Fig. 1. These curves

Fig. 1. Effect of time on color development.

indicate that the color develops to maximum intensity in less than 10 minutes and then fades slowly. For practical purposes a standard reaction time of 7 minutes was chosen. The solutions of sarin and sodium pyrophosphate peroxide were mixed and various intervals of time were allowed to elapse before introduction of the solution of redox indicator. The color intensity was then measured as usual. Table I gives the figures for

TABLE I

EFFECT OF TIME DELAY IN ADDING ACIDIFIED INDICATOR SOLUTION TO PERPHOSPHONATE ION SOLUTION

optical density at the absorption maximum in this experiment. From these data, which are indicative of the stability of the perphosphonate ion, 30 seconds was selected as the optimum interval before the addition of the indicator solution.

Acidity of the Solution in Which the Color Developed

Solutions of sarin and sodium pyrophosphate peroxide were mixed as usual. To this mixture was added leuco compound I(a) dissolved in a solution containing a constant concentration of sodium chloride (the optimum, 6.5×10^{-2} gram-ions/liter) and different concentrations of sulphuric acid, which controlled the pH values of the medium in which the color developed.

The effect of pH on the color developed in the Schoenemann reaction at constant chloride ion concentration is given in Fig. 2. The results indicate an optimum acidity of around pH 1.6.

FIG. 2. Effect of pH on color development.

Concentration of Chloride Ion

To the solutions of sarin and sodium pyrophosphate peroxide, mixed as before, was added a solution of the leuco compound, prepared in solutions of 1:50 sulphuric acid containing different concentrations of chloride ion as sodium chloride.

From the results obtained on varying the concentration of chloride ion at constant pH 1.69 (Fig. 3) a concentration between 5×10^{-2} and 1 gram-ion/liter would seem to be optimum. In an attempt to determine the part played by chloride ion in the mechanism of the color formation, a solution of about 100 p.p.m. of sarin containing 3% sodium chloride was used instead of the usual 5 p.p.m. sarin solution. When the test was performed as previously outlined, but withholding the leuco compound, strong

FIG. 3. Effect of chloride ion concentration on color development.

chlorine odor was apparent. Chemical proof of the presence of free chlorine was established by the color obtained on drawing the vapors in the flask through a filter paper moistened with a 0.1% *o*-dianisidine dihydrochloride solution which acted as a redox indicator for the chlorine.

The effect of chloride ion was studied when *o*-dianisidine was used as the indicator. *o*-Dianisidine dihydrochloride was converted to the free base with sodium carbonate, carefully washed free of chloride, and dissolved in absolute ethyl alcohol. The alcohol solution was brought to a boil and sulphuric acid added. The white sulphate salt was filtered and recrystallized from water in the dark. The Schoenemann reaction was carried out as previously described (1), employing the *o*-dianisidine dihydrochloride. The time of formation and intensity of the color formed was the same for the hydrochloride and sulphate. Therefore, it is evident that chloride ion is not essential when *o*-dianisidine is used as the indicator.

Chlorine

A positive test was obtained when a solution of 6 p.p.m. of aqueous chlorine was used instead of the sarin solution, presumably because of oxidation of the leuco compound by hypochlorous acid in the acid medium. When, however, a time interval of 3 minutes was allowed to elapse between the addition of the oxidizing solution and the solution of leuco compound, no color was formed, probably because the alkaline peroxide had sufficient time to oxidize the hypochlorite. Thus the perphosphonate ion as well as hypochlorite will oxidize the *o*-dianisidine but only hypochlorite will oxidize the triarylmethane compounds.

Cyanide Ion

The standard test was carried out, using a sarin solution containing 200 p.p.m. of potassium cyanide. No color was produced in the test.

Other Anticholinesterase Agents

"Tabun", which is a phosphonocyanide ester rather than a phosphonofluoride ester, was used in aqueous solution instead of sarin. The standard test was applied. No color

was obtained unless the tabun was freshly distilled and the aqueous solution just made up, whereupon a faint color appeared.

Acid-Base Titration of the Leuco Compound

Compound I(a) was dissolved in 1 *N* hydrochloric acid to give a 0.05 *M* solution. An aliquot of this solution was titrated with 1 *N* sodium hydroxide, using a Coleman model 3A pH Electrometer with a glass electrode.

The results for the acid-base titration are given in Fig. 4. These indicate an end

FIG. 4. pH of formation of mono ion of compounds.

point of pH 2.2 for the formation of the mono ion of the compound according to equation 2.

DISCUSSION

A number of facts pertaining to the Schoenemann reaction are of interest in elucidating the mechanism of reaction. The presence of chloride ion is essential to color development in the Schoenemann reaction when the triarylmethane compounds are used as indicators but it is not essential when *o*-dianisidine is used. Free chlorine is formed under the conditions of this reaction when the indicator is not present, presumably by interaction of the essential chloride ion and perphosphonate ion.

The Schoenemann reaction medium is initially alkaline (pH 9 to 10.5) and then acidified to pH 1.6 to 2.2. Therefore, a study of the oxidation-reduction reactions of free halogen in acidic and basic media may reveal some information to explain chloride ion dependence and mechanism of the reaction. All couples are written according to the convention used by Latimer (5).

The reaction between perphosphonate ion and chloride ion in basic solution may be considered as a combination of two couples.

and

These are both equally dependent on hydroxyl ion concentration so that for the reaction to occur the potential (3) must be considerably more negative than -0.94 v. However, in alkaline peroxide solution hypochlorite ion appeared to be oxidized to chlorite or chlorate. This was evident from the fact that, when a solution of chlorine was used in place of sarin, oxidation of leuco compound took place only if acid indicator solution was added immediately after the alkaline peroxide solution, but if the hypochlorite and alkaline peroxide were allowed to react for 3 to 4 minutes prior to addition of indicator no dye was formed. This indicates the OCl^- is being oxidized to ClO_2^- and ClO_3^- ions, which have lower oxidation potential than OCl^- and are therefore unable to oxidize the indicator.

Further, when sarin was present along with hypochlorite and some time was allowed to elapse between addition of peroxide and indicator, dye formation was evident almost on a quantitative basis, which would indicate that perphosphonate ion formed in alkaline solution is not reacting with hypochlorite ion and is still available to oxidize chloride ion upon acidification. It is thus evident that the reaction between perphosphonate ion and chloride ion to produce free chlorine and hypochlorous acid must occur in acid solution, probably according to equations 5 and 6.

In acid solution the chlorine or hypochlorous acid appearing in accordance with equation 7 acts as an oxidizing agent on leuco compound in solution.

The equilibrium at pH 1.8 is such that the mole fraction of chlorine is 0.7 and that of hypochlorous acid is 0.3 (3). The perphosphonate ion alone cannot oxidize the leuco compound because it decomposes too readily in acid solution (1). Probably as the solution becomes more acid during mixing, the perphosphonate ion reacts with the large excess of chloride ion more rapidly than with the small amount of leuco compound, which is appreciably soluble only below pH 2.2. The HOCl formed is not removed by excess peroxide because in acid solution equation 8 applies to peroxide and the potential here is not adequate for reaction.

For the same reason the dye is not affected by acid peroxide although in alkaline solution it is oxidatively destroyed by peroxide.

The mechanism can then be summarized as follows. Perphosphonate is first produced (equation 1). Then, as the alkaline and acid solutions are mixed and the pH goes from 10.5 to 1.6, reaction proceeds as in equation 9.

At optimum chloride ion concentration and pH the dye is produced (equation 10).

On the basis of the above mechanism an explanation of chloride ion dependence and failure of the reaction with tabun can be attempted.

The increase in dye formation with an increase of chloride concentration up to 5×10^{-1} gram-ions/liter can be considered as indicative of an increase in hypochlorous acid concentration as the result of an increase in collision frequency between perphosphonate and chloride ions and a decrease in collision frequency between perphosphonate ions. Assuming a 100% yield of perphosphonate ion the ratio of chloride ion to perphosphonate ion with 10^{-3} gram-ions/liter of chloride ion and 5 p.p.m. of sarin is approximately 1 to 30 while with 1 gram-ion/liter it is approximately 1 to 30,000. The decrease in dye yield with chloride ion concentration greater than 1 gram-ion/liter may be the result of a decrease in available hypochlorite. From equation 7 it is evident that an increase of chloride ion increases the proportion of chlorine to hypochlorite in solution. As the experiments were conducted in an open system with vigorous stirring, chlorine would escape and result in a decrease in available hypochlorous acid and generated dye.

Cyanide ion was shown to prevent dye formation. It is possible that perphosphonate ion in alkaline solution is reduced by the CN⁻ ion.

Therefore, the hydrolysis of tabun to give cyanide ion explains the negative results obtained with it in the Schoenemann reaction when these indicators are used.

STRESSES AND STRAINS IN ADSORBENT-ADSORBATE SYSTEMS. II¹

E. A. FLOOD

ABSTRACT

It has been shown previously that when adsorbates act as single component complexes, i.e. behave as single substances in complex force fields, volumetric mean adsorbate and mean adsorbent stress intensities can be calculated from adsorption isotherm data. When potentials of surface regions in the micropore system of a porous adsorbent are statistically independent of pore structure, linear mean stress intensities of the solid are related to volumetric means through an equation containing a structure factor which is independent of the nature and pressure of the adsorbed gas.

In this paper we present adsorption extension data for an active carbon rod when exposed to helium, hydrogen, nitrogen, argon, krypton, and water at pressures up to 1600 p.s.i. The data suggest that the potentials of the capillary regions are not independent of structure. An empirical correlation factor is introduced and the resulting semiempirical equation describes the data probably within the experimental error.

The results suggest that in cases of moderately strong adsorption, adsorption potentials of thick-walled capillary regions are higher than those of thin-walled regions.

INTRODUCTION

Length changes of porous solid adsorbents resulting from adsorption of vapors have been studied by a number of investigators: Meehan (9), Bangham (2, 3), McBain (8), McIntosh (1, 7), Wiig (13), Yates (14), etc., the work of Bangham and co-workers in Egypt and that of McIntosh and co-workers in this country being especially notable.

It has been customary to correlate these dimensional changes with the changes in the more or less fictitious solid surface tensions or with the so-called "spreading pressures", the changes in surface tensions or spreading pressures being based on the Gibbs "adsorption isotherm", i.e. on the Gibbs model interface. The Gibbs model interface is a very convenient mathematical fiction for the treatment of cases where interfacial volumes are small compared with the whole system under consideration. However, such two-dimensional model interfaces are entirely unsuitable for the treatment of systems where the interfacial volumes are relatively large and where the behavior of the system depends largely on the distribution of densities, stress intensities, viscosities, etc. of materials within the surface regions. Since we have been mainly concerned with flow rates of adsorbed materials we have found it convenient to describe the adsorbate as a volume of a single component subjected to a complex force field, i.e., as a single component complex (5).

When vapors are adsorbed by relatively rigid porous adsorbents and the adsorbates behave as single component complexes, volumetric mean stress intensities of adsorbates and adsorbents can be calculated from relevant adsorption isotherm data, provided that the relevant isotherms correspond to paths of thermodynamic reversibility (5, 6).

We have shown that these volumetric mean stress intensities are given by the following equations:

$$[1] \quad \bar{p}_a^v = \int_0^P \rho_a / \rho \cdot dP = \alpha P,$$

$$[2] \quad \bar{p}_c^v = [1 + \phi - \phi\alpha]P,$$

¹Manuscript received May 24, 1956.

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa.

Issued as N.R.C. No. 4163.

where $\bar{p}_a^v$ = volumetric mean stress intensity of adsorbate within the porous adsorbent,
 ρ_a = volumetric mean density of adsorbate within adsorbent,
 P = pressure of adsorbate fluid outside of porous adsorbent, i.e., the equilibrium pressure,
 ρ = density of adsorbable fluid outside of adsorbent, i.e., the uniform density of the liquid or gas in equilibrium with adsorbate,
 $\bar{p}_c^v$ = volumetric mean elastic or reversible stress intensity of the porous solid ($\bar{p}_c^v = 0$ when $P = 0$),
 ϕ = void volume/solid volume = v_a/v_c
 $(v_a + v_c = \text{total volume of the porous body})$,
 $\alpha = \bar{p}_a^v/P$ = mean value of ρ_a/ρ averaged over the pressure interval $0 \rightarrow P$.
 Thus α is readily obtained from the adsorption isotherm.

The above relations are based on the equation $\Delta \bar{F}_c^v = v_c \Delta \bar{p}_c^v$ where $\Delta \bar{F}_c^v$ is the volumetric mean change in Gibbs free energy (or thermodynamic potential) resulting from isothermal changes in reversible or elastic states of stress which do not change the volume materially. For many purposes this is practically identical with assuming that $\Delta \bar{F}_c^v$ is proportional to the change in "solid surface tension" or "spreading pressure".

It is important to note, however, that porous active adsorbents are not normally thermodynamically uniform bodies, and hence that $\delta \Delta F_c$ for the various solid elements of the assembly are not uniform throughout the body. Hence $\Delta \bar{F}_c^v$ and $\Delta \bar{p}_c^v$ may be made up from widely differing elements; thus while $\Delta \bar{F}_c^v$ and $\Delta \bar{p}_c^v$ may be strongly negative for a given adsorption reaction, in some regions $\delta \Delta F_c$ may be positive.

The changes in length of an assembly of solid elements of different sizes and shapes will be dependent not only on $\Delta \bar{p}_c^v$ but on the actual distribution of the stress intensities and their correlation with the structure and elastic properties of the elements of the assembly. It is mathematically quite possible for $\Delta \bar{p}_c^v$ to be zero while the whole porous assembly either increases or decreases its dimensions. The general problem of correlating the net strains of a complex assembly with the changes in the internal force structure will be very involved indeed. Anything like a complete mathematical description would involve a very complex tensor or similar analysis and would require a microscopically detailed knowledge of the whole adsorption reaction (12). However, by reference to ideal systems the influence of the various physical and statistical factors on adsorption extension behavior can be illustrated very simply. Thus consider a linear array of elements of an isotropic solid of lengths l_i where each of the equal elementary lengths may be subjected to particular stress intensity component changes, δp_{ci} , resolved along the l direction. We may write for the change in length of each element:

$$\delta l_i = A_i \cdot l_i \cdot \delta p_{ci} + B_i' \cdot l_i \cdot \delta p_{ci}^2 + C_i' \cdot l_i \cdot \delta p_{ci}^3 \dots$$

and if A_i , B_i , C_i are constant we can write:

$$[3] \quad \frac{\delta L}{L} = \frac{\sum \delta l_i}{\sum l_i} = A \cdot \bar{\delta p}_c^L + B' \cdot \bar{\delta p}_c^2 + C' \cdot \bar{\delta p}_c^3 \dots$$

where A , B' , C' etc. are constants characteristic of the solid material and $\bar{\delta p}_c^L \cdot \bar{\delta p}_c^2$, etc. are linear average quantities.²

²If A_i , B_i , C_i etc. and δp_{ci} are statistically independent, but not constant, Equation [3] becomes $\delta L/L = \bar{A}^L \cdot \bar{\delta p}_c^L$; if not statistically independent, Equation [3] becomes $\delta L/L = K \cdot \bar{A}^L \cdot \bar{\delta p}_c^L$ where $K \geq 1$. If A_i and δp_{ci} are both increasing functions of l , $K > 1$.

Equation [3] may be written:

$$\delta L/L = A \cdot \overline{\delta p_e^L} + B'' \cdot B' (\overline{\delta p_e^L})^2 + C'' \cdot C' (\overline{\delta p_e^L})^3 \dots$$

where B'' , C'' are dependent on the distribution of stress intensities and thus are not necessarily properties of the adsorbent alone. For solids which obey Hooke's Law approximately, B' , C' etc. are small compared with A . Hence the approximate equation,

$$[4] \quad \delta L/L = A(1 + B \overline{\delta p_e^L}) \overline{\delta p_e^L}$$

where A and B are regarded as properties of the adsorbent only, should be reasonably valid for small changes in length of such assemblies. Since thermodynamic considerations enable us to correlate volumetric mean stress intensities with adsorption data, the problem resolves itself into the correlation of the linear mean stress intensities with the corresponding volumetric means and hence with corresponding adsorption isotherms. This correlation should if at all possible lead to formulae containing only measurable variables and constants characteristic of the adsorbent and adsorbate, respectively. In systems where "the forces resulting from adsorption", "the solid areas" etc. may be regarded as statistical variables, we shall show that the linear mean stress intensity changes can be correlated with the adsorption data by means of an equation of the form

$$\overline{p_e^L} = [1 + \phi \cdot K_s \cdot K_p - \phi \cdot K_s \cdot K_p \cdot \alpha] P,$$

where $\overline{p_e^L}$ is the linear mean stress intensity change of the solid, K_s is a constant factor (≥ 1) dependent only upon the structure and elastic properties of the solid, and K_p is a factor dependent upon the nature and equilibrium pressure of the adsorbed fluid. When the effective surface force field is independent of the solid structure (i.e. of pore sizes, elastic properties etc.) K_p will be unity. Again, where $\Delta \overline{p_a^V}$ is a uniform change in hydrostatic pressure, K_p will be unity for the corresponding change in $\overline{p_e^L}$. However, in general K_p will be pressure dependent and may be greater or less than unity.

Accordingly, if the underlying assumptions are valid the adsorption extension of porous adsorbents should be given to a close approximation by

$$[5] \quad \begin{cases} \delta L/L = A(1 + B \overline{p_e^L}) \overline{p_e^L}, \\ \overline{p_e^L} = [1 + \phi \cdot K_s \cdot K_p - \phi \cdot K_s \cdot K_p \cdot \alpha] P. \end{cases}$$

We have shown previously (6) that Equation [5], with $K_p = 1$ and $B = 0$, can be used to describe a number of experimental results fairly well. Further, that in the case of activated carbon, A corresponds closely with the linear compressibility of graphite and that plausible model pore systems can be constructed which are consistent with the observed values of K_s , ϕ , and the mechanical properties of the carbon generally.³

In what follows we present some simple illustrations of the statistical relations upon which Equation [5] is based, together with some additional experimental data. The new data indicate that K_p cannot be taken as unity, and hence, that in the general case we cannot regard the adsorption potential of the capillary or surface regions as statistically independent of the solid structure.

³It will be noted that when $\delta L/L$ is not measured by $\overline{\delta p_e^V}$, i.e., where $K_s \cdot K_p \neq 1$ and $\overline{\delta p_e^V} \neq \overline{\delta p_e^L}$, it implies that there is a distortion in the sense that while the assembly as a whole may retain its shape, either particles of the assembly change their shape or their change in volume per unit volume is different, i.e., small particles swell more than large particles, or vice versa, and thus $\delta v_a \neq \delta v_e$.

THEORETICAL ILLUSTRATIONS

Let a porous solid of length L be divided into thin sections perpendicular to L and of thickness l_i . Let A_i be the area of the i th section, a_i the area of the fluid-filled holes, and c_i the area of the solid. Thus $A_i = a_i + c_i$. Let F_i be the total external force acting normally on A_i and in equilibrium with the forces F_{ai} and F_{ci} exerted by the fluid and solid respectively. Let $P_i = F_i/A_i$, $p_{ai} = F_{ai}/a_i$, and $p_{ci} = F_{ci}/c_i$ be the corresponding mean stress intensities parallel to L . Then, balancing forces,

$$A_i P_i = a_i \cdot p_{ai} + c_i \cdot p_{ci}$$

and summing over all sections,

$$\sum P_i \cdot A_i \cdot l_i = \sum p_{ai} \cdot a_i \cdot l_i + \sum p_{ci} \cdot c_i \cdot l_i.$$

Supposing P and A constant (independent of l) we have

$$vP = v_a \cdot \bar{p}_a^v + v_c \cdot \bar{p}_c^v$$

and

$$\bar{p}_c^v = P + (P - \bar{p}_a^v) \cdot v_a / v_c = [1 + \phi - \phi\alpha]P$$

where $\phi = v_a/v_c$, $v = v_a + v_c$, and $\bar{p}_a^v$ and $\bar{p}_c^v$ are volumetric average stress intensities of the fluid and solid respectively. Also $v_a = \bar{a}^L \cdot L$, where $\bar{a}^L$ is the linear average area of the holes averaged along the length L . Similarly $v_c = \bar{c}^L \cdot L$ and $A = \bar{a}^L + \bar{c}^L$. If A is large compared with the average area of single holes in the i th section, a_i and c_i will be virtually constant. Accordingly the area A is taken so as to be comparable with the average area of single holes in each section. Thus a_i and c_i may be regarded as functions of the stochastic variable l_i .

If the porous solid were immersed in a fluid of pressure P with which it did not interact at all, the stress intensity of the solid would be simply the hydrostatic pressure P . But if surface forces are involved we can describe the action of these forces in terms of the adsorbate pressure and write $p_{ci} = P + (P - p_{ai}) \cdot a_i/c_i$ where p_{ci} is the change in the solid stress intensity component parallel to L due to immersion in the fluid of hydrostatic pressure P . Hence,

$$\bar{p}_c^L = \frac{\sum p_{ci} \cdot l_i}{\sum l_i} = P + \frac{\sum (P - p_{ai}) \cdot a_i / c_i \cdot l_i}{\sum l_i}.$$

If p_{ai} and c_i are constant, then

$$\bar{p}_c^L = P + (P - \bar{p}_a^v) \cdot \bar{a}^L / \bar{c}^L = P + (P - \bar{p}_a^v) \cdot v_a / v_c = \bar{p}_c^v.$$

If c_i varies with l_i while p_{ai} is constant, we can write

$$[6] \quad \bar{p}_c^L = P + (P - \bar{p}_a^v) \cdot K_s \cdot \bar{a}^L / \bar{c}^L = [1 + \phi \cdot K_s - \phi \cdot K_s \cdot \alpha]P$$

where K_s is a numerical factor which is necessarily greater than unity and whose value depends only on the variation of the solid cross sectional area c_i with l_i . Thus K_s is a constant descriptive of the solid structure but independent of the nature and equilibrium pressure of the fluid.

Equation [6] may be written $\bar{p}_c^L = [c_1 - c_2\alpha]P$, where only α is dependent on P and

upon the nature of the fluid. In this case the adsorption extension would be given by an equation of the form⁴

$$\delta L/L = A(c_1 - c_2\alpha)P + AB(c_1 - c_2\alpha)^2 P^2.$$

By comparison with observed values of $\delta L/L$ for various observed values of α and P with different gases ($\delta L/L$, α , and P are capable of wide variation and are readily measured) the constants A , B , C_1 , and C_2 could be found. It will be noted that v_a must be known in order to obtain α from isotherm data. If the value of v_a used in calculating α were too large it would introduce a constant factor which would appear in the value of c_2 . This would be the case where v_a is based on "helium density" determinations of the active carbon, since even at room temperature helium is appreciably adsorbed (11). However, since the error in this case would be small, it would be possible to evaluate the constants approximately, and then from helium extension behavior using the approximate values of the other constants to estimate the helium adsorption, correct v_a , and redetermine the constants.

However, this procedure depends upon the assumption that c_1 and c_2 are independent of the nature of the fluid, i.e. that c_1 and c_2 are independent of α and of P . Thus it depends on the assumption that the adsorbate pressure is statistically independent of the solid structure.⁵

For the more general case, Equation [6] can be written:

$$\begin{aligned} [7] \quad \bar{p}_c^L &= P + (P - \bar{p}_a^V) \cdot K_p \cdot K_s \cdot \bar{a}^L / \bar{c}^L \\ &= [1 + \phi \cdot K_s \cdot K_p - \phi \cdot K_s \cdot K_p \cdot \alpha] P \end{aligned}$$

where K_p is dependent on the relation of p_{ai} to a_i or to c_i . While K_s is necessarily greater than unity, K_p may be greater or less than unity and may be negative as well as positive. Thus K_p will be greater than unity where the adsorbate pressures or volumetric mean potentials are larger in the regions where the fluid areas are larger and the solid areas, c_i , smaller. Conversely, K_p will be less than unity when the adsorbate pressures are larger in the smaller holes with the thicker walls. In this latter case we should expect K_p to vary with the equilibrium pressure of the adsorbate, when the adsorbate is not an ideal gas. Thus when the mean potential of the volume of the smaller holes is greater than that of the larger holes, the density and hence the pressure will increase with increasing equilibrium pressure relatively more rapidly in the smaller holes. This will continue until the adsorbate density in both the smaller and larger holes becomes high and the com-

⁴When $B \rightarrow 0$ and $\alpha \gg 1$, this is equivalent to stating that the elongation is proportional to the change in spreading pressure.

⁵It must be emphasized that when K_p differs from unity this is not to be regarded as arising primarily from lack of uniformity of adsorbate pressures but rather from a correlation between the lack of uniformity of adsorbate pressure and the lack of uniformity of structure. Such a correlation has important physical implications. If adsorbate pressures, no matter how highly variable, no matter how lacking in uniformity, are statistically independent of structure, K_p will be unity.

The influence of the various physical factors can be illustrated in terms of change in solid surface free energies. Thus instead of writing $p_{ci} = P + (P - p_{ai}) \cdot a_i / c_i$, we can write $p_{ci} = P + \gamma_i \lambda_i / c_i$, where γ_i is the change in solid surface tension perpendicular to c_i , λ_i the length of the common perimeter of solid and void areas etc. This treatment is somewhat more complex than presented above since we now have possible correlations between the three quantities, γ_i , λ_i , and c_i . It is felt that the placing of the emphasis on adsorbate stresses which can be correlated directly with adsorption data is perhaps a more direct approach than is involved in the change of surface tension treatment. Further, it is felt that in such fine grained porous bodies the field exerted by the solid is not confined to the solid surface but extends appreciably into the micropore volume. It will be noted that when K_p is assumed unity in the treatment above, it is equivalent to assuming that the change in solid surface tension is statistically independent of structure, i.e., of λ and c .

compressibility low. At this stage further increase in equilibrium pressure will increase the pressures more nearly equally in the larger and smaller pores. In this case K_p will be initially considerably less than unity but will increase with increasing equilibrium pressure and eventually approach unity. In the case of pores of molecular dimensions, efficient close packing may be hindered so that the density in larger pores can exceed that in the very small holes. In this case K_p might eventually exceed unity by small factors. It is important to note that when the quantity adsorbed remains constant as the equilibrium pressure is changed, it implies that the adsorbate is everywhere virtually incompressible and of practically the same density. Under these conditions changes in equilibrium pressures are accompanied by a nearly uniform change in hydrostatic pressure of the adsorbate. K_p is necessarily unity for uniform changes in adsorbate pressures.

Thus fairly reliable estimates of K_s can be obtained from observed contractions on desorption from saturation with water, when the desorption isotherm branch is nearly horizontal over the region concerned.

We have assumed that the elastic constants A , B etc. of the solid are the same everywhere regardless of variations in thickness of the material. If these constants are not independent of structure, the effect of such correlations on the length changes will be to introduce a factor which is somewhat similar to K_s . Thus values of K_s estimated from adsorption-extension where K_p can be taken as unity will be a product of both of these factors.

EXPERIMENTAL RESULTS

Adsorption-extension data have been obtained for an activated carbon rod (Rod 3) when subjected to hydrostatic pressures of helium, hydrogen, nitrogen, argon, and krypton. The data appear in Figs. 1 and 2. Since the adsorption extension of Rod 3 in nitrogen is almost the same as that reported previously for Rod 1 (a similar rod from the same batch) it may be supposed that the adsorption-extensions of Rods 1 and 3 with other gases will be essentially similar. Accordingly, the adsorption-extension of Rod 1 in water vapor and liquid water is plotted together with the new data. (Because of the pressure scale used the adsorption-extension in water vapor appears as a vertical rise. The remainder of the H_2O curve shows the contraction as the liquid water pressure increases.)

In Fig. 1 the solid lines, with the exception of the H_2O extension, were calculated from

$$\delta L/L = -0.8 \times 10^{-7} (1 - 2/3 \cdot 10^{-5} \cdot \bar{p}_c^L) \bar{p}_c^L$$

where $\bar{p}_c^L = [4.5 - 3.5\alpha]P$. Thus the product $\phi \cdot K_s \cdot K_p$ is assumed equal to 3.5 and independent of pressure and the nature of the gas. This formula yields an extension for H_2O at saturation which is much too low. The calculated curve for H_2O is that reported previously and is based on $\delta L/L = -1.1 \times 10^{-7} \cdot \bar{p}_c^L$ where $\bar{p}_c^L = [5.8 - 4.8\alpha]P \rightarrow -4.8\alpha P$ (α is very large, $\approx 40,000$).

An examination of the data shows that Equation [6] cannot be made to fit them.

The data for krypton especially indicate a K_p which is an increasing function of P . While, in the case of these particular carbon rods, the water desorption isotherms near saturation are not horizontal, the variation in adsorbate density is comparatively small, and accordingly the expansion behavior of the rods near saturation should correspond

FIG. 1. Elongation as a function of fluid pressure, 25°C. Solid lines (except H₂O) calculated from $\delta L/L = -0.8 \times 10^{-7} (1 - 2/3 \cdot 10^{-5} \cdot \bar{p}_c^L) \bar{p}_c^L$, $\bar{p}_c^L = (4.5 - 3.5\alpha)P$. Observed points, Rod 3: O, ●, krypton (adsorption, desorption); X, argon; □, nitrogen; △, hydrogen; Φ, helium; Rod 1: ▽, H₂O.

FIG. 2. Elongation as a function of fluid pressure, 25°C. Solid lines calculated from $\delta L/L = -0.88 \times 10^{-7} (1 - 1/2 \cdot 10^{-5} \cdot \bar{p}_c^L) \bar{p}_c^L$, $\bar{p}_c^L = [1 + 5K_p - 5K_p\alpha]P$. Observed points, Rod 3: O, ●, krypton (adsorption, desorption); X, argon; □, nitrogen; △, hydrogen; Φ, helium; Rod 1: ▽, H₂O.

fairly closely to Equation [6] with $K_p = 1$ and thus afford a measure of K_s . It was found that both the water and helium adsorption-extension could be fitted very closely by means of the equation

$$\delta L/L = -0.88 \times 10^{-7} (1 - 1/2 \cdot 10^{-5} \cdot \bar{p}_c^L) \bar{p}_c^L$$

where $\bar{p}_c^L = [6 - 5\alpha]P$. This is equivalent to putting $K_p = 1$ and $\phi \cdot K_s = 5$.

As we have shown, selective adsorption yields a K_p factor greater or less than unity according as the adsorption is relatively greater in the larger or smaller pores. For non-condensable gases, the former case leads to a K_p which is a decreasing function of P , the latter to an increasing function of P .

In carbons with mean pore diameters considerably greater than the diameters of the adsorbate molecules, one might expect selective adsorption of large gas molecules in the smaller pores. In such cases the adsorption should be fairly large, i.e., α should be

fairly large. If α is very large the fluid in both large and small pores should reach high densities at relatively low equilibrium pressures and thus K_p tend toward unity at relatively low equilibrium pressures. Evidently the value of α itself should afford some measure of these selective trends. Accordingly, we put $K_p = 1 - D\alpha^{\frac{1}{2}}$ and found suitable values for D by trial. While this formula has no theoretical basis and cannot be correct for large values of α , all of the data⁶ can be described practically within the experimental error by its use. The solid lines in Fig. 2 are plotted from

$$\delta L/L = -0.88 \times 10^{-7} (1 - 1/2 \cdot 10^{-5} \cdot \bar{p}_c^L) \bar{p}_c^L$$

and

$$\bar{p}_c^L = [1 + \phi \cdot K_s \cdot K_p - \phi \cdot K_s \cdot K_p \cdot \alpha] P$$

where $\phi = 1.304$; $K_s = 3.834$; $K_p = 1 - D\alpha^{\frac{1}{2}}$; and $D = 0$ for H_2O and helium, 0.116 for krypton, 0.168 for A and N_2 , and 0.172 for H_2 .

It may be pointed out that both the compressibility and the variation of compressibility with pressure in the formula correspond quite closely to those of graphite under a pressure of about 10^4 lb. per sq. in. (4). Further, that the departure of K_p from unity is greatest in the case of krypton as might be expected. Thus all of the data are described practically quantitatively using only one arbitrary constant whose values vary in a physically plausible manner. It will be noted that the length changes vary from -5 (-20 for the liquid water from saturation to 2000 lb./in.) to $+360$ with a probable error of measurement of less than ± 2 , while the variations in values of P and α in the equation cover ranges from 0 to 2000 lb./in. and 0 to 40,000 respectively.

APPENDIX I—EXPERIMENTAL DETAILS

1. Materials

Activated Carbon Rods

Except where noted, all experiments were carried out with carbon rod No. 3. This carbon rod is essentially similar to Rod 1 whose properties have been reported previously (6). Like Rod 1 it was selected from a batch of long, straight zinc chloride activated rods especially prepared for us by courtesy of the National Carbon Company.

Rod 3 is 109.7 mm. in length and has a mean diameter of 1.79 mm. Thus the geometric or total volume is 0.276 cc. The carbon volume as measured by helium displacement and corrected for helium adsorption is 0.434 cc. per cc. and the void volume 0.566 cc. per cc. Assuming the mercury density to be the same as Rod 1, this yields a carbon density of 1.75. (If not corrected for helium adsorption, the helium density is 1.95.)

In selecting Rod 3 from the batch some care was taken to obtain a rod giving a similar nitrogen extension to Rod 1 and for which equilibrium was rapidly attained on either increase or decrease of the equilibrium pressure. In the case of one rod, it was noticed that even 1 or 2 hours after expansion from higher pressures there was a small slow evolution of gas. When this rod was heated for 6 to 8 hours at $600^\circ C$. the equilibrium was obtained quite rapidly. Rod 3 was heated during 4 to 5 hours at $500^\circ C$. alternately in a high vacuum and in a pure dry helium stream. On cooling to room temperature in helium it was exposed to saturated water vapor and finally to air. Helium extension measurements were made both before and after exposure to hydrogen and krypton. A few nitrogen-extension and adsorption points were taken at the end of the experiments. These points fell on the curves obtained at the beginning of the series. Accordingly, it

⁶Excepting water vapor at low relative pressures (cf. Appendix II).

seems unlikely that changes in surface complexes or chemisorbed material can have influenced our results appreciably.

Gases

The helium, hydrogen, nitrogen, argon, and krypton were supplied by the Dominion Oxygen Company, and were specified as not less than 99.99% pure. The krypton was spectroscopically pure. Except in the case of krypton the gases were passed through a bed of activated charcoal suitably cooled (liquid nitrogen in the case of He and H₂, solid CO₂ in the case of N₂ and A). The krypton was used as supplied.

2. Experimental Procedures and Methods

The procedures used throughout were essentially similar to those reported previously (6). The main modifications were as follows: The whole apparatus was enclosed in a thermostatic air bath, the temperature of which was kept constant at 24.8° C. within $\pm 0.1^\circ$ C. The room containing the apparatus was also thermostatically controlled and maintained at 27° C. to usually within $\pm 2^\circ$ C.

Pressures in the range 14 to 500 p.s.i. were measured by means of a piston gauge. Higher pressures were measured by means of a Bourdon-type gauge calibrated by the Metrology Section of the National Research Council. Pressures from 1 atm. to 1 cm. Hg were measured by means of a mercury manometer constructed of precision bore 20 mm. glass tubing together with a reasonably high grade cathetometer. Mercury pressure readings were corrected for temperature, the value of g etc. Manometric pressure readings of the order of $\frac{1}{2}$ atm. were reproducible within considerably better than 0.01%. With the piston gauge, differences of the order of one part in 10^4 could be readily detected (the accuracy of the piston gauge was limited by the accuracy of determining the barometric pressure, oil "head" of leads etc.).⁷ These pressures are considered to be correct within $\pm 0.2\%$ or better. The Bourdon gauge dial readings are considered correct within about $\pm \frac{1}{2}$ a scale division, i.e., within ± 5 p.s.i. or $\pm 1\%$ in the neighborhood of 500 p.s.i., and within $\pm 0.3\%$ at 1500 p.s.i. Thus in the range of pressure 600–1200 p.s.i. the data are considered to be somewhat less reliable than in either the higher or lower (piston gauge) range. Length changes were measured essentially as described previously. In place of the travelling microscope used previously, two rigidly fixed parallel microscopes with micrometer eyepieces were used. The scale was 10 times larger than that used previously and reproducibility of individual length change measurements was usually within $\pm 2 \times 10^{-4}$ mm. The larger values of $\delta L/L$ reported are considered to be correct within $\pm 1\%$, the maximum helium contraction within $\pm 30\%$.

Measurements of ρ_a/ρ at various pressures were based upon the following equation:

$$v_x = v - v_c + v_a(a - 1)$$

where v is the volume of a container and v_x is the apparent volume of the container. v_c is the carbon volume, v_a the void volume, and $a = \rho_a/\rho$ = the mean density of gas within v_a divided by ρ , the density of the gas in the tube. Two different procedures were used. At low pressures ($5\text{--}10^{-2}$ mm.) gas from a second known volume (about equal to v_x) was expanded into an evacuated charcoal filled container, the empty volume of which was only a little larger than $v_a + v_c$. This procedure is not capable of great accuracy

⁷There is also an appreciable correction due to the different "capillary depressions" of the mercury in the U-tube in contact with oil on one side and gas on the other.

because of the difficulty of measuring low gas pressures of the small volumes (0.5–10.0 cc.). However, when a is appreciably greater than unity, approximate limiting values of a can be obtained.⁸ At high pressures, gas was expanded out from the high pressure capillary of volume v_x into a large volume (about $10^2 \times v_x$) where the pressure could be accurately measured. If v_0 represents the volume after expansion (corrected for the change in a , i.e., if v_L = the large volume, $v_0 = v_L + v - v_c + v_a(a' - 1)$, where a' is the value of a at the low pressure after expansion). If $(p_0 v_0)'$ is the pv value after expansion from the tube containing the charcoal at the high pressure P_1 and $(p_0 v_0)$ is the pv value after expansion from the empty tube at P_1 , then a is given by:

$$a = \frac{v_a + v_c}{v_a} + \frac{v}{v_a} \left\{ \frac{(p_0 v_0)'(P_1 - (p_0 v_0)/P_1)}{(p_0 v_0)/P_1} \right\}.$$

Thus by plotting $(p_0 v_0)'/P$ and $(p_0 v_0)/P$ against P we can obtain a or ρ_a/ρ without having to correct for deviations from the gas laws except at the low pressures p_0 , where the corrections are small and well known. v_c was first determined by helium displacement at higher pressures. Fig. 3 shows the apparent volumes of the high pressure capillary and leads as obtained from helium expansion data with and without the carbon rod.⁹ The volumes are calculated using Schneider's virial coefficient for helium (10). Assuming no adsorption at 1700 lb. v_c was taken as 0.105 and $v_a = 0.276 - 0.105 = 0.171$. Then a or ρ_a/ρ was plotted as a function of P and $\int_0^P \rho_a/\rho \cdot dP = \alpha P$ calculated for all of the gases.

Since Halsey (11) has shown that the energy of interaction of helium and activated carbon is quite considerable it is to be expected that helium adsorption at 1700 p.s.i. at room temperature would be appreciable. That the helium is adsorbed is suggested by the decreasing values of v_c . Helium adsorption is also indicated by the low compressibility of the carbon in helium (Figs. 1 and 2).

In order to estimate helium adsorption, we have assumed that the ratio of the surface potentials for krypton and helium for our carbon rod is similar to that reported by Steele and Halsey (11). Taking 4000 cal. as the mean potential per mole for krypton together with Van der Waal's constants for krypton, we have calculated, using (a) a Leonard-Jones 6–12 potential and (b) a square potential, the surface area and mean distance between surfaces that are necessary to be consistent with the known micropore volume and krypton adsorption data for our carbon using both a platelet and cubic model pore system. Surface areas of the order of 500 sq. m./g. with distance apart 10 Å for the platelet model and about 700 sq. m./g. and 20 Å side length for the cubic model are thus obtained. For the same models and a surface potential for helium of 700 cal. per mole of gas adsorbed the calculated value of ρ_a/ρ for helium at 1700 p.s.i. varies from about 1.09 to 1.15 depending on the model and form of potential function. Accordingly, the value of ρ_a/ρ for helium at 1700 p.s.i. was taken as 1.1 and all the values of ρ_a/ρ for the other gases multiplied by 1.1. In Figs. 4 and 5 values of ρ_a/ρ (after multiplying by 1.1) are plotted as functions of P .

⁸In general, the rise in " a " from equilibrium pressure of 1 mm. to 10^{-2} mm. is comparatively small. Accordingly the Jura type error in the areas $\int_0^P v dP$ or $\int_0^P \rho_a/\rho \cdot dP$ are not significant unless " a " rises to quite unreasonable values at pressures below 10^{-2} mm.

⁹The discontinuity between 600 and 800 p.s.i. is considered to be due to discrepancy in gauge calibrations. The Bourdon gauge is considered to give pressure readings which are too low at the lower end of the scale. The graph indicates some distortion of v which was allowed for in calculation of a .

FIG. 3. Apparent volume of capillary as a function of helium pressure, 25°C. $\circ$, empty volumes; $\square$, with carbon Rod 3 present.

FIG. 4. Ratios of densities of gas within carbon void volume to corresponding equilibrium gas densities. $\square$, helium; $\triangle$, hydrogen; $\circ$, nitrogen; $\times$, argon; $+$, krypton.

APPENDIX II

While mathematically K_p can be either much greater than unity or much less than unity, even negative, physical considerations suggest that at higher fluid adsorbate densities K_p should approach unity, both because, in general, reactions of fluids with highly localized fields tend toward more uniform residual fields as well as because of the relative incompressibilities of adsorbates approaching liquid densities.

As reported previously, at low relative pressures of H_2O vapor, these rods show contractions in length and radius as the equilibrium pressure increases from zero. Along

FIG. 5. ρ_a/ρ , α , and $\bar{p}_a^v$ as functions of krypton equilibrium pressure, 25° C. Left-hand ordinate, ρ_a/ρ and $1/P \int_0^P \rho_a/\rho \cdot dP$ or α . Right-hand ordinate, p.s.i. $\times 10^3$. Abscissa, equilibrium pressure p.s.i. $\times 10^2$. Solid line, curve drawn through observed values of ρ_a/ρ . Dotted line, $1/P \times$ area under solid line, i.e. α or $1/P \int_0^P \rho_a/\rho \cdot dP$. Broken line, volumetric mean pressure of adsorbed krypton.

these paths $\Delta \bar{p}_a^v$ must be positive if no thermodynamically irreversible processes occur. (The contractions we are referring to here must not be confused with those very marked contractions observed on H_2O desorption by McIntosh and others which are due to hysteresis effects. Negative values of $\Delta \bar{p}_a^v$ are to be expected on decreasing equilibrium pressure paths in cases of marked hysteresis.) While it might appear at first sight that $\Delta \bar{p}_e^v$ cannot be negative while $\Delta \bar{p}_e^L$ is strongly positive, it is apparent that if the sum $\sum (P - p_{ai}) \cdot a_i / c_i \cdot l_i$ includes both positive and negative values of $P - p_{ai}$, when positive $P - p_{ai}$ is associated with very small c_i , the positive values may be so much more strongly weighted that the sum is positive while the corresponding sum $\sum (P - p_{ai}) \cdot a_i \cdot l_i$ is negative.¹⁰

At higher relative pressures and higher adsorbate densities, we might expect the elastic behavior of the assembly to depend largely on its gross mechanical structure, i.e., on its pore sizes and shapes as measured by K_s , K_p being nearly unity.

Although by inverse coupling a mechanical system can be constructed which will decrease in over-all dimensions when each individual member of the system increases its length, such an arrangement seems quite impossible in the case of a more or less random assembly of interconnected solid particles. Accordingly if contractions occur along thermodynamically reversible paths of increasing equilibrium pressure, they must be associated with positive $\delta \Delta F_e$ in some regions of the solid.

At low surface coverages the elastic behavior of such assemblies should depend relatively more on the detailed structure of the surface fields and relatively less on the over-all mechanical or pore structure. In the case of surface fields whose equipotential contours have sharp maxima and minima, where the maxima are separated by distances of molecular dimensions, adsorption may reduce the field energy in the region of the maxima while increasing the energy in the region of the minima. This could result from such "co-operative effects" as attractive forces of adsorbate molecules or in the case of rod-like molecules, from "bridging" effects, where the distances between sites (maxima) are somewhat greater than the bond distances between the atoms or groups held by the

¹⁰Such considerations cannot lead to large positive values of $\Delta \bar{p}_e^L$ for small constant P . When P is not constant from section to section $\Delta \bar{p}_e^L$ can be large and positive for small $\bar{P}^L$ while $\Delta \bar{p}_e^v$ is negative.

sites. In either of these two cases, if the supporting solid is relatively weak in the regions of the minima, the resulting contractions in these regions can easily outweigh the expansions of the regions of the maxima and K_p become negative. These two mechanisms can be partially distinguished. At coverages approaching zero the attractive co-operative effects must vanish, and hence K_p must be positive at very low pressures and become negative as the co-operative effects come into play. On the other hand, bridging effects do not necessarily vanish as the adsorbate density approaches zero. Thus where K_p is negative from zero equilibrium pressures it may be taken as evidence of bridging effects. As we have seen, in both cases K_p should become positive at higher adsorbate densities.

While in a previous paper it was suggested that the initial contraction observed with H_2O vapor may have been due to irreversible condensation phenomena, this contraction may well have been due to one of the above mechanisms. It seems improbable that the small contractions observed by McIntosh (7) with butane, ethyl chloride, and dimethyl ether at low relative pressures can all have been due to irreversible condensations.

ACKNOWLEDGMENT

The author is indebted to Dr. J. A. Morrison for valuable suggestions and criticisms of a draft form of this paper.

The author is also indebted to Dr. R. D. Heyding and to Dr. P. H. Stirling for their help in constructing the apparatus.

SYNTHESIS OF 3,5-DI-*O*-METHYL-D-GLUCOSE¹

C. T. BISHOP

ABSTRACT

3,5-Di-*O*-methyl-D-glucose has been synthesized by methylation of 1,2-*O*-isopropylidene-6-*O*-trityl-D-glucofuranose and removal of the blocking groups by acid hydrolysis. The di-*O*-methyl glucose furnished a crystalline osazone without loss of a methoxyl group and yielded a monobasic and dibasic acid when oxidized by bromine and nitric acid respectively. Both acids formed gamma lactones and crystalline amides by which the parent compound is characterized. The foregoing reactions proved the structure of 3,5-di-*O*-methyl-D-glucose predicted by its method of synthesis.

INTRODUCTION

In a review of the methyl ethers of glucose published in 1950, Bourne and Peat (1) reported that 3,5-di-*O*-methyl-D-glucose was the only dimethyl ether of the cyclic forms of D-glucose that had not been prepared. The present publication describes a short synthesis of 3,5-di-*O*-methyl-D-glucose and proof of its structure.

While the work reported here was in progress, Huffman *et al.* (3) reported a synthesis of 3,5-di-*O*-methyl-D-glucose using the same blocking groups but a slightly different sequence of reactions. These authors characterized the 3,5-di-*O*-methyl-D-glucose as the crystalline 3,5-di-*O*-methyl-D-gluconamide and the structure of the parent sugar was proved by oxidation with periodate to yield the known 2,4-di-*O*-methyl-D-arabinose. In the present report the sequence of reactions in the synthesis furnished a new compound of D-glucose, 1,2-*O*-isopropylidene-6-*O*-trityl-D-glucofuranose, and 3,5-di-*O*-methyl-D-glucose was further characterized as the new crystalline diamide of 3,5-di-*O*-methyl-D-glucaric acid. The physical constants previously reported (3) for the sirupy 3,5-di-*O*-methyl-D-glucose and the crystalline 3,5-di-*O*-methyl-D-gluconamide were confirmed in the present work and an independent proof of structure of the 3,5-di-*O*-methyl-D-glucose was obtained. The work reported here is therefore complementary to that of Huffman *et al.* (3) and parallels it only in the preparation of 3,5-di-*O*-methyl-D-gluconamide.

The synthesis was achieved by the following series of reactions: D-glucose $\rightarrow$ 1,2;5,6-di-*O*-isopropylidene-D-glucofuranose $\rightarrow$ 1,2-*O*-isopropylidene-D-glucofuranose $\rightarrow$ 1,2-*O*-isopropylidene-6-*O*-trityl-D-glucofuranose $\rightarrow$ 1,2-*O*-isopropylidene-3,5-di-*O*-methyl-6-*O*-trityl-D-glucose $\rightarrow$ 3,5-di-*O*-methyl-D-glucose. The structure of the 3,5-di-*O*-methyl-D-glucose was proved by the following facts: the compound formed an osazone without loss of a methoxyl group showing that a free hydroxyl group was present at C₂. Oxidation of the di-*O*-methyl glucose with bromine afforded a gamma lactone, recognized by its slow rate of hydrolysis, which proved that a free hydroxyl group was located at C₄. Nitric acid oxidation of the di-*O*-methyl glucose yielded a glucaric acid without loss of any methoxyl group, thus showing that hydroxyl groups were located at C₁ and at C₆. It was clear, therefore, from the above evidence that the two methyl groups in the di-*O*-methyl glucose occupied positions 3 and 5, a result to be expected from the mode of synthesis.

EXPERIMENTAL

Paper strip chromatograms were run in butanol: ethanol: water—5:1:4, and sugars were located on the paper by aniline oxalate spray reagent (2). Evaporations were carried out at 40° C. or less and all melting points are corrected. Specific rotations are equilibrium values unless otherwise stated.

1,2-O-Isopropylidene-6-O-trityl-D-glucofuranose (I)

To 1,2-*O*-isopropylidene-D-glucofuranose (m.p. 158–159.5° C., $[\alpha]_D^{24} = -12^\circ$, 12.8 g.) in dry pyridine (120 ml.) was added triphenylchloromethane (15.66 g.) and the solution was allowed to stand at room temperature for 24 hours. Water was then added until a permanent turbidity formed and after 2 hours the mixture was poured into a large excess (1 liter) of ice water. The product separated as a white gum which was washed three times with water by decantation and was then dissolved in chloroform. To remove pyridine the chloroform solution was washed with cold 3% aqueous acetic acid till the washings were acid (test paper) and then with water till the washings were neutral. The washed chloroform solution was dried over anhydrous sodium sulphate and then evaporated to yield 1,2-*O*-isopropylidene-6-*O*-trityl-D-glucofuranose (I) as a puffy, aerated glass (25.4 g., 98%) having $[\alpha]_D^{24} = -21^\circ \pm 1^\circ$ ($c = 2.6\%$ in methanol), $= -3^\circ \pm 2^\circ$ ($c = 2.1\%$ in chloroform). Analysis: Calc. for $C_{28}H_{30}O_6$: C, 72.7%; H, 6.54%; trityl, 52.6%. Found: C, 72.56%; H, 6.27%; trityl, 52.4%.

1,2-O-Isopropylidene-3,5-di-O-methyl-6-O-trityl-D-glucofuranose (II)

(a) Compound I (25 g.) was refluxed in methyl iodide (250 ml.) and silver oxide (25 g.) was added in eight equal portions at half-hour intervals (6). The mixture was refluxed overnight and filtered, and the silver salts were washed with chloroform. The partially methylated product was recovered by evaporation of the combined filtrate and washings. A total of four such methylations yielded a product (22 g.) having a constant methoxyl content of 10% as compared to the theoretical value of 12.65% for II.

(b) In a separate experiment a portion (200 mg.) of the product methylated by Purdie's reagents was hydrolyzed as described below for the preparation of III. Examination of the hydrolyzate by paper strip chromatography showed that it contained a di-*O*-methyl and a mono-*O*-methyl ether of glucose. The mono-*O*-methyl derivative crystallized from a methanol solution of the mixture and its physical constants, m.p. 162–163.5° C. and $[\alpha]_D^{25} = +60^\circ \pm 2^\circ$ ($c = 2\%$ in water), were in good agreement with those reported (4) for 3-*O*-methyl-D-glucose. No other mono-*O*-methyl isomer could be detected and the di-*O*-methyl-D-glucose was chromatographically identical with 3,5-di-*O*-methyl-D-glucose. It was therefore apparent that the hydroxyl group at C₅ was resistant to methylation, an observation also made by Huffman *et al.* (3).

To a solution of the partially methylated product (21.8 g.) in tetrahydrofuran (170 ml.), sodium hydroxide pellets (23 g.) were added. The mixture was stirred vigorously during the dropwise addition of dimethyl sulphate (50 ml.). Stirring was continued for a further 20 hours after which sufficient water was added to dissolve all solids and the solution was warmed at 55° C. for 1½ hours. Tetrahydrofuran was evaporated and the residual aqueous mixture was extracted five times with one-half its volume of fresh portions of chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated to yield 21.0 g. (78%) of 1,2-*O*-isopropylidene-3,5-di-*O*-methyl-6-*O*-trityl-D-glucofuranose. Samples for analyses were dried to constant weight at 60° C. and 0.02 mm. over magnesium perchlorate. The product, thus dried, showed no hydroxyl absorption band at

3400–3500 cm^{-1} in its infrared spectrum and had $[\alpha]_D^{27} = -30^\circ \pm 2^\circ$ ($c = 1.4\%$ in ethanol). Analysis: Calc. for $\text{C}_{30}\text{H}_{34}\text{O}_6$: C, 73.4%; H, 6.98%; OCH_3 , 12.65%; trityl, 49.6%. Found: C, 71.79%; H, 6.66%; OCH_3 , 12.5%; trityl, 49.1%.

3,5-Di-O-methyl-D-glucose (III)

Compound II (21 g.) was dissolved in ethanol (140 ml.) and 12% aqueous hydrochloric acid was added until a slight permanent turbidity developed (60 ml.). This solution was then refluxed on a boiling water bath for 5 hours. Ethanol was removed by evaporation and the triphenylcarbinol which precipitated was filtered and washed thoroughly with hot water. The clear aqueous solution was neutralized by Amberlite IR-4B resin and evaporated to yield a golden yellow sirup, 7.2 g., 77% yield or 59% based on 1,2-*O*-isopropylidene-D-glucofuranose. Examination of this product by paper chromatography showed that it contained traces of a mono-*O*-methyl-D-glucose. A portion (5.5 g.) of the sirup was therefore chromatographed on Celite (5), this procedure yielding chromatographically pure 3,5-di-*O*-methyl-D-glucose (III) as a straw colored sirup. A sample was distilled for analysis, b.p. (bath temperature) 165–170° C. at 0.04 mm., and showed $[\alpha]_D^{26} = -20^\circ \pm 2^\circ$ ($c = 1.1\%$ in water).

Analysis: Calc. for $\text{C}_8\text{H}_{16}\text{O}_6$: C, 46.15%; H, 7.75%; OCH_3 , 29.8%. Found: C, 46.96%; H, 7.99%; OCH_3 , 29.9%.

Osazone Formation

When the 3,5-di-*O*-methyl-D-glucose (63 mg.) was heated with phenyl hydrazine hydrochloride (400 mg.) and sodium acetate (400 mg.) in water (3 ml.) in a boiling water bath for 2 hours, the corresponding osazone was obtained, m.p. 64–65° decomp., $[\alpha]_D^{25} = -83^\circ$ in ethanol ($c = 1.5\%$), after recrystallization from aqueous ethanol.

Analysis: Calc. for $\text{C}_{20}\text{H}_{26}\text{O}_4\text{N}_4$: C, 62.16%; H, 6.78%; N, 14.50%; OCH_3 , 16.06%. Found: C, 62.15%; H, 6.55%; N, 13.90%; OCH_3 , 16.0%.

The 3,5-di-*O*-methyl-D-glucose phenylosazone was extremely unstable, the carbon content decreasing to values of 61.07%, 60.96% after the sample had been exposed to air for successive 2 hour periods.

3,5-Di-O-methyl-D-glucono- γ -lactone

A solution of 3,5-di-*O*-methyl-D-glucose (100 mg.) in water (2 ml.) was oxidized by bromine (0.3 ml.) in the presence of barium carbonate (30 mg.). The oxidation was allowed to proceed in the dark at room temperature for 24 hours. The mixture was acidified with *N* hydrochloric acid and bromine was removed by aeration. The clear, colorless, aqueous solution was then extracted continuously with chloroform for 36 hours. Evaporation of the chloroform extract yielded sirupy 3,5-di-*O*-methyl-D-gluconic acid which was heated at 95° C. and 0.02 mm. for 2 hours to yield 3,5-di-*O*-methyl-D-glucono- γ -lactone (51 mg.).

Analysis: Calc. for $\text{C}_8\text{H}_{14}\text{O}_6$: OCH_3 , 30.1%. Found: OCH_3 , 29.2%. $[\alpha]_D^{25} = +14^\circ \rightarrow +6^\circ$ in four days ($c = 1\%$).

3,5-Di-O-methyl-D-gluconamide

3,5-Di-*O*-methyl-D-gluconic acid was converted to its methyl ester by refluxing with 2% methanolic hydrogen chloride for 18 hours. Reaction of the ester with methanolic ammonia at 5° C. and evaporation of the solvent yielded 3,5-di-*O*-methyl-D-gluconamide, m.p. 148–150° C., $[\alpha]_D^{26} = +23^\circ \pm 2^\circ$ ($c = 1.5\%$ in methanol); reported (3) m.p. 150–152° C., $[\alpha]_D^{23} = +29^\circ$ ($c = 0.7\%$ in methanol).

3,5-Di-O-methyl-D-glucosaccharo-1,4-lactone

A sample (53 mg.) of 3,5-di-O-methyl-D-glucose was heated for 1 hour in nitric acid (sp. gr. 1.2, 2.5 ml.) on a boiling water bath. The solution was then evaporated under diminished pressure at 35° C. and nitric acid was removed from the residue by repeated addition and evaporation of water. The residual yellow sirup was then dried to constant weight (46 mg.) over solid potassium hydroxide at 0.02 mm. This product gave the correct analysis for a monolactone of a di-O-methyl glucosaccharic acid and showed the slow hydrolysis in water, measured by change in rotation, characteristic of furanolactones; $[\alpha]_D^{25} = +5^\circ \rightarrow -3^\circ$ in four days ($c = 2.2\%$ in water).

Analysis: Calc. for $C_8H_{12}O_7$ (monolactone): OCH_3 , 28.2%. Calc. for $C_8H_{10}O_6$ (dilactone): OCH_3 , 30.85%. Found: OCH_3 , 28.5%.

3,5-Di-O-methyl-D-glucosaccharodiamide

3,5-Di-O-methyl-D-glucosaccharo-1,4-lactone (150 mg.) was shaken with an excess of ethereal diazomethane until gas evolution ceased. The ether and excess diazomethane were removed by evaporation under diminished pressure at 30° C. and the residue was taken up in methanolic ammonia (6 ml.). After being stored at 5° C. for 2 days the solution was evaporated slowly in a partially evacuated desiccator to yield crystalline 3,5-di-O-methyl-D-glucosaccharodiamide (100 mg.), which was recrystallized from ethanol to a constant m.p. of 164–165° C.; $[\alpha]_D^{25} = +19 \pm 2^\circ$ ($c = 1.7\%$ in methanol). This compound gave a positive Weerman test (7) for α -hydroxy amides.

Analysis: Calc. for $C_8H_{16}O_6N_2$: C, 40.67%; H, 6.83%; N, 11.86%; OCH_3 , 26.3%. Found: C, 39.92%; H, 6.57%; N, 11.38%; OCH_3 , 25.6%.

ACKNOWLEDGMENTS

The author would like to thank F. Rollin for carrying out the infrared analyses reported here.

THE ANALYSIS OF NUCLEAR MAGNETIC RESONANCE SPECTRA

I. SYSTEMS OF TWO AND THREE NUCLEI¹

H. J. BERNSTEIN, J. A. POPLE,² AND W. G. SCHNEIDER

ABSTRACT

This paper is concerned with the general problem of the interpretation and analysis of nuclear magnetic resonance spectra of systems in which chemical shift and spin-coupling constants are of the same order of magnitude. Only nuclei of spin $1/2$ are considered. Detailed methods are developed for:

- (a) Two chemically non-equivalent nuclei of the same species (written AB),
- (b) Three nuclei of the same species, two of which are equivalent (written AB_2),
- (c) Three nuclei (ABX), two of which are of the same species (AB) and the third (X) is either a different species or has a resonance signal well separated from A and B .

Proton resonance spectra of S-guaiazulene, 2,6-lutidine, and 2,3-lutidine are reported and used as examples of the methods of analysis.

1. INTRODUCTION

The broad features of the nuclear magnetic resonance spectra of fluids can be explained in terms of transitions of non-interacting nuclei between the Zeeman levels split by an external magnetic field. Nuclei of the same species which are chemically non-equivalent may resonate at different applied fields on account of different electronic screening effects. This type of displacement is usually called a chemical shift. Under higher resolution, the absorption bands are observed to possess further fine structure which can be attributed to the indirect interaction of nuclear moments via the electrons (4, 6, 9, 10). If there are nuclei of two different species present, or if the chemical shift between non-equivalent nuclei of the same species is large, this fine structure is often of a fairly simple multiplet form and can be interpreted in terms of rules based on a simple interaction Hamiltonian and first-order perturbation theory (5). If several coupling constants are involved, however, the multiplet structure becomes more complicated. Hahn and Maxwell (6) have analyzed spectra for several types of groupings of nuclei and McConnell, McLean, and Reilly (8) have given a general method of dealing with spin multiplets and have discussed 1,1-difluoroethylene as an example.

The resonance spectra become more complex again in substances where there are non-equivalent nuclei of the same species whose relative chemical shifts are of the same order of magnitude as the splittings due to spin coupling. If the chemical shifts are still moderately large, higher order perturbation methods can be used with some effect (1, 2) but, eventually, individual multiplets become merged in a general mixed group of lines which may have few features of regularity. One is then faced with the problem of interpreting such a band system, assigning each line to a definite transition, and finally extracting numerical values for the chemical shift and spin-coupling constants. The present series of papers will be concerned with the details of such analyses. Spectra will be classified according to the number and arrangement of nuclei in various nuclear groupings. A complete understanding and fingerprinting of characteristic bands of simple groups is an essential step towards the interpretation of the spectra of more complex molecules.

Issued as N.R.C. No. 4166.

²Visiting Research Associate, Summer, 1956. Permanent address: Department of Theoretical Chemistry, University of Cambridge, England.

Some theoretical work on spectra of this type has already been published by Hahn and Maxwell (7) and by Bannerjee, Das, and Saha (3). We shall consider a wider range of groupings, illustrating some cases by reporting measurements on appropriate examples and giving detailed assignments and analyses. To make the presentation complete we shall give a review of the basic quantum-mechanical formulation and include the analysis of some groups which have already been treated by slightly different methods in the references quoted above.

2. CLASSIFICATION OF NUCLEAR GROUPS

It is convenient to introduce a notation for typical groups of nuclei which may appear in molecules and which will possess characteristic NMR spectra. We shall use the symbols $A, B, \dots$ for non-equivalent nuclei of the same species whose relative chemical shifts are of the same order of magnitude as the spin couplings between them. $X, Y, \dots$ will be used for another such set whose signals are not close to those of the set $A, B, \dots$. The nuclei in the set $X, Y, \dots$ may or may not be of the same species as those in the set $A, B, \dots$. The only feature that is important in the theory is that the chemical shift between the groups $A, B, \dots$ and $X, Y, \dots$ is large compared with any of the spin couplings. Equivalent nuclei will be described by the same symbol. Thus 1,1-difluoroethylene (I) is an example of A_2X_2 , for the carbon nuclei have no moments and may be

I

II

ignored. The protons in thiophene (II), on the other hand, would be described as an A_2B_2 group, for the chemical shift between the α and β hydrogens is observed to be relatively small.

In later sections of this paper, we shall give a detailed analysis of the NMR spectra characteristic of groups of two and three nuclei AB , AB_2 , and ABX , all having spin $\frac{1}{2}$.

3. QUANTUM-MECHANICAL CALCULATION OF ENERGY LEVELS AND TRANSITION INTENSITIES

The basic quantum-mechanical method of finding the energies and transition intensities corresponding to the stationary states of the nuclear spin system has been described by several authors (4, 5, 6, 8, 9, 10) and we shall only summarize those features which are necessary for further development. McConnell, McLean, and Reilly (8) have given a full treatment and have developed the theory in a way which makes maximum use of molecular symmetry. We shall follow their notation to some extent.

The Hamiltonian consists of two parts,

$$[3.1] \quad \mathcal{H} = \mathcal{H}^{(0)} + \mathcal{H}^{(1)}.$$

$\mathcal{H}^{(0)}$ corresponds to the interaction of the nuclear magnetic moments with the external field. It is given by

$$[3.2] \quad \mathcal{H}^{(0)} = \sum_i \eta_i H_i I_z(i),$$

where $2\pi\eta_i$ is the gyromagnetic ratio of nucleus i , H_i the magnetic field at this nucleus, and $I_z(i)$ the spin angular momentum component in the z -direction (in units of $\hbar/2\pi$).

For nuclei of spin $\frac{1}{2}$, $I_z(i)$ can take values $+\frac{1}{2}$ or $-\frac{1}{2}$. The sign convention is such that the external field is in the *negative* z -direction so that nuclei with positive spins have high energies. The magnetic field H_i will vary from one nucleus to another because of different electronic screening.

The other part of the Hamiltonian corresponds to the spin coupling and can be written

$$[3.3] \quad \mathcal{H}^{(1)} = \sum_{i < j} J_{ij} \mathbf{I}(i) \cdot \mathbf{I}(j),$$

where $\mathbf{I}(i)$ is the vector spin angular momentum (in units of $\hbar/2\pi$). J_{ij} is the coupling constant between nuclei i and j and will have the dimensions of energy.

In the present paper we shall deal only with groups of nuclei of spin $\frac{1}{2}$ so that $I_z = \pm \frac{1}{2}$ and there will only be two wave functions α and β for each nucleus. For a system of p such nuclei, there will be 2^p possible energy states. All the wave functions can be written as linear combinations of 2^p basic product functions such as

$$[3.4] \quad \psi_n = \alpha(1) \beta(2) \alpha(3) \dots \beta(p).$$

This product will usually be shortened to $\alpha\beta\alpha \dots \beta$. If the nuclei were actually independent, these products would themselves be stationary state wave functions. The interaction Hamiltonian [3.3], however, causes mixing and the correct stationary state functions are those linear combinations of these products which diagonalize the matrix of the Hamiltonian [3.1]. The corresponding energies are solutions of the secular equation

$$[3.5] \quad |\mathcal{H}_{mn} - E \delta_{mn}| = 0$$

where $\delta_{mn} = 1$ if $m = n$, and is zero otherwise.

McConnell, McLean, and Reilly (8) have indicated how it may be simpler to work with a different set of basic functions which belong to irreducible representations of the symmetry group. Thus, for two equivalent nuclei, one would replace the basic set $\alpha\alpha, \alpha\beta, \beta\alpha, \beta\beta$ by

$$[3.6] \quad \alpha\alpha, (\alpha\beta + \beta\alpha)/\sqrt{2}, (\alpha\beta - \beta\alpha)/\sqrt{2}, \beta\beta.$$

The third of these is antisymmetric with respect to interchange of the nuclei, all others being symmetric. Other examples of the use of symmetrized basic functions will be encountered later.

The secular equation [3.5] factorizes into equations of lower degree in E if we make use of the following *mixing rules*:

- (1) There is no mixing between states of different total spin F_z where

$$[3.7] \quad F_z = \sum_i I_z(i).$$

- (2) There is no mixing between states of different symmetry.

We therefore classify the basic functions by symmetry and total spin. It is then only necessary to diagonalize the submatrix $\mathcal{H}_{mn}$ of those elements which have common symmetry and spin. The set of functions [3.6], for example, all differ from one another either in spin or symmetry. There is, therefore, no mixing and these are the correct stationary state wave functions for the symmetrical two-nuclear system A_2 .

There are simple rules for evaluating the matrix elements $\mathcal{H}_{mn}$ between single products

ψ_m and ψ_n of the type [3.4] (McConnell, McLean, and Reilly (8)). We repeat these for completeness. First

$$[3.8] \quad (\psi_m | \mathcal{H}^{(0)} | \psi_m) = \frac{1}{2} \sum_i \eta_i H_i S_i$$

where $S_i = +1$ if nucleus i has α -spin in ψ_m and $S_i = -1$ if it has β -spin. The matrix element $(\psi_m | \mathcal{H}^{(0)} | \psi_n)$ ($m \neq n$) vanishes.

The matrix elements of $\mathcal{H}^{(1)}$ are given by

$$[3.9] \quad (\psi_m | \mathcal{H}^{(1)} | \psi_m) = \frac{1}{4} \sum_{i < j} J_{ij} T_{ij}$$

where $T_{ij} = +1$ or -1 according as spins i and j are parallel or antiparallel in ψ_m . Thus, for example,

$$[3.10] \quad (\alpha\beta\alpha | \mathcal{H}^{(1)} | \alpha\beta\alpha) = \frac{1}{4} (-J_{12} + J_{13} - J_{23}).$$

Finally

$$[3.11] \quad (\psi_m | \mathcal{H}^{(1)} | \psi_n) = \frac{1}{2} U J_{ij} \quad (m \neq n)$$

where $U = 1$ if ψ_m only differs from ψ_n by an interchange of spins i and j and is zero otherwise. For example

$$[3.12] \quad \begin{aligned} (\alpha\beta\alpha\beta | \mathcal{H}^{(1)} | \beta\alpha\alpha\beta) &= \frac{1}{2} J_{12}, \\ (\alpha\beta\alpha\beta | \mathcal{H}^{(1)} | \beta\alpha\beta\alpha) &= 0. \end{aligned}$$

If the basic set consists of some linear combinations of products, corresponding matrix elements are easily evaluated by expansion.

Having obtained a set of energy levels and corresponding wave functions, selection rules for transitions are required. McConnell *et al.* (8) derive the following two selection rules:

- (1) In any allowed transition, the change of total spin

$$[3.13] \quad \Delta F = \pm 1.$$

- (2) All allowed transitions must be between two states of the same symmetry.

The intensity of the transition between two states p and q is proportional to the square of the transition moment

$$[3.14] \quad (\phi_p | M_x | \phi_q)$$

where ϕ_p, ϕ_q are the stationary state wave functions and M_x is the x -component of the magnetic moment operator

$$[3.15] \quad M_x = \sum_i \eta_i I_x(i).$$

The matrix element [3.14] can be expanded in terms of matrix elements of single products $(\psi_p | M_x | \psi_q)$. This is zero unless ψ_p and ψ_q differ only in the spin of one nucleus i , in which case it is equal to $\eta_i/2$.

4. TWO NUCLEI AB

The simplest system in which the effects of chemical shift and spin coupling are intermingled consists of two non-equivalent nuclei of the same species isolated from the

effects of any other nuclear moments. If the applied field is H_0 , the local fields at nuclei A and B can be written

$$\begin{aligned} H_A &= H_0(1 - \sigma_A) \\ H_B &= H_0(1 - \sigma_B) \end{aligned} \quad [4.1]$$

where σ_A and σ_B are non-dimensional screening constants. The relative chemical shift can be measured by the difference $\sigma_B - \sigma_A$, which may, of course, take either sign.

The basic functions and the diagonal matrix elements are (if the spin-coupling constant is J):

$$\begin{array}{ccccc} n & \psi_n & F_z & \mathcal{H}_{nn} & \\ & AB & & & \\ [4.2] & 1 & \alpha\alpha & 1 & \eta H_0(1 - \frac{1}{2}\sigma_A - \frac{1}{2}\sigma_B) + \frac{1}{4}J \\ & 2 & \alpha\beta & 0 & \eta H_0(-\frac{1}{2}\sigma_A + \frac{1}{2}\sigma_B) - \frac{1}{4}J \\ & 3 & \beta\alpha & 0 & \eta H_0(\frac{1}{2}\sigma_A - \frac{1}{2}\sigma_B) - \frac{1}{4}J \\ & 4 & \beta\beta & -1 & \eta H_0(-1 + \frac{1}{2}\sigma_A + \frac{1}{2}\sigma_B) + \frac{1}{4}J \end{array}$$

The only non-vanishing off-diagonal element is

$$[4.3] \quad \mathcal{H}_{23} = \frac{1}{2}J.$$

The only mixing that will occur, therefore, is between ψ_2 and ψ_3 . If we define a positive quantity C and an angle θ by

$$\begin{aligned} C \cos 2\theta &= \frac{1}{2}\eta H_0(\sigma_B - \sigma_A), \\ [4.4] \quad C \sin 2\theta &= \frac{1}{2}J \end{aligned}$$

the stationary state wave functions ϕ_n and energies E_n are given by:

$$\begin{array}{ccccc} n & \phi_n & E_n & & \\ [4.5] & 1 & \alpha\alpha & \eta H_0(1 - \frac{1}{2}\sigma_A - \frac{1}{2}\sigma_B) + \frac{1}{4}J & \\ & 2 & \cos \theta(\alpha\beta) + \sin \theta(\beta\alpha) & -\frac{1}{4}J + C & \\ & 3 & -\sin \theta(\alpha\beta) + \cos \theta(\beta\alpha) & -\frac{1}{4}J - C & \\ & 4 & \beta\beta & \eta H_0(-1 + \frac{1}{2}\sigma_A + \frac{1}{2}\sigma_B) + \frac{1}{4}J & \end{array}$$

The allowed transitions with corresponding energies (relative to the mean $\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B)$) and relative intensities are given in Table I.

TABLE I
TRANSITION ENERGIES AND INTENSITIES FOR AB

Transition	Energy	Relative intensity
$3 \rightarrow 1$	$\frac{1}{2}J + C$	$1 - \sin 2\theta$
$4 \rightarrow 2$	$-\frac{1}{2}J + C$	$1 + \sin 2\theta$
$2 \rightarrow 1$	$\frac{1}{2}J - C$	$1 + \sin 2\theta$
$4 \rightarrow 3$	$-\frac{1}{2}J - C$	$1 - \sin 2\theta$

The general appearance of this spectrum depends only on the ratio $|J/\eta H_0(\sigma_B - \sigma_A)|$. If we suppose that the signs are such that $\sigma_B > \sigma_A$ and $J > 0$, so that B is more screened than A , the spectrum is as illustrated in Fig. 1. As we start from small J , the spectrum changes from two doublets into a symmetrical group of four lines, the inner pair being

FIG. 1. Typical spectra for two nuclei AB .

stronger than the outer. Eventually the two central lines degenerate into a single one and the outer ones become forbidden, so that only a single signal is observed for A_2 . In the intermediate stage we may still describe the right-hand pair qualitatively as predominantly A -lines, although the actual transition is a mixed one in which there is some change of spin of the B -nucleus.

If either or both of $(\sigma_B - \sigma_A)$ and J changes sign, it is easily seen from [4.4] and Table I that the appearance of the spectrum remains identical, although the detailed assignment shown in Fig. 1 may change. Thus, from an AB spectrum, it is not possible to determine which of the two nuclei is more screened, nor is it possible to obtain the sign of the coupling constant J .

The numerical analysis of such a spectrum is straightforward. The separation between either the right-hand pair or the left-hand pair is equal to $|J|$. The total separation of the extreme lines is $|J| + 2C$, which gives C and consequently $|\sigma_B - \sigma_A|$ using [4.4].

Spectrum of S-Guaiazulene

As an example of a spectrum in which two-nuclei systems AB occur we consider the ring protons of S-guaiazulene.

There are two sets of AB nuclei; the two hydrogens on the 1 and 2 positions of the five-membered ring, and the two hydrogens on the 6 and 7 positions of the seven-membered ring.

The spectrum of the sample contained in a 5 mm. spinning tube was measured with a Varian V-4300 NMR spectrometer, equipped with field stabilizer, at a fixed frequency of 40 Mc./sec. The more prominent signals in this spectrum (as well as in the other spectra presented in this paper) were cycled by the side-band technique to an accuracy of $\pm \frac{1}{2}$ c./sec. and the remaining signal separations were obtained by interpolation on the recorder chart. Where necessary a capillary containing cyclohexane was introduced in the spinning sample to provide a reference signal for the cycling procedure. The error in the frequency measurements gives rise to an inherent error of about 4-5% in the final values of the chemical shift and in the spin-spin coupling constants derived from the spectrum. The error in the measured intensities (areas) of the individual signals is considerably larger being of the order of 10% for strong, well-resolved signals.

FIG. 2. Spectrum of the ring protons of S-guaiazulene at 40 Mc./sec.

The spectrum of the ring protons of S-guaiazulene is shown in Fig. 2. The separation of the signals is indicated in c./sec. in the direction of increasing magnetic field. Neglecting the small doubling in the signals at 0 and 52.3 c./sec., the spectrum can be broken down into a single line (0 c./sec., arising from proton 4) and two quartets of the *AB* type overlapping at 41.3 c./sec. The quartet (18.9, 22.6, 37.6, 41.3) approximates Fig. 1(a) and the other (41.3, 52.3, 60.5, 72.0) is similar to Fig. 1(b). The doubling of the signals at 0 and 52.3 c./sec. can be explained by introducing a coupling constant between protons 4 and 6. This might reasonably be expected to be larger than the coupling between 4 and 7, 1, or 2. On this hypothesis, therefore, the signals at 41.3 and 52.3 are assigned to proton 6, the doubling at 41.3 being unobserved because of the overlap. Consequently the other signals of this quartet (60.5, 72.0) originate from proton 7.* It is not possible, however, to distinguish between the signals of protons 1 and 2.

*The possibility of spin coupling between protons 4 and 6, and the tertiary hydrogen of the isopropyl group cannot be excluded. This would not alter the above assignment.

Application of the above formulae (Table I) leads to the analysis given in Table II. The value $J_{46} = 1.3$ c./sec. is obtained from the doubling of the signals at 0 and 52.3 c./sec. (see under case *ABX* below).

TABLE II
ENERGIES AND RELATIVE INTENSITIES IN THE SPECTRUM OF S-GUAIAZULENE

Transition*	Origin	Energy (c./sec.)	Relative intensity†	
			Calc.	Obs.
	4	0	2.00	2.2
3 → 1	1 and 2	18.9	0.80	0.7
4 → 2	"	22.6	1.20	1.2
2 → 1	"	37.6	1.20	1.1
4 → 3	"	41.3	0.80	1.2
3 → 1	6	41.3	0.42	
4 → 2	6	52.3	1.58	1.7
2 → 1	7	60.5	1.58	1.6
4 → 3	7	72.0	0.42	0.3
		$J_{12} = 3.7$ c./sec.	$\eta H_0 \sigma_1 - \sigma_2 = 18.3$ c./sec.	
		$J_{67} = 11.5$ c./sec.	$\eta H_0 (\sigma_7 - \sigma_6) = 16.0$ c./sec.	
		$J_{46} = 1.3$ c./sec.		

*In the actual experimental arrangement, the applied field is varied to obtain resonance at a fixed frequency. Therefore, the higher energy transitions are observed at lower applied fields.

†Intensities are normalized to give total ring proton intensity of 10.

5. THREE NUCLEI AB_2

If we have a system of three nuclei, two of which are equivalent, there are two different spin-coupling constants J and J' . This arrangement has a symmetry of reflection in

the plane bisecting the BB line. As explained in Section 3, it is then convenient to replace the basic set of product functions $\alpha\alpha\alpha$, $\alpha\alpha\beta$, $\alpha\beta\alpha$, ... by a set all of which are either symmetric or antisymmetric under such a reflection. We have already seen that for two equivalent nuclei, such a set is $\alpha\alpha$, $(\alpha\beta + \beta\alpha)/\sqrt{2}$, $(\alpha\beta - \beta\alpha)/\sqrt{2}$, $\beta\beta$. Combining these with either α or β for nucleus A , we get the basic set listed in Table III. The symbols s and a are used to denote symmetric and antisymmetric states, respectively, and the value of the total spin F_z is appended as a suffix. Screening constants are again defined by

$$[5.1] \quad \begin{aligned} H_A &= H_0(1 - \sigma_A), \\ H_B &= H_0(1 - \sigma_B) \end{aligned}$$

and we then obtain diagonal elements of $\mathcal{H}$ as given in the table. The only off-diagonal matrix elements are between $1s_{\frac{1}{2}}$ and $2s_{\frac{1}{2}}$ and between $1s_{-\frac{1}{2}}$ and $2s_{-\frac{1}{2}}$. These are both equal to $J/\sqrt{2}$.

The functions $s_{3/2}$, $a_{\frac{1}{2}}$, and $s_{-3/2}$ do not mix and are therefore themselves stationary state wave functions. To find the symmetric stationary state functions for spins $\pm \frac{1}{2}$,

TABLE III
BASIC FUNCTIONS AND DIAGONAL MATRIX ELEMENTS FOR AB_2

Function	ABB	Diagonal matrix element
$s_{3/2}$	$\alpha\alpha\alpha$	$\frac{1}{2}\eta H_0(3-\sigma_A-2\sigma_B) + \frac{1}{4}(2J+J')$
$1s_{1/2}$	$\alpha(\alpha\beta+\beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(1-\sigma_A) + \frac{1}{4}J'$
$2s_{1/2}$	$\beta\alpha\alpha$	$\frac{1}{2}\eta H_0(1+\sigma_A-2\sigma_B) + \frac{1}{4}(-2J+J')$
$a_{1/2}$	$\alpha(\alpha\beta-\beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(1-\sigma_A) - \frac{3}{4}J'$
$a_{-1/2}$	$\beta(\alpha\beta-\beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(-1+\sigma_A) - \frac{3}{4}J'$
$1s_{-1/2}$	$\alpha\beta\beta$	$\frac{1}{2}\eta H_0(-1-\sigma_A+2\sigma_B) + \frac{1}{4}(-2J+J')$
$2s_{-1/2}$	$\beta(\alpha\beta+\beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(-1+\sigma_A) + \frac{1}{4}J'$
$s_{-3/2}$	$\beta\beta\beta$	$\frac{1}{2}\eta H_0(-3-\sigma_A-2\sigma_B) + \frac{1}{4}(2J+J')$

we have to solve 2×2 secular equations. We define positive quantities C_+ , C_- and angles θ_+ , θ_- by

$$\begin{aligned}
 C_+ \cos 2\theta_+ &= \eta H_0(\sigma_B - \sigma_A) + \frac{1}{4}J, \\
 C_+ \sin 2\theta_+ &= J/\sqrt{2}, \\
 C_- \cos 2\theta_- &= \eta H_0(\sigma_B - \sigma_A) - \frac{1}{4}J, \\
 C_- \sin 2\theta_- &= J/\sqrt{2}.
 \end{aligned}
 \tag{5.2}$$

Corresponding wave functions and energies are:

State	Wave function	Energy
$1's_{\frac{1}{2}}$	$\cos \theta_+ \alpha(\alpha\beta + \beta\alpha)/\sqrt{2} + \sin \theta_+ \beta\alpha\alpha$	$\frac{1}{2}\eta H_0(1 - \sigma_B) + \frac{1}{4}(J' - J) + C_+$
$2's_{\frac{1}{2}}$	$-\sin \theta_+ \alpha(\alpha\beta + \beta\alpha)/\sqrt{2} + \cos \theta_+ \beta\alpha\alpha$	$\frac{1}{2}\eta H_0(1 - \sigma_B) + \frac{1}{4}(J' - J) - C_+$
$1's_{-\frac{1}{2}}$	$\cos \theta_- \alpha\beta\beta + \sin \theta_- \beta(\alpha\beta + \beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(-1 + \sigma_B) + \frac{1}{4}(J' - J) + C_-$
$2's_{-\frac{1}{2}}$	$-\sin \theta_- \alpha\beta\beta + \cos \theta_- \beta(\alpha\beta + \beta\alpha)/\sqrt{2}$	$\frac{1}{2}\eta H_0(-1 + \sigma_B) + \frac{1}{4}(J' - J) - C_-$

$$\tag{5.3}$$

The observable transition energies together with relative intensities are given in Table IV. Each transition may be labelled according to its behavior in the limit when the spin coupling constants J and J' tend to zero. The labelling given in the table is appropriate for the case $\sigma_B > \sigma_A$, that is the B nuclei are more shielded than the A . In this case θ_+ , $\theta_- \rightarrow 0$ as $J, J' \rightarrow 0$. Thus, for example, the transition $2's_{\frac{1}{2}} \rightarrow s_{3/2}$ becomes $\beta\alpha\alpha \rightarrow \alpha\alpha\alpha$ and is, therefore, labelled an A transition, since in this limit only the A -spin is changed. The transition $1's_{-\frac{1}{2}} \rightarrow 2's_{\frac{1}{2}}$, on the other hand, becomes $\alpha\beta\beta \rightarrow \beta\alpha\alpha$ and cannot be described as A or B . In the limit it will correspond to the simultaneous change of spin of all three nuclei and may be referred to as a *combination line*. It is actually forbidden in the limit, but should appear with non-zero intensity in the general intermediate case. However, the same band also becomes forbidden in the other limit of zero chemical shift so that its intensity is always low.

If $\sigma_B < \sigma_A$, that is if the single nucleus is more highly screened, θ_+ , $\theta_- \rightarrow \frac{1}{2}\pi$ as $J, J' \rightarrow 0$, so that some relabelling is necessary in Table IV.

All the transition energies and intensities are independent of the B - B coupling constant J' , so that the structure of the spectrum, apart from a scaling factor, is a function only of the non-dimensional ratio $J/\eta H_0(\sigma_B - \sigma_A)$. The pattern of lines for a series of values of this ratio is illustrated in Fig. 3 for $\sigma_B > \sigma_A$ and $J > 0$.

TABLE IV
 ENERGIES AND INTENSITIES FOR AB_2

Transition	Origin*	Energy	Relative intensity
1. $2's_{1/2} \rightarrow s_{3/2}$	A	$\frac{1}{2}\eta H_0(2-\sigma_A-\sigma_B) + \frac{3}{4}J + C_+$	$[\sqrt{2} \sin \theta_+ - \cos \theta_+]^2$
2. $2's_{-1/2} \rightarrow 1's_{1/2}$	A	$\eta H_0(1-\sigma_B) + C_+ + C_-$	$[\sqrt{2} \sin(\theta_+ - \theta_-) + \cos \theta_+ \cos \theta_-]^2$
3. $a_{-1/2} \rightarrow a_{1/2}$	A	$\eta H_0(1-\sigma_A)$	1
4. $s_{-3/2} \rightarrow 1's_{-1/2}$	A	$\frac{1}{2}\eta H_0(2-\sigma_A-\sigma_B) - \frac{3}{4}J + C_-$	$[\sqrt{2} \sin \theta_- + \cos \theta_-]^2$
5. $1's_{-1/2} \rightarrow 1's_{1/2}$	B	$\eta H_0(1-\sigma_B) + C_+ - C_-$	$[\sqrt{2} \cos(\theta_+ - \theta_-) + \cos \theta_+ \sin \theta_-]^2$
6. $1's_{1/2} \rightarrow s_{3/2}$	B	$\frac{1}{2}\eta H_0(2-\sigma_A-\sigma_B) + \frac{3}{4}J - C_+$	$[\sqrt{2} \cos \theta_+ + \sin \theta_+]^2$
7. $2's_{-1/2} \rightarrow 2's_{1/2}$	B	$\eta H_0(1-\sigma_B) - C_+ + C_-$	$[\sqrt{2} \cos(\theta_+ - \theta_-) - \sin \theta_+ \cos \theta_-]^2$
8. $s_{-3/2} \rightarrow 2's_{-1/2}$	B	$\frac{1}{2}\eta H_0(2-\sigma_A-\sigma_B) - \frac{3}{4}J - C_-$	$[\sqrt{2} \cos \theta_- - \sin \theta_-]^2$
9. $1's_{-1/2} \rightarrow 2's_{1/2}$	Comb.	$\eta H_0(1-\sigma_B) - C_+ - C_-$	$[\sqrt{2} \sin(\theta_+ - \theta_-) + \sin \theta_+ \sin \theta_-]^2$

*Based on $\sigma_B > \sigma_A$.

FIG. 3. Typical spectra of three nuclei AB_2 (numbering as in Table IV).

If $\sigma_B > \sigma_A$ and $J < 0$, the appearance of the spectrum is identical although the assignment in terms of the numbering in Table IV needs revising. If $\sigma_B < \sigma_A$, the patterns have to be reversed. From such a spectrum, therefore, it is possible to determine $\sigma_B - \sigma_A$ including sign, but only the magnitude of J .

The following features, which are of use in the practical analysis of a spectrum, may be noted from Table IV:

(a) Line 3 immediately gives the position of pure chemical shift for the A-nucleus, unmodified by spin coupling.

(b) The corresponding position for the B nuclei is the mean of the transitions 5 and 7.

Numerical values of the transition energies of Table IV (lines 1-9) are given for a range of values of this ratio in Table V. All energies are measured relative to the undisplaced *A*-line (line 3) and the scale is adjusted so that the chemical shift is one unit.

In practice, there may be difficulties in resolving lines which are close together, and values of the chemical shift and *J* are better obtained by adjusting the ratio $J/\eta H_0(\sigma_B - \sigma_A)$ using Table V until the best fit of the pattern is obtained.

TABLE V
ENERGIES OF TRANSITIONS RELATIVE TO UNDISPLACED *A*-LINE

Spectrum of 2,6-Lutidine

As an example of the application of these formulae we have measured and analyzed the spectrum of the ring protons on 2,6-lutidine. In this molecule these protons are expected to have a simple spectrum since the complicating effects of coupling with the

methyl protons and the nitrogen nucleus are relatively small because of extra separation.

The spectrum of 2,6-lutidine is reproduced in Fig. 4 and is easily fitted into the scheme of Fig. 3. The best over-all fit of pattern is obtained with the ratio $J/\eta H_0(\sigma_B - \sigma_A)$ equal to 0.375. Adjustment of the scale then gives:

$$\begin{aligned}
 \text{Chemical shift} \quad \eta H_0(\sigma_B - \sigma_A) &= 21.9 \text{ c./sec.} \\
 [5.4] \quad J &= 8.2 \text{ c./sec.}
 \end{aligned}$$

The spectrum of 2,6-lutidine at lower resolution has been analyzed previously by Baker (2). Values of 16 and 6 c./sec. were found for the chemical shift and spin-spin coupling

FIG. 4. Ring proton spectrum of 2,6-lutidine at 40 Mc./sec. (numbering as in Table IV).

constant respectively. The calculated energies and intensities using the parameters from [5.4] are compared with observed values in Table VI. Lines 5 and 6 are unresolved in this spectrum; this is consistent with the small calculated separation. The combination signal was not observed, presumably because of its very low intensity.

TABLE VI
COMPARISON OF CALCULATED AND OBSERVED SPECTRUM FOR 2,6-LUTIDINE

6. THREE NUCLEI ABX

We now consider the case of two nuclei, A , B , where the relative chemical shift is of the same order of magnitude as the spin-coupling constants, coupled to a third nucleus X which may either be of a different species or of the same species with its signal well separated from the AB region. We will deal with the latter case, although the notation

is easily modified to apply to the former. There will be three coupling constants, as follows:

If the external field is H_0 , the fields at the three nuclei will be written

$$\begin{aligned} H_A &= H_0(1 - \sigma_A), \\ H_B &= H_0(1 - \sigma_B), \\ H_X &= H_0(1 - \sigma_X). \end{aligned} \quad [6.1]$$

In this case we may, without loss of generality, suppose that $\sigma_B > \sigma_A$.

The most convenient set of basic functions, since there is no symmetry, are single products of the type $\alpha\beta\alpha$. These functions and the corresponding diagonal matrix elements are:

	ABX	Diagonal matrix element
1.	$\alpha\alpha\alpha$	$\frac{1}{2}\eta H_0(3 - \sigma_A - \sigma_B - \sigma_X) + \frac{1}{4}(J_{AB} + J_{AX} + J_{BX})$
2.	$\alpha\alpha\beta$	$\frac{1}{2}\eta H_0(1 - \sigma_A - \sigma_B + \sigma_X) + \frac{1}{4}(J_{AB} - J_{AX} - J_{BX})$
3.	$\alpha\beta\alpha$	$\frac{1}{2}\eta H_0(1 - \sigma_A + \sigma_B - \sigma_X) + \frac{1}{4}(-J_{AB} + J_{AX} - J_{BX})$
4.	$\beta\alpha\alpha$	$\frac{1}{2}\eta H_0(1 + \sigma_A - \sigma_B - \sigma_X) + \frac{1}{4}(-J_{AB} - J_{AX} + J_{BX})$
5.	$\alpha\beta\beta$	$\frac{1}{2}\eta H_0(-1 - \sigma_A + \sigma_B + \sigma_X) + \frac{1}{4}(-J_{AB} - J_{AX} + J_{BX})$
6.	$\beta\alpha\beta$	$\frac{1}{2}\eta H_0(-1 + \sigma_A - \sigma_B + \sigma_X) + \frac{1}{4}(-J_{AB} + J_{AX} - J_{BX})$
7.	$\beta\beta\alpha$	$\frac{1}{2}\eta H_0(-1 + \sigma_A + \sigma_B - \sigma_X) + \frac{1}{4}(J_{AB} - J_{AX} - J_{BX})$
8.	$\beta\beta\beta$	$\frac{1}{2}\eta H_0(-3 + \sigma_A + \sigma_B + \sigma_X) + \frac{1}{4}(J_{AB} + J_{AX} + J_{BX})$

[6.2]

The off-diagonal matrix elements of the Hamiltonian will involve only the coupling constants, J_{AB} , J_{AX} , and J_{BX} . The non-vanishing ones are:

$$\begin{aligned} \mathcal{H}_{23} &= \frac{1}{2}J_{BX} & \mathcal{H}_{56} &= \frac{1}{2}J_{AB} \\ \mathcal{H}_{24} &= \frac{1}{2}J_{AX} & \mathcal{H}_{57} &= \frac{1}{2}J_{AX} \\ \mathcal{H}_{34} &= \frac{1}{2}J_{AB} & \mathcal{H}_{67} &= \frac{1}{2}J_{BX} \end{aligned} \quad [6.3]$$

This gives the complete matrix for the general problem of three nuclei ABC .

Now we are assuming that $\eta H_0 \sigma_X$ is large compared with any of the spin-coupling constants. This means that there will be mixing between functions 3 and 4 but neither will mix appreciably with function 2 although it has the same total spin. Similarly there will be mixing only between 5 and 6. The problem is therefore reduced to the solution of 2×2 secular equations and the final energy levels can then be written in explicit analytical form. If we define

$$\begin{aligned} D_+ \cos 2\phi_+ &= \frac{1}{2}\eta H_0(\sigma_B - \sigma_A) + \frac{1}{4}(J_{AX} - J_{BX}), \\ D_+ \sin 2\phi_+ &= \frac{1}{2}J_{AB}, \\ D_- \cos 2\phi_- &= \frac{1}{2}\eta H_0(\sigma_B - \sigma_A) - \frac{1}{4}(J_{AX} - J_{BX}), \\ D_- \sin 2\phi_- &= \frac{1}{2}J_{AB}, \end{aligned} \quad [6.4]$$

the mixed wave functions and energy levels are:

State	Wave function	Energy
3'	$\cos \phi_+(\alpha\beta\alpha) + \sin \phi_+(\beta\alpha\alpha)$	$\frac{1}{2}\eta H_0(1 - \sigma_X) - \frac{1}{4}J_{AB} + D_+$
4'	$-\sin \phi_+(\alpha\beta\alpha) + \cos \phi_+(\beta\alpha\alpha)$	$\frac{1}{2}\eta H_0(1 - \sigma_X) - \frac{1}{4}J_{AB} - D_+$
[6.5]		
5'	$\cos \phi_-(\alpha\beta\beta) + \sin \phi_-(\beta\alpha\beta)$	$\frac{1}{2}\eta H_0(-1 + \sigma_X) - \frac{1}{4}J_{AB} + D_-$
6'	$-\sin \phi_-(\alpha\beta\beta) + \cos \phi_-(\beta\alpha\beta)$	$\frac{1}{2}\eta H_0(-1 + \sigma_X) - \frac{1}{4}J_{AB} - D_-$

Once again we may classify the lines according to their origin in the absence of spin coupling. Of the total of 15 possible transitions, four will arise from each of the three nuclei and there will be three combination lines. Again the latter are generally weak. A complete table of transition energies and intensities is given in Table VII.

TABLE VII
ENERGIES AND INTENSITIES FOR ABX

Transition	Origin	Energy	Relative intensity
1. 8 $\rightarrow$ 6'	B	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) - \frac{1}{4}(2J_{AB} + J_{AX} + J_{BX}) - D_-$	$(\cos \phi_- - \sin \phi_-)^2$
2. 7 $\rightarrow$ 4'	B	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) - \frac{1}{4}(2J_{AB} - J_{AX} - J_{BX}) - D_+$	$(\cos \phi_+ - \sin \phi_+)^2$
3. 5' $\rightarrow$ 2	B	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) + \frac{1}{4}(2J_{AB} - J_{AX} - J_{BX}) - D_-$	$(\cos \phi_- + \sin \phi_-)^2$
4. 3' $\rightarrow$ 1	B	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) + \frac{1}{4}(2J_{AB} + J_{AX} + J_{BX}) - D_+$	$(\cos \phi_+ + \sin \phi_+)^2$
5. 8 $\rightarrow$ 5'	A	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) - \frac{1}{4}(2J_{AB} + J_{AX} + J_{BX}) + D_-$	$(\cos \phi_- + \sin \phi_-)^2$
6. 7 $\rightarrow$ 3'	A	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) - \frac{1}{4}(2J_{AB} - J_{AX} - J_{BX}) + D_+$	$(\cos \phi_+ + \sin \phi_+)^2$
7. 6' $\rightarrow$ 2	A	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) + \frac{1}{4}(2J_{AB} - J_{AX} - J_{BX}) + D_-$	$(\cos \phi_- - \sin \phi_-)^2$
8. 4' $\rightarrow$ 1	A	$\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B) + \frac{1}{4}(2J_{AB} + J_{AX} + J_{BX}) + D_+$	$(\cos \phi_+ - \sin \phi_+)^2$
9. 8 $\rightarrow$ 7	X	$\eta H_0(1 - \sigma_X) - \frac{1}{2}(J_{AX} + J_{BX})$	1
10. 5' $\rightarrow$ 3'	X	$\eta H_0(1 - \sigma_X) + D_+ - D_-$	$\cos^2(\phi_+ - \phi_-)$
11. 6' $\rightarrow$ 4'	X	$\eta H_0(1 - \sigma_X) - D_+ + D_-$	$\cos^2(\phi_+ + \phi_-)$
12. 2 $\rightarrow$ 1	X	$\eta H_0(1 - \sigma_X) + \frac{1}{2}(J_{AX} + J_{BX})$	1
13. 7 $\rightarrow$ 2	Comb.	$\eta H_0(1 + \sigma_X)$	0
14. 5' $\rightarrow$ 4'	Comb.	$\eta H_0(1 - \sigma_X) - D_+ - D_-$	$\sin^2(\phi_+ - \phi_-)$
15. 6' $\rightarrow$ 3'	Comb.	$\eta H_0(1 - \sigma_X) + D_+ + D_-$	$\sin^2(\phi_+ + \phi_-)$

Spectra of this type are most readily interpreted by considering the coupling constants J_{AX} and J_{BX} as perturbations. If these are both zero, the AB region of the spectrum will consist of four lines as discussed in section 4. In Table VII these four lines correspond to the pairs (1, 2), (3, 4), (5, 6), and (7, 8). If J_{AX} and J_{BX} are now introduced, the two B pairs are both split by

$$[6.6] \quad \frac{1}{2}(J_{AX} + J_{BX}) + (D_- - D_+)$$

and the two A pairs by

$$[6.7] \quad \frac{1}{2}(J_{AX} + J_{BX}) - (D_- - D_+).$$

If the coupling constants J_{AX} and J_{BX} are equal, the splittings will be identical ($D_+ = D_-$). If $J_{AX} < J_{BX}$ then $D_+ < D_-$ and, if the sum $J_{AX} + J_{BX}$ is positive, the B -splitting will be larger. However, if the signs of both J_{AX} and J_{BX} are reversed, there will be no change in the observed spectrum. This is illustrated schematically in Fig. 5. If the splittings are considerably larger than shown in this figure, there may be some crossing of lines. Also the A -splitting expression [6.7] may be negative, in which case the assignment in Fig. 5 would be 1, 2, 3, 4, 6, 5, 8, 7 from right to left.

Some check on the assignments in the AB region can be obtained from the structure of the X spectrum, which is closely related. There is a symmetrical quartet (Fig. 6)

X

FIG. 5. Relation of AB region of ABX spectrum to the pure AB spectrum.
 FIG. 6. X signals in the ABX spectrum.

which is such that the 9–10 separation is equal to the A -splittings [6.7] and the 9–11 separation is equal to the B -splittings [6.6]. If [6.7] is negative, the assignment of the X spectrum would be 10, 9, 12, 11, from right to left.

Spectra with the biggest coupling between X and A can be described in a similar manner. The A -splittings would then be greater ($D_+ > D_-$) and the X signals would have to be reassigned 9, 11, 10, 12 or 11, 9, 12, 10.

Spectrum of 2,3-Lutidine

The analysis of an ABX spectrum will be illustrated by the ring protons in 2,3-lutidine.

In this molecule the signals from the proton in the 6-position (H_6) are well separated from the other two (H_5 and H_4). The complete spectrum is shown in Fig. 7.

All 12 non-combination lines are clearly visible. Comparison with Fig. 5 shows that we have the coupling case $J_{BX} > J_{AX}$. Since we expect the coupling between protons attached to neighboring carbon atoms to be dominant, we assign the B signals to H_5 .

The splittings of the pairs in the AB region are 4.6, 4.5, 1.5, and 1.5 c./sec. The corresponding separations in the X signal are 4.8, 4.8, 1.7, and 1.7 c./sec., in good agreement with the theory. As mentioned above, there are two possible assignments, which we will consider in turn.

Assignment 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12

From the average values of the splittings we have

$$\begin{aligned}
 [6.8] \quad \frac{1}{2}(J_{AX} + J_{BX}) + (D_- - D_+) &= 4.7, \\
 \frac{1}{2}(J_{AX} + J_{BX}) - (D_- - D_+) &= 1.6.
 \end{aligned}$$

FIG. 7. Ring proton spectrum of 2,3-lutidine at 40 Mc./sec.

From Table VII we see that the coupling constant J_{AB} is equal to the separation between lines 1 and 3 (7.7 c./sec.) or between lines 5 and 7 (7.0 c./sec.). We, therefore, choose the mean value 7.35 c./sec.

The value D_+ is equal to half the separation between lines 2 and 6 or between 4 and 8 (mean value 6.15 c./sec.). Similarly D_- is half the separation between lines 1 and 5 or 3 and 7 (mean value 7.7 c./sec.). From the definitions [6.4] we deduce:

$$[6.9] \quad \eta H_0(\sigma_B - \sigma_A) = 11.8 \text{ c./sec.}, \quad J_{BX} - J_{AX} = 3.55 \text{ c./sec.}$$

Combining [6.9] with [6.8] we obtain values for all parameters.

Assignment 1, 2, 3, 4, 6, 5, 8, 7, 10, 9, 12, 11

Equations [6.8] have to be replaced by

$$[6.10] \quad \begin{aligned} \frac{1}{2}(J_{AX} + J_{BX}) + (D_- - D_+) &= 4.7, \\ \frac{1}{2}(J_{AX} + J_{BX}) - (D_- - D_+) &= -1.6. \end{aligned}$$

The other steps are as before and we obtain

$$[6.11] \quad J = 7.35 \text{ c./sec.}, \quad D_+ = 5.4 \text{ c./sec.}, \quad D_- = 8.4 \text{ c./sec.}$$

The other chemical shift parameter $\eta H_0 \sigma_X$ is easily obtained by fitting the separation between any of the lines in the AB and X spectra. The sum of the transition energies for lines 2, 3, 6, and 7 is equal to $\frac{1}{2}\eta H_0(2 - \sigma_A - \sigma_B)$ and when combined with $\eta H_0(\sigma_B - \sigma_A)$ gives the origin of signals A and B . The two complete sets of parameters are given in Table VIII. The observed energies and intensities are compared with those calculated from these parameters in Table IX.

The agreement between calculated and observed energies is equally good for either assignment. From the calculated intensities it appears that it should be possible, in principle, to distinguish between the two assignments. However, the observed intensities, obtained by estimating area under the incompletely resolved peaks, are not yet accurate enough for this purpose.

TABLE VIII
CHEMICAL SHIFTS AND COUPLING CONSTANTS FOR 2,3-LUTIDINE (C./SEC.)*

	First assignment	Second assignment
Chemical shift $\eta H_0(\sigma_A - \sigma_X)$ (hydrogen 6-hydrogen 4)	43.4	43.4
Chemical shift $\eta H_0(\sigma_B - \sigma_A)$ (hydrogen 4-hydrogen 5)	11.7	11.5
J_{56} (J_{BX})	5.0	5.2
J_{45} (J_{AB})	7.35	7.35
J_{46} (J_{AX})	1.3	-2.0

*The signs of the spin-coupling constants are undetermined. The sign of J_{AB} may be negative and the signs of J_{AX} and J_{BX} may be reversed simultaneously.

TABLE IX

RADIATION-INDUCED EXCHANGE OF DEUTERIUM BETWEEN HEAVY WATER AND DISSOLVED HYDROGEN¹

J. BARDWELL² AND P. J. DYNE

ABSTRACT

Exchange of deuterium between deuterium oxide and molecular hydrogen is induced by gamma rays from Co⁶⁰. The reaction was studied by irradiating heavy water solutions saturated with hydrogen gas, and then analyzing the gas with a mass spectrometer. The reaction rate conforms to the exponential exchange law. The exchange yield is independent of dose rate and of hydrogen concentration over a moderate range. Prolonged irradiation leads to a steady state where the isotopic composition of the gas is close to that of the solution. This state differs greatly from that for thermodynamic equilibrium at room temperature.

INTRODUCTION

The exchange of hydrogen isotopes between water and molecular hydrogen provides a method for the preparation of heavy water (12, 13). The method depends upon the fact that the equilibrium constant for the exchange reaction

varies considerably with temperature, being 3.6 at 25° C. for H₂O and HDO in the liquid state* and calculated by Urey (17) to be 1.36 at 527° C. This last value has been confirmed experimentally (3, 4, 15) within the uncertainties in Urey's calculations. It is reasonable to assume that the catalyzed exchange depends upon the transitory existence of adsorbed hydrogen atoms.

When aqueous solutions are exposed to high energy radiations chemical transformations occur that are explained, in part, by the postulate of dissociation of water into H atoms and OH radicals (2). It was of interest, therefore, to discover whether the exchange of hydrogen isotopes, represented by Equation 1, could be induced by high energy radiations, for example by gamma rays from Co⁶⁰.

In this paper some experiments will be reported dealing with the kinetics and position of equilibrium of the exchange reaction between dissolved hydrogen gas and slightly enriched water (1% D₂O or less). The progress of the exchange was followed by collecting the dissolved gas and analyzing it for HD with a mass spectrometer.

While this investigation was in progress, Gordon and Hart published some results of an investigation of the gamma-ray induced reaction between D₂ and H₂O (8). They found that both HD and H₂ are formed, the production of H₂ being much greater than could be accounted for by exchange of HD with H₂O. They also observed that the yield is affected by pH.

EXPERIMENTAL

Apparatus

The apparatus used for preparing and irradiating solutions of hydrogen is shown in Fig. 1. A cylindrical radiation cell (volume 32 ml.) was connected by two capillaries to a

*Obtained by a short extrapolation from the data of Cerrai et al. (4) and corrected according to the method of Kirshenbaum (Ref. 11, p. 25) for the difference in vapor pressures between H₂O and HDO.

FIG. 1. The irradiation apparatus.

bulb (volume 118 ml.) to which was sealed a stopcock. During irradiation the apparatus was held upright, so that liquid completely filled in the capillaries and thus served to isolate the solution, during irradiation, from hydrogen gas contained in the bulb. The design of the apparatus was such that contact of the solution with stopcock grease was minimized.

The remainder of the apparatus consisted of a vacuum system, one part of which served for adding purified hydrogen, one for removing surplus undissolved gas after irradiation, and one for collecting dissolved gas for analysis.

Preparation of Solution for Irradiation

A solution of heavy water containing 0.749 mole % D_2O was prepared by mixing weighed quantities of pure D_2O and water that had been redistilled from potassium permanganate. Other solutions containing 0.264, 0.382, and 0.504 mole % D_2O were prepared by further dilutions with redistilled water. In all cases allowance was made for the deuterium content of ordinary water, taken as 0.015 mole % D_2O (11). Although it is convenient to express the concentrations of such solutions as mole % D_2O , it is realized that in these dilute solutions the only deuterated species present in significant quantity is HDO.

After the radiation apparatus had been thoroughly cleaned and rinsed, heavy water solution (33 ml.) was introduced. The liquid was then freed of dissolved air by repeated freezing and pumping. The temperature of the apparatus was adjusted to $25^\circ C.$, and purified hydrogen admitted. The hydrogen used was purified by being passed through a hot palladium thimble (6) and a liquid nitrogen trap. When the desired partial pressure of hydrogen was reached (usually 726 mm.) the stopcock was closed and the apparatus detached from the vacuum system. A solution of hydrogen was then prepared by shaking

the apparatus vigorously for 15 minutes. That this procedure succeeded in giving a saturated solution was verified by collecting and measuring the dissolved gas, by the method described below. The amount collected was 2.5×10^{-5} moles, which corresponds to a concentration of hydrogen in the solution of 7.6×10^{-4} moles/liter. The accepted value of the solubility at 25° C. and a partial pressure of 726 mm. is 7.52×10^{-4} moles/liter (19).

Irradiation Method

The source consisted of three capsules each holding approximately 70 curies of Co^{60} . The capsules could be moved radially within a lead castle and a high intensity of radiation resulted when all three were brought in contact with the solution container. The rate of energy deposition within the radiation cell was determined by the standard ferrous ion method. The *G*-value of this dosimeter was taken as 15.5 ions oxidized per 100 ev. absorbed (10). Most of the experiments described below were done with a dose rate of 1.01×10^{22} ev./liter/hr. The temperature of the source room was $25 \pm 2^\circ \text{C}$.

Method of Collecting Dissolved Gas

Immediately after each irradiation the solution in the capillaries was frozen, by surrounding the capillaries with pulverized dry ice, and the hydrogen gas in the bulb was pumped off and discarded. During this step the irradiated solution remained intact, being protected from degassing by the ice in the capillaries. After the ice had melted, the apparatus was inverted and the irradiated solution was degassed by being heated to 50° C. The liquid was then frozen with a slurry of dry ice in acetone. The gas was collected by an apparatus consisting of a liquid nitrogen trap, for removal of water vapor, a Toepler pump modified to serve also as a McLeod gauge, and a detachable calibrated gas holder (volume about 3 ml.). The collected gas was then analyzed with a mass spectrometer, and the liquid used as a solvent for hydrogen in the next experiment. Repeated use of the liquid was permissible since its deuterium content was reduced by only one part in 10^5 in each experiment.

Deuterium Analysis

The isotopic composition of the extracted gas was determined with a Model 21-201 Consolidated Nier mass spectrometer. The instrument was calibrated by a method similar to that of Alfin-Slater, Rock, and Swislocki (1). Known mixtures of HD and H_2 were prepared from heavy water solutions by the zinc reduction method (9). Mass spectrometric analysis of the gases obtained yielded the mass 3: mass 2 ratios given in Table I. The calibration curve is shown in Fig. 2. A standard experimental procedure was followed in all the mass spectrometric analyses, and care was taken to minimize instrumental errors such as the "memory effect" (1, 11).

RESULTS

Exchange Equilibrium

Results showing the progress of the radiation-induced exchange reaction are shown in Fig. 3 where the deuterium content of the dissolved gas is plotted against irradiation time and dose. The values obtained on prolonged irradiation (not shown in Fig. 3) are given in Table II, together with values of the equilibrium constant for the reaction

calculated from these data. The average value of this equilibrium constant is 0.83. The equilibrium constant for the exchange written in Equation 1 is the reciprocal of this quantity, i.e. approximately 1.2. This value may be compared with the known equilibrium constants for the catalyzed exchange, viz. 3.6 at 25° C. and 1.2 at 750° C. (4, 17).

TABLE II

EXCHANGE EQUILIBRIUM FOR THE RADIATION INDUCED
REACTION: $\text{H}_2 + \text{HDO} \rightleftharpoons \text{HD} + \text{H}_2\text{O}$

Mole % D_2O in water	Irradiation time (hours)	Atom % deuterium in gas	K_{eq}
0.382	41.4	0.306	0.80
0.749	65.0	0.643	0.86

FIG. 3. Progress of radiation induced exchange of deuterium between heavy water solution and dissolved hydrogen.

FIG. 4. Graphical test of exponential exchange law. F is the fractional exchange.

Exchange Kinetics

Consideration of the kinetics of simple exchange reaction shows that the transfer of a tracer atom follows an exponential law (5, 7, 18). Conformity to this law is revealed by a linear relation between $\log(1-F)$ and time, where F is the fractional exchange; here, the fractional exchange is the ratio of the deuterium content of the gas at time t to the content when equilibrium is reached. Values of F were calculated for the data given in Fig. 3 using as equilibrium compositions the experimental compositions of the gas obtained after prolonged irradiation (Table II). In Fig. 4 $\log(1-F)$ is plotted against time of irradiation and it is seen that the results conform satisfactorily to the theoretical relationship. Furthermore the results with two concentrations of heavy water fall on the same line.

Calculation of Exchange Rate, R

In considering the effect of experimental variables, it is convenient to define the exchange rate, R , as the number of gram-atoms of hydrogen (including deuterium) exchanged per liter per hour. It may be shown (18) that R is related to the change of F by the equation:

$$Rt = -(A)(B)/[(A)+(B)] \ln(1-F) \quad [2]$$

(A) and (B) are the concentrations of the two compounds participating in the exchange, expressed as gram-atoms of the exchanging element per liter. Since here the water concentration, (B), is vastly greater than the molecular hydrogen concentration, Equation 2 reduces to:

$$Rt = -(A) \ln(1-F) \quad [3]$$

or

$$R = -2.303(A) d \log(1-F)/dt. \quad [4]$$

(A) is the number of gram-atoms of hydrogen, in the form of molecular hydrogen, per liter, i.e. twice the solubility of hydrogen in moles per liter. For the results plotted in Fig. 4, (A) is 1.50×10^{-3} gram-atoms per liter. When this value, together with the slope of the line in Fig. 4, is substituted in Equation 4, R is found to be 1.57×10^{-4} gram-atoms/liter/hr. with a dose rate of 1.01×10^{22} ev./liter/hr.

Calculation of Exchange Yield, G

The yield of a radiation induced reaction is expressed as the number of atoms produced by 100 ev. of absorbed energy, and is designated by G . If the dose rate is d electron volts per liter per hour and the exchange rate is R gram-atoms/liter/hr., the exchange yield is given by:

$$G = 100N_A R/d \quad [5]$$

N_A is Avogadro's number. The results shown in Fig. 4 give a G -value of 0.94 hydrogen atoms exchanged per 100 ev.

Effect of Dose Rate on R and G

Energy deposition in the irradiated solution was reduced from 1.01×10^{22} ev./liter/hour to 0.185×10^{22} ev./liter/hr. by withdrawing each Co^{60} capsule 4.5 cm. from the solution container. Irradiations of 5.46 and of 10.92 hours were done, and the values of R and G calculated using Equations 4 and 5. The results are shown in Table III. A more than fivefold change in dose rate is seen to have very little effect on the exchange yield.

TABLE III
EFFECT OF DOSE RATE ON R AND G
Hydrogen pressure, 726 mm. Mole % D_2O in water, 0.749.

Dose rate, ev./l./hr.	Exchange rate, R , g-atom/l./hr.	Exchange yield, G , atoms per 100 ev.
1.01×10^{22}	1.57×10^{-4}	0.94
0.185×10^{22}	0.320×10^{-4}	1.04

Effect of Hydrogen Concentration

In one experiment the partial pressure of hydrogen was reduced from 726 mm. to 363 mm. and the resulting solution irradiated for 1 hour. It was assumed that the concentration of dissolved hydrogen was proportional to the partial pressure. The results are shown in Table IV. Evidently R and G are not strongly dependent on hydrogen concentration.

TABLE IV
EFFECT OF CONCENTRATION OF DISSOLVED HYDROGEN
Mole % D_2O in water, 0.749. Dose rate, 1.01×10^{22} ev./l./hr.

Partial pressure of hydrogen, mm.	Exchange rate, R , g-atom/l./hr.	Exchange yield, G , atoms per 100 ev.
363	1.65×10^{-4}	0.99
726	1.57×10^{-4}	0.94

Irradiation of Gas-free Water

A conceivable interpretation of the foregoing results was that H_2 and HD were being formed by direct decomposition of the heavy water solution. This possibility was explored in an experiment where the addition of hydrogen was omitted entirely, the liquid used being degassed by alternate freezing and pumping until the pressure of gas, non-condensable by liquid nitrogen, was 0.004 mm. The degassed liquid was then irradiated at maximum intensity for 20 hours. After the irradiation, the degassing procedure was repeated and the total amount of gas present in the apparatus measured. The quantity of gas found was barely measurable with the apparatus used, being at most 10^{-8} moles. Since approximately 2×10^{-5} moles of gas would be needed to explain the observed production of HD , it is clear that solution decomposition cannot account for the apparent exchange.

The D_2 - H_2O Exchange

An attempt was made to follow the exchange by observing the alteration in the isotopic composition of the liquid instead of the gas. In one experiment natural water (0.015 mole % D_2O) was saturated with deuterium gas (99.5% D_2) at one atmosphere pressure, and the solution was irradiated at maximum intensity for 10 periods of 8 hours each. After each 8 hour period the water was resaturated with deuterium gas and again irradiated. At the end of the experiment the water was analyzed for HDO using an infrared method (14, 16). The deuterium oxide content, expressed as D_2O , was now 0.023 mole %. The increase, although definite, was too small to permit convenient quantitative study of the reaction. Furthermore, calculation of a reliable G -value is impossible because the D/H ratio of the dissolved gas is changing continuously throughout the experiment. The result does, however, show directly that water is involved in the exchange.

DISCUSSION

As the results given in this paper are of a preliminary nature, no extensive discussion of the exchange mechanism will be attempted. The observation that the G -value is independent of dose rate and hydrogen concentration is similar to the result obtained by Gordon and Hart for the D_2 - H_2O exchange (8). When the actual magnitudes of the G -values of the two exchanges are compared, interesting differences appear. For the D_2 - H_2O exchange Gordon and Hart reported a G -value of about 2.7 (8). This is about three times the values reported here for the H_2 -HDO exchange. As we have been able to obtain results in other experiments consistent with those of Gordon and Hart for the D_2 - H_2O system, there is no likelihood that the difference is experimental and it must be attributed to an isotope effect. This could be both in the initial process of forming radicals H or D and OH or OD from HDO and in the subsequent reactions of these species with D_2 or H_2 respectively.

The most interesting feature of the results reported above is the equilibrium state reached when irradiation is prolonged. It has been shown that here the isotopic composition of the gas approaches that of the heavy water solution, the apparent equilibrium constant for reaction [1] being 1.2. There is little doubt that the true equilibrium constant at 25° C. is 3.6 (4). This discrepancy shows that the radiation cannot be regarded as simply a catalyst for the exchange. Apparently the radiation itself dictates a final steady state, far removed from that for thermodynamic equilibrium at room temperature.

The results show clearly that there exists a "radiation steady state" which, in the absence of radiation, is metastable relative to the thermal equilibrium state. It has been pointed out that when one attempts to describe the radiation steady state by a formal equilibrium constant, the value obtained resembles that for thermal equilibrium at a high temperature (approximately 750° C.). More detailed interpretation of the radiation steady state requires consideration of the relative rates of production of H and D atoms and OH and OD radicals and knowledge of their subsequent reactions.

ACKNOWLEDGMENTS

The authors are greatly indebted to Dr. R. H. Betts for many valuable suggestions, and to R. Jones, J. H. Graham, and M. Daoust for doing the mass spectrometric analyses.

MASS SPECTROMETRIC STUDY OF THE SPECIES CS, SO, AND CCl₂ PRODUCED IN PRIMARY HETEROGENEOUS REACTIONS¹

L. P. BLANCHARD² AND P. LE GOFF

ABSTRACT

In a flow system and at very low pressures, the reactions of CS₂, H₂S, SO₂, and CCl₄, on pure and carburized tungsten ribbons, were studied at 1300–2000° K.

In the decomposition of CS₂, on *pure* tungsten, CS and S₂ are found—in that of H₂S, H₂ and S₂—in that of SO₂, O₂ and SO or S₂, according to the temperature—CCl₄ gives CCl₂, Cl₂, and Cl. H₂, S₂, and Cl₂ molecules are probably formed by recombination on the walls of atoms produced on the ribbon. With *carburized* tungsten the formation of S₂ and O₂ is replaced by that of CS and CO. On the contrary, no decarburization occurs with chlorine.

Ionization potentials of the different species are measured and the deduced bond dissociation energies are discussed.

INTRODUCTION

The details of the experimental technique used in this work have been described elsewhere (4). The substance which is to be decomposed is made to flow through a reaction chamber in which a tungsten ribbon has been mounted. The vapor, at a pressure of 10⁻⁵ mm. Hg, is pumped through the chamber at the rate of 5 liters per second. When the ribbon is heated to a temperature T , the steady state concentration of X changes from $[X]_0$ to $[X]_T$. It can be shown that the collision efficiency b leading to the decomposition of the gas is governed by the following equation: $b = (1-u)/v_m u$ where u is the ratio $[X]_T/[X]_0$, or that fraction of X which has not reacted, and v_m is a constant depending on the geometry of the reacting surface—in this case $v_m = 2.5$. Analyses of reactants and products are carried out by means of a mass spectrometer, the ionization chamber of which forms an integral part of the reaction vessel.

The ratio u is readily obtained from variations in the intensity of the parent-peak of X provided, of course, that no product from the reaction contributes to the intensity of this same peak. For all peaks in the spectrum of X , a ratio v of the intensity of each peak when the ribbon is hot to that when it is cold can be determined. The difference $(v-u)$ is proportional to the concentration of reaction products which contribute to the intensity of the peak under consideration. When products with mass peaks other than those observed in the spectrum of X are formed, a unit w proportional to the concentration of the product is obtained by taking the ratio of the intensity of each peak to that of the parent-peak X_0 .

As described in preceding articles (5, 6), results of investigations on the decomposition of hydrocarbon vapors on tungsten surfaces have brought to light the formation of a carbon (or tungsten-carbide) layer at the surface of the ribbon. Furthermore, the rate of diffusion of carbon in tungsten was found to play a fundamental role in the mechanisms of reactions, particularly so in the formation of methyl radicals (7). Results obtained on the role that this layer plays in the decomposition of substances containing sulphur or chlorine are given below.

Decomposition of CS₂

The decomposition of CS₂ on both pure and carburized tungsten ribbons was investigated from 1500° to 2100° K. The principal peak variations that were observed

FIG. 1. Relative variations of ion intensities in the mass spectrum of CS_2 with the temperature of a pure tungsten and a carburized tungsten ribbon.

have been reproduced in Fig. 1. For the sake of clarity all experimental points have been omitted, though the error involved is of the same order of magnitude as that shown in Fig. 4 for the decomposition of CCl_4 .

With increasing temperature the intensity of the parent-peak, mass 76, was found to decrease, starting from about 1400°K . This was accompanied by increases in the intensities of mass 44 (CS^+) and mass 64 (S_2^+), while that of mass 32 (S^+) remained essentially constant. From the observed peak increases, one would be led to believe that CS_2 decomposes as follows:

Furthermore the nature of these products was confirmed by the measurement of their appearance potentials (A.P.)—mass 32 (S^+): 12.5 ± 0.4 v.; mass 44 (CS^+): 11.8 ± 0.2 v.; and mass 64 (S_2^+): 10.0 ± 0.3 v.—which were determined with the tungsten ribbon maintained at 1850°K . The A.P.'s of the last two peaks are not incompatible with the figures given by Smyth and Blewett (10) namely:

$$10.6 \pm 0.3 \text{ v. for } \text{CS}^+ \text{ from CS and } 10.7 \pm 0.3 \text{ v. for } \text{S}_2^+ \text{ from } \text{S}_2.*$$

Though the presence of atomic sulphur could not be detected even from the A.P. of mass 32, given above,—the ionization potential (I.P.) of S being 10.3 volts (3)—thermodynamic calculations (12) show that the sulphur leaving the hot ribbon should be in the atomic state. A high probability of recombination (≈ 1) of S on the reactor walls would readily explain its *apparent* absence. This is supported by the fact that the usual polymers of sulphur were observed: S_2 , some S_4 , but no S_3 or S_5 .

Dyne and Ramsay (1) found that CS radicals have a relatively long life—up to 4 minutes—which seems to have been borne out in this work by the fact that no recom-

*The above results along with the A.P. of CS^+ from CS_2 , which was found to be 15.7 ± 0.1 v., enabled the dissociation energy of the bond (SC—S) to be calculated at 90 ± 7 kcal. per mole. It is interesting to note that though the A.P.'s of the ions CS^+ from CS and from CS_2 were both about 1 volt above the figures reported earlier (10), the difference between the two values led to a dissociation energy of the bond (SC—S) which is in good agreement with that given in this last reference.

bination products of CS were detected. This leads to reactions for the decomposition of CS₂ which agree both with experimental results and thermodynamics:

The possibility that CS₂ decomposed directly to sulphur and carbon was discarded when no carbon monoxide was formed after the carbon disulphide was replaced by oxygen on the hot non-carburized tungsten ribbon. Trace amounts of carbon dissolved in tungsten are known to be highly reactive in the presence of oxygen (6, 8).

When the pure tungsten was replaced by a ribbon containing under 3% carbon by weight, the decomposition of CS₂ at all temperatures was found to proceed at a faster rate. The main difference, however, resided in the fact that at 1700° K. the intensity of mass 64 (S₂⁺) went through a maximum. At the same time mass 44 (CS⁺) increased more than in the previous case.

From 1400° to 1700° K. the decomposition of CS₂ appears to be the same as in reactions [II] and [III]; above 1700° K, when the mobility of carbon in tungsten becomes great, the surface of the ribbon is supplied with a more than ample amount of carbon, and under these conditions, decarburization of the tungsten begins to take place by the following reaction:

From known thermodynamic properties though in general they were poorly defined (9, 12), it was possible to verify that the reactions postulated for the decomposition of CS₂ are possible under the operating conditions that were used: temperatures between 1300° K. and 2100° K. and a pressure of CS₂ equal to 2×10⁻⁵ mm. mercury. It should be noted however, that it is practically impossible to calculate with any degree of accuracy from this data the equilibrium constant of reaction [IV]. For example at 2000° K. it is found that the value of *K* lies somewhere between 3×10⁻⁶ and 7×10⁻⁴. It will be seen further on that CS and CS₂ are found simultaneously in the decomposition products of H₂S and SO₂, coming from a carburized tungsten ribbon, which tends to prove that even at 2000° K. and at a pressure of 10⁻⁵ mm. mercury the equilibrium of reaction [IV] is not entirely displaced to the right, as is the case in the analogous reaction:

On pure carbon surfaces, even at the highest temperature—2100° K.—no decomposition of CS₂ could be detected.

Decomposition of H₂S

In the decomposition of H₂S on pure tungsten the observed products are S₂ and H₂. Here, as in the case of CS₂, atomic sulphur is believed to come away from the hot tungsten surface and undergo a recombination process on the cooler reactor walls. As pointed out earlier (4) it is not possible to establish whether hydrogen is formed on the hot ribbon in the atomic or molecular state.

The search for HS radicals was somewhat misleading. As shown in Fig. 2, the curve for mass 33 (HS⁺) lies slightly above that for mass 34 (H₂S⁺). To explain this it must be remembered that the error involved in the experimental points that determined the position of these curves is almost as large as the difference existing between the two

FIG. 2. Relative variations of ion intensities in the mass spectrum of H_2S with the temperature of a pure tungsten and a carburized tungsten ribbon.

curves. Furthermore a study of the appearance potential of HS^+ at different ribbon temperatures showed no variations in the observed value: 12.7 ± 0.4 volts.

On carburized tungsten the decomposition of H_2S proceeded at a faster rate at all temperatures. H_2 , CS , and CS_2 were the principal products. As shown in Fig. 2 a very small concentration of S_2 was observed—the dashed line plotted at 100 times its actual height. This concentration dropped off above 1800°K , while that of CS increased sharply. This is explained by the fact that decarburization of the ribbon by sulphur becomes important only when the mobility of carbon in tungsten is sufficiently great, i.e. above 1800°K .

Again no HS radicals could be detected.

Above 1800°K , the deviation of the S^+ curve away from the H_2S^+ curve is attributed to the contributions from CS and CS_2 .

The ionization potential of the CS radical was again easily measured. The figure obtained, 11.9 ± 0.3 v., agrees well with that obtained during the decomposition of CS_2 . The A.P. of S_2^+ was 10.3 ± 0.2 v. in both cases, i.e., on pure tungsten and on carburized tungsten. This corresponds to the I.P. of S_2 (10).

Summarizing the decomposition of H_2S :

(a) On pure tungsten

(b) On carburized tungsten

(c) While on pure carbon surfaces, no decomposition could be detected even at 2100°K .

Decomposition of SO_2

The decomposition of SO_2 on pure and carburized tungsten was investigated from 1300° to 2100° K. On *pure tungsten* the appearance potential of mass 64, which was 13.0 ± 0.3 v. at 1300° K.—this being the ionization potential of $\text{SO}_2(11)$ —was only 10.7 ± 0.5 v. at 1900° K. As this corresponds to the I.P. of S_2 , it was concluded that S_2 , especially at the higher temperatures, is an abundant final product of the reaction. Since this substance also contributes to the intensity of mass 64, the parent-peak of SO_2 , it was not possible to associate variations in intensity of this peak with the relative abundance u of SO_2 in the reaction chamber. This fact is illustrated further by the curves in Fig. 3.

Fig. 3. Relative variations of ion intensities in the mass spectrum of SO_2 with the temperature of a pure tungsten and a carburized tungsten ribbon.

It can be seen that v of SO_2^+ does not decrease as rapidly as does v of SO^+ . In fact above 1700° K., v of SO_2^+ assumes a greater value than that for v of SO^+ . The true curve u for SO_2^+ lies somewhere below the v curves given in this figure.

The small but definite difference which was found between v of SO^+ and v of SO_2^+ indicated that some SO was formed, especially between 1300 and 1700° K. The appearance potential of SO^+ from SO_2 , which was 16.1 ± 0.2 v., dropped to 12.1 ± 0.3 v. when the temperature was raised to 1700° K. This new potential is believed to be the ionization potential of the substance SO^* .

The continuous increase in v of mass 32 with increasing temperature from about 1700° K. was attributed to the formation of O_2 when the appearance potential of this peak at 1900° K. was found to be 12.6 ± 0.2 v. This figure agrees well with the I.P. of O_2 , which is reported to be 12.5 v. (3) and not with that of atomic sulphur at 10.3 v. From these results it was concluded that below 1700° K. and on pure tungsten the decomposition of SO_2 proceeded as follows:

*From the above potentials a dissociation energy for the bond (OS—O) was calculated at 92 ± 7 kcal. per mole assuming, of course, the usual restrictions: no excess of electronic or kinetic energy.

From the previously mentioned thermodynamic data (9, 12), it was found that at equilibrium the ratio $[\text{SO}]/[\text{SO}_2]$ should be 0.015 at 1300° K. and 1.5 at 2000° K. for a pressure of SO_2 of about 10^{-5} mm. Hg.

On the other hand, above 1700° K. one would be led to conclude that SO_2 decomposes according to reaction [IX]:

But this reaction is impossible from a thermodynamic point of view since, even at 2000° K., the ratio $[\text{O}_2]/[\text{SO}_2]$ would not surpass 0.05 at equilibrium.

Instead, reaction [X],

is postulated, since calculations show that at 2000° K. the ratio $[\text{O}_2]/[\text{SO}_2]$ should be approximately 1.6 at equilibrium. Furthermore it was shown in the decomposition of CS_2 that S_2 at these temperatures is entirely dissociated, and that the apparent absence of atomic sulphur can only be explained by a rapid recombination on the cooler walls.*†

On carburized tungsten the reaction proceeded in general at a faster rate. The formation of O_2 and some S_2 observed on pure tungsten gave way to an abundance of CO and CS. As in the case of H_2S , the simultaneous formation of CS and CS_2 was again observed though the abundance of CS_2 was relatively small. As can be seen in Fig. 3, at the lower temperatures a greater amount of SO was formed. A measurement of the appearance potential of this peak confirmed the presence of the particle SO. Again the peak at mass 64 was perturbed by the formation of a lesser amount of S_2 —identified by A.P. determination.

At temperatures as low as 1200° K., SO_2 invariably reacts with carbon on the surface of the ribbon according to reaction [XI]:

But as the temperature is raised to approximately 1700° K. the instability of SO becomes more important, resulting in further reactions with carbon (see reaction XII) with the subsequent equilibrium of reaction [IV].

It was calculated that at equilibrium, reaction [XII] is totally displaced to the right even at 2000° K. The particle SO in the presence of carbon is thus seen to be unstable. The big increase with temperature of peak 32 must be attributed to S^+ ions from the spectra of CS and CS_2 : its appearance potential curve presents two breaks around 12.5 v. and 14 v.

Attempts to decompose SO_2 on pure carbon drew negative results even at 2100° K.

Decomposition of CCl_4

The mass spectrum of CCl_4 ‡ showed that the intensity of the parent-peak was too small to follow any changes occurring in the abundance of this substance, and conse-

*During the decomposition of SO_2 on pure tungsten small concentrations of CO and CS were recorded. The presence of these substances is explained by the decomposition of hydrocarbon vapors coming from the vacuum pumps. This vapor though at a pressure of 10^{-8} mm. Hg deposits between 20 and 30 atoms of carbon per molecule on the tungsten surface (6, 8), which in turn are immediately transformed to CO and CS.

†At the temperatures used in this work, the compound WS_2 would be completely dissociated (9).

‡Mass spectrum of CCl_4 with an electron energy of 50 ev.: $\text{CCl}_4^+ < 0.1$; $\text{CCl}_3^+ = 100.0$; $\text{CCl}_2^+ = 26.8$; $\text{CCl}^+ = 32.7$; $\text{Cl}^+ = 23.8$; $\text{Cl}_2 \approx 2$; $\text{Cl}^- \approx 0.5$.

quently that recourse to some other peak was necessary. A study of the ion CCl_3^+ revealed that though the intensity of this peak decreased with increasing temperature, its appearance potential remained constant at 11.7 ± 0.3 v.† As this figure is much higher than the I.P. of the CCl_3 radical—8.78 volts (2)—it was assumed that the concentration of CCl_3 radicals formed by the decomposition reaction of CCl_4 was insignificantly small and that the intensity of the CCl_3^+ peak at all temperatures was therefore proportional to the concentration of CCl_4 in the system.

The large increase in intensity of the CCl_2^+ peak—see Fig. 4—would indicate that CCl_2 radicals were formed in the reaction. The contribution of these radicals to the CCl^+ peak would readily explain the moderate difference that was found to exist between u and v of CCl^+ .

FIG. 4. Relative variations of ion intensities in the mass spectrum of CCl_4 with the temperature of a pure tungsten ribbon.

The decomposition of CCl_4 gave rise not only to CCl_2 radicals but also to chlorine, as can be seen from the increases in intensity of mass 35 and mass 70. It would appear from the curves in Fig. 4 that Cl_2 was the predominant product below 1600°K ., while the abundance of Cl atoms assumed a greater importance above 1600°K . This result is supported by the fact that at 1700°K . the A.P. of mass 35 was 13.2 ± 0.2 v., a value which agrees with the I.P. of Cl at 13.00 v. (3). However it must be noted that thermodynamic calculations show that at equilibrium chlorine should leave the ribbon entirely in the atomic state at any of the temperatures here considered.

On carburized tungsten the results were essentially the same as were obtained with pure tungsten, leading to the conclusion that chlorine or chlorinated compounds do not react rapidly—if at all—with carbon dissolved in tungsten as is the case with compounds

† This result agrees well with two other determinations: 11.67 ± 0.10 (2) and 11.83 ± 0.05 v. (13).

containing oxygen or sulphur. This excluded in particular the following interesting reaction:

With the ribbon maintained at 1700°K. , the I.P. of the CCl_2 radical was $13.2 \pm 0.2 \text{ v.}$, and the A.P. of CCl^+ from CCl_2 was $16.3 \pm 0.2 \text{ v.}$ The A.P.'s of the corresponding ions obtained from CCl_4 were respectively: $16.5 \pm 0.2 \text{ v.}$ and $19.4 \pm 0.1 \text{ v.}$ With these figures two different values for the dissociation energy of the (CCl_2-Cl) bond have been calculated. This situation arose from the fact that the nature of the species— Cl , Cl_2 , or Cl^- —formed in the ionization-dissociation process along with the positive ions is not known. The energies involved in the formation of these substances are quite large and cannot be overlooked—the electronic affinity of chlorine being 3.8 volts and the dissociation energy of the $(\text{Cl}-\text{Cl})$ bond being 2.47 volts. The four possible processes involved in the formation of CCl_2^+ ions from CCl_4 are given in Table I.

TABLE I
ENERGY CHANGES INVOLVED IN THE PROCESSES THAT YIELD CCl_2^+ FROM CCl_4

No.	Ionization process	Δ_I in volts
Ia	$e^- + \text{CCl}_4 \rightarrow \text{CCl}_2^+ + 2\text{Cl} + 2e^-$	0.0
Ib	" $\rightarrow$ " $+ \text{Cl}_2 + 2e^-$	2.47
Ic	" $\rightarrow$ " $+ \text{Cl} + \text{Cl}^- + e^-$	3.8
Id	" $\rightarrow$ " $+ 2\text{Cl}^-$	7.6

Assuming that the particles do not have any excess electronic or kinetic energy, the equation for the A.P. of CCl_2^+ from CCl_4 can be written as follows:

$$[1] \quad A(\text{CCl}_2^+, \text{CCl}_4) = I(\text{CCl}_2) + D(\text{CCl}_2-\text{Cl}) + D(\text{CCl}_3-\text{Cl}) - \Delta_I$$

where Δ_I is a term which is readily deduced from the electronic affinity of chlorine or the dissociation energy of the $(\text{Cl}-\text{Cl})$ bond, and assumes a different value depending on the process involved (see Table I).

The formation of CCl^+ from CCl_4 can be obtained by five different processes. These have been outlined in Table II along with the various energies Δ_{II} involved, the A.P. equation in this case being:

$$[2] \quad A(\text{CCl}^+, \text{CCl}_4) = I(\text{CCl}) + D(\text{CCl}-\text{Cl}) + D(\text{CCl}_2-\text{Cl}) + D(\text{CCl}_3-\text{Cl}) - \Delta_{II}$$

The A.P. equation for the formation of CCl^+ from CCl_2 is as follows:

$$[3] \quad A(\text{CCl}^+, \text{CCl}_2) = I(\text{CCl}) + D(\text{CCl}-\text{Cl}) - \Delta_{III}$$

where Δ_{III} in this case depends on one of two possible processes (see Table III).

TABLE II
ENERGY CHANGES INVOLVED IN THE PROCESSES THAT YIELD CCl^+ FROM CCl_4

No.	Ionization process	Energy Δ_{II} in volts
IIa	$e^- + \text{CCl}_4 \rightarrow \text{CCl}^+ + 3\text{Cl} + 2e^-$	0.0
IIb	" $\rightarrow$ " $+ \text{Cl}_2 + \text{Cl} + 2e^-$	2.47
IIc	" $\rightarrow$ " $+ 2\text{Cl} + \text{Cl}^- + e^-$	3.8
IId	" $\rightarrow$ " $+ \text{Cl}_2 + \text{Cl}^- + e^-$	6.27
IIe	" $\rightarrow$ " $+ \text{Cl} + 2\text{Cl}^-$	7.6

TABLE III
ENERGY CHANGES INVOLVED IN THE PROCESSES THAT YIELD CCl^+ FROM CCl_2

No.	Ionization process	Energy Δ_{III} in volts
IIIa	$e^- + \text{CCl}_2 \rightarrow \text{CCl}^+ + \text{Cl} + 2e^-$	0.0
IIIb	$e^- + \text{CCl}_2 \rightarrow \text{CCl}^+ + \text{Cl}^- + e^-$	3.8

Substituting in equations [1], [2], and [3] the numerical values obtained in this work along with the dissociation energy of the bond ($\text{CCl}_3\text{—Cl}$) reported recently by Lossing *et al.* (2)— 2.95 ± 0.15 v.—two expressions for the dissociation energy of the ($\text{CCl}_2\text{—Cl}$) bond were deduced:

$$(a) D(\text{CCl}_2\text{—Cl}) = \Delta_{\text{I}} + 0.35 \pm 0.4 \text{ volts,}$$

$$(b) D(\text{CCl}_2\text{—Cl}) = \Delta_{\text{II}} - \Delta_{\text{III}} + 0.15 \pm 0.4 \text{ volts.}$$

An examination of the data given in Tables I, II, and III will show that two and only two solutions will satisfy both equations simultaneously.

First solution: $\Delta_{\text{I}} = \Delta_{\text{II}} = 2.47$ v. and $\Delta_{\text{III}} = 0$;
hence $D(\text{CCl}_2\text{—Cl}) = 62 \pm 7$ kcal./mole.

In this case the actual processes involved would be Ib, IIb, and IIIa, thus indicating that the ionization-dissociation of CCl_4 tends towards the formation of Cl or even Cl_2 when possible, and away from the formation of Cl^- .

Second solution: $\Delta_{\text{I}} = \Delta_{\text{III}} = 3.8$ v. and $\Delta_{\text{II}} = 7.6$ v.
hence $D(\text{CCl}_2\text{—Cl}) = 93 \pm 7$ kcal./mole.

In this case the actual processes involved would be Ic, IIc, and IIIb. The tendencies would be reversed, favoring the formation of Cl^- .

The authors are inclined to believe that the first solution is the more likely one. The value 93 kcal./mole for $D(\text{CCl}_2\text{—Cl})$ is highly improbable since it is so much greater than that of $D(\text{CCl}_3\text{—Cl}) = 67.9 \pm 3$ kcal./mole (2).

In the somewhat analogous problem of the four C—H bond dissociation energies in methane, $D(\text{CH}_2\text{—H})$ is probably about the same or not much greater than $D(\text{CH}_3\text{—H})$.

Furthermore with an electron potential of 50 volts, the intensity of the Cl^- peak was less than 0.005 times the intensity of the CCl_3^+ peak. It could be concluded that negative ions, Cl^- , do not perturb the appearance potential measurements. Restrictions nevertheless have already been made for this type of reasoning (2).

Further results on the influence of the carbon content of tungsten on the heterogeneous reactions of these and other gaseous substances are to be published soon in the "Journal de Chimie Physique".

RÉSUMÉ

On étudie les réactions, à très basse pression et en régime dynamique, de CS_2 , H_2S , SO_2 et CCl_4 , sur des rubans de tungstène pur ou carburé portés à $1300^\circ\text{--}2000^\circ\text{K}$.

Dans la décomposition de CS_2 sur tungstène *pur*, on observe les particules CS et S_2 —dans celle de H_2S , on trouve H_2 et S_2 —dans celle de SO_2 , on trouve O_2 et SO ou S_2 suivant la température, enfin CCl_4 donne CCl_2 , Cl_2 et Cl. Les molécules H_2 , S_2 et Cl_2 résultent probablement de la recombinaison sur les parois d'atomes formés sur le ruban. Sur

métal *carburé*, la formation de S_2 et O_2 est remplacée par celle de CS et CO. Par contre, le chlore ne donne lieu à aucune décarburation du métal.

On mesure les potentiels d'ionisation des diverses particules formées et on discute les valeurs des énergies de dissociation de liaisons qui s'en déduisent.

ACKNOWLEDGMENTS

The assistance of Miss Ruth Valentin in obtaining many of the experimental results is gratefully acknowledged.

The work described here was carried out in the laboratories of Professor M. Letort, to whom the authors are indebted for the facilities which were placed at their disposal.

One of us (L.P.B.) is indebted to the National Research Council of Canada for a Postdoctorate Overseas Fellowship.

NOTES

EFFECT OF pH ON THE SEDIMENTATION OF SERUM ALBUMINS AND OVALBUMIN¹

P. A. CHARLWOOD² AND ADOLF ENS

Recent density measurements (3) in these laboratories have shown that the change in partial specific volume of ovalbumin between pH 5 and pH 2 is in quantitative agreement with expectation, whereas bovine, human, and horse serum albumins show a change less than that predicted from titration data. If this lack of agreement were due to alterations in molecular configuration, these changes could also affect the sedimentation rate. Since no references to the pH dependence of the sedimentation coefficients of ovalbumin and human serum albumin could be found and published data on horse and bovine serum albumins were inadequate, these four proteins were investigated over the pH range 2 to 10.

The proteins were taken from the batches used in the density studies (3), stock solutions in many cases being identical. Immediately before sedimentation measurements, the protein solutions, which had been dialyzed near pH 5, were mixed with suitable buffers to give a protein concentration of 0.32 to 0.36% and a total ionic strength of 0.2, of which 0.15 was due to potassium chloride. A few samples of bovine serum albumin, after being examined close to pH 2.8, were redialyzed to pH 2.0 or pH 6.6.

Sedimentation measurements were made at 59,780 r.p.m. in a Spinco ultracentrifuge, in the usual way. Ten photographs were taken at 8-minute intervals during each run. The rotor temperature was automatically controlled at 25.0° C.

The results (Fig. 1), corrected to water at 20° C. using the partial specific volume values recently obtained at pH 5 (3), refer to finite protein concentrations, but will differ only slightly from values extrapolated to zero concentration (5, 7), and will show the same variation with changes in pH. Ovalbumin shows a constant value of $s_{20,w}$ in the ranges pH 1.9 to 3.5 and pH 4.0 to 9.7, a barely perceptible increase occurring between pH 3.5 and pH 4.0. The sedimentation coefficients of the three serum albumins show a pronounced rise between pH 2 and pH 5, and then either remain constant or decrease slightly. The results of Svedberg and Sjögren (9) for horse serum albumin show the same trend as those in Fig. 1, but are rather widely scattered, a result partially attributable to their wider range of protein concentration.

An aggregate appeared in bovine serum albumin solutions near pH 2.8, which seemed to dissociate almost reversibly on dialysis to lower or higher pH (Fig. 2). Saroff *et al.* (8) and Bro *et al.* (1), studying 1% solutions of this protein at low pH in the ultracentrifuge, have also observed aggregates. Points shown on the curve in Fig. 1 refer only to the non-aggregated component. Harrington *et al.* (5), working with bovine serum albumin between pH 2 and pH 5, obtained results similar to those recorded in Fig. 1.

Apart from this exception, no evidence for alterations in the molecular weights of the albumins at low pH was found (5, 7, 11, 12). The striking alterations in the sedimentation coefficients of the serum albumins between pH 5 and pH 2 must, therefore, be ascribed

FIG. 1. Sedimentation coefficients of albumins as a function of pH at ionic strength 0.2. (Protein concentration approximately 0.35%.)

FIG. 2. Ultracentrifuge patterns of bovine serum albumin (0.35%) in ionic strength 0.2 solution, 80 minutes after top speed (59,780 r.p.m.) was reached. Sedimentation is from right to left: (A) pH 2.8; (B) pH 6.6, redialyzed from pH 2.8; (C) pH 2.0, redialyzed from pH 2.8.

to an expansion or unfolding of the molecules, for which evidence has also been adduced on other grounds (10, 11, 12). The exact nature of this molecular alteration is still a matter of discussion (6).

The concept of an extension or expansion of the serum albumin molecules accords with the partial specific volume findings. The increase of $\bar{v}$ between pH 5 and pH 2 is much less than that expected on the basis of titration data. This would be accounted for if the altered configuration of the protein molecules at the lower pH permitted solvent to reach hitherto inaccessible, or "excluded", regions. Between pH 5 and pH 10, where the experimentally observed change in partial specific volume agrees with the calculated value, the change of sedimentation coefficient is small, or possibly zero.

The sedimentation coefficient of ovalbumin appears to be slightly, but significantly, lower in the low pH range. This indicates a small change in the molecular configuration, far less marked than for the serum albumins, and evidently too slight to be detected by density measurements. This behavior is in accord with other evidence indicating that the ovalbumin molecule is a fairly rigid compact structure which usually undergoes major alterations irreversibly (4).

NATURE OF THE ADSORPTION PROCESS RESPONSIBLE FOR JOSHI EFFECT

C. N. RAMACHANDRA RAO

The Joshi effect (2, 3, 4) (Δi) is the instantaneous and reversible variation of the discharge current observed when a gas discharge tube excited by an electric field is irradiated with a light source. This variation can be either a decrease or an increase in the current. On a cathode-ray oscillograph this effect is observed as a variation in the amplitude and/or number of pulses. While a decrease in the current due to irradiation is referred to as the negative Joshi effect ($-\Delta i$), an increase in the current is referred to as the positive Joshi effect ($+\Delta i$). One of the important steps in the mechanism of Joshi effect is the formation of an adsorption layer on the container walls due to adsorption of ions and excited particles. Although there is no direct experimental evidence to show that the adsorption process is fundamental to Joshi effect, many experimental results seem to support such a point of view.

to an expansion or unfolding of the molecules, for which evidence has also been adduced on other grounds (10, 11, 12). The exact nature of this molecular alteration is still a matter of discussion (6).

The concept of an extension or expansion of the serum albumin molecules accords with the partial specific volume findings. NATURE OF THE ADSORPTION PROCESS RESPONSIBLE FOR JOSHI EFFECT

C. N. RAMACHANDRA RAO

The Joshi effect (2, 3, 4) (Δi) is the instantaneous and reversible variation of the discharge current observed when a gas discharge tube excited by an electric field is irradiated with a light source. This variation can be either a decrease or an increase in the current. On a cathode-ray oscillograph this effect is observed as a variation in the amplitude and/or number of pulses. While a decrease in the current due to irradiation is referred to as the negative Joshi effect ($-\Delta i$), an increase in the current is referred to as the positive Joshi effect ($+\Delta i$). One of the important steps in the mechanism of Joshi effect is the formation of an adsorption layer on the container walls due to adsorption of ions and excited particles. Although there is no direct experimental evidence to show that the adsorption process is fundamental to Joshi effect, many experimental results seem to support such a point of view.

In this note, the nature of the adsorption process which is responsible for Joshi effect is discussed on the basis of a careful examination and analysis of experimental results.

(i) It has been found that in order to initiate Joshi effect in a freshly prepared discharge tube, it is necessary to "age" (maintain the discharge for a period of time) the tube at a constant potential (V) (3, 9). This time-development of the effect has been found to be a rate process, following the first order reaction rates (6). All the stages in the production of Joshi effect are instantaneous and fully reversible and consequently the time-development of Δi under "aging" is determined by the slowest step, the formation of the adsorption layer on the walls of the vessel. (ii) The kinetics of "aging" and the magnitude of $-\Delta i$ depend on the surface of the electrodes and that of the vessel (7). Coatings of polar substances like potassium chloride are found to increase the magnitude of $-\Delta i$ markedly. (iii) The influence of "aging" on the magnitude of Joshi effect is more prominent in soft soda glass vessels rather than in hard glass vessels or Geissler tubes (9). It is interesting to note that formation of surface compounds under discharge on the walls of the vessel (like NaCl in chlorine, NaBr in bromine, NaOH in water vapor, etc., due to combination with Na^+ ions liberated under discharge because of the electrolytic conduction of glass) is also greater on soft soda glass vessels (12). (iv) Δi is observed only at potentials, $V \geq V_m$, where V_m is the threshold potential of the discharge. The threshold potential of a discharge has been defined as that potential at or above which only chemical reactions can take place under discharge (2).

It has been often stated that physical adsorption is instantaneous and chemisorption takes time. So, physical adsorption of a gas would be complete within the first ~ 5 minutes after the introduction of the gas into the vessel. Although no definite generalizations can be made about the various possible species of particles produced in a discharge and the nature of their adsorption on glass, it is highly probable that chemisorption associated with large activation energy is fundamental to the formation of the adsorption layer, being particularly favored under discharge conditions (5). Accordingly, Mohanty finds that the energy of activation of the reaction during "aging" is of a high order (8). The non-occurrence of Joshi effect in inert gases is possibly due to their negligible chemisorption on glass under electrical discharge (1).

In the light of the above findings it can be seen that any theory of Joshi effect based on the physical adsorption of gases or vapors on the walls of the discharge tube is not feasible. Ramaiah (10), on the basis of his observation that Joshi effect in water vapor in a cleaned and degassed vessel was appreciable without "aging" and that "aging" disfavored the effect, concludes that physical adsorption of the gas is primary to the production of the Joshi effect. However, "aging" was found necessary to initiate the effect in iodine vapor even in a thoroughly cleaned and degassed vessel, by Saxena and the author (11). Since physical adsorption of a gas is determined by the critical temperature of the gas, it may be considerable in the case of chlorine or water vapor at laboratory temperatures. But the negative Joshi effect is observed (even up to 100% current suppression) in gases like hydrogen, oxygen, nitrogen, etc., the critical temperatures of which are very low compared to that of water vapor. It is therefore not possible to account for these observations on the basis of the physical adsorption of the gases on glass. On the other hand, it can be said that the magnitude of Joshi effect is more pronounced on surfaces favoring chemisorption or surface compound formation. Naturally, any such surface phenomenon as Joshi effect will be affected by the slightest change in the conditions of the surface of the vessel or the electrodes.

ACKNOWLEDGMENT

STUDIES OF HYDROXYL SUBSTITUTED GUAIACYL COMPOUNDS¹

E. A. KVASNICKA AND R. R. McLAUGHLIN

ABSTRACT

A new identification reaction for the distinction between α - and β - or γ -substituted guaiacyl derivatives is described. Relations between structure and distribution coefficients are given and a deviation from Reichl's rule noted. The synthesis of 1-(3-methoxy-4-hydroxyphenyl)-2-propanol is described.

In continuation of the identification of spruce sulphite liquor components (3) it became of interest to develop a method for the identification of lignin degradation products which contain aliphatic hydroxyl groups. As a beginning, the series of 3-methoxy-4-hydroxyphenyl propane compounds containing hydroxyl groups in the side chain was selected. For this purpose 1-(3-methoxy-4-hydroxyphenyl)-2-propanol was prepared by the reduction of the corresponding ketone, 1-(3-methoxy-4-hydroxyphenyl)-2-propanone. The other members of the series were already available.

It was found that diazotized *p*-nitraniline fluoborate and diazotized sulphanilic acid give color reactions with this series which permit a distinction to be made between the α -hydroxy compounds and the β - or γ -hydroxy compounds. Further, this color differentiation is not confined to the hydroxyl derivatives, but is valid also for compounds containing a carbonyl group in the α , β , or γ position in the side chain. These facts are illustrated in Table I.

TABLE I
COLOR REACTIONS OF SOME GUAIACYL DERIVATIVES

Reagent	Color with α -substituted derivatives	Color with β - or γ -substituted derivatives
Diazotized sulphanilic acid	Orange	Red
Diazotized <i>p</i> -nitraniline fluoborate	Purple	Gray blue
Derivatives tested (R = 3-methoxy-4-hydroxyphenyl group):		
	R·CH ₂ OH	R·CH ₂ ·CHOH·CH ₃
	R·CHOH·CH ₃	R·CH ₂ ·CH ₂ ·CH ₂ OH
	R·CHOH·CH ₂ ·CH ₃	R·CH ₂ ·CO·CH ₃
	R·CHO	R·CH ₂ ·COOH
	R·CO·CH ₃	R·CH ₂ ·CH ₂ ·COOH
	R·CO·CH ₂ ·CH ₃	
	R·CO ₂ ·H	

¹Manuscript received in original form November 14, 1955, and, as revised, June 26, 1956.
Contribution from the Department of Chemical Engineering, University of Toronto, Toronto, Ontario.

R_F values for the hydroxyl substituted compounds were determined from a large number of paper chromatograms, and from these the corresponding values of the expression $\log R_F/(1-R_F)$ were calculated. According to Reichl (4), in an homologous series such values consist of the sum of constants for each group in the molecule. Consequently, in such a series if the value for the first member in the series and the constants for each of the substituent groups be known, then the R_F value for a particular member of the series can be calculated. For the series studied here this is only partially true, for, as shown in Table II, whereas the value of $\log R_F/(1-R_F)$ changes uniformly as one and

TABLE II
RELATIONSHIP BETWEEN LENGTH OF SIDE CHAIN, POSITION OF HYDROXYL GROUP,
AND VALUE OF $\log R_F/(1-R_F)$ FOR CERTAIN GUAIACYL COMPOUNDS

Position of hydroxyl group	Compound	R_F	$\log \frac{R_F}{1-R_F}$	Compound	R_F	$\log \frac{R_F}{1-R_F}$	Compound	R_F	$\log \frac{R_F}{1-R_F}$
α	R·CH ₂ ·OH	0.06	-1.19	R·CHOH·CH ₃	0.17	-0.69	R·CHOH·CH ₂ ·CH ₃	0.39	-0.19
β				R·CH ₂ ·CH ₂ OH	0.10	-0.95	R·CH ₂ ·CHOH·CH ₃	0.26	-0.45
γ							R·CH ₂ ·CH ₂ ·CH ₂ OH	0.20	-0.60

then two methyl groups are added to the side chain, as shown horizontally opposite " α " and " β ", it does not remain constant (as according to Reichl it ought to do) since the hydroxyl group is moved from the α to the β to the γ position, as shown by the two right-hand vertical columns. Probably this is because of interaction between the hydroxyl group and the substituted benzene nucleus.

Ultraviolet spectra failed to provide a means of differentiation. The compounds examined were (R = guaiacyl group): R·CH₂OH, R·CH₂·CHOH·CH₃, R·CH₂·CH₂·CH₂OH, R·CH₂·CO·CH₃, R·CH₂·CH₂·COOH. All showed maximum absorption in 95% ethanol at 280.5–281.6 m μ which shifted to 294–297 m μ in *N* potassium hydroxide. The isosbestic points were in the ranges 283.2–286.5, 267.7–269.2, and 231–231.8 m μ .

EXPERIMENTAL PART

Preparation of 1-(3-Methoxy-4-hydroxyphenyl)-2-propanol

Vanillyl methyl ketone (6.5 g., 0.36 mole) was dissolved in 50 ml. methanol and 20 ml. 2 *N* sodium hydroxide was added. The addition of 1 g. sodium borohydride caused a slight evolution of gas. The mixture was heated slowly and refluxed for 1 hour on the steam bath. After concentration under reduced pressure to 12–15 ml. the solution was cooled and 25 ml. water added slowly. Diluted hydrochloric acid was added and the mixture extracted four times with 25 ml. portions of chloroform. The extract was shaken twice with an excess of sodium bisulphite solution (21%), dried over sodium sulphate, and transferred to a bulb tube. After evaporation of the solvent under reduced pressure, the residue was distilled (air bath, 130–150° C., 0.5 mm.) to yield an almost colorless, viscous liquid which solidified after a few hours. Yield: 5.27 g. (80%); m.p. 36–37° C.

Found: C, 66.02; H, 7.82; OCH₃, 17.12. Calc. for C₁₀H₁₄O₃: C, 66.07; H, 7.71; OCH₃, 16.94.

Color Reactions

(a) A 1% solution in acetone of diazotized *p*-nitraniline fluoborate was sprayed on the chromatogram, followed by treatment with alkali.

(b) Diazotized sulphanilic acid, prepared according to Koessler and Hanke (2), was sprayed on the chromatogram, followed by treatment with alkali.

R_F values for the compounds listed in Table II, and the method of measuring them, are recorded by the authors (3), with the exception of the value for 1-(3-methoxy-4-hydroxyphenyl)-2-ethanol, which was found by the method used in the reference just cited to be 0.10.

U.V. spectra were determined with a Beckmann Spectrophotometer (Model DU). Isosbestic points were determined by superposition of the neutral and basic (1 g. KOH/l.) spectra and of several spectra of solutions with intermediate pH values (1).

CONSTITUTION OF A DEGRADED POLYSACCHARIDE FROM WHEAT BRAN¹

J. SCHMORAK,² C. T. BISHOP, AND G. A. ADAMS

ABSTRACT

Graded acid hydrolysis of a soluble wheat bran hemicellulose containing L-arabinose (50%), D-xylose (38.5%), and D-glucuronic acid (9.0%) preferentially removed the L-arabinose giving an insoluble acidic polysaccharide in approximately 25% yield by weight. Methylation studies, periodate oxidation data, and hypoiodite end group estimations showed that the degraded polysaccharide was composed of repeating units of 7-8 D-xylopyranose residues joined by $\beta,1\rightarrow4$ linkages. To this repeating unit, one D-glucuronic acid unit was attached by a $1\rightarrow2$ glycosidic bond. The cellulolytic enzyme of *Myrothecium verrucaria*, which is specific for $\beta,1\rightarrow4$ glycosidic linkages, hydrolyzed the degraded polysaccharide although it had no effect on the parent hemicellulose.

A previous examination of a polysaccharide from wheat bran (3) showed that it was a complex polysaccharide containing L-arabinose, D-xylose, and D-glucuronic acid residues. The bran polysaccharide differed from other polysaccharides of the wheat plant including those from flour (14), straw (1), and leaf (2), by reason of more branching and the presence of more L-arabinose than D-xylose (3). The predominance of L-arabinose made it difficult to determine the mode of linkage between the smaller number of D-xylose residues by periodate oxidation and methylation studies. Partial acid hydrolysis followed by studies of enzyme action seemed to indicate that the xylan portion of the bran polysaccharide was structurally different from the other xylans isolated from the wheat plant (3). Therefore, to complete the investigation of polysaccharides of the wheat plant, it seemed desirable to attempt the isolation of a representative fraction of the xylan portion of the wheat bran polysaccharide and the determination of its structure. The results of this work are reported here.

In the previous investigation (3) a small amount of hexosan material was separated from the main portion of the pentosan hemicellulose by solvent fractionation of their acetates. However, the pentosan portion of the hemicellulose, which formed the starting material for the present investigation, did not yield more than one polysaccharide by any of three fractionation procedures. In the present work, two further attempts were made to see if more than one polysaccharide could be obtained from the arabinose-rich pentosan of wheat bran. The pentosan yielded identical fractions when fractionally precipitated by ethanol from water at pH 6.0 or 3.0 and electrophoresis of the pentosan in borate buffer revealed only one large band. It has already been shown (4) that the uronic acid units in wheat bran hemicellulose are linked glycosidically to the xylan portion of the polysaccharide and if the L-arabinose had been present as a separate, distinct araban, then electrophoresis should have shown two bands, one caused by the acidic xylan and one by the neutral araban. These results, together with those of the fractionation experiments, strongly suggested that in the pentosan portion of wheat bran hemicellulose the units of D-glucuronic acid, D-xylose, and L-arabinose are linked together in one polysaccharide.

To examine the structure of the xylan portion of the polysaccharide, it was necessary to reduce the arabinose content to a trace level. Partial hydrolysis by oxalic acid, under conditions established by a series of preliminary experiments, removed essentially all of the L-arabinose units, leaving a degraded acidic polysaccharide. The L-arabinose residues were split from the hemicellulose as monosaccharide units but the amount of D-xylose removed as such was relatively small. However, a considerable amount of D-xylose was removed by partial hydrolysis and must have been split off as dialyzable oligosaccharides because the yield of degraded acidic xylan (25.4%) was approximately equivalent to only 50% of the D-xylose present originally. The considerable decrease in degree of polymerization (D.P.), 300 to 7-8, caused by partial hydrolysis was further evidence of extensive molecular degradation. However, the D.P. estimations were based on reducing end group determinations and, being number average values, were measurements of the repeating units only and not of particle size. Therefore, it was felt that the residual acidic xylan, although severely degraded, could be regarded as reasonably representative of the xylan portion of the wheat bran polysaccharide.

Although the original polysaccharide was soluble in water, removal of the L-arabinose units resulted in complete water insolubility of the residue. These results are similar to those found by Perlin during a study of wheat flour pentosans (14) and were explained by the hypothesis that removal of L-arabinose side chains permits a closer association of the residual straight chain xylan resulting in a less soluble aggregate.

When oxidized by periodate, the degraded acidic xylan consumed 1.03 moles of periodate and yielded 0.46 moles of formic acid per mole anhydropentose unit while the undegraded hemicellulose had consumed 0.59 moles of periodate with the concurrent release of 0.18 moles of formic acid per anhydropentose unit. These increased values for periodate consumption and formic acid production were undoubtedly caused by the creation of more vicinal hydroxyl groups and more terminal units brought about by the removal of L-arabinose side chains and degradation of the xylan molecules.

The cellulolytic enzyme isolated from the mold *Myrothecium verrucaria* (16) hydrolyzed wheat straw xylan (5) but did not attack the pentosan from wheat bran even when 70% of the L-arabinose had been removed (3). However, removal of more L-arabinose resulted in a gradual increase in enzymic attack on the xylan residue by which a considerable quantity of oligosaccharides of D-xylose were liberated (Table I). It has been shown previously that the purified enzyme preparation used here is quite specific for $\beta,1\rightarrow4$ linkages between D-glucose (16) or D-xylose (5) residues. It was therefore con-

*Calculated as glucose.

cluded that the D-xylose residues in the degraded acidic xylan from wheat bran were linked $\beta,1\rightarrow4$ and that in the original hemicellulose, enzymic attack on these linkages was hindered by the large amount of L-arabinose present. In the previous investigation on wheat bran hemicellulose (3), resistance to enzyme action of the polysaccharide from which 70% of the L-arabinose units had been removed was attributed to a xylan structure different from the $\beta,1\rightarrow4$ type found in wheat straw and leaf.

The degraded acidic xylan from wheat bran was methylated and the methyl ether was fractionated. All fractions were identical so the methylated polysaccharide was methanolized and hydrolyzed to yield the following components: (1) 2-O-(2,3,4-tri-O-methyl-D-glucuronosyl)-3-O-methyl-D-xylose, (2) 2-O-methyl-D-xylose, (3) 2,3-di-O-methyl-D-xylose, and (4) 2,3,4-tri-O-methyl-D-xylose in approximate molar ratios of 1:0.5:5:1.

The 2,3,4-tri-O-methyl-D-xylose represented the non-reducing end group of the hemicellulose and the quantity recovered showed that there was one non-reducing end group for every 7-8 anhydropentose residues. The 2,3-di-O-methyl-D-xylose must have arisen from D-xylopyranose units linked through C₁ and C₄. The high proportion of this sugar showed that the polysaccharide had predominantly a straight chain structure. Confirmation of the identity of the methylated aldobiouronic with that previously examined in the original hemicellulose (4) was established from chromatographic evidence. The small amount of 2-O-methyl-D-xylose could have arisen from a branch point in the polysaccharide or from incomplete methylation. Because of the difficulty of detecting incomplete methylation, the structural significance of 2-O-methyl-D-xylose was difficult to assess.

On the basis of the experimental findings, it is possible to propose a structure for the degraded acidic xylan. It consists of repeating units made up of 7-8 D-xylopyranose residues joined by $1\rightarrow4$ linkages which are presumably in the β configuration because of the negative rotation of the polysaccharide and its methyl ether. To each repeating unit one D-glucuronic acid unit is attached by a $1\rightarrow2$ glycosidic bond and yields an aldobiouronic acid on hydrolysis. The size of the repeating unit was established by the methylation data, periodate oxidation, and hypoiodite end group estimation, all of which gave concordant results. The periodate oxidation results agreed with the calculated values for a straight chain xylan linked $1\rightarrow4$. Further confirmation of the proposed structure was provided by the enzymic hydrolysis results.

Although the araboxylan of wheat bran has been shown to have a highly branched structure, the xylan portion of the molecule is essentially linear and similar to those found in other parts of the wheat plant. This general type of xylan structure is common to many hemicelluloses (1, 6, 7, 9) and variations in properties appear to be due to the nature and extent of the side branches.

EXPERIMENTAL

Paper Chromatography

Chromatographic separations were carried out at $22^{\circ}\pm4^{\circ}$ C. by the descending method of Whatman No. 1 filter paper using the following solvent systems: (A) ethyl acetate: pyridine: water (2:1:2), (B) *n*-butanol: ethanol: water: concentrated ammonium hydroxide (40:10:47:3), (C) 2-butanone: water (2:1), (D) *n*-butanol: ethanol: water (5:4:1), and (E) *n*-butanol saturated with water. The sugars were located on the paper by aniline oxalate (10) and *p*-anisidine (11) spray reagents.

Fractionation and Analysis of Hemicellulose Fractions

The hemicellulose was prepared from wheat bran as described previously (3). An aqueous solution of the hemicellulose (1%) was clarified by centrifugation, the pH was adjusted to the required value (pH 6.0 or 3.0), and the hemicellulose was fractionally precipitated by the stepwise addition of ethanol. Fractions were collected over the range of 60% through 80% ethanol by volume, washed twice with ethanol-water mixtures of the same composition as the mother liquor, then washed with ethanol, and ether, and dried *in vacuo* over phosphorus pentoxide. Ten fractions were collected from the precipitation at pH 6.0 and 11 from that at pH 3.0, the recoveries being 91 and 95% respectively. An aliquot of each fraction was hydrolyzed with 0.3 *N* sulphuric acid at 100° for 16 hours. The hydrolyzate was neutralized with barium carbonate and chromatographed in solvent *A*. Visual inspection showed no apparent difference in the amounts of arabinose and xylose in the various fractions. Quantitative determinations of arabinose:xylose ratio were made using the method of Flood *et al.* (8) on two representative fractions recovered at pH 6.0 and pH 3.0 respectively. Neither varied significantly from the arabinose:xylose ratio of the original hemicellulose, i.e. 1.0:0.78.

Electrophoresis

A 1% aqueous solution of polysaccharide was dialyzed for 48 hours against two changes of 0.05 *M* borate buffer (pH 9.2) and subjected to electrophoresis in a Perkin-Elmer apparatus at 5.2 ma. and 5.25 volts/cm. (13). The electrophoretic separation was continued for 4.5 hours and photographs were taken of both the ascending and descending arms at the end of 0.5, 2, and 4 hour periods. Examination of the electrophoretic patterns showed that only one large band was present.

Preparation and Properties of Degraded Hemicellulose

Bran hemicellulose (50 mg.) was heated in a sealed tube at 100° with solutions of oxalic acid of various strengths (0.004 *N*, 0.008 *N*, 0.015 *N*, and 0.02 *N*) for various times (6, 8, 10, 12, 14, 16, and 18 hours). At the end of each hydrolysis period, the solution was dialyzed free of oxalate ion and the unhydrolyzed portion recovered by freeze drying. This material was hydrolyzed with *N* H₂SO₄ at 100° C. for 15 hours and the chromatogram of the hydrolyzate was examined visually for the presence of arabinose. The criterion for a suitable product was the removal of arabinose to negligible amounts. These conditions were provided by hydrolysis with 0.02 *N* oxalic acid for 10 hours at 100° or with 0.015 *N* oxalic for 18 hours at 100°. The yield of degraded polysaccharide under these two sets of conditions varied between 25 and 27% of the original material. Although the original hemicellulose was water soluble, the degraded product was insoluble.

For purposes of structural studies a larger amount of the degraded hemicellulose was prepared as follows: Twenty grams of the bran hemicellulose was heated at 100° C. with 2000 ml. of 0.015 *N* oxalic acid for 18 hours. A test of the unhydrolyzed residue showed the presence of an appreciable amount of arabinose and a further 3 hour period of heating was necessary to remove arabinose completely. The recovered degraded hemicellulose had an ash content of 13.5%. The following data were calculated on an ash free basis: yield, 25.4%; $[\alpha]_D^{25} -60 \pm 1^\circ$ (*c*, 1.2% in 2% NaOH); uronic acid, 13%; D.P., 7-8 by hypoiodite oxidation (6).

Total hydrolysis of the degraded hemicellulose and chromatographic separation of the components showed that xylose was the only sugar present; estimation of reducing

power by the Somogyi method (15) after hydrolysis showed 85% of the material to be xylose (ash free). Electrophoretic examination of the neutral hydrolyzate on paper strips in *N*/40 phosphate buffer at 5 ma./cm. and 900 volts showed the presence of an acid which had the same mobility and color reaction with *p*-anisidine as did glucuronic acid. The method did not distinguish between D-glucuronic acid and 4-*O*-methyl-D-glucuronic acid.

Periodate Oxidation

The hemicellulose (100 mg.) suspended in water (120 ml.) was oxidized by sodium metaperiodate (0.03 *M*, 30 ml.) in the absence of light at 16°. At various time intervals analyses were carried out for periodate consumption and formic acid production (6). The oxidation was essentially complete in 120 hours with the consumption of 1.03 moles periodate and production of 0.46 moles formic acid per mole anhydropentose unit.

Enzymic Hydrolysis

Samples (15 mg.) of the hemicellulose residues recovered after 0, 2, 4, 6, 8, and 10 hour hydrolysis with 0.02 *N* oxalic acid were incubated with a purified cellulolytic enzyme isolated from *Myrothecium verrucaria* (16). The hemicellulose was shaken for 1.5 hours with acetate buffer (14 ml., pH 5.0, ionic strength 0.05) and enzyme solution (1.0 ml., 300 µg. enzyme protein/ml.) was added to each test solution. The solutions were incubated at 35° C. in baffled flasks in a rotary shaker. Samples (1 ml.) were withdrawn at 0, 2, and 4 hours for determination of total reducing power (15). The results are given in Table I. Chromatographic examination of one solution (8-hour oxalic acid hydrolyzate) after 4 hours enzymic hydrolysis showed a trace of xylose but relatively large amounts of xylobiose, xylotriose, and higher oligosaccharides.

Methylation and Hydrolysis of Methylated Hemicellulose

Degraded hemicellulose (3.91 g.) was methylated with dimethyl sulphate and sodium hydroxide (40%) as described previously (1). After each two successive methylation treatments, the partly methylated crude product was recovered by neutralization, dialysis, and evaporation. After 12 treatments the product was soluble in methyl iodide and methylation was continued with Purdie's reagent using methyl iodide (50 ml.) and silver oxide (5 g.) for each treatment. Three treatments by this method yielded a product whose infrared spectrum showed only a trace of free hydroxyl band at 3450 cm.⁻¹. On drying under reduced pressure the methylated sirup became a crisp yellow solid; yield, 1.94 g.; OCH₃, 38.3% (theoretical value for dimethyl xylan, 38.8%); $[\alpha]_D^{25} -40^\circ \pm 2^\circ$ (*c*, 0.74 in chloroform). Fractional precipitation of the product from its chloroform solution by petroleum ether (b.p. 30–60° C.) yielded three fractions which did not differ significantly in methoxyl contents or specific rotation, and hence the product was considered as a homogeneous material.

Hydrolysis

Methylated hemicellulose (50 mg.) was heated with methanolic hydrogen chloride (5 ml.; 8%) in a sealed tube at 100° C. for 12 hours. The methyl glycosides were hydrolyzed with hydrochloric acid (10 ml., 0.5 *N*) for 10 hours at 100° C. The methylated reducing sugars were examined chromatographically on paper using solvent C. Authentic samples of D-xylose, 2-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2,3,4-tri-*O*-methyl-D-xylose served as reference substances and *p*-anisidine was the spray reagent used. Four sugar derivatives were detected on the chromatogram and tentative identi-

fications were made based on color reactions and position relative to known reference compounds as follows: Fraction 1, a trimethyl pentose corresponding to 2,3,4-tri-*O*-methyl-D-xylose; Fraction 2, a dimethyl pentose corresponding to 2,3-di-*O*-methyl-D-xylose; Fraction 3, a monomethyl pentose corresponding to 2-*O*-methyl-D-xylose, and Fraction 4, methylated uronic acid. The methylated sugars were estimated by the alkaline hypiodite method (6) and were found to be in an approximate molar ratio of 1:5:0.5:1.

Separation of the Methylated Sugars

The methylated sugars (1.25 g.) obtained by methanolysis and hydrolysis of the methylated hemicellulose were separated on a Celite column as described by Lemieux *et al.* (12). The solvent used was butanol saturated with 1% aqueous ammonium hydroxide; the base prevented streaking of uronic acid which otherwise moved with the monomethyl sugar. The eluted sugars were collected by means of an automatic fraction collector. The various fractions were detected by spotting a sample from every fifth tube on a chromatogram and developing with solvent *B*. The preponderance of Fraction 2 caused some overlapping with Fraction 1 and necessitated re-running the latter fraction on another column. The uronic acid (Fraction 4) was recovered by extruding the Celite column and extracting with water. The methylated sugars and uronic acid fraction were filtered and taken to dryness at 40° C.

Examination of Methylated Sugar Fractions

Fraction 1

This fraction was clarified of Celite by treatment with charcoal in aqueous solution to give a yellow sirup. Using solvent *C* only a single sugar was shown on a paper chromatogram and the R_f 0.86–0.88 corresponded to that of 2,3,4-tri-*O*-methyl-D-xylose. The sirup partly crystallized and recrystallization from ethyl ether containing a small amount of petroleum ether yielded 2,3,4-tri-*O*-methyl-D-xylose, m.p. 89–90° undepressed on admixture with an authentic sample, and $[\alpha]_D^{25} +21^\circ \pm 2^\circ$ (c , 0.9% in water).

Fraction 2

Chromatographic examination of the clarified sirup in solvent *B* showed only one sugar corresponding to 2,3-di-*O*-methyl-D-xylose (R_f 0.67–0.68, solvent *C*). Other characteristics, $[\alpha]_D^{25} +24^\circ \pm 2^\circ$; η_D^{25} 1.4733; OCH_3 , 34.8% (calculated for $\text{C}_7\text{H}_{14}\text{O}_5$: OCH_3 , 34.8%), were the same as for 2,3-di-*O*-methyl-D-xylose. A crystalline anilide was prepared, m.p. 123–124°, and its X-ray diffraction pattern was identical with that of 2,3-di-*O*-methyl-*N*-phenylxylosylamine.

Fraction 3

Clarification of the material with charcoal in aqueous solution removed Celite and colored substances giving a yellow sirup. Chromatographic examination showed the presence of only one component having the same mobility in solvent *B* as 2-*O*-methyl-D-xylose (R_f 0.24–0.25). The product crystallized from ethyl acetate and after recrystallization from the same solvent had m.p. 132–133°, $[\alpha]_D^{25} +33^\circ \pm 2^\circ$.

Fraction 4

The uronic acid fraction (122 mg.) had an $[\alpha]_D^{25} = +67^\circ \pm 1^\circ$ (c , 1.2% in water); $\text{OCH}_3 = 38.1\%$ (calculated for $\text{C}_{16}\text{H}_{28}\text{O}_{11}$: $\text{OCH}_3 = 39.2\%$); equivalent weight: calculated, 396; found, 421. The uronic acid compound proved to be a methylated adol-

biouronic acid, 2-*O*-(2,3,4-tri-*O*-methyl-D-glucuronosyl)-3-*O*-methyl-D-xylose as deduced from the following experimental findings.

The methylated uronic acid component (95 mg.) was converted to its methyl ester methyl glycoside by refluxing in methanolic hydrogen chloride (2%). This product (96 mg.) was dissolved in dry ethyl ether (25 ml.) and reduced by dropwise addition over a period of 2 hours to a stirred suspension of lithium aluminum hydride (300 mg.) in ethyl ether (40 ml.). The reaction mixture was heated under gentle reflux for 30 minutes, cooled, and the unused lithium aluminum hydride decomposed by ethyl acetate and water was added to the mixture. The mixture was evaporated to dryness and the glycoside of the neutral disaccharide was removed by extraction with ethyl acetate. The disaccharide (49 mg.) was hydrolyzed by being heated with *N* sulphuric acid (3 ml.) at 100° for 8 hours. Removal of the acid with barium carbonate, deionization of the filtrate with Amberlite IR-120, and evaporation at 40° yielded a yellow sirup (28 mg.). Separation of the methylated sugars on paper chromatograms yielded insufficient material for the usual chemical methods of identification and hence identification was based on chromatographic data. One sugar was identified as 3-*O*-methyl-D-xylose, R_f 0.25 (solvent *C*), 0.43 (solvent *E*), 0.52 (solvent *D*), and 0.66 (solvent *A*). These R_f values were the same for an authentic sample of 3-*O*-methyl-D-xylose and were readily distinguished in all solvents, from those of 2-*O*-methyl-D-xylose. The other sugar was identified as 2,3,4-tri-*O*-methyl-D-glucose, R_f 0.73 (solvent *C*), 0.74 (solvent *E*), 0.85 (solvent *D*), and 0.90 (solvent *B*), these values being identical with those of an authentic sample of 2,3,4-tri-*O*-methyl-D-glucose.

AN INVESTIGATION OF THE GAS-PHASE OXIDATION OF ACETALDEHYDE BY MEANS OF A RAPID-SCANNING MASS SPECTROMETER¹

L. P. BLANCHARD, J. B. FARMER, AND C. OUELLET

ABSTRACT

A mass spectrometer equipped for continuous sampling and capable of producing 60 spectra per second has been used to follow the oxidation of acetaldehyde at temperatures in the region of 250° C. In normal slow oxidation peracetic acid was formed and then decomposed into carbon dioxide, methanol, and water. Under flame conditions peracetic acid built up in an autocatalytic manner during the induction period and vanished suddenly at the onset of the flame. Possible reaction mechanisms are discussed. Temperature surges during cool and hot flames are estimated.

INTRODUCTION

The gas-phase oxidation of acetaldehyde has been the subject of numerous investigations both in the temperature range from 100° C. to 200° C. where the reaction lasts for minutes or hours (5, 14, 15) and at higher temperatures where it is over in a matter of seconds (1, 9, 16, 17, 18); in this latter region, cool or hot flames are observed under appropriate conditions. For slow reactions the conventional means of chemical analysis are generally adequate but for fast ones, particularly when flames occur, the mass spectrometer becomes a most valuable research tool. The present paper describes a mass-spectrometric investigation at temperatures around 250° C. of the acetaldehyde oxidation. This was carried out with a view to comparing the characteristics of the three modes of reaction, namely the slow oxidation, the cool flame, and the hot flame.

EXPERIMENTAL

A previous publication from this laboratory (12) has reported the successful completion of a mass spectrometer designed to study fast gas-phase reactions such as those involved in combustion. The instrument has since been developed with the aim of improving its performance and simplifying its operation. It is relevant to include here a general description of the apparatus used in the experiments.

A cylindrical quartz reaction vessel, 4.5 cm. in diameter and 12.5 cm. long, heated electrically to any desired temperature up to 300° C., formed an integral part of the ion source (see Fig. 1). Sealed in the side of the vessel was a quartz-diaphragm leak identical with the ones used by Lossing and co-workers (13) in the mass-spectrometric study of free radicals. A sample of the gaseous mixture in the reaction vessel flowed through the microscopic hole of the leak (diameter 30 microns, length 10 microns) into the ionization chamber and the stream was evacuated with a high-speed pumping system. About five per cent of the contents of the vessel effused in the first 2 minutes. The distance from the leak to the electron beam was 15 mm., which is longer than the mean free path of the molecules in this region. It was established that, with reaction-vessel pressures up to 100 mm. Hg, the flow through the leak itself was predominantly molecular in nature. Hence, in this range, the sample path was essentially collision-free, a condition which is desirable for two reasons. Firstly, it prevents gas-phase reactions between species leaving the vessel. Secondly, it permits quantitative data to be obtained from mass spectra because peak intensities are then directly proportional to concentrations and component

spectra are superimposable in a linear fashion. Hence, all measurements were taken with pressures less than 100 mm. Hg.

The mass spectrometer was a sector-field instrument equipped with a Nier-type ion source. The slits were set for a resolving power of one in 75, which was adequate for the analysis of the products of the acetaldehyde-oxygen reaction. Spectra from 12 to 80 atomic mass units were scanned 60 times per second by sawtooth modulation of the ion-acceleration voltage. Peaks due to hydrogen ions were scanned with a reduced magnetic field. The collector signal was amplified by an ion-electron multiplier followed by a vacuum-tube amplifier. It was then displayed on the screen of a cathode-ray oscilloscope (Tektronix 512), the time base of which was operated in synchronism with the spectrometer scan. In order to preserve the definition of the spectra, the amplifying system was required to have a frequency response which was level from d-c. to 100 kc./second with input currents in the range from 10^{-13} to 10^{-10} amp. The rapidly-varying mass spectra obtained during the course of a combustion reaction could be recorded with a motion-picture camera. The records were made with a Paillard-Bolex H16 camera using Ilford Type 5B52 16 mm. film. After processing, the film was examined frame by frame in a microfilm reader and the heights of the various peaks were measured from the projected images.

It was not possible to heat the mass-spectrometer filament in the conventional way with alternating current of line frequency because the resulting modulation of the electron and ion beams was passed by the low-time-constant amplifiers and the ripple was superimposed on the final spectrum. Hence, the filament was operated with rectified and well-filtered current. The voltage was stabilized but no attempt at emission stabilization was made. When oxygen was first admitted into the spectrometer after organic compounds were tested or even after a period of pumping, the emission of the tantalum filament fell to a small fraction of its normal value but it recovered gradually during a period of about 5 minutes. The appearance of a carbon monoxide spectrum showed that a carbonaceous layer was being removed from the tantalum. Afterwards, the emission was relatively insensitive to the presence of oxygen so the practice was established of treating the filament with oxygen for 5 minutes before each run. A slight carbon monoxide spectrum persisted when oxygen-containing mixtures were tested, and the results were corrected accordingly.

A known amount of argon was added to each reaction mixture. This was useful for three reasons. Firstly, if the electron emission varied slightly during a run, the intensity of the argon peak indicated the extent of this variation and the other peaks could be corrected proportionally. Secondly, when the instrument was calibrated, the sensitivity for each pure gas was expressed as the ratio of the intensity of the principal peak to the intensity of the peak of argon when this latter gas was present at the same partial pressure. Hence, even if the absolute sensitivity of the instrument changed, owing to poisoning of the multiplier dynodes for example, the amount of a given gas in a mixture could still be calculated as a fraction of the argon partial pressure. A third reason for the inclusion of argon was that it acted as a thermometer. During a flame, the temperature rise produced an increase in the partial pressure of the inert gas and the magnitude of the rise could be estimated from the intensity of the spectrum peak.

The acetaldehyde used in the experiments was obtained from the Matheson Company Inc. and was purified by fractionation. The oxygen (medical grade) and the argon (99.6% pure) were both obtained from the Ohio Chemical Company. For each run, the gases were premixed in a 1-liter bulb in such quantities that, after expansion into the reaction vessel, the desired partial pressures would result. About half a second was required for the gases to enter the vessel and achieve temperature equilibrium. Oil diffusion pumps were used throughout in order to avoid the anomalous effects which have sometimes been reported (9, 18) in oxidation systems when mercury has been present.

The mass spectra of acetaldehyde and oxygen were determined by introducing these substances independently into the reaction vessel. As mentioned above, a known quantity of argon was added in order to measure the sensitivity for each gas relative to that for argon. Calibrations were also made for the products which were suspected from a qualitative examination of the combustion spectra. All calibrations were performed with a reaction-vessel temperature of 250° C.

RESULTS

As explained previously, instrumental factors limited the investigation to total pressures below 100 mm. Hg. In all experiments the initial mixture consisted of acetaldehyde, oxygen, and argon with partial pressures in the proportion 2:2:1. By altering the temperature and the total pressure it was found possible to obtain the three typical reactions of slow oxidation, cool flame, and hot flame.

At 242° C. and 80 mm. pressure, the acetaldehyde disappeared by slow oxidation in about 1 minute. Photographs were taken at 10-second intervals. The results are illustrated in Fig. 2 in which the relative intensities of the principal mass-spectral peaks are plotted against time. The intensity of the ^{40}Ar peak is taken as 100 units. The peaks at masses 29 (due mainly to CHO^+) and 32 (due mainly to O_2^+) indicate roughly the disappearance of acetaldehyde and oxygen, respectively. Peak 60 rises during the consumption of acetaldehyde pointing to the formation of acetic acid. However, this peak falls rapidly during the later stage of the reaction. Acetic acid would be expected to be quite stable under the conditions of the experiment so it is concluded that the 60 peak is derived, at least in part, from the unstable peracetic acid which is known to be the main oxidation product at lower temperatures. The peracid parent peak was not detected even with a 30-fold increase in amplifier sensitivity. A solution of peracetic acid was prepared by the method of Findley, Swern, and Scanlon (7), and a few drops were completely vaporized into the reaction vessel. Again, no parent was seen. It seems, therefore, that peracetic

FIG. 2. Relative intensities of the principal mass-spectral peaks during slow oxidation. Argon-40 peak = 100 units.

FIG. 3. Relative intensities of the principal mass-spectral peaks during cool flame.

acid either lacks a parent peak because of the instability of the $\text{CH}_3\text{COOOH}^+$ ion or that it decomposes to acetic acid in the ion source before ionization. The increases in the 44, 31, 28, and 18 peaks are interpreted as being due to the formation, respectively, of carbon dioxide, methanol, carbon monoxide, and water. Formaldehyde, ethane, methane, and hydrogen are judged to be absent.

At 258°C ., an 80 mm. mixture produced a cool flame after an induction period of a few seconds. The faint blue glow was visible in a darkened room. To record the phenomenon, the motion-picture camera was run continuously at eight frames per second. Fig. 3 shows clearly the induction period in which there was little apparent change and the flame period, lasting about half a second, in which about 50% of the reactants was consumed. The remaining aldehyde subsequently disappeared by slow oxidation, as evidenced by the curves to the right of the figure, plotted on a compressed scale. From the transient increase in intensity of the argon-40 peak during the cool flame it is estimated that the maximum temperature was 410°C . Since all the other peak intensities are expressed as a percentage of the argon intensity, the curves in the non-isothermal region represent concentrations rather than pressures.

From the 60 peak it is obvious that acid formed in considerable quantity during the slow oxidation phase, but during the induction period and the cool flame the peak was very small. The curve of Fig. 4 was obtained in a separate experiment using 10 times the sensitivity; the ^{36}A peak, which was of a comparable height, was used as the standard. The acid built up in a seemingly-exponential manner until the onset of the cool flame, when it was partially consumed. This behavior lends further support to the view that the acid is, at least partly, peracetic acid because the comparatively-stable acetic acid would be unlikely to decompose in a fraction of a second even at the elevated temperature

FIG. 4. Variation of peak 60 (peracetic acid) during cool flame.

FIG. 5. Relative intensities of the principal mass-spectral peaks during hot flame.

of the flame. The maximum pressure of acid at the time of the cool flame is estimated to be about 1 mm. This is based on the acetic acid sensitivity figure since no pure peracetic acid was available for calibration.

The changes in peaks 44 and 31 show that carbon dioxide and methanol are cool-flame products. There is a net increase in peak 30 when allowance has been made for the methanol contribution and this is assigned to formaldehyde. Ethane is excluded because there is no net increase in peaks 26 and 27, which are important in the spectrum of this compound. The increase in peak 28 remains large when corrections have been made for the other substances present and for the formation of carbon monoxide on the filament, and this must be the result of carbon monoxide formation in the flame. Peak 18 is from water. Peak 16 exhibits a small net increase indicating methane. Hydrogen was found as a minor product. With a knowledge of the sensitivities relative to argon of the various pure substances it was possible to assess quantitatively the composition of the reaction products. The first two columns of Table I summarize the results for the slow oxidation and cool flame. The slow-oxidation analysis applies to the time in the reaction when 16.5 mm. of acetaldehyde had been consumed. This facilitates comparison with the cool-flame oxidation in which this same amount of aldehyde was consumed.

Newitt, Baxt, and Kelkar (18) published a diagram indicating the temperatures and pressures with which they observed slow oxidation, cool flames, and hot flames. The diagram contains a so-called low-temperature ignition peninsula where, at certain pressures, hot flames occur at lower temperatures than the cool flames for the same mixture. Using a 2:2:1 mixture of reactants as before, this condition was found to prevail with a temperature of 242°C. and a total pressure of 90 mm. After a short induction period, a bright yellow flame appeared. Photographs were taken at eight frames per second and the results are shown in Fig. 5. The flame temperature estimated

TABLE I

PRODUCTS FORMED IN THE THREE MODES OF OXIDATION OF ACETALDEHYDE
The initial mixtures consisted of acetaldehyde, oxygen, and argon in the proportions 2:2:1. The units are mm. Hg at the temperature of the experiment

	Experimental conditions and mode of oxidation		
	242° C., 80 mm., slow oxidation	258° C., 80 mm., cool flame	242° C., 90 mm., hot flame
CH ₃ CHO consumed	16.5	16.5	32.5
O ₂ consumed	16	14	34
Acid formed	7	0.5	—
CO ₂	6	3	11
CH ₃ OH	1	5	—
HCHO	—	5	—
CO	0.5	13	62
C ₂ H ₂	—	—	1.5
H ₂ O	3	6	30
CH ₄	—	Small	Small
H ₂	—	3	12

from the argon peak is 525° C. As the duration of the flame was very short, the delineation of the pulse is based on only a few frames of film and the amplitude may actually be higher. Because of the need for greater amplifier sensitivity, the measurements on the 60 peak were taken in a separate experiment. Nevertheless, it was possible to locate precisely on each film the onset of ignition so the time scale of the different curves may be considered accurate in the flame region. The acid concentration is seen to increase linearly during the induction period until a fraction of a second before the flame when the rate of formation accelerates sharply. Most of the acetaldehyde-oxygen mixture together with most of the acid vanishes in the flame. The maximum acid pressure is put at about 4 mm. The products of the hot flame are carbon dioxide, carbon monoxide, acetylene, water, methane, and hydrogen; the estimated amounts are listed in Table I. Since the hot flame gave rise to a considerable permanent increase in pressure, the flow of the products into the spectrometer was not truly molecular and this reduces the accuracy of the analysis.

Mixtures of acetaldehyde, oxygen, and argon in the ratio 2:4:1 were found to ignite violently. A bright blue flash was seen and the explosion was clearly audible. Examination of the mass spectra indicated that hydrogen was absent from the final products, presumably because with excess oxygen conditions were favorable for its ignition.

DISCUSSION

It is generally agreed that at temperatures below 200° C. acetaldehyde is oxidized to peracetic acid by a free-radical mechanism and the following kinetic scheme involving degenerate branching chains has been suggested (14) in order to explain the experimental facts:

The present work shows that in slow oxidation at 242° C. peracetic acid is still formed although the presence of a little carbon monoxide indicates that some of the acetyl radicals, instead of reacting with oxygen, decompose thus:

Under the conditions of the experiment, the peracetic acid decomposed rapidly, presumably according to equation [4] by the fission of the O—O bond, and decomposition of the resulting CH_3CO_2 radical would yield the observed carbon dioxide:

The formation of methanol is most readily explained by the oxidation of the methyl radical to the methoxy radical and a subsequent hydrogen abstraction:

or

Reactions [9] and [10] have been invoked by several authors (3, 8) and they appear to be well substantiated. An objection to the proposed mechanism is that it predicts the formation of carbon dioxide and methanol in equal amounts whereas carbon dioxide is actually formed in excess. The hydroxyl radicals from hydroperoxide decomposition are the obvious source of water.

The curve of Fig. 4 strongly suggests that peracetic acid plays a vital role in triggering a cool flame in acetaldehyde. Previous workers have detected peroxide during the induction period of an acetaldehyde cool flame, and it was proved by Aivazov, Keyer, and Neiman (1) that the addition of a small quantity of peracetic acid shortened the induction period. McDowell and Thomas (15) have reported experiments on the oxidation of acetaldehyde at temperatures just below the cool-flame limit. Their analyses showed that peracetic acid was initially formed but then disappeared at a fast rate, thus leading one to believe that the cool flame results from the peracid decomposition. No peaks other than those associated with the acid were seen to rise during the induction period. The 30 peak was carefully checked in a search for traces of formaldehyde. Also, the 34 peak for traces of hydrogen peroxide. The exponential growth of peroxide and its abrupt decay recall the observations of Bardwell and Hinshelwood (2) in their study of cool flames in methyl ethyl ketone and the explanation is probably similar to the one advanced by those authors. Certainly, the experimental facts are consistent with the occurrence of the following sequence of events. During the first part of the induction period, the peracetic acid is formed by normal slow oxidation and, as the concentration builds up, the rate of decomposition by reaction [4] increases accordingly. Self-heating by this exothermic reaction further accelerates the process and a flame eventually results. Total consumption of the aldehyde is prevented by a self-quenching action in the flame which may be explained as follows. As the temperature rises, the supply of peracetic acid is cut off because of the instability of the acetyl radical, and isothermal conditions are restored. The view that the acetyl radical decomposes at the temperature of the flame (410° C.) is verified by the formation of carbon monoxide; it is seen from Table I that carbon monoxide was vastly more abundant in the cool flame than in the slow oxidation. The carbon dioxide, on the other hand, being formed from peracetic acid, is down in quantity.

Methanol and formaldehyde are major cool-flame products. It is supposed that methanol is formed by the abstraction reaction [11] as in the slow oxidation. However, under the conditions of the flame, the concentration of methoxy radicals is greatly enhanced and one may have to consider an interradsical reaction such as

Such a reaction also accounts for the observed formaldehyde. It has been shown that under certain conditions, methanol (6) and formaldehyde (4) act as oxidation retarders and it is plausible that they should contribute to the quenching of the cool flame. However, the fact that they have no marked effect on the slow oxidation which follows the flame makes this seem improbable. The formation in the flame of a small amount of methane may be due to abstraction by methyl radicals:

or to an interradsical reaction:

Hydrogen was found in a small but significant amount and this undoubtedly points to the previous formation of hydrogen atoms. The suggested source of these is the thermal decomposition of methoxy radicals:

In this connection, it is of interest to note that Kondrat'ev *et al.* (11) have reported an unsuccessful search for hydrogen atoms in acetaldehyde cool flames. They introduced into the reaction mixture a thermocouple coated with $\text{ZnO} \cdot \text{Cr}_2\text{O}_3$ and looked for the temperature rise which would be expected to follow the recombination of the atoms on the oxide surface.

It appears from Fig. 5 that a hot flame originates in the same way as a cool one with the accumulation of peracetic acid. The difference seems to be that the peracid achieves a higher concentration before self-heating begins, with the result that the subsequent temperature rise is greater. Self-quenching is ineffective presumably because new high-temperature reaction chains come into play. The large yield of hydrogen suggests that hydrogen atoms, formed as in reaction [15] for example, may be important chain carriers. The cool flame products, methanol and formaldehyde, are no longer found. The products are predominantly carbon dioxide, carbon monoxide, and water. The presence of some acetylene implies the prior formation of the CH radical. Acetylene has been detected as a product of the reaction of methyl radicals with oxygen at 1000°C . (10) and the CH emission bands in flames are well-known, but the chemistry of the CH radical remains obscure.

RÉSUMÉ

L'oxydation de l'acétaldéhyde dans la région de 250°C . a été étudiée au moyen d'un spectromètre de masse à échantillonnage continu, capable de donner 60 spectres par seconde. Dans l'oxydation lente normale il se forme de l'acide peracétique qui se décompose en anhydride carbonique, méthanol, et eau. Dans les conditions où l'on obtient des flammes, il y a accumulation autocatalytique d'acide peracétique durant la période d'induction; ce composé disparaît soudainement au moment de l'inflammation. On discute quelques mécanismes de réaction possibles. On peut estimer les hausses de température qui accompagnent la flamme froide et la flamme chaude.

INFLUENCE DE L'OXYDE NITRIQUE ET D'AUTRES INHIBITEURS SUR L'OXYDATION LENTE DE L'ÉTHÉR¹

ANDRÉ LEMAY² ET CYRIAS OUELLET

RÉSUMÉ

L'action de petites quantités d'oxyde nitrique sur l'oxydation lente de l'éther diéthylique en phase gazeuse dépend essentiellement du moment où l'on injecte cet inhibiteur. L'hypothèse d'une initiation secondaire des chaînes par décomposition d'un hydroperoxyde insensible à NO explique les faits observés: inhibition puissante et durable au début de la réaction, puissante mais brève durant la baisse de pression, nulle au moment où l'oxygène est épuisé, faible après la disparition de l'oxygène. Dans les conditions où il ne s'accumule pas d'hydroperoxyde, on n'observe qu'une inhibition simple. Le propylène exerce les mêmes effets mais est 10 fois moins actif. Le formaldéhyde n'inhibe la réaction que s'il est injecté avant les réactifs. L'inhibition par l'acide bromhydrique se complique d'une activation de la surface.

INTRODUCTION

Le présent mémoire contient une description des phénomènes provoqués en ajoutant de petites doses d'inhibiteurs à diverses époques d'une oxydation lente en phase gazeuse. Dans une telle réaction, on peut envisager deux modes d'initiation des chaînes. Au début, l'attaque par l'oxygène donne lieu à une initiation du type

processus rare mais donnant naissance à des chaînes longues. Lorsque la réaction est assez avancée pour qu'il y ait accumulation appréciable d'un produit peroxydique, la décomposition de ce dernier

fait apparaître un nouveau mode d'initiation de chaînes du type

qui peut devenir prépondérant. Un mécanisme de ce genre a été postulé par Niclauss (8) ainsi que McDowell et Farmer (6) pour l'oxydation de l'acétaldéhyde. On peut supposer qu'un inhibiteur agira différemment suivant que la réaction est plus ou moins avancée. Par exemple, l'action de l'oxyde nitrique pourrait être puissante sur les chaînes longues et rares initiées suivant [1], mais nulle sur la décomposition [2] et faible sur les chaînes nombreuses mais courtes initiées par [3].

Dans le but de vérifier ces hypothèses, nous avons injecté des inhibiteurs à diverses époques, au cours de l'oxydation lente de l'éther diéthylique en phase gazeuse, réaction étudiée par Eastwood et Hinshelwood (2) et par Lemay et Ouellet (4). Ces derniers ont montré qu'on peut effectuer cette réaction dans des conditions où elle présente deux phases nettement séparées: une phase initiale de consommation d'oxygène, avec baisse de la pression totale et accumulation d'un hydroperoxyde, et une seconde phase caractérisée par la décomposition de l'hydroperoxyde et un accroissement de pression. Cette seconde phase se révèle le plus clairement après la disparition complète de l'oxygène. La montée de pression qui l'accompagne a été prise à tort comme mesure de la vitesse

d'oxydation (2). L'oxydation de l'éther, parce qu'elle a lieu à des températures relativement basses où les peroxydes ont une vie assez longue, a été choisie comme objet de cette étude.

MÉTHODE EXPÉRIMENTALE

L'appareil et le mode opératoire employés pour étudier la réaction d'oxydation ont été décrits précédemment (3, 4); la chambre à réaction est un cylindre en Pyrex de 4.4×14 cm. et les variations de pression sont enregistrées électriquement. Pour injecter au moment choisi une petite quantité d'un gaz étranger, on se sert d'un tube capillaire qui pénètre jusqu'au centre de la chambre. De cette façon, le gaz ajouté se répand rapidement dans tout le mélange en réaction. La quantité injectée se lit directement sous forme d'un saut brusque enregistré par le manomètre. On tient compte, lorsqu'il y a lieu, du gaz emprisonné dans l'injecteur, dont le volume est 1% de celui de la chambre. Cet injecteur capillaire sert aussi à aspirer des échantillons du mélange gazeux dans un analyseur magnétique servant au dosage de l'oxygène résiduel.

L'éther est débarrassé de l'eau et des peroxydes par passage à travers une colonne d'alumine activée (1). L'oxygène provient d'un cylindre et les autres gaz, de marque Mathieson, sont prélevés directement des cylindres. Le formaldéhyde est préparé par chauffage de paraformaldéhyde.

RÉSULTATS ET DISCUSSION

Sur les figures, un trait pointillé indique la pression au cours d'une réaction témoin, tandis qu'un trait plein représente la pression au cours de la réaction étudiée, avant et après l'injection d'inhibiteur. Le moment où a lieu l'injection est marqué par une flèche. Ces variations de pression sont enregistrées de façon continue à 0.1 mm. Hg près.

Addition d'oxyde nitrique

L'oxyde nitrique a été ajouté de trois façons: (a) en l'injectant dans la chambre à réaction évacuée, immédiatement avant d'y introduire les réactifs, (b) en l'injectant après les réactifs, à divers moments au cours de la réaction et (c) en l'incorporant au mélange froid de réactifs avant l'introduction de ces derniers dans la chambre. On verra que les effets produits sont très différents.

Au début de la réaction, il n'y a pas d'hydroperoxyde dans le système; l'oxydation est initiée uniquement suivant le mode [1]. L'injection de 0.3 mm. d'oxyde nitrique dans la chambre à réaction avant l'introduction des réactifs ou immédiatement après cette dernière (figure 1A) réduit le taux d'abaissement de la pression et de la consommation de l'oxygène (figure 2A) par un facteur de l'ordre de 30, ce qui donne une indication grossière de la longueur des chaînes à cette époque de la réaction. Il en résulte une longue période d'induction durant laquelle l'oxyde nitrique est consommé lentement par les radicaux qu'il attaque.

Lorsque la réaction est plus avancée, il s'est accumulé de l'hydroperoxyde et le second mode d'initiation [3] devient important. On sait (10) que l'oxyde nitrique n'inhibe pas la décomposition de l'hydroperoxyde de butyle tertiaire. Par analogie, on peut prévoir que cet inhibiteur n'empêchera pas la décomposition [2], mais bloquera seulement les chaînes qui en résultent, tarissant ainsi la source de régénération de l'hydroperoxyde. On constate, en effet, que l'injection d'environ 3 mm. d'oxyde nitrique arrête temporairement la consommation d'oxygène (figure 2B), démasquant ainsi l'accroissement de pression (figure 1B) provenant de la décomposition de l'hydroperoxyde et peut-être

FIG. 1. Courbes de pression de réactions normales (en pointillé) de mélanges équimoléculaires d'éther et d'oxygène à 168°C . et de réactions inhibées (traits pleins) par l'injection d'oxyde nitrique aux moments indiqués par des flèches.

FIG. 2. A et B—Influence de l'oxyde nitrique ajouté avant ou pendant la réaction sur la pression totale P et la pression partielle P_{O} de l'oxygène.

C—Influence du peroxyde d'azote (0.7 mm.) ajouté avant les réactifs. Mélanges équimoléculaires à 168°C . Les courbes pointillées se rapportent aux réactions normales.

aussi d'autres réactions secondaires. Cependant, l'inhibiteur est consommé assez rapidement par les radicaux provenant de [2] et [3], de sorte qu'après un arrêt temporaire, les chaînes d'oxydation reprennent leur cours et la pression se met de nouveau à baisser jusqu'à épuisement de l'oxygène. A partir de ce moment, la pression s'élève de nouveau par suite de la décomposition, tout comme elle le faisait durant la période d'inhibition. Les amplitudes totales des deux baisses et des deux hausses de pression sont sensiblement les mêmes que si ces variations n'avaient pas été interrompues, comme on peut s'en rendre compte en les comparant avec celles de la réaction témoin (courbe pointillée).

A l'époque du minimum de pression, c'est-à-dire au moment où il ne reste plus d'oxygène, la réaction devient insensible à 3 mm. d'oxyde nitrique (figure 1C). On voit, de plus,

que ce gaz est consommé, probablement par des radicaux provenant de la décomposition de l'hydroperoxyde, puisque la courbe ascendante de pression rejoint bientôt celle de la réaction témoin.

Un peu plus tard (figure 1D) l'oxyde nitrique (2.5 mm.) inhibe partiellement la hausse de pression. Ceci porte à croire qu'à cette époque avancée de la réaction, l'accroissement de la pression ne résulte plus uniquement de la décomposition d'un hydroperoxyde, mais aussi de la décomposition en chaîne, sensible à l'oxyde nitrique, d'un autre produit. Il s'agit peut-être, dans notre cas, d'une pyrolyse de l'acétaldéhyde induite par des traces d'oxygène (5) ou par les radicaux provenant de la réaction [2]. Nous avons constaté que l'importance relative de cette inhibition tardive croît avec la proportion d'éther dans le mélange initial.

Les résultats décrits ci-dessus ont été obtenus à 168° C. avec des mélanges équimoléculaires d'éther et d'oxygène. On observe des effets semblables (3) en se servant de mélanges contenant un excès de l'un ou l'autre réactif, soit 33% et 67% d'éther en volume. Pour les mélanges riches en éther, on trouve que l'inhibition par injection d'oxyde nitrique avant les réactifs est un peu moins forte que pour les mélanges équimoléculaires; par contre, l'inhibition par injection après le minimum de pression est un peu plus forte.

L'incorporation préalable de 3% d'oxyde nitrique à un mélange froid quelques minutes avant l'introduction de ce dernier dans la chambre à réaction a pour conséquence une période d'induction d'environ 20 minutes, après laquelle les variations de pression (figure 3) sont celles d'une réaction normale un peu ralentie. L'arrêt initial de la réaction est donc moins prolongé que celui qu'on obtient en injectant ce gaz avant les réactifs. Une partie de l'oxyde nitrique disparaît probablement par réaction avec l'oxygène.

Action de l'oxyde nitrique sur une réaction catalysée par la surface

S'il est possible d'effectuer la réaction dans des conditions où l'hydroperoxyde ne s'accumule pas, on doit s'attendre à des effets plus simples. Ces conditions ont été réalisées en induisant de chlorure de potassium les parois de la chambre à réaction. On sait déjà (4, 9) qu'une telle surface catalyse la décomposition de l'hydroperoxyde au point de supprimer la baisse initiale de pression et de donner lieu à des courbes de pression telles que les courbes pointillées de la figure 4, pour les réactions non inhibées. Dans ces conditions, l'inhibiteur produit toujours un arrêt simple et prolongé de la réaction, comme on le voit en injectant 1 mm. d'oxyde nitrique avant les réactifs (figure 4A) ou 3 mm. au bout de 4 minutes (figure 4B).

L'inhibition est prolongée parce que la trace d'hydroperoxyde présente n'engendre pas assez de radicaux pour détruire tout l'inhibiteur ajouté et permettre à la réaction de reprendre son cours. On peut dire que l'inhibition sera prolongée toutes les fois qu'il reste un excès d'oxyde nitrique après épuisement de l'hydroperoxyde. Ceci a été vérifié pour une réaction telle que celle de la figure 1, s'effectuant dans un vase à surface non traitée. Il suffit d'ajouter au bout de 4 minutes de l'oxyde nitrique en excès (13 mm.) pour que la hausse de pression semblable à celle de la figure 1B soit suivie, non plus d'une baisse, mais d'un long palier indiquant que la décomposition de l'hydroperoxyde n'a pas suffi à éliminer l'inhibiteur.

On peut rapprocher ces effets de l'inhibition bien connue de la pyrolyse des hydrocarbures par l'oxyde nitrique (13). Ils en diffèrent cependant par plusieurs particularités. L'inhibition de l'oxydation de l'éther obtenue par injection avant les réactifs est beaucoup plus puissante que celle des pyrolyses. Par exemple, on voit sur la figure 5 qu'une

FIG. 3. Courbe de pression totale pour un mélange contenant 3 mm. d'oxyde nitrique incorporé à froid.

Fig. 4. Réaction d'un mélange équimoléculaire à 168°C., dans un récipient enduit de chlorure de potassium. Réaction normale en pointillé; réaction inhibée en trait plein.

FIG. 5. Vitesses relatives de la réaction dans un mélange équimoléculaire à 168°C., en fonction des quantités de formaldéhyde et d'oxyde nitrique injectées avant les réactifs.

inhibition d'environ 95% est produite par 0.3% d'oxyde nitrique. La réaction dite résiduelle, si intéressante dans le cas des pyrolyses (12, 14), est ici pratiquement inexistante. On ne sait pas dans quelle mesure l'atténuation du pouvoir inhibiteur de l'oxyde nitrique au cours d'une pyrolyse est susceptible d'être expliquée par un mécanisme d'initiation secondaire analogue à celui que nous postulons.

Addition de peroxyde d'azote

On doit se demander dans quelle mesure l'inhibition peut être attribuable au peroxyde d'azote formé par réaction de l'oxyde nitrique avec l'oxygène. On sait que ce gaz inhibe l'oxydation de l'acétaldéhyde (7). Un certain nombre des expériences décrites ci-dessus ont été répétées en remplaçant l'oxyde par le peroxyde (3). Ajouté avant ou durant la réaction, cet inhibiteur ne provoque qu'un bref ralentissement (de 2 à 5 minutes) de la variation de pression et de la consommation d'oxygène, comme on le voit sur la figure 2C. Son action est beaucoup plus faible que celle de l'oxyde, n'est pas fonction de l'époque de l'injection et ne semble pas être accompagnée de la consommation du gaz ajouté. Ces différences suffisent à montrer que, dans l'ensemble, les effets décrits dans la section précédente sont attribuables directement à l'oxyde nitrique.

L'oxydation des hydrocarbures par le peroxyde d'azote est bien connue. Dans quelques expériences à 189°C. avec des mélanges équimoléculaires d'éther et de peroxyde d'azote,

nous avons observé des augmentations de pression de l'ordre de 10% en 30 minutes. Nous avons vérifié que, vers 170° C., cette réaction est trop lente pour intervenir dans les effets décrits plus haut, surtout aux faibles pressions partielles de peroxyde d'azote employées. Nous n'avons pas encore étudié cette réaction en détail.

Addition de propylène

Le propylène exerce, sur les divers stages de la réaction, une action sélective (3) semblable à celle de l'oxyde nitrique; cependant, les quantités de propylène requises pour produire les mêmes effets sont environ 10 fois plus grandes. Il est à noter que ce rapport est le même que pour l'inhibition des pyrolyses par ces deux gaz.

Addition de formaldéhyde

Le comportement du formaldéhyde est singulier; il n'agit que s'il est injecté avant les réactifs. Dans ce cas, il provoque une période d'induction semblable à celle de la figure 3, d'autant plus longue que la quantité injectée est plus grande, et suivie d'une réaction à peu près normale. Cette inhibition initiale est représentée sur la figure 5. Par contre, si le formaldéhyde est ajouté durant la baisse ou la hausse de pression, il ne modifie pas le cours de la réaction. La courbe de pression rejoint en moins d'une minute celle de la réaction témoin, montrant que le gaz ajouté est rapidement consommé et reste sans effet sur le cours de la réaction.

On peut donc dire que le formaldéhyde inhibe fortement l'oxydation initiée par le processus [1], mais non celle initiée par [3] et qu'il n'affecte ni la décomposition ni la régénération de l'hydroperoxyde. Il se peut que le formaldéhyde s'attaque à un porteur de chaînes qui intervient uniquement dans l'oxydation primaire, ou qu'il détruise aussi un porteur des chaînes secondaires, mais par une réaction telle que $\text{OH} + \text{HCHO} \rightarrow \text{H}_2\text{O} + \text{HCO}$ qui engendre un nouveau radical capable de propager la chaîne. Dans ce cas, le fait que cet inhibiteur devient inactif quelques instants après le début de la réaction indiquerait que l'initiation secondaire devient très tôt prépondérante. Un autre type d'explication consiste à supposer que le formaldéhyde est rapidement éliminé du système par réaction avec un produit, par exemple un peroxyde ou un alcool. Dans ce cas, cependant, on s'attendrait à ce qu'il ne devienne inactif qu'après un temps assez long.

Addition d'acide bromhydrique

On sait que l'acide bromhydrique peut catalyser un transfert d'hydrogène (11) par un mécanisme tel que

Il était donc intéressant d'étudier son action sur notre réaction (3). Au lieu de l'accélération prévue de la phase initiale, on observe une période d'induction d'environ 4 minutes suivie d'une réaction normale, quand on injecte 0.5 mm. de ce gaz avant les réactifs. Si on l'ajoute après les réactifs, il n'y a plus de période d'induction, mais la baisse et la hausse de pression sont ralenties. Il n'a pas été possible d'étudier en détail les effets de ce gaz, car il altère l'activité de la surface de telle façon que les réactions effectuées subséquentement ressemblent en tous points à celles que l'on obtient lorsque la surface est enduite de chlorure de potassium (courbes pointillées de la figure 4). Il semble donc agir à la fois comme inhibiteur des chaînes d'oxydation et comme catalyseur de la décomposition hétérogène du peroxyde.

CONCLUSION

Les effets très complexes produits par l'injection de petites doses d'inhibiteurs à diverses étapes de l'oxydation lente de l'éther s'expliquent dans l'hypothèse d'un double mode d'initiation des chaînes. En variant la dose et le moment de l'injection, on peut contrôler le cours de la réaction. L'application de cette méthode à d'autres oxydations révélerait sans doute des particularités intéressantes susceptibles d'aider à en élucider le mécanisme.

REMERCIEMENTS

Les auteurs adressent leurs remerciements au Conseil national de Recherches pour les bourses accordées à l'un d'eux (A.L.) et au Comité des Recherches pour la Défense, par lequel ce travail a été subventionné (octroi DRB-5001-09; Projet D44-5001-09).

SUMMARY

The effect of small quantities of nitric oxide upon the slow, gas-phase oxidation of diethyl ether depends essentially upon the moment at which this inhibitor is injected. By assuming that the decomposition of a hydroperoxide, not sensitive to nitric oxide, acts as a secondary chain-initiating process, it is possible to account for the observed effects. The inhibition is strong and lasting in the early reaction, strong but of short duration during the pressure drop, non-existent at the moment when the oxygen disappears, and weak in the later stages. Under conditions where no hydroperoxide builds up, straight inhibition is observed at all stages. Propylene acts as nitric oxide but is 10 times less potent. Formaldehyde inhibits the reaction only if it is injected before the reactants. Inhibition by hydrobromic acid is complicated by surface activation.

STEROIDS AND RELATED PRODUCTS

VII. THE SYNTHESIS OF 17 α -METHYLCORTICOSTERONE^{1,2}

CH. R. ENGEL

ABSTRACT

The synthesis of 17 α -methylcorticosterone, a new biologically active homologue of corticosterone and analogue of cortisol, is described. In the course of the work it was observed that the 17-methyl group greatly impeded both the formation and the hydrolysis of a 20-ketal. On the other hand, evidence was obtained that the 11-keto group is not completely unreactive towards ethylene glycol, in the presence of *p*-toluenesulphonic acid.

The interesting biological activities of the 17 α -methylated sex hormones and the fact that the most potent glucocorticoid and antiarthritic cortical adrenal hormones also possess a 17 α -substituent, in the form of a hydroxy group, prompted us in this laboratory to attempt the preparation of the 17 α -methyl analogues of 11-oxygenated corticoids. We reported recently (6, 7) the synthesis of 11-dehydro-17 α -methylcorticosterone (I), the 17-methyl analogue of cortisone; in the present paper, the synthesis of 17 α -methylcorticosterone (X), the homologue of the important hormone corticosterone and the 17 α -methyl analogue of the most potent natural glucocorticoid, cortisol, is recorded.

Since it did not seem advisable to expose the relatively labile 11 β -hydroxy group to the vigorous reaction conditions necessary for the elaboration of the ketol side chain in the presence of a 17-methyl group (7, 9, 11), it was decided to introduce the 11 β -hydroxy moiety by reduction of an 11-keto adduct possessing already the 17-methylated ketol side chain. The distinctly different reactivities of carbonyl functions in positions 3 and 20 on the one hand and in position 11 on the other hand allow the selective protection in positions 3 and 20 of a 3,11,20-triketone in the 17-non-methylated series; since the remaining free 11-ketone can be reduced to the corresponding alcohol and since the protecting groups can be removed subsequently, these differences in reactivity of the carbonyl functions make it possible to transform a hydroxy triketone of the 11-dehydrocorticosterone type to a dihydroxy diketone of the corticosterone type. One of the most successful methods for this type of conversion is due to Bernstein and his co-workers (2, compare also 16 and 19), who effect the protection of the 3- and 20-carbonyl functions by the formation of a *bis*-ethylene ketal, reduce subsequently the free 11-ketone by the action of a metal hydride, and finally liberate the 3- and 20-ketone functions by acid hydrolysis. Allen, Bernstein, and Littell (1) showed also that sodium borohydride reduced the 11-ketone almost quantitatively to the 11-alcohol with the desired β -configuration (compare also 10, 12, 16).

It had to be expected that the application of this method to the 17 α -methyl series would encounter serious obstacles. It is indeed well established that reactions involving functional groups of the side chain proceed only with considerable difficulty in the presence of a 17-methyl substituent (7, 8, 9, 11, 18) and it is further known that condensation reactions with 20-carbonyl groups are prone to steric hindrance, even in the

Contribution from the Collip Medical Research Laboratory, the University of Western Ontario, London, Ontario. The subject of this publication was part of a communication presented before the 3rd International Congress of Biochemistry, Brussels, August, 1955.

²For Paper VI of this series see Reference (8).

17-non-methylated series, for instance to hindrance exerted by ester groupings in position 21 (2, 24). Hence, the starting material for the series of experiments described here, 11-dehydro-17 α -methylcorticosterone (I) (7), was subjected to the action of ethylene glycol, in the presence of *p*-toluenesulphonic acid and with constant removal of water, for a period exceeding the usual reaction time by a factor of three. From the amorphous reaction product no pure crystalline substance could be isolated. It appeared likely that the unreactive 20-ketone had only been ketalized in part and, furthermore, the possibility had to be considered that under the reaction conditions the 11-ketone function too might have undergone ketalization to some extent.³ The crude reaction product could thus be expected to represent a mixture of the desired 3,20-diketal IV with the 3-monoketal III and possibly the 3,11-diketal II.⁴ The infrared absorption spectrum of the product (Fig. 1b) was in agreement with this assumption; the absence of the Δ^4 -3-carbonyl band indicated complete protection of the 3-ketone; on the other hand, whereas the starting material I shows clearly the band of a dicarbonyl adduct, with a definite inflection point (Fig. 1a), the corresponding band of the product of ketalization showed no inflection point and had lost some of its asymmetry; however, the curve did not correspond completely to the typical band of a single carbonyl function. The result of the blue tetrazolium test lent further support to the above-mentioned assumption; the color test, although sluggish, was still positive, indicating that the original 20-oxo-21-hydroxy function had been retained at least in part.

FIG. 1. Carbonyl regions of infrared absorption spectra in KBr: (a) of compound I; (b) of ketalization product (II, III, IV); (c) of sodium borohydride reduction product (V, VI, VII).

It seemed inadvisable to attempt the completion of the partial ketalization of the 20-ketone by subjecting the mixture anew to the same treatment, since the appearance of the product had already deteriorated during the first treatment and since the possibility of concomitant and undesired ketalization in position 11 could not be excluded. Hence, the crude mixture was reduced with sodium borohydride in tetrahydrofuran; in order to ensure that the complexity of the mixture would not be increased by incomplete reduction, the excess of reducing agent employed and the reaction period were increased

³Recently Magerlein and Levin (14) have indeed observed, independently of our work, the formation of an ethylene ketal from an 11-oxo-20 β -hydroxy steroid in 50% yield when the reaction period was extended to 72 hours.

⁴The formation in small yield of a 3,11,20-triketal has also to be considered but is not represented in the reaction scheme and not further discussed since no experimental proof for its presence was found.

far beyond the conditions under which complete reduction of the 11-ketone function had been achieved in analogous cases (1). The infrared spectrum of the reduction product (Fig. 1c) was indeed devoid of carbonyl bands. Again, no single, pure component could be isolated from the mixture, which would have comprised the 20,21-dihydroxy-3,11-diketal V, the 11 β ,20,21-trihydroxy-3-monoketal VI, and the desired 11,21-dihydroxy-3,20-diketal VII if it had originated from the mixture of the adducts II, III, and IV.⁵

Formula X

⁵Whereas a high stereospecificity in the reduction of the 11-ketone to the 11 β -alcohol could be assumed (compare above) no definite assignment of configuration of the 20-hydroxy group is made (compare also below).

An attempt was then made to free the protected keto functions by hydrolysis with aqueous sulphuric acid in methanol (2) and to separate subsequently the components of the resulting mixture. The infrared spectrum of the reaction product showed clearly that the Δ^4 -3-keto moiety had been restored but a second band in the carbonyl region, attributable to an 11- or 20-keto function, was only of very low intensity and very badly defined. Prolongation of the acid treatment did not result in any appreciable change of the product. Upon acetylation and subsequent chromatography of part of the mixture there was obtained, in very low yield, material showing in the infrared the expected Δ^4 -3-keto moiety and the bands characteristic of an acetate grouping, as well as a second carbonyl function of higher intensity than the corresponding band of the crude non-acetylated product; however, the low yield and lack of purity of the product made it impossible to pursue this line of experiment. Evidently, acid hydrolysis is not a suitable method for the cleavage of a 20-ketal in the presence of a 17-methyl group. In order to effect the liberation of the keto groups more successfully, the original mixture obtained by the sodium borohydride reduction (compare V, VI, VII) was subjected to an exchange reaction with absolute acetone, in the presence of *p*-toluenesulphonic acid, a procedure introduced by Schinz into the terpene field (22) and subsequently successfully applied in the case of various steroidal ketals (3, 4, 19, 20). Partial precipitation of the reaction product with water afforded a crystalline material which yielded upon repeated recrystallization from ethanol a pure substance to which the structure of the Δ^4 -3-oxo-11 β ,20 ξ ,21-trihydroxy-17 α -methylpregnene-20,21-acetonide (IX) is assigned. Both the elementary composition and the absorption spectra of the product are in excellent agreement with this assignment. The infrared spectrum (Fig. 2a) exhibits a single, non-associated hydroxyl band, corresponding to the 11 β -hydroxy function, and a single carbonyl band typical of the Δ^4 -3-ketone; the presence of the latter was also confirmed by the ultraviolet absorption spectrum. The product remained unchanged when treated with an excess of acetic anhydride in pyridine, which corresponds indeed to the behavior of an 11 β -alcohol. The formation of the acetonide IX from the triol VI is perfectly plausible under the described reaction conditions.⁶

The infrared spectrum of the not completely purified acetonide showed an additional, badly defined band of low intensity in the carbonyl region. When the material was hydrolyzed with aqueous acetic acid there was obtained an amorphous product, the infrared spectrum of which was in agreement with the expected structure of the triol XII, in the crude state; the second, very weak carbonyl absorption band, which should have been absent from a completely pure sample, was again visible. Acetylation of the crude product and subsequent chromatography gave two crystalline substances; the one less readily eluted from the aluminum oxide column had an infrared spectrum in perfect agreement with the expected structure of the 11 β -hydroxy-20,21-diacetoxy ketone XIIa.⁷ The infrared spectrum of the substance eluted first was in accord with the structure of the corresponding 11-oxo-20,21-diacetate XIa (Fig. 2b); it showed again the bands of a 20,21-diacetate and of the Δ^4 -3-keto moiety but was also characterized by an additional carbonyl band in the 11-ketone region and by the absence of hydroxyl absorption; the ultraviolet spectrum⁸ showed the typical maximum of a Δ^4 -3,11-diketone. This series

⁶Previously Sarret has reported the preparation of an acetonide from a 20 β ,21-diol by the action of acetone and zinc chloride (21).

⁷It should be noted that when the infrared spectrum was taken in KBr the hydroxy band and the carbonyl bands were split.

⁸The author is indebted to Mr. R. A. Latimer, Science Service Laboratory, London, Ont., for kindly measuring this ultraviolet absorption spectrum on a Beckman Model DK1 Recording Spectrophotometer.

of experiments not only confirms the structure of the acetonide IX and hence the original formation of the monoketal III (further transformed to the adducts VI, IX, XII, and XIIa), but also lends support to the assumption that during the ketalization reaction some 3,11-diketal II had been formed; in the course of the described reactions this substance would have indeed been transformed, through the adducts V, VIII, and XI, to the diacetoxo diketone XIa.

No definite assignment for the configuration of the 20-hydroxy groups of the adducts V and VI, obtained by sodium borohydride reduction of the corresponding 20-ketones, and of their derivatives VIII, XI, and XIa and IX, XII, and XIIa, has been made. The infrared spectra of the diacetates XIa and XIIa are in agreement with the spectra of 20 β ,21-diacetoxo steroids (5, 13) and it is well established that in the 17-unsubstituted series sodium borohydride reduction leads predominantly to 20 β -alcohols (compare 15, 17); it is, however, also known that a 17 α -hydroxy group lowers the yield of formation of 20 β -hydroxypregnanes in this type of reaction (17) and hence it seems indicated not to make absolute predictions concerning the extent of steric influence of the even more hindering 17 α -methyl group.

FIG. 2. Infrared absorption spectra in KBr: (a) of compound IX; (b) of compound XIa; (c) of compound XIII.

After the acetonide fraction of the reaction mixture, obtained during the exchange reaction with acetone, had been removed by precipitation with slightly alkaline water, the remaining mother liquors were extracted and worked up in the usual manner. To the product thus obtained in the crude and semicrystalline state and representing approximately 30% of the total reaction product, the structure of the desired 17 α -methylcorticosterone (X) is ascribed. The infrared spectrum clearly shows the bands of a Δ^4 -3-keto group, a second well-defined carbonyl function attributable either to an 11- or a 20-ketone, and a broad, multiple, associated hydroxyl band. The product gave a pronounced blue tetrazolium reaction, which is in accord with the 20-oxo-21-hydroxy structure and which excludes the isomeric 11-oxo-20,21-dihydroxy structure of XI; furthermore, the ultraviolet absorption maximum at 241 m μ indicates a Δ^4 -3-keto moiety in the absence of an 11-ketone. Acetylation gave a crystalline monoacetate (XIII) of the expected elementary composition, with a well-defined single, non-associated hydroxyl band in the infrared (Fig. 2c); acetylation of a 20,21-diol (XI) or of an 11 α ,21-diol would have given a diacetate under the reaction conditions. The infrared spectrum also clearly exhibited the typical absorption of a 21-acetoxy-20-ketone (13), a further proof for the 20-oxo-21-hydroxy structure of X. The Δ^4 -3-keto function, clearly detectable in the infrared, was corroborated by the absorption maximum in the ultraviolet at 241 m μ , again indicating the absence of an 11-ketone. Hydrolysis with bicarbonate (compare 7) restored again the free alcohol (X).

Dr. E. H. Venning kindly tested 17 α -methylcorticosterone acetate (XIII) for glucocorticoid activity, using the assay developed in her laboratory (23). In this test the product was found to possess approximately 40% of the activity of cortisone acetate, which corresponds to almost twice the activity of 11-dehydro-17 α -methylcorticosterone acetate (7).

EXPERIMENTAL^{9, 10, 11}

Treatment of 11-Dehydro-17 α -methylcorticosterone (I) with Ethylene Glycol (Mixture II, III, IV)

A solution of 1.127 g. of 11-dehydro-17 α -methylcorticosterone (I), m.p. 152–156°, in 85 cc. of absolute benzene was reduced to 73 cc. There was subsequently added 18 cc. of freshly distilled ethylene glycol and 44 mg. of *p*-toluenesulphonic acid and the mixture was refluxed with exclusion of moisture for 6 hours. During this time the moist benzene was removed with the help of a water trap. The refluxing was continued for another 6 hours, with vigorous stirring and with intermittent separation of slightly moist benzene. The reaction mixture was poured into iced saturated sodium bicarbonate solution and extracted with ether. The ethereal solution was washed with iced 1% sodium carbonate solution and with water and taken to dryness. There was obtained 1.447 g. of an amorphous material which resisted crystallization; it yielded 39 mg. of a solid, m.p. 105°, [α]_D²⁷ -0.8° (*c*, 10.55 in CHCl₃-pyridine). Both the foamy material and the solid fraction had an identical infrared spectrum (compare Fig. 1b): $\nu_{\text{max}}^{\text{KBr}}$ 3425 cm.⁻¹ (associated hydroxyl), 1693 cm.⁻¹ (carbonyl), 1668 cm.⁻¹ (Δ^5 -double bond). The product reacted slowly and sluggishly with blue tetrazolium and was used without further purification for the following reactions.

⁹The melting points were taken in evacuated capillaries and the temperatures were corrected.

¹⁰The microanalyses were performed by Mr. J. F. Alicino, Metuchen, N.J., to whom high appreciation is expressed.

¹¹The aluminum oxide used for chromatography was treated as described under footnote 31 of Reference (9). Sincere thanks are due to Messrs. Merck and Co., Montreal, for kindly providing their activated aluminum oxide.

Reduction of the Ketalization Product with Sodium Borohydride (Mixture V, VI, VII)

A solution of 1.435 g. of the above-described crude ketalization product in 125 cc. of tetrahydrofuran was refluxed for 20 hours, with vigorous stirring, with 2.05 g. of sodium borohydride and with 17.5 cc. of a 2.5% sodium hydroxide solution. The mixture was refluxed a further 21 hours and subsequently filtered. After addition of water and removal of the tetrahydrofuran *in vacuo* the product was extracted with ether, the ethereal solution was washed to neutral and dried. After evaporation of the solvent there was obtained 1.483 g. of an amorphous product, resisting all attempts of crystallization and giving a positive tetranitromethane test; $\nu_{\text{max}}^{\text{KBr}}$ 3405–3435 cm^{-1} (associated hydroxyl), no carbonyl absorption, 1668 cm^{-1} (peak badly defined) (Δ^5 -double bond); (compare Fig. 1c). There was also isolated 44 mg. of acidic material which was not further investigated.

Attempted Hydrolysis of the Reduction Mixture with Sulphuric Acid

A solution of 296 mg. of the above-described crude reduction mixture in 15 cc. of methanol was flushed with nitrogen and there was added 1.5 cc. of 8% (v/v) sulphuric acid. The flask was again flushed with nitrogen and the mixture was refluxed for 35 minutes under nitrogen. After cooling and dilution with ice water, the mixture was extracted with ether and the organic solution was washed with 2% iced sodium carbonate solution and water and was dried. After removal of the solvent there remained 285 mg. of an amorphous material, $\nu_{\text{max}}^{\text{KBr}}$ 3415 cm^{-1} (hydroxyl), 1689 cm^{-1} (low intensity, 64% transmission) (carbonyl), 1658 cm^{-1} (28% transmission) (Δ^4 -3-ketone), 1615 cm^{-1} (3-keto- Δ^4 -double bond).

The product, which did not crystallize, was refluxed for a further 150 minutes, under nitrogen, with 2 cc. of 8% sulphuric acid in 15 cc. of methanol; the solvent and acid displaced by the nitrogen current were replaced during the reaction. The mixture was worked up as described above and there was obtained 294 mg. of an amorphous product with an infrared spectrum almost identical with the one exhibited by the material prior to its second treatment with sulphuric acid.

Acetylation.—To a solution of the above-described product (294 mg.) in 4.5 cc. of pyridine was added 2.5 cc. of acetic anhydride. The flask was flushed with nitrogen, sealed, and stored at 25° for 18 hours. The usual working up afforded 309 mg. of a thick yellow oil which was dissolved in 2 cc. of benzene and chromatographed on 9.5 g. of aluminum oxide. Benzene-ether (4:1) eluted 48 mg. of an amorphous product, showing in the infrared (smear) a broad band in the carbonyl region, with two maxima at 1730 cm^{-1} and 1712 cm^{-1} and the Δ^4 -3-ketone doublet at 1660 and 1613 cm^{-1} . The product resisted all attempts of crystallization and was not further investigated. The first ether fractions of the chromatogram (4 mg.) had an infrared absorption spectrum compatible with crude diacetate XIIa; $\nu_{\text{max}}^{\text{smear}}$ 3420 cm^{-1} (11 β -hydroxyl), 1735 cm^{-1} (20,21-diacetate), 1657 and 1615 cm^{-1} (Δ^4 -3-ketone doublet).

Cleavage of the Reduction Product with Acetone [Δ^4 -3-Oxo-11 β ,20 ξ ,21-trihydroxy-17 α -methylpregnene-20,21-acetonide (IX) and 17 α -Methylcorticosterone (X)]

(a) A solution of 298 mg. of the crude sodium borohydride reduction product (see above) in 25 cc. of absolute acetone was flushed with carbon dioxide and there was added 32 mg. of *p*-toluenesulphonic acid. The air was again displaced with carbon dioxide, the flask was sealed and kept for 36 hours at room temperature. Upon addition of 30 cc. of water and 1 cc. of saturated bicarbonate solution, crystals formed. Filtration afforded

176 mg. of brownish-yellow crystalline material, m.p. 248–259°; $\nu_{\text{max}}^{\text{KBr}}$ 3390 cm^{-1} (non-associated 11 β -hydroxyl), 1704 cm^{-1} (low intensity, transmission 65%) (11-ketone), 1656 cm^{-1} (18% transmission) (Δ^4 -3-ketone), 1613 cm^{-1} (3-keto- Δ^4 -double bond). Repeated recrystallization from ethanol afforded acetonide IX, m.p. 273–276°; $\lambda_{\text{max}}^{\text{EtOH}}$ 242 $\text{m}\mu$ (log ϵ 4.2), $\nu_{\text{max}}^{\text{KBr}}$ 3390 cm^{-1} (11 β -hydroxyl), 1656 and 1615 cm^{-1} (Δ^4 -3-ketone doublet); (compare Fig. 2a). The product was recrystallized twice more from methanol for analysis; needles, m.p. 279–280°, $[\alpha]_{\text{D}}^{28}$ 109.6° (c , 0.505 in CHCl_3). Anal. Calc. for $\text{C}_{25}\text{H}_{38}\text{O}_4$: C, 74.59; H, 9.52. Found: C, 74.66; H, 9.41.

The mother liquors from the separation of the crude acetonide fraction were extracted with ether, the ethereal solution was washed with iced 2% sodium carbonate and iced 1% sodium hydroxide solutions and with water and was dried. Removal of the solvents afforded 92 mg. of a partly crystalline material [crude 17 α -methylcorticosterone (X)], giving a pronounced blue tetrazolium reaction; $\lambda_{\text{max}}^{\text{EtOH}}$ 241 $\text{m}\mu$ (log ϵ 4.0); $\nu_{\text{max}}^{\text{smear}}$ 3375 cm^{-1} (associated hydroxyl), 1688 cm^{-1} (17-methyl-20-ketone), 1654 and 1617 cm^{-1} (Δ^4 -3-ketone doublet).

Acetylation of acetonide IX.—A sample of acetonide IX (22 mg., m.p. 273–278°) was dissolved in 1.5 cc. of pyridine and was treated with 0.8 cc. of acetic anhydride, at room temperature for 13 hours, under nitrogen. The usual working up afforded 29 mg. of a crude crystalline product which gave, upon purification with methanol, 20 mg. of the starting material, acetonide IX, m.p. 267–275°, not depressed upon admixture with authentic material; the infrared spectrum of the product was identical with that of the starting material (acetonide IX).

Acetylation of 17 α -methylcorticosterone (acetate XIII).—A solution of 80 mg. of crude 17 α -methylcorticosterone (X) in 2.5 cc. of pyridine was flushed with nitrogen and there was added 1.5 cc. of acetic anhydride; the mixture was again flushed with nitrogen, sealed, and stored for 17 hours at room temperature. The usual working up afforded 100 mg. of a product crystallizing from ether–acetone–hexane in colorless needles, m.p. 183.5–188°. Two recrystallizations raised the melting point to 193–195.5°; $[\alpha]_{\text{D}}^{29}$ 119° (c , 0.924 in CHCl_3); $\lambda_{\text{max}}^{\text{EtOH}}$ 241 $\text{m}\mu$ (log ϵ 4.2); $\nu_{\text{max}}^{\text{KBr}}$ 3500 cm^{-1} (non-associated 11 β -hydroxyl), 1746 and 1710 cm^{-1} (21-acetoxy-20-ketone doublet), 1659 and 1617 cm^{-1} (Δ^4 -3-ketone doublet); (compare Fig. 2c). Anal. Calc. for $\text{C}_{24}\text{H}_{34}\text{O}_5$: C, 71.61; H, 8.51. Found: C, 71.41; H, 8.66.

Hydrolysis of acetate XIII [17 α -methylcorticosterone (X)].—A solution of 25 mg. of mother liquors of acetate XIII in 2.5 cc. of methanol was treated during 5 days with 26 mg. of potassium bicarbonate in 0.4 cc. of water, at room temperature and under nitrogen, as described previously (7). The usual working up afforded 30 mg. of a crude, partly crystalline product, $\nu_{\text{max}}^{\text{smear}}$ 3420 cm^{-1} (associated hydroxyl), 1686 cm^{-1} (17-methyl-20-ketone), 1656 and 1646 cm^{-1} (split Δ^4 -3-keto band), 1618 cm^{-1} (3-keto- Δ^4 -double bond). The product was chromatographed on *Davidson's* silica gel 923; benzene–ethyl acetate (1:1 and 1:2) eluted small cubes, m.p. 203–205°, $\nu_{\text{max}}^{\text{CHCl}_3}$ 3575 cm^{-1} (non-associated 11 β -hydroxyl), 3475 cm^{-1} (associated 21-hydroxyl), 1697 cm^{-1} (20-ketone), 1665 and 1616 cm^{-1} (Δ^4 -3-ketone doublet).

(b) In another run, 275 mg. of the crude sodium borohydride reduction mixture was refluxed with 33 mg. of *p*-toluenesulphonic acid in 25 cc. of absolute acetone for 3 hours, under carbon dioxide, and with the exclusion of moisture. The mixture was allowed to stand 12 hours and was refluxed under carbon dioxide for another 2 hours. The product was worked up as described above and there was obtained 111 mg. of crude acetonide IX

(containing some acetonide VIII, see below), m.p. 241–247.5°, 83 mg. of an acetonide fraction of lesser purity, and 86 mg. of crude, partly crystalline 17 α -methylcorticosterone (X). Part of the latter (80 mg.) was acetylated, as described above, with 1.5 cc. of acetic anhydride in 2.5 cc. of pyridine, under nitrogen, and gave 85 mg. of acetate XIII, melting after one recrystallization from ether–acetone–hexane at 192–195°, melting point not depressed upon admixture with authentic material, infrared spectrum identical with authentic acetate XIII.

Δ^4 -3,11-Dioxo-20 ξ ,21-diacetoxy-17 α -methylpregnene (XIa) and Δ^4 -3-Oxo-11 β -hydroxy-20 ξ ,21-diacetoxy-17 α -methylpregnene (XIIa)

A solution of 115 mg. of not completely purified acetonide IX (containing some acetonide VIII, slight 11-carbonyl absorption in the infrared), m.p. 260–280°, in 5 cc. of acetic acid and 5 cc. of water was heated under carbon dioxide for 65 minutes on a boiling water bath. Subsequently, the mixture was diluted with water, extracted with ether, and the ethereal solution was washed with sodium bicarbonate solution and water and was dried. After removal of the solvent there was obtained 108 mg. of a foamy material (XII, contaminated with XI), $\nu_{\text{max}}^{\text{KBr}}$ 3440, 3420 cm^{-1} (associated hydroxyl), 1702 cm^{-1} (low intensity, 73% transmission) (11-ketone), 1659 and 1615 cm^{-1} (Δ^4 -3-ketone doublet). The product was acetylated without further purification with 2.5 cc. of acetic anhydride in 3 cc. of pyridine, under nitrogen, at 45° for 55 minutes and at room temperature for 16 hours. The usual working up gave 115 mg. of an amorphous product which was chromatographed on 4 g. of aluminum oxide. Petroleum ether–benzene (1:4) eluted 6 mg. of *diacetate* XIa, crystallizing from ether–hexane, m.p. 189–192°, showing occasionally a double melting point 188–192°/260°; $\lambda_{\text{max}}^{\text{EtOH}}$ 238 μ ($\log \epsilon$ 4.5); $\nu_{\text{max}}^{\text{KBr}}$ 1735 cm^{-1} (20,21-diacetate), 1702 cm^{-1} (11-ketone), 1666 and 1619 cm^{-1} (Δ^4 -3-ketone doublet), 1375 cm^{-1} (20-acetate), 1245 and 1232 cm^{-1} (acetate); (compare Fig. 2b); $\nu_{\text{max}}^{\text{CHCl}_3}$ 1738 cm^{-1} (20,21-diacetate), 1707 cm^{-1} (11-ketone), 1668 and 1615 cm^{-1} (Δ^4 -3-ketone doublet). The following benzene fractions eluted a mixture and benzene–ether (4:1, 1:1) and ether eluted 40 mg. of a substance crystallizing from ether–hexane. This product (crude *diacetate* XIIa) was rechromatographed on 2 g. of aluminum oxide. Petroleum ether–benzene eluted another 4 mg. of *diacetate* XIa, the benzene fractions eluted a mixture, and the benzene–ether and ether fractions afforded 23 mg. of *diacetate* XIIa, which was purified by further chromatography; m.p. 199.5–202.5°, $\nu_{\text{max}}^{\text{KBr}}$ 3542 and 3420 cm^{-1} (split 11 β -hydroxy band),¹² 1743 and 1720 cm^{-1} (split 20,21-diacetate), 1670 and 1656 cm^{-1} (split Δ^4 -3-carbonyl band), 1617 cm^{-1} (3-keto- Δ^4 -double bond), 1375 cm^{-1} (methyl of 20-acetate), 1236 cm^{-1} (acetate); $\nu_{\text{max}}^{\text{CHCl}_3}$ 1737 cm^{-1} (20,21-diacetate), 1667 and 1618 cm^{-1} (Δ^4 -3-ketone doublet), 1375 cm^{-1} (methyl of 20-acetate).

ACKNOWLEDGMENTS

Sincere thanks are rendered to Mr. R. Heckadon and to Miss H. Bitenc for excellent and devoted technical assistance. The author is deeply indebted to Mr. R. W. White, Science Service Laboratory, London, Ontario, and to Dr. R. N. Jones, National Research Council, Ottawa, for their invaluable and unfailing help with infrared spectral analyses and for their enlightening discussions on this subject. The kindness of Dr. E. H. Venning, Royal Victoria Hospital, Montreal, in performing the mentioned bio-assay was highly

¹²Occasionally the band is not split; in this case the maximum of the non-associated hydroxyl band lies at 3402 cm^{-1} .

appreciated. The author wishes to acknowledge gratefully support from the Canadian Life Insurance Officers Association enabling him to carry out this study. Sincere thanks are due to the Ontario Division of the Canadian Cancer Society and to the Ciba Company Ltd., Montreal, for assisting this project financially. The kind interest of Dean J. B. Collip was greatly appreciated.

TOXIC FLUORINE COMPOUNDS

XIII. ω -FLUOROALKYL ETHERS^{1,2}

F. L. M. PATTISON, W. C. HOWELL, AND R. G. WOOLFORD

ABSTRACT

Representative ω -fluoroalkyl ethers have been synthesized. Their toxicological properties provide evidence for the rupture *in vivo* of the ether link. The compound 2-fluoro-1',2',2',2'-tetrachlorodiethyl ether (XIII) shows outstanding activity as a systemic insecticide.

The characteristic toxicological properties of the ω -fluorine atom have been outlined in earlier reports in this series. In this paper are described representative ω -fluoroalkyl ethers (Table I), prepared for comparison with the ω -fluoroalcohols (16). It was maintained that if the toxicities of these ethers followed the usual dichotomous pattern (16), one could argue that the ether link was being split *in vivo*, giving the corresponding ω -fluoroalcohols.

PREPARATION

First to be examined were two ω -fluoroalkyl methyl ethers, $F(CH_2)_nOCH_3$. 6-Fluorohexyl methyl ether was prepared initially by treatment of 6-fluorohexyl bromide with sodium methylate (23% yield); however, considerable quantities of 6-fluoro-1-hexene were also isolated, indicating that milder conditions were necessary. Consequently the method of Stevens and Deans (20) was examined and found to be satisfactory. This involves the addition of the appropriate alcohol to sodium naphthalene (19) and treatment of the resultant alkoxide with methyl iodide. 5-Fluoroamyl and 6-fluorohexyl methyl ethers were thus obtained in yields of 37% and 75% respectively. The yield of 5-fluoroamyl methyl ether was subsequently raised to 70% by reversing the order of addition; thus, by slow addition of the sodium naphthalene to 5-fluoropentanol, the alcohol was always in excess and side reactions were minimized.

Three 4-fluorobutyl ethers were prepared by the following reactions:

4,4'-Dichlorodibutyl ether (I), prepared (1, 2) from tetrahydrofuran, was readily converted to 4,4'-difluorodibutyl ether (II) (39% yield) by heating for 10 hours with excess anhydrous potassium fluoride in diethylene glycol at 125°. The fluorochloro ether (III) was prepared in 41% yield by the technique of partial fluorination (6, 15), whereby the reaction is carried out at a slightly higher temperature (130–150°) under reduced pressure,

Contribution from the Department of Chemistry, University of Western Ontario, London, Ontario. Issued as D.R.B. Report No. SW-31.

²For Part XII, see Ref. 10.

with the product being continuously removed by distillation. The fluorocyano ether (IV) was obtained in excellent yield by treatment of III with sodium cyanide. Attempted methanolysis of this to 4-fluoro-4'-carbomethoxydibutyl ether, using methanol and anhydrous hydrogen chloride, resulted in the formation of 4-fluorobutanol (4, 16) in 70.4% yield. The ether linkage is thus susceptible to hydrolytic cleavage even under these mild conditions; this is consistent with the biochemical behavior described below.

Following the observation of Schrader (18) that certain fluorinated polyethers, notably V and VI, are good systemic insecticides, and bearing in mind the ether linkage in the structure of the efficient contact insecticide 2-thiocyano-2'-*n*-butoxydiethyl ether (VII), we prepared two 2-fluoroethyl ethers for screening as contact and systemic insecticides. The first of these, 2-fluoro-2'-*n*-butoxydiethyl ether (X), is structurally similar to the

thiocyanate (VII); it was prepared from butyl carbitol (VIII) by conversion to the bromide (IX), followed by fluorination:

The second, 2-fluoro-1',2',2',2'-tetrachlorodiethyl ether (XIII), contains both the 2-fluoroethyl ether group, referred to above, and the trichloromethyl group, associated with the well-known insecticide DDT; it was readily prepared from 2-fluoroethanol (XI) and chloral by treatment of the intermediate hemiacetal (XII) with phosphorus pentachloride:

Several simple 2-fluoroethyl ethers were prepared in the course of other work. 2-Fluoroethyl methyl ether and 2-fluorodiethyl ether have been described previously (17). 2-Fluoro-2'-chlorodiethyl ether and 2,2'-difluorodiethyl ether were prepared in low yield by fluorination of 2,2'-dichlorodiethyl ether with potassium fluoride in a stainless-steel autoclave; both compounds have been prepared by other workers (7, 8).

PROPERTIES

The toxicities of 5-fluoroamyl and 6-fluorohexyl methyl ethers (Table I) approximate those of 5-fluoropentanol and 6-fluorohexanol (16), and thus afford *a priori* evidence for the rupture of the ether linkage *in vivo*. Consistent with this mechanism are the toxicities of 2-fluoroethyl methyl ether (LD₅₀ 15 mg./kg.), 2-fluoro-2'-*n*-butoxydiethyl ether (X), and 2-fluoro-1',2',2',2'-tetrachlorodiethyl ether (XIII), all of which are similar to that of 2-fluoroethanol (LD₅₀ 10 mg./kg.) (16) on a molar basis.

^aAlexander and Schniepp (1) report b.p. 84-86° at 0.5 mm. and n_D^{25} 1.4567.

This biochemical cleavage of the ether linkage is strikingly confirmed by the results obtained with the four butyl ethers (I-IV). The dichloro ether (I), containing no fluorine, is non-toxic. The toxicities of the fluorochloro and fluorocyano ethers (III and IV) are almost identical, and both are very similar to that of 4-fluorobutanol, on a molar basis and within the limits of biological variation. The difluoro ether (II) can theoretically give rise to twice the quantity of 4-fluorobutanol on hydrolytic fission, and, according to expectation, is approximately twice as toxic as the two monofluoro ethers. The intimate relationship of these compounds can clearly be seen by considering the LD₅₀ figures in terms of mg. of fluorine/kg. (Table II).

TABLE II
COMPARISON OF TOXICITIES OF 4-FLUOROBUTYL ETHERS

	LD ₅₀ for mice (intraperitoneal)	
	Mg. of compound/kg.	Mg. of fluorine/kg.
4-Fluorobutanol	0.9	0.18
4-Fluoro-4'-chlorodibutyl ether	1.32	0.14
4-Fluoro-4'-cyanodibutyl ether	1.5	0.16
4,4'-Difluorodibutyl ether	0.82	0.18

While the metabolic scission of methyl and ethyl *aromatic* ethers has long been recognized (3, 9, 21), little is known regarding the fate of *aliphatic* ethers *in vivo*. All of the above toxicity results provide circumstantial evidence for the rupture of ω -fluoroalkyl ethers in the animal body. It is probably not unreasonable to extend these conclusions to unfluorinated analogues by inferring the existence of a biological mechanism capable of promoting the rupture of simple aliphatic ethers.

All of the fluoroethers listed in Table I with the exception of IV have been tested as insecticides (12, 13), in particular for systemic activity. No appreciable phytotoxicity was observed with any of the compounds at the concentrations examined (0.1% or less). Contact toxicity was low for most of the members, but the butoxy ether (X) showed positive activity. Fumigant activity varied widely with the different compounds, with the butoxy ether (X) and 6-fluorohexyl methyl ether showing fairly strong activity. Systemic action was strong with several of the members, and outstanding with 2-fluoro-1',2',2',2'-tetrachlorodiethyl ether (XIII) (14).

On preliminary testing, XIII appears to be about 15 times more potent than Schradan as a systemic insecticide; moreover, its mammalian toxicity (*ca.* 48 mg./kg., intraperitoneally to mice) appears to be less than that of Schradan (18 mg./kg., orally to rats). To compare the systemic activity of the two compounds, English broad bean seedlings, heavily infested with aphids, were washed free from soil and placed in different concentrations of the test solutions; the approximate insect mortality was observed after 24 and 48 hours. Results are shown in Table III. It can be seen that the fluoro ether (XIII) is active at concentrations as low as 1.3 p.p.m.

During the testing of XIII, the insect mortality continued to increase for at least three days. This may have been due to a relatively slow rate of translocation, and/or to some necessary biochemical transformation resulting in the formation of a more active species. It is not unlikely that the latter is 2-fluoroethanol, a compound which we have

TABLE III
MORTALITY OF *Aphis fabae* ON BROAD BEAN SEEDLINGS

Concentration of insecticide, %	Insect mortality, %			
	Compound XIII		Schradan	
	24 hr.	48 hr.	24 hr.	48 hr.
Control	0	0	0	0
0.02	98		64	
0.002	85		25	
0.001	41	90	17	50
0.0005	42	90	14	30
0.00025	27	90	2	30
0.00013	23	75	0	0

shown to be an effective systemic insecticide in its own right.³ In line with our studies on mammalian toxicity (16), 3-fluoropropanol was found to be inactive as a systemic insecticide.

In order to demonstrate that both the 2-fluoroethyl and chlorine-containing moieties of XIII are essential for high activity, the following compounds, containing one but not both of the moieties, were tested:

2-fluoroethyl methyl ether, $\text{FCH}_2\text{CH}_2\text{OCH}_3$,
2-fluoro-2'-*n*-butoxydiethyl ether, $\text{FCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OBu}$,
1,2,2,2-tetrachlorodiethyl ether (11), $\text{CH}_3\text{CH}_2\text{OCHClCCl}_3$.

All three were found to be less active than XIII, a fact implying that for high activity both moieties of XIII must be present in the same molecule.

EXPERIMENTAL⁴

6-Fluorohexyl Methyl Ether

(a) *From 6-fluorohexyl bromide.*—Clean metallic sodium (1.27 g., 0.05 g-atom) was dissolved in absolute methanol (5 g.), and to the solution was added 6-fluorohexyl bromide (15) (9 g., 0.054 mole). The mixture was heated under reflux for 2 hours, cooled, diluted with water, and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulphate. After removal of the ether, fractionation of the product gave 6-fluorohexyl methyl ether (1.5 g., 23%).

(b) *From 6-fluorohexanol.*—Sodium naphthalene was prepared (19) in an atmosphere of dry nitrogen. Small lengths of sodium wire (1.95 g.) were added to a solution of pure, dry naphthalene (10.7 g.) in pure, anhydrous 1,2-dimethoxyethane (100 ml.). The mixture was stirred vigorously. After about 15 minutes, the color changed to a dull green which gradually darkened as more sodium dissolved. The temperature was maintained at 20–25° by intermittent cooling. The sodium had dissolved completely after about 2 hours. 6-Fluorohexanol (16) was added slowly, and with vigorous stirring, to this freshly prepared solution of sodium naphthalene until there was a sharp color change from deep green to pale yellowish green, indicating that an equivalent of alcohol had been added. In this experiment, 5.0 g. of 6-fluorohexanol caused the permanent color change. The mixture was cooled to 20° or less, and methyl iodide (8.0 g.) was slowly added. Stirring

³It is surprising that Schrader, in referring to the high activity of certain of its esters, ethers, and acetals, has stated (18) that 2-fluoroethanol itself shows no activity as an insecticide.

⁴Physical constants and analytical results are listed in Table I.

was continued for 1 hour after the addition was complete. The mixture was diluted with water (150 ml.) and extracted with ether. The extracts, after being dried over anhydrous sodium sulphate, were distilled, yielding a small forerun of 1,2-dimethoxyethane and then 6-fluorohexyl methyl ether (4.2 g., 75%).

5-Fluoroamyl Methyl Ether

Sodium naphthalene was prepared as described above, using naphthalene (12 g.) in 1,2-dimethoxyethane, and sodium (2.1 g.). This freshly prepared solution was slowly added to 5-fluoropentanol (16) (5 g.) through a delivery tube under nitrogen pressure until a permanent deep green color persisted. Vigorous stirring and cooling were employed throughout the reaction. A further quantity of 5-fluoropentanol was added until a final medium-green end point was attained. A total of 6.5 g. of 5-fluoropentanol was used. With cooling and stirring, methyl iodide (12 g.) was slowly added. Stirring was continued for 1 hour after the addition was complete. Isolation and purification were carried out as described above, yielding 5-fluoroamyl methyl ether (5.2 g., 70%).

4,4'-Difluorodibutyl Ether (II)

A mixture of 4,4'-dichlorodibutyl ether (I) (1, 2) (85 g., 0.43 mole), anhydrous potassium fluoride (80 g., 1.38 moles), and anhydrous diethylene glycol (400 g.) was heated with vigorous stirring at 125° for 10 hours. The mixture was cooled, diluted with an equal volume of water, and extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulphate. After removal of the ether, the residue on distillation yielded crude 4,4'-difluorodibutyl ether (31.6 g., 45%). Redistillation gave the pure ether (27.6 g., 39%).

4-Fluoro-4'-chlorodibutyl Ether (III)

A mixture of 4,4'-dichlorodibutyl ether (I) (1, 2) (88.0 g., 0.44 mole), anhydrous potassium fluoride (38.0 g., 0.66 mole), and anhydrous diethylene glycol (400 g.) was placed in a 1-liter three-necked flask, equipped with a stirrer, a thermometer, and a vacuum distillation take-off. The pressure of the system was reduced to 30 mm., and the mixture was heated to 132°, whereupon a liquid started slowly to distill (b.p. 120-125°). For the next 2½ hours, the reaction temperature was adjusted to give a slow, even rate of distillation, ultimately reaching 155°. The distillate (consisting of two layers) was dissolved in ether, washed successively with water, 10% aqueous sodium carbonate, and water again, and dried over anhydrous magnesium sulphate. After removal of the ether, the residue on fractionation yielded 4,4'-difluorodibutyl ether (3.4 g., 5.3%), 4-fluoro-4'-chlorodibutyl ether (26.3 g., 33% conversion, 41% yield), and finally unchanged 4,4'-dichlorodibutyl ether (18.1 g.).

4-Fluoro-4'-cyanodibutyl Ether (IV)

A mixture of 4-fluoro-4'-chlorodibutyl ether (III) (19.5 g., 0.107 mole), sodium cyanide (10.0 g., 0.204 mole), sodium iodide (16.0 g., 0.107 mole), and 80% ethanol (20 ml.) was heated under reflux for 4 hours. The mixture was cooled, diluted with water, and extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulphate. After removal of the ether, the residue on fractionation through a modified Podbielniak column yielded the cyanide (IV) (16.9 g., 91%).

On attempted methanolysis to the corresponding ester using methanol and anhydrous hydrogen chloride, the only product isolated was 4-fluorobutanol (70.4%), of boiling

point 54–56° at 10 mm. and n_D^{25} 1.3958; Gryszkiewicz-Trochimowski (4) reports b.p. 52–53° at 11 mm.

2-Fluoro-2'-n-butoxydiethyl Ether (X)

Butyl carbitol (VIII) (100 g., 0.62 mole) was slowly added to phosphorus tribromide (83.8 g., 0.31 mole) with external cooling. The mixture was slowly heated to ensure completion of the reaction; this was accompanied by a series of small explosions in the reaction vessel, possibly due to peroxide decomposition. The mixture was cooled and diluted with water. The organic layer was separated, washed, dried, and distilled, yielding the crude bromide (IX) (106 g., 76%), of boiling point 99–104° at 13 mm. This was used in the subsequent fluorination without further purification.

A mixture of the crude bromide (IX) (100 g., 0.445 mole), anhydrous potassium fluoride (65 g., 1.12 moles), and butyl carbitol (500 g.) was heated at 140–150° for 10 hours with vigorous stirring. The contents of the flask were then directly distilled under reduced pressure through a 30 cm. Vigreux column until the boiling point of butyl carbitol was reached. The distillate was dissolved in ether and dried over anhydrous sodium sulphate. After removal of the ether, fractionation of the residue gave the fluoro ether (X) (11.5 g., 18%) and unreacted bromide (12 g.).

2-Fluoro-1',2',2',2'-tetrachlorodiethyl Ether⁵ (XIII)

Chloral (105.5 g., 0.715 mole) and 2-fluoroethanol (XI) (5) (63.6 g., 0.99 mole) were slowly mixed, and allowed to cool to room temperature. Freshly distilled, anhydrous ether (120 ml.) was added, and this solution of the hemiacetal (XII) was added slowly and with shaking to phosphorus pentachloride (199.0 g., 0.93 mole) in anhydrous ether (105 ml.). The temperature of the mixture was maintained between 15° and 20° by means of an ice bath. After it was left for 30 minutes, the mixture was poured onto crushed ice and stirred vigorously until the evolution of hydrogen chloride ceased. The resultant mixture was transferred to a large beaker immersed in ice, and an ice-cold 35% aqueous solution of sodium hydroxide was slowly added with stirring until the mixture was just alkaline to litmus. The mixture was steam distilled, and the organic layer was separated, washed, and dried over anhydrous calcium chloride. After removal of the ether, fractionation yielded the pure ether (XIII) (88.3 g., 53.5%).

Preparation of Solutions for Testing as Systemic Insecticides⁶

The following typical procedure was used for compounds which are only slightly soluble in water. 2-Fluoro-1',2',2',2'-tetrachlorodiethyl ether (0.1 ml.) was dissolved in acetone (100 ml.), and a drop of Atlas Detergent No. G8916P was added. One milliliter of this solution was suspended in 100 ml. of water, thus giving a concentration of 0.001%. Serial dilutions gave the lower concentrations listed in Table III.

A RELATIONSHIP BETWEEN THE CONFORMATIONS OF CYCLOHEXANE DERIVATIVES AND THEIR PHYSICAL PROPERTIES¹

R. B. KELLY²

ABSTRACT

A relationship between the conformations of isomeric cyclohexane derivatives and their physical properties is discussed. The relationship is applied to a variety of polysubstituted monocyclic and polycyclic compounds, to cyclohexenes, and to pyranosides.

It is evident from the paper of Pitzer and Beckett (23) and later works (1, 2, 4) that for *cis-trans* pairs of disubstituted cyclohexanes, the isomer which has the higher index of refraction and the higher density is the isomer with the less conformational stability. Therefore, by stating the Auwers-Skita rule (3) in terms of conformational stabilities rather than *cis-trans* relationships, the anomalies experienced on application of the classical rule to 1,3-disubstituted cyclohexanes are obviated.

Allinger (1, 2) has proposed a more general rule (cf. Kelly cited by Barton and Cookson (4)) relating configurational stability to physical properties and has shown that his rule is valid for a variety of compounds. Allinger offers a rationalization of his rule and anticipates its validity for the more complex polysubstituted systems to be considered in the present paper.

In the interests of clarity and for convenience, the relationship to be discussed will be stated (as a "rule") in a form slightly different from that of Allinger's rule, thus: For isomeric cyclohexane and tetrahydropyran derivatives similarly substituted on corresponding ring carbon atoms, the refractive indices and densities increase with increasing number of axial substituents. In the majority of cases an equivalent statement would be that the conformational stabilities of such isomers bear an inverse relationship to their refractive indices and densities. The relative conformational stabilities are derived from the principles of conformational analysis (4).

The above statement is, in effect, a generalized version of the Auwers-Skita rule but it has the advantage of removing the confusion with regard to 1,3-disubstituted cyclohexanes. Furthermore, it accommodates polysubstituted cyclohexanes and di- and tri-cyclic compounds formed by the fusion of cyclohexane rings. For application to di- and poly-cyclic systems, substitution is regarded with respect to the most highly substituted ring (for example the central ring of perhydrophenanthrene).

In the following sections the relationship is assessed with regard to a wide variety of compounds, some of which have several asymmetric centers.

MONOCYCLIC COMPOUNDS

The application of the Auwers-Skita rule to disubstituted cyclohexanes is well known; therefore these compounds will not be discussed in detail here. The 3-*t*-butylcyclohexanols I (n_D^{25} , 1.4660) and II (n_D^{25} , 1.4684) (28) illustrate the accommodation of 1,3-disubstituted cyclohexanes by the revised rule where these compounds are exceptions to the classical rule.

¹Manuscript received in original form August 3, 1955, and, as revised, October 10, 1956. Presented at the Chemical Institute of Canada Organic Chemistry Division Symposium at Guelph, Ontario, September 6 and 7, 1956.

²Present address: Merck & Co. Limited, 560 De Courcelle Street, Montreal, Quebec.

The 1,2-dihalocyclohexanes merit special consideration because the *trans* isomers are known to exist as equilibrium mixtures of the diaxial and the diequatorial conformations (6, 14, 27) but from the data summarized in Table I it seems apparent that the concentration of the diaxial form is not large enough to reduce the stability of the *trans* isomers below that of the corresponding *cis* isomers; consequently there are no exceptions.

TABLE I
PHYSICAL PROPERTIES OF 1,2-DIHALOCYCLOHEXANES (8)

Cyclohexane derivatives	n_D^{25}	d_4^{25}
<i>trans</i> -1,2-Dichloro	1.4888	1.180
<i>cis</i> -1,2-Dichloro	1.4953	1.199
<i>trans</i> -1,2-Dibromo	1.5507	1.784
<i>cis</i> -1,2-Dibromo	1.5518	1.803
<i>trans</i> -1-Bromo-2-chloro	1.5173	1.479
<i>cis</i> -1-Bromo-2-chloro	1.5238	1.508

Data from the recent literature (12, 13) affords an opportunity of assessing the relationship with regard to cyclohexene derivatives. The geometry of the cyclohexene ring (III and IV) gives rise to bonds corresponding to axial and equatorial bonds at C₅ and C₆ and to quasi-axial and quasi-equatorial bonds (5) at C₁ and C₄. If the methyl group of 5-methyl-2-cyclohexenyl acetate is assigned to the more stable equatorial orientation* the *cis* isomer has the more stable conformation III while the *trans* isomer has the less stable conformation IV.

In agreement with the rule, the latter isomer has the higher refractive index and density (Table II). Two further examples of 1,3-disubstituted cyclohexenes which, with the

*For compounds of this type uncertainty or an error in this assignment does not result in an incorrect interpretation of the rule.

TABLE II
PHYSICAL PROPERTIES OF CYCLOHEXENE DERIVATIVES (12, 13)

Cyclohexene	n_D^{25}	d_{25}^{25}
<i>cis</i> -5-Methyl-2-cyclohexenyl acetate	1.4508	0.9677
<i>trans</i> -5-Methyl-2-cyclohexenyl acetate	1.4532	0.979
<i>cis</i> -5-Methyl-2-cyclohexenyl chloride	1.4730	0.9952
<i>trans</i> -5-Methyl-2-cyclohexenyl chloride	1.4778	0.998
<i>cis</i> -Ethyl-5-methyl-2-cyclohexenyl ether	1.4402	0.8690 (d_4^{25})
<i>trans</i> -Ethyl-5-methyl-2-cyclohexenyl ether	1.4447	0.8663 (d_4^{25})

exception of the densities of the last pair, are in accordance with the rule are also given in Table II.

In terms of the concepts of conformational analysis the menthols may be represented as follows (21): menthol V, eee (C_1-CH_3 , C_3-OH , and C_4 -isopropyl all in the equatorial orientation); neomenthol, eae (C_1-CH_3 and C_4 -isopropyl in the equatorial orientation and C_3-OH in the axial orientation); isomenthol, aee; neoisomenthol, aae. Written in this order the menthols appear in decreasing order of stability as predicted on a conformation basis.

Similarly the carvomenthols, written in decreasing order of stability, may be represented thus (21): carvomenthol VI, eee; neocarvomenthol, eae; isocarvomenthol, aee; neoisocarvomenthol, aae. In writing the carvomenthols in this manner it is assumed that Bose's (9) analysis is correct, although it seems that some justification can be found in the hydrogenation experiments of Johnston and Read (18) for representing isocarvomenthol as aae and neoisocarvomenthol as aee. If the latter structures are correct, these two carvomenthols should be interchanged to be placed in the correct order of relative stability.

TABLE III
PHYSICAL PROPERTIES OF MENTHOLS AND MENTHYLAMINES

Menthol	Neo	Iso	Neoiso	References
Menthols				
n_D^{60} (l) 1.4461-62	(d) 1.4448		(d) 1.4503	24
(dl) 1.4461-65	(dl) 1.4450	(dl) 1.4510	(dl) 1.4504	24
n_D^{20} (l) 1.46096	(d) 1.46030			29
(dl) 1.46150	(dl) 1.46040			29
Menthylamines				
n_D^{25} (l) 1.4600	(d) 1.4614			25
d_4^{25} (l) 0.8525	(d) 0.8551			25

From the data presented in Tables III and IV it is seen that, with the exception of one slight discrepancy in the densities of isocarvomenthol, which may not be real, the carvomenthols are in agreement with the rule. The menthols exhibit two apparent exceptions; for conformity to the rule the physical properties of menthol and neomenthol on the one hand and isomenthol and neoisomenthol on the other should be interchanged. However, the corresponding amines of the former pair are in agreement with the rule.

The data (11) summarized in Table V demonstrate the validity of the rule for derivatives of *trans* (VII)- and *cis* (VIII)-6,6-dimethyl-2-hydroxycyclohexanecarboxylic acid.

DICYCLIC COMPOUNDS

There are in the literature numerous examples of isomeric substituted decalins which are in agreement with the rule on the premise that a *trans*-decalin is more stable than a *cis*-decalin. But an adequate analysis of these compounds is for the present impossible because of the lack of the required data on isomeric substituted decalins in which the

exact orientation of the substituents has been determined. The situation is further complicated in the case of the *cis*-decalins because of the possibility that ring conversion may give rise to an equilibrium mixture of the two possible conformations (20).

Attention is directed to the physical properties of the α - and β -decalyl acetates given by Huckel *et al.* (16), which except for one discrepancy are in accordance with the rule.

The solution of the stereochemistry of the natural and synthetic cyperones by McQuillin (19) affords an opportunity to test further the application of the rule to dicyclic compounds. It was shown that the synthetic isomer has conformation IX (n_D^{20} , 1.5343; d , 1.006) and the natural isomer has conformation X (n_D^{20} , 1.5292; d , 0.9946). As a consequence of the more stable equatorial orientation of the isopropenyl side chain, X has the more stable conformation and, in accordance with the rule, has lower values for its physical properties than IX.

PERHYDROANTHRACENES

Cook, McGinnis, and Mitchell (10) have tentatively assigned structures to three perhydroanthracenes by consideration of the method of production by hydrogenation of corresponding unsaturated compounds. It seems significant that the structural assignments by Cook *et al.*, the relative energy values (E) assigned to the structure by Johnson (17) on a theoretical basis, and the physical properties are accommodated without exception (Table VI).

TABLE VI
PERHYDROANTHRACENES (10)

<i>c-s-t</i>	32	2.4	1.4700	0.8788
<i>c-s-c</i>	62	6.4	1.4810	0.9021

PYRANOSIDES

The evidence presented in Table VII suggests that the rule is also applicable to the pyranosides. The "instability ratings" in Table VII have been assigned by means of a modification of the arbitrary system used by Reeves (26) to show that the normal conformation of a pyranoside (C1 or 1C chair form) can be predicted on a conformational basis. The instability ratings are meant to be a measure of the relative stabilities of the isomers within each group. An ordinary axial group has been assigned one instability

unit; $\Delta 2$ instability (26), 2.5 units; C_5-CH_2OH group in the axial orientation, but not involved in the Hassel and Ottar effect (26), 2.0 units; C_5-CH_2OH group with Hassel and Ottar effect, 2.5 units. If the instability ratings (total instability units) of the C1 and 1C conformations of a particular pyranoside differ by one unit, or less, then the pyranoside is assigned the C1 $\leftrightarrow$ 1C conformation; if the difference is greater than one unit, then the pyranoside is assigned exclusively to the conformation with the smaller instability rating (cf. Reeves (26)). By adopting this system the two cases (those of methyl- β -D-mannosides and methyl- α -D-gulosides) where the stable conformations predicted by Reeves differed from the experimentally determined normal conformations were brought into line.

In Table VII isomers which may be directly compared are grouped together and each group is arranged in decreasing order of predicted stability. All compounds, with the exception of the arabinosides, belong to the D-series.

*A temperature coefficient of 0.0004 units per degree has been used to convert to n_D^{20} .

†References cited in this manner give the page number of Vogel und Georg "Tabellen der Zucker und ihrer Derivate", Edwards Brothers Inc., Ann Arbor, Mich.

‡A temperature coefficient (22) of 0.00036 units per degree has been used to convert the pentose derivatives to n_D^{20} .

With the exception of the methyl- α -L-arabinoside, the order of stabilities predicted on a conformational basis and the corresponding values of the refractive indices are in agreement with the proposed rule.

Although there are a few exceptions, some of which may be attributable to the experimental difficulties of obtaining pure compounds, it seems evident that the relationship discussed in the present communication should be useful as a guide for the solution of stereochemical problems. Certain qualifications may prove to be necessary, particularly with regard to relative conformational stabilities (for example the case of the hydrindans (2)).

TRIARYLMETHANE COMPOUNDS AS REDOX INDICATORS IN THE SCHOENEMANN REACTION

II. SYNTHESSES OF THE TRIARYLMETHANES¹

D. MORISON SMITH, R. BLANCHFIELD, J. L. THOMPSON, AND G. A. GRANT

ABSTRACT

The syntheses and properties of a series of 4,4'-thienylidene bis[N,N-dimethylaniline] compounds, variously substituted in the thiophene ring, are reported. These compounds were tested as redox indicators in the Schoenemann reaction for the detection of phosphonofluoridate esters in solution. The most effective indicator was 4,4'-(5-methyl-4-propyl-2-thienylidene)bis[N,N-dimethylaniline].

INTRODUCTION

The previous paper of this series (9) dealt with the mechanism of the Schoenemann reaction when a triarylmethane compound was used as the redox indicator. It was suggested that the perphosphonate formed from the interaction of the phosphonofluoridate esters and alkaline peroxide liberated hypochlorous acid from chloride ion upon acidification. The hypochlorous acid then oxidized some of the leuco compound to the violet dye.

It was proposed to employ this modified Schoenemann reaction to determine very low concentrations of the phosphonofluoridate ester. The compound most suitable for this purpose would have, in the dye form, the highest extinction coefficient under the optimum conditions for the reaction. It would also have a redox potential between -0.7 and -1.0 volts.

To determine the most suitable triarylmethane compound for this reaction, variously substituted triarylmethanes were synthesized within a restricted range of substitution. The compounds tested in the preliminary screening were modifications of leucomalachite green with the unsubstituted benzene ring replaced by the furan or thiophene nucleus. Leucomalachite green itself and the furan analogue prepared by the usual method (7) were found to be ineffective as indicators in this reaction sequence as they were oxidized by the peroxide employed to react with the phosphonofluoridate esters.

However, "thiophene malachite green" (I: $R = R' = R'' = H$) showed promise, and the compounds made for testing in this reaction were therefore all of type I with various R groups. Alkyl substituents proved particularly effective; thus mainly compounds of this type were investigated.

EXPERIMENTAL

The general method of preparation consisted of the synthesis of various substituted thiophenealdehydes and their condensation with dimethylaniline by the use of anhydrous zinc chloride. In all cases the condensation reaction described by Mason and Nord (16) was employed to form the leuco base.

I(a) 4,4'-Thenylidene bis[N,N-dimethylaniline] (I: R = R' = H)

The 2-thiophenealdehyde was prepared on a large scale by a method reported by Hartough (10 (pp. 310 and 510), 11, 12) and Angyal *et al.* (2).

I(b) 4,4'-5-Methyl-2-thenylidene bis[N,N-dimethylaniline] (I: R = CH₃, R' = R'' = H)

The 5-methyl-2-thiophenealdehyde was prepared by the formylation of 2-methylthiophene employing the Weston and Michaels method (23).

The 2-methylthiophene was prepared by Huang-Minlon's modification of the Wolff-Kishner reduction (17).

An alternative route to 2-methylthiophene was the reaction of levulinic acid with "phosphorus heptasulphide" (P₄S₇). The procedure given in Organic Syntheses (19) was modified as follows. A mixture of the monosodium salt of the alkyl succinic or levulinic acid (0.2 mole), sea sand or pumice (40 g.), and phosphorus heptasulphide (110 g.) was dry distilled from a 1 liter flask in a current of oxygen-free nitrogen. The reaction flask was heated gradually to 300° C. or higher. The liquid distillate was collected in an ice-cooled receiver and the gaseous distillate washed by being bubbled through chilled ether using a wash bottle fitted with a fritted glass gas dispersion disk. Two consecutive runs were made and the products from the condenser, receiver, and wash bottle were transferred to a separatory funnel and washed three times with 10% sodium hydroxide. The ethereal solution was dried over sodium sulphate and the ether removed by distillation. The product was then distilled at atmospheric pressure. The yield, using levulinic acid, was below 20% of the theoretical.

I(c) 4,4'-(5-Ethyl-2-thenylidene) bis[N,N-dimethylaniline] (I: R = C₂H₅, R' = R'' = H)

The 5-ethyl-2-thiophenealdehyde was prepared by applying to 2-ethylthiophene the Vilsmeier modifications of the formylation (23, 15). This latter compound was prepared by the reduction of 2-acetothienone using a modified Wolff-Kishner reaction (17), and the 2-acetothienone was made by acetylation of thiophene with acetyl chloride using stannic chloride as catalyst (14).

I(d) 4,4'-(5-Propyl-2-thenylidene) bis[N,N-dimethylaniline] (I: R = CH, R' = R'' = H)

This leuco compound was synthesized exactly as described for the ethyl substituted compound (I(c)) (16, 23, 15, 17) except that propionyl chloride was used to give 2-propiothienone in the Friedel-Crafts acylation (14).

I(e) 4,4'-(5-Phenyl-2-thenylidene) bis[N,N-dimethylaniline] (I: R = C₆H₅, R' = R'' = H)

The 5-phenyl-2-thiophenealdehyde was prepared by the application of the Vilsmeier formylation to 5-phenylthiophene. The product was not distilled, however, but was crystallized from ethyl alcohol - water; melting point 92° to 93° C. The 5-phenylthiophene was synthesized as described by Gomberg (8).

I(f) 4,4'-(5-Chloro-2-thenylidene) bis[N,N-dimethylaniline] (I: R = Cl, R' = R'' = H)

The 5-chloro-2-thiophenealdehyde formylation (23, 15) of 5-chlorothiophene, which is available commercially.

I(g) 4,4'-(5-Bromo-2-thenylidene)bis[N,N-dimethylaniline] (I: R = Br, R' = R'' = H)

The 5-bromo-2-thiophenealdehyde was prepared by the modified formylation (23, 15). Phosphorus oxybromide had to be used to catalyze the formylation of bromothiophene, since the use of phosphorus oxychloride led to a halogen interchange between the thiophene and the catalyst and gave a mixture of products.

I(h) 4,4'-(5-Acetamido-2-thenylidene)bis[N,N-dimethylaniline] (I: R = CH₃CONH, R' = R'' = H)

5-Acetamido-2-thiophenealdehyde was prepared from 2-acetamidothiophene by the modification of the Vilsmeier reaction introduced by Campaigne and Archer (5).

The acetamidothiophene was made from thiophene by nitration using the procedure of Steinkopf (20), reduction with tin according to the directions in Hartough (10, p. 513), and acetylation of the tin salt by the method of Steinkopf (21).

I(i) 4,4'-(3-Methyl-2-thenylidene)bis[N,N-dimethylaniline] (I: R = R' = R'' = CH₃)

This leuco compound was synthesized in the regular manner. The 3-methyl-2-thiophenealdehyde was the product of the modified Vilsmeier reaction (23, 15) using 3-methylthiophene.

The 3-methylthiophene was obtained by reacting phosphorus heptasulphide and sodium pyrotartrate (19). The yield in this case was from 33 to 38% of the theoretical amount of 3-methylthiophene. The sodium pyrotartrate (monosodium salt of α -methyl succinic acid) was made by the procedure described in Organic Syntheses (3).

I(j) 4,4'-(3,4-Dimethyl-2-thenylidene)bis[N,N-dimethylaniline] (I: R = H, R' = CH₃)

This material was prepared from the 3,4-dimethyl-2-thiophenealdehyde, which was produced by the modified formylation (23, 15) of 3,4-dimethylthiophene.

This dialkylthiophene was obtained by a new application of the Hinsberg condensation of dicarbonyl compounds with thiodiglycolic ester (13). For this series of reactions, 0.2 mole of thiodiglycolic ester, prepared according to the method of Overberger and co-workers (18), in 200 ml. of absolute methanol was added to a solution of 0.2 mole of diacetyl in 200 ml. of absolute methanol. The solution was cooled to -20°C . with vigorous stirring and to it was added a solution of 12 g. of sodium metal in 120 ml. of methanol. The reaction mixture was allowed to reach room temperature gradually and was stirred for 4 hours. Water was then added and the organic solvent was removed by distillation on a steam bath. This process saponified the ester to the acid. The aqueous residue was then cooled, acidified, and filtered. The plaster-like material was dried in air. The yield was about 50%. The acid so obtained, 3,4-dimethylthiophene-2,5-dicarboxylic acid, was decarboxylated to 3,4-dimethylthiophene in 20% yield by dry distillation of three parts of acid with one part of precipitated copper powder.

I(k) 4,4'-(4,5-Dimethyl-2-thenylidene)bis[N,N-dimethylaniline] (I: R = R' = CH₃, R'' = H)

The 4,5-dimethyl-2-thiophenealdehyde was prepared from 4,5-dimethylthiophene by the formylation method previously described (23, 15).

The alkylthiophene was the product of the Huang-Minlon modification of the Wolff-Kishner reduction of 3-methyl-2-thiophenealdehyde, the latter compound being the product of the formylation (23, 15) of 3-methylthiophene.

A second method used for obtaining the 4,5-dimethylthiophene was by cyclizing

sodium β -methyllevulinate with phosphorus heptasulphide. This was carried out using the procedure recorded under compound I(b) but the yields were from 5 to 10%. The sodium salt was obtained from β -methyllevulinic acid, according to the directions of Steinkopf (22). The ester was prepared by the alkylation of ethyl acetosuccinate with methyl iodide following the method of Bruhl (4), the ethyl acetosuccinate having been synthesized as in Organic Syntheses (1).

I(l) 4,4'-(5-Ethyl-4-methyl-2-thenylidene)bis[*N,N*-dimethylaniline] (I: R = C₂H₅, R' = CH₃, R'' = H)

This compound was prepared employing procedures outlined for compound I(k) (15, 16, 17, 23). The 5-ethyl-4-methylthiophene was synthesized from 3-methylthiophene and the 3-methylthiophene was obtained by cyclizing pyrotartrate with phosphorus heptasulphide.

I(m) 4,4'-(4-Ethyl-5-methyl-2-thenylidene)bis[*N,N*-dimethylaniline] (I: R = CH₃, R' = C₂H₅, R'' = H)

This compound was produced by the usual chain of reactions from 2-methyl-3-ethylthiophene to the aldehyde (23, 15) and then to the leuco compound (16).

The 2-methyl-3-ethylthiophene was produced in 10 to 20% yield by the ring closure of sodium β -ethyllevulinate with phosphorus heptasulphide described under compound I(b). The sodium β -ethyllevulinate was obtained exactly as described earlier for β -methyllevulinate (compound I(k), second method) using ethyl iodide instead of methyl iodide for the alkylation (1, 4, 22).

I(n) 4,4'-(4-Methyl-5-propyl-2-thenylidene)bis[*N,N*-dimethylaniline] (I: R = CH₃, R' = CH₃, R'' = H)

This material was prepared like compound I(l), using propionyl chloride instead of acetyl chloride in the original Friedel-Crafts acylation of 3-methylthiophene.

I(o) 4,4'-(3,4-Diphenyl-2-thenylidene)bis[*N,N*-dimethylaniline] (I: R = H, R' = R'' = C₆H₅)

The 3,4-diphenyl-2-thiophenealdehyde was obtained by the modified Vilsmeier formylation (23, 15) of 3,4-diphenylthiophene.

The 3,4-diphenylthiophene was produced by decarboxylating 3,4-diphenylthiophene-2,5-dicarboxylic acid with copper chromite catalyst in quinoline. A mixture of the diacid (three parts) and copper chromite (one part) was refluxed for 1 hour in quinoline. The reaction mixture was then cooled and the quinoline was precipitated with the theoretical quantity of zinc chloride dissolved in 6 *N* hydrochloric acid. The insoluble quinoline-zinc chloride-hydrochloride salt was then extracted six times by being ground in a mortar with portions of benzene, and filtered. The benzene extracts were dried and concentrated. The organic residue was recrystallized from ethanol. The yield was 35%.

The above diacid was synthesized by the Hinsberg condensation of benzil with thiodiglycolic acid (13). This procedure was modified by using 200 ml. of ether as solvent for the benzil and carrying out the reaction at 10° C.

I(p) 4,4'-(5-Bromo-4-methyl-2-thenylidene)bis[*N,N*-dimethylaniline] (I: R = Br, R' = CH₃, R'' = H)

The 5-bromo-4-methyl-2-thiophenealdehyde was the produce of the modified Vilsmeier reaction (23, 15), using phosphorus oxybromide. The bromomethylthiophene was synthe-

sized by peroxide-free bromination of 3-methylthiophene with one molar equivalent of N-bromosuccinimide. This gave a mixture similar to that obtained by Dittmer and co-workers (6) which was separated by fractional distillation.

Purification of Leuco Compounds

Most of the substances were crystallized several times from ethanol-water, and some from benzene-ethanol; in some cases the compounds were dissolved in chloroform and chromatographed through an alumina column. After compounds I(e) and I(m) were tested, there was insufficient pure sample left for melting point determination and analysis. The melting points were determined on a Kofler block.

Procedure for Testing the Leuco Compounds as Redox Indicators in the Schoenemann Reaction Sequence

The procedure mentioned in the first paper of this series (9) was followed. One milliliter of a 4% aqueous solution of sodium pyrophosphate peroxide ($\text{Na}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}_2$) was added to 10 ml. of an aqueous solution of sarin, the isopropyl ester of methyl phosphonofluoridic acid, whose concentration of from 5 to 10 p.p.m. had been accurately determined. The solutions of sarin and sodium pyrophosphate peroxide were mixed and, within 30 seconds, 1 ml. of a 1:16 hydrochloric acid solution of the leuco compound was added. The blank was made up in the same fashion, using distilled water in place of the sarin solution. Optical density readings were taken in 1 cm. Corex cells using the Beckman Model DU spectrophotometer. Measurements were made at the absorption maximum, 7 minutes after the mixing of the acidified indicator and perphosphonate solutions. Previous experience justified the use of Beer's law to calculate the optical densities for all samples at a sarin concentration of 5 p.p.m.

RESULTS AND DISCUSSION

The melting points and analyses for the compounds prepared are given in Table I.

Although great care was taken to purify the compounds, melting point ranges up to 7° C. were noted. The agreement between the calculated and observed values for the

elemental analyses suggested that the correct compounds had been synthesized and were more than 95% pure.

Substitution in the thiophene ring of these leuco dyes appeared to have an influence upon their effectiveness as redox indicators in the Schoenemann reaction. This effectiveness is expressed quantitatively in Table II. A given type of substitution may affect the

following parameters: the redox potential; the extinction coefficient of the dye formed; the efficiency of the oxidation of the leuco compound by the hypochlorous acid; the stability of the dye, once formed, to the bleaching action of the medium (probably related to the potential at which destructive oxidation of the dye would occur); and the solubility of the leuco compound.

Although it is not certain which, if any, of these parameters is involved, some trends have been observed. Monosubstituted compounds with phenyl or halogen in the 5-position of the thiophene ring (compounds I(e), I(f), and I(g)) gave about the same absorption intensity on reaction as the parent leuco thiophene malachite green. Alkyl substitution in the 3-position had an adverse effect (compound I(i)) also apparent in the 3,4-dimethyl compound (I(j)). The intensity values were of a much higher order with 4,5-dialkyl substitution (compounds I(k), I(l), I(m), I(n)). A synergistic effect was observed when the 4,5-substituents were both alkyl, which was not observed when the 5-substituent was halogen (compound I(p)). The most effective members of this class had a long aliphatic side chain in position 5 and a methyl group (the shortest possible side chain) in position 4 (compounds I(k), I(l), and I(n)). Further comments on the effect of substitution on the dye spectra will be given in a later paper.

ULTRAVIOLET IRRADIATION OF PYRIMIDINE DERIVATIVES

I. 1,3-DIMETHYLURACIL¹A. M. MOORE² AND C. H. THOMSON³

ABSTRACT

The isolation, analysis, and synthesis of the principal product of the ultraviolet (2537 Å) irradiation of aqueous 1,3-dimethyluracil has made it possible to establish that the irradiation results in hydration of the 5:6 double bond of the uracil ring to form 1,3-dimethyl-6-oxyhydrouracil. This hydration is spontaneously reversible, the dehydration being catalyzed by either acid or base. Kinetic studies of the catalyzed regeneration reactions are reported.

INTRODUCTION

In a preliminary note (6) we have reported the isolation of the principal product of ultraviolet irradiation of aqueous 1,3-dimethyluracil. The isolated material shares with the photodecomposition products of certain other pyrimidine derivatives, such as uridylic acid and cytidine deoxyriboside, the property of regenerating the parent compound in acid or alkaline solution (7), a phenomenon first observed by Sinsheimer and Hastings (12) in the case of irradiated solutions of uracil and uridine.

1,3-Dimethyluracil (I) was selected by us as a model for the investigation of the nature of this reaction chiefly because of its convenient solubility properties.

The present paper gives a complete account of the isolation procedure and additional information regarding the properties of the photodecomposition product of 1,3-dimethyluracil. It also includes the results of kinetic studies and evidence which establishes the structure of the product of irradiation as 1,3-dimethyl-6-oxyhydrouracil (II).

EXPERIMENTAL AND RESULTS

Materials

The 1,3-dimethyluracil used in these experiments was synthesized from uracil by the method of Davidson and Baudisch (1) and purified by repeated recrystallization from hot ethanol: m.p. 123°, lit. (1) m.p. 123–124°. Calc. for C₈H₈N₂O₂: N, 20.00%. Found: N, 20.04%. Molar absorptivity at 2660 Å, 8.60 × 10³, in water.

Irradiation

The irradiation vessel consisted of a double-walled, cylindrical, quartz tube made from coaxial tubes of inner diameters 1.7 and 2.7 cm. and 1.5 mm. wall thickness. The

annular space between these served as a jacket through which water was passed to control the temperature at about 10°.

Fifty-milliliter portions of a 0.2 *M* aqueous solution of 1,3-dimethyluracil were irradiated in the inner tube (Fig. 1) while an air stream was bubbled through the solutions to keep them well mixed.

FIG. 1. Irradiation apparatus. (A) Double-walled quartz tube. (B) Mercury-vapor lamps.

The source of ultraviolet light was a set of six low-pressure, mercury-vapor lamps (15 watt, G.E. Germicidal Lamps) arranged symmetrically about the quartz tube and approximately 0.5 cm. from it (Fig. 1). The array of lights was surrounded by a cylindrical metal shield and was air-cooled. This light source emits about 90% of its energy at a wavelength of 2537 Å.

Irradiation of the solution was continued until examination of aliquots indicated that the optical density at 2660 Å, the maximum of the first ultraviolet absorption band of 1,3-dimethyluracil, had fallen to about one-third of its original value (80 to 100 hours irradiation).

Isolation of the Principal Product of Irradiation

1,3-Dimethyluracil may be extracted readily from its water solution with chloroform (partition coefficient, at 20°, 3.47 in favor of the chloroform) whereas tests showed that the acid-reversible product of irradiation remained in the water phase (partition coefficient about 0.03).

The irradiated solution was therefore extracted five times with 50 ml. portions of chloroform. In the early experiments, the aqueous layer was then lyophilized; in later preparations, after the chloroform extraction, it was found to be sufficient to evaporate the solution at room temperature with an air stream directed against its surface.

The residue was a crystalline solid varying in color from pink to violet in different runs. It was found that this color could be completely removed by dissolving the solid in chloroform (10 ml.), passing the solution through a short column (2 cm. $\times$ 1 cm.) of alumina (Merck, "for absorption"), and washing with chloroform (3 $\times$ 10 ml.). The colored products remained on the alumina whereas the "reversible" product passed through with the chloroform. It was found to be important to avoid prolonged contact of the solution with the alumina since the latter catalyzes the regeneration of 1,3-dimethyluracil and thus diminishes the yield of product.

The colorless solution obtained from the column was evaporated in an air stream at room temperature, dried over P_2O_5 , redissolved in chloroform (5 ml.), and induced to crystallize by the addition of *n*-hexane (10 ml.) followed by storage at 4°. The pure white needles were recrystallized five times in the same way. The final product was dried *in vacuo* over P_2O_5 . Yield, in different runs, 0.6 to 0.7 g. (57 to 66% of theory).

Properties of the Isolated Compound

The physical properties, analysis, and molecular weight of the "reversible" product have been reported previously (6). Our purest preparations have a melting point of 104–105°.

When a weighed portion of the compound is heated at 100° for 5 minutes at pH 1 (HCl) or pH 10 (NH_4OH) it is quantitatively converted to 1,3-dimethyluracil (Fig. 2). Since aqueous solutions of the photolysis product show only end-absorption (below 2500 Å) in the ultraviolet, this reconversion to 1,3-dimethyluracil, which may be followed spectrophotometrically at 2660 Å, provides a convenient procedure for analysis and has been used in the kinetic studies reported here. The absence of any detectable change in the absorption spectrum of 1,3-dimethyluracil within the pH range 1 to 11 makes the interpretation particularly simple.

FIG. 2. Absorption curves. (A) Product of irradiation, $10^{-4} M$ in water. Points on curve (B), product of irradiation, $10^{-4} M$, after heating at 100° for 5 minutes at pH 1. Solid curve (B), $10^{-4} M$ 1,3-dimethyluracil in water.

FIG. 3. Difference spectra showing the changes in optical density that occur on treating with acid the product of photolysis of 1,3-dimethyluracil (solid line) and the product of reduction of 5,5-dibromo-1,3-di-methyl-6-oxy-hydrouracil (open circles); both $10^{-4} M$.

Kinetics of the Acid- and Base-catalyzed Regeneration of 1,3-Dimethyluracil

The regeneration of 1,3-dimethyluracil from the product of irradiation as a result of acid or base catalysis at a constant pH follows first order kinetics as shown in Figs. 4 and 5.

FIG. 4. Progress curves, at various temperatures, for the acid-catalyzed regeneration of 1,3-dimethyluracil from its product of photolysis (0.05 *M* acetate buffer, pH 4.76). *D* is the optical density at 2660 Å.

FIG. 5. Progress curves at 25° for the alkali-catalyzed regeneration of 1,3-dimethyluracil from its product of photolysis. *D* is the optical density at 2660 Å.

Using the first order rate constants derived from the data of Fig. 4, an Arrhenius plot yields a straight line (7) the slope of which corresponds to an activation energy for the regeneration process of 22.6 kilocalories per mole at pH 4.76.

The variation of the velocity constant with pH has been reported earlier (7). The product of photolysis is most stable at pH 5. Between pH 1 and 5 the velocity constant varies linearly with the hydrogen ion concentration so that:

$$-dc/dt = k[H^+][c]$$

where *c* is the molar concentration of irradiation product and *k* has the value 0.0324 l.sec.⁻¹mole⁻¹ at 20°.

Heterocatalytic Regeneration

In the course of the purification studies it was observed that the amount of free 1,3-dimethyluracil in a chloroform solution of the partially purified product of photolysis was greatly increased if the solution was passed through a column of aluminum oxide 5 cm. long.

Also, when 25 ml. of a 10^{-3} *M* aqueous solution of the isolated product of irradiation was stirred for 15 minutes at room temperature with platinum black (prepared by reducing with hydrogen 0.2 g. of Adams' catalyst (3)) and the solution was then filtered and examined spectrophotometrically, conversion to 1,3-dimethyluracil, to the extent of 36%, was found to have occurred. Control solutions similarly stirred and filtered but not exposed to the platinum exhibited no significant change.

Synthesis of 1,3-Dimethyl-6-oxy-hydrouracil

For comparison with the product of photolysis of 1,3-dimethyluracil, it was desired to synthesize 1,3-dimethyl-6-oxy-hydrouracil. The most direct route to this compound appeared to be by the reduction of the easily accessible 5,5-dibromo-1,3-dimethyl-6-oxy-hydrouracil (5).

In view of the sensitivity of the product of photolysis to extremes of pH, strongly acidic or alkaline reducing agents had to be avoided. Even catalytic reduction using platinum and hydrogen generates hydrogen bromide which must be continuously neutralized; this reduction is further complicated by the catalytic action of platinum noted earlier. Very small yields (about 7%) of the desired product have been obtained by this method using Adams' catalyst.

More satisfactory results have been obtained by using zinc dust as the reducing agent at pH 4 to 5.

The procedure finally adopted was as follows: 2.0 g. of freshly prepared 5,5-dibromo-1,3-dimethyl-6-oxy-hydrouracil (5) (m.p. 134–136°, lit. m.p. 135–136°) were dissolved in 200 ml. of water at room temperature. A magnetic stirrer operating rapidly was used to promote solution which otherwise was very slow. When solution was complete 2.0 g. of zinc dust was added, followed by 1.0 ml. of glacial acetic acid, and rapid stirring was continued. After about 2 minutes the unreacted zinc was filtered off and the solution was extracted four times with 100 ml. portions of chloroform to remove 1,3-dimethyluracil formed as a by-product.

Spectrophotometric examination of an aliquot of the aqueous solution at this stage indicated a yield of about 25% of the desired product based on the increase in optical density at 2660 Å on acid treatment.

The zinc was largely removed by addition of 2.8 g. of potassium oxalate dissolved in 25 ml. of water. The precipitated zinc oxalate was filtered off after standing for 2 hours and the filtrate was evaporated to dryness at room temperature in several large Petri dishes in a rapid air stream.

The residue was dried *in vacuo* over anhydrous magnesium perchlorate and was then extracted eight times with 40 ml. portions of chloroform. The combined chloroform extracts were evaporated at room temperature to yield 0.244 g. of product (24.9%).

It was recrystallized from chloroform-hexane mixtures in the manner used to purify the product of photolysis. The dried crystals had characteristics as follows: M.p. 107–108°. Calc. for $C_6H_{10}N_2O_3$: N, 17.72%. Found: N, 17.7%. Equivalent weight for conversion to 1,3-dimethyluracil, 154.6; calc. 158. Mixed melting point with the purified product of photolysis of 1,3-dimethyluracil: 106–107°.

Comparison of Product of Photolysis of 1,3-Dimethyluracil with Synthetic 1,3-Dimethyl-6-oxy-hydrouracil

A 10^{-4} M aqueous solution of synthetic 1,3-dimethyl-6-oxy-hydrouracil was examined spectrophotometrically before and after treatment with hydrochloric acid (pH 1; 100°; 5 minutes). The spectral changes that occurred are recorded as the difference spectrum in Fig. 3 where comparison is made with the corresponding data for the product of photolysis of 1,3-dimethyluracil. The agreement is within the experimental error throughout the range of wavelengths studied.

The equivalent weight of either preparation for the conversion to 1,3-dimethyluracil was not significantly different from the theoretical value of 158, and the nitrogen contents are in close agreement with expectation. The mixed melting point did not differ from the melting point of the synthetic compound alone. Finally, in Fig. 6, are shown the X-ray powder diffraction patterns obtained for the two preparations. The agreement would appear to be complete.

DISCUSSION

The molecular weight estimations and the elementary analysis of the product of photolysis of 1,3-dimethyluracil reported earlier (6) are conclusive in indicating that the principal effect of light of wavelength 2537 Å is to cause the addition of 1 molecule of water to 1 molecule of 1,3-dimethyluracil. The loss of the ultraviolet absorption band during irradiation and, more specifically, the inability of the reaction product to react with bromine water, provide strong evidence that the addition of water has resulted in the loss of the 5:6 double bond of the 1,3-dimethyluracil.

It remained to be decided whether, on addition of the water, the OH group became attached at position 5 or position 6. The synthesis of 1,3-dimethyl-6-oxy-hydrouracil and its evident identity with the product of photolysis would appear to have settled this point.

The dehydration of 1,3-dimethyl-6-oxy-hydrouracil by either acid or base catalysis is first order at constant pH. In the acid-catalyzed reaction, the linear dependence of the velocity constant on the hydrogen ion concentration implies that the rate-determining reaction is the combination of a molecule of the compound with a proton. This is then followed, presumably, by the rapid loss of H_3O^+ with the formation of the 5:6 double bond. It may be noted that this double bond is conjugated with the carbonyl group at position 4 and that this acid-catalyzed reaction is evidently analogous to the well-known, acid-catalyzed, reversible addition of water to such conjugated systems (4). The analogy may be made clearer if we write just that portion of the pyrimidine ring involved:

PLATE I

FIG. 6. X-ray powder diffraction patterns. (*A*) Synthetic 1,3-dimethyl-6-oxy-hydrouacil. (*B*) Purified product of irradiation of 1,3-dimethyluracil. (North American Philips camera, diameter 114.59 mm., Cu K_{α} radiation, 6 hours' exposure.)

The activation energy of the over-all reaction was found to be 22.6 kilocalories per mole at pH 4.76. This is near the lower end of the range of activation energies for the dehydration of β -hydroxy-carbonyl compounds observed during the extensive studies of H. J. Lucas and co-workers (8-11, 13).

ACKNOWLEDGMENT

We are indebted to Mr. R. R. Boucher of the Research Metallurgy Branch, Atomic Energy of Canada Limited, for making the X-ray diffraction pictures reported here.

A QUANTITATIVE INFRARED SPECTROMETRIC STUDY OF MOLECULAR ASSOCIATION IN ALCOHOLS¹

ADOLF ENS² AND F. E. MURRAY³

ABSTRACT

The absorption spectra of methanol, ethanol, isobutanol, *tert*-amyl alcohol, and octanol-2 were studied in the wavelength region of the first harmonic of the O—H vibration. The data obtained were used in each case to calculate the number of monomers combined to form an association polymer and the equilibrium constant for the association reaction in carbon tetrachloride solution. It was found for all alcohols studied that the association number was between three and four.

INTRODUCTION

A number of attempts have been made to estimate the association number for various alcohols using cryoscopic measurements (2, 3) and infrared spectroscopy (1, 4, 7, 8, 9). In the spectroscopic work, it was found that the O—H vibration of alcohols yields a single sharp band at low concentrations of the alcohol. As concentration is increased, absorption at the wavelength of this sharp band increases very slowly but a diffuse polymer band appears at a slightly longer wavelength. The magnitudes of the two bands are measures of monomer and polymer concentration in the solution.

Results by several authors (11, 13) have indicated that in alcohol solutions at high concentrations, the alcohol exists as a cyclic polymer. If a cyclic association polymer (ROH)_n is formed by combination of *n* monomer molecules, the over-all reaction may be written

where *n* is the number of monomers in the ring. If *C*₁ and *C*₂ are the concentrations in moles per liter of monomer and cyclic polymer respectively, the equilibrium constant for the above reaction is

$$[1] \quad K = (C_2/C_1)^n.$$

Since *K* is a constant, the association number *n* is given by the relation

$$[2] \quad n = d \log C_2 / d \log C_1.$$

From equation [2], *n* could be obtained if *C*₁ and *C*₂ were known for a number of total alcohol concentrations.

According to Beer's law, the concentration of monomer is related to the spectral absorbance by the equation

$$[3] \quad C_1 = \alpha/k_1$$

where *k*₁ is the absorption coefficient and *α* the absorbance for the monomer. An equation similar to [3] involving *C*₂ and *k*₂ applies to the polymer. It is, however, impossible to obtain *k*₂ and some workers have assumed *k*₂ equal to *k*₁ to facilitate calculation of *n*. Errera and Sack (5) and Smith and Creitz (12) interpreted their results to indicate

¹Manuscript received October 22, 1956.

Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.

²Holder of a Bursary from the National Research Council of Canada.

³Present address: British Columbia Research Council, University of British Columbia, Vancouver 8, British Columbia.

formation of dimers as well as higher polymers of indefinite size in the alcohols which they studied.

In this study, the concentration of polymer was obtained by difference (10) and n obtained by a graphical method. The effects of molecular size and shape on the values of n and K were investigated by studying a group of five alcohols which varied in molecular weight and contained primary, secondary, and tertiary types. All measurements were made using a Beckman DK-1 recording spectrophotometer which yielded excellent quantitative results.

An expression for n was obtained in the following way: The total concentration C of the solute based on the molecular weight of the monomer is

$$[4] \quad C = C_1 + nC_2,$$

where it is assumed that the concentrations of the intermediate species are negligibly small. From equations [1] and [4],

$$KC_1^n = (C - C_1)/n$$

and using equation [3]

$$[5] \quad K(\alpha/k_1)^n = (C - \alpha/k_1)/n.$$

In logarithmic form, equation [5] becomes

$$[6] \quad \log(C - \alpha/k_1) = n \log \alpha - n \log k_1 + \log Kn.$$

If K , k_1 , and n are constants, then

$$[7] \quad n = d \log(C - \alpha/k_1) / d \log \alpha.$$

The association number n is obtained from the slope of a straight line plot of $\log(C - \alpha/k_1)$ against $\log \alpha$.

In general, the assumptions involved in the present study are those made by Mecke (10). Mecke's treatment is applicable to an assortment of polymer sizes whereas the present simplified treatment assumes that there are two stable species in the solution, the monomer and the cyclic end-product of polymerization. Mecke was able to calculate n at a chosen concentration while the values obtained here are averages over a range of concentrations. Peak heights are used throughout to measure monomer concentration.

EXPERIMENTAL

All measurements were made at room temperature using a Beckman model DK-1 recording spectrophotometer with quartz optics and 1 cm. cells. The solvent, carbon tetrachloride, was Eastman's spectro grade and showed no absorption against air in the wavelength range studied. The alcohols were generally of the best grade obtainable and were further purified before use by distillation through a column of 15 theoretical plates. Absolute ethanol was prepared by a standard method as given by Fieser (6). The absorbance values obtained were found to be readily reproducible.

RESULTS

Fig. 1 shows the absorbance of carbon tetrachloride solutions of methanol at the concentrations 0.16, 1.24, 2.47, and 4.95 moles per liter. The monomer absorption peak appears at $1413 \pm 3 \text{ m}\mu$, with the diffuse polymer band appearing at concentrations above 0.16 molar and at slightly longer wavelengths. Figs 2, 3, 4, and 5 show similar results for ethanol, isobutanol, *tert*-amyl alcohol, and octanol-2 at the indicated concentrations.

FIG. 1. Absorption spectra of methanol in carbon tetrachloride solution at concentrations of 0.16, 1.24, 2.47, and 4.95 moles/liter.

FIG. 2. Absorption spectra of ethanol in carbon tetrachloride solution at concentrations of 0.11, 0.43, 1.70, and 6.82 moles/liter.

FIG. 3. Absorption spectra of isobutanol in carbon tetrachloride solution at concentrations of 0.14, 0.27, 1.08, and 4.32 moles/liter.

FIG. 4. Absorption spectra of *tert*-amyl alcohol in carbon tetrachloride solution at concentrations of 0.23, 0.92, and 3.67 moles/liter.

FIG. 5. Absorption spectra of octanol-2 in carbon tetrachloride solution at concentrations of 0.08, 0.63, and 2.52 moles/liter.

FIGS. 6-8. Absorbance of the monomer species of methanol and octanol-2 (Fig. 6), of ethanol and isobutanol (Fig. 7), and of *tert*-amyl alcohol (Fig. 8) as a function of the total concentration of alcohol in carbon tetrachloride solution.

Figs. 6, 7, and 8 show the absorbance due to monomer as a function of the total concentration of the alcohol present. From these curves, values of k_1 , the absorption coefficients for the monomer species, were obtained for each alcohol. As shown in Figs. 1 to 5, the polymer absorption band is very small at low concentrations. When the solution is extremely dilute, only monomer is present so that k_1 for each alcohol will be the slope of the concentration-absorbance curve when the concentration approaches zero. Values of k_1 obtained for each of the alcohols studied are given in Table I.

TABLE I

Alcohol	Wavelength of free O—H band ($m\mu$)	k_1	n	K
Methanol	1413 ± 3	1.41	3.83	18
Ethanol	1417 ± 3	1.30	3.54	11
Isobutanol	1415 ± 3	1.50	3.66	12
<i>tert</i> -Amyl alcohol	1424 ± 3	1.24	3.51	1.0
Octanol-2	1421 ± 3	1.69	3.17	7.6

In Fig. 9, $\log \alpha$ is plotted against $\log(C - \alpha/k_1)$ for each of the alcohols studied. Values of n obtained from the slopes of these lines are given in Table I. Using the calculated values of k_1 and n as in Table I, K 's were obtained by extrapolating the straight lines in Fig. 9 to $\log \alpha$ equals zero and substituting into equation (6). The equilibrium constants obtained are given in Table I.

FIG. 9. Dependence of $\log \alpha$ on $\log(C - \alpha/k)$ for all of the alcohols investigated. $\circ$ Methanol, $\bullet$ ethanol, $\circ$ *tert*-amyl alcohol, $\ominus$ octanol-2, $\bullet$ isobutanol.

DISCUSSION

Equilibrium constants obtained indicate that the fraction of monomer in the associated form decreases sharply from methanol to the next primary alcohol. There is little difference in K values between ethanol and isobutanol, but the value drops considerably for the large secondary alcohol octanol-2. As might be expected, the value of K for the tertiary alcohol was much smaller than for the primary and secondary ones.

Despite the fact that the fraction of the alcohol in the associated form changes sharply in passing from methanol to *tert*-amyl alcohol, the association numbers for the two alcohols are almost the same. This seems to indicate that there is one polymer structure common to all the alcohols studied. This is most likely a ring structure as proposed by Pauling (11) which would impose an upper limit on the association number. Values of n obtained will be slightly high owing to neglect of the intermediate species in the polymerization reaction. On the other hand, values of n will be lower than they should be if there is any overlap of the polymer and monomer absorption bands. According to Mecke (10), no overlapping occurs. The most probable ring structure for methanol appears to be one containing four monomers as proposed by Weltner and Pitzer (13),

rather than three, the value obtained by Mecke (10). There is no indication from this work that a hexameric ring is formed for any of the alcohols studied as was suggested by Pauling (11).

SEARCH FOR SUCCESSIVE NEUTRON CAPTURE REACTIONS ON Mg^{26} , Si^{30} , AND Cr^{54} ¹

L. P. ROY² AND L. YAFFE

ABSTRACT

Stable nuclides exposed to intense neutron fluxes may produce second order reactions by successive capture of two neutrons. This method has been applied in the present work in an attempt to determine the pile neutron capture cross section of three unstable nuclides, namely: Mg^{27} , Si^{31} , and Cr^{55} . A maximum value of 0.04 barn has been obtained for the cross section of Mg^{27} . Assuming that Si^{32} and Cr^{56} are long-lived, minimal ratios of 600 and 270 years/barn respectively were obtained for $t_{1/2} \text{Si}^{32}/\sigma \text{Si}^{31}$ and $t_{1/2} \text{Cr}^{56}/\sigma \text{Cr}^{55}$.

A. INTRODUCTION

In a sample exposed to a strong neutron flux there may be an appreciable chance that a nucleus that has already captured one neutron will capture a further neutron. The intermediate product may be radioactive and, as has been outlined in a previous paper (5), cross sections of several unstable nuclides have been measured in this manner.

We have attempted to determine the neutron capture cross sections of the unstable nuclides Mg^{27} , Si^{31} , and Cr^{55} in the following manner. When magnesium is bombarded with neutrons the following reactions will occur:

Mg^{28} has previously been produced only in charged particle reactions and in a reactor by the use of the (t, p) reaction (1, 2, 4, 6, 7). (The tritons were produced by the (n, α) reaction on Li^6 .)

The Mg^{28} in our experiment was to be detected by measuring the Al^{28} daughter.

Similarly if silicon is bombarded in a high neutron flux, the following reactions would take place.

¹Manuscript received October 22, 1956.

²Holder of a Shawinigan Chemical Scholarship (1952-53), a National Research Council Studentship (1953-54), and a Province of Quebec Bursary (1954-55). Present address: Atomic Energy of Canada Limited, Chalk River, Ontario.

When this investigation was begun Si^{32} was unknown. It was recently reported (3) as a spallation product of chlorine. The half-life was calculated to be 710 years (on the basis of the amount of P^{32} separated), assuming that the cross section for formation of Si^{32} was the same as that for the formation of Si^{31} .

More recently Turkevich and Samuels (8) were able to detect the presence of P^{32} 2 years after the neutron irradiation of large amounts of silica. They calculated a value of 600 years/barn for the ratio of the half-life of Si^{32} to the neutron capture cross section of Si^{31} . Consequently this would lead one to expect a value of about 1 barn for the neutron capture cross section of Si^{31} .

In this experiment attempts were made to detect Si^{32} by the measurements of radiations from the daughter product P^{32} .

Similarly with chromium the following reaction would be produced:

The production of Cr^{56} has not been reported so that its decay characteristics are unknown. Attempts were made to detect the Mn^{56} daughter.

The differential and integrated equations which apply during a neutron irradiation of duration T have been discussed previously as well as the possible methods of determining the neutron capture cross sections of unstable nuclides (9).

B. EXPERIMENTAL

1. Magnesium-Aluminum System

Samples of about 2 grams each of spectroscopically pure magnesium oxide were sealed in small quartz ampoules and irradiated either in the NRX nuclear reactor at Chalk River or in the Materials Testing Reactor at Arco, Idaho, for a few days under intense neutron fluxes. After irradiation, the magnesium oxide was removed from the quartz ampoule, dissolved in 6 *M* hydrochloric acid, and scavenged many times with copper sulphide. Magnesium hydroxide was precipitated with 6 *M* sodium hydroxide after addition of sodium and potassium holdback carriers. The magnesium was dissolved in 6 *M* hydrochloric acid, scavenged again with copper sulphide, and reprecipitated with 6 *M* sodium hydroxide. The cycle was repeated five times. Finally the precipitate was dissolved in 6 *M* hydrochloric acid and a known amount of aluminum carrier was added to the solution which had been buffered with 1 to 2 g. of ammonium chloride. After the secular equilibrium $\text{Mg}^{28} \rightarrow \text{Al}^{28}$ had been established, the aluminum was precipitated with 6 *M* ammonium hydroxide.

The aluminum hydroxide was dissolved in 6 *N* hydrochloric acid and diluted, magnesium carrier was added, the solution was buffered with ammonium chloride, and aluminum hydroxide reprecipitated. The precipitate was redissolved and 5 ml. of a 25% potassium iodide solution and 5 ml. of a saturated potassium iodate solution added. The solution was decolorized by the addition of 1 or 2 ml. of a 20% sodium thiosulphate solution. The precipitated aluminum hydroxide was washed with hot 2% ammonium nitrate solution. (This procedure was adopted since it gave a precipitate which settled

readily.) The precipitate was mounted on an aluminum tray and the activity determined by means of a calibrated end window Geiger-Müller counter.

The above procedure could not be done in less than 10–12 minutes (4–5 half-lives of Al^{28}). As a result further attempts were made to detect the Al^{28} in equilibrium with highly-purified Mg^{28} . The irradiated magnesium oxide was leached with water until successive extractions showed no appreciable activity. The magnesium was now purified by repeated sulphide and hydroxide scavenges and magnesium ammonium phosphate precipitations. The Al^{28} was now allowed to grow. The β rays from Mg^{28} have a maximum energy of 0.45 Mev., while those from Al^{28} have a maximum energy of 2.9 Mev. Thus Al^{28} may be measured in the presence of Mg^{28} by differential absorption.

2. Silicon-Phosphorus System

Spectroscopically pure and enriched samples of silica were sealed in quartz ampoules and irradiated either in the NRX heavy water reactor at Chalk River or in the MTR at Arco for a few weeks. The irradiated silica was dissolved in boiling 6 *M* sodium hydroxide. The solution was treated with 6 *M* nitric acid and then evaporated to dryness in order to precipitate the silica. The residue was taken up with dilute nitric acid and centrifuged. The resulting solution was then evaporated twice more in order to precipitate the silica quantitatively. The cycle was repeated many times until there was no trace of P^{32} , which had been formed during the irradiation. The radiochemically pure silica samples were then allowed to stand for 4 to 6 weeks after addition of a known amount of phosphorus carrier. After this time, the phosphorus was precipitated as zirconium phosphate, the zirconium precipitate was dissolved in hydrofluoric acid and the solution scavenged many times with lanthanum fluoride and arsenic sulphide precipitations. The phosphorus was precipitated as ammonium phosphomolybdate, then converted to zirconium phosphate. The cycle was repeated many times. The phosphorus was finally converted to ammonium magnesium phosphate and any P^{32} activity determined with a calibrated Geiger-Müller counter.

3. Chromium-Manganese System

Spectroscopically pure and enriched samples of chromium oxide were irradiated either in the NRX nuclear reactor at Chalk River or in the MTR at Arco for a few weeks. The chromium oxide was dissolved by fusion with sodium peroxide in a nickel crucible and the solution scavenged with copper sulphide. The chromium was reduced to the +3 state with a few drops of hydrogen peroxide, precipitated as chromium hydroxide, dissolved in concentrated nitric acid, and oxidized to the +6 state with solid potassium chlorate. The chromate was converted to the perchromic acid by treatment with hydrogen peroxide, the solution being kept near the freezing point, and extracted with cold ethyl ether. The chromium was reoxidized to the chromate state and precipitated as barium chromate which was dissolved in concentrated nitric acid. The solution was scavenged with manganese dioxide. To the pure chromium solution was added a known amount of manganese carrier and the solution allowed to stand for one day before the manganese was separated. The solution was reduced with hydrogen peroxide and oxidized with solid potassium chlorate in concentrated nitric acid. Under these conditions the chromium was oxidized to the soluble chromate while the manganese was carried down as manganese dioxide which was subsequently purified by reduction and oxidation steps in presence of inactive chromium carrier. The radiochemically pure manganese dioxide was finally transferred to an aluminum tray and any Mn^{56} activity determined by means of a calibrated Geiger-Müller counter.

C. RESULTS

No activity in the separated aluminum samples which could be definitely assigned to Al^{28} was found. A maximum activity of 3.5 counts/minute after a decontamination factor of about 10^8 was detected above the natural background (20 counts/minute). If the various corrections (decay, chemical yield, counter efficiency, absorption, etc.) are made to convert this to the disintegration rate at the time of separation (a factor of ~ 200) then a maximum cross section of 0.1 barn results for Mg^{27} .

In the second method (measurement of Al^{28} arising out of the equilibrium) an activity of 2 counts per minute over the natural background was obtained by the end window G-M. counter through an aluminum absorber having a thickness of 339 mg./cm². After the various corrections were made if this activity were all attributable to Al^{28} , a maximum value of 0.04 barn is obtained.

Similarly the amounts of P^{32} and Mn^{56} activity were so small that only maximum amounts could be attributed to these nuclides. Again, after a decontamination factor of about 10^8 , activities of only 2-5 counts/minute above the natural background were found. Assuming that Si^{32} and Cr^{56} are long-lived, minimum values of 600 and 270 years/barn were found for the ratios $t_{1/2} \text{Si}^{32}/\sigma \text{Si}^{31}$ and $t_{1/2} \text{Cr}^{56}/\sigma \text{Cr}^{55}$ where the symbols $t_{1/2}$ and σ refer to half-life and neutron capture cross section respectively. The values quoted are the best values obtained, i.e. from experiments where the neutron flux was highest ($\sim 2 \times 10^{14}$ n./cm.²/sec.). The value of 600 years/barn agrees with that found by Turkevich and Samuels (8).

ACKNOWLEDGMENTS

One of us (L.P.R.) wishes to express his gratitude to Shawinigan Chemicals Limited, the National Research Council of Canada, and the Province of Quebec for financial assistance during the course of this and allied researches.

NOTES

THE REACTION OF NITROMETHANE WITH FLUORENONE AND BENZOPHENONE IN POLYPHOSPHORIC ACID

F. A. L. ANET, P. M. G. BAVIN,¹ AND M. J. S. DEWAR

In an attempt to prepare 9-fluorenylidenenitromethane,* regarded as a possible intermediate for 9-nitrophenanthrene, fluorenone and nitromethane were heated to 190° with polyphosphoric acid. The product was fluorenone oxime, isolated in excellent yield. Whilst most oximes are rearranged to amides by polyphosphoric acid below 120°, it has been shown that fluorenone oxime rearranges only at 180° (5). The discrepancy with our result is probably due to differences in the composition of the polyphosphoric acid. Horning (5) apparently used commercial polyphosphoric acid whilst we used a mixture of two parts of sirupy phosphoric acid to one of phosphorus pentoxide.

Later experiments showed that nitromethane was hydrolyzed to formic acid and a hydroxylamine salt by polyphosphoric acid (cf. 12). Oximation of fluorenone occurred equally readily when hydroxylamine hydrochloride replaced the nitromethane. Since oximes are generally prepared in basic media or weakly acidic buffers (4) this method may provide a useful alternative, especially for stable ketones which, like fluorenone, are otherwise unreactive.

Under these conditions, benzophenone gave an excellent yield of benzanilide, using either nitromethane or hydroxylamine hydrochloride. Snyder, Elston, and Kellom (11) have reported the formation of aniline by the reaction of benzophenone with hydroxylamine hydrochloride in polyphosphoric acid at 160°, a reaction which probably proceeds via benzophenone oxime and benzanilide. Here, again, the variation in the products obtained may be due to differences in the composition of the polyphosphoric acid. By raising the reaction temperature to 250°, fluorenone gave phenanthridone directly and in good yield (cf. 5).

The ready accessibility of fluorenone oxime by this method suggests its use as an intermediate. A suitable procedure for its conversion to *N*-acetyl-9-fluorenylamine and 9-fluorenylamine hydrochloride is described. Fluorenone oxime-*O*-tosylate failed to undergo ring-expansion during formolysis, this behavior paralleling that of 9-fluorenylid-enemethyl tosylate (1).

Attempts to prepare 9-fluorenylidenenitromethane by base-catalyzed condensation of fluorenone with nitromethane failed (cf. cyclohexanone (6)).

EXPERIMENTAL

The spectra were taken with a Beckman DK-2 Spectrophotometer. Melting points are uncorrected and were obtained with a Leitz hot-stage microscope.

Fluorenone Oxime

A solution of fluorenone (40 g.) in nitromethane (40 ml.) was added dropwise with shaking to polyphosphoric acid (250 ml.) at 190-200°, in a flask equipped with an efficient

¹National Research Council Postdoctorate Fellow, 1954-56. Present address: Chemistry Department, The Ohio State University, Columbus 10, Ohio, U.S.A.

*A reported preparation of this compound seems to be ambiguous (13).

reflux condenser. The rate of refluxing rapidly diminished and after half an hour the dark solution was poured onto crushed ice. The solid which precipitated was collected, washed, and dissolved in a warm solution of potassium hydroxide (60 g.) in water (400 ml.). After it was stirred with Norite, the solution was filtered through a layer of Celite on a sintered plate and the filtrate acidified with dilute hydrochloric acid. The solid was collected, washed, and dried at 110° and then crystallized from xylene, giving long yellow needles, m.p. 198° (36 g.) (reported m.p. 195° (14)). Found: C, 79.76; H, 4.52; N, 6.97%. Calculated for $C_{13}H_9NO$: C, 79.98; H, 4.65; N, 7.17%.

The oxime showed an OH stretching band at 2800 cm^{-1} , (CS_2 solution). Its *acetate* crystallized from hexane as pale yellow needles, m.p. 79–80° (reported m.p. 79° (9)). The *O-methyl ether* formed bright yellow blades from methanol, m.p. 149–150° (reported m.p. 145–146° (9)).

The *tosylate*, yellow needles from benzene–hexane, m.p. 168–170°, was recovered unchanged after boiling under reflux for 24 hours with 93% formic acid.

Fluorenone oxime was recovered unchanged after prolonged boiling with formic acid. Attempts to induce it to enter the Diels–Alder reaction with excess maleic anhydride also failed (cf. 9-fluorenylidene methane (2)). Its acetate could not be cyclized by a wide variety of reagents, tars or unreacted material being recovered.

Nitromethane was added dropwise to polyphosphoric acid maintained at 200°. After half an hour, the reflux condenser was replaced by a distilling head. The distillate which collected was shown to be formic acid.

Fluorenone oxime was prepared equally readily and in the same yield when nitromethane was replaced by hydroxylamine hydrochloride.

Benzanilide

The preparation was carried out as described for fluorenone oxime, using either nitromethane or hydroxylamine hydrochloride. Crystallization from aqueous ethanol (Norite) gave colorless plates, m.p. and mixed m.p. 163–165° (91%).

Phenanthridone

The fluorenone oxime preparation was repeated at 250–255°. The product was crystallized from ethanol (Norite), giving slightly yellow needles (67%), obtained colorless after one sublimation, m.p. 300–301° (reported m.p. 295° (7)).

Derivatives of 9-Fluorenylamine

Hydrogenation of fluorenone oxime over palladized charcoal gave a product smelling strongly of ammonia. The following procedure was used: Fluorenone oxime (5 g.) was dissolved in ethanol (200 ml.) and the solution saturated with dry ammonia. Palladium on charcoal (10%, 0.3 g.) was added and the mixture hydrogenated at 60 p.s.i. for 24 hours. After it was filtered through Celite, the solution was evaporated to give a greenish semisolid mass. This was warmed for a few minutes with acetic anhydride (10 ml.) and then boiled with water. The solid was collected and crystallized from xylene, giving long silky needles, m.p. 278° (3.9 g.). It sintered at 260° (reported m.p. 261° (10)). Found: C, 80.76; H, 5.76; N, 6.52%. Calculated for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%. The ultraviolet spectrum closely resembled that of fluorene:

$$\begin{aligned}\lambda_{\max} & 304, 293, 268, 258, 233 \text{ m}\mu; \\ \log \epsilon & 3.79, 3.82, 4.37, 4.37, 4.33.\end{aligned}$$

Thus this product is *N*-acetyl-9-fluorenylamine, and not a derivative of 9-iminofluorene.

The preceding *N*-acetyl compound was hydrolyzed by boiling under reflux for 24 hours with ethanolic hydrochloric acid. On cooling, prismatic needles of 9-fluorenylamine hydrochloride (87%) separated, m.p. 215° with transition to plates, which finally melted at 238–240° (reported m.p. 257° (8)). It was obtained less easily directly from the amine. Its ultraviolet spectrum also resembled that of fluorene.

Several attempts were made to diazotize 9-fluorenylamine hydrochloride, a mixture of dioxane and sulphuric and acetic acids being used as solvent. The solution showed a characteristic ultraviolet spectrum at the end of the reaction, having a well-resolved low intensity band system:

$\lambda_{\max}$ 385.0, 365.7, 352.8, 341.0, 330.2, 320.2 m μ ;

Relative intensities 15, 43, 63, 61, 47, 33.

Attempts to isolate this product failed, since it was apparently formed in small yield. Its ultraviolet spectrum resembles that of fluoranthene more than that of phenanthrene (3).

Attempts to condense fluorenone with nitromethane in ethanol or methanol, and in the presence of base (sodium or potassium hydroxide or alkoxide), gave only tars and unreacted fluorenone (cf. 6).

ANOMALOUS APPARENT DIELECTRIC CONSTANTS OF GASES ON SEVERAL POROUS ADSORBENTS¹

S. E. PETRIE² AND R. MCINTOSH

ABSTRACT

Changes in the capacity of a test cell which contained porous Vycor glass have been measured following the adsorption of butane and ethyl chloride. The results are similar to those obtained by Snelgrove and McIntosh using silica gel and these adsorbates. That is, a sudden drop in the apparent polarization is observed at a well defined quantity of adsorbed gas. This observation thus appears characteristic of porous adsorbents. To explain the phenomenon one may postulate a low density for the material of low apparent polarizability, or its location in a different electrical field in the heterogeneous dielectric. The former is ruled out with Vycor glass because of insufficient pore volume. The latter approach has been examined using the "cluster" treatment of Channen and McIntosh with the data for silica gel systems as well as porous glass. The attempt has proved only partially successful.

INTRODUCTION

In a series of papers from this laboratory, experimental data have been reported showing the effect of an adsorbed gas on the electrical capacity of a cell containing a solid adsorbent (4, 5, 6, 7, 8, 9). These data have been used to calculate apparent dielectric constants of the adsorbed phase. The method of calculation most frequently employed in the papers has been based upon a treatment for solid powders due to Böttcher (6), although other methods have been used for comparison (4). In general, the extended Böttcher treatment has appeared the most satisfactory, because, in the case of the non-polar adsorbate, butane, good agreement with the value for bulk liquid butane at the same temperature has been obtained on non-porous rutile, on activated silica gel, and, as reported below, on porous Vycor glass. In a recent paper the reasons are given why a comparison of computed results with the value of the liquid material is considered valid for a non-polar adsorbate (2). It is concluded that induced dipoles should be of no importance, and unless the electronic and atomic polarizabilities of the adsorbed molecules are seriously modified, the adsorbate should be indistinguishable from bulk matter. Provided, then, that the correct assumption is made regarding the volume fraction of the test cell which is occupied by the adsorbate, the same dielectric constant should be found as for the same substance at the same density in a bulk phase. These statements do not apply to polar adsorbates, because the contribution to polarization made by the orientation of the dipole will presumably differ from that in a bulk phase. It is interesting to note that the variation of the orientational polarization as the surface becomes more nearly saturated makes possible the detection of the completed unimolecular layer on a

²Graduate student and holder of a National Research Council Studentship.

non-porous adsorbent (4, 8, 9). Below the quantity adsorbed required to complete the unimolecular layer, the adsorbed molecules seem to be rotational oscillators. This is suggested by the theoretical predictions (2) that the polarization should be less than for a freely rotating dipole of the same magnitude, and that the temperature dependence of polarization should be negligible to a first approximation. Where experiment, as interpreted with the aid of the extended Böttcher treatment of calculation, indicates that these criteria are met, the adsorbed molecules have been considered to behave as rotational oscillators. Provisionally this seems to be the case for ethyl chloride adsorbed on rutile, in both the first and higher molecular layers, since Channen (3) was unable to detect any temperature coefficient over a 60° range of temperature. It seems surprising, however, that in the higher layers the molecules are not free to rotate.

The most difficult finding to interpret has been the discovery with both polar and non-polar adsorbates on a porous adsorbent, that there is a sudden change of apparent dielectric constant at some critical value of the volume adsorbed (4, 6, 8, 9). (See also Fig. 1.) In the case of butane on silica gel an attempt to explain the finding was made by postulating that the density of the adsorbed film of low apparent dielectric constant was much below the density of the liquid state, which is the value of density normally assumed (6). The required value of density was then calculated, and the value appeared possible since there was sufficient volume in the test cell to accept the matter at that density. In the case of butane on porous glass the pore volume of the glass was known, and it was immediately obvious that such an explanation could not suffice, since the pore volume was too low.

The alternative to this attempt at rationalization was to assume that for some reason the adsorbate, at a critical quantity adsorbed, begins to be taken up in a region where the internal field is quite different from that in which the first quantities adsorbed are located.³ It should be noted that this effect occurs with porous adsorbents only, and that it is found for both polar and non-polar adsorbates. These facts emphasize that the structure of the adsorbent is what is involved. Moreover, in the case of porous glass, the sudden change of apparent dielectric constant occurs at approximately the amount adsorbed where hysteresis becomes apparent in the adsorption isotherm (See Table I). These data suggest that a correlation exists between the quantity adsorbed at the sudden change of polarization and the quantity required to complete the unimolecular layer. However, this correlation is not found when silica gel is the adsorbent (6). Furthermore, the behavior of polar molecules on non-porous rutile indicates that the completion of the first layer should be marked by an increased polarization. Since also the computation of the quantity in the unimolecular layer requires the use of the B.E.T. equation on a porous adsorbent, it seemed advisable to consider the situation in terms of the experimentally observable quantity adsorbed when appreciable amounts begin to adsorb by what is probably a mechanism of capillary condensation. The inception of the hysteresis loop no doubt marks the beginning of this mechanism, although appreciable adsorption by such means occurs only at greater amounts adsorbed.

The simplest procedure to follow on the assumption of distinct fields was to use the

³The expression, $\delta_2 F_2 = (1/4\pi C_2) \{ \epsilon - \epsilon_i - [3\epsilon(\epsilon_0 - 1)/(2\epsilon + \epsilon_0)] \delta_3 \} E$, can readily be developed on the basis of the extended Böttcher treatment. Since the term involving $\epsilon_0 - 1$ is negligible in the usual range of equilibrium pressures, it follows that F_2 is constant whenever experiment reveals a linear variation of ΔC with quantity adsorbed. Where a sudden change of slope occurs in such linear plots, either F_2 or C_2 must be considered to change abruptly. A change of C_2 , the polarizability, of a non-polar adsorbate, seems unlikely, as has been stressed already, so that the variation must be attributed to F_2 . This conclusion is not based upon the assumption of the Onsager cavity field in the voids, since the term involving $\epsilon_0 - 1$ would be negligible on any reasonable assumption.

extended Böttcher treatment for the first quantities adsorbed since it yields a reasonable value for the dielectric constant of butane. Adsorbate beyond the critical quantity was considered to adsorb within the particle,⁴ and a treatment akin to the cluster treatment (4) was applied. Thus, for adsorbed matter greater than the critical quantity, the particle, the void space, and adsorbate within the particle are first treated as a single entity, and its dielectric constant is calculated by means of the extended Böttcher treatment. Next the dielectric constant of the composite is separated, again by the extended Böttcher treatment, into the contributions from the solid and the adsorbed phase.

No very specific remarks may be made about the locations of the adsorbed matter treated in these two ways. The attempted solution of the problem is a purely empirical one to be justified or discarded on the basis of the results obtained. Clearly, from what has been said, the regions have been thought of as external and internal surfaces of the particles, since porous particles are involved. As the data given below will show, the procedure has been only partially successful, and in view of its empirical nature this is not surprising. However, no other suggestion to rationalize the results for non-polar adsorbates on porous adsorbents has been forthcoming, and the attempt which has been made may stimulate discussion and further enquiry.

EXPERIMENTAL

The procedures used in obtaining the electrical and adsorption data were essentially those described previously (9). All the electrical measurements in the data given were made at a frequency of 3.70 Mc. per second.

Granules of porous Vycor glass, number 7930, were obtained from Corning Glass Works, Pittsburgh, Pa. The granules were ground when wet in a colloid mill and then dried in an oven at 120° C. The particles, which passed through a 40 mesh screen and were held on a 60 mesh screen, were evacuated in the electrical cell at a temperature of 120° C. until a stick vacuum was obtained at 120° C.

The pore volume of the glass, 37.0%, was calculated from the quantity of water the glass would adsorb at a relative pressure close to saturation, as determined from data obtained by Amberg (1), and with the assumption that the density of the adsorbed phase was that of the bulk liquid at the same temperature. In the calculations reported below, a value of 0.45 cc. per gram was taken as the pore volume of the silica gel. This value was supplied by the Davison Chemical Corp., Baltimore, Maryland.

RESULTS

The Non-polar Adsorbate, Butane

Plots of the change of capacitance of the test cell filled with glass versus volume of butane adsorbed at various temperatures are illustrated in Fig. 1 (note the resemblance to the plots of butane on silica gel illustrated in Fig. 5 of Ref. 7). The plots show two linear sections of which the second has a lower slope than the first. Extrapolation of the lines defines a critical value of the quantity of gas adsorbed on the Vycor glass at which a sudden change in the apparent polarization of the adsorbed phase occurs. Over the temperature range studied, the temperature coefficient is negligible. Within experimental error, the position of the discontinuity of the slope is independent of temperature, and it

⁴Professor J. J. Hermans in a private communication has suggested the use of a porous block of the adsorbent. This would eliminate voids between particles and restrict the type of void to the range of sizes in the porous adsorbent.

FIG. 1. Plots of capacity increments versus quantity adsorbed for butane on porous Vycor glass.

occurs at a quantity of gas adsorbed somewhat below the beginning of the hysteresis loop. Typical values of the volumes of gas adsorbed at the inception of the hysteresis loop, the position of the discontinuity of the slope, and the completion of the unimolecular layer are given in Table I, for both butane and ethyl chloride adsorbed on Vycor glass.

TABLE I
A COMPARISON OF SIGNIFICANT QUANTITIES ADSORBED (CC. AT N.T.P.)

Adsorbate	Temp., °C.	Vol. adsorbed at inception of hysteresis loop	Vol. adsorbed at position of discontinuity	Vol. adsorbed at completion of monolayer
Butane	-6.4	95	68	78
Ethyl chloride	14.4	120	95	99

In Table II, the dielectric constants calculated by means of the extension of Böttcher's powder method are given for butane adsorbed on porous glass. The density of the adsorbed phase was assumed to be that of the bulk liquid at the same temperature.

Although there appears to be good agreement between the values of the dielectric constant for the first linear section and those of the bulk liquid, the values along the

-19.0	1.88	1.55	1.82	1.64	1.84

second linear section are somewhat lower. Similar data have been reported by Snelgrove, Greenspan, and McIntosh (7) for butane adsorbed on dry silica gel.

In the work of Snelgrove, Greenspan, and McIntosh, different types of adsorption sites were postulated as a possible explanation for the sudden change in the dielectric properties. By varying the condition of the adsorbing surface with the addition of various known quantities of water prior to adsorption of butane it was hoped that information concerning the adsorption sites could be obtained. The critical quantity of butane adsorbed decreased as the quantity of water increased, until several hundred cc. of water measured at N.T.P. had been adsorbed, and then, it remained constant. The polarizations of both linear sections decreased as the quantity of water increased. The decrease for the second section, however, was greater than for the first. This caused an increasing separation between the values of the dielectric constants for the two regions. The dielectric results are tabulated in Table III.

The extension to Böttcher's powder method gives dielectric constants along the first linear sections that agree fairly well with those of the bulk liquid for a non-polar adsorbate. It fails to give, however, a common value of the dielectric constant for the two regions. Since the concept of a low density proved to be erroneous, the abrupt change in the apparent polarization must be caused by a change in the field. The apparent polarization remains constant throughout the hysteresis loop, and it is independent of whether measurements are obtained on adsorption or desorption in this region. It was assumed, therefore, that the field in the pores was different from that in the voids between particles. Along the first region, it was postulated that adsorption took place on the surfaces between particles, and that the extension to Böttcher's powder method was applicable. The adsorbent volume fraction included the pore volume fraction. After the critical volume was reached, adsorption was regarded as taking place within the pores. If the particle, its pore volume, and the gas adsorbed in the pores are treated as an entity in the second region, an application of the extended Böttcher formula yields an average dielectric constant for the particles, when the polarization and the volume fraction of the adsorbed phase in the initial adsorption region are regarded as constant to a first approximation. The average dielectric constant obtained in this manner can be separated by means of the extended Böttcher treatment into contributions from the solid and the adsorbed phase. The void

volume fraction is now the pore volume fraction that is not occupied by the adsorbed film.

An assumption had to be made regarding the distribution of the water between the two adsorption regions of the silica gel prior to the adsorption of butane. When the water alone is adsorbed on the silica gel, the sudden change of apparent polarization does not occur until 235 cc. (of gas at N.T.P.) is adsorbed. It was assumed, therefore, that quantities of water below this amount would be adsorbed in the first adsorption region, and that the quantities in excess of this amount would be adsorbed in the second. The free space between granules and within granules was computed from these assumptions, and modified, of course, because of the butane which was subsequently added.

The dielectric data calculated from the cluster method are given in Tables II and III for Vycor glass and silica gel respectively.

The Polar Adsorbates, Ethyl Chloride and Water

Plots of the change of capacitance of the test cell containing Vycor glass versus volume adsorbed for a polar adsorbate resemble those for a non-polar adsorbate (Fig. 2). Similar

FIG. 2. Plots of capacity increments versus quantity adsorbed for ethyl chloride on porous Vycor glass.

plots were obtained with water and ethyl chloride on silica gel (7). Again, the critical quantity of gas adsorbed is independent of temperature. With ethyl chloride adsorbed on silica gel, the critical quantity of adsorbed gas decreases as the amount of water adsorbed prior to adsorption of ethyl chloride increases.

The dielectric results calculated from the extension to Böttcher's powder method and the cluster method are given in Tables IV, V, and VI. In applying the cluster treatment, void space between and within particles was calculated as it was for butane. The results for water are considerably improved, but those for ethyl chloride only slightly. Over the temperature range studied the temperature coefficient of the polarization of ethyl chloride is small, and that for water is zero within experimental error along the first linear section. These results are somewhat similar to those obtained by Channen for ethyl chloride on rutile (3).

DISCUSSION

It can be seen that the attempt to deal separately with the two linear sections of the data, characteristic of all gases on porous adsorbents, is only partially successful. The effect of the method of computation is, in general, to lower the value of the dielectric constant along the first region to some extent, and to raise that of the second region

slightly. In two cases only are the changes sufficient to suggest that the procedure has merit. For butane on both dry and wet silica gel the values are seen to be quite similar for both adsorption regions, although they are now somewhat lower than the refractive index value. For water on silica gel the anomalous value of polarization (greater than 1.0) for the first region is reduced and a value quite close to that for liquid water is obtained. However, the disparity between values for the two adsorption regions still persists for this latter case. The inequality also remains for ethyl chloride on silica gel, whether wet or dry. Similarly, there is insufficient change to bring the values for both linear sections into agreement for any adsorbate on Vycor glass.

In view of these findings, it is clear that employment of the cluster treatment for the adsorbed matter along the second linear section is not an adequate solution to the problem. Since, however, an assignment of a low density value to the adsorbate for this region has been proved incorrect, some type of treatment which accounts for a difference in fields must be sought. That the experimental observation of an apparently low polarization seems specific to porous adsorbents is surely significant. It then appears mandatory to attribute the effect to the existence of pores and a different electrical field within them. As the inception of hysteresis in the isotherm and the sudden change of apparent polarization occur at approximately the same quantity adsorbed, a belief in the essential correctness of this type of attack on the problem is strengthened.

ACKNOWLEDGMENT

Grateful acknowledgment is made to the National Research Council for financial support of this work and the award of a studentship to S.E.P.

We are indebted to E. W. Channen for valuable discussions.

THE INFRARED AND RAMAN SPECTRA OF DISULPHUR DECAFLUORIDE (S₂F₁₀)¹

J. K. WILMSHURST² AND H. J. BERNSTEIN

ABSTRACT

The infrared spectrum of S₂F₁₀ has been obtained for the vapor from 5 to 35 μ and for the solid at liquid nitrogen temperatures from 10 to 24 μ . The Raman spectrum, together with depolarization ratios, was obtained for the liquid. A vibrational assignment has been made consistent with either D_{4d} or D_{4h} symmetry and all the fundamentals identified except two low FSSF bending frequencies and the inactive torsional frequency. A normal co-ordinate calculation located the bending frequencies at 37 and 57 cm.⁻¹ while a simple potential energy calculation gave a torsional frequency of 89 cm.⁻¹ corresponding to a potential barrier of 2780 cm.⁻¹.

The infrared spectrum only of disulphur decafluoride has previously been reported from 7 to 20 μ (3, 4). From electron diffraction measurements (6) the molecule has been shown to be a symmetric top consisting of two octahedral SF₆ groups linked together with an S—S bond in a dumbbell type structure. The relative orientation of the two SF₆ groups with respect to each other, corresponding to an eclipsed or staggered model (point symmetry D_{4h} or D_{4d} respectively), was not determined. For this particular molecule, the selection rules for the vapor, concerning the fundamental and binary overtone and combination frequencies, give the same allowed Raman and infrared transitions, depolarization ratios, and band envelopes for both point groups D_{4d} and D_{4h} .

In the present investigation the Raman spectrum of the liquid with depolarization ratios was obtained, and the infrared spectrum of the vapor was extended to cover the 5–35 μ region. The infrared spectrum of the solid at liquid nitrogen temperatures was also obtained from 10 to 24 μ . With the aid of some normal co-ordinate calculations all the fundamentals could be assigned to observed bands on the basis of D_{4h} or D_{4d} symmetry, with the exception of the two low lying skeletal bending frequencies and the inactive torsional mode. The low bending frequencies were calculated to be 57 cm.⁻¹ and 37 cm.⁻¹ from the normal co-ordinate calculation (Appendix 1), while the torsional frequency was calculated, assuming D_{4d} symmetry, to lie at 89 cm.⁻¹ (Appendix 2).

The infrared spectrum of solid S₂F₁₀ and its assignment indicated that the crystal site symmetry has, at most, a twofold axis.

EXPERIMENTAL

The sample of S₂F₁₀ (purified as in Ref. 6) was kindly made available by Dr. J. Dale of the Defence Research Laboratories, Ottawa. The Raman spectrum of the liquid* was obtained with a White grating Raman spectrometer with photoelectric recording (10), the depolarization ratios being determined by the method of Edsall and Wilson (5)

DISCUSSION

The previously reported infrared spectra of S₂F₁₀ (3, 4) are contained in the more complete spectrum obtained in the present investigation with the exception of a few minor bands that were reported as weak in the previous data. The Raman spectrum was complicated to a small extent by an enhancement of the grating ghosts due to slight photodecomposition of the S₂F₁₀, which had been exposed to the Hg arc without NaNO₂ filter. This did not unduly affect the analysis of the spectrum.

The vibrational assignment for this molecule is best discussed under the respective symmetry species. Throughout the discussion the species will be written assuming the molecule has *D*_{4d} symmetry with the corresponding species in brackets for *D*_{4h} symmetry.

The a₁(a_{1g}) Vibrations

Normally, the totally symmetric vibrational frequencies of a molecule are strongly polarized and can be assigned immediately on the basis of the Raman polarization data. With S₂F₁₀, however, though the selection rules show that there should be four totally symmetric frequencies, only three bands at 908, 690, and 246 cm.⁻¹ are observed to be strongly polarized and these can be assigned with reasonable certainty to ν_1 , ν_2 , and ν_4 , respectively. The remaining totally symmetric frequency ν_3 arises from an FSF' bending vibration, which, from the geometry, can be seen to be nearly a pure bending mode and is therefore expected to be only weakly polarized (7).

The bands most likely to arise from this FSF' bending vibration are those at 504 cm.⁻¹, 423 cm.⁻¹, or perhaps a band nearly coincident with that at 246 cm.⁻¹. To distinguish between these possibilities a simple normal co-ordinate calculation was performed using a potential energy function of the form

$$2V_{a_1} = k_1 Q_{SS}^2 + 2k_2 Q_{SF}^2 + 8k_2 Q_{SF'}^2 + (8k_6 + 8k_7) \delta_{FSF'}^2 + (8e_1 - 8e_2) Q_{SS} \delta_{FSF'}$$

for the *a*₁ modes, where the force constants are defined in the more general force field in Appendix 1. There are four force constants (or linear combinations of force constants) and it is possible to calculate all four by using the three observed frequencies ν_1 , ν_2 , and ν_4 and any one of the possibilities for ν_3 . This was performed for $\nu_3 = 504$, 423, and 246 cm.⁻¹ in turn and the results (Table III) indicate that the assignment $\nu_3 = 423$ cm.⁻¹

TABLE III
FORCE CONSTANTS CALCULATED FROM THE *a*₁ FREQUENCIES

Assignment for ν_3	k_1	k_2	$k_6 + k_7$	$e_1 - e_2$
504	3.84	5.33	3.18	-1.16
423	2.95	5.33	1.75	-0.63
246	0.84	5.33	0.33	Imaginary

gives a value for k_1 , the SS stretching force constant, in line with the values 2.5 in H₂S₂(11) and 2.04 in S₈ (2).

The b₂(a_{2u}) Vibrations

The *b*₂ vibrational frequencies would be expected to be very similar to the *a*₁ type frequencies, since the only difference in the vibrational modes is that in the *a*₁ modes

both SF_5 groups are vibrating in phase, while in the b_2 modes the SF_5 groups are vibrating out of phase. Thus the observed bands at 938, 683, and 412 cm^{-1} are assigned to ν_6 , ν_7 , and ν_8 respectively by analogy with ν_1 , ν_2 , and ν_3 .

The $e_2(b_{1g}, b_{2g}, b_{1u}, b_{2u})$ Vibrations

ν_9 , the SF' stretching mode, would be expected to occur around 690 cm^{-1} analogous to ν_2 and ν_7 , and is associated with the observed Raman band at 728 cm^{-1} . From a normal co-ordinate calculation (see Appendix 1) using the bending force constant determined from SF_6 (12), the $F'SF'$ bending frequency ν_{10} was calculated to be 524 cm^{-1} , identifying the observed Raman band at 504 cm^{-1} with this mode. The remaining $F'SF$ bending frequency ν_{11} was not obvious from the Raman spectrum but a normal co-ordinate calculation using the bending force constants obtained from the more general treatment of the a_1 and b_1 frequencies (Appendix 1) gave a calculated frequency at 275 cm^{-1} . In the observed Raman spectrum a weak band does occur at 283 cm^{-1} but this is at the exact frequency of one of the grating ghosts in the Raman spectrometer which may possibly obscure ν_{11} . However, assuming the relative intensities of the ghost bands to remain constant from spectrum to spectrum, this band is estimated to have about twice the intensity of the usual ghost at 283 cm^{-1} . Thus ν_{11} could be assigned to the band at 283 cm^{-1} . Of course, ν_{11} , which should be expected to occur only weakly, may actually be hidden under the strong band at 246 cm^{-1} . The former assignment, however, is chosen in the present discussion.

The $e_1(e_u)$ Vibrations

The e_1 vibrations should give rise to perpendicular type bands with a pronounced Q branch. Three such bands were observed at 826, 571, and 544 cm^{-1} and these are assigned to ν_{16} , ν_{17} , and ν_{18} respectively. The remaining type e_1 mode, ν_{19} , corresponding to a bending of the linear FSSF chain would be expected to occur at a low frequency and was not observed. However, from a normal co-ordinate calculation (Appendix 1) ν_{19} was calculated to be 37 cm^{-1} .

The $e_3(e_g)$ Vibrations

The e_1 and e_3 vibrations differ only in that in the former the two SF_5 groups are vibrating in phase, while in the latter they are vibrating out of phase. Thus the e_1 and e_3 frequencies should be very similar, with the e_3 frequencies being slightly greater than the e_1 modes because of the difference in coupling between the two SF_5 groups in the different vibrational species. With this in mind, therefore, the three remaining observed Raman bands at 856, 634, and 624 cm^{-1} are assigned to ν_{12} , ν_{13} , and ν_{14} respectively.

As with the e_1 modes, ν_{15} , corresponding to the bending of the FSSF chain, was not observed, but was calculated to be 57 cm^{-1} , higher than ν_{19} as would be expected.

The $b_1(a_{1u})$ Vibration

The b_1 vibration is inactive in both the infrared and Raman spectrum, and from the large moment of inertia of each SF_5 group it would be expected to have a low frequency. Normally, the torsional frequency about a single bond is best obtained from thermodynamic data, but if one knows the geometrical barrier to overcome to allow a rotation about the bond it becomes possible to calculate the potential barrier hindering this rotation from a simple force constant method as proposed by Bäck (1). In S_2F_{10} the structure of lowest energy is most likely the staggered configuration D_{4d} in agreement

with the lowest energy structure D_{3d} in the ethane type molecules. To determine the potential barrier hindering rotation, it is assumed firstly that the closest approach of the two SF₅ groups is limited by the repulsive forces of the opposed fluorine atoms on opposite groups, this being reasonable since the S—S bond length is 2.20 Å as compared with a normal S—S bond length of 2.05 Å in H₂S₂ and 2.00 Å in S₂Cl₂ (9), and secondly that during a rotation of the two SF₅ groups from one staggered form to another, the F'F' distance between the two groups remains constant, which is consistent with the first assumption since the F'F' distance is the distance of closest approach. A simple calculation (see Appendix 2) gives the height of the potential barrier as $V_{\max} = 2780$ cm.⁻¹. This corresponds to a torsional frequency $\nu_5 = 89$ cm.⁻¹.

Vibrational Spectrum of Solid S₂F₁₀

The infrared spectrum of solid S₂F₁₀ at liquid nitrogen temperatures was obtained in the hope that the crystal site symmetry may be such as to distinguish between the point groups D_{4h} and D_{4d} for the free molecule on the basis of the increase in the number of infrared active fundamentals and the removal of degeneracies.

However, in the observed spectrum from 1000 to 450 cm.⁻¹ (Fig. 3), nearly all the bands could be assigned to corresponding bands in the spectrum of the vapor or to combination bands with a lattice frequency of the order of 40 cm.⁻¹, and only two bands at 894 and 683 cm.⁻¹ have been assigned to Raman active fundamentals $\nu_1(a_1)$ and $\nu_2(a_1)$ made infrared active by the crystal symmetry (Table IV). The intensity of ν_2 in the solid is surprising and probably arises owing to Fermi resonance with the infrared active fundamental ν_7 .

TABLE IV
VIBRATIONAL ASSIGNMENT FOR SOLID S₂F₁₀

Infrared, cm. ⁻¹ (solid)	Infrared, cm. ⁻¹ (vapor)	Raman, cm. ⁻¹ (liquid)	Assignment
~526 sh	—	—	$\nu_{17} - 40 = 530$

~795 sh	786	—	$\nu_4 + \nu_{18} = 786$
802	—	—	—
806	826	—	$\nu_{16}(e_1)$
819	—	—	$\nu_6 - 2 \times 40 = 820$
826	—	—	$\nu_{11} + \nu_{18} = 823$
842	—	—	$\nu_{16} + 40 = 846$
894	—	908	$\nu_1(a_1)$
900	938	—	$\nu_6(b_2)$
920	~915	—	$\nu_4 + \nu_7 = 922$
945	—	—	$\nu_6 + 40 = 940$
970	—	—	$\nu_6 + 2 \times 40 = 980$

The three type e_1 infrared active bands of gaseous S_2F_{10} are split into two components in the solid, which verifies the assignment of these bands and suggests that the site symmetry of solid S_2F_{10} has a twofold axis at most. This lower site symmetry is also consistent with the assignment of the bands at 894 and 683 cm^{-1} to ν_1 and ν_2 and the suggested Fermi resonance between ν_2 and ν_7 .

Combination Bands

All the remaining bands in the infrared spectrum of S_2F_{10} vapor can be reasonably assigned to summation or difference tones of the fundamentals. Of these, only six bands needed explanation in terms of the three calculated fundamentals ν_5 , ν_{15} , and ν_{19} and the agreement in each case was quite satisfactory.

In solid S_2F_{10} the remaining bands were assigned to combination tones of the fundamentals, but in this case it was considered necessary to include a lattice frequency at 40 cm^{-1} , 11 bands being assigned satisfactorily as sum and difference tones of this frequency or its first overtone with the fundamentals. Of course, $\nu_{19} = 37 \text{ cm}^{-1}$ and $\nu_5 = 89 \text{ cm}^{-1}$ could have been used in place of the lattice frequency to account for the binary and ternary combinations, but the lattice mode was preferred since the bands assigned as combinations with its frequency did not occur in the vapor state.

APPENDIX 1

The particular geometry of the S_2F_{10} molecule is such that the secular equation for the non-degenerate species containing an S—F' stretching mode can be factorized when a simple valence force potential function is assumed to describe the molecule. In such cases the SF' stretching mode factorizes out, simplifying the original secular equation for the species by one degree. If a more general valence force field is assumed to describe the molecule, this factorization can still be obtained if all interactions with the S—F' bond are assumed zero, except interactions between the SF' stretching of different bonds in the same SF'_4 group.

For the S_2F_{10} molecule a valence force field was assumed to describe the molecule and it was made as general as was consistent with the number of observed frequencies by introducing suitably significant interactions in such a way that the factorizations mentioned above would still be possible.

The resulting valence force potential function was:

$$\begin{aligned}
 2V = & k_1 Q_{SS}^2 + k_2 (Q_{SF}^2 + Q_{SF'}^2) + 2g_1 (Q_{SF} + Q_{SF'}) Q_{SS} + k_3 r R (\delta_{FSS}^2 + \delta_{SSF'}^2) \\
 & + 2h_1 r R (\delta_{FSS} \delta_{SSF'}) + \sum_{i=1}^4 k_4 (Q_{SF'i}^2 + Q_{SF'i'}^2) + \sum_{\substack{i,j=1 \\ j=i\pm 1}}^4 2g_2 (Q_{SF'i} Q_{SF'j} + Q_{SF'i'} Q_{SF'j'}) \\
 & + \sum_{i=1}^4 k_5 r^2 (\delta_{F'i SF'i+1}^2 + \delta_{F'i SF'i-1}^2) + \sum_{i=1}^4 k_6 r^2 (\delta_{F SF'i}^2 + \delta_{F SF'i'}^2) \\
 & + \sum_{i=1}^4 k_7 r^2 (\delta_{SSF'i}^2 + \delta_{SSF'i'}^2) + \sum_{i=1}^4 e_1 r (\delta_{F SF'i} + \delta_{F SF'i'}) Q_{SS} \\
 & + \sum_{i=1}^4 e_2 r (\delta_{SSF'i} + \delta_{SSF'i'}) Q_{SS}
 \end{aligned}$$

where the Q 's refer to bond extensions,
the δ 's refer to angle bendings,

S and $\underline{S}$, F and $\underline{F}$ refer to the atoms in the different SF₅ groups, and F' refers to an atom not on the fourfold axis, as defined in the footnote to Table I,

r = S—F bond length,

R = S—S bond length.

Proceeding in the usual manner, the secular equations

$$\det(FG - \lambda I) = 0$$

were set up for the different vibrational species. The terms in the symmetrical F and G matrices for the different symmetry species are given below. In all equations M = mass of S and m = mass of F.

The $a_1(a_{1g})$ species

$$f_{11} = 8k_4 + 16g_2$$

$$f_{22} = 2k_2$$

$$f_{33} = k_1$$

$$f_{44} = 8k_6 + 8k_7$$

$$f_{12} = f_{13} = f_{14} = f_{24} = 0$$

$$f_{23} = 2g_1$$

$$f_{34} = 4e_1 - 4e_2$$

$$g_{11} = \frac{1}{8m}$$

$$g_{22} = \frac{1}{2M} + \frac{1}{2m}$$

$$g_{33} = \frac{2}{M}$$

$$g_{44} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{12} = g_{13} = g_{14} = 0$$

$$g_{23} = -\frac{1}{M}$$

$$g_{24} = -\frac{1}{2M}$$

$$g_{34} = \frac{1}{M}$$

The $b_2(a_{2u})$ species

$$f_{11} = 8k_4 + 16g_2$$

$$f_{22} = 2k_2$$

$$f_{33} = 8k_6 + 8k_7$$

$$f_{12} = f_{13} = f_{23} = 0$$

$$g_{11} = \frac{1}{8m}$$

$$g_{22} = \frac{1}{2M} + \frac{1}{2m}$$

$$g_{33} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{23} = -\frac{1}{2M}$$

$$g_{12} = g_{13} = 0$$

The e_2 species

$$(b_{1g}, b_{2u}) \begin{cases} f_{11} = 8k_4 - 16g_2 \\ f_{22} = 8k_6 + 8k_7 \end{cases}$$

$$(b_{1u}, b_{2g}) \begin{cases} f_{33} = 8k_5 \\ f_{12} = f_{13} = f_{23} = 0 \end{cases}$$

$$g_{11} = \frac{1}{8m}$$

$$g_{22} = \frac{1}{8m}$$

$$g_{33} = \frac{1}{2m}$$

$$g_{12} = g_{13} = g_{23} = 0$$

The $e_1(e_u)$ species

$$f_{11} = 4k_4$$

$$f_{22} = 4k_6 + \frac{R}{r}(2k_3 + 2h_1)$$

$$f_{33} = 4k_7 + \frac{R}{r}(2k_3 + 2h_1)$$

$$f_{44} = 8k_5$$

$$f_{23} = \frac{R}{r}(2k_3 + 2h_1)$$

$$f_{12} = f_{13} = f_{14} = f_{24} = f_{34} = 0$$

$$g_{11} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{22} = \frac{1}{2M} + \frac{5}{8m}$$

$$g_{33} = \frac{1}{8m}$$

$$g_{44} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{12} = g_{14} = -\frac{1}{2M}$$

$$g_{13} = g_{34} = 0$$

$$g_{23} = -\frac{1}{8m}$$

$$g_{24} = \frac{1}{2M}$$

The $e_3(e_g)$ species

$$f_{11} = 4k_4$$

$$f_{22} = 4k_6 + (2k_3 - 2h_1)\frac{R}{r}$$

$$f_{33} = 4k_7 \frac{r^2}{R^2} + (2k_3 - 2h_1)\frac{r}{R}$$

$$f_{44} = 8k_5$$

$$f_{23} = 2k_3 - 2h_1$$

$$f_{12} = f_{13} = f_{14} = f_{24} = f_{34} = 0$$

$$g_{11} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{22} = \frac{1}{2M} + \frac{5}{8m}$$

$$g_{33} = \frac{2}{M} + \frac{1}{8m} \frac{R^2}{r^2}$$

$$g_{44} = \frac{1}{2M} + \frac{1}{8m}$$

$$g_{12} = g_{14} = -\frac{1}{2M}$$

$$g_{13} = -\frac{1}{M}$$

$$g_{23} = \frac{1}{M} - \frac{1}{8m} \frac{R}{r}$$

$$g_{24} = \frac{1}{2M}$$

$$g_{34} = \frac{1}{M}$$

TABLE V

CALCULATED VALENCE FORCE TYPE CONSTANTS FOR S_2F_{10}

$k_1 = 2.806 \times 10^6$ dynes cm. ⁻¹	$g_1 = 0.406 \times 10^5$ dynes cm. ⁻¹
$k_2 = 5.582$ "	$g_2 = -0.164$ "
$k_3 = 0.162$ "	$h_1 = -0.118$ "
$k_4 = 5.602$ "	$e_1 - e_2 = -0.465$ "
$k_5 = 0.711$ "	
$k_6 = 0.711$ "	
$k_7 = 0.134$ "	

Using the equations derived above and the observed frequencies given in Table II, all the force constants and the three unknown frequencies ν_{11} , ν_{15} , and ν_{19} were calculated. The force constants are given in Table V.

Of interest is the good agreement between k_2 and k_4 (the SF and SF' stretching constant respectively), as would perhaps be expected. This excellent agreement indicated that the F'SF' bending constant could be made equal to k_6 , the FSF' bending constant, and this was actually assumed.

APPENDIX 2

Assuming the S₂F₁₀ molecule to have the staggered configuration D_{4d} , then on rotation of one SF₆ group relative to the other the bonds and angles that are most likely to undergo a change are the SS bond and the FSF' and F'SS angles. Thus the potential barrier $V_{\max}$ hindering rotation can be written after Bäck (1) as

$$\begin{aligned} [1] \quad V_{\max} &= \frac{1}{2}k_1 Q_{SS}^2 + \frac{8}{2}(k_6 + k_7)r^2 \delta_{SSF'}^2 \\ &= \frac{1}{2}k_1 Q_{SS}^2 + \frac{8}{2}Kr^2 \delta_{SSF'}^2 \end{aligned}$$

where $K = k_6 + k_7$.

Consequently

$$[2] \quad dV_{\max} = 0 = k_1 Q_{SS} \frac{dQ_{SS}}{d\delta_{SSF'}} + 8Kr^2 \delta_{SSF'}.$$

Assuming that the F'F' distance between the two SF₆ groups is the same in the eclipsed configuration as in the staggered configuration,

$$[3] \quad 2Q_{SS} + 4r\delta_{SSF'} = \frac{\sqrt{2}r^2}{R}(\sqrt{2}-1).$$

Thus solving the three equations 1, 2, and 3 we obtain

$$V_{\max} = Kr^2 \left\{ \frac{K}{k_1} + \frac{1}{2} \right\} \frac{r^2}{R^2} (3 - 2\sqrt{2}) \left[1 + 4 \frac{K}{k_1} + 4 \left(\frac{K}{k_1} \right)^2 \right]^{-1}.$$

The torsional frequency corresponding to this potential barrier is given by

$$\nu_t = 2N \sqrt{V_{\max} A}$$

where N = number of potential minima,

and A = rotational constant about the torsional axis.

THE ENTROPIES OF IONS IN AQUEOUS SOLUTION

II. AN EMPIRICAL EQUATION FOR OXY-ANIONS¹

A. M. COUTURE² AND K. J. LAIDLER

ABSTRACT

The entropies of oxy-anions in aqueous solution are shown to obey the empirical relationship

$$\bar{S}_{\text{abs}}^0 = 40.2 + (3/2)R \ln M - 27.2 z^2 / 0.25nr$$

with a mean deviation of 3.6 e.u. In this equation $\bar{S}_{\text{abs}}^0$ is the entropy relative to a value of -5.5 e.u. for the proton, M is the molecular weight, z the number of charges on the ion, n the number of charge-bearing ligands, r is equal to $r_{12} + 1.40$, where r_{12} is the interatomic distance between the central atom and the surrounding oxygens, and 1.40 is the van der Waals radius of oxygen. The significance of the empirical equation is discussed.

INTRODUCTION

In a recent paper (7), Part I of this series, it has been shown that the absolute entropies of ions (related to a value of -5.5 e.u. for the proton) are accurately represented by the empirical equation

$$[1] \quad \bar{S}_{\text{abs}}^0 = 10.2 + (3/2)R \ln M - 11.6z^2/r_u.$$

Here M is the atomic weight, z the valency, and r_u the univalent radius as defined by Pauling (11). The applicability of the equation is almost, but not quite, as good if the ordinary crystal radii are employed. The equation is to be contrasted with other empirical equations, due to Powell and Latimer (13) and others (2, 3, 6), in which the entropy is related to z/r_e^2 , where r_e is an effective radius obtained by the addition of a constant term to the crystal radii. The applicability of such equations is, in our view, fortuitous, arising from the choice of arbitrary entropies (based on a value of zero for the proton) and from the use of corrected radii. Our Equation [1] is consistent with Born's simple electrostatic model for ions in solution (1) although, for reasons to be discussed elsewhere (12), the coefficient of 11.6 is slightly but significantly different from that predicted by the Born equation.

In view of the applicability of equations involving z^2/r to the entropies of monatomic ions we are at present attempting to develop similar equations for polyatomic ions. The present paper is concerned with inorganic oxy-anions. The paper which follows (5) deals with the partial molal volumes of these ions, following a treatment recently proposed (4) for the volumes of monatomic ions.

THE DATA

The conventional partial molal entropies of a number of oxy-anions (10), based on a value of zero for the proton, are shown in the second column of Table I. These have been converted into absolute entropies by the addition of $5.5 |z_-|$, where $|z_-|$ is the number of negative charges on the ion, and the results are shown in the third column.

Also shown in the table are the values of r_{12} , the distance between the center of the central atom and the center of the surrounding oxygen atoms; these values have been

derived from Pauling's covalent radii (11). The fourth column of Table I shows the values of $r_{12}+1.40$; since 1.40 Å is the van der Waals radius of oxygen the distance $r_{12}+1.40$ represents the radius of a sphere that completely circumscribes the anion.

AN EMPIRICAL EQUATION

An inspection of Table I reveals that the entropy decreases as the charge increases, but increases as the interatomic distance and the number of charge-bearing ligands increase. Further examination shows that the entropy shows a dependence on z^2/r , where $r = r_{12}+1.40$. Fig. 1 shows a plot of $\bar{S}^0_{\text{abs}}$ against z^2/r , and it is seen that the points are grouped according to the number of *charge-bearing* ligands, n . There is no grouping in terms of the total number of ligands.

Since it is the number of charge-bearing ligands that is important, it follows that the distribution of charges plays an important role. An attempt was made to correlate the entropies with dipole moments as well as with z^2 , but this proved unsuccessful. One can only make estimates of the dipole moments of ions, but one knows that the moments for certain symmetrical ions (e.g. SO₄⁼⁼, PO₄⁼⁼, NO₃⁻) must be zero. Even for these ions of zero moment there is still a grouping with respect to the number of charge-bearing ligands. More is therefore involved than the dipole moment.

The groups corresponding to the different values of n can be brought together if the

FIG. 1. A plot of $\bar{S}^0_{\text{abs}}$ against z^2/r , where r is equal to $r_{12} + 1.40$. The points are seen to be grouped according to the number of charge-bearing ligands, n .

effective radius r ($=r_{12} + 1.40$) is multiplied by n : in other words, if the entropies are plotted against z^2/rn . As with the monatomic ions, the correlation is improved if one subtracts from the entropies the quantity $(3/2)R \ln M$, where M is the molecular weight. This term, as discussed in Part I (7), is related to the non-electrostatic contribution to the entropy. Values of $\bar{S}^0_{\text{abs}} - (3/2)R \ln M$ are shown in Table I, and are plotted against $z^2/0.25nr$ (also listed in Table I) in Fig. 2. The use of $z^2/0.25nr$ instead of z^2/nr is purely a matter of convenience. For ions like SO_4^{--} , for which n is 4, $z^2/0.25nr$ becomes z^2/r , while r is correspondingly reduced for values of n of less than 4.

The points in Fig. 2 are seen to lie close to a straight line. By the method of least squares the equation of the line was found to be

$$[2] \quad \bar{S}^0_{\text{abs}} = 40.2 + (3/2)R \ln M - 27.2 z^2/0.25nr$$

with a mean deviation of 3.6 e.u.

FIG. 2. A plot of $\bar{S}^0_{\text{abs}} - (3/2)R \ln M$ against $z^2/0.25nr$. The mean deviation from the straight line is 3.6 e.u.

The use of r_{12} in place of r was also investigated, but the correlation was then not quite as satisfactory.

DISCUSSION

Equation [2] is seen to be of the same general form as Eq. [1], which was obtained for monatomic ions. It again consists of a non-electrostatic part $(40.2 + (3/2)R \ln M)$ and an electrostatic part, the final term. The correlation is again with z^2 rather than with z .

The relationships expressed in Eq. [2] may be explained on the basis of a very simple model. The ions with four charge-bearing ligands may conveniently be regarded as standard, and for them $0.25nr$ represents the radius of the circumscribing sphere. If, for example, n is 2, the radius appearing in the denominator, $0.25nr$, is one half the radius of the circumscribing sphere; the behavior of such an ion (as far as entropy is concerned) is therefore equivalent to that of an ion having half the radius of the circumscribing sphere. This is not surprising, since for such an ion the water molecules have much more access to the charge-bearing centers.

The fact that it is the number of charge-bearing ligands that counts, and not the total number of ligands, is of some special interest and significance. As far as the electrostatic contribution to the entropy is concerned it is evidently only the total charge and the

distribution of charges that are important. For the ions under consideration in the present paper a non-charge-bearing ligand can be only an OH group, and the empirical equation implies that the presence or absence of an OH group is immaterial as far as entropy is concerned. That this is really the case from the experimental point of view is revealed by an inspection of Figs. 1 and 2 in which it may be seen, for example, that the ions H_2AsO_4^- , HSO_3^- , and ClO_2^- , with very similar z^2/r values, have almost identical entropies; this is so in spite of the fact that the ions contain 2, 1, and 0 non-charge-bearing ligands (OH) respectively. These OH groups will, of course, behave very much like the OH groups in the surrounding water molecules. It is true that they should contribute some non-electrostatic entropy, but such a contribution is very small and is partly taken into account in the $(3/2)R \ln M$ term.

Subsequent papers will deal with the entropies of other complex ions and with the application of the present conclusions to kinetic problems (8, 9).

THE PARTIAL MOLAL VOLUMES OF IONS IN AQUEOUS SOLUTION

II. AN EMPIRICAL EQUATION FOR OXY-ANIONS¹

A. M. COUTURE² AND K. J. LAIDLER

ABSTRACT

The partial molal volumes of oxy-anions, obtained from density data, have been correlated with the radius, the charge, and the number of ligands of the ions. The volumes relative to a value of -6.0 ml. for the proton are represented by the equation:

$$\bar{V}'_{-} = 58.8 + 0.89r^3 - 26|z_{-}|$$

where r and z_{-} have the same significance as in the preceding paper on entropies. The equation is compared with the one for monatomic ions, and the significance of the effective radius r is discussed.

INTRODUCTION

It has recently been shown (1) that partial molal volumes of monatomic ions in aqueous solution can be expressed as a simple function of the charge and the crystal radius. This correlation suggested that, as it is the case with entropies (2), a similar situation might exist for more complex ions. The present communication is therefore concerned with obtaining such an empirical equation for oxy-anions.

EMPIRICAL EQUATION

The equation proposed (1) to correlate the partial molal volumes of all monatomic cations and anions is

$$[1] \quad \bar{V}'_{\pm} = 16 + 4.9r^3 - 26|z_{\pm}|$$

where $\bar{V}'_{\pm}$ refers to volumes based on a value of -6.0 ml. for $\bar{V}'_{H^{+}}$, r is the Goldschmidt crystal radius (3), and $|z_{\pm}|$ the absolute value of the charge. An interpretation of this equation was given: the first two terms are considered to be related to the intrinsic volume of the ion, and the final term to the electrostriction of the water molecules surrounding the ion.

The same terms should also appear in the volume of the oxy-anions. These volumes, both on the scale of $\bar{V}_{H^{+}} = 0$ and $\bar{V}'_{H^{+}} = -6.0$ ml., are listed in Table I; the volumes have been calculated from density data (4) and agree with the few values given by Owen and Brinkley (5). The problem with oxy-anions is to define a suitable effective radius and to elucidate the effect of charge-bearing ligands. Since the use of $0.25nr$ (where n is the number of charge-bearing ligands and r the sum of the Pauling (6) interatomic distance, r_{12} , and the van der Waals radius of the oxygen atom) was very suitable in the case of entropies (2), we have attempted to employ it here as an effective radius. These values of $0.25nr$ are also included in Table I. From the study of the variation of the volumes with the cube of this radius and with the charge, we arrived at the following equation for the volume related to the value of -6.0 ml. for the proton:

$$[2] \quad \bar{V}'_{-} = 58.8 + 0.89(0.25nr)^3 - 26|z_{-}|.$$

A plot of $\bar{V}'_- + 26|z_-|$ versus $(0.25nr)^3$ appears in Fig. 1 and the mean deviation in the volume is 3.5 ml. The corresponding equation for $\bar{V}'_-$ (related to zero for the proton) is

$$[3] \quad \bar{V}'_- = 58.8 + 0.89 (0.25nr)^3 - 32|z_-|.$$

FIG. 1. A plot of $\bar{V}'_- + 26|z_-|$ against $(0.25nr)^3$.

DISCUSSION

Although the radius ($r = r_{12} + 1.40$) is corrected empirically to take into account the effect of the charge-bearing ligands, the effective radius thus obtained is easily visualized. The ion with four charge-bearing ligands is taken as the standard and its effective radius is r . As the number of charge-bearing ligands decreases the effective radius is reduced in the same proportion; hence

$$\begin{aligned} r_e &= \frac{3}{4}r \text{ if } n = 3, \\ r_e &= \frac{1}{2}r \text{ if } n = 2, \\ r_e &= \frac{1}{4}r \text{ if } n = 1. \end{aligned}$$

The ligands ($-\text{OH}$) which cannot have a charge are discarded as they make no more contribution to the volume than if they belonged to the water molecules surrounding the ion.

An effective radius may be calculated by considering only the volumes of the atoms involved, i.e.

$$[4] \quad r_{\text{calc}} = \sqrt[3]{r_{\text{covalent}}^3 (\text{central atom}) + n(1.40)^3}$$

(where $1.40 \text{ \AA}$ is the van der Waals radius of O). If this r_{calc} and the r obtained empirically are compared, they are found to agree very closely for $n = 3$; r_{calc} is smaller than r when $n = 4$ but is larger when $n = 2$ or 1. These differences arise in part from the uncertainty in the radii of the atoms combined to form oxy-anions owing to a certain amount of interpenetration. Moreover, depending on the number of atoms involved, there is some dead space unavailable to water molecules, and this dead space is included in r but not in r_{calc} .

It is interesting to note that the coefficient of $|z|$ is the same in Equation [2] as in Equation [1]. The $|z|$ term is related in both cases to the electrostriction of the water molecules in the neighborhood of the ion, and the fact that two empirical equations, obtained independently for two types of ions, agree in the coefficient of this term is very probably more than a coincidence: it is an indication that the scale on which the volumes are based is an absolute scale and hence that -6.0 ml. is the true partial molal volume of the proton. On the scale where $\bar{V}_{\text{H}^+} = 0$, the coefficient of $|z|$ is -20 for monatomic cations but -32 for oxy-anions. The coefficient of $|z|$ for the monatomic anions should also be -32 , which it is not (it is -20). However, it must be pointed out that all the monatomic anions are univalent with the exception of $\text{S}^{=}$, so that the accuracy of the slope in a plot of $(\bar{V}_- - 4.9r^3)$ against $|z|$ depends solely on the accuracy of the volume of $\text{S}^{=}$; if it were not for $\text{S}^{=}$ the slope, which is the coefficient of $|z|$, could have any value. There are several reasons for doubting the accuracy of $\bar{V}_{\text{S}^{=}}$: (1) it is derived from the partial molal volume of only one solute, Na_2S ; (2) if an attempt is made to bring together monatomic cations and anions, $\text{S}^{=}$ does not agree with the general equation, thus leading to the conclusion that this equation applies only to monatomic cations and univalent monatomic anions; (3) the equation for oxy-anions points to a dependence on $-26|z_-|$ for $\bar{V}'$ and on $-32|z_-|$ for $\bar{V}$, and all monatomic anions except $\text{S}^{=}$ can be made to fit such a dependence. The evidence thus points to -6.0 ml. as the absolute volume of the proton.

The coefficients of r^3 do not correspond, but this was not expected since the two r 's are different, one being the crystal radius, and the other being derived empirically.

LYCOPODIUM ALKALOIDS

V. OXIDATION AND REDUCTION STUDIES ON ANNOTININE AND ITS DERIVATIVES¹

E. E. BETTS² AND DAVID B. MACLEAN

ABSTRACT

Annotinine lactam $C_{16}H_{19}O_4N$ has been converted by the action of dilute sulphuric acid to the lactamdiol, $C_{16}H_{21}O_5N$. Oxidation studies on the lactamdiol have confirmed the presence of the epoxide ring in the alkaloid and have established the six-membered character of the lactam ring. The allylamine structure of unsaturated lactone A, $C_{16}H_{21}O_3N$, has been confirmed and a number of intermediate oxidation products of this compound have been isolated and characterized. Raney nickel reduction of annotinine yielded hydroxy annotinine, $C_{16}H_{23}O_3N$, and saturated lactone A, $C_{16}H_{23}O_3N$. Catalytic reduction of annotinine lactam over Adams' catalyst in acidic medium converted it partially to annotinine.

Annotinine, $C_{16}H_{21}O_3N$, is the major alkaloid of *Lycopodium annotinum* L. Because of its availability and reactivity the chemistry of this alkaloid has been studied more intensively than others of the *Lycopodium* group. Annotinine contains a tertiary nitrogen, an oxide ring, a lactone ring, and a combination of four carbocyclic and heterocyclic rings (8). An epoxide ring structure and its relationship to the nitrogen atom was proposed by MacLean and Prime (7) and has been supported by the work of Anet and Marion (1) and of Wiesner *et al.* (4). The lactone ring is apparently a γ -lactone from its infrared spectrum (9). Wiesner *et al.* (5) have related the position of the lactone ring to the other functions in the molecule. These relationships can be expressed in the following manner:

Evidence for the size and nature of the four principal rings in the molecule has been obtained by infrared spectroscopy and by dehydrogenation experiments. The infrared spectrum of annotinine lactam, $C_{16}H_{19}O_4N$, has suggested that the nitrogen-containing ring carrying the epoxide function is six-membered, although the possibility of a larger ring is not excluded (9). Similarly, when the secondary hydroxyl group derived from the lactone function was converted to a ketone, the infrared spectrum indicated that the ring bearing this function was six-membered or larger (10). A series of dehydrogenation studies on annotinine and its derivatives has been carried out by Wiesner and his associates. By a careful characterization of the products of these reactions and an exceptionally clever interpretation of their origin, they have proposed several plausible structures for the alkaloid (10, 12, 13).

There is still lacking, however, unequivocal chemical confirmation of many of the structural features of the molecule even to the size of the oxide and lactone rings. Furthermore, it has never been established that derivatives of annotinine which have been used in dehydrogenation studies have not suffered rearrangements in the course of their preparation. In this communication we present good evidence for the presence of the epoxide function and for the six-membered character of the nitrogen ring carrying this

¹Manuscript received November 6, 1956.

Contribution from the Burke Chemical Laboratories, Hamilton College, McMaster University, Hamilton, Ontario.

²Holder of a National Research Council Studentship, 1955-56.

function. In the course of our work we also had occasion to examine some reactions of unsaturated lactone A (8, 9) and wish to report in particular on some oxidation studies on this compound. Annotinine derivatives used in dehydrogenation studies have been related to annotinine, thus precluding the possibility of rearrangement in their preparation. Finally, and as a matter of interest, we have been able to convert annotinine lactam to annotinine.

Annotinine, $C_{16}H_{21}O_3N$ (I), has been converted in good yield into annotinine lactam, $C_{16}H_{19}O_4N$ (II) (7). Treatment of II with boiling aqueous sulphuric acid converted it to annotinine lactamdiol, $C_{16}H_{21}O_5N$ (III), which should contain the following arrangement

of groups: $\text{>N}-\overset{\text{O}}{\parallel}{\text{C}}-\text{CHOH}-\text{CHOH}-$. It would be expected to react readily with

glycol cleavage reagents. However, periodate did not react, but lead tetraacetate slowly oxidized the molecule with consumption of 3 moles of the reagent. Two moles of reagent would be consumed in cleavage and the third in oxidation of the liberated formic acid. Oxidation of III with potassium permanganate in acetic acid or with chromic acid in glacial acetic acid converted it in low yield into two products, one neutral and one acidic. The neutral product $C_{15}H_{17}O_4N$ (IV) had three strong absorption bands in the carbonyl region of the infrared at 1708 cm^{-1} , 1760 cm^{-1} , and 1780 cm^{-1} corresponding respectively to a γ -lactam, a five-membered cyclic ketone, and a lactone ring. Treatment of IV with sodium borohydride in ethanol converted it to $C_{15}H_{19}O_4N$ (V), which now had two bands in the carbonyl region of the infrared at 1682 cm^{-1} corresponding to a γ -lactam and at 1780 cm^{-1} to a γ -lactone. The band at 1760 cm^{-1} had disappeared and a new band at 3335 cm^{-1} in the hydroxyl region had appeared. The formation of the γ -lactam with loss of a single carbon supports the proposal of a six-membered nitrogen ring at this site.

The acidic fraction $C_{15}H_{19}O_5N$ (VI) had three peaks in the carbonyl region of the infrared at 1610 cm^{-1} , 1705 cm^{-1} , and 1775 cm^{-1} attributed to amide, carboxylic acid, and γ -lactone functions respectively. Hydrolysis of VI with dilute sulphuric acid yielded formic acid in equimolar amount and the amino acid $C_{14}H_{19}O_4N$ (VII), identified through its methyl ester, previously reported by Anet and Marion (1) and by Wiesner (4). Compound VI is obviously the N-formyl derivative of amino acid VII. The low yield of IV and VI is likely due to the concomitant formation of amino acid VII, and indeed, its presence has been detected.

The formation of these products can be explained with the aid of the accompanying partial formula.

An initial fission of the system at (a) would yield a carbamic acid which would lose CO_2 to yield the secondary amine. Oxidation of center 3 would yield an α -keto acid which by cyclization would yield IV. Fission at (b) followed by oxidation at each center would form an N-oxalyl carboxylic acid which in the medium would decarboxylate to VI. Either IV or VI or their progenitors would yield VII by hydrolysis or oxidation or a combination of the two.

The compound designated unsaturated lactone A, $C_{16}H_{21}O_2N$ (VIII), has been assigned an allylamine structure by Anet and Marion on the basis of its origin and a comparison of its pK_a with that of its dihydro derivative (1). A compound of this structure would be expected to react readily with cyanogen bromide. However, VIII was recovered in 80% yield or better when it was treated with cyanogen bromide under a variety of experimental conditions. Because of this anomalous result we decided to reinvestigate the composition of two products of the barium permanganate oxidation of VIII isolated some years ago. One of these compounds, $C_{15}H_{19}O_5N$, proved to be identical with VI. The second compound, isolated as its methyl ester, $C_{17}H_{21}O_6N$ (IX), had four bands in the carbonyl region of the infrared. A double peak at 1633 cm^{-1} and 1645 cm^{-1} was assigned to an amide function while bands at 1710 cm^{-1} , 1743 cm^{-1} , and 1780 cm^{-1} were assigned to keto carbonyl, carbomethoxy, and γ -lactone functions respectively. Hydrolysis of IX with dilute sulphuric acid yielded formic acid and a trace of compound IV, thereby establishing the structure of IX. The amino acid VII is the major oxidation product as already established by Anet and Marion (1).

The formation of formyl derivatives on oxidation, coupled with its inertness toward cyanogen bromide, suggested that VIII might contain a vinylamine rather than an allylamine structure. To clarify this point VIII was treated with ozone. Ozonolysis of a vinylamine should yield an N-formyl derivative while an allylamine would be expected to yield an amino dicarboxylic acid. The reaction took neither course, but instead yielded the conjugated lactam, $C_{16}H_{19}O_3N$ (X), previously isolated by MacLean and Prime (7) and by Anet and Marion (1). The formation of X can be rationalized more readily from an allylamine structure than from the alternative vinylamine formulation.

The several oxidation products are depicted by the partial formulas below:

The formation of X can be accommodated by formation of a hydroperoxide at the methylene carbon and its subsequent decomposition. If we assume that X is an intermediate in the permanganate oxidation, then VI could arise by hydroxylation of X followed by cleavage as indicated previously in its derivation from III. The amino acid VII is the product of complete oxidation and hydrolysis. The formation of X can be accounted for by the following sequence:³

Two derivatives of annotinine which have been used in dehydrogenation studies are the amino acid VII (1, 11) and the methyl ester derived from anhydro annotinine lactam chlorohydrin (XI) (12, 13). Compound XI was readily oxidized to VII, which in turn was also prepared from VIII. Both VIII and XI were formed by dehydration reactions in acid media where a rearrangement of the carbon skeleton of annotinine was possible, if not probable. We have now established that VIII and therefore XI have the same skeletal structure as the parent alkaloid. Annotinine was reduced with hydrogen over Raney nickel to yield two products, $C_{16}H_{23}O_3N$ (XII) and $C_{16}H_{23}O_2N$ (XIII). Compound XII was hydroxy annotinine formed by fission of the oxide ring, while XIII resulted from complete removal of the oxide ring and was identical with the dihydro derivative of VIII. The isolation of XIII indicates that the original skeletal arrangement of annotinine is preserved in both VIII and XI.

A method of converting annotinine lactam to annotinine was accidentally discovered in the course of some experiments on alternate methods of preparation of hydroxy annotinine lactam (XIV) (7). Reduction of the lactam II over platinum catalyst in neutral or in basic medium yielded XIV. In the presence of small amounts of hydrochloric acid, annotinine and annotinine lactam chlorohydrin were recovered. The formation of the chlorohydrin requires no comment while the unusual reduction is most likely a peculiarity of the α,β -epoxy lactam system.

EXPERIMENTAL

Preparation of Annotinine Lactamdior, $C_{16}H_{21}O_5N$ (III)

Annotinine lactam (2 g.) was refluxed overnight with 40 ml. of 10% sulphuric acid containing a few drops of dioxane to facilitate solution. The dioxane was boiled off, and the solution was cooled, made alkaline with ammonium hydroxide, and extracted four times with chloroform. The combined chloroform extracts were dried over sodium sulphate and then taken to dryness. The residue (1.64 g.) was recrystallized from acetone and melted at $238-239^\circ C$.⁴

Calc. for $C_{16}H_{21}O_5N$: C, 62.54; H, 6.84; N, 4.56%. Found: C, 62.89, 62.78; H, 6.75, 6.82; N, 4.76%.

³We are indebted to the referee for suggesting this mechanism for the formation of compound X.

⁴All melting points are corrected.

The infrared spectrum⁵ (nujol) had two bands in the hydroxyl region at 3530 cm.⁻¹ (sharp) and 3300 cm.⁻¹ (broad), one in the lactone region at 1770 cm.⁻¹, and one in the lactam region at 1620 cm.⁻¹.

Treatment of Annotinine Lactamdiol with Lead Tetraacetate

Annotinine lactamdiol (0.1537 g.) was dissolved in 50 ml. of aldehyde-free glacial acetic acid and mixed with 50 ml. of 0.1472 *N* lead tetraacetate in glacial acetic acid. Aliquots were removed at regular intervals and added to 20 ml. of buffer solution containing 5 g. of potassium iodide and 62.5 g. of sodium acetate per 250 ml. of solution according to the procedure of Hackett and McClenahan (3). The excess iodine was titrated with standard sodium thiosulphate solution. A blank solution was run concurrently. The results are tabulated below.

Time in hours	Mole ratio of Pb(OAc) ₄ consumed
24	0.35
48	0.79
72	1.17
91	1.48
117	1.94
143	2.33
167	2.65
191	2.84
215	3.06
238	3.10

Chromic Acid Oxidation of Annotinine Lactamdiol (III)

A solution of 0.30 g. of annotinine lactamdiol in 5 ml. of glacial acetic acid was warmed to 60° and a solution of chromic acid in glacial acetic acid was added until the yellow color persisted. Excess oxidant was destroyed with methanol and the solution evaporated to dryness under reduced pressure. The residue was dissolved in water, made alkaline with ammonia, and extracted with chloroform. The chloroform extracts were washed with acid, dried over sodium sulphate, and evaporated to dryness. The residue, after several recrystallizations from ether, melted at 197–199° C.

Calc. for C₁₅H₁₇O₄N: C, 65.49; H, 6.23%. Found: C, 65.92, 65.79; H, 6.23, 6.24%.

The infrared spectrum in chloroform solution had three bands in the carbonyl region at 1708 cm.⁻¹, 1760 cm.⁻¹, and 1780 cm.⁻¹ attributed to γ -lactam, 5-membered cyclic ketone, and γ -lactone functions respectively.

The alkaline aqueous solution from the chloroform extraction above was acidified with sulphuric acid and extracted with chloroform. The chloroform extracts were dried over anhydrous sodium sulphate and then evaporated to dryness. The residue, 0.030 g. after recrystallization from ether, melted at 205° C.

Calc. for C₁₅H₁₉O₅N: C, 61.43; H, 6.48; N, 4.77%. Found: C, 61.40, 61.59; H, 6.63, 6.48; N, 4.85, 5.14%.

The infrared spectrum (nujol) had bands at 1610 cm.⁻¹, 1705 cm.⁻¹, and 1775 cm.⁻¹ attributed to amide, carboxylic acid, and γ -lactone functions respectively.

The methyl ester was prepared by treatment of a methanolic solution of the acid with a solution of diazomethane in ether. After several recrystallizations from ether, the ester melted at 122–123° C.

⁵Infrared spectra were determined on a Perkin-Elmer No. 21 recording spectrophotometer.

Calc. for $C_{16}H_{21}O_5N$: C, 62.54; H, 6.84; N, 4.56; OMe, 10.08%. Found: C, 62.45, 62.45; H, 7.22, 6.76; N, 4.41, 4.71; OMe, 10.15%.

The infrared spectrum in nujol showed a double peak at 1653 and 1665 cm^{-1} in the amide region, a peak at 1730 cm^{-1} assigned to the carbomethoxy group, and a peak at 1788 cm^{-1} attributed to the γ -lactone function.

Permanganate Oxidation of Annotinine Lactamdiol

A solution of 0.50 g. of III in 50 ml. of glacial acetic acid was treated with an aqueous solution of potassium permanganate until the pink color was persistent. The excess permanganate was destroyed with methanol and the mixture was evaporated to dryness. The residue suspended in H_2O , was treated with sulphur dioxide to reduce the manganese dioxide. The acidic solution was then exhaustively extracted with chloroform. The chloroform extracts were worked up as in the procedure above to yield the γ -lactam IV (0.1 g.) and the acid VI (0.1 g.). The aqueous solution from the chloroform extraction was continuously extracted with ether to yield a small sample of the sulphate of amino acid VII identified by its melting point and its infrared spectrum.

Hydrolysis of the Acid $C_{15}H_{19}O_5N$ (VI)

The procedure followed was that of Woodward and Brehm (14) for the determination of formic acid from N-formyl derivatives. The acid (0.2158 g.) was refluxed for 2 hours with 20 cc. of 2 N sulphuric acid. The solution was then distilled and water added to keep the volume approximately constant. The distillate was collected in fractions and titrated with 0.1 N sodium hydroxide.

The amount of volatile acid collected corresponded to 0.95 mole per mole of original acid VI. In another run the aqueous distillate gave a positive test for formic acid with mercuric chloride as described in Feigl (2) and also reduced permanganate and bromine.

The aqueous residue after removal of the formic acid was treated alternately with barium hydroxide and sulphuric acid to remove inorganic ions. Evaporation of the solution yielded an amino acid residue which was converted to its methyl ester by diazomethane. The amino acid methyl ester was identical (mixed melting point and infrared spectra) with the methyl ester of amino acid VII prepared from unsaturated lactone A (1).

Reduction of $C_{15}H_{17}O_4N$ (IV) with Sodium Borohydride

A solution of compound IV (0.100 g.) in 10 ml. of ethanol was added slowly with stirring to a solution of sodium borohydride (0.200 g.) in 10 ml. of ethanol at room temperature. The reaction mixture was stirred for 2 hours before decomposing the excess borohydride first with formaldehyde and then with acetic acid until faintly acid. The solution was then evaporated to dryness under reduced pressure. The residue was dissolved in water, made alkaline with ammonia, and extracted with chloroform. The dried chloroform extracts were evaporated to dryness to yield 0.09 g. of residue which, after three recrystallizations from acetone, melted at 254–255° C.

Calc. for $C_{15}H_{19}O_4N$: C, 64.95; H, 6.90%. Found: C, 64.90, 65.19; H, 6.96, 6.86%.

The infrared spectrum in nujol had absorption bands at 3335 cm^{-1} in the hydroxyl region, at 1682 cm^{-1} in the γ -lactam region, and at 1781 cm^{-1} in the lactone region.

Oxidation of Unsaturated Lactone A (VIII) with Barium Permanganate

Unsaturated lactone A (VIII) was prepared by the procedure outlined by Manske and Marion (8). Incidentally, this procedure proved superior to that described by Meier,

Meister, and Marion (9). The compound VIII (1.86 g.) was dissolved in acetone and treated with aqueous barium permanganate solution until the pink color persisted. The excess permanganate was destroyed by warming with methanol. The manganese dioxide was reduced with sulphur dioxide and the organic solvents steam distilled. The solution was then repeatedly extracted with chloroform. The combined extracts were dried and evaporated to dryness to yield 0.7 g. of residue. Upon addition of acetone a crystalline precipitate separated which, after several recrystallizations from acetone, melted at 205° C. The melting point was not depressed on admixture with the acid $C_{15}H_{19}O_5N$ (VI) prepared from the lactamdiol. Their infrared spectra were also identical. Total yield: 0.4 g.

The acetone mother liquors from the separation of VI were freed of acetone, taken up in methanol, and treated with a solution of diazomethane in ether. Concentration of the solution yielded a crystalline ester which, after recrystallization from methanol, melted at 193–195° C. with some decomposition. Yield: 0.070 g.

Calc. for $C_{17}H_{21}O_6N$: C, 60.89; H, 6.27; N, 4.18; OMe, 9.25%. Found: C, 60.90, 61.00; H, 6.77, 6.74; N, 4.11, 4.30; OMe, 9.09, 9.35%.

The infrared spectrum (nujol) had a double peak at 1633 cm^{-1} and 1645 cm^{-1} in the amide region and single peaks at 1710 cm^{-1} , 1743 cm^{-1} , and 1780 cm^{-1} , corresponding to carbonyl, carbomethoxy, and γ -lactone groups respectively.

Continuous ether extraction of the aqueous solution from the chloroform extraction above yielded the sulphate of the amino acid $C_{14}H_{19}O_4N$.

Hydrolysis of the Ester $C_{17}H_{21}O_6N$ (IX)

The ester IX (0.215 g.) was hydrolyzed with 20 ml. 2 *N* sulphuric acid by the procedure described previously for the acid VI. The amount of volatile acid collected corresponded to 1 mole per mole of ester used. The aqueous hydrolytic medium was extracted with chloroform to yield a small residue (0.02 g.) which had an infrared spectrum identical with IV. Recrystallization of the residue from ether yielded a few crystals which did not depress the melting point of compound IV.

Ozonolysis of Unsaturated Lactone A (VIII)

A solution of VIII (0.36 g.) dissolved in 35 ml. of anhydrous ethyl acetate was treated with excess ozone at -30° (the ozone concentration in the oxygen stream was approximately 3.5% and the time of treatment was 45 minutes). Adams' catalyst (0.025 g.) was added to the cold solution, which was immediately placed under hydrogen pressure (10 p.s.i.g.) for 2 hours. The catalyst was then removed by filtration and the filtrate taken to dryness. The residue was taken up in chloroform, washed with aqueous ammonia, and aqueous hydrochloric acid. Evaporation of the chloroform yielded a residue (0.23 g.) which was dissolved in benzene and adsorbed on alumina. Elution with one volume per cent methanol in benzene yielded 0.18 g. of a compound which melted at 174° C. after recrystallization from ether. This compound proved identical (infrared spectrum and mixed melting point) with the compound $C_{16}H_{19}O_3N$ prepared by dehydration of hydroxy annotinine lactam by MacLean and Prime (7).

Treatment of Unsaturated Lactone A (VIII) with Cyanogen Bromide

The lactone VIII was treated with excess cyanogen bromide in anhydrous benzene at room temperature, at 60° C., and at reflux temperature. In each case approximately 80% of the starting material was recovered. The remaining 20% was recovered as a

neutral amorphous precipitate which showed absorption in the infrared at 1770 cm^{-1} in the lactone region and at 1650 cm^{-1} unassigned. There was only very slight absorption in the $\text{N}-\text{C}\equiv\text{N}$ region at 2200 cm^{-1} . Attempts to purify this compound proved unsuccessful.

Hydrogenolysis of Annotinine over Raney Nickel

Annotinine (1.4 g.) was dissolved in 75 ml. of methanol containing 0.3 g. Raney nickel and treated with hydrogen at 150°C . and 2600 p.s.i.g. for a period of 12 hours. The reaction mixture was freed of catalyst, evaporated to dryness, dissolved in chloroform, and adsorbed on a column of alumina. Two products were isolated. The least strongly adsorbed fraction melted at 108°C ., 0.3 g. (22%), and proved identical with the reduction product of VIII (infrared spectrum and mixed melting point). The second product melted after recrystallization from methanol at 205°C . Yield: 0.43 g. (31%).

Calc. for $\text{C}_{16}\text{H}_{23}\text{O}_3\text{N}$: C, 69.30; H, 8.31; N, 5.0%. Found: C, 69.21, 69.11; H, 8.28, 8.31; N, 4.75, 4.70%.

The infrared absorption spectrum showed bands at 3515 cm^{-1} in the hydroxyl region and at 1752 cm^{-1} in the lactone region.

Reduction of Annotinine Lactam in Acid Medium

Annotinine lactam (0.30 g.) was dissolved in 50 ml. methanol and treated with 0.10 g. of Adams' catalyst and three drops of concentrated hydrochloric acid. The mixture was then shaken with hydrogen for 18 hours at 60 p.s.i.g. The catalyst was removed by filtration and the methanol evaporated to dryness. The residue was taken up in fresh methanol from which there separated 0.1 g. of a white crystalline precipitate which melted at 275°C . Recrystallization raised the melting point to 287°C . In admixture with an authentic sample of annotinine lactam chlorohydrin there was no depression in the melting point.

When the mother liquors from the separation of the chlorohydrin above were concentrated almost to dryness and treated with acetone, another compound separated (0.18 g.). After recrystallization from acetone-methanol it melted at $210-211^\circ\text{C}$. This material was very soluble in water and methanol, but insoluble in acetone, ether, and chloroform. It gave a Beilstein halogen test and its behavior indicated that it was a salt. The compound proved to be identical with annotinine hydrochloride hemihydrate (6) by melting point and mixed melting point. On basification with ammonia and ether extraction, annotinine was recovered.

Reduction of Annotinine Lactam in Alkaline Medium

Annotinine lactam (1.0 g.) was dissolved in 100 ml. of methanol, 0.25 g. of Adams' catalyst and a few drops of NH_3 were added, and the mixture subjected to a hydrogen pressure of 56 p.s.i.g. for 24 hours. The catalyst was removed by filtration and the methanol evaporated to dryness. The white residue was taken up in fresh methanol from which a crystalline material separated which melted at $298-300^\circ\text{C}$. alone or in admixture with pure hydroxy annotinine lactam ($\text{C}_{16}\text{H}_{21}\text{O}_4\text{N}$). Further concentration yielded a second crop of impure $\text{C}_{16}\text{H}_{21}\text{O}_4\text{N}$ melting at 298° but sintering at 280°C . A third crop of crystals separated which melted from $210-218^\circ\text{C}$. Fraction 3 was separated by the use of acetone. The acetone-soluble fraction was recrystallized from methanol to yield slightly impure starting material, m.p. $218-222^\circ\text{C}$., alone or in admixture with pure $\text{C}_{16}\text{H}_{19}\text{O}_4\text{N}$. Further recrystallization resulted in the isolation of a pure sample. In all,

0.51 g. of $C_{16}H_{21}O_4N$ was recovered from the reaction while the residue comprised slightly impure starting material.

REARRANGEMENT STUDIES WITH C¹⁴

III. THE FRIEDEL-CRAFTS ALKYLATION OF ANISOLE WITH 2-PHENYLETHYL-1-C¹⁴ CHLORIDE AND 2-PHENYLETHANOL-1-C¹⁴¹

C. C. LEE,² A. G. FORMAN,³ AND A. ROSENTHAL⁴

ABSTRACT

The Friedel-Crafts alkylation of anisole with 2-phenylethyl-1-C¹⁴ chloride and 2-phenylethanol-1-C¹⁴ resulted in a product, *p*-methoxydibenzyl, which showed isotope position rearrangement corresponding to an essentially 50% rearrangement of the C¹⁴ labeled atoms from the C-1 to the C-2 positions in the original chloride and alcohol. If one were to assume that both rearrangement and alkylation involve the same intermediate, these results may be explained on the basis of either an ionic mechanism for the Friedel-Crafts alkylation, the rearrangement being attributed to the formation of the phenylethyl cation, or a displacement mechanism in which the alkylation product is formed from a reaction between anisole and a rearranged polarized complex of aluminum chloride and alkylating agent. The possibility that rearrangement in the Friedel-Crafts alkylation may arise from a process separate from and prior to the alkylation stage itself is also discussed. On this basis, the intermediates involved in the rearrangement and alkylation stages will not necessarily have to be the same.

INTRODUCTION

The observed rearrangements of alkyl groups in Friedel-Crafts alkylation reactions, such as the formation of isopropylbenzene from the reaction of benzene with *n*-propyl chloride in the presence of aluminum chloride, have served as part of the evidence in support of a mechanism for the Friedel-Crafts alkylation involving ionization of the alkyl halide under influence of the catalyst, followed by an electrophilic substitution on the aromatic nucleus by the carbonium ion (9). Where a rearranged product is found, it may be attributed to a rearrangement of the alkyl carbonium ion, often observed in many S_N1 type reactions (16). In a recent study using the tracer technique, Roberts, Ropp, and Neville (12) showed that there is no rearrangement in the Friedel-Crafts ethylation of benzene with ethyl-2-C¹⁴ chloride. The observation was interpreted on the basis that the Friedel-Crafts ethylation of benzene may result from either a displacement mechanism, as suggested by Brown and co-workers (1, 6), which would involve no free ethyl fragments, or a carbonium ion mechanism in which the ions reacted with the aromatic nuclei so rapidly as to exclude internal hydride shifts. The present paper deals with another application of the tracer method in the study of rearrangements in the Friedel-Crafts alkylation. The isotope position rearrangement observed in the alkylation of anisole with 2-phenylethyl-1-C¹⁴ chloride and 2-phenylethanol-1-C¹⁴, as depicted below, is reported.

RESULTS AND DISCUSSION

2-Phenylethanol-1-C¹⁴ was prepared by the lithium aluminum hydride reduction of phenylacetic acid-1-C¹⁴. Conversion of the alcohol to the chloride was effected with thionyl chloride in pyridine (8). That all the C¹⁴ activity was located at the C-1 position was shown by the permanganate oxidation of both the alcohol and the chloride to give nonradioactive benzoic acid.

The alkylation of anisole with either 2-phenylethyl-1-C¹⁴ chloride or 2-phenylethanol-1-C¹⁴ was effected using an excess of anisole as solvent and slightly over one and a half molar equivalents of anhydrous aluminum chloride at 100° C. for several hours. The *p*-methoxydibenzyl obtained was assayed for radioactivity and then oxidized with potassium permanganate to yield anisic acid.

As a check on the total activity, the 2-phenylethyl-1-C¹⁴ chloride was converted to hydrocinnamic acid whose radioactivity was found to be essentially identical with that of the corresponding *p*-methoxydibenzyl. In the alcohol runs, the radioactivity of the phenylurethan of 2-phenylethanol-1-C¹⁴ was also shown to be the same as the corresponding *p*-methoxydibenzyl products.

If there were no rearrangement in the reactions studied, 100% of the total radioactivity in the *p*-methoxydibenzyl should be recovered in the anisic acid. The results from duplicate chloride and alcohol runs are tabulated in Table I, the percentage rearrangement being the difference between 100% and the percentage of total activity actually recovered in the anisic acid.

TABLE I
REARRANGEMENTS IN THE ALKYLATION OF ANISOLE

Alkylating agent	Compound counted*	Observed activity (c.p.m./sample)†		Corrected activity (c.p.m. on molar basis)‡		% activity in anisic acid		% rearrangement	
		Run I	Run II	Run I	Run II	Run I	Run II	Run I	Run II
C ₆ H ₅ CH ₂ C ¹⁴ H ₂ OH	C ₆ H ₅ NHCOOCH ₂ CH ₂ C ₆ H ₅	590		8850

*All compounds were converted to barium carbonate and counted as infinitely thick samples of constant geometry in a windowless gas flow counter.

†All samples were counted for a sufficient length of time to ensure statistical deviation of not more than 1–2%.

‡Corrected for the dilution due to non-labeled C atoms. Equals the observed activity multiplied by the number of C atoms per molecule of the compound counted.

These results clearly indicate that essentially 50% rearrangement has taken place in the alkylation of anisole, in the presence of aluminum chloride, by both 2-phenylethyl-1-C¹⁴ chloride and 2-phenylethanol-1-C¹⁴. Although, under our experimental conditions, the yield of alkylation product was only in the order of 10%, results obtained from radioactivity assay of this product are valid. It is, therefore, a fact that 50% rearrangement has taken place at some stage of the reaction process or processes that led to the formation of the isolated alkylation product, *p*-methoxydibenzyl. Such a complete

*The possibility that the alcohol may undergo prior conversion to the chloride before alkylation is not excluded by the present results.

equilibration of the labeled atoms in the C-1 and C-2 positions of the original chloride and alcohol may best be accounted for by the assumption that the phenylethyl cation is involved, the rearrangement being the result of a 1,2-phenyl shift, or its equivalent, the formation of a phenonium ion (7, 8, 11). These findings, however, do not indicate what exact role such a cation may play in the alkylation step itself in the Friedel-Crafts reaction.

Two possible mechanisms for the Friedel-Crafts alkylation have received considerable current discussion. One of these is an ionic mechanism involving an electrophilic attack on the aromatic ring by a carbonium ion or ion pair (5). The other, believed to be applicable to alkylations with primary halides, postulates a displacement mechanism with the aromatic compound contributing to the breaking of the carbon-halogen bond in the transition state (1, 6). Both of these mechanisms may actually be considered limiting cases of a general process closely related to other types of displacement reactions of alkyl halides (6). In the absence of corroborating kinetic data, isotope position rearrangement alone is not capable of confirming or contradicting mechanisms dealing with the alkylation stage of the Friedel-Crafts reaction. However, if one were to assume that the same intermediate is involved in both rearrangement and alkylation, the present results may be explained on the basis of either an ionic mechanism, the rearrangement being attributed to the formation of the phenylethyl cation, or a displacement mechanism in which the product is formed from a reaction between anisole and a rearranged polarized complex of aluminum chloride and alkylating agent.

The present results may also be accounted for in another way. It is possible that rearrangement observed in the Friedel-Crafts alkylation may arise from a process that is separate from the alkylation stage itself. The finding of Roberts and co-workers (12) that the alkylation of benzene with ethyl-2-C¹⁴ chloride resulted in no rearrangement, while simple contact of the same chloride with aluminum chloride, prior to its use in the alkylation, gave rise to an ethylbenzene with almost 50% rearrangement of the labeled atoms in the ethyl group, appears to indicate that alkylation and rearrangement can be independent of each other. Isotope position rearrangement has also been demonstrated in C¹⁴-labeled *t*-amyl and *t*-butyl chlorides under the influence of aluminum chloride (10), while the rearrangement of *n*-propyl to isopropyl chloride by contact with aluminum chloride has also been reported (15). Moreover, the work of Hart and others (3, 4) has shown that in the alkylation of phenol with optically active 1-phenylethyl chloride, racemization occurred independently of alkylation, an appreciable part of the observed loss of optical purity being due to racemization prior to alkylation.

On the basis that separate processes account for rearrangement and alkylation in Friedel-Crafts alkylation reactions, the 50% rearrangement observed in the present studies may be visualized as resulting from the action of aluminum chloride on 2-phenylethyl-1-C¹⁴ chloride and 2-phenylethanol-1-C¹⁴. The aluminum chloride, being a strong Lewis acid, promotes the formation of the labeled phenylethyl cation, affording an opportunity for the 1,2-phenyl shift. The rate of this catalyst-promoted rearrangement must be faster or at least comparable to the rate of alkylation. The phenylethyl system would thus have the opportunity of attaining complete equilibration before yielding the final alkylation product. According to this picture, a rearranged product obtained in a Friedel-Crafts alkylation may be the result of a reaction between the aromatic reactant and a priorly rearranged alkylating agent. The intermediates involved in the rearrangement stage and the alkylation stage do not, therefore, necessarily have to be the same.

If the observed rearrangement in the phenylethylation of anisole were the result of the action of aluminum chloride, effected prior to the alkylation reaction itself, it should be of interest to study whether any rearrangement would take place when 2-phenylethyl-1-C¹⁴ chloride or 2-phenylethanol-1-C¹⁴ is allowed to come into contact with aluminum chloride. However, preliminary trials showed that no 2-phenylethyl chloride could be recovered after this chloride was treated with aluminum chloride for 1 to 2 hours at 100° C., the temperature used in the phenylethylation. With 2-phenylethanol-1-C¹⁴, some alcohol was recovered after treatment with aluminum chloride at 100° C. for periods of 15 minutes, 2 hours, or 8 hours. Part of the recovered alcohol was converted to the phenylurethan and other portions oxidized to benzoic acid. Radioactivity assays showed rearrangements of only 0.5 to 2.9% as indicated by the activities of the samples of benzoic acid (see Table II). While these results pointed to the fact that the 2-phenyl-

TABLE II
REARRANGEMENT OF 2-PHENYLETHANOL-1-C¹⁴ AFTER CONTACT WITH ALUMINUM CHLORIDE

Contact time	% alcohol recovered	Corrected activity (c.p.m. on molar basis)		
		Phenylurethan of recovered alcohol	Benzoic acid from recovered alcohol	Per cent rearrangement
15 minutes	38.1	6480±90	35±14	0.5
2 hours	28.6	5505±75	119±14	2.2
8 hours	15.5	5550±75	161±16	2.9

ethanol recovered after contact with aluminum chloride has rearranged only to a small extent, they do not necessarily exclude the possibility that the 50% rearrangement observed in the product of phenylethylation of anisole may be due to a process separate from the alkylation stage. Since the amount of 2-phenylethanol recovered after the aluminum chloride treatment was very small, the Friedel-Crafts alkylation product may be derived from that portion of 2-phenylethanol which was not recoverable after contact with aluminum chloride.

EXPERIMENTAL

The preparation of 2-phenylethanol-1-C¹⁴ and 2-phenylethyl-1-C¹⁴ chloride, the oxidation of these compounds to benzoic acid, the conversion of the alcohol to the phenylurethan, and the chloride to hydrocinnamic acid have all been previously reported (7, 8).

Alkylation of Anisole with 2-Phenylethanol-1-C¹⁴

Anisole (130 g., 1.20 moles) was placed in a three-necked 250 ml. flask equipped with stirrer, dropping funnel, and condenser. Aluminum chloride (30 g., 0.23 moles) was added and the mixture stirred until solution was effected. 2-Phenylethanol-1-C¹⁴ (17 g., 0.14 moles) was added and the resulting solution, with vigorous stirring, heated on a boiling water bath for 8 hours. The wine-colored solution was then poured into an ice-hydrochloric acid mixture, the organic layer separated, and the aqueous layer extracted with two 100 ml. portions of ether. The combined organic solutions were next washed with five 100 ml. portions of 5% sodium hydroxide and then with dilute hydrochloric acid. It was followed by washing with dilute sodium bicarbonate solution and water. After the mixture had been dried overnight over anhydrous magnesium sulphate,

the solvents were removed and the residue fractionated *in vacuo*. The product was collected over the range 157–163° C. at a pressure of 6 mm. (lit. (14), b.p. at 8 mm., 166–167° C.). On storage for several days in a refrigerator, the liquid product partially solidified. It was then recrystallized three times from 95% methanol. Yields of recrystallized *p*-methoxydibenzyl for the various runs ranged between 2.82 and 2.96 g. (9.7–10.2%), m.p. 60–61° C. (lit. (2, 14), m.p. 61–62° C. and 60–61° C.).

Alkylation of Anisole with 2-Phenylethyl-1-C¹⁴ Chloride

Anisole (130 g., 1.20 moles) was placed in a three-necked 250 ml. flask equipped with stirrer, dropping funnel, and condenser. Aluminum chloride (30 g., 0.23 moles) was added and the mixture stirred until solution was effected. 2-Phenylethyl-1-C¹⁴ chloride (19.3 g., 0.14 moles) was then introduced and the resulting mixture heated, with continued vigorous stirring, on a boiling water bath for 6 hours. The reaction mixture was hydrolyzed and worked up as described in the alcohol run. Yields of thrice recrystallized *p*-methoxydibenzyl, m.p. 60–61° C., ranged from 9.0 to 9.8%.

Oxidation of p-Methoxydibenzyl

In a two-necked 1000 ml. flask equipped with condenser and stirrer were placed 500 ml. of 3.2% potassium permanganate solution, 3.5 g. of potassium hydroxide, and 2.0 g. of *p*-methoxydibenzyl. The mixture was refluxed, with stirring, for 120 hours. After the mixture was cooled, the manganese dioxide was filtered off and the colorless filtrate was slowly evaporated to about 200 ml. before it was acidified with dilute sulphuric acid. The resulting solution was repeatedly extracted with ether and the combined extracts dried and then evaporated to dryness. The residue was dissolved in dilute sodium hydroxide, washed with ether, and reacidified. Ether extraction of the acidified solution was repeated, followed by the drying and removal of the ether, and two recrystallizations of the resulting residue yielded pure anisic acid, m.p. 183–184° C. (lit. (13), m.p. 184° C.). Yields for the various runs averaged 0.15 g. (10%).

Considerable amounts of amorphous material may be recovered from the mother liquors after the separation of pure anisic acid. However, attempts to isolate crystalline benzoic acid from this amorphous residue were not successful.

Contact of 2-Phenylethanol-1-C¹⁴ with AlCl₃

2-Phenylethanol-1-C¹⁴ (8.4 g., 0.069 moles) was poured onto 15 g. (0.11 moles) of aluminum chloride. A reflux condenser fitted with drying tube was attached and the mixture heated on a boiling water bath. It was then cooled and transferred into an ice – hydrochloric acid mixture, and then repeatedly extracted with ether. The combined extracts were washed with dilute sodium bicarbonate solution and water. After the extracts were dried over anhydrous magnesium sulphate, the ether was removed and the residue distilled at reduced pressure. Half-gram samples of the recovered alcohol were converted to the phenylurethan and to benzoic acid, respectively, by the usual procedures. The weights of alcohol recovered after various lengths of contact time are listed below.

Contact time	Weight of alcohol recovered
15 minutes	3.2 g.
2 hours	2.4 g.
8 hours	1.3 g.

THE INFRARED SPECTRA OF CH₄, CH₃D, CH₂D₂, CD₃H, AND CD₄¹

J. K. WILMSHURST² AND H. J. BERNSTEIN

ABSTRACT

The infrared spectra of all the deuterated methanes of high isotopic purity have been obtained with prism resolution and 27 of the 29 fundamentals were observed. The frequencies observed have been compared with the previous grating and prism data and 'best' values of the fundamentals have been suggested. The present data are considered to give more reliable frequencies for most of the fundamentals of CH₃D, CH₂D₂, and CD₃H than were previously available.

INTRODUCTION

The infrared spectra of CH₄ (2, 4, 5, 6, 8, 9, 11, 17, 23), CH₃D (2, 3, 13), CH₂D₂ (2, 3), CD₃H (2), and CD₄ (2, 18, 24) have been studied previously, but since the data for CH₂D₂ and CD₃H were obtained only under low resolution, and since new synthetic methods (19) have now made the deuterated methanes available in very high purity, it was considered worth while to reinvestigate all spectra.

The present work was also intended as a survey of the infrared spectra of the methanes preliminary to determining infrared band intensities and bond dipole moments.

EXPERIMENTAL

CH₄, CH₃D, CH₂D₂, CD₃H, and CD₄ were obtained in cylinders of 10 liters at N.T.P. from Merck and Co., Montreal, Canada. The spectra were measured with a Perkin-Elmer model 12-C double pass spectrometer equipped with LiF and NaCl optics and are shown in Figs. 1, 2, 3, 4, and 5 respectively. A 10 cm. gas cell with KBr windows was used in all cases. All the methanes were found by mass spectrographic analysis to be better than 98% pure.

EXPERIMENTAL RESULTS

A rotational analysis was not performed for CH₄, CH₃D, and CD₄ since the higher resolution spectra obtained with grating spectrometers have already been analyzed. For CH₂D₂ and CD₃H the resolution available here and the overlapping of different bands did not warrant any rotational analysis. Accordingly then, the frequencies recorded are not necessarily for the true band centers but have been taken at the position of maximum intensity in the bands. This approximation to the band center is probably good for parallel bands, which usually have a very sharp Q branch, but for perpendicular bands, where Coriolis coupling can be quite important, the approximation may be poor.

In Table VII the frequencies of the fundamentals observed in the present investigation are compared with available grating or prism values previously reported and the 'best' value of each fundamental frequency is indicated.

In the following discussion the individual methanes will be treated separately. The numbering of the frequencies is that used by Herzberg (14).

CH₄

Methane belongs to the point group T_d and has one totally symmetric and one doubly-degenerate fundamental, both of which are infrared inactive. The two triply-degenerate

¹Manuscript received November 6, 1956.

²National Research Council Postdoctorate Fellow, 1955.

fundamentals, ν_3 and ν_4 , are infrared active and have been observed at 3020 cm^{-1} and 1301 cm^{-1} respectively in the present investigation. Owing to Coriolis interaction between $\nu_2(e)$ and $\nu_4(f_2)$, the former becomes infrared active and is observed at 1535 cm^{-1} . The observed spectrum is given in Fig. 1.

FIG. 1. The infrared spectrum of gaseous CH_4 in a 10 cm. cell.

The agreement between the fundamentals observed here and the grating values previously reported is good (see Table VII) with the exception of $\nu_4(f_2)$ which appears to be 5 cm^{-1} too low, probably owing to the effect of Coriolis coupling in which case the observed position of maximum intensity is not such a good estimate of the band center.

The observed band centers and their assignments are given in Table I.

TABLE I
OBSERVED INFRARED SPECTRUM OF CH_4

$\nu\text{ (cm}^{-1}\text{)}$	Assignment
1301	$\nu_4(f_2)$
1535	$\nu_2(e)$
2601	$2\nu_2 = 2602(A_1 + E)$
2826	$\nu_2 + \nu_4 = 2836(F_1 + F_2)$
3020	$\nu_3(f_2)$

CH_3D

Monodeuteromethane is a symmetric top belonging to the point group C_{3v} . The three totally symmetric type a_1 vibrations and three doubly-degenerate type e modes are all infrared active. The observed spectrum is given in Fig. 2.

FIG. 2. The infrared spectrum of gaseous CH_3D in a 10 cm. cell.

The rotational constants of CH_3D are calculated (8) as $A = 5.26 \text{ cm}^{-1}$ and $B = 3.89 \text{ cm}^{-1}$ with $r_{\text{CH}} = 1.0925 \text{ \AA}$. The strong Q branch at 2200 cm^{-1} is assigned as the center of $\nu_1(a_1)$, the C—D stretching mode. This band has associated with it P and R branches which exhibit rotational spacings of about 7.7 cm^{-1} which is consistent with the above B value. Another parallel type band exhibiting rotational spacings of about 7.5 cm^{-1} occurs at 1300 cm^{-1} and is assigned to $\nu_{4a}(a_1)$, the CH_3 symmetrical bending mode. The remaining type a_1 vibration $\nu_{3a}(a_1)$, arising from the C—H stretching, is not obvious from any of the band structures, but is considered to be associated with the pair of nearly equal maxima at 2914 and 2973 cm^{-1} owing to Fermi resonance with $2\nu_2 = 2942 \text{ cm}^{-1}$. The corresponding unperturbed position of $\nu_{3a}(a_1)$ is taken as 2945 cm^{-1} .

The three prominent maxima at 3021 , 1471 , and 1155 cm^{-1} are assigned to $\nu_{3b}(e)$, the C—H stretching mode; $\nu_2(e)$, the CH_3 bending mode; and $\nu_{4b}(e)$, the C—D bending mode, respectively.

The frequencies observed here are for the most part in poor agreement with the grating values determined by Ginsburg and Barker (13), being lower in every case, by 1 cm^{-1} at 1155 cm^{-1} , 7 cm^{-1} at 1300 – 1500 cm^{-1} , 5 cm^{-1} at 2200 cm^{-1} , and 10 cm^{-1} at 2900 – 3030 cm^{-1} .

It is felt that the accuracy of the present work is probably superior to that of Ginsburg and Barker, since the recent grating data of Boyd and Thompson (3) give the band center for ν_1 of CH_3D at 2200.03 cm^{-1} in excellent agreement with the value reported here of 2200 cm^{-1} , but in poor agreement with Ginsburg and Barker's value of 2205.25 cm^{-1} . It would appear desirable in view of the discrepancies reported here to re-examine all of the bands of CH_3D under high resolution in order to obtain more accurate band centers.

The assignment for $\nu_{3a}(a_1)$ presented here (Table II) differs from that reported in Herzberg (16). In the previous assignment (13) the high frequency component of the doublet at 2914 and 2973 cm^{-1} was taken as $\nu_{3a}(a_1)$, whereas here this doublet is considered to arise from Fermi resonance between $2\nu_2$ and ν_{3a} , giving an unperturbed value of ν_{3a} around 2945 cm^{-1} . Normal co-ordinate calculations also support this assignment (12, 20, 22).

TABLE II
 OBSERVED INFRARED SPECTRUM OF CH₃D

ν (cm. ⁻¹)	Assignment
1155	$\nu_{4b}(e)$
1300	$\nu_{4a}(a_1)$
1471	$\nu_2(e)$
2200	$\nu_1(a_1)$
2317	$2\nu_{4b} = 2310(A_1 + E)$
2600	$2\nu_{4a} = 2600(A_1)$
2914 } 2973 }	Fermi resonance between $\nu_{3a}(a_1) = 2945$ and $2\nu_2 = 2942(A_1)$
3021	$\nu_{3b}(e)$
3505	$\nu_1 + \nu_{4a} = 3500(A_1)$

CH₂D₂

Dideuteromethane belongs to the point group C_{2v} and has nine nondegenerate vibrations, four of species a_1 , one of a_2 , and two each of b_1 and b_2 . All but the a_2 mode are infrared active. The infrared spectrum is shown in Fig. 3.

The b_1 vibrations give rise to type C bands and the b_2 to type A bands. These have pronounced Q branches. The b_1 and b_2 stretching modes are assigned as 3013 and 2234 cm.⁻¹ respectively, while the b_1 and b_2 rocking motions occur at 1090 and 1234 cm.⁻¹ respectively, the 1090 cm.⁻¹ band being taken, in preference to that at 1033 cm.⁻¹, to give agreement with the Teller Redlich product rule. The totally symmetric vibrations will produce type B bands. From the graphs given by Badger and Zumwalt (1), for band envelopes of B type bands, the spacing of the doublet Q branch should be about 13.4 cm.⁻¹. Three type B bands were observed at 2976, 2202, and 1436 cm.⁻¹, with doublet spacings of 15, 12, and 12 cm.⁻¹ respectively. The first of these bands is assigned to $\nu_{3a}(a_1)$, the C—H stretching mode, the second to $\nu_1(a_1)$, the C—D stretching mode, and the third to $\nu_{2a}(a_1)$, the symmetrical bending mode of the CH₂ group. The remaining type a_1 mode corresponding to the symmetrical bending of the CD₂ group did not have a typical type B structure but was associated with the band at 1033 cm.⁻¹. The weak band observed at 1329 cm.⁻¹, corresponding to a band at 1333 cm.⁻¹ in the Raman spectrum (21), is considered to be $\nu_{2b}(a_2)$ made infrared active by Coriolis coupling. The observed frequencies are given in Table III together with their assignments.

Three bands of CH₂D₂, as an impurity in CH₃D, have previously been observed with a grating instrument by Ginsburg and Barker (13) and again, as in their spectrum of CH₃D, were higher in frequency than those reported here. Some of the other bands of CH₂D₂ have been observed in mixtures of the deuterated methanes under low-resolution (2) and the agreement with our data is reasonably satisfactory considering the overlapping of the bands in the mixtures. One outstanding point of disagreement occurs in the Raman spectrum (21) where ν_1 is placed at 2139 cm.⁻¹, as compared to the present assignment of 2202 cm.⁻¹. Unfortunately no indication of the relative intensity of the Raman bands was reported and it may be that the band at 2180 cm.⁻¹ assigned to $2\nu_{4c}$ is actually ν_1 . However, even here the discrepancy is still large. An investigation of the Raman spectra of all the deuterated methanes is now in progress and it is hoped that this point will be cleared up.

CD₃H

Trideuteromethane, like CH₃D, belongs to the point group C_{3v} . There are three modes of species a_1 and three of species e , all six being infrared active. The observed spectrum is given in Fig. 4.

FIG. 3. The infrared spectrum of gaseous CH_2D_2 in a 10 cm. cell.

~2275	$\nu_{4a} + \nu_{4c} = 2267(B_2)$	3529	$\{ 2\nu_{4c} + \nu_{4b} = 3558(B_1)$
2474	$\nu_{2a} + \nu_{4a} = 2469(A_1)$		$\nu_{4a} + \nu_{4b} + \nu_{2a} = 3559(B_1)$
2559	$\{ 2\nu_{4c} = 2468(A_1)$		
	$\nu_{2b} + \nu_{4c} = 2563(B_1)$		

The rotational constants (7) for CD_3H are $A = 2.63 \text{ cm}^{-1}$ and $B = 3.28 \text{ cm}^{-1}$. The strong Q branch at 2993 cm^{-1} is assigned as the center of $\nu_{3a}(a_1)$, the C—H stretching mode. This band has associated with it P and R branches which exhibit rotational spacings of about 6.5 cm^{-1} , which is consistent with the above B value. The strong Q branch at 2142 cm^{-1} , with rotational spacing in the P branch of about 6.7 cm^{-1} , is assigned as

FIG. 4. The infrared spectrum of gaseous CD_3H in a 10 cm. cell.

the center of $\nu_1(a_1)$, the C—D stretching mode. The remaining type a_1 frequency ν_{4a} is associated with either of the two strong Q branches at 1036 or 1003 cm^{-1} . Without a detailed analysis the rotational spacing here is no guide to the assignment, owing to Coriolis coupling between the two modes, but an application of the Teller Redlich ratio rule (15) to CH_3D and CD_3H favors the assignment of the 1003 cm^{-1} band to $\nu_{4a}(a_1)$. The band at 1036 cm^{-1} is then taken as $\nu_{4b}(e)$, the CD_3 bending mode. The other bending mode, $\nu_2(e)$, is assigned to the perpendicular band at 1291 cm^{-1} .

Assuming the band around 2260 cm^{-1} to have the same structure as that at 1291 cm^{-1} , the center is taken at 2263 cm^{-1} and the band assigned to $\nu_{3b}(e)$, a C—D stretching vibration. The observed frequencies and their assignments are given in Table IV.

TABLE IV
OBSERVED INFRARED SPECTRUM OF CD_3H

ν (cm^{-1})	Assignment
1003	$\nu_{4a}(a_1)$
1036	$\nu_{4b}(e)$
1237?	$\nu_{3b} - \nu_{4b} = 1227(A_1 + A_2 + E)$
1291	$\nu_2(e)$
2062	$2\nu_{4b} = 2072(A_1 + E)$
2142	$\nu_1(a_1)$
2263	$\nu_{3b}(e)$
2332	$\nu_2 + \nu_{4b} = 2327(A_1 + A_2 + E)$
2568	$2\nu_2 = 2582(A_1 + E)$
2993	$\nu_{3a}(a_1)$
~3051	$2\nu_{4b} + \nu_{4a} = 3075(A_1 + E)$
3181	$\nu_1 + \nu_{4b} = 3178(E)$
3283	$\nu_{3b} + \nu_{4b} = 3299(A_1 + A_2 + E)$
3315 } 3327 }	$\nu_2 + \nu_{4a} + \nu_{4b} = 3330(A_1 + A_2 + E)$
3456	$\nu_1 + \nu_2 = 3433(E)?$

CD_3H has previously been investigated only under low resolution in a mixture of the other deuterated methanes (2), and the reported frequencies agree as well as might be expected with those found here.

CD_4

Tetradeuteromethane, like CH_4 , belongs to the point group T_d and has only two infrared active vibrations $\nu_3(f_2) = 2258 \text{ cm}^{-1}$, a C—D stretching mode, and $\nu_4(f_2) = 994 \text{ cm}^{-1}$, the bending mode. As in CH_4 , the vibration $\nu_2(e)$ is made active by Coriolis coupling and occurs at 1098 cm^{-1} . The spectrum is given in Fig. 5.

The agreement between the frequencies reported here and the band centers obtained from a rotational analysis of the grating data is good for $\nu_3(f_2)$ where the Coriolis coupling

FIG. 5. The infrared spectrum of gaseous CD_4 in a 10 cm. cell.

is very small, but is poorer for $\nu_2(e)$ and $\nu_4(f_2)$ where the Coriolis coupling is much larger, the grating values (18) for these two band-centers being 1092 cm^{-1} and 996 cm^{-1} respectively.

The assignment of the three bands at 2940 , 2994 , and 3106 cm^{-1} is not straightforward, but we suggest the possible assignments $3\nu_4$ ($=2982$), $2\nu_4 + \nu_2$ ($=3086$), and $2\nu_2 + \nu_4$ ($=3190$), the high anharmonicity being in keeping with the triple tones and their relatively high intensities.

Kaylor and Nielsen (18) agree with the first of these assignments, but assume the band at 2994 to be due to CD_3H as an impurity, while that at 3106 is assigned to $\nu_1 + \nu_4$ ($=3081$). However, the mass spectrometric analysis of our sample indicated that there was only 0.2% CD_3H present, and it is, therefore, unlikely that this moderately strong band can be explained as an impurity. Again, the assignment of 3106 cm^{-1} to $\nu_1 + \nu_4$ gives a negative anharmonicity and this does not seem likely for a combination tone involving a C—D stretching mode.

*Adopted frequencies were chosen for calculating the ratios and sums.
†Calculated assuming $r_{\text{CH}} = 1.0925$ (see Ref. 15).

CONCLUSION

It may be seen from the spectra that accurate intensity work can be done on only relatively few bands in the five molecules, viz. (1301+1535) and 3020 cm^{-1} in CH_4 ; 2200 cm^{-1} in CH_3D ; 1291 and 2993 in CD_3H ; (994+1098) and 2258 cm^{-1} in CD_4 . Because of this limitation our further interest in the measurement of band intensities has not been pursued.

THE SYNTHESSES AND REACTIONS OF ALKYLATED FURANS¹

WM. H. BROWN² AND GEORGE F WRIGHT³

ABSTRACT

The reaction of 2-chloromercurifuran with *t*-butyl bromide does not yield 2-*t*-butylfuran. Instead 2,5-di-*t*-butylfuran, 2,2,7,7-tetramethyloctane-3,6-dione, and 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan are produced. Air-oxidation of di-*t*-butylfuran yields *trans*-2,2,7,7-tetramethyl-4-octene-3,6-dione (converted to the *cis* isomer photochemically) which forms a dibromide identical with the dibromo substitution product from tetramethyloctanedione. Cold nitric acid oxidation of di-*t*-butylfuran or tetramethyloctanedione yields 4-hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione, but hot nitric acid oxidation of the tetramethyloctanedione yields the expected 2-trimethylacetyl-5-*t*-butylisoxazole. The corresponding oxidation product of *t*-butyltrimethylpentylfuran has not been identified, although it yields 2,2,4,4-tetramethylpentanoic acid, indicative of the isoöctyl substituent, upon hydrolysis. The same acid is obtained by permanganate oxidation of Friedel-Crafts-synthesized 2,5-di-[2,4,4-trimethyl-2-pentyl]furan, a compound which yields *trans*-2,2,4,4,9,9,11,11-octamethyl-6-dodecene-5,8-dione.

Recently alkylfurans have been prepared from furan by Pines and Vesely (13) by use of the boron-trim fluoride-catalyzed reaction with olefins. Earlier Gilman and Wright described the preparation of difurylmethane by reaction of furfuryl chloride with 2-chloromercurifuran (7). At the present time we are reporting the extension of this reaction with chloromercurifuran (I) by use of aliphatic halides.

We have found that *t*-butyl bromide reacts readily with I in chloroform as a medium. The product, however, is not the expected 2-*t*-butylfuran. Instead, 2,5-di-*t*-butylfuran (II), 2,2,7,7-tetramethyloctane-3,6-dione (III), and 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV) have been isolated from the reaction mixture in the ratio of about 3 : 1 : 1. The presence of III as a product can be accounted for by the hydrolysis of II while working up the reaction mixture. The yields are low (30% over-all in a typical run). Much resinous material is formed even when the reaction is carried out at reasonably low temperatures (30–40°).

The structures of II and III have been established by the following reactions: When II is treated with bromine water it is converted to 4,5-dibromo-2,2,7,7-tetramethyloctane-3,6-dione (VI). The same product, VI, is formed when III is treated with bromine water. Authentic III was prepared by the method of Wahlberg (19) involving the decarboxylation of 2,2,7,7-tetramethyl-4-carboxy-3,6-octanedione in ether. Kharasch, McBay, and Urry (10) have also described a method for the preparation of III by the action of diacetyl peroxide on pinacolone. Wahlberg (19) has reported a dioxime of III melting at 265°. It is probably an uncorrected value, since in the present investigation the dioxime was found to melt at 277°.

When 2,5-di-*t*-butylfuran (II) is allowed to stand at room temperature over a period of 1 month, it is oxidized, apparently by atmospheric oxygen, to *trans*-2,2,7,7-tetramethyl-4-octene-3,6-dione (V), a pale yellow solid, m.p. 110–111°. The same compound, V, is also formed, along with 4,5-dichloro-2,2,7,7-tetramethyloctane-3,6-dione, when II is treated with acidified hypochlorite solution. Schenck (14, 15, 16, 17, 18) has investigated the autoxidation of furans extensively. In the case of 2,5-dimethylfuran he obtained *trans*-diacetylene, a pale yellow solid, m.p. 77–78°.

¹Manuscript received November 12, 1956.

Contribution from the Departments of Chemistry, Ontario Agricultural College and University of Toronto.

²Associate Professor of Chemistry, Ontario Agricultural College, Guelph, Ontario.

³Professor of Chemistry, University of Toronto, Toronto, Ontario.

Trans-2,2,7,7-tetramethyl-4-octene-3,6-dione (V) is easily converted to the colorless *cis*-modification, m.p. 46°, by exposure to strong sunlight in acetone or hexanesolution. Similar observations have been made by Martin, Bett, Romans, and Tidridge (12) in the conversion of *trans*-di-*p*-toluylethylene to the *cis*-isomer by irradiation under mercury vapor light (404.7 mμ). In the case of V, absorption is strong in the region 390–410 mμ, while the *cis*-isomer is relatively transparent over the same range. Of interest, also, is the fact that *trans*-V readily forms a dioxime, m.p. 184°, while *cis*-V fails to react with hydroxylamine. *Trans*-V reacts readily with bromine to form 4,5-dibromo-2,2,7,7-tetramethyloctane-3,6-dione (VI).

The presence of 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV) as a product of the reaction between 2-chloromercurifuran (I) and *t*-butyl bromide is surprising but comprehensible. Probably it is formed by an alkylation type of reaction involving two molecules of either *t*-butyl bromide or isobutylene (derived from *t*-butyl bromide) to form diisobutylene (isoöctene), which subsequently alkylates furan.

The synthesis of authentic 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV) was accomplished by alkylating 2-*t*-butylfuran (prepared by the general method of Pines and Vesely (13)) with diisobutylene. Attempts to prepare IV by the alkylation of 2,4,4-trimethyl-2-pentyl-2-furan with isobutylene failed. When IV is treated with bromine water the product is 4,5-dibromo-2,2,7,7,9,9-hexamethyldecane-3,6-dione (VII).

The determination of the molecular weight of VII by the Rast method gave values one-half (206) of that required by theory (412). The same is true for 4,5-dibromo-2,2,7,7-tetramethyloctane-3,6-dione (VI). It has been observed that in both instances decomposition of the bromo compound occurs during the heating period of the molecular weight determination. When the chloro derivative of III (4,5-dichloro-2,2,7,7-tetramethyloctane-3,6-dione) was prepared, values comparable with theory have been obtained for this latter compound.

When [2,4,4-trimethyl-2-pentyl]-2-furan is allowed to stand at room temperature, the original water-white liquid slowly turns yellow and, after 6 weeks, crystals appear. These crystals have been shown to be maleic acid by preparation of the di-*p*-nitrobenzyl ester. Oxidation of 2,4,4-trimethyl-2-pentyl-2-furan with neutral permanganate yields the expected 2,2,4,4-tetramethylpentanoic acid. The authentic acid has been prepared by the method of Whitmore, Wheeler, and Surmatis (20).

During the course of the investigation, 2,5-bis[2,4,4-trimethyl-2-pentyl]furan was also prepared. Unlike 2,5-di-*t*-butylfuran (II), it does not undergo autoxidation readily. However, it is easily oxidized to pale yellow *trans*-2,2,4,4,9,9,11,11-octamethyl-6-dodecene-5,8-dione by the action of dilute nitric acid. A similar reaction has been reported by Lutz and Wilder (11) with compounds such as 2,5-diphenylfuran. In this latter case, however, *cis*-1,2-dibenzoyl-ethylene is formed. When *trans*-octamethyldodecenedione, m.p. 78.5–79.5°, is dissolved in hexane and exposed to strong sunlight, through Pyrex for 12 hours, it is converted to the colorless *cis*-modification, m.p. 55.5–56.5°.

Treatment of 2,5-di-*t*-butylfuran (II) with nitric acid under the conditions employed by Lutz and Wilder (11) yields neither the expected *cis*- nor *trans*-2,2,7,7-tetramethyl-4-octene-3,6-dione (V). Instead, there is obtained 4-hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII) and 4-acetoxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (IX). Treatment of 2,2,7,7-tetramethyloctane-3,6-dione (III) under the same conditions also results in the formation of VIII. When IX is saponified with aqueous sodium hydroxide, VIII is formed. When VIII is treated with acetic anhydride,

IX is the product. The structure for VIII is supported by the fact that it may also be prepared by the addition of nitrous acid to *cis*-2,2,7,7-tetramethyl-4-octene-3,6-dione (V). A similar addition of nitrosyl chloride to *trans*-dibenzoyl ethylene has recently been reported by Beelik and Brown (2).

Alkaline hydrolysis of VIII leads to the formation of ammonia, pivalic acid (trimethylacetic acid), and trimethylpyruvic acid which lends credence to the structure proposed for VIII. Oximation of VIII must occur at the carbonyl function adjacent to the isonitroso function, since the oxime (XI), when steam distilled from alkaline solution, readily loses water and forms the corresponding furazan (XII).

Catalytic hydrogenation of VIII causes the formation of two water-soluble products. In one case, VIII appears to take up 3 moles of hydrogen, while in the other case 1 mole of hydrogen apparently adds. These hydrogenation products have not been investigated further.

When 2,2,7,7-tetramethyloctane-3,6-dione (III) is treated with hot nitric acid, the expected 2-trimethylacetyl-5-*t*-butylisoxazole, XIII, is obtained. Since XIII is a liquid, the oxime, XIV, m.p. 177°, has been prepared, purified, and analyzed. The oxime (XIV) reacts readily with phenylisocyanate and with 2,4-dinitrophenylhydrazine. According to analyses these products seem to be derivatives of XIV rather than of the isomeric 3-*t*-butyl-4-[2-keto-3,3-dimethylbutyl]furazan which might have been expected in consideration of previous work (1, 4).

When 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV) is treated with nitric acid (best diluted with acetic acid) a product ($C_{12}H_{21}NO_3$) is produced. This substance, which forms a derivative ($C_8H_{15}NO_2$)_n upon treatment with hydroxylamine, has not of itself been identified. However it is converted under hydrolytic conditions either with acid or alkali to 2,2,4,4-tetramethylpentanoic acid. The presence of the 2,4,4-trimethyl-2-pentyl substituent in IV is thus established.

We are grateful to DuPont of Canada for generous supplies of furan.

EXPERIMENTAL

All melting points have been corrected against reliable standards. Molecular weights were determined by the Rast method.

2-t-Butylfuran

In a three-necked 250-ml. Grignard-type flask, fitted with a stirrer, reflux condenser, and surrounded by an ice-salt bath at -10°, was placed 68 g. (1.0 mole) of furan (DuPont). To the furan, with stirring, was added 2.5 ml. of boron trifluoride etherate (B&A Code 1471) in 2.5 ml. of anhydrous ether. Into this solution was bubbled 56 g. (2.0 mole) of isobutylene (C. P. Matheson) over a period of 75 minutes. Stirring was continued for another 2 hours at 0°. At the end of this time, the contents of the flask had become dark brown. After 125 ml. of water was added to the flask, the mixture was extracted twice with 100-ml. portions of ether, the ether solution washed with saturated aqueous sodium carbonate solution and then dried over anhydrous calcium chloride. The ether was flashed off leaving a brown liquid as a residue. Fractional distillation through a column as described by Bower and Cook (3) yielded two fractions. The first fraction, a colorless liquid, weighed 3.5 g. (2.8%), b.p. 116-117° at 737 mm.; n_D^{20} 1.4373, n_D^{25} 1.4351, d_4^{20} 0.869.

*2,5-Di-*t*-butylfuran (II)**(a) From 2-Chloromercurifuran (I) and *t*-Butyl Bromide*

A slurry of 121.2 g. (0.4 mole) of 2-chloromercurifuran in 220 ml. of chloroform in a three-necked, round-bottom flask fitted with a stirrer was treated with 5 ml. of 95% ethanol and 137.0 g. (1.0 mole) of *t*-butyl bromide. After it was stirred for 7 minutes, the reaction mixture warmed up to the boiling point of chloroform. The heat reaction subsided after 30 minutes and stirring was continued intermittently for 13 days. It was found that the reaction should be allowed to proceed for a minimum of 4 days. Runs worked up after the initial heat reaction had subsided gave negligible yields. At the end of this time, the dark reddish-brown chloroform solution was filtered from the precipitated mercuric halide, extracted 10 times with 100-ml. portions of water, and then with 100 ml. of 5% aqueous sodium hydroxide solution. The chloroform was flashed off leaving a dark brown oil which was distilled under diminished pressure from a Claisen flask. In this manner, 25.5 g. of faintly yellow oil, b.p. 50–105° (10 mm.), was obtained. Three fractions were obtained from this oil. The first fraction weighed 13.3 g. (18.5%); b.p. 49–53° (5 mm.), 210° (760 mm.); n_D^{20} 1.4376; $d_4^{26.5}$ 0.854; M_D calc., 56.41, found, 56.70. Anal. Calc. for $C_{12}H_{20}O$: C, 79.9; H, 11.1. Found: C, 80.1; H, 11.4.

*(b) From 3-Chloromercurifuran and *t*-Butyl Bromide*

When a slurry of 4.9 g. (0.016 mole) of 3-chloromercurifuran, prepared according to the method of Gilman and Wright (7), in 10 ml. of chloroform and 2 ml. of 95% ethanol, was treated with 5.5 g. (0.040 mole) of *t*-butyl bromide the mercurial dissolved and the resulting solution turned reddish-brown over a period of 3 days. After the reaction mixture had been worked up as previously described two oils were obtained by fractional distillation. The first oil weighed 0.56 g. (19%) and boiled at 40–50° at 1–2 mm.

*(c) From Furan and *t*-Butyl Bromide in the Presence of Mercuric Bromide*

When a mixture of 34 g. (0.5 mole) of furan, and 36 g. (0.1 mole) of mercuric bromide in 100 ml. of chloroform, was treated with 24 g. (0.18 mole) of *t*-butyl bromide no apparent reaction occurred after stirring for 10 minutes. However, when 15 ml. of 95% ethanol was added to the mixture, heat was evolved immediately and the reaction mixture began to darken. The heat reaction was sustained by the dropwise addition of a further 113 g. (0.82 mole) of *t*-butyl bromide over a period of 30 minutes. After an additional 20 minutes, the reaction mixture was worked up as described in part (a), and 3.1 g. (3.5%) of 2,5-di-*t*-butylfuran was obtained.

(d) From Furan and Isobutylene

A second fraction, a colorless liquid, obtained during the preparation of 2-*t*-butylfuran from furan and isobutylene, weighed 3.6 g. (4.0%); b.p. 61–62° at 16–17 mm.; n_D^{20} 1.4369; d_4^{20} 0.837.

All the oils (a, b, c, and d) were shown to be identical, since on treatment with bromine they all yielded the same product, 4,5-dibromo-2,2,7,7-tetramethyloctane-3,6-dione (VI).

*2-*t*-Butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV)**(a) From 2-Chloromercurifuran (I) and *t*-Butyl Bromide*

The second fraction, obtained during the preparation of 2,5-di-*t*-butylfuran from 2-chloromercurifuran and *t*-butyl bromide (see (a) above), weighed 4.2 g. (5.4%); b.p.

98–99° at 10 mm.; n_D^{20} 1.4518; d_4^{20} 0.869. Anal. Calc. for $C_{16}H_{28}O$: C, 81.3; H, 11.9; mol. wt., 236. Found: C, 81.2; H, 11.5; mol. wt., 248.

(b) *From 3-Chloromercurifuran and t-Butyl Bromide*

The second oil from the distillation described in (b) above weighed 0.40 g. (13%) and boiled at 75–85° at 1–2 mm.

(c) *From Furan and t-Butyl Bromide in the Presence of Mercuric Bromide*

From the reaction mixture obtained by treating furan with *t*-butyl bromide in the presence of mercuric bromide, (c) above, there was obtained 0.9 g. (1.3%) of 2-*t*-butyl-5-isoöctylfuran.

(d) *From 2-t-Butylfuran and Diisobutylene*

In a three-necked 50-ml. Grignard-type flask, fitted with a stirrer, reflux condenser, and cooled externally with tap water (13°), were placed 2.3 g. (0.02 mole) of 2-*t*-butylfuran and 0.5 ml. of boron trifluoride etherate (B&A Code 1471) in 0.5 ml. of anhydrous ether. Diisobutylene, 4.4 g. (0.04 mole), was added dropwise, with stirring, over a period of 20 minutes. After the addition was completed, the reaction mixture was allowed to warm up to room temperature and was stirred for 2 hours. After it had been left for another 16 hours the reaction mixture was poured into 25 ml. of water. Additional ether, 10 ml., was added and the ether phase was washed once with 10 ml. of water, then 10 ml. of saturated aqueous sodium carbonate solution. Finally, the ether solution was dried over anhydrous calcium chloride. After the ether was flashed off, the remaining brown oil was distilled, yielding 3.6 g. (76%) of colorless liquid; b.p. 113–115° at 16–17 mm.; n_D^{20} 1.4522; d_4^{20} 0.839.

All the oils (a, b, c, and d) were shown to be identical, since on treatment with bromine they all yielded the same product, VII.

2,2,7,7-Tetramethyloctane-3,6-dione (III)

A third fraction from (a) above weighed 4.5 g. (4.4%); b.p. 106–107° at 10 mm.; m.p. 16.5–18.0°; n_D^{20} 1.4396. Anal. Calc. for $C_{12}H_{22}O_2$: C, 72.7; H, 11.2. Found: C, 72.0; H, 11.1.

2,2,7,7-Tetramethyloctane-3,6-dione Dioxime

To a solution of 1.0 g. (0.014 mole) of hydroxylamine hydrochloride and 1.0 g. (0.007 mole) of sodium acetate trihydrate in 8 ml. of water was added 0.50 g. (0.0025 mole) of III. This mixture was warmed on the steam bath for 15 minutes, sufficient 95% ethanol being added to dissolve the diketone. A white solid separated. The mixture was cooled, 50 ml. of water added, and the white solid filtered off. The crude product weighed 0.49 g. (99%). It was purified by crystallization from glacial acetic acid yielding 0.10 g. (20%) of white plates; m.p. 277° with decomposition. Anal. Calc. for $C_{12}H_{24}N_2O_2$: N, 12.3. Found: N, 12.2.

2,2,7,7-Tetramethyloctane-3,6-dione Mono-2,4-dinitrophenylhydrazone

To a solution of 0.08 g. (0.0004 mole) of 2,4-dinitrophenylhydrazine in 0.5 ml. of 93% sulphuric acid and 2 ml. of ethanol was added a solution of 0.10 g. (0.0005 mole) of III in 3 ml. of 95% ethanol. After the solution had been left at room temperature for 30 minutes, orange needles began to form. After 6 hours, 0.12 g. (79%) of orange needles was filtered off. Crystallization from ethanol–water gave 0.08 g. (53%) of fine orange needles, m.p. 122–123°. Further purification was achieved by passing a chloroform solution of the product through a chromatographic column containing alumina (Merck

#71707). This procedure gave a material melting at 129–130°. Anal. Calc. for $C_{18}H_{26}N_4O_8$: N, 14.8. Found: N, 14.8.

2,2,7,7-Tetramethyloctane-3,6-dione Bis-2,4-dinitrophenylhydrazone

To a solution of 0.36 g. (0.0018 mole) of 2,4-dinitrophenylhydrazine in 1.5 ml. of 93% sulphuric acid and 20 ml. of 95% ethanol was added a solution of 0.20 g. (0.0010 mole) of III in 5 ml. of 95% ethanol. After the solution had been left at room temperature for 20 minutes, yellowish-orange needles began to form. After 1 hour, 0.24 g. (40%) of crude product was filtered off, m.p. 150–165°. Crystallization from 95% ethanol gave 0.10 g. (17%) of orange needles, m.p. 228°. Anal. Calc. for $C_{24}H_{30}N_8O_8$: N, 20.1. Found: N, 19.4.

trans-2,2,7,7-Tetramethyl-4-octene-3,6-dione (V)

A 7-g. sample of 2,5-di-*t*-butylfuran which had been left for 45 days was observed to have formed a crystalline precipitate. The light yellow solid was filtered off. It weighed 0.08 g. and melted at 105–107°. Crystallization from methanol–water gave 0.05 g. of faintly yellow plates, m.p. 110–111°. Anal. Calc. for $C_{12}H_{20}O_2$: C, 73.4; H, 10.3. Found: C, 73.7; H, 10.2.

trans-2,2,7,7-Tetramethyl-4-octene-3,6-dione Dioxime

A solution of 0.10 g. (0.0005 mole) of the unsaturated diketone, V, 0.10 g. (0.0014 mole) of hydroxylamine hydrochloride, and 0.10 ml. of pyridine in 1.5 ml. of 95% ethanol was refluxed for 1.5 hours on the steam bath. At the end of this time, the ethanol was removed in a current of air. A white solid precipitated. After 5 ml. of water had been added to the mixture, the solid material was filtered off and washed free from pyridine on the filter. The crude material weighed 0.10 g. and melted at 156–164° with decomposition. Crystallization from ethanol–water gave 0.04 g. (35%) of purified product melting at 184°. Anal. Calc. for $C_{12}H_{22}N_2O_2$: C, 63.7; H, 9.80; N, 12.4. Found: C, 63.7; H, 10.1; N, 12.3.

cis-2,2,7,7-Tetramethyl-4-octene-3,6-dione (V)

A pale yellow solution of 0.06 g. (0.0003 mole) of *trans*-V in 10 ml. of hexane was placed in a Pyrex flask in bright sunlight for 3 hours. At the end of this time, the solution was colorless. After the hexane was removed in a current of air at room temperature, there remained 0.06 g. (100%) of colorless flat needles, m.p. 44.5–45.0°. Anal. Calc. for $C_{12}H_{20}O_2$: C, 73.4; H, 10.3. Found: C, 74.1; H, 10.3.

4,5-Dibromo-2,2,7,7-Tetramethyloctane-3,6-dione (VI)

(a) *From 2,5-Di-*t*-butylfuran (II)*

To 50 ml. of saturated bromine water was added 0.5 g. (0.0028 mole) of 2,5-di-*t*-butylfuran. After 2 minutes, a white solid began to form, mixed with the oil. The mixture was allowed to stand for 10 hours, at the end of which time 0.41 g. of crude product was obtained. Crystallization from absolute methanol yielded 0.25 g. (25%) of colorless needles (m.p. 117.5°) with a characteristic sweet odor. Anal. Calc. for $C_{12}H_{20}Br_2O_2$: C, 40.5; H, 5.66; Br, 44.9. Found: C, 40.6; H, 5.63; Br, 45.6.

(b) *From 2,2,7,7-Tetramethyloctane-3,6-dione (III)*

In this instance the mixture of bromine water and diketone had to be warmed on the steam bath to promote the reaction. The yield of purified product, m.p. 117.5°, was 4.5%.

(c) From *trans*-2,2,7,7-Tetramethyl-4-octene-3,6-dione (V)

A solution of 0.04 g. (0.0002 mole) of the diketone, V, in 10 ml. of 10% methanol solution of bromine was warmed on the steam bath for 30 minutes, and then allowed to stand overnight at room temperature. Water was then added and a white solid separated. The crude product was purified by crystallization from methanol-water. It weighed 0.04 g. (56%) and melted at 117.5°.

All three products were shown to be identical by mixture melting point.

4,5-Dichloro-2,2,7,7-Tetramethyloctane-3,6-dione

When 3.6 g. (0.02 mole) of 2,5-di-*t*-butylfuran was treated with sodium hypochlorite solution (Javelle water, 7% available chlorine) in excess and the resulting mixture was acidified with hydrochloric acid a pale yellow solid formed in about 3 minutes. Crystallization from methanol gave 0.90 g. (25%) of pale yellow plates, m.p. 110–111°. This compound was shown to be *trans*-III by mixture melting point with an authentic sample.

Further treatment with acidified hypochlorite solution yielded a second solid which, when crystallized from methanol (11.3 ml./g.), gave 1.43 g. (27%) of coarse white needles, m.p. 125–126°. Anal. Calc. for $C_{12}H_{20}Cl_2O_2$: Cl, 26.6; mol. wt., 267. Found: Cl, 26.9; mol. wt., 282.

6,7-Dibromo-2,2,4,4,9,9-hexamethyldecane-5,8-dione (VII)

When 0.5 g. (0.002 mole) of 2-*t*-butyl-5-[2,4,4-trimethyl-2-pentyl]furan, IV, was treated with excess bromine water over a period of 6 days, 0.02 g. (23%) of white needles formed. Crystallization from isopropyl alcohol-water gave 0.010 g. (12%) of white needles, m.p. 80–81°. Anal. Calc. for $C_{16}H_{28}Br_2O_2$: C, 46.6; H, 6.84; Br, 38.8. Found: C, 47.0; H, 6.86, Br, 39.0.

2-Chloromercuri-5-*t*-butylfuran

A solution of 0.50 g. (0.0040 mole) of 2-*t*-butylfuran in 5 ml. of 95% ethanol was added to 24 ml. of mercurating solution as described by Gilman and Wright (7). After the mixture had been left at room temperature with occasional shaking for 48 hours, the resulting light brown solid, 0.52 g., was removed by filtration. Crystallization from ethanol-water gave 0.33 g. (23%) of white stubby needles, m.p. 164–165°. A mixture melting point of the substance with 2-chloromercuri-5-*t*-butylfuran, m.p. 164–165°, prepared according to the method of Gilman and Wright (7) and Gilman and Calloway (6) showed no depression. Gilman and Burtner (5) report the melting point as 174–175°. Although these mercurials were adequate for derivative identification, it seems evident that one of these two reactions must give an abnormal product. Anal. Calc. for $C_8H_{11}ClHgO$: C, 26.7; H, 3.09. Found: C, 26.4; H, 3.10.

[2,4,4-Trimethyl-2-pentyl]-2-furan

In a 500-ml. three-necked round-bottom flask, fitted with a stirrer, reflux condenser, and cooled externally with tap water (12°), was placed 136 g. (2.00 mole) of furan (DuPont). Addition of 5 ml. of boron trifluoride etherate (B&A Code 1471) in 5 ml. of anhydrous ether over a period of 15 minutes caused the formation of a small amount of brown insoluble substance. To this mixture was added 112 g. (1.00 mole) of diisobutylene (Shell Oil Co.) over a period of 25 minutes. Stirring was continued for another 2 hours at 12° and then for an additional 17 hours at 25°. The dark brown mixture was washed three times with 75-ml. portions of water and twice with 50-ml. portions of saturated aqueous sodium carbonate solution, followed by a further two washings

with 75-ml. portions of water. After filtering, a brown liquid, which fluoresced green, was obtained. It was dried over anhydrous calcium chloride. Fractional distillation yielded two products. The first fraction, a colorless liquid, weighed 32 g. (18%) and had b.p. 72–73° at 12–13 mm.; n_D^{20} 1.4567; d_4^{20} 0.877. Anal. Calc. for $C_{12}H_{20}O$: C, 79.9; H, 11.1. Found: C, 80.2; H, 11.2.

2,5-Di-[2,4,4-trimethyl-2-pentyl]furan

A second fraction, a very pale yellow oil, from the preceding distillation, weighed 21 g. (14%). It had b.p. 113–144° at 1–2 mm.; n_D^{20} 1.4651; d_4^{20} 0.866. Anal. Calc. for $C_{20}H_{36}O$: C, 82.1; H, 12.4. Found: C, 82.1; H, 12.2.

Oxidation of [2,4,4-Trimethyl-2-pentyl]-2-furan

(a) *Autoxidation to Yield Maleic Acid*

When pure trimethylpentylfuran was allowed to stand at room temperature, the original colorless liquid took on a yellow color over a period of 6 weeks and colorless crystals (needles) began to deposit. These crystals, after being washed with hexane, had m.p. 141–142°. They were identified as maleic acid both by mixture melting point with authentic maleic acid, prepared by the method of Hurd, Roe, and Williams (9), and also by mixture melting point of the di-*p*-nitrobenzyl ester with authentic di-*p*-nitrobenzyl ester of maleic acid. No success attended our efforts to isolate a second moiety as the result of the autoxidation of the trimethylpentylfuran.

(b) *Permanganate Oxidation to Yield 2,2,4,4-Tetramethylpentanoic Acid*

When 9.0 g. (0.05 mole) of [2,4,4-trimethyl-2-pentyl]-2-furan and 200 ml. of water were placed in a 1-liter, three-necked flask equipped with stirrer and reflux condenser and finely ground potassium permanganate was added over a period of 2 days, 23.8 g. (0.15 mole) of the latter was consumed. During the addition period the flask was heated on a steam bath. After the manganese dioxide had been filtered off, the clear colorless filtrate was acidified with hydrochloric acid whereupon an oil separated. The oil failed to crystallize after chilling to 5° and seeding with authentic 2,2,4,4-tetramethylpentanoic acid prepared by the method of Whitmore, Wheeler, and Surmatis (20). The mixture was extracted with ether (3 times with 75 ml. portions) and the ether solution dried over anhydrous sodium sulphate. After the ether was flashed off there remained 3.5 g. (43%) of a colorless oil. Distillation gave 2.3 g. (29%) of colorless oil, b.p. 82° at 2–3 mm. Preparation of the amide by a conventional method gave thin plates, m.p. 68.0–69.5°. A mixture melting point of the amide with authentic amide of tetramethylpentanoic acid showed no depression.

trans-2,2,4,4,9,9,11,11-Octamethyl-6-dodecene-5,8-dione

When 2.9 g. (0.01 mole) of 2,5-di-[2,4,4-trimethyl-2-pentyl]furan was treated with 20 ml. of 35% nitric acid solution at room temperature a yellow solid formed over a period of 8 days. The crude material weighed 1.7 g. When it was crystallized from 90% methanol (13 ml./g.) 1.3 g. (42%) of pale yellow needles, m.p. 78.5–79.5°, was obtained. Anal. Calc. for $C_{20}H_{36}O_2$: C, 77.8; H, 11.8. Found: C, 77.8; H, 11.9.

cis-2,2,4,4,9,9,11,11-Octamethyl-6-dodecene-5,8-dione

A pale yellow solution of 0.20 g. (0.0006 mole) of the *trans*-isomer in 2 ml. of hexane was irradiated with sunlight through Pyrex for 12 hours over a period of 2 days. When the hexane was removed under diminished pressure there remained 0.20 g. (100%) of white solid, m.p. 53–54°. Crystallization from methanol gave 0.16 g. (80%) of white

crystals, m.p. 55.5–56.5°. Anal. Calc. for $C_{20}H_{36}O_2$: C, 77.8; H, 11.8. Found: C, 77.8; H, 11.9.

4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII)

(a) *From 2,2,7,7-Tetramethyloctane-3,6 dione (III) and Nitric Acid*

When 0.25 g. (0.0013 mole) of III was treated with 6 ml. of 35% nitric acid a precipitate formed within 15 minutes. After the solution had been left for 2 days, 0.38 g. of crude white solid was filtered off. Crystallization from hexane gave 0.14 g. (46%) of white needles, m.p. 162°. Anal. Calc. for $C_{12}H_{21}NO_4$: C, 59.2; H, 8.70; N, 5.75. Found: C, 59.4; H, 8.55; N, 5.35.

(b) *From 2,5-Di-*t*-butylfuran (II) and Nitrous Acid*

To an aqueous solution of nitrous acid, prepared by dissolving 0.5 g. of sodium nitrite in 4 ml. of water and adding excess hydrochloric acid, was added 0.25 g. (0.0014 mole) of 2,5-di-*t*-butylfuran. After the solution was left for 30 minutes a crystalline substance formed. It weighed 0.13 g. Crystallization from petroleum ether (60–70°) gave 0.03 g. (90%) of white needles melting at 162°. The product was identical with that obtained by the action of nitric acid on III.

(c) *From cis-2,2,7,7-Tetramethyl-4-octene-3,6-dione (V) and Nitrous Acid*

A solution of 0.010 g. (0.00005 mole) of *cis*-V in 1 ml. of dioxane and 1 ml. of water was treated with 0.2 g. (0.003 mole) of sodium nitrite and 0.5 ml. of glacial acetic acid. The mixture was allowed to stand for 12 hours. At the end of this time, 4 ml. of water was added. A white solid separated. Crystallization from hexane gave 0.005 g. (41%) of white needles, m.p. 162°.

(d) *From 4-Acetoxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (IX)*

A solution of 0.10 g. (0.00035 mole), of IX in 1 ml. of 5% aqueous sodium hydroxide was prepared by adding the sodium hydroxide solution dropwise to the solid material. In 4 minutes, solution was complete. The solution was slightly yellow in color. After 5 minutes a precipitate appeared. On the addition of 3 ml. of water the precipitate did not dissolve. The solution had a pH of 11 (Hydron Paper). The precipitate was filtered off, washed with water, and dried by suction. It weighed 0.05 g. (59%) and melted at 160–161°. A mixture melting point with authentic VIII was not depressed.

(e) *From 2,5-Di-*t*-butylfuran (II) and Nitric Acid*

A solution of 5.0 g. (0.028 mole) of 2,5-di-*t*-butylfuran in 30 ml. of glacial acetic acid was added slowly to a rapidly stirred solution of 5 ml. of 70% nitric acid in 10 ml. of glacial acetic acid. Heat was evolved and a temperature of 25–30° was maintained throughout the reaction time by means of a water bath. Oxides of nitrogen were evolved during the addition. After 45 minutes a heavy white crystalline precipitate formed and the liquid became lime-green in color. The white solid was filtered off, washed with glacial acetic acid, and dried by suction on the filter. The washings were added to the filtrate, which was set aside to check for further precipitation. The product weighed 1.05 g. (15%) and melted at 162°. Crystallization from ethanol–water, methanol–water, and petroleum ether did not raise the melting point. No further precipitation occurred in the filtrate. After the addition of 150 ml. of water a gummy precipitate, weighing 4.0 g., was obtained. The filtrate from this operation was shown to contain trimethylpyruvic acid. The phenylhydrazone of this acid was prepared according to the procedure of Glucksmann (8), who reported the melting point as 157–158°. We found the melting point to be 166.5°. Anal. Calc. for $C_{12}H_{16}N_2O_2$: N, 12.7. Found: N, 12.6.

Fractional crystallization of the 4.0 g. of crude gummy solid from petroleum ether (60–64°) yielded 0.6 g. (9%) of white needles, m.p. 162°, which were shown to be VIII for an over-all yield of 24%.

4-Acetoxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (IX)

(a) *From 2,5-Di-*t*-butylfuran (II), Nitric Acid, and Glacial Acetic Acid*

From the preceding fractional crystallization, there was also isolated 0.5 g. (6%) of coarse white crystals, m.p. 104–105°. Anal. Calc. for $C_{14}H_{23}NO_5$: C, 58.9; H, 8.18; N, 4.91. Found: C, 59.0; H, 8.12; N, 4.92.

(b) *From 4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII)*

When 0.12 g. (0.0005 mole) of VIII was warmed on the steam bath with 5 ml. of acetic anhydride for 5.5 hours, a pale yellow solution resulted. Addition of 50 ml. of water to this solution caused the separation of a colorless oil which crystallized on standing for 15 hours at room temperature. It weighed 0.05 g. (35%) and melted at 96–103°. Crystallization from hexane gave coarse white needles, m.p. 105°. A mixture melting point with the product obtained in (a) above showed no depression.

4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione Monoxime (XI)

To a solution of 1.0 g. (0.014 mole) of hydroxylamine hydrochloride and 1.0 ml. (0.013 mole) of pyridine in 10 ml. of 95% ethanol was added 0.58 g. (0.0024 mole) of VIII. The resulting solution was refluxed for 2 hours, then the ethanol removed in a current of air and 15 ml. of water added. The resulting white solid was filtered off and dried by suction. The crude product weighed 0.67 g. and melted at 172°. Crystallization from benzene gave 0.40 g. (65%) of white plates melting at 193–194° with decomposition. Anal. Calc. for $C_{12}H_{22}O_4N_2$: C, 55.8; H, 8.59; N, 10.8. Found: C, 55.9; H, 8.36; N, 10.6.

4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione Mono-2,4-dinitrophenylhydrazone

To a solution of 0.16 g. (0.0008 mole) of 2,4-dinitrophenylhydrazine in 1 ml. of 93% sulphuric acid and 3 ml. of 95% ethanol was added a solution of 0.243 g. (0.001 mole) of VIII in 7 ml. of 95% ethanol. The resulting solution was allowed to stand at room temperature for 18 hours. At the end of this time, 75 ml. of water was added to the reaction mixture causing the precipitation of 0.34 g. (100%) of a yellowish-orange solid, m.p. 180–185°. Crystallization from ethanol–water gave 0.22 g. (65%) of coarse orange needles, m.p. 210–211°. Anal. Calc. for $C_{18}H_{26}N_6O_7$: N, 16.6. Found: N, 16.3.

*3-*t*-Butyl-4-[2-keto-1-hydroxy-3,3-dimethylbutyl]furazan (XII)*

To 5 ml. of 5% aqueous sodium hydroxide solution was added 0.24 g. (0.0009 mole) of XI. The solid dissolved readily and in 2 minutes the solution began to turn yellow. The solution was immediately steam distilled and a colorless oil obtained as a distillate. This oil, on standing, crystallized to a white solid which weighed 0.03 g. (14%) and melted at 62°. Crystallization from methanol–water did not raise the melting point. Anal. Calc. for $C_{12}H_{20}N_2O_3$: C, 60.0; H, 8.39; N, 11.7. Found: C, 60.0; H, 8.43; N, 11.3.

The alkaline residue from the steam distillation above yielded a phenylhydrazone which was identified as the phenylhydrazone of trimethylpyruvic acid by mixture melting point with an authentic sample, m.p. 166.5°. This melting point (water–ethanol crystallization) is higher than that (157–158°) previously reported (8).

2,4-Dinitrophenylhydrazone of 3-t-Butyl-4-[2-keto-1-hydroxy-3,3-dimethylbutyl]furan

To a solution of 0.034 g. (0.00017 mole) of 2,4-dinitrophenylhydrazine, in 0.25 ml. of 93% sulphuric acid and 1 ml. of 95% ethanol, was added a solution of 0.05 g. (0.0002 mole) of XII in 2 ml. of 95% ethanol. After the solution was left at room temperature for 6 hours, an orange-colored crystalline solid began to separate. Seven days later 0.07 g. (98%) of orange prisms, m.p. 264–266°, was filtered off. Crystallization from glacial acetic acid gave 0.03 g. (42%) of pure product, m.p. 270–271°, with decomposition. Anal. Calc. for $C_{18}H_{24}N_6O_6$: N, 20.0. Found: N, 20.1.

2,4-Dinitrophenylhydrazone of Trimethylpyruvic Acid

Trimethylpyruvic acid was prepared according to the method of Glucksmann (8). Treatment of an aqueous solution of the acid with an excess of a saturated solution of 2,4-dinitrophenylhydrazine in 2% hydrochloric acid solution readily gave the 2,4-dinitrophenylhydrazone in the form of long canary-yellow needles. When purified by crystallization from ethanol–water it melts at 176.0–176.5°. Anal. Calc. for $C_{12}H_{14}N_4O_6$: N, 18.1. Found: N, 17.5.

Alkaline Hydrolysis of 4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII) to Yield Pivalic Acid (Trimethylacetic Acid) and Trimethylpyruvic Acid

A solution of 1.0 g. (0.004 mole) of VIII in 20 ml. of 5% aqueous sodium hydroxide turned yellow when warmed and ammonia was given off. The solution was acidified with sulphuric acid and steam distilled. A colorless oil was obtained as a product, mixed with water. The mixture was extracted with ether and the ether extract dried over Drierite. After the ether was evaporated, 0.49 g. of faintly yellow liquid remained. A 0.1 g. portion of this liquid was dissolved in 2 ml. of ether and treated with excess ammonia solution. When the solution was evaporated to dryness a white crystalline substance melting at 132° was obtained. Sublimation under diminished pressure (15 mm. Hg) gave a pure product melting at 138°. A mixture melting point with ammonium pivalate (ammonium trimethylacetate) showed no depression.

In another experiment 0.13 g. (0.005 mole) of VIII was dissolved in 5 ml. of 5% aqueous sodium hydroxide and warmed on the steam bath for 1 hour. At the end of this time, the solution was acidified with hydrochloric acid and treated with an excess of a saturated solution of 2,4-dinitrophenylhydrazine in 2% hydrochloric acid solution. A canary-yellow precipitate formed. On crystallization from ethanol–water this substance gave canary-yellow needles melting at 176.0–176.5°. A mixture melting point with the 2,4-dinitrophenylhydrazone of trimethylpyruvic acid showed no depression.

3-Trimethylacetyl-5-t-butylisoxazole (XIII)

When 2.7 g. (0.013 mole) of 2,2,7,7-tetramethyloctane-3,6-dione (III) in 40 ml. of glacial acetic acid was treated with 5 ml. of nitric acid (70%; sp. gr. 1.42) and warmed on the steam bath for 2 hours, oxides of nitrogen were evolved. After the darkening solution had been concentrated to a volume of 20 ml. it was made alkaline by the addition of 10% sodium carbonate solution. A red oil separated which was taken up in ether and dried over anhydrous sodium sulphate. After the ether was flashed off there remained 2.7 g. (99%) of a reddish-brown oil. Distillation gave 1.5 g. (55%) of orange-colored oil, b.p. 90–100° at 2 mm. The compound was converted to its oxime for analysis.

3-Trimethylacetyl-5-t-butylisoxazole Oxime (XIV)

A solution of 1.0 g. (0.0048 mole) of 3-trimethylacetyl-5-t-butylisoxazole (XIII) in 10 ml. of absolute ethanol was treated with 1.39 g. (0.02 mole) of hydroxylamine hydro-

chloride and 1.58 g. (0.02 mole) of pyridine. The mixture was refluxed for 2 hours at the end of which time the alcohol was removed in a current of air. After the addition of water to the mixture, a yellow gummy mass formed. The material was taken into solution in hot hexane and on cooling 0.10 g. of white needles, m.p. 168–170°, with decomposition, was obtained. A second crop weighed 0.22 g., m.p. 146–155. The total yield of crude product was 31%. Subsequent crystallization from hexane and ethanol–water gave 0.10 g. (9.3%) of white needles, m.p. 177° (decomposition with gas formation). Anal. Calc. for $C_{12}H_{20}N_2O_2$: C, 64.2; H, 8.99; N, 12.5; mol. wt., 224. Found: C, 64.1; H, 9.08; N, 12.2; mol. wt., 213.

When 3-trimethylacetyl-5-*t*-butylisoxazole oxime (XIV) was treated with 2,4-dinitrophenylhydrazine, a yellow product, which melted at 184°, was obtained. According to analysis this may be 3-trimethylacetyl-5-*t*-butylisoxazole dinitrophenylhydrazone. Anal. Calc. for $C_{18}H_{23}N_5O_5$: C, 55.5; H, 5.95; N, 18.0. Found: C, 55.5; H, 6.03; N, 18.4.

When 0.10 g. (0.00045 mole) of the isoxazole oxime, XIV, in 2.5 ml. of absolute ether was treated with 0.07 g. (0.0006 mole) of phenylisocyanate for 12 days some N,N'-diphenylurea had precipitated. Decantation of the etherous supernatant layer followed by evaporation left 0.16 g. of white solid which was crystallized from hexane, 0.11 g. (71%), m.p. 121.5–122.5°. This product may be N-[5-*t*-butylisoxazol-3-methanoyl]-N-*t*-butyl-N'-phenylurea. Further crystallization of this substance from ethanol–water gave 0.075 g. (49%), m.p. 123.0–123.8°. Anal. Calc. for $C_{19}H_{25}N_3O_3$: C, 66.4; H, 7.34. Found: C, 67.0; H, 7.38.

Catalytic Hydrogenation of 4-Hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII)

When 1.0 g. (0.004 mole) of VIII in 50 ml. of absolute ethanol was hydrogenated for 44 hours at 50 p.s.i.g., using a total of 0.3 g. of platinum oxide catalyst in 0.1 g. portions, 13 lb. (pressure) of hydrogen was absorbed. (A Parr low-pressure hydrogenation apparatus was used.) The drop in pressure corresponded to 0.013 mole of hydrogen or 3 moles of hydrogen per mole of 4-hydroxy-5-isonitroso-2,2,7,7-tetramethyloctane-3,6-dione (VIII). When the ethanol was removed under diminished pressure there remained 0.94 g. of a thick yellow oil which slowly changed to a gummy solid. Fractional crystallization from water yielded two products.

The first product, clusters of flat rectangles, weighed 0.17 g. (17%), m.p. 136°. Anal. Calc. for $C_{12}H_{27}NO_4$: C, 57.8; H, 10.9; N, 5.62. Found: C, 57.9; H, 10.9; N, 5.66.

The second product, which crystallized in the form of fine white needles, weighed 0.02 g. (1.9%) and melted at 150°. Anal. Calc. for $C_{12}H_{23}NO_4$: C, 58.8; H, 9.45; N, 5.71. Found: C, 58.7; H, 9.58; N, 6.34.

*Action of Nitric Acid on 2-*t*-Butyl-5-[2,4,4-trimethyl-2-pentyl]furan (IV) to Form $C_{12}H_{21}NO_3$*

A solution of 2.3 g. (0.010 mole) of IV in 25 ml. of glacial acetic acid was added dropwise to a stirred solution of 5 ml. of nitric acid (70%; sp. gr. 1.42) in 15 ml. of glacial acetic acid at 23–24°. After 35 minutes, a crystalline precipitate began to form. Stirring was continued for 2 hours. The precipitate was filtered off, washed with glacial acetic acid, and dried by suction. It weighed 0.69 g. (30%) and melted at 175–176°. The filtrate was allowed to stand for 1 hour. No further precipitation occurred. Crystallization of the crude material from ethanol–water gave 0.55 g. (24%) of colorless needles, m.p. 177.5°. Anal. Calc. for $C_{12}H_{21}NO_3$: C, 63.4; H, 9.31; N, 6.16; mol. wt., 227. Found: C, 63.5; H, 9.24; N, 6.24; mol. wt., 236.

The same product resulted when IV was treated with an aqueous solution of nitrous or nitric acid, but the yields were much lower.

When a solution of 0.25 g. (0.0011 mole) of $C_{12}H_{21}NO_3$ in 5 ml. of 95% ethanol was treated with 0.38 g. (0.0055 mole) of hydroxylamine hydrochloride and 0.45 g. (0.0055 mole) of anhydrous sodium acetate a reaction occurred during 36 hours of reflux. Subsequently when water was added 0.03 g. (12%) of original $C_{12}H_{21}NO_3$ was recovered. Further aqueous dilution precipitated 0.16 g. (64 wt. %) which, crystallized from methanol-water, left 0.10 g. (40 wt. %), m.p. 143–144° with gassing. Anal. Calc. for $C_8H_{15}NO_2$: C, 61.1; H, 9.40; N, 8.91; mol. wt., 157. Found: C, 61.5; H, 9.33; N, 8.92; mol. wt., 258.

2,2,4,4-Tetramethylpentanoic Acid from $C_{12}H_{21}NO_3$

(a) Alkaline Hydrolysis

When 0.05 g. (0.00022 mole) of $C_{12}H_{21}NO_3$ was treated with 2 ml. of hot 5% aqueous sodium hydroxide solution the solid slowly dissolved during 20 minutes and ammonia was evolved. The system, cooled and acidified by hydrochloric acid, yielded 0.01 g. (29%), m.p. 40–44°. Crystallization from methanol-water raised this melting point to 44.0–44.5°. A mixture melting point with authentic 2,2,4,4-tetramethylpentanoic acid (20) was not depressed.

(b) Acid Hydrolysis

During 12 hours a system comprising 0.56 g. (0.0025 mole) of $C_{12}H_{21}NO_3$ in 20% hydrochloric acid was boiled under reflux. The resulting yellow oil (0.41 g.) dissolved almost entirely in 5% aqueous sodium hydroxide. The solution, after ether extraction, was acidified to give 0.23 g. (58%) of tetramethylpentanoic acid, m.p. 43.5–44.5°. A mixture melting point was not lowered.

The acidic filtrate, treated with dinitrophenylhydrazine in methanolic hydrochloric acid, yielded a dinitrophenylhydrazone, m.p. 170–172°.

NUCLEAR MAGNETIC RESONANCE MEASUREMENTS OF COMPLEXES OF CHLOROFORM WITH AROMATIC MOLECULES AND OLEFINS¹

L. W. REEVES² AND W. G. SCHNEIDER

ABSTRACT

In order to study the effect of association with π -donors, the proton resonance signal of chloroform in the aromatic solvents benzene, toluene, mesitylene, chlorobenzene, *o*-dichlorobenzene, bromobenzene, nitrobenzene and in the olefinic solvents 1-hexene, cyclohexene, and cyclohexadiene was measured as a function of concentration. The observed shifts of the resonance signal are indicative of specific complex formation. In the aromatic solvents benzene, toluene, and mesitylene, complex formation results in an anomalous shift of the chloroform resonance to high field, which can be attributed to a large induced diamagnetism resulting from the circulation of π -electrons in the aromatic ring. An approximate calculation indicates that the chloroform molecule in the complex is oriented with the hydrogen atom near the six-fold axis above the plane of the aromatic ring and the chlorines directed away from the ring. In nitrobenzene this type of association with chloroform gives way to *n*-donor association with the oxygen atom of the nitro group. This type of association also occurs to some extent in the halogenated benzenes. A small shift of the chloroform signal to low field is observed with the olefinic solvents, which is attributable to weak π -donor association. Analysis of the freezing-point diagrams of the binary systems with chloroform provide further evidence of complex formation.

Molecular complexes between hydrogen chloride and molecules containing π -orbitals such as olefins, acetylenes, and benzene derivatives have been previously reported (5). The composition of the molecular compounds formed in the solid phase was demonstrated by thermal analysis. To account for the binding forces in these complexes it was postulated that weak hydrogen bonds are formed in which the π -orbitals of the unsaturated hydrocarbons function as donors, in contrast to ordinary hydrogen bonds involving lone pair electron donors (*n*-donors). In order to obtain further confirmation of the existence of complexes of this type in solutions of hydrogen chloride in unsaturated hydrocarbons, proton magnetic resonance measurements were undertaken. It was subsequently observed that chloroform behaved similarly to hydrogen chloride both with respect to complex formation with π -donor molecules and with respect to the nature of the chemical shifts derived from proton resonance measurements. Accordingly the greater part of the present work was carried out using chloroform as the acceptor molecule rather than hydrogen chloride. This had the advantage that the measurements could be carried out at room temperature, whereas with hydrogen chloride the measurements must be carried out at low temperatures to avoid excessive pressures.

Nuclear resonance measurements provide a very useful means of studying hydrogen bonding, since it has been demonstrated (1, 11, 12, 4) that the hydrogen involved gives rise to a resonance signal which is shifted to lower field relative to its position in the absence of hydrogen bonding. Thus for example the proton resonance signal of the OH group in ethanol just above its melting point (where almost maximum hydrogen bonding occurs) is shifted to low field by almost five parts per million relative to the signal obtained from a very dilute solution of ethanol in carbon tetrachloride (where complete dissociation is assumed).

EXPERIMENTAL

Chloroform was purified by being shaken with water to remove the alcohol added, then dried and fractionally distilled. Mesitylene was distilled, the portion within $\pm 0.2^\circ$ of the boiling point of 164.7°C . only being selected. The proton resonance in this purified material was identical with the analytical reagent available commercially. All other chemicals used were standard analytical grade.

The magnetic resonance of the proton was detected on the Varian V-4300 NMR Spectrometer, operating at a constant frequency of 40 Mc./s. Chemical shifts were measured by superimposing an audio-frequency, and using the side bands which develop to determine the shift between two signals in cycles per second (1). A standard external reference capillary of water at room temperature was included in each sample. The sample plus reference capillary were contained in a spinning glass sample tube approximately 6 mm. in inside diameter. Chemical shifts were measured to an accuracy of ± 0.5 c./s. except at high dilution. The chemical shifts were corrected at each dilution for bulk diamagnetic susceptibility differences, details of which are given in the appendix.

RESULTS

Preliminary NMR measurements were carried out with solutions of hydrogen chloride in toluene and in mesitylene at low temperatures ($\sim -50^\circ \text{C}$.). The proton resonance of hydrogen chloride in these solutions appeared on the *high* field side of the methyl signals of the hydrocarbons, indicating a shift opposite in direction to that anticipated. However, such a result could arise if the hydrogen chloride itself were sufficiently strongly associated. Addition of toluene or mesitylene would then cause dissociation of the hydrogen chloride as well as the formation of complexes with it, the former process however dominating the shift of the proton resonance, which would be to high field. To test this possibility the temperature dependence of the proton resonance in pure liquid hydrogen chloride was measured. This was found to be rather large and hence indicative of moderately strong association. Further confirmation of association was obtained by dilution of the hydrogen chloride with cyclohexane. Again the proton resonance shift of hydrogen chloride was to high field but the shift was only about half as large as in toluene or mesitylene. Hence after allowing for association of hydrochloric acid with itself there remains a net shift to high field of the hydrogen chloride resonance attributable to complex formation with toluene or mesitylene. The origin of this shift, which is opposite in sign to that encountered with ordinary hydrogen bonding, will be discussed below.

In order to eliminate as far as possible the complication of the acceptor molecule (hydrogen chloride) associating with itself, some experiments were carried out using chloroform as the acceptor molecule. Solutions of chloroform in toluene and mesitylene gave rise to a shift of the resonance signal of the chloroform hydrogen to high field with respect to its position in pure chloroform. The shift was not quite as large as the corresponding shift with hydrogen chloride. However the temperature dependence of the pure chloroform signal, and its shift on dilution with cyclohexane, were much smaller indicating less self-association. Accordingly in subsequent measurements, chloroform was used.

The chemical shifts of the chloroform proton (in cycles per second at 40 Mc./s. corrected for bulk magnetic susceptibility) as a function of concentration of chloroform in mesitylene, toluene, benzene, and cyclohexane are plotted in Fig. 1. The chemical shift of the

FIG. 1. *a.* Mesitylene. *b.* Toluene. *c.* Benzene. *d.* Cyclohexane.

proton signal in each solution is shown relative to pure liquid chloroform. In each solution the shift is to higher field with increasing dilution. It is seen that the total shift of the chloroform proton signal in mesitylene, toluene, and benzene is quite large, indicative of complex formation between chloroform and the aromatic hydrocarbons. The corresponding shift in cyclohexane is considerably smaller, the dilution shift amounting to 11 c./s. Since for the present purpose cyclohexane may be regarded as an inert solvent, this shift is a measure of the self-association of pure liquid chloroform, and although it is smaller in magnitude than that of pure liquid hydrogen chloride, it is by no means negligible. Further confirmation of this association was obtained by observing the temperature dependence of the resonance signal in pure chloroform. This was found to shift by 5 c./s. (relative to a cyclopentane external reference) as the temperature was varied from -52°C. to $+50^{\circ}\text{C.}$ The possibility of specific interactions in pure chloroform has been previously recognized (6).

Since the dilution shift of the chloroform resonance signal due to self-association will occur in all the solutions studied, this must be corrected for in order to obtain a measure of the shift arising from the interaction of chloroform with the aromatic molecules. The correction was made by subtracting from the chloroform proton shift, measured in benzene, toluene, and mesitylene, at each concentration, the corresponding dilution shift of chloroform in the inert solvent cyclohexane. The corrected shifts are shown plotted against concentration in Fig. 2. The total shifts of the chloroform at infinite dilution in the respective solvents are listed in Table I together with the corresponding corrected shifts. Fig. 3 summarizes the chemical shift data of chloroform (corrected for self-association) in a number of other solvents whose molecules might be expected to exhibit π -donor association with chloroform.

Valuable confirmation of specific molecular association and molecular compound formation can be gained from the freezing-point diagram. Employing procedures previously described (5) freezing point diagrams of the binary systems of chloroform with

FIG. 2.

FIG. 3.

each of the aromatic or olefinic solvents were determined. These are shown in Figs. 4, 5, and 6. The melting points of molecular compounds and eutectic temperatures are listed in Table II. Of the three compounds benzene, toluene, and mesitylene, all but benzene show 1 : 1 molecular compounds with chloroform. The high melting point of benzene may obscure a molecular compound in the freezing-point diagram although a molecular compound with benzene is just barely perceptible if the stronger acceptor, hydrogen chloride, is used in place of chloroform (5). None of the other aromatic compounds, chlorobenzene, *o*-dichlorobenzene, bromobenzene, and nitrobenzene, show a molecular compound with chloroform in the freezing-point diagrams. Among the three

olefins 1-hexene, cyclohexene, and cyclohexadiene, only the first gave a molecular compound with chloroform whose composition is 2 : 1 (chloroform to hexene). Absence of a molecular compound in the binary freezing-point diagram does not of course preclude a specific interaction between the components, particularly if such interaction is weak, as it may well be with chloroform. If a stronger acceptor molecule, such as hydrogen chloride, is used in place of chloroform the anticipated molecular compound may appear. This was confirmed in the case of cyclohexene (Fig. 6).

FIG. 5.

DISCUSSION OF RESULTS

It is evident from Fig. 2 and Table I that even after the "dilution shift" of chloroform is allowed for, there is a large net shift of the NMR signal of the chloroform proton in solution in each of the three solvents benzene, toluene, and mesitylene. This shift, which may be termed the "interaction shift", is to higher magnetic field. This is in sharp contrast to the corresponding shift to low field observed in hydrogen bonding involving lone pair donors, as for example in the alcohols, or in chloroform when the latter is associated with acetone or triethylamine (11). A partial explanation of the different behavior of the chloroform proton resonance in the aromatic solvents may be sought in the magnetic behavior of the aromatic molecules themselves. A molecule such as benzene

FIG. 6.

has a large diamagnetic anisotropy. Because of its mobile π electrons, in the presence of a magnetic field, a large diamagnetic circulating current is induced in the plane of the aromatic ring (10, 2). The secondary magnetic field due to this "ring" current is such that it reinforces the applied field at a point outside the ring, but in a plane with the ring, and it opposes the applied field at a point above or below the plane of the ring. Accordingly a proton which finds itself in the latter position will have its nuclear magnetic resonance signal displaced to higher field (if the resonance frequency is maintained constant).

It seems very likely therefore that the aromatic "ring" diamagnetism can account for the chloroform proton resonance shift to high field in the aromatic solvents. This implies a specific interaction with the aromatic molecules such that the chloroform hydrogen is preferentially located above or below the plane of the aromatic ring, since if the mutual orientation of the two kinds of molecules were completely random the field enhancement due to the ring current would be considerably smaller. The above preferred orientation is just that to be expected if the chloroform hydrogen interacts with the donor π electrons of the benzene ring. If the chloroform interaction shifts in benzene, toluene, and mesitylene, which amount to an average value of 55 c./s., are interpreted in this manner, this result can then be utilized to obtain a rough measure of

the distance of the chloroform proton from the plane of the aromatic ring in the molecular complex.

In the calculation it is assumed that in the molecular complex the hydrogen atom of the chloroform is above the plane of the aromatic ring in the vicinity of the six-fold symmetry axis. The molecular axis of the chloroform molecule could be parallel with the latter axis, although this is not a necessary assumption. Considering the aromatic ring as a circular loop of radius, a , equal to $1.4 \text{ \AA}$, the current induced by an applied magnetic field, H_0 , is given by (see Ref. 10)

$$[1] \quad i = 3e^2 H_0 / 2\pi m c$$

where e and m are the electronic charge and mass, and c is the velocity of light. The small field H on the axis of a circular coil of radius a at the point P (as shown in the diagram) is given by

$$[2] \quad \Delta H = 2\pi i a^2 / r^3.$$

Substituting for the ring current, i , from eq. [1] gives

$$[3] \quad \Delta H / H = 3e^2 a^2 / m c^2 r^3 = \delta,$$

which gives the chemical shift, δ , of a proton at P , expressed in dimensionless units (p.p.m.). Averaging over all orientations of the molecule in the field introduces a factor of $\overline{\cos^2 \theta} = 1/3$, so we have finally for the enhanced chemical shift,

$$[4] \quad \delta = e^2 a^2 / m c^2 r^3.$$

Taking the chemical shift due to the ring current as 55 c./s. (see above) or 1.37 p.p.m., the value of $3.43 \text{ \AA}$ is obtained for r . The distance OP , which is the average distance of the chloroform proton from the plane of the ring, is then found to be $3.1 \text{ \AA}$. The above calculation is rather approximate, and this figure is perhaps slightly high,* but it supports the general interpretation that the interaction of the aromatic ring is directly

*The assumption that the chloroform proton is on the six-fold axis of the benzene ring may not be justified. Any displacement from this position parallel to the plane of the ring would give a smaller calculated distance.

with the chloroform hydrogen. An alternative mutual orientation of the two molecules where the chloroform molecular axis is also parallel with the six-fold axis of benzene, but with the three chlorine atoms instead of the hydrogen atom situated adjacent to the aromatic ring, appears to be ruled out by the above calculation.

Similar conclusions to the above have also been arrived at independently by Bothner-By and Glick (3), who carried out a detailed study of the effect of volume susceptibility on the proton resonance of certain aliphatic compounds dissolved in aromatic solvents. The latter were found to have an anomalous volume susceptibility due to the induced "ring" diamagnetism, shifting the proton signal on the average by approximately 25 c./s. (no correction was attempted for the "dilution shift" of the aliphatic solute). The shift of the chloroform signal in benzene and toluene was found to be considerably larger than this and was attributed to specific complex formation whereby the chloroform hydrogen is preferentially oriented normal to the plane of the aromatic ring.

Molecular complex formation between chloroform and mesitylene or toluene is confirmed by the freezing-point diagrams (Fig. 4). The nature of the forces involved in the complex is not clear. It has previously been suggested (5) that the complexes formed between π -donor molecules and hydrogen chloride may involve a weak hydrogen bond. Chloroform may be expected to behave similarly with π -donor molecules. Recent infrared measurements by Huggins and Pimentel (8) lend further support to this conclusion. It was found that the intensity of the C—D stretching frequency of chloroform-*d* in various solvents, including benzene and mesitylene, was considerably enhanced, indicating complex formation analogous to hydrogen bonding. Frequency shifts were small or absent.

The above explanation implies that the interaction is primarily electrostatic in nature or arises from strong polarization forces. Charge transfer forces (9) may provide a possible alternative mode of interaction. In this connection the ultraviolet absorption spectra of solutions of chloroform in mesitylene and of hydrogen chloride in mesitylene were measured.* No absorption resembling a charge transfer spectrum could be found in the near ultraviolet (to 2300 Å), nor was there any noticeable shift of the mesitylene absorption. Consequently the question of whether charge transfer forces are involved or whether the interaction is primarily of electrostatic origin cannot be definitely answered.

The shift of the chloroform hydrogen in solution in the aromatic solvents chlorobenzene, *o*-dichlorobenzene, bromobenzene, and nitrobenzene involves further considerations. It is known that the introduction of electron-withdrawing substituents reduces the π -donor capacity of the aromatic ring. However the induced "ring" diamagnetism should still be operative. From the work of Bothner-By and Glick (3) this should give rise to a maximum shift to high field of about 25 c./s. for the chloroform proton, assuming no specific complex formation. From Table I and Fig. 3 it is seen that only chlorobenzene approaches this expectation; the maximum shifts in *o*-dichlorobenzene and bromobenzene are smaller and in nitrobenzene it is very nearly zero. This can only be accounted for by assuming another type of association with chloroform in which the halogen atoms or the nitro-group of the solvent molecules act as n -donors for the chloroform hydrogen. The halogen substituents may be expected to be rather weak donors; the oxygen atom of the nitro group should be a much stronger donor. We thus have two possible modes of association, as shown schematically in the following diagram:

*We are greatly indebted to Dr. Jan Kommandeur for carrying out these measurements.

The NMR measurements are then consistent with the conclusion that in the solvents benzene, toluene, and mesitylene, only complexes of type I (π -donor association) occur. In the solvents chlorobenzene, *o*-dichlorobenzene, bromobenzene, and nitrobenzene complexes of both types I and II may occur although in nitrobenzene type II (n -donor association) predominates. Possibly because of the high melting point of nitrobenzene, a 1 : 1 molecular compound in the freezing point diagram may be obscured (see Fig. 5).

The interaction shift of chloroform in the olefinic solvents 1-hexene, cyclohexene, and cyclohexadiene is small and to lower field (relative to pure liquid chloroform). Here the anomalous "ring" diamagnetism is absent and hence the observed shift may be regarded as characteristic of chloroform association with an olefinic π -bond. This type of association may be expected to be considerably weaker than, say, the n -donor association of chloroform in acetone. The chloroform shift (interaction shift) in acetone was observed to be 30.9* c./s. (11), which is to be compared with an average value of 7 c./s. in the olefinic solvents employed in the present measurements. The freezing-point diagrams (e.g. cyclohexene, Fig. 6) would suggest that with a stronger acceptor molecule such as hydrogen chloride, the NMR shift of the interacting hydrogen may be considerably larger.

ACKNOWLEDGMENTS

We wish to acknowledge the assistance of Mr. Yves Lupien in carrying out the freezing point measurements in these systems.

APPENDIX

In the present work a small sealed capillary containing water was added to the chloroform solutions being measured. This served as an external reference signal, from which the separation (in cycles per second) of the resonance signal of the chloroform proton was measured. A similar measurement was carried out for pure liquid chloroform, which gave an observed shift of 103 c./s. or 2.58 parts per million relative to the water reference signal which appears at higher field. In order to compare the observed shifts of the chloroform signal in the various solutions measured, a correction for the bulk magnetic susceptibility of the solutions is required. If δ'_{CHCl_3} and δ'_s are respectively the observed shift of pure chloroform, and of chloroform in a solution, both measured relative to water (in p.p.m.), the corrected shifts are given by (see Ref. 7)

$$[1] \quad \delta_{\text{CHCl}_3} = \delta'_{\text{CHCl}_3} + \frac{2}{3}\pi(\chi_{\text{CHCl}_3} - \chi_{\text{H}_2\text{O}}),$$

$$[2] \quad \delta_s = \delta'_s + \frac{2}{3}\pi(\chi_s - \chi_{\text{H}_2\text{O}}),$$

*The infinite dilution shift of 11.5 c./s. in cyclohexane has been added to the value 20.4 c./s., quoted in the paper of Pimentel, Shoolery, and Huggins, to allow for self-association of chloroform itself.

where $\chi_{\text{H}_2\text{O}}$, χ_{CHCl_3} , and χ_s are respectively the volume susceptibilities of water, chloroform, and the chloroform solution. The latter was assumed to be additive in the volume fraction of the two components of the binary solution, i.e., $\chi_s = v_1\chi_1 + v_2\chi_2$ where v_1 and v_2 are volume fractions.

If the measurements are carried out at a fixed resonance frequency of 40 Mc./s., as in the present work, equations [1] and [2] can be conveniently expressed in terms of frequency units (cycles per second):

$$[1'] \quad \Delta\nu_{\text{CHCl}_3} = \Delta\nu'_{\text{CHCl}_3} + 83.8(\chi_{\text{CHCl}_3} - \chi_{\text{H}_2\text{O}}) \times 10^6,$$

$$[2'] \quad \Delta\nu_s = \Delta\nu'_s + 83.8(\chi_s - \chi_{\text{H}_2\text{O}}) \times 10^6.$$

It was convenient in the present work to refer the chloroform proton signal measured in the various solutions in terms of a net shift relative to the proton signal in pure liquid chloroform. This is obtained simply as the difference of equations [1] and [2] or [1'] and [2'].

Values of the volume susceptibilities were derived largely from the mass susceptibility values given in the International Critical Tables and the Landolt-Bornstein Tables. Since fairly large discrepancies appeared for some compounds, the values used for the present corrections are listed in the following table.

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES

III. O - α -D-MANNOPYRANOSYL-(1 $\rightarrow$ 2)- O - α -D-MANNOPYRANOSYL-(1 $\rightarrow$ 2)-D-MANNOSE¹

P. A. J. GORIN² AND A. S. PERLIN

ABSTRACT

A trisaccharide obtained after acetolysis of *Saccharomyces rouxii* mannan is shown to be O - α -D-mannopyranosyl-(1 $\rightarrow$ 2)- O - α -D-mannopyranosyl-(1 $\rightarrow$ 2)-D-mannose. Methylation and lead tetraacetate oxidation techniques define the positions of the glycosidic linkages. The configurations of the two linkages are determined through use of two novel degradative methods which yield 2- O - α -D-mannopyranosyl-D-mannose and 2- O - α -D-mannopyranosyl-glycerol, each containing one of the glycosidic linkages of the parent trisaccharide.

An earlier paper (7) described a mannan which was isolated from a fermenting culture of *Saccharomyces rouxii* (15). Two oligosaccharides were obtained after acetolysis of the polysaccharide, one of which was found to be 2- O - α -D-mannopyranosyl-D-mannose and the other an amorphous trisaccharide composed of D-mannose units. The latter is now shown to be O - α -D-mannopyranosyl-(1 $\rightarrow$ 2)- O - α -D-mannopyranosyl-(1 $\rightarrow$ 2)-D-mannose (I).

Methylation of the trisaccharide and hydrolysis of the methylated product yielded two parts of crystalline 3,4,6-tri- O -methyl-D-mannose (2), and one part of 2,3,4,6-tetra- O -methyl-D-mannose, characterized as the corresponding D-mannonic acid phenylhydrazide (5). The positions of both glycosidic linkages of the trisaccharide are therefore 1,2-.

The compound consumed lead tetraacetate only slowly, and in the potassiumacetate-catalyzed oxidation the trisaccharide and the corresponding triitol each yielded one mole of formaldehyde, in agreement with the formulation of a 1,2-linkage at the reducing end (4). Further, the central D-mannose unit in the triitol consumed 1 mole of lead tetraacetate, as expected for a 1,2- (or 1,4-) linkage, but its rate of oxidation was slow relative to the oxidative attack at the end-units. It has been noted elsewhere (14) that in the glucose and xylose series a *trans*-2,3-diol adjacent to a 1,4-glycosidic linkage is not oxidized by lead tetraacetate. The current results demonstrate a resistance to oxidation also by a *trans*-3,4-diol in a mannose residue adjacent to a 1,2- α -mannosidic linkage.

To determine the configurations of the two glycosidic linkages it was proposed to chemically degrade the trisaccharide and obtain two disaccharides, each containing one of the glycosidic linkages of the parent compound. This approach has been successfully employed, for example, by Wolfrom *et al.* (16) who obtained maltitol and isomaltose by partial hydrolysis of reduced panose, and more recently by Kuhn *et al.* (11), for a trisaccharide from human milk. In the present study, selective degradation of the mannotriose was achieved by the use of novel methods which permitted preferential removal either of the non-reducing end-unit or of the reducing end-unit.

The non-reducing end-unit was removed in the following way. The mannotriose (I) was first reduced with sodium borohydride (17) to an amorphous mannotriitol (II)

characterized as its duodecabenzoate. This was then treated with 3 moles of lead tetraacetate, and the oxidation product reduced with sodium borohydride to give an amorphous mannosyl-glycerol (III), which yielded a solid nona-*p*-nitrobenzoate. These steps are analogous to the stepwise degradation of 2-*O*- α -D-mannopyranosyl-D-mannose (3). The mannosyl-glycerol (III) was then oxidized with two moles of lead tetraacetate which, in agreement with the results noted above, preferentially attacked the terminal D-mannose unit and produced the dialdehyde (IV). Treatment of this product with phenylhydrazine acetate according to the method of Barry (1) afforded 2-*O*- α -D-mannopyranosyl-glycerol (V) (3) characterized as its hexa-*p*-nitrobenzoate derivative. The 1,2-glycosidic linkage between the central residue and the reducing end-unit was thus found to possess the α -configuration.

Partial hydrolysis of oligosaccharide osazones has been suggested as a possible means for preferential removal of reducing end-units (6). However, this method was not applicable to the mannotriose, which cannot form an osazone. An alternative method for the reducing end-unit was therefore developed. The trisaccharide was oxidized with bromine water in the presence of calcium benzoate (10) to the mannosyl-mannonic acid isolated as the silver salt (VI), which in turn was oxidized with 3 moles of lead tetraacetate to give presumably a salt of *O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-*O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-L-glycerotriuronic acid (VII). Treatment of the latter with hot dilute acetic acid readily hydrolyzed off the tartronic semialdehyde residue, affording 2-*O*- α -D-mannopyranosyl-D-mannose (VIII), characterized by reduction with sodium borohydride to crystalline 2-*O*- α -D-mannopyranosyl-D-mannitol (7). It was evident, therefore, that the glycosidic linkage between the non-reducing end-unit and the central residue of the trisaccharide also possesses the α -configuration.

As previously noted (7), the disaccharide, 2-*O*- α -D-mannopyranosyl-D-mannose, represents 10% of the polysaccharide, and the present trisaccharide, 25%. The high

total yield obtained of these two compounds shows that the 1,2-glycosidic linkages in the polymer have predominantly, if not entirely, the α -configuration. The configuration of the 1,6-linkage, the other major type present, is yet to be determined.

EXPERIMENTAL

Evaporations were carried out under reduced pressure at 40° C. Optical rotations were measured at 27° C. All melting points are uncorrected. Paper chromatograms were developed using Whatman No. 1 filter paper, *n*-butanol-ethanol-water (40:11:19 v/v) as solvent, and *p*-anisidine hydrochloride (9) and ammoniacal silver nitrate (12) as spray reagents.

Positions of Linkage in the Trisaccharide

The mannotriose (298 mg.) ($[\alpha]_D +55^\circ$, c , 1.5, water) was methylated six times with aqueous sodium hydroxide-methyl sulphate. After destruction of excess methyl sulphate the aqueous solution was neutralized using acetic acid and then extracted continuously with chloroform. The extract was dried over magnesium sulphate, filtered, and evaporated to a sirup (301 mg.) which was distilled rapidly at 1 mm. pressure. The product (181 mg.) was heated at 100° C. for 18 hours in 90% formic acid (5 ml.). The hydrolyzate was then concentrated to a sirup which was dissolved in water and heated at 100° C. for 30 minutes, the procedure being repeated three times.

The mixture of *O*-methyl sugars, which on paper chromatographic examination was shown to contain no di-*O*-methyl mannose, was fractionated on a cellulose column (8). Benzene-ethanol-water (10:1:trace, v/v) eluted the tetra-*O*-methyl component (53 mg.), $[\alpha]_D +25^\circ$ (c , 1.7, methanol). Oxidation of this sugar by bromine water, followed by lactonization and treatment of the lactone with an equivalent of phenylhydrazine in refluxing ethanol, yielded, after three recrystallizations from benzene, 2,3,4,6-tetra-*O*-methyl-D-mannonic acid phenylhydrazide. The substance had m.p. and mixed m.p. 180°-181° C. and gave an X-ray diffraction pattern identical with that of an authentic specimen. Calculated for $C_{16}H_{26}O_6N_2$: $-\text{OCH}_3$, 36.2%. Found: $-\text{OCH}_3$, 35.8%.

The tri-*O*-methyl fraction was eluted by benzene-ethanol-water (7:1:trace, v/v) and crystallized on evaporation of the solvent; yield, 97 mg. After recrystallization twice from ether the product (51 mg.) had m.p. 95°-99° C. undepressed on admixture with authentic 3,4,6-tri-*O*-methyl-D-mannose and $[\alpha]_D +20^\circ \rightarrow +7^\circ$ (constant value; c , 1.15, water). The infrared spectrum of the product was identical with that of the known material. Calculated for $C_9H_{18}O_6$: C, 48.64%; H, 8.16%. Found: C, 48.92%; H, 8.11%. Only 18 mg. of the product could not be induced to crystallize.

A sample of the trisaccharide was treated with excess lead tetraacetate in acetic acid. The consumption of reagent, moles per mole, after 5, 31, and 55 minutes was 0.03, 0.27, and 0.42, respectively. In 90% acetic acid and in the presence of potassium acetate, lead tetraacetate oxidation (13) liberated 1.0 mole of formaldehyde per mole in 1 hour's reaction time.

O- α -D-Mannopyranosyl-(1 $\rightarrow$ 2)-*O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-D-mannitol

The mannotriose (683 mg.) was treated with sodium borohydride (200 mg.) in water (20 ml.) for 18 hours. The solution was acidified with acetic acid, treated with Amberlite IR-120, and then concentrated to a solid. The latter was dissolved in methanol, which was evaporated off. This process was repeated three times to give the amorphous manntriitol (674 mg.) which had $[\alpha]_D +49^\circ$ (c , 0.8, water). On oxidation of the manntriitol with

lead tetraacetate in 90% acetic acid containing potassium acetate the production of formic acid was constant in 40 minutes' reaction time at 2.3 moles per mole; the consumption of lead tetraacetate was 5.0 moles per mole. These values corresponded to oxidation of the two end-units, which would require 2.6 moles of formic acid (13) and 5.0 moles of lead tetraacetate per mole. During the next 1.5 hours the consumption of oxidant increased to 5.7 moles per mole, and a further 1 hour's reaction time raised the value to 5.8 moles per mole. This slow oxidation without further production of formic acid was interpreted as involving the central D-mannose unit. The yield of formaldehyde was 0.9 moles per mole (requires 1.0 mole per mole).

The mannotriitol (30 mg.) was benzoylated in a mixture of pyridine (0.20 ml.), benzoyl chloride (0.13 ml.), and chloroform (0.30 ml.). After 3 hours at room temperature the sugar had dissolved and the reaction mixture was added to chloroform, which was washed with 0.1 *N* sulphuric acid, aqueous sodium bicarbonate, and water successively, dried over magnesium sulphate, filtered, and evaporated to a white solid. The duodecabenzoate was purified by two precipitations from methanol. Yield 53 mg., m.p. 96°–98° C., and $[\alpha]_D -4^\circ$ (*c*, 0.8, chloroform). Calculated for $C_{102}H_{81}O_{28}$: C, 69.36%; H, 4.65%. Found: C, 69.81%; H, 4.65%.

O- α -D-Mannopyranosyl-(1 $\rightarrow$ 2)-*O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-glycerol

The mannotriitol (516 mg.) was dissolved in water (2 ml.), acetic acid (200 ml.) added, and the mixture treated with lead tetraacetate (1.35 g., 3.0 molar equivalents). After 18 hours lead was precipitated as lead oxalate by the addition of oxalic acid and the solution was filtered. The filtrate was evaporated to dryness and the residue was dissolved in water (50 ml.) containing sodium borohydride (500 mg.). After 1 hour the reaction mixture was worked up as described above. The amorphous mannobiosyl-glycerol thus formed (294 mg.) had $[\alpha]_D +49^\circ$ (*c*, 1.4, water) and acid hydrolysis of the material gave mannose and glycerol which were detected on a paper chromatogram.

The glycerol derivative (45 mg.) was heated at 80° C. for 30 minutes in pyridine (1.7 ml.) containing *p*-nitrobenzoyl chloride (280 mg.). The precipitate which formed on addition of the reaction mixture to aqueous sodium bicarbonate was filtered off after 30 minutes and reprecipitated from acetone-ethanol. The amorphous white nona-*p*-nitrobenzoate (60 mg.) had m.p. 128°–131° C. and $[\alpha]_D -3^\circ$ (*c*, 0.8, chloroform). Calculated for $C_{78}H_{55}O_{40}N_9$: C, 53.29%; H, 3.15%. Found: C, 53.03%; H, 3.20%.

The mannobiosyl-glycerol was oxidized with lead tetraacetate in acetic acid containing a trace of water. The reaction was very slow, only 0.16 and 0.90 mole per mole being consumed after 2 and 20 hours respectively.

2-*O*- α -D-Mannopyranosyl-glycerol

Mannobiosyl-glycerol was oxidized with lead tetraacetate under the conditions mentioned immediately above except that the proportion of water in the reaction mixture was increased.

The sugar (248 mg.) was dissolved in water (1 ml.) and made up to 50 ml. with acetic acid to which lead tetraacetate (560 mg.; 2.1 molar equivalents) was added. After 18 hours all of the reagent had been consumed and 10% oxalic acid in acetic acid (1.3 ml.) was added. The precipitate which formed was filtered off and the filtrate evaporated to dryness. The residue was dissolved in water (25 ml.) containing phenylhydrazine (1 ml.) and acetic acid (1 ml.) and the solution heated at 100° C. for 30 minutes. The mixture was evaporated to a sirup, which was dissolved in aqueous ammonia. The solution was

extracted twice with chloroform, treated with Amberlites IR-120 and IR-4B, and evaporated to a sirup (122 mg.). The material was fractionated on a cellulose column using *n*-butanol saturated with water as the mobile phase. 2-*O*- α -D-Mannopyranosyl-glycerol (42 mg.) was isolated as a sirup and identified by its infrared absorption spectrum and its $[\alpha]_D$, which was $+59^\circ$ (*c*, 1.4, water) (3).

The mannosyl-glycerol (28 mg.) was converted to its hexa-*p*-nitrobenzoate derivative by the method described above. The product (60 mg.), which was precipitated twice from ethanol-acetone, had m.p. 108° – 110° C., $[\alpha]_D$ -71° (*c*, 0.7, chloroform) and an infrared absorption spectrum identical with that of the α - but not the β -anomer. Calculated for $C_{51}H_{36}O_{26}N_6$: C, 53.31%; H, 3.15%. Found: C, 53.17%; H, 3.12%.

2-*O*- α -D-Mannopyranosyl-D-mannose

The mannatriose (373 mg.) was oxidized with bromine (0.04 ml.) in water (25 ml.) containing calcium benzoate (300 mg.). After 3 days the solution did not reduce Fehling's solution and bromine was aerated off. The solution was treated with Amberlite IR-120, extracted three times with chloroform, and then neutralized with silver carbonate. The insoluble material was filtered off and the filtrate evaporated to a small volume. Addition of an excess of ethanol precipitated a white powder, presumably the silver salt of the trisaccharide aldonic acid, which was isolated. Yield 251 mg.

A sample of the product was oxidized with lead tetraacetate in 99% acetic acid. The observed rate of oxidation was as follows:

Time, min.	0	4	13	30	55	125	185
Reagent uptake, moles per mole	0	1.7	2.6	3.2	3.5	4.0	4.2

This relatively rapid uptake of slightly over 3 moles per mole of reagent, which was followed by a slower oxidation, corresponded to the formation of a good proportion of the expected *O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-*O*- α -D-mannopyranosyl-(1 $\rightarrow$ 2)-L-glycero-triuronic acid.

Therefore the silver salt (230 mg.) was dissolved in water (2 ml.) to which acetic acid (200 ml.) was added, and the mixture treated with lead tetraacetate (500 mg.; 3 molar equivalents). After 18 hours the solution was evaporated to a solid mass, which was dissolved in water, and 10% oxalic acid in acetic acid (1.1 ml.) added. The solution was filtered and water was added until the volume was 40 ml. Acetic acid (4 ml.) was added and the solution was heated at 100° C. for 1 hour. It was then shown to contain a material which gave a spot on a paper chromatogram corresponding to 2-*O*- α -D-mannopyranosyl-D-mannose.

The solution was evaporated to dryness and the residue was reduced with sodium borohydride (200 mg.) in water (20 ml.). After 18 hours the reaction mixture was worked up as described above and the product was purified by chromatography on a cellulose column using ethyl acetate-acetic acid-water (9:2:2, v/v). Yield 107 mg. Four recrystallizations from ethanol-methanol gave a product with $[\alpha]_D$ $+36^\circ$ (*c*, 1.0, water) and m.p. 136° – 137° C., undepressed on admixture with 2-*O*- α -D-mannopyranosyl-D-mannitol. The crystals gave an infrared absorption spectrum and an X-ray diffraction pattern identical with those of the known compound. Calculated for $C_{12}H_{24}O_{11}$: C, 42.10%; H, 6.48%. Found: C, 41.94%; H, 6.52%.

An attempt to degrade the hydroxy-malondialdehyde derivative, prepared by careful lead tetraacetate oxidation of the reducing end-unit of the trisaccharide, using the conditions as for the corresponding *glycerotriuronic acid* derivative (VII), was unsuccessful.

THE SECOND VIRIAL COEFFICIENT OF CARBON DIOXIDE AT LOW TEMPERATURES¹

D. COOK²

ABSTRACT

The fixed volume expansion method for gas compressibility measurements previously employed under conditions of high temperature and high pressure has now been developed for low temperature and low pressure measurements. A sensitive diaphragm null-pressure detector, operating as a capacitor, has been incorporated into the gas pipettes, and eliminates troublesome dead space corrections. The advantages and limitations of the method are discussed. Measurements of the second virial coefficient of carbon dioxide in the temperature range -60°C. to $+30^{\circ}\text{C.}$, and in the pressure range 0.5 to 2.5 atmospheres, are reported.

INTRODUCTION

Previous measurements in these laboratories of the compressibilities of gases by the expansion method have been made in the pressure region of 60 to 70 atm. and from 0° to 700°C. , using an expansion technique. From these measurements the second, third, and in some cases the fourth virial coefficients, as well as the intermolecular force parameters, have been evaluated for a number of gases. One disadvantage of the above method is the elaborate computational procedure required for deriving the virial coefficients from the primary measurements when higher coefficients are involved. The method, as previously employed, is also not very suitable for low temperature measurements. For these reasons an attempt was made to develop an expansion method which could be used at low temperatures and low pressures by means of which the second virial coefficient could be easily derived. By working at low pressures the higher virial coefficients can usually be neglected and this greatly simplifies the analysis of the data. The present paper describes an apparatus designed for compressibility measurements of gases from $+200^{\circ}\text{C.}$ to -180°C. in the pressure range 0.5 to 2.5 atmospheres. Measurements of the second virial coefficient of carbon dioxide from $+30^{\circ}\text{C.}$ to -60°C. are reported.

APPARATUS

One of the disadvantages of the high pressure apparatus used hitherto has been the necessity of making dead space corrections for that part of the gas sample in the lines leading to the mercury U tube which must be outside the thermostat. This U tube is the means of balancing the pressure in the gas sample with the externally applied pressure. With this arrangement, too, there is always the risk that mercury may be forced over into the high pressure cell. To avoid these difficulties a sensitive diaphragm was used as the pressure sensitive device and null detector. This has the advantage that it can be incorporated into the equilibrium cell, thus eliminating dead space corrections.

Fig. 1 shows a diagram of the equilibrium cell. It was made of K Monel, and consists of a large pipette *A*, of about 1000 cm.³ capacity connected to a smaller pipette of about 63 cm.³ capacity. Valves *V*₁ and *V*₂ control the filling of the cell and evacuation of the small pipette after expansion.

FIG. 1. The diaphragm cell.

The lower half of the cell (below the diaphragm *D*) contains the capacitance probe *E*, insulated from the outside of the cell by quartz insulators *F*. A metal nut *I*, tightening on a crimped spring washer *H*, backed by a flat metal washer *G*, held the probe assembly together. Holes drilled through parallel to the axis permitted the flow of gas. A pin *J* supported a wire *L*, which was mounted coaxially with the tube *M* being supported with glass disks *N* as insulators. The tube *M* serves as the lead to the manometer and pressure balancing device and also provides a shielded lead for the wire *L*, the other end *Q* connecting to the capacitance bridge. The lid *K* was soft-soldered in position after assembly of the probe unit.

The Diaphragm

Construction of the diaphragm involves a compromise between two opposing factors. For maximum sensitivity the thinner the diaphragm the better. For minimum hysteresis (maximum zero stability) a thicker diaphragm is preferable. Accordingly a 4 in. diameter

K Monel diaphragm, thickness 0.006 in., was made embodying the following features. Three 0.010 in. corrugations were pressed in the diaphragm at radii $1\frac{3}{8}$ in., $1\frac{1}{2}$ in., and $1\frac{5}{8}$ in. to give added strength, while at a radius of $1\frac{7}{8}$ in. a 0.015 in. groove was pressed to serve as a locating groove. Corresponding locating grooves were machined on each half of the diaphragm holder. The peaks of the latter grooves were displaced 0.010 in. towards the periphery to stretch the diaphragm slightly. This procedure and the corrugations served to ensure that no "oil can" effects developed in the diaphragm. The forming of the diaphragm was accomplished using a masonite die, on which the corrugation profile was accurately machined, in conjunction with a hard rubber (100 durometer hardness) disk in a steel cup. A hydraulic press requiring about 20 tons pressure was needed to form the corrugations.

Mounting the diaphragm in the cell presented some difficulty. It was hoped that it would be possible to weld the diaphragm into the cell by making the flanges at R very thin so that the minimum of heat need be applied. However, several test strips proved that the amount of heat required to weld the diaphragm satisfactorily was enough to alter its elastic properties. Even with silver brazing the diaphragm became quite brittle and cracked in several places, as did the quartz insulators. Ultimately soft-soldering provided a satisfactory method, but naturally limited the temperature range over which the cell could be used. After the diaphragm was soldered it was considered advisable to leave four small clamps in place for added support.

The ends of the two halves of the cell next to the diaphragm were made with a curved surface (exaggerated in Fig. 1). This amounted to 0.003 in. at the center, or a radius of 45 ft. This had the effect of making a small pressure change (diaphragm displacement) show as large a capacitance change as possible. To achieve this curvature a series of steps about 0.0003 in. in height were cut on the face and the ridges polished off with a fine paper. The surface was gauged afterwards and found to be very close to the required curvature.

In practice it was necessary to calibrate the diaphragm null point, C_0 , in terms of zero deflection capacitance at zero pressure difference (both sides of the diaphragm connected together) as C_0 is a function of both temperature and pressure. At lower temperatures C_0 increases as the cell contracts. At higher pressures it decreases. Calibration was effected by allowing gas to flow into both halves of the equilibrium cell and the manometer, and taking measurements of total pressure and C_0 at intervals of about 30 cm. Hg. The isotherms of C_0 against pressure so obtained were linear, but the slope varied slightly with temperature. It was usual to check C_0 two or three times in the course of one series of expansions. After several deflections of the diaphragm the zero stability appeared to be of the order of 0.1 $\mu\mu\text{f.}$ (the total zero deflection capacitance of the diaphragm was about 400 $\mu\mu\text{f.}$). The sensitivity was of the order of 0.1 cm. Hg per $\mu\mu\text{f.}$

Capacitances were measured on a General Radio Type 716-C capacitance bridge together with a Type 1231-B amplifier and null detector. The bridge was graduated in units of 0.2 $\mu\mu\text{f.}$ but could be interpolated to 0.02 $\mu\mu\text{f.}$ A standard frequency of 1 kc. was used throughout the measurements after passing through a General Radio Type 1231-P6 filter. Connections from the bridge to the probe in the cell were made using low capacitance shielded cable. All terminals were properly shielded.

Cell Thermostat and Temperature Measurement

At temperatures below room temperature a double Dewar arrangement proved satisfactory. The inner Dewar contained methanol and was adequately stirred. The

outer Dewar contained solid CO_2 and methanol for operating temperatures down to about -40°C .; below this, liquid nitrogen was used. The temperature sensitive element for temperature control was a metal sheathed platinum resistance thermometer. The bridge and photocell circuit has been described previously (6). It is estimated that this arrangement gives control to $\pm 0.005^\circ\text{C}$. but on account of the large thermal capacity of the cell its temperature variation is probably about $\pm 0.002^\circ\text{C}$.

The Manometer

Standard wall Pyrex glass tubing of 1 in. internal diameter was used to construct a manometer 2 meters long. It was designed so that the two mercury menisci were vertically above one another by means of a crossover. It was filled with clean twice-distilled mercury. The upper limb was kept permanently evacuated. The manometer was housed in a thermostat containing well-circulated oil whose temperature was controlled with a sensitive mercury thermoregulator. The temperature variation of the oil was $\pm 0.005^\circ\text{C}$.; however the large thermal capacity of the mercury (about 400 cm.³) may make the variation somewhat less than this figure. Connections to the manometer made it possible to raise or lower the balancing pressure quickly. A fine adjustment permitted pressure changes of the order of 0.001 cm. Hg to be made.

A 2 meter stainless steel bar, made and calibrated by the Gaertner Scientific Corporation, was used for measuring the height of the mercury column. The graduations were in centimeters and millimeters. It was freely suspended inside the manometer thermostat and used as a guide to line up the manometer into a vertical position. A $2\frac{1}{2}$ meter cathetometer with vernier attachment was used to interpolate between the millimeter divisions of the 2 meter bar. It was adjusted to the vertical by means of a plumb line. To eliminate vibration both manometer and cathetometer were bracketed to a 2 ft. thick main wall with large iron plates.

OPERATION OF THE APPARATUS

The expansion method and technique has been described elsewhere (5), so only brief details will be given here. The method of using the diaphragm is new and a description of the technique of handling it follows:

Because of the variation of the diaphragm "zero" (the value of the capacitance with the pressure equalized on both sides of the diaphragm) with temperature and pressure, it was necessary to calibrate this before each run. To determine this calibration curve, the cell including all the leads, and the manometer, were thoroughly evacuated using a mercury diffusion pump. The gas under investigation was then allowed to flow into the cell, lines, and manometer. At intervals of about 30 cm. Hg the gas flow was stopped and the pressure and capacitance measured after equilibrium was reached. A calibration curve could then be drawn up, which always proved to be linear.

The apparatus was then ready for a series of expansions to be carried out. After each expansion into the small pipette the pressure was adjusted to rough balance as quickly as possible, the new pressure then giving a new capacitance. Adjusting the bridge to this new value enabled the fine pressure adjustment to be carried out. After the final expansion on any particular isotherm, the pressure was equalized on both sides of the diaphragm (by means of an interconnecting valve, not shown on Fig. 1) and readings of pressure and capacitance taken. The point so obtained nearly always lay on, or very near, the original calibration curve.

The time taken to reach equilibrium varied, depending on the temperature. At the

higher temperatures about 15 to 20 minutes was generally sufficient. At lower temperatures this had to be extended to about 30 to 40 minutes.

MATERIALS USED

Carbon dioxide as supplied by the Mathieson Company was transferred to an all-metal storage bomb fitted with a high pressure valve. During this process it was sublimed twice between two glass traps with continuous pumping. Its estimated purity was greater than 99.9% CO₂.

RESULTS

The equation of state of a gas may be written

$$[1] \quad pV/RT = 1 + B_T^*/V + C_T^*/V^2 + \dots$$

where B_T^* and C_T^* are the virial coefficients. However it is equally permissible over a limited pressure range to use the equation

$$[2] \quad pV = A_T + B_T p + C_T p^2 + \dots$$

The two sets of virial coefficients are related as follows:

$$[3] \quad B_T^* = B_T, \quad C_T^* = RTC_T + B_T^2.$$

For interpreting data derived from the expansion method, equation [2] is best used in the form

$$[4] \quad p_1/p_2 = N + p_1(N-1)B_T/A_T + p_1^2(N-p_2/p_1)C_T/A_T + \dots$$

where p_1 and p_2 are the pressures before and after expansion respectively, and N is a ratio of the volumes of the two pipettes.

Equation [4] shows that if C_T is negligible a plot of the pressure ratio against the pressure should give a straight line whose intercept is N and whose slope is related to the second virial coefficient. Any contribution from the third virial coefficient would be largest at low temperatures and where the pressure approached the condensation pressure. Although there was a very slight indication of some curvature on the -60°C . isotherm, no other isotherm showed this. Hence it must be concluded that because of the small size of the deviation from linearity and the nature of the scatter of the points there would be no justification for evaluating a third virial coefficient from these measurements. Accordingly, the method adopted for evaluation of the second virial coefficients was the simple linear least squares method.

Fig. 2 shows the isotherms of p_1/p_2 against pressure. The value of N was not predetermined but Fig. 2 and Table I show the intercepts to be confined to a small range. Table I

TABLE I

T ($^\circ\text{C}$.)	$-10^3 B_T$ (Amagat)	$-B$ (cm. ³ mole ⁻¹)	N

FIG. 3. Second virial coefficient of CO_2 . $\circ$ Present measurements; $\triangle$ Reference (2); $\square$ Reference (4).

shows the values of N and B_T , the latter being given in Amagat units and also in $\text{cm}^3 \text{mole}^{-1}$. Amagat units can simply be changed to $\text{cm}^3 \text{mole}^{-1}$ by multiplying by the normal volume of CO_2 (viz., the volume of 1 mole of gas at 1 atm. and $0^\circ \text{C.} = 22265 \text{ cm}^3 \text{mole}^{-1}$). Standard errors in N and B_T were derived by the method described by Margenau and Murphy (3).

The virial coefficients thus obtained are shown graphically in Fig. 3 plotted against temperature. Also plotted are the high temperature points previously obtained, and some low temperature points of Schäfer (4).

DISCUSSION

In the region where the previous data on CO_2 and the present measurements overlap, the agreement is almost within the experimental error. Although no standard errors were available for the high temperature work this was thought to be accurate to about 0.5 to 1% or about 1 to 2 $\text{cm}^3 \text{mole}^{-1}$. The present method is not as accurate as this, but it should be pointed out that the results having the least confidence in the high pressure method are those in the region of the critical temperature, i.e., around 30°C. However, a recent investigation of the compressibility of CO_2 at 0°C. gives a value of B of $-152 \text{ cm}^3 \text{mole}^{-1}$. This is the best value from a series of measurements (1). The normal volume derived from the latter work is $22262.6 \text{ cm}^3 \text{mole}^{-1}$, in good agreement with that used by MacCormack and Schneider (2). The only other low temperature values are those of Schäfer (4), also indicated in Fig. 2. Schäfer's results and the present data also agree within the experimental error at 0°C. , but at lower temperatures our data seem to be significantly lower.

A critical survey of the accuracy of the method is difficult. To give some idea of the scatter in the experimental points these are plotted for a typical isotherm in Fig. 4. Naturally the scatter gets worse at low pressures. For this reason the expansions down any particular isotherm were stopped at about 50 cm. Hg. It is felt that temperature

FIG. 4. Experimental points for a typical isotherm.

fluctuations in either the cell thermostat or the manometer thermostat would be too small to have any significant effect on the measured pressure. A simple calculation shows that a variation in the cell thermostat of 0.002°C . would produce a pressure change of the order of 1 in 10^5 . The pressure change due to a manometer thermostat temperature change of 0.005°C . would be of the same order. Since no volume measurements are made using the expansion technique, the remaining variable is the pressure. It is probably in the measurement of this variable that the greatest error lies.

Whereas with a piston gauge, as used in the high pressure method, a precision of about 1 in 2×10^5 can be obtained at 40 atm., the present low pressure method has a precision of about 1 in 2×10^4 at 100 cm. Hg (40 atm. and 100 cm. Hg are approximately half way down the p_1/p_2 against p_1 isotherm for the high pressure and low pressure method respectively). This order of precision in the pressure measurements is able to account very closely for the standard deviation of the value of p_1/p_2 at any given p_1 , which is of the order of 0.00012.

The method offers good possibilities of measuring second virial coefficients to the order of accuracy of about ± 10 to $15\text{ cm}^3\text{ mole}^{-1}$. The operation of the diaphragm seems to be satisfactory provided the zero deflection capacitance is checked occasionally to detect any hysteresis.

In the quest for greater precision in the pressure measurements no fast easy method seems to offer itself with the present experimental arrangement. The necessity for checking the diaphragm calibration a few times in the course of each isotherm involves contact between the gas under investigation and the manometer mercury and may therefore introduce some unreproducibility in the latter. The system of using fixed points for precision manometry has many advantages but is impractical in this application. It is rather remarkable that no very precise method has been developed for measuring pressures in this range, other than the mercury column, which, if pushed to its limit requires tedious attention to many details. An instrument comparable in accuracy and ease of manipulation to the free piston gauge for high pressures would be invaluable in the region around 1 atm.

Apart from the disadvantage of a somewhat lower precision relative to the high pressure expansion method the low pressure method here described has several advantages. The computational work required to obtain values of the second virial coefficient is greatly reduced and no dead space corrections are required. The method may be employed over a fairly wide temperature range. Finally, although in common with all low pressure methods, it is subject to the limitations of mercury-column manometry, this is of less serious concern when gases or vapors with large second virial coefficients are to be measured.

ACKNOWLEDGMENT

I am indebted to Dr. W. G. Schneider for his constant encouragement and advice, and to Mr. W. A. Stevenson for his invaluable assistance in the construction of much of the apparatus.

NOTES

REARRANGEMENT STUDIES WITH C¹⁴

IV. THE ABSENCE OF REARRANGEMENT IN THE SCHMIDT REACTION WITH 3-PHENYLPROPIONIC ACID-2-C¹⁴ *

C. C. LEE, G. P. SLATER, AND J. W. T. SPINKS

The Schmidt reaction is usually considered to include the transformation of carboxylic acids to amines and of ketones to amides by the action of hydrazoic acid and a strong mineral acid catalyst such as sulphuric acid. The mechanism of the reaction with RCOOH is generally depicted as involving a migration of R, with an unshared electron-pair, to an electron-deficient nitrogen after a union or co-ordination between the carbon atom of the carboxyl and a nitrogen atom of hydrazoic acid (2, 13). No rearrangement in the R group would be expected since the R group migrates with complete retention of configuration as observed in the similar Hofmann, Lossen, and Curtius reactions (2). However, in 1949, Schuerch and Huntress (11) assumed the formation and rearrangement of an intermediate carbonium ion to account for the products obtained in the Schmidt reaction with triethylacetic acid. The degradation of C¹⁴-labeled carboxylic acids by the Schmidt reaction has been employed in both biochemical (6, 12) and mechanistic (9) studies, and if the degradation of labeled RCOOH should proceed through an intermediate R⁺ ion, isotope position rearrangement in the R group would invalidate conclusions drawn from such degradative data.

Recently, Phares and Long (8) have demonstrated the feasibility of degrading C¹⁴-labeled succinic acid by the Schmidt reaction. However, in this case, it is not possible to tell whether any isotope position rearrangement has taken place in the symmetrical product, ethylenediamine. Phares has also reported the Schmidt degradation of acetic and propionic acids labeled with C¹⁴ in various positions (7). Although the activity in practically all the unlabeled fragments was negligibly low as expected, the degradation of propionic acid-3-C¹⁴ showed an average of 1.5% of the total activity in the C-2 position. Phares attributed this to contamination. On the other hand, if one were to assume that the ethyl cation is an intermediate in the Schmidt reaction with propionic acid-3-C¹⁴, the activity found in the C-2 position may be conceived as arising from a 1,2-hydride shift in the ethyl cation. Isotope position rearrangement of this order of magnitude in the ethyl cationic system has actually been observed by Roberts and Yancey (10). These workers have found that, in the reaction of ethylamine-1-C¹⁴ with nitrous acid, the resulting labeled ethyl alcohol contained 1.5% of the rearranged product, ethyl-2-C¹⁴ alcohol.

In view of the above considerations, it was thought to be worth while to investigate whether isotope position rearrangement would take place in a Schmidt reaction with an acid which would be expected to give rise to a considerable degree of rearrangement if the reaction were to proceed through a carbonium ion intermediate. The Schmidt reaction with 3-phenylpropionic acid-2-C¹⁴ (hydrocinnamic acid-2-C¹⁴) was, therefore,

*For Paper III, see Reference 3.

carried out. Should the reaction proceed through an R^+ intermediate, isotope position rearrangement in the phenylethyl cationic system would be expected since rearrangements of up to 50%, or complete equilibration, of the C^{14} -labeled atoms from the C-1 to the C-2 positions in the phenylethyl system have been observed in several reactions where the phenylethyl cation was likely involved (3, 4, 5).

3-Phenylpropionic acid-2- C^{14} , or hydrocinnamic acid-2- C^{14} , was prepared from treatment of 2-phenylethyl-1- C^{14} -magnesium chloride with carbon dioxide as previously described (5).

A chloroform solution of 3.5 g. of 3-phenylpropionic acid-2- C^{14} was placed in a three-necked round-bottomed flask fitted with reflux condenser, dropping funnel, thermometer, and magnetic stirrer. An excess of hydrazoic acid in chloroform solution, prepared as described by Wolff (13), was introduced. Concentrated sulphuric acid (12 ml.) was then added dropwise with constant stirring. The reaction vessel was immersed in a water bath maintained at 40–45° C. Additional hydrazoic acid solution was occasionally added to ensure complete reaction. After it had been stirred for 2 hours, the resulting mixture was poured into ice water, and the aqueous layer separated. The organic layer was further extracted with water and the combined aqueous extracts made basic with 50% sodium hydroxide solution. The product was steam distilled into dilute hydrochloric acid. After the distillate had been evaporated to dryness, the residue was recrystallized from absolute ethanol to yield 2.4 g. (65%) of 2-phenylethylamine hydrochloride, m.p. 217° C., lit., m.p. 217° C. (1).

Part of the 2-phenylethylamine hydrochloride was converted to benzoic acid by alkaline potassium permanganate oxidation (4).

All compounds were assayed for radioactivity, the results being listed below.

	3-Phenylpropionic acid-2- C^{14}	2-Phenylethylamine hydrochloride	Benzoic acid	
			Run I	Run II
Corrected activity* (c.p.m. on a molar basis)	13,869±93	13,336±84	4±7	7±7

*All compounds were converted to barium carbonate and counted as infinitely thick samples of constant geometry in a gas flow Geiger counter. Correction for dilution by non-labeled carbon atoms was made by multiplying the observed activity by the number of carbon atoms per molecule in the compound counted.

The fact that the benzoic acid derived from the oxidation of 2-phenylethylamine hydrochloride obtained in the Schmidt reaction with 3-phenylpropionic acid-2- C^{14} contained no radioactivity clearly indicates that there is no isotope position rearrangement. The phenylethyl cation is, therefore, not involved in this reaction. Thus it would appear quite reasonable to conclude that, with the probable exception of such special cases as triethylacetic acid, the Schmidt reaction with $RCOOH$, in general, does not involve R^+ ion as an intermediate. One may, therefore, utilize this reaction for degradation of labeled compounds without undue suspicion that isotope position rearrangements might occur during the process of the degradation.

†Éthanol = 95%.

‡Suspension dans le fluorolube.

dextrogyre le rattache bien au type *c*. Nous présentons au Tableau II quelques données caractéristiques des deux éthers éthyliques et pour fins de comparaison, des deux éthers méthyliques partiellement décrits antérieurement (1).

Nous concluons de l'éthérification par le diazométhane principalement que les céto-énols Ib et Ic se forment en parties sensiblement égales lorsque la dicétone Ia s'énolise. L'équilibre $Ia \rightleftharpoons Ib \rightleftharpoons Ic$ se déplace largement en faveur de Ib au cours de l'éthérification lente par l'éthanol; l'empêchement stérique créé par le groupe méthyle en tête de pont est à l'origine de ce fait.

Le mode opératoire 3 convient bien à la synthèse de l'homoépicamphre; il permet d'éviter la séparation laborieuse des éthers IIb et IIc décrite dans le premier travail (1), car par simple cristallisation, on retire 70% d'éther IIIb du mélange brut des éthers IIIb et IIIc.

PARTIE EXPÉRIMENTALE³

Action du diazoéthane sur la dicétone I

A une solution de 3 g. de dicétone I dans 45 ml. d'éther anhydre et 5 ml. d'éthanol 95%, on ajoute rapidement, à 0°, 180 ml. (100% d'excès) d'une solution éthérée de diazoéthane (préparée selon (3, 6), concentration 1.11%). Après un repos de quelques

³Les points de fusion (p.f.) ne sont pas corrigés; ils ont été déterminés en tubes capillaires, dans un appareil de Thiele. Les spectres ultraviolets ont été déterminés au moyen d'un spectromètre Beckman DU et les spectres infrarouges, au moyen d'un spectromètre Perkin-Elmer, modèle 112, à simple faisceau et parcours double (optique NaCl). Les pouvoirs rotatoires ont été mesurés en solution benzénique. Les analyses sont de Geller Microanalytical Laboratories, Hackensack, N.J.

minutes, on évapore le solvant sous vide ordinaire et reprend par de l'éther qu'on lave par NaOH 10% et par de l'eau; on sèche et évapore l'éther. Le résidu est distillé; p.é. 150–157° (17 mm.), 3.11 g. (90% de la théorie), $[\alpha]_D^{23} -0.7^\circ$ ($c = 4.37$). Ce mélange et ceux résultant de deux préparations similaires (au total 17.3 g.) sont abandonnés à température ambiante pendant quelques jours; on essore alors 8.2 g. de cristaux, p.f. 30–40° s'élevant à 72.5° par cristallisations répétées dans l'éther de pétrole (p.é. 40–60°). Le liquide résiduel est fractionné dans un ballon de Vigreux (à 17 mm., en faisant passer un courant d'azote par le capillaire). Les deux premières fractions laissent déposer l'éthoxy-4 triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (IIIb) (0.5 g.) qui est recristallisée dans l'éther de pétrole (p.é. 40–60°): prismes incolores, p.f. 72.5°; $[\alpha]_D^{23} = -20.8^\circ$ ($c = 4.03$). Calculé pour $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Trouvé: C, 75.17; H, 9.68%. La troisième fraction et le résidu de distillation se cristallisent partiellement; l'éthoxy-4 triméthyl-5,8,8 bicyclo[3,2,1]octène-3 one-2 (IIIc) (0.3 g.) est essorée et recristallisée dans l'éther de pétrole (p.é. 40–60°): aiguilles incolores, p.f. 52°; $[\alpha]_D^{23} = +27.9^\circ$ ($c = 4.06$). Calculé pour $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Trouvé: C, 74.55, 74.32; H, 9.18, 9.58%.

Homoépicamphre

L'éther IIIb a été transformé, selon la méthode décrite en (1), en homoépicamphre p.f. 202.5°, $[\alpha]_D^{23} = +133.2^\circ$ ($c = 4.06$), dont la dinitro-2,4 phénylhydrazone fond à 178° seule ou en mélange avec une dinitro-2,4 phénylhydrazone d'homoépicamphre authentique (1).

Action de l'éthanol sur la dicétone I

Cinq grammes de dicétone I, 10 ml. d'éthanol anhydre et 40 ml. de benzène sont chauffés à l'ébullition à reflux en présence de 50 mg. d'acide *p*-toluènesulfonique; l'eau qui se forme est éliminée au fur et à mesure de sa formation au moyen d'un séparateur d'eau. Après 20 heures, les solvants sont distillés à pression ordinaire, le résidu repris par de l'éther. On isole à la manière habituelle 1.2 g. de dicétone non entrée en réaction et 4.5 g. de neutres (78% de la théorie), solide p.f. brut 55–70°, $[\alpha]_D^{23} = -10.1^\circ$ ($c = 4.05$). Par cristallisation des parties neutres (éther de pétrole, p.é. 40–50°), on obtient 70% d'éther IIIb pur, p.f. 72.5° (Rupe et Frey (4) indiquent: p.f. 72°).

Action du méthanol sur la dicétone I

Mode opératoire original de Rupe et Häfliger (5): 5 g. de dicétone I donnent 3.16 g. (58.6% de la théorie) du mélange des éthers IIb et IIc, p.é. 155° sous 22 mm., $[\alpha]_D^{23} = -1.4^\circ$ ($c = 4.01$).

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada de l'aide financière, subvention (H.F.) et bourse d'études (B.M.), qu'il nous a accordée. Nous remercions aussi M. le Professeur Sandorfy de sa collaboration dans l'étude des spectres infrarouges.

2-(β -DIALKYLAMINOETHYLMERCAPTO)-2-IMIDAZOLINES

STANLEY O. WINTHROP AND GORDON A. GRANT

The reaction (1) of imidazoline-2-thione (I) with alkyl or aralkyl halides readily gives the corresponding 2-alkylmercapto or 2-aralkylmercapto-2-imidazoline salts. This reaction has been used by us for the preparation of a series of 2-(β -dialkylaminoethylmercapto)-2-imidazolines (II). 2-Benzhydrylmercapto-2-imidazoline was also prepared by this method.

These compounds were screened by our Pharmacology Department. Some of them were found to have mild analgesic activity.

EXPERIMENTAL¹*2-(β -Dimethylaminoethylmercapto)-2-imidazolinium Chloride Hydrochloride*

Imidazoline-2-thione² (10 g., 0.093 mole) and β -dimethylaminoethylchloride hydrochloride (13.4 g., 0.093 mole) were dissolved in 175 ml. of isopropanol and refluxed for 48 hours. The solution was then evaporated to about 75 ml. On cooling, 12 g. of product separated out, m.p. 179–183° C. Two recrystallizations from isopropanol raised the melting point to 183.5–184.5° C. Calc. for $\text{C}_7\text{H}_{17}\text{N}_3\text{SCl}_2$: C, 34.15; H, 6.96; S, 13.02; Cl, 28.80. Found: C, 34.22; H, 7.02; S, 13.02; Cl, 28.89.

2-(β -Diethylaminoethylmercapto)-2-imidazolinium Chloride Hydrochloride

In the same manner as the above procedure, imidazoline-2-thione (7.8 g., 0.075 mole) and β -diisopropylaminoethylchloride hydrochloride (15.1 g., 0.075 mole) gave 20 g. of product, m.p. 217–219° C. One recrystallization from ether-ethanol raised the melting point to 218–219° C. Calc. for $\text{C}_{11}\text{H}_{25}\text{N}_3\text{SCl}_2$: N, 13.91; S, 10.60; Cl, 23.47. Found: N, 15.05; S, 11.96; Cl, 25.82.

2-(β -Diisopropylaminoethylmercapto)-2-imidazolinium Chloride Hydrochloride

This compound, m.p. 188–190° C., was prepared in a 92% yield by the same procedure as were the previous two homologues. One recrystallization from ethanol gave an analytically pure material, m.p. 193–194° C. Calc. for $\text{C}_9\text{H}_{21}\text{N}_3\text{SCl}_2$: N, 15.32; S, 11.69; Cl, 25.86. Found: N, 15.05; S, 11.96; Cl, 25.82.

¹All melting points are uncorrected.

²Sharpley Chemical Inc., Philadelphia 9, Pa.

2-(β-Diisopropylaminoethylmercapto)-2-imidazoline (Free Base)

2-(β-Diisopropylaminoethylmercapto)-2-imidazolinium chloride hydrochloride (12.5 g., 0.0415 mole) was dissolved in a 100 ml. of methanol and a solution of sodium methoxide (4.55 g., 0.083 mole) in 100 ml. of methanol was slowly added with stirring. The solution was then filtered to remove the precipitated sodium chloride and the filtrate evaporated down *in vacuo* at room temperature, leaving 7 g. of product as a viscous oil. Attempts to induce this oil to crystallize have not been successful to-date. The free base decomposed readily on heating with the production of a mercaptan-like odor. It was characterized by conversion to its acid salts.

Free base (1.0 g.) was dissolved in 10 ml. of ether and excess hydrobromic acid in a little isopropanol was added. The 2-(β-diisopropylaminoethylmercapto)-2-imidazolinium bromide hydrobromide precipitated as an oil which crystallized on trituration with an ether-isopropanol mix to yield 1.3 g. with m.p. 202–205° C. One recrystallization from ether-ethanol raised the melting point to 206–207° C. Calc. for $C_{11}H_{25}N_3SBr_2$: N, 10.74; S, 8.19; Br, 40.85. Found: N, 10.72; S, 8.37; Br, 40.92.

The free base was also converted to its dihydrogen sulphate addition salt by an identical procedure. The salt melted at 145–146° C. after two recrystallizations from ether-isopropanol. Calc. for $C_{11}H_{27}N_3S_3O_8$: SO_4 ion, 15.04; N, 9.87. Found: SO_4 ion, 15.03; N, 9.73.

2-Benzhydrylmercapto-2-imidazolinium Bromide Hydrobromide

Imidazoline-2-thione (2.55 g., 0.025 mole) and benzhydrylbromide (6.2 g., 0.025 mole) were dissolved in 20 ml. of ethanol and refluxed for 2 hours. The ethanol was then removed *in vacuo* and the oil residue crystallized from an isopropanol-benzene mix to yield 6.2 g. of product, m.p. 135–150° C. Two recrystallizations from ether-isopropanol raised the melting point to 174–176° C. Calc. for $C_{16}H_{17}N_2SBr_2$: C, 55.02; H, 4.91; N, 8.02; Br, 22.89. Found: C, 55.10; H, 5.04; N, 8.00; Br, 22.78.

ACKNOWLEDGMENT

The authors are grateful to Mr. W. J. Turnbull for the microanalytical data and to Dr. C. I. Chappel for the pharmacological screening.

KINETICS OF THE THERMAL DECOMPOSITION OF HYDROGEN PEROXIDE VAPOR¹

PAUL A. GIGUÈRE AND I. D. LIU

ABSTRACT

The rates of thermal decomposition of hydrogen peroxide vapor were measured by the static method at low pressures (0.2 to 20 mm. Hg), over the temperature range 300°–600° C., in carefully cleaned glass vessels. The reaction was of the first order with respect to time and the final products were only water and oxygen. Around 400° C. the character of the reaction changed gradually from heterogeneous (surface effects, low activation energy) to homogeneous (reproducible rates in various vessels). With initial pressures of about 10 mm. Hg the experimental rates above 400° lead to an apparent activation energy of 43 kcal. and a frequency factor of $10^{10.7}$. After correction for the residual surface decomposition, the rate equation becomes

$$k = 10^{13} \exp(-48,000/RT) \text{ sec.}^{-1}$$

in good agreement with the accepted value for the O—O bond dissociation energy. The reaction rates increased regularly with pressure.

Packing the reaction vessels with glass rods and adding various gases (including nitric oxide and propylene) had no appreciable effect on the gas-phase reaction. Deuterium peroxide vapor decomposed at the same rate as hydrogen peroxide under comparable conditions. The results may be explained adequately by the following non-chain mechanism for the uncatalyzed decomposition:

INTRODUCTION

One of the very first chemical reactions of which the rate was measured was the spontaneous decomposition of hydrogen peroxide (Thenard, 1818). Yet, in spite of countless investigations, our understanding of this deceptively simple reaction is still far from adequate. Obviously the major difficulty here comes from the extreme sensitivity of hydrogen peroxide to all sorts of catalysts. In recent years two independent investigators (15, 24) have shown that under suitable conditions, such as in a flow system, the homogeneous decomposition becomes measurable at temperatures somewhat above 400° C. Because of the uncertainty in analyzing the data in a flow experiment we felt that a study by the static method, if successful, would yield more reliable results, particularly for the activation energy. In fact we were able to follow the reaction at temperatures appreciably higher than heretofore (up to 600° C.) and it was possible to evaluate with good accuracy the relative importance of the surface and volume reactions.

EXPERIMENTAL

The reaction vessels, generally 2-liter flasks, were either of Pyrex or Vycor. First they were cleaned thoroughly with hot fuming sulphuric acid and, after they were rinsed,

¹Manuscript received September 24, 1956.

Contribution from the Department of Chemistry, Laval University, Quebec, Que. This work was supported by the Office of Scientific Research of the United States Air Force under contract No. AF 18 (600)-492.

they were either fused in a blast lamp as described before (8), or treated for a few hours with hot, concentrated hydrogen peroxide. Even after such treatments the Pyrex flasks required some preliminary runs (a dozen or so) before yielding reproducible results. Vycor flasks, on the contrary, gave immediately consistent results. In addition they could be used safely above 500° C.

The reaction vessels were heated in a heavily insulated electric furnace (Fig. 1) the temperature of which was controlled to within $\pm 0.3^\circ$ and read to $\pm 0.7^\circ$ by means of

FIG. 1. Apparatus used to follow the thermal decomposition of hydrogen peroxide vapor.

an electronic thermometer. The sensitive element of the latter (platinum coil on quartz) was calibrated against a certified platinum resistance thermometer (Leeds and Northrup) up to 470° C. Beyond that range a large-scale, well adjusted extrapolation gave an accuracy estimated at 1.5° or better. Temperature gradients inside the furnace were minimized by enclosing the glass flasks within thick hemispheres of aluminum bronze. Aluminum foil provided good thermal contact between the flask and the metal shell. The thermometer bulb was inserted directly in a slot in one of the hemispheres.

A large three-way stopcock S_1 , lubricated with silicone grease, connected the reaction chamber either with the vacuum system or with the reagents. The rate of the reaction was followed by recording the pressure increase with a pressure transducer T . The characteristics of these devices and their use in the present investigation have been described elsewhere (10). At first glass spoon-gauges coupled to a linear transducer were used; later this fragile combination was replaced by the all-metal transducers with identical results. The dead volume of the reaction system outside the furnace was only of the order of 50 cc.; these parts were kept at 90° C. to prevent condensation of the vapor. Tests confirmed that the decomposition of the peroxide vapor in the dead space was negligible. The reaction vessel was filled by evaporation of the sample of liquid peroxide kept in a small bulb H at 70°–80° C. Because of the low volatility of hydrogen peroxide the maximum pressure obtainable in a reasonable time by that technique was not higher than 20 mm. Hg. Higher pressures require boilers of special construction (21).

To study the effect of various added gases on the reaction rate an auxiliary reservoir was needed for mixing the reagents. To that end a 5-liter flask, kept at about 150° C.

in a heating mantle, was connected to the reaction system. The peroxide vapor was first introduced, as described above, then the other gas at a given partial pressure, from a storage vessel fitted with a second pressure transducer. The peroxide vapor mixed with the various gases used did not react measurably at 150° in the storage vessel. The preparation of the hydrogen peroxide samples 99.9% pure from Becco's 90% product has been described before. The deuterium peroxide, about 95%, was obtained by fractional distillation of the product from dissociation of heavy water in the electrical discharge (11). The various gases, presumably 98–99% pure, were taken directly from cylinders without further purification. Good reproducibility was achieved only by following rigorously the same experimental procedure. For instance, the reaction chamber had to be evacuated for the same length of time between runs (20 to 30 minutes depending on the temperature) and the initial pressure of reactants had to be constant in any given series. The experiments were scattered with respect to temperature to minimize any aging of the glass surface, albeit no sign of this ever appeared.

RESULTS

The majority of the some 700 runs carried out were in the temperature range 400°–500° C. and at initial pressures of 8 to 10 mm. Hg where the reproducibility was generally good (Fig. 2). As a rule consecutive runs yielded the same rate constant within the accuracy of measurements; non-consecutive runs with a given vessel generally agreed within 10 or 15%. All the runs (save a few in coated vessels) gave time–pressure curves strictly of the first order. Little attention was paid to the heterogeneous decomposition in the region below 400° C. as it has been studied extensively before (for a review cf. (22)). Its sole importance in this investigation was to provide a basis for correcting the rates at higher temperatures for any residual surface reaction. The apparent activation energy for this process was rather low, 10–12 kcal. as found before. The rates, however, were at least 30 times slower (for instance $k = 3 \times 10^{-4}$ sec.⁻¹ at 350° C.) than the slowest ones obtained previously under comparable conditions (8). As a consequence the transition temperature from heterogeneous to homogeneous decomposition was lowered to about 400° (Fig. 3).

In one series of runs the surface was increased by packing the reaction vessel with Pyrex tubes 8 mm. in diameter sealed at both ends under reduced pressure, and arranged as evenly as possible in space inside the flask. Increase in the surface-to-volume ratio from 0.4 to 0.7 and 1.1 cm.⁻¹ produced only a slight increase in the reaction rate above 400–425° C. but a more substantial rate increase of the heterogeneous reaction (Fig. 3). Likewise addition of various gases (air, oxygen, argon, and helium) had only minor effects on the rate as may be judged from Table I. In general an increase in total pressure accelerated the reaction slightly, the various gases being comparable in that respect. The curves of Fig. 4 illustrate the dependence of the reaction rate on the total initial pressure. The levelling off at low pressures is undoubtedly the result of increasing importance of the surface reaction. This is confirmed by the accompanying drop in apparent activation energy, down to 38 kcal. at 0.3 mm. Hg. The low-pressure limit at which the decomposition could be followed with the type of transducer used (Statham Laboratories, Model P97–0.05d) was of the order of 0.2 mm. Hg. The reaction was then slowed down enough to enable measurements up to 600° C. ($k = 2.5 \times 10^{-2}$ sec.⁻¹) in a 2-liter Vycor vessel.

Nitric oxide and propylene, commonly used as a test for free radicals in organic re-

actions, had no more effect on the reaction than the other gases reported above, at least in low concentrations (below 3%). Higher concentrations resulted in side reactions which were not investigated further. Hydrogen, in suitable quantities, led to mild explosions (second limit) but only after nearly all the hydrogen peroxide had decomposed. This interesting phenomenon is being studied in detail and will be described elsewhere. Under

otherwise comparable conditions the vapor from more dilute hydrogen peroxide (90%) as well as that from the isotopic peroxide D_2O_2 (95%) was found to decompose at the same rate as the 99.9% material generally used (Fig. 5).

Coatings of fused salts were also tried as they have been claimed to be much more inactive than glass or quartz towards the decomposition of hydrogen peroxide (15). However, they were found unsuitable for measurements in a static system. Fused boric acid turned out to be very hygroscopic, the pressure of peroxide (or water) vapor decreasing quickly with time instead of increasing. Borax, even after it was fired at about $750^\circ C$., produced very fast, and approximately zero-order decomposition, resulting, no doubt, from diffusion to and from some active spots.

DISCUSSION

The Mechanism

The above results may be explained satisfactorily, if not uniquely, in terms of the following mechanism for the homogeneous decomposition:

This sequence of elementary reactions involving no chains adds up to the over-all process

We intend to show hereafter that other possible steps are either ruled out or less probable than the above for various reasons. Obviously, mere observations of pressure changes in the system are not sufficient for that purpose and we must rely strongly on evidence from other sources such as spectroscopy, mass spectrometry, electrical discharge work, etc.

It is now well established that the first act in the homogeneous decomposition of hydrogen peroxide is the fission of the O—O bond [1] following activation, thermal or otherwise. Ample evidence for this is provided by the high concentrations of OH radicals found spectroscopically in hydrogen peroxide vapor dissociated by ultraviolet light (28), in the flash photolysis (16) or in an electrical discharge (7). Recent attempts at pyrolysis with the toluene carrier technique have yielded sizable quantities of phenol (23). It must be mentioned, however, that in the *catalyzed* decomposition, no *free* hydroxyls seem to be present. This is indicated by the recent demonstration of Stone and Taylor (25) that carbon monoxide does not react with hydrogen peroxide vapor decomposing heterogeneously at about 110° C., whereas upon irradiation with actinic light the reaction

occurs immediately.

The other conceivable initial step

may be excluded on the grounds that (a) the O—H bond is twice as strong as the O—O bond, and (b) no molecular hydrogen is produced in the reaction. Indeed, it has been proved that both the catalyzed (22) and the photochemical decompositions (29) yield only water and oxygen after equation [5]. As a check we had the non-condensable gas, after complete thermal decomposition, analyzed by mass spectrometry. A sample from hydrogen peroxide decomposition at 470° C. showed 0.1% hydrogen, very near to the limit of detection of that method (0.08%), whereas a sample from deuterium peroxide showed no trace whatsoever of deuterium gas. Therefore, formation of free hydrogen atoms at any stage of the reaction is extremely improbable. Otherwise measurable amounts of hydrogen would appear in the final products as the results of secondary reactions such as:

and even

Incidentally, the formation of free oxygen atoms in the homogeneous decomposition seems just as unlikely as that of hydrogen atoms. The reaction

sometimes postulated is certainly too complex for a single act in the gas phase. Similarly the reaction

suggested by Weiss (30) involves, like reaction [10], a forbidden transition from a singlet to a triplet electronic state. Accordingly, no O⁺ ions have been found in the electron impact dissociation of hydrogen peroxide in a mass spectrometer although the conditions for their detection were very favorable (18).

The most probable step following the initial one is the attack of the parent compound by OH radicals [2], which must be extremely fast. This was confirmed recently by the mass

spectrometric investigations of Foner and Hudson (6) where the highest concentrations of HO_2 radicals were achieved by reacting OH radicals—from dissociated water or hydrogen peroxide vapor—with hydrogen peroxide at low pressures. Also in agreement is the spectroscopic observation that OH radicals disappear much more rapidly in dissociated peroxide vapor than in water vapor (7). Recombination of hydroxyl radicals

need not be considered here since in a non-chain mechanism it results in no over-all reaction. At any rate the probability of such three-body collisions in the gas phase is negligible considering the very low steady-state concentration of OH radicals in the presence of hydrogen peroxide [2].

As for the chain-propagating step

first proposed by Haber and Willstätter (12), it must have an appreciable activation energy, because of its complexity, making it less probable than various termination steps in the gas-phase reaction. As shown below, the present results, as well as those for the photochemical decomposition (29), do not require a chain mechanism. Rather they disprove any appreciable contribution from chains. True, under certain conditions the decomposition of hydrogen peroxide becomes explosive. However, Satterfield and his co-workers (20, 21) have shown that these explosions must be of the thermal type since they usually require a high local temperature: ignition by a spark, by a heated filament, or by fast catalytic decomposition on some very active spot. From extrapolation of their data it would appear that in the high-pressure range of our measurements we were operating within the ignition limits of hydrogen peroxide vapor. Finally it may be recalled here that in the much studied reaction between hydrogen and oxygen, HO_2 radicals are always considered as leading to chain termination rather than propagation (14).

Of the various conceivable termination steps, the most likely are certainly the dismutation reactions [3] and [4]. Again the latter appears by far the less probable of the two, at least until the last stages of the decomposition, owing to the exceedingly strong competition of step [2] for OH radicals.

The Rate Equation

Because of its relatively high activation energy the first step [1] must be rate-determining. Consequently, if the decomposition were a truly elementary process its activation energy should be approximately equal to the bond dissociation energy $D(\text{HO—OH})$, on the very plausible assumption that the reverse reaction requires no activation energy. So far this quantity was taken as 51 kcal. (9) from pertinent thermochemical data and using the generally accepted value $D(\text{O—H}) = 100.2$ kcal. based on the equilibrium measurements of Dwyer and Oldenberg (4). However, this numerical value was admittedly not beyond doubt and it was hoped that the measurements could be repeated with more accuracy (17). Later on they were shown to be open to some criticism (5); an assumed linear relationship between absorption intensity and concentration of OH would tend to make the above value a lower limit. Very recently Barrow and Downie (1) have reported an accurate spectroscopic determination involving only a short Birge-Sponer extrapolation and leading to a slightly higher value of $D(\text{O—H})$, 101.4 ± 0.5 kcal. This is considered the most reliable to date (13) and we will adopt it for the present

discussion. Consequently the value of $D(\text{HO}-\text{OH})$ is found to be 48.5 kcal. from accepted heats of reaction reduced to 0° K. (9, 19).

Now the present reaction rates measured at initial pressures of about 10 mm. Hg and at temperatures above 400° C. may be fitted fairly closely to the equation

$$k = 10^{10.7} \exp(-42,500/RT) \text{ sec.}^{-1}$$

A discrepancy of 6 kcal. is certainly beyond the estimated uncertainty of our experimental activation energy. On further analysis of the results, however, we reflected that the observed rate constants, k_e , were the sum of two terms: k_g for the gas-phase reaction and k_s for the residual surface reaction. The experimental rates should, therefore, be corrected for the latter, a fairly important correction particularly in the transition range, 400°–430° C. To that end the low-temperature portion of the Arrhenius curve extending down to about 300° (Fig. 3) was extrapolated as accurately as possible into the region of homogeneous decomposition and the approximate k_s thus obtained were subtracted from the measured k_e above 400° C. Because of the mutual interference of the two

decomposition processes this correction yields only a first approximation. However, no significant improvement was obtained after iteration. The recalculated rate constants for three different reaction vessels are given in Table II, from which it is seen that the average activation energy for the homogeneous process alone, $E = 48 \pm 3$ kcal., agrees well with the above value of $D(\text{HO}-\text{OH})$. The graph in Fig. 6 shows that in our experi-

FIG. 6. Fraction of hydrogen peroxide vapor decomposing homogeneously at various temperatures in 2-liter flasks.

ments the decomposition was homogeneous to the extent of about 60% at 400° C. and 90% at 450° C. in 2-liter vessels. Obviously the uncertainty here is greater than for the original data. The results for the decomposition of deuterium peroxide were not numerous enough for similar calculations; at any rate expected difference between the dissociation energy of the two isotopic molecules (about 1 kcal.) is well within the accuracy of our measurements.

In the above reasoning a number of minor points have been overlooked, such as the following two, for instance: (a) The transition state theory of unimolecular reactions (26) predicts that the observed activation energy will be greater than the corresponding bond energy by RT , i.e. some 1.5 kcal. in our case. (b) The decomposition of gaseous hydrogen peroxide is exothermic by about 26 kcal. at 400°–500° C. Now, assuming that convection is unimportant, the mean time for establishment of stationary states in peroxide vapor is found to be of the order of half a minute in a 500 ml. flask and 1 minute in a 2-liter flask. Therefore, the self-heating effect becomes appreciable in the higher temperature and pressure ranges, as may be judged from the figures in Table III calculated by the method of Benson (3). This effect, like the previous one, is still within the estimated accuracy of the calculated activation energy.

Substitution of the corrected activation energy 48 kcal. in the Arrhenius equation leads to a frequency factor A near the expected value for a unimolecular reaction 10^{13} .

We are inclined to consider the excellent agreement of our recalculated results with the predictions of the theory as a confirmation that the homogeneous decomposition of

TABLE III
TEMPERATURE GRADIENTS IN THE DECOMPOSITION OF HYDROGEN PEROXIDE VAPOR

Size of vessel	Initial pressure, mm. Hg					
	5		10		15	
	Temperature, ° C.					
	430°	480°	430°	480°	430°	480°
500 ml.	0.25°	1.4°	0.68°	4.3°	1.1°	6.6°
2 liters	0.64°	3.6°	1.7°	11°	2.7°	17°

hydrogen peroxide vapor proceeds mainly, if not exclusively, through initial splitting into OH radicals followed by fast, non-chain reactions. Any appreciable contribution from chains would imply higher rates than those observed. In point of fact this constitutes stronger evidence against a chain mechanism than the few tests mentioned above. Thus the negative effect from a threefold increase of the surface-to-volume ratio (Fig. 3) could be explained if chains were initiated *and* broken on the surface. Likewise, the failure of such standard chain inhibitors as nitric oxide and propylene (Table I) is of no definite significance here because so little is known of the reactions of these molecules with hydrogen peroxide.

According to the theory of simple unimolecular reactions (27) the specific reaction rate at a given temperature approaches a constant value k_{∞} at a certain limiting value of the concentration or pressure, as shown in Fig. 5. (As explained before these curves do not fall off steadily at lower pressures because of increasing relative importance of the surface reaction.) Now a rough estimate of this upper-limit pressure may be made from the relationship derived by Benson (2) between the average rate of decomposition $\bar{k}(\epsilon)$ and the normal vibration frequencies of the activated complex ($\bar{\nu}$). Using for the latter some plausible averages, around 1000 cm^{-1} as in most bond-breaking reactions, we find, for the present case, $\bar{k}(\epsilon) = 3.1 \times 10^8 \text{ sec}^{-1}$ at 475° C . The collision frequency z^0 at that temperature being $3 \times 10^{-10} \text{ sec}^{-1}$ and the number of molecules per unit volume $N^0 = 1.3 \times 10^{16} \times p$, the limiting pressure is found to be

$$p = 3 \times 10^8 / 1.3 \times 10^{16} \times 3.1 \times 10^{-10} = 75 \text{ mm. Hg.}$$

A short extrapolation of the curves in Fig. 4 confirms that this result is roughly of the right order of magnitude. Because of the experimental difficulties involved we have not yet succeeded in checking that point.

In conclusion the above results emphasize the futility of attempting to measure the purely homogeneous decomposition of hydrogen peroxide at ordinary temperature. From the rate equation for the thermal reaction it is clear that in the complete absence of catalysts and high-energy radiation hydrogen peroxide would be indefinitely stable at moderate temperatures (average life of the order of 10^7 years at 100° C .).

RÉSUMÉ

On a mesuré la vitesse de décomposition du peroxyde d'hydrogène à l'état gazeux dans un système statique sous des pressions allant de 0.2 à 20 mm. de mercure et dans l'intervalle de température entre 300° et 600° C . La réaction était toujours du premier ordre et les seuls produits étaient la vapeur d'eau et l'oxygène. Au-dessus de 400° C . et

dans des récipients de verre soigneusement nettoyés la réaction homogène l'emportait sur la réaction de surface, et l'énergie d'activation passait brusquement de 10 ou 12 kcal. à environ 43 kcal. En corrigeant les résultats expérimentaux pour la décomposition catalytique on arrive à l'expression

$$k = 10^{13} \exp(-48000/RT) \text{ sec.}^{-1}$$

pour la réaction homogène entre 400° et 500° C. et sous des pressions supérieures à 10 mm. L'énergie d'activation ainsi obtenue est à peu près égale à l'énergie de dissociation de la liaison O—O. Le peroxyde de deutérium se décompose à la même vitesse que le peroxyde d'hydrogène dans les mêmes conditions. Les résultats peuvent s'expliquer adéquatement par une suite de réactions élémentaires, sans chaînes.

ACKNOWLEDGMENTS

The authors are grateful to their colleagues Prof. C. Ouellet and Dr. P. Ausloos for many helpful discussions, and to Dr. F. Lossing and Miss F. Gauthier from the National Research Council, Ottawa, for the mass spectrometric analyses.

SURFACE STUDIES USING ION EXCHANGE AUTOCHROMATOGRAPHY¹

RUTH E. KREHBIEL² AND J. W. T. SPINKS

ABSTRACT

In order to investigate surface exchange phenomena in detail, a new method, the method of ion exchange autochromatography, has been developed. Its application to the study of finely divided precipitates of strontium sulphate is described.

INTRODUCTION

The heterogeneous exchange between the ions on the surface of an ionic crystal and the ions in a solution has been widely used as the basis for a radioactive method for determining the "active" surface area of finely divided solids (for recent summaries see 7, 17). Tracers isotopic with either the cation or the anion of the crystals may be used and should, on the basis of simple theory, yield the same calculated surface area. This is indeed the case in experiments in which doubly labelled saturated PbSO_4 solutions are shaken with PbSO_4 precipitates, but is not the case when saturated solutions containing $\text{Sr}^{90}\text{S}^{35}\text{O}_4$ are shaken with SrSO_4 precipitates (9, 12). For the latter, the apparent areas, as determined using Sr^{90} ion and $\text{S}^{35}\text{O}_4^{=}$, are in the ratio of about 2:1. If one wished to investigate examples of this behavior, in which however the differences were less marked, it would be possible to improve the procedure by shaking the same doubly labelled solution with successive fresh portions of precipitate. In this way small differences would be amplified as in successive batch extractions. Such successive batch extractions are often more conveniently carried out in a column, as in column chromatography.

Ion exchange chromatography is, of course, already a well established technique and has led to such accomplishments as the separation of rare earth elements by Spedding and his co-workers (10) and the development, on the theoretical side, of a theory of partition chromatography based on the equilibrium stage concept (4) which has since been applied to ion exchange chromatography (6, 16).

Typical ion exchange resins have yielded very high values for the number of theoretical plates per unit length of column (E. G. Dowex 50; 100 plates per cm. in Ref. 1).

Marked isotope effects have been observed for hydrogen (2), carbon (8), sodium (1), lithium (13), potassium (13), and nitrogen (11), the column experiments of Spedding, Powell, and Svec with nitrogen being particularly striking.

The application of the chromatographic method to the present problem leads to *ion-exchange autochromatography*, in which the solute in the eluant and the material of the column packing are identical. Thus in the present experiments a column of SrSO_4 precipitate is eluted with saturated doubly labelled SrSO_4 solution.

EXPERIMENTAL

Materials and Methods

Radioactive strontium.— Sr^{89} was obtained as strontium carbonate from the Atomic Energy of Canada Ltd.; activity, 0.41 mc. in 2.63 g. SrCO_3 .

Radioactive sulphur.— S^{35} was obtained as carrier free sulphuric acid in dilute HCl solution from the Atomic Energy of Canada Ltd.; specific activity, 0.5 mc. per ml.

²Present address: National Research Council, Ottawa, Canada.

Preparation of radioactive $\text{Sr}^{89}\text{S}^{35}\text{O}_4$ precipitate and saturated solution.—The 2.63 g. $\text{Sr}^{89}\text{CO}_3$ was dissolved in 50 ml. dilute hydrochloric acid solution. Two milliliters of this solution was added to a mixture of 200 λ active sulphuric acid solution in 5 ml. 0.18 N H_2SO_4 solution in a centrifuge tube. The tube was heated in a boiling water bath for 30 minutes. At the end of this time the mixture was centrifuged, the supernatant decanted, and the precipitate washed five times with water. The active $\text{Sr}^{89}\text{S}^{35}\text{O}_4$ precipitate was then transferred to a glass stoppered liter flask, filled with distilled water. The solution was shaken at intervals over a period of 3 days at room temperature (25°C .), after which time the specific activity of the solution remained constant and the solution was assumed to be saturated.

Preparation of inactive SrSO_4 precipitate.—Two hundred and ten grams of $\text{Sr}(\text{NO}_3)_2$ was dissolved in 750 ml. distilled water, heated to 60°C ., and filtered. To this hot solution was added, with stirring, 120 ml. hot 9 M H_2SO_4 solution and the resulting mixture was gently boiled for 20 minutes. Three portions of SrSO_4 precipitate, prepared in this way, were combined and washed with 10 successive 3 liter portions of distilled water. The precipitate was then transferred to a wide mouthed, glass stoppered bottle and allowed to age 1 week before use. In a shaking type exchange experiment, this precipitate showed the type of behavior described by Singleton and Stow (9, 12).

Description of column.—The column was made of Pyrex glass, 31 cm. long, with an inner diameter of 12 mm. Surrounding the column was a water jacket of outer diameter 22 mm. The bottom of the column was joined to a 24/40 ground-glass joint. A sintered glass disk of fine porosity was sealed into the upper end of a corresponding 24/40 ground-glass joint, the bottom of which was tapered to fit a hole in a rubber stopper. The joint facilitated both the extrusion of the material in the column and the cleaning of the column.

Measurement of radioactivity.—Activities of samples were measured using an end window type geiger tube, window thickness 3.5 mg./sq. cm., and scaler (Nuclear Instrument and Chemical Co. model 165), with the usual corrections being made for background. Standard aluminum counting dishes, 3.1 cm. diameter, were used in a fixed geometry. In each case, 2 ml. of the solution to be counted was pipetted into the dish and evaporated by means of a heat lamp. Since the solubility of SrSO_4 is only 0.110 g. per liter, a negligible weight of precipitate remains and self-absorption can be neglected. Each sample was counted twice, once to get the combined activity of Sr^{89} and S^{35} and again through a 21.2 mg./cm.² aluminum absorber. This was found experimentally to stop all the sulphur radiation* but transmitted 82% of the strontium radiation, and it was then possible to calculate what the separate activities of both strontium and sulphur would be in the absence of the absorber.

General Experimental Procedure (3)

The column was fitted by means of a one-holed rubber stopper to a 500 ml. suction flask and clamped in an upright position. The wet precipitate was poured into the column and packed by means of suction applied to the flask. When the liquid head above the precipitate had just disappeared, the suction was discontinued and a suitable volume of saturated SrSO_4 solution, labelled in both the Sr^{++} and $\text{SO}_4^{=}$, was added at the top of the column and drawn through the column by suction. Following this, successive additions of 5 ml. portions of inactive saturated solution were made. The eluate was collected in 5 ml. portions in test tubes.

*The range for S^{35} is greater than 21 mg./cm.² Part of the stopping is due to the counter window and a small thickness of air.

Two milliliters of each eluate fraction was measured into a counting dish and evaporated for counting. The measured activities were plotted as the per cent of the activity in a 2 ml. sample of the original saturated active solution added to the column, versus the total volume eluted.

In some experiments the distribution of the activity on the column was determined. After the passage of the active solution through the column, the column material was extruded and cut into slices. The slices of precipitate were placed on counting dishes, and dried and counted. The measured activities were corrected for self-absorption using a correction curve. A self-absorption curve was determined by successively adding layers of active precipitate to counting dishes; each time the precipitate was dried, weighed, and both S and Sr were counted. The results were plotted as activity against precipitate weight. It was found that for sulphur the count remained constant for a precipitate weight of 0.4 g. or more in a dish 3.1 cm. in diameter. This meant that any sample over 0.4 g. in weight constituted an infinitely thick sample for counting sulphur activity. The strontium count rose only slowly relative to precipitate weight after about 2 g.

The self-absorption curve was then converted to a correction curve (Fig. 1) in which the activity at 2.70 g. precipitate weight was arbitrarily taken to be 100% and the other points were plotted relative to it. Activities of column slices were then corrected to the standard 2.70 g. weight.

Several experiments were also carried out at elevated temperatures. This was accomplished by pumping water from a constant temperature bath through the jacket surrounding the column, and proceeding with the rest of the experiment in the manner already described.

Results for a Typical Elution Experiment

In a typical elution experiment the column was packed with SrSO_4 precipitate to a height of 11 cm. Fifty milliliters of active saturated solution was then added to the column and drawn through by suction applied to the arm of the flask. The 50 ml. resulting eluate was discarded. The column was next eluted with 210 ml. inactive saturated SrSO_4 solution. The inactive solution was added 5 ml. at a time with a pipette. The eluate was collected in 5 ml. portions in test tubes placed in the suction flask, the pump being disconnected after each 5 ml. had passed through the column. The average flow rate

FIG. 1. Correction curve relating measured activity to activity for a standard precipitate weight of 2.7 g.; ●, Sr; ○, S.

FIGS. 2 and 4. Elution curve for strontium sulphate; sample activity as per cent of original specific activity versus total effluent volume (25° and 36° C. respectively): $\bullet$, Sr; $\circ$, S.

FIGS. 3 and 5. Distribution of Sr^{89} and $\text{S}^{35}\text{O}_4^{2-}$ on a column of precipitated strontium sulphate (25° and 36° C. respectively): $\bullet$, Sr; $\circ$, S.

through the 11 cm. column was 0.56 ml./minute. The temperature of the column was 25° C. Two milliliters of the 5 ml. sample was pipetted into an aluminum counting dish and evaporated under a heat lamp. The dried samples were then counted both for total activity and Sr activity using the 21.2 mg./cm.² absorber. Two milliliters of the original solution was also counted for S^{35} and Sr^{89} activity. The counting time was 10 minutes for each sample. The results are given in Fig. 2 in which the activities of the effluent samples are plotted as per cent of original specific activity versus total effluent volume.

The 11 cm. of precipitate was extruded from the column using a rubber disk, which fitted the inside of the column, and a glass rod. The wet precipitate was weighed, dried at 110° C., and weighed again. From this it was determined that the free volume in the column was 8.75 ml. and that the precipitate dry weight was 17.89 g.

Results for a Typical Extrusion Experiment

The conditions of the above experiment were closely approximated to determine the distribution of the activities on the column. Fifty milliliters active solution was added to an 11 cm. column of precipitate at 25° C. The flow rate through the column was 1 ml./minute. The column was then rapidly washed with 10 ml. distilled water to remove most of the activity not adsorbed on the column.

The column was then extruded, and the precipitate sliced, dried, weighed, and counted as described earlier. Using Fig. 1, the measured activity of each sample was corrected to the activity which would have been obtained if the sample weight had been 2.70 g. The sulphur counts were also multiplied by 6 to make them comparable to the strontium counts. The results are plotted in Fig. 3 as activity of the slice of precipitate versus cumulative weight of precipitate, zero weight indicating the top of the column.

Experiments at 36° C.

The ordinary elution experiment was also carried out at a somewhat higher temperature by the circulation of water from a constant temperature bath through the jacket surrounding the column.

The results of an experiment carried out at 36° C. are plotted in Fig. 4. In this case 50 ml. active solution and 130 ml. inactive solution were passed through the 11 cm. column at a flow rate of 0.63 ml./minute.

The free volume of the column was 8.10 ml. and the precipitate weight was 19.68 g.

The distribution of activity on the column was also determined at 36° C. Again 50 ml. active solution was passed through an 11 cm. column, and the column was washed with 10 ml. distilled water.

The results are plotted in Fig. 5.

Remarks Concerning Additional Experimental Results

A total of 22 elution experiments were carried out and all displayed the characteristic trend of the $\text{S}^{35}\text{O}_4^{=}$ appearing in the eluate before the Sr^{89} ion and the sulphur reaching its activity peak before the strontium. In the extrusion experiments the strontium activity was always concentrated closer to the top of the column than the sulphur activity.

DISCUSSION

The foregoing elution experiments confirm the earlier evidence of Singleton (9) and Stow (12) that the exchange properties of Sr^{++} and $\text{SO}_4^{=}$ ions in the surface of a SrSO_4 precipitate are different. The separation of $\text{S}^{35}\text{O}_4^{=}$ and Sr^{89} in a typical elution experiment was demonstrated conclusively.

In all elution experiments, the S activity appeared before the Sr activity in the eluate. Also, the Sr^{++} was adsorbed closer to the top of the column than was the $\text{SO}_4^{=}$ ion. These results are qualitatively in agreement with the amount of exchange as determined by Stow, Singleton, and Spinks, the strontium being adsorbed more strongly than the sulphur.

Attempts to analyze the problem quantitatively have not proved very successful. From the general similarity of the present experiments to column chromatography it is tempting to apply the theory developed for resin columns (6, 14, 15). However, an exact application of the theory is out of the question since, owing to the limited solubility of SrSO_4 , 5.6 column volumes (50 ml.) were used to dissolve the radioactive sample whereas

a negligibly small sample should be used. Thus the quantitative values for the number of theoretical plates, based on this analogy, are not of much value (from Fig. 2, 11.9 plates for sulphur and 17.2 plates for strontium).

The equilibrium distribution coefficients between solutes and resin can ordinarily be used to calculate the positions of the elution peaks. In Fig. 2, the ratio of the peak volumes is $14.8/12.2 = 1.21$, which is much smaller than the ratio of the distribution coefficients reported earlier (approximately 1.9 (12)). However, this discrepancy might well be due to the fact that the precipitates used were made at different times and might, therefore, have had somewhat different surface properties. The same explanation would also account for the fact that the peaks occur much earlier than one would have expected from the equilibrium values.

The elution curves are not completely symmetrical but show instead a considerable tail as compared to published curves for substances such as the rare earths adsorbed on resins (5). According to theory, the curves become the more symmetrical the closer the approach to equilibrium conditions, and it would thus seem that the present experiments were carried out under non-equilibrium conditions. The upper limit to the flow rate used was determined by the pressure which could be applied in our particular experiments. Most experiments were carried out near this upper limit as a matter of expediency since it enabled one to complete an experiment in the course of a day. Any considerable lowering of the flow rate, say by a factor of 10, would have lengthened the experiment unreasonably.

Actually, equilibrium experiments (9, 12) have shown that surface exchange is virtually complete within a few minutes so that the major cause of this asymmetry cannot reasonably be attributed to non-equilibrium conditions across the film of liquid adjacent to the crystal surface. It may, however, be due to the superimposed slower exchange involving ions within the bulk of the crystal (possibly in cracks or other surface defects). Previous equilibrium studies (see Fig. 1, Ref. 12) have indicated that under the present experimental conditions a very appreciable fraction (25% or more) of the radioactive ions may become involved in the latter type of exchange. Since this process is very slow, it could account qualitatively for the very pronounced "tail" in the elution curves. The anomalous effect of increase in temperature is in qualitative agreement with this; increasing the temperature increases the fraction of ions penetrating the bulk of the crystal and hence broadens the elution peaks as observed. (This is opposite to the usual effect where increasing the temperature causes the ion exchange column to operate closer to equilibrium and hence increases the number of theoretical plates (15).)

Complete separation of all the Sr^{89} and all the $\text{S}^{35}\text{O}_4^-$ was not obtained, although the first fraction of $\text{S}^{35}\text{O}_4^-$ coming through was free from Sr^{89} . This result is to be expected from the mathematical considerations of a column (5). There always will be some overlapping between the elution curves since the column must be infinitely long to secure complete separation. The degree of separation will be dependent on the difference in equilibrium distribution coefficients.

It would be desirable to do experiments, using high specific activity SrSO_4 , which might be expected to parallel the resin column experiments more closely.

By using two separately measurable isotopes of the same element, isotope separation occurring in surface exchange phenomena could also be studied and might be expected to be of considerable theoretical (and possibly practical) importance. It would seem that situations parallel to the above experiments must occur quite often in nature and would lead to appreciable isotopic fractionation.

THE OLEFINIC BOND IN GELSEMINE¹

LÉO MARION AND K. SARGEANT²

ABSTRACT

The readily reducible double bond of gelsemine has been shown to be present in a vinyl side chain and not in an exocyclic methylene group as had been previously assumed. Oxidation of the olefinic double bond in N(a)-methylgelsemine with sodium metaperiodate in the presence of a catalytic amount of osmium tetroxide gave an aldehyde having one carbon less than the starting material. That the product was an aldehyde and not a ketone was proved (a) by conversion to an oxime which was readily dehydrated to a nitrile, and (b) by Wolff-Kishner reduction to a compound containing a C—CH₃ group not present in the aldehyde itself.

The presence in gelsemine of one readily reducible double bond was first reported by Chu and Chou (1), who prepared dihydrogelsemine. Gibson and Robinson (2) have shown by the Kuhn-Roth method that dihydrogelsemine contains a C—CH₃ group, whereas gelsemine contains no such group. They concluded that an exocyclic methylene group was present in the alkaloid. Later Goutarel, Janot, Prelog, Sneed, and Taylor (3) obtained formaldehyde on ozonolysis of gelsemine and interpreted this as confirming the conclusion of Gibson and Robinson. The exocyclic methylene group has since been generally accepted.

At a meeting of the American Chemical Society, Dr. E. Wenkert first questioned the validity of the conclusion drawn by Gibson and Robinson (2) and mentioned observations in his laboratory indicating that the olefinic double bond of gelsemine could well be present in a vinyl group. This prompted a re-examination of the problem.

The infrared absorption spectrum of gelsemine contained two absorption peaks, one at 991 cm.⁻¹ and the other at 909 cm.⁻¹, that could be attributed to a vinyl group. The spectrum of dihydrogelsemine no longer contained a band at 909 cm.⁻¹ but showed a sharp peak at 996 cm.⁻¹. It is therefore difficult to decide unequivocally the nature of the substitution about the double bond from the infrared evidence, since only one of the two bands seems to disappear on removal of the olefinic bond. On the other hand, the presence in dihydrogelsemine of a C—CH₃ which is absent in gelsemine (2) and the formation of formaldehyde in the ozonolysis of the alkaloid (3) are both compatible with either an exocyclic methylene group or a vinyl side chain. We now wish to place on record experiments which afford a rigorous proof of the presence of a vinyl group in gelsemine.

The nuclear magnetic resonance spectrum of dihydrogelsemine showed a triplet peak which was absent in that of gelsemine. Were an exocyclic methyl group present in the former compound instead of an ethyl group, a doublet would have been observed. Furthermore, the oxidation of dihydrogelsemine with chromic acid according to the method of Lemieux and Purves (5) gave rise to a mixture of acetic and propionic acids.³ The production of propionic acid indicates the presence of an ethyl group in dihydrogelsemine.

In view of these preliminary indications of the presence of a vinyl side chain in the

³This oxidation, separation of the acids by chromatography on Celite, and characterization of the acids by the infrared spectra of their sodium salts in potassium bromide pellets was kindly carried out by Dr. R. U. Lemieux and Mr. J. P. Barrette at the University of Ottawa.

alkaloid, an attempt was made to isolate the basic residue remaining after scission of the olefinic linkage.⁴ Use was made of a recently introduced simplification of the older method of oxidation with osmium tetroxide. It has been shown by Pappo, Allen, Lemieux, and Johnson (6) that sodium metaperiodate, in the presence of catalytic amounts of osmium tetroxide, may be used to cleave olefinic linkages under mild conditions. Application of the method of oxidation to N(a)-methylgelsemine ($C_{21}H_{24}O_2N_2$) gave in good yield a new compound ($C_{20}H_{22}O_3N_2$) having lost CH_2 and containing one more oxygen. The infrared absorption spectrum of N(a)-methylgelsemine (Fig. 1, curve 1) contained

FIG. 1. Infrared absorption spectra of 1, N(a)-methylgelsemine; 2, the aldehyde derived from it; 3, the corresponding nitrile.

a band at 1702 cm^{-1} attributable to the oxindole carbonyl and bands at 911, 988, and 1645 cm^{-1} due to the olefinic linkage. The infrared absorption spectrum of the oxidation product (Fig. 1, curve 2) contained two bands in the carbonyl region, at 1702 cm^{-1} and at 1719 cm^{-1} , attributable one to the oxindole carbonyl, the other to a newly formed carbonyl; further, there were no bands corresponding to those of an olefinic linkage,⁵ but there was a sharp peak at 2735 cm^{-1} which is characteristic of the C—H stretching of an aldehyde group.

⁴A preliminary account of the results has been published in *J. Am. Chem. Soc.* **78**, 5127 (1956).

⁵As in the spectra of other dihydro derivatives of gelsemine, however, there was an unaccountable absorption band at ca. 990 cm^{-1} , i.e., a double peak at 982–994 cm^{-1} .

Chemical evidence that the oxidation product ($C_{20}H_{22}O_3N_2$) was an aldehyde was soon forthcoming. The product was converted into an oxime ($C_{20}H_{23}O_3N_3$) which, on treatment with acetic anhydride and pyridine for several hours, yielded the corresponding nitrile ($C_{20}H_{21}O_2N_3$). The infrared absorption spectrum of this nitrile (Fig. 1, curve 3) contained a band at 1711 cm^{-1} due to the oxindole carbonyl, and a very sharp band at 2255 cm^{-1} characteristic of the $C\equiv N$ vibration. The production of a nitrile under such conditions shows undoubtedly that the oxime was derived from an aldehyde.

Additional proof of the aldehyde nature of the oxidation product was obtained by its Wolff-Kishner reduction. This reaction gave rise to a compound ($C_{20}H_{24}O_2N_2$) which, by the Kuhn-Roth determination, was shown to contain a $C-CH_3$ group, whereas no such group could be detected in the oxidation product. In this reaction, such a group could be generated only by reduction of an aldehyde. The infrared absorption spectrum of the Wolff-Kishner reduction product ($C_{20}H_{24}O_2N_2$) showed a band at 1707 cm^{-1} due to the oxindole carbonyl, but the second carbonyl band and the band at 2735 cm^{-1} present in the spectrum of the oxidation product had disappeared.

It is possible, therefore, to conclude unequivocally that the readily reducible bond in gelsemine is present in a vinyl side chain.

A comparison of the basic strengths of the various products described with those of N(a)-methylgelsemine and dihydrogelsemine is revealing. There is a drop of pK_a in going from N(a)-methylgelsemine (7.25) to the aldehydic compound (6.15) of 1.1 units, and in going from the latter to the nitrile (4.95) of a further 1.2 units. On the other hand, the Wolff-Kishner reduction of the aldehyde gives a product with a pK_a of 7.65, which is the same as that of dihydrogelsemine. The marked effect on the basic strength caused by changing the vinyl group first to an aldehyde, then to a nitrile, and finally to a methyl shows that the vinyl side chain must be located relatively close to the basic nitrogen N(b).

EXPERIMENTAL

All infrared absorption spectra were taken with nujol mulls on a Perkin-Elmer double beam spectrophotometer, model 21B, using a sodium chloride prism. The specific rotations were measured in chloroform solutions and the pK_a values determined in 80% ethanol solutions.

Oxidation of N(a)-Methylgelsemine

N(a)-Methylgelsemine was prepared from gelsemine as described by Goutarel, Janot, Prelog, and Sneed (4), m.p. $140-141^\circ$, pK_a 7.25. A solution of N(a)-methylgelsemine (2.0 g.) in dioxane (50 ml.) and water (15 ml.) was stirred with osmium tetroxide (50 mg.) and after half an hour finely powdered sodium metaperiodate (2.65 g.) was added to the dark mixture in small lots in the course of a half-hour (6). The solution became pale yellow and a colorless precipitate separated. Stirring was continued for 1.5 hours and water (100 ml.) was added. This produced a clear solution which was extracted with chloroform and the extract evaporated to dryness. It left a black residue which was redissolved in chloroform. This solution was extracted with hydrochloric acid, and the extract made basic and extracted with chloroform. This last extract yielded a basic fraction that crystallized readily from a mixture of acetone and *n*-hexane as colorless plates, wt. 1.3 g., m.p. $192-194^\circ$. A further quantity (0.2 g.) of less pure material, m.p. $186-190^\circ$, was obtained from the mother liquors. An analytical sample was recrystallized twice from the same mixture, m.p. $192-194^\circ$, $[\alpha]_D -16.3^\circ \pm 1.4^\circ$ (*c*, 2.09), pK_a 6.15. Found: C, 71.10; H, 6.62; N, 8.53; N.CH₃, 8.61%. Calc. for $C_{20}H_{22}O_3N_2$: C, 70.98;

H, 6.55; N, 8.28; $2N\cdot CH_3$, 8.88%. A Kuhn-Roth determination of $C-CH_3$ was nil. Infrared, Fig. 1, curve 2.

Preparation of an Oxime

Hydroxylamine hydrochloride (150 mg.) in methanol (15 ml.) and water (5 ml.) was added to a solution of the aldehyde described above (250 mg.) in methanol (10 ml.), and the clear solution was heated under reflux in the presence of suspended sodium bicarbonate (400 mg.) for 18 hours. Evaporation to dryness left a residue, the chloroform soluble portion of which separated from methanol as colorless prismatic needles, wt. 224 mg., m.p. 267–268°. Recrystallization from the same solvent did not improve the melting point. Found: C, 68.21; H, 6.75; N, 11.81%. Calc. for $C_{20}H_{23}O_3N_3$: C, 67.97; H, 6.56; N, 11.89%.

Dehydration of the Oxime to a Nitrile

A solution of the oxime (500 mg.) in acetic anhydride (15 ml.) and pyridine (0.5 ml.) was kept at 100° for 18 hours. The solvent was removed under reduced pressure and the residue chromatographed on alumina (Woelm, Grade III, neutral, 30 g.) from a benzene solution. The product was eluted with benzene-ether mixtures. It separated from a mixture of acetone and *n*-hexane as colorless plates, wt. 134 mg., m.p. 238–240°. After two recrystallizations from the same mixture, it melted at 240–241°, $[\alpha]_D -41.0 \pm 0.5^\circ$ (*c.* 2.05), pK_a 4.95. Found: C, 71.57; H, 6.42; N, 12.49%. Calc. for $C_{20}H_{21}O_2N_3$: C, 71.62; H, 6.31; N, 12.53%. Infrared, Fig. 1, curve 3.

Further elution of the alumina column with methanol gave a substance which crystallized from methanol as prismatic needles, wt. 175 mg., m.p. 267–268° either alone or in admixture with the oxime.

Wolff-Kishner Reduction of the Aldehyde

A solution of the aldehyde (500 mg.) in triethylene glycol (10 ml.) and 85% hydrazine hydrate (5 ml.) was heated under reflux at 140° for 2 hours. Sodium hydroxide (500 mg.) was added and the mixture kept at 165° for 1 hour. The condenser was removed, and the temperature raised further to 205° and maintained for 4 hours. The basic material obtained from a chloroform extract of the cooled reaction mixture crystallized from acetone as colorless prismatic needles, wt. 124 mg., m.p. 172–174°. After two recrystallizations from the same solvent, the product melted at 173–175°. $[\alpha]_D +12.1 \pm 1.0^\circ$ (*c.* 2.06), pK_a 7.65. Found: C, 74.19; H, 7.56; N, 8.79; $C-CH_3$, 4.11%. Calc. for $C_{20}H_{24}O_2N_2$: C, 74.04; H, 7.46; N, 8.64; $1C-CH_3$: 4.63%.

ACKNOWLEDGMENT

We are particularly indebted to Dr. R. U. Lemieux, University of Ottawa, who with Mr. J. P. Barrette carried out the oxidation of dihydrogelsemine to propionic acid, and to Dr. W. G. Schneider of these Laboratories for the Nuclear Magnetic Resonance spectra and their interpretation. We also express our gratitude to Mr. R. Lauzon for recording the infrared spectra.

FREE RADICALS BY MASS SPECTROMETRY

XII. PRIMARY STEPS IN THE MERCURY PHOTOSENSITIZED DECOMPOSITIONS OF ACETONE AND ACETALDEHYDE¹

F. P. LOSSING

ABSTRACT

The primary step in the mercury (Hg^3P_1) photosensitized decomposition of acetone at 55°C . results in the formation of methyl and acetyl radicals. At least 25% of the acetyl radicals are sufficiently long-lived to suffer collision with a second excited mercury atom, the products being ketene and a hydrogen atom. The primary step in the decomposition of acetaldehyde is at least 95% to form methyl and formyl radicals. The methane found was shown by tracer experiments to be the product of a secondary reaction, probably that between methyl and formyl radicals. Other secondary reactions are discussed.

INTRODUCTION

Acetaldehyde

Although a great many studies have been made of the direct photolysis of acetaldehyde and acetone, very few experiments on the mercury photosensitized reactions of these compounds have been reported. Using the Paneth technique, the detection of radicals in the mercury photosensitized decomposition of acetaldehyde has been briefly described (23). Cvetanović (7) reported a few experiments on the mercury sensitized decomposition, the products being CO , CH_4 , H_2 , and C_2H_6 . He concluded that CH_3 radicals were undoubtedly a product of the reaction. The quenching cross section of acetaldehyde for Hg^3P_1 atoms was found (6) to be 29 (relative to *n*-butane equal to 3.6). In the absence of other reported data it is of interest to review briefly the results of direct photolysis experiments. These results have been discussed recently by Steacie in some detail (21). Three primary processes have been proposed:

There appears to be ample evidence that free radicals are produced in the reaction. Using the mirror technique, the presence of radicals in the direct photolysis has been clearly demonstrated. By this means, Pearson and Purcell (20) identified the radicals as methyl, and concluded that at 100°C . fewer methyl radicals were produced than from acetone under the same conditions. This would be consistent with a part of the reaction proceeding by reaction [2] although the calculation is probably not very reliable. Volman *et al.* (23) showed that radicals were produced at wavelengths from 2537 Å to 3130 Å.

A number of workers have studied the photolysis in the presence of iodine on the assumption that the ratio of methyl iodide to methane in the products would give the ratio of the quantum efficiencies of reactions [1] and [2]. In this way Gorin (11) found the sum of the quantum yields to be about 1 at 2537 Å and 3130 Å although the ratio of efficiencies changed from 1/2.9 at 2537 Å to 2.6/1 at 3130 Å. A re-examination of the photolysis in the presence of iodine by Blacet and co-workers (2, 3) led to the different conclusion that at 3130 Å $\Phi_{\text{CO}} \approx \Phi_{\text{CH}_3\text{I}} = 0.20$ and $\Phi_{\text{CH}_4} \approx 0.013$, and that reaction [1]

Issued as N.R.C. No. 4238.

predominated. At shorter wavelengths $\Phi_{\text{CH}_3\text{I}}$ rose slightly and Φ_{CH_4} increased greatly, the latter becoming almost equal to $\Phi_{\text{CH}_3\text{I}}$ at 2380 Å. This work indicated a significant increase in the efficiency of reaction [2] at shorter wavelengths. Later work on the iodine inhibited photolysis of acetone (17) suggested that iodine may deactivate excited acetaldehyde molecules. This interpretation of the results of Buchanan (4) has been suggested by Steacie (21), who concluded that the interpretation of the results of photolysis in the presence of iodine becomes a matter of some complexity, and that these experiments do not give the relative efficiencies of reactions [1] and [2] in the absence of iodine.

From experiments using deuterioacetaldehyde, Zemaný and Burton (24) concluded that free radicals were certainly produced, but that a small amount of decomposition into CH_4 and CO occurred as well. Blacet and Brinton (1), using CH_3CDO , showed that the isotopic composition of the methane produced approached that corresponding to the intramolecular reaction [2] as other methane-producing reactions were suppressed by iodine.

Recently, work by Calvert, Pitts, and Thompson (5) showed that at 3130 Å the limiting quantum yield of reaction [1] at high temperatures is about 0.8. They suggested that the quantum yield of 0.2 found for this process in the iodine-inhibited photolysis might correspond to an excited state of acetaldehyde which dissociated in one of its first vibrations, and hence would not be quenched by iodine. Other longer-lived states formed could lead to radical formation in the absence of iodine. Their results set an upper limit of about 0.20 for the primary efficiency of reaction [2].

From flash photolysis experiments, Khan, Norrish, and Porter (13) concluded that the products formed from acetaldehyde corresponded to $\leq 46\%$ of [1], 43% (or more) of [2], and 11% of [3].

On the whole there is considerable evidence that reaction [2] may occur to a significant extent in the photolysis at 2537 Å, although there is some question as to the interpretation of the results.

Acetone

A few experiments on the mercury photosensitized decomposition of acetone were described by Steacie and Darwent (22) from which they concluded that the mechanism was similar to that of the direct photolysis. The quenching cross section of acetone for Hg^3P_1 atoms was measured by Darwent, Phibbs, and Hurtubise (8) to be $32 \times 10^{-16} \text{ cm}^2$, almost the same as that of propylene ($31 \times 10^{-16} \text{ cm}^2$) and slightly less than that of isobutene ($37 \times 10^{-16} \text{ cm}^2$). Cvetanović (6) found a slightly higher value.

McNesby, Gordon, and Smith (16) reported that no hydrogen was formed in the mercury photosensitized decomposition, and that the possible primary step

could be ruled out.

Some preliminary experiments were reported recently from this laboratory (10) in which methyl and acetyl radicals were detected in the mercury photosensitized decomposition of acetone using mass spectrometry.

The direct photolysis of acetone has been the subject of a large number of publications and it appears to be well established that the primary step is entirely a free radical one (19, 21):

The lifetime of the acetyl radical at the shorter wavelengths may be quite short as a result of energy carry-over, and the primary step is then effectively

There appears to be no evidence for intramolecular rearrangements leading to methane or ethane production.

Although the primary processes in mercury photosensitized reactions may not be the same as in the direct photolysis, it was thought that some evidence for the nature of the primary steps would be of interest, and that this might be obtained by direct observation of the radical and non-radical primary products by the use of a mass spectrometer. In particular the ratios of the free radical and the intramolecular rearrangement processes such as

comparable to reactions [1] and [2], might be estimated.

EXPERIMENTAL

The photosensitized reactions were carried out in a reactor attached to a mass spectrometer, the apparatus having been described in detail in a previous publication (14). From the illuminated zone, the reaction products, including radicals, were allowed to enter the ionization chamber of the mass spectrometer and were identified by observation of the mass spectra using low electron energy. Quantitative measurements of the amounts of products formed were made using 50 volt electrons. The sensitivities of the instrument to the stable products and reactants were measured from standard samples using a Consolidated Electrodynamics Corp. micromanometer. Helium was added to the standard samples to bring the total pressure up to that used in the flow system during the decomposition experiments (1 cm. Hg). The sensitivity of methyl radicals was taken as 0.47 of that of methane, as measured previously (15). A correction was made for the formation of methane from methyl in the ionization chamber as was found necessary in earlier work (12). This correction was of importance in measuring the small amount of methane produced in the acetone reaction. In order to find out if this correction was of the same magnitude as found previously, some experiments were made in which CD_3COCD_3 was photodecomposed in the reactor. The methane produced was found to be about one-half CD_3H and the rest CD_4 . After allowing for the small percentage of H atoms present in the sample of deuterioacetone, it was seen that the amount of CD_3H formed was almost exactly $0.1 \times [\text{CH}_3]$ as found earlier (12). This amount must be formed by abstraction from water absorbed on the walls of the ionization chamber. After passing CD_3COCD_3 through the reactor for 1 hour, the amount of CD_3H formed on illumination had decreased appreciably, presumably as a result of deuterization of the adsorbed water. On returning to CH_3COCH_3 a small temporary formation of CH_3D was observed. This experiment shows that the correction used for the methane production was of the right magnitude.

The Reactor and Its Operation

A schematic representation of the reactor is given in Fig. 1. For convenience, the axis of the reactor is shown as being horizontal rather than vertical. The reactant, at a partial

FIG. 1. Schematic diagram of reactor.

pressure of less than 10 microns, was carried in a stream of helium saturated* with mercury vapor at 55° C. The extent of decomposition and the composition of the products were determined by comparing the mass spectra obtained in the presence and absence of irradiation. In order to aid in distinguishing between primary and secondary products, use was made of a movable shutter surrounding the reactor. The length of the illuminated zone, and consequently the contact time, could in this way be varied conveniently. The relation between the extent of reaction (Δ) and the length of the illuminated zone can be understood by reference to Fig. 1. The concentrations of reactant and products are, of course, those existing at the tip of the leak (point A). With the end of the shutter at position B, a small amount of 2537 Å radiation could enter the reactor obliquely between the shutter and the water jacket. For this reason a small amount of reaction was found to occur when the measured length of the illuminated zone was zero. As the shutter is withdrawn toward position C, the amount of reactant decomposed should follow an almost linear relation with length, as shown by the line X. The concentration of a radical might be expected to follow a relation roughly like that of line Y, its shape depending on the mechanism of removal of the radical. This line could be above the line X for part of the course if, as in acetone, two methyl radicals were ultimately produced for one molecule decomposed. Both of these lines should extrapolate roughly to the point B. The product of the combination of radicals should follow a relation such as that shown by line Z. However, the contact time available for combination and abstraction steps is not that corresponding to the length BC, but that corresponding to the length AC. For this reason the line Z may not extrapolate to point B for fast bimolecular reactions but would have an apparent origin at point A. The interpretation of the data would have been simplified had it been possible to design a reactor in which the distance AB was zero. Owing to the considerable dimensions of the movable water jacket and the ion source, it was not possible to make the distance AB less than 1.5 cm. with the design used.

At the flow rate used in this work, the contact time corresponding to a 10 mm. length of reactor was 0.34 millisecond at 55° C.

Some difficulty was encountered, in the case of acetone, with the formation of an opaque deposit on the walls of the reactor. This caused a decrease in the extent of de-

*The completeness of saturation was doubtful.

composition during the time taken to scan the spectrum of the reaction products. To avoid this difficulty the partial pressure of acetone had to be reduced to less than 2μ , at which pressure the effect was not too serious.

Materials

The acetone and acetaldehyde used were Eastman Kodak White Label products. After these were thoroughly outgassed, the mass spectra showed no sign of impurities. The acetone- d_6 was supplied by Merck and Company (Canada). From the mass spectrum the sample was found to be 98 mole % of acetone- d_6 . The deuterioacetaldehyde was prepared by Dr. L. C. Leitch. It contained 91 mole % of CD_3CDO . The standard samples used for sensitivity measurements were cylinder gases purified where necessary. The ketene standard was the gift of Mr. J. Shoosmith.

RESULTS AND DISCUSSION

Acetone

Using low energy electrons for detecting radicals (9), methyl radicals in considerable abundance were found among the products of the mercury photosensitized decomposition of acetone. With higher pressures of acetone, acetyl radicals (mass 43) and biacetyl (mass 86) were also detectable (10). Other products identified using low energy electrons were carbon monoxide, ethane, ketene, and a trace of methane. The amounts of acetone decomposed and of products formed with the shutter in different positions were determined from the 50 volt mass spectra. These data are given in Table I. The low carbon

TABLE I
DECOMPOSITION OF ACETONE

1.61 ₀	1.48 ₈	9	7.5 ₈	0.12 ₂	0.09 ₀	0.00 ₀	0.11 ₀	0.02 ₄	0.03 ₁	0.02 ₈	99	85	81

and oxygen balances probably result from the formation of the solid material mentioned above. At this pressure of acetone, the amounts of acetyl radicals and biacetyl detected were negligibly small.

The change in composition of the products as a function of the length of the illuminated zone can be seen from Fig. 2. The lines for acetone decomposed and for CO formed do not extrapolate to the measured zero position (*B*, Fig. 1) but to a position 2 or 3 mm. below it. This may be a result of scattered or reflected light entering the reactor below point *B*. It is evident that methyl radicals and CO are the major primary products and that the small amount of methane is produced in a secondary reaction. The presence of significant amounts of ketene and hydrogen is interesting, as they are not found in the direct photolysis. The following modes of formation of ketene may be considered:

FIG. 2. Decomposition of acetone.

Reactions [9] and [10] can at once be eliminated as a source of ketene since the methane yield is too small. The absence of acetaldehyde as a product rules out reaction [11]. The thermal decomposition of the acetyl radical is known to proceed only by

rather than by reaction [12], the quantum yield of CO in the direct photolysis above 100°C . being 1 within the experimental error (19). The remaining possibility, reaction [13], is not improbable under conditions of high concentrations of excited mercury atoms such as exist in the present experiments. A similar reaction between radicals and excited atoms appeared to occur in the photosensitized decomposition of propylene and the butenes (14). Reaction [13] would also explain the formation of hydrogen, which was not a product under the conditions existing in the experiments of McNesby *et al.* (16). It should be noted that the hydrogen yield is approximately twice what would be expected on the yield of one atom per ketene formed. At these low concentrations of H atoms it is possible that all the molecular hydrogen arises from a reaction in the ion source between H atoms and water adsorbed on the walls of the ionization chamber. A similar reaction of methyl radicals is discussed above.

If reaction [13] can be taken as the origin of the ketene, then each ketene molecule represents an acetyl radical which has survived sufficiently long to collide with a second excited mercury atom. In the three experiments given in Table I, the ratio of ketene to acetone decomposed is respectively 0.22, 0.25, and 0.25. Evidently at least 25% of the acetyl radicals formed in the primary step do not carry over sufficient energy to dissociate immediately. Since the amounts of biacetyl and acetyl detected were small,

the remaining 75% of the acetyl radicals formed must dissociate to form $\text{CH}_3 + \text{CO}$ by one or more of the three possible modes:

Noyes and Dorfman (18) concluded that in the direct photolysis of acetone at 2537 Å, 22% of the acetyl radicals formed dissociated immediately by reaction [15]. Since the cross section for reaction [16] is unknown and the rate of reaction [14] at such low pressures is uncertain, the present data do not provide an estimate of the importance of reaction [15] in the mercury photosensitized decomposition of acetone.

The following reactions would account for the composition of the products:

Two other reactions leading to the removal of acetyl radicals may also occur:

There is no evidence for alternative primary steps such as reactions [4] or [9]. This is in agreement with the findings of McNesby *et al.* (16).

Acetaldehyde

Using low electron energies, methyl radicals were found in abundance as a product of the decomposition of acetaldehyde. With higher pressures of acetaldehyde ($>10\mu$) a small increase in the mass 29 peak was detected and may be attributable to the CHO radical. The formation of ethane in large amounts caused interference at mass 29 and decreased the sensitivity available for the detection of CHO. The appearance of a parent peak at mass 58, although not positively identified as that of glyoxal, the dimer of CHO, also suggested strongly that the CHO radical was present.

From a comparison of the 50 volt mass spectra obtained with and without illumination, the amount of decomposition of acetaldehyde and the composition of the products were obtained. The results obtained with different contact times are given in Table II. With

FIG. 3. Decomposition of acetaldehyde.

the low pressures of acetaldehyde used, the CHO and (CHO)₂ concentrations were negligible, and the products listed give fairly complete carbon and oxygen balances. The relation between the composition of the products and the contact time is shown in Fig. 3. The yield of CO was unity within the experimental error, and it is evident that a primary reaction to produce methyl radicals predominated. However, the yield of methane was much higher than was found for acetone. Either methane was produced in the primary step, or it was formed by a fast bimolecular reaction, such as

The disappearance of CHO by thermal decomposition or by collision with an excited mercury atom would lead to the formation of hydrogen and CO, but it can be seen that the yield of H₂ is much less than one-half the yield of CO. Reaction [21] must therefore be considered as a possible source of methane.

In order to determine how much of the methane arose from reaction [21] some experiments were carried out in which CD₃CDO was decomposed in the presence of varying amounts of CH₃CHO. If the methane were produced in a primary step, the addition of CH₃CHO should not affect the yield of CD₄ from CD₃CDO. For these experiments the length of the reaction zone was 18 mm. The results are given in Table III. In the absence of CH₃CHO some CD₃H was formed, partly as a result of the 9% of acetaldehyde which contained one protium atom, and partly as a result of the reaction of CD₃ with adsorbed water as described earlier. This fraction should be approximately constant and should not affect the yield of CD₄ to any great extent. As can be seen from Table III, the yield of CD₄ per molecule of CD₃CDO decomposed, although almost independent of the partial pressure of CD₃CDO in the absence of CH₃CHO, decreased significantly when CH₃CHO was added. The yield (CD₄ formed/CD₃CDO decomposed) is shown in Fig. 4 plotted

FIG. 4. CD₄ production from CD₃CDO-CH₃CHO mixtures.

against the mole fraction of CD₃CDO. Within the experimental error the line can be extrapolated to the origin. This indicates that the methane is not produced in the primary step, but by a bimolecular process. The most probable process is reaction [21], which, to explain the yield curves given in Fig. 3, would have to be at least as fast as the combination of methyl radicals at this pressure. The alternative reaction between methyl and formyl,

appeared to be slow at these pressures, since only a very slight formation of CD₃CHO and CH₃CDO occurred when the mixture was illuminated. The formation of hydrogen shows that a considerable fraction of the CHO radicals disappeared by one or both of the following reactions:

As in the case of acetyl, the present data do not allow a calculation of the relative importance of these two reactions.

The probable error in the data shown in Fig. 4 is difficult to estimate, but these results would indicate that less than 0.05 of the primary step proceeds by the intramolecular rearrangement to form methane and carbon monoxide.

CONCLUSION

From these experiments it appears that the reaction of Hg^3P_1 atoms with acetone results in a dissociation into methyl and acetyl radicals, similar to the direct photolysis at 2537 Å. One-quarter of the acetyl radicals formed in this step do not dissociate immediately but react with a second excited mercury atom to form ketene and a hydrogen atom. Since other reactions removing acetyl are probable, it is evident that considerably more than one-quarter of the radicals survive the primary act. This is not inconsistent with a fraction of 0.78 surviving the primary act in the direct photolysis (18).

The reaction of acetaldehyde with Hg^3P_1 atoms leads to a dissociation into methyl (and presumably formyl) radicals to the extent of at least 95%. The methane found as a product results from the reaction

This reaction must be at least as fast at 55° C. and low pressures as the combination of methyl radicals to form ethane. Owing to experimental uncertainties, a molecular rearrangement comprising 5% or less of the primary act cannot be ruled out. This limit for the rearrangement process is considerably lower than has been suggested in the direct photolysis at 2537 Å, but recent work at 3130 Å (5) raises some doubts as to the reliability of the earlier data.

ACKNOWLEDGMENT

The author wishes to thank Dr. K. O. Kutschke and Dr. R. J. Cvetanović for many helpful discussions.

HYDROGENOLYSIS OF CARBOHYDRATES

II. REDUCTION OF METHYL α -D-GLUCOPYRANOSIDE¹

E. VON RUDLOFF, D. E. STUETZ,² AND H. F. BAUER³

ABSTRACT

The hydrogenolysis of methyl α -D-glucopyranoside at elevated temperatures and pressures with copper chromite as catalyst and anhydrous dioxane as solvent was studied. The reaction produced a complex mixture of alcohols, the major components being 2-hydroxymethyl-4,5-dihydroxytetrahydropyran, methanol, isomeric hexanediols, 1,2-propanediol, and ethanediol.

A previous communication (1) describes the hydrogenolysis of methyl β -L-arabopyranoside using copper chromium oxide as catalyst and dioxane as solvent. At 240° C. and 250 atmospheres pressure *cis*- and *trans*-3,4-dihydroxytetrahydropyran were the major reaction products, showing that the carbon skeleton of methyl arabopyranoside is relatively stable to hydrogenolysis conditions necessary to cleave the carbon-oxygen bonds of free hydroxyl groups.

The investigation has now been extended to a study of the reaction of hydrogen with methyl α -D-glucopyranoside under the same reaction conditions. The hydrogenolysis proceeded readily, and after 3 hours' reaction time very little starting material could be detected. The product, unlike that in the reaction with methyl arabopyranoside however, was a complex mixture consisting of about 20% 2-hydroxymethyl-4,5-dihydroxytetrahydropyran (I); 10% isomeric hexanediols; 7% 1,2-propanediol; 5% ethanediol; smaller amounts of glycerol, *n*-hexanol, and unidentified compounds; 21% water; and 13% methanol. These results clearly indicate that the cyclic skeleton of glucopyranoside is considerably less resistant to reductive degradation than that of arabopyranoside.

Zartman and Adkins (15) have studied the reaction of hydrogen with methyl α -D-glucopyranoside using ethanol as solvent and slightly higher temperatures and pressures than in the present work. These authors fractionally distilled the reaction product *in vacuo* with a Widmer column and obtained, besides water, methanol, and ethanol, about 15% 1,2-propanediol, 9% hexanetriol, 7.5% hexanetetrol, and 5% of a compound tentatively identified as 2-(4-hydroxytetrahydrofuryl)-methyl carbinol, leaving about 25% unaccounted for. In view of the difficulties encountered during the present work in the separation of mixed polyols by fractional distillation, it is possible that some of the fractions obtained by Zartman and Adkins were mixtures. The finding of a tetrahydrofurfuryl alcohol as the only cyclic product is surprising, but may be due to the use of ethanol as solvent. Also, it is conceivable that under the somewhat more drastic conditions used by these authors, tetrahydropyran alcohols are extensively degraded.

Fractional distillation *in vacuo* of the reaction product obtained after evaporation of the dioxane did not give a clear-cut separation of the components, but 2-hydroxymethyl-4,5-dihydroxytetrahydropyran and small amounts of *n*-hexanol and *meso*-3,4-hexanediol could be isolated in a pure state. At temperatures above 160° C. decomposition or interaction between the polyols appeared to occur. To overcome this difficulty,

the hydrogenolysis product was acetylated and then fractionally distilled at 8 mm. pressure in a 28 mm. Podbielniak column. Although a large number of fractions was collected, none could be shown, by paper chromatography, to consist of a single compound. Nearly all fractions contained varying amounts of 1,2-propanediol, ethanediol, and glycerol, indicating that azeotrope formation had occurred. Acetates are known to form azeotropic mixtures, but azeotrope formation by mixtures of acetates of diols and glycerol appear not to have been reported previously (8). Many neighboring fractions were found to contain the same components in varying amounts and were, therefore, combined to give the 12 fractions described in Table I. The compounds reported

above were obtained from these combined fractions by solvent segregation and re-distillation of the free alcohols. 1,2-Propanediol, ethanediol, and glycerol were determined by the chromatographic procedure of Dal Nogare (3). Water and methanol were determined as previously described (1) before evaporation of the dioxane. Some material appears to be lost during evaporation of the solvent and also during distillation steps, indicating that volatile products other than water, methanol, and dioxane having boiling points below that of *n*-hexanol may be present.

On determining the methoxyl content of various fractions high values were obtained even for those where no methoxyl content was expected. It was discovered subsequently that some of the free polyols, including ethane-, 1,2-propane-, and 2,3-butanediols as well as glycerol, give high values (13) for methoxyl content using the standard analytical procedure (7). This procedure, therefore, cannot be applied in the determination of methyl ethers when aliphatic polyols are present.

The structure of 2-hydroxymethyl-4,5-dihydroxytetrahydropyran (I) was determined as follows: the triol was oxidized with periodic acid and the resulting dialdehyde (II) was reduced with sodium borohydride to give an open-chain triol ether (III). This triol ether was synthesized by reaction of ethyl iodoacetate (IV) with L-malic acid diethyl ester (V) in the presence of sodium, and subsequent reduction of the resulting triester (VI) with lithium aluminum hydride.

The open-chain α -diols and glycerol were characterized by periodic acid oxidation and identification of the aldehydes thus obtained. Glycerol was further characterized by

Feigl's spot test (5). Of the isomeric hexanediols, *meso*-3,4-hexanediol could be obtained in a pure state by recrystallization. The liquid *DL*-3,4-hexanediol presented more difficulty and it is doubtful whether the compound finally analyzed was completely free from the *meso* isomer. 1,4-Hexanediol, also a liquid, was obtained free from α -glycols by destroying the latter with periodate.

As was noticed previously (1) when the starting material contained reducing material in excess of about 0.03% (calculated as glucose) as determined with Somogyi's reagent, the catalyst sometimes suffered decomposition. The technical methyl α -D-glucopyranoside initially used (0.46% reducing value calculated as glucose) was, therefore, recrystallized several times from methanol or ethanol until a satisfactory product was obtained.

EXPERIMENTAL

All melting points are corrected and were measured with a Leitz heating stage microscope. Fractional distillation was carried out with a Podbielniak packed (28 mm.) or a Podbielniak spinning band (8 mm.) column. The determinations of water, methanol, reducing values with Somogyi's reagent, and infrared spectra were carried out in the same manner as previously described (1).

Paper chromatograms were obtained by using Whatman No. 1 filter paper and either benzene-ethanol-water (15:4:1 v/v, upper phase) or *n*-butanol-ethanol-water (40:11:19 v/v) as solvent systems. The polyols were detected by use of the periodate-permanganate (10) and the silver nitrate - ammonia (11) spray reagents.

Alcohols were acetylated in the usual manner by reaction with excess acetic anhydride in the presence of sodium acetate (1%, based on the weight of acetic anhydride). Acetates were deacetylated by a modification of the procedure of Braun (2). The acetate (5 g.) was dissolved in anhydrous methanol (50 ml.) and treated with sodium (100 mg.) dissolved in anhydrous methanol (20 ml.) at room temperature for 30 to 48 hours. To this was added acetic acid (1 ml.) and the solution was reduced to a small volume (5 to 10 ml.) by evaporation of the solvent at 45°-50° C. To the residue was added water (5 ml.) and the solution was treated with excess ion exchange resin (Amberlite IR-120). When countercurrent distribution was employed the filtered solution was used without further treatment. In other experiments the filtered solution was evaporated to dryness and the residue was distilled *in vacuo*.

Hydrogenolysis Procedure

The same procedure as that previously described was employed. Methyl α -D-glucopyranoside, technical grade having m.p. 169°–170.5° C., $[\alpha]_D +159.0^\circ$ (in water) and 0.46% reducing value (calculated as glucose), was recrystallized three times from methanol to give a product having m.p. 170.5°–171.5° C., $[\alpha]_D +159.4^\circ$ (in water) and 0.029% reducing value. The purified product, 100 g., was hydrogenated at 240° C. and under a pressure of 170 atmospheres for 7 hours in the presence of copper chromite catalyst, 10 g., and 1000 ml. dry dioxane. The product was found to contain water, 21 g., methanol, 13 g., and yielded on evaporation of the solvent a clear colorless sirup, 65 g., n_D^{20} 1.4580. On being dried for about 3 hours on an oil pump, the residue, 55 g., had n_D^{20} 1.4630.

When the reaction time was reduced to 4 or 3 hours a product was obtained which did not differ noticeably from the above product, and paper chromatograms of the reaction product showed only traces of starting material to be present.

2-Hydroxymethyl-4,5-dihydroxytetrahydropyran

The sirup obtained from the hydrogenolyses experiments, after removal of the solvent, was fractionally distilled at 9 mm. The distillation was stopped when the temperature of the distillate reached 205° C. The residue, which constituted about one-third of the sirup, was then acetylated in the usual manner. The acetylated product was distilled *in vacuo* and yielded a viscous colorless liquid, b.p. 191.5°–193.5° C. at 12–13 mm., n_D^{20} 1.4579, d_4^{20} 1.203, $[\alpha]_D^{25} -1.83^\circ$ (*c*, 7.04, ethanol). Calculated for $C_{12}H_{18}O_7$: C, 52.55%; H, 6.62%; acetyl, 47.1%; MR, 62.01. Found: C, 52.71%; H, 6.62%; acetyl, 47.1%; MR, 62.20; molecular weight 274.3. A product giving identical data was isolated when the residue from the fractional distillation of the acetylated hydrogenation product was distilled at 0.1–0.2 mm. pressure, and was furthermore isolated in large amounts from fractions 11 and 12 (see Table I).

The acetate was saponified in the usual manner and yielded on distillation *in vacuo* a very viscous, colorless substance, b.p. 163–167° C. (air bath) at 0.04 mm., n_D^{20} 1.5080; $[\alpha]_D^{20} +10.2^\circ$ (*c*, 1.9 water). Calculated for $C_6H_{12}O_4$: C, 48.64%; H, 8.16%. Found: C, 48.74%; H, 8.02%. A quantitative periodate oxidation of a small amount of this compound consumed 97.8 and 100.5% of the calculated amount of oxidant (one α -glycol group per mole) in 1 and 2 hours' reaction time respectively, with no further consumption of oxidant during the next 3 hours. The free polyol formed a *p*-nitrobenzoate in good yield, which was, however, difficult to purify, m.p. 249°–250° C. Calculated for $C_{27}H_{21}N_3O_{13}$: C, 54.46%; H, 3.56%; N, 7.05%. Found: C, 54.73%; H, 3.59%; N, 6.87%.

The structure of the triol was determined as follows: 934.6 mg. (6.30 mM.) was dissolved in water (5 ml.) and to the solution was added, with shaking, periodic acid (2.96 g., 10 mM.) dissolved in water (15 ml.). After 1 hour at room temperature, the solution was neutralized by the addition of 1 *N* sodium hydroxide solution (15 ml.). To this solution was added sodium borohydride (1.51 g., 22.2 mM.) dissolved in water (15 ml.). After 16 to 18 hours at room temperature the reaction mixture was neutralized with 10% hydrochloric acid solution and then evaporated at 50° C. on a rotary evaporator. To the residue was added a 4% solution of hydrochloric acid in methanol (20 ml.), and the resulting mixture was filtered. The precipitate was washed with small amounts of methanol, the filtrate and washings were combined, dried over anhydrous sodium sulphate, and then evaporated to give a viscous sirup (0.450 g., 48% of theory). This material was then distilled *in vacuo*, b.p. 140°–150° C. (air bath) at 0.03 mm. and, except for a small aliquot of about 50 mg., acetylated in the usual manner. The acetate was distilled

in vacuo, yielding 0.630 g. of the acetate of the triol-ether III, b.p. 135°–140° C. (air bath) at 0.04 mm., n_D^{20} 1.4468. Calculated for $C_{12}H_{20}O_7$: C, 52.16%; H, 7.30%; acetyl, 46.75%. Found: C, 51.99%; H, 7.32%; acetyl, 46.4%.

The triol-ether III (50 mg.) was treated with excess boron trifluoride and acetic anhydride for 3½ hours at 60° C. Methanol was added dropwise and the product was concentrated *in vacuo* to give a sirup, which was poured into an aqueous solution of sodium bicarbonate. The solution was extracted repeatedly with chloroform and the extract dried over anhydrous sodium sulphate. The solvent was evaporated *in vacuo*, the residue deacetylated, and then analyzed by paper chromatography. Spots having R_f values identical with those of ethanediol and 1,2,4-butanetriol were detected and consequently the structure III was tentatively assigned to the cleavage and reduction product.

The triol-ether III was synthesized by reaction of L-malic acid ethyl ester (IV) (3.8 g., 20 mM.) with sodium (0.46 g., 20 mM.), adding ethyl iodoacetate (V) (8.6 g., 40 mM.) and powdered potassium iodide (about 0.5 gm.) and refluxing the mixture, with stirring, in the presence of xylene (100 ml.) for 72 hours. The reaction mixture was filtered through celite filter aid, treated with sodium bicarbonate, and dried over anhydrous sodium sulphate. The solution was evaporated to dryness and the residue was distilled *in vacuo*, yielding the ester VI, b.p. 115°–120° C. (air bath) at 0.2 mm., n_D^{20} 1.4468. Calculated for $C_{12}H_{20}O_7$: saponification equivalent, 92.09. Found: saponification equivalent, 93.6. This ester was reduced with lithium aluminum hydride in the usual manner and the alcohol thus obtained was acetylated. The acetate was distilled *in vacuo*, b.p. 135°–140° C. (air bath) at 0.04 mm., n_D^{20} 1.4458. The infrared spectrum of this acetate and that of the acetate of the triol-ether III obtained from the triol I were identical.

Hexanediols

Preliminary analysis by paper chromatography of the alcohols obtained from fractions 5, 6, and 7 (see Table I) showed that these fractions were composed mainly of a compound having an R_f value of about 0.75 (benzene–ethanol–water solvent). Besides this only traces of material corresponding to 1,2-propanediol and glycerol and an unknown compound with $R_f = 0.45$ were detected.

An aliquot of each fraction (5.00 g.) was deacetylated and subjected to a five stage countercurrent distribution, using water (5 ml.) and chloroform (25 ml.) as solvents. The chloroform solutions were combined and evaporated to dryness. Fraction 5 yielded a crystalline product (2.50 g.), m.p. 42°–50° C. This material was recrystallized six times from petrol (b.p. 64°–66° C.), which contained a small amount of acetone, to give *meso*-3,4-hexanediol, m.p. 89.0°–89.5° C. (Young *et al.* (14) report m.p. 88.0°–88.2° C. and van Risseghem (12) m.p. 90.1°–90.2° C.). Calculated for $C_6H_{14}O_2$: C, 60.98%; H, 11.94%. Found: C, 60.81%; H, 12.01%. The 3,5-dinitrobenzoate, m.p. 190°–191° C. (reported (14) m.p. 190° C. and that of the D,L-isomer m.p. 167°–168° C.), was obtained only in fair yield and the *p*-nitrobenzoate was, therefore, prepared. This was obtained in excellent yield, crude m.p. 163°–168° C., and after four crystallizations from petrol (b.p. 64°–66° C.) containing either ethyl acetate, acetone, or 2-butanone gave a m.p. 172°–174° C., which did not change on further recrystallization. Calculated for $C_{20}H_{20}N_2O_8$: C, 57.69%; H, 4.84%; N, 6.73%. Found: C, 57.69%; H, 4.86%; N, 6.70%.

Fraction 7, when treated similarly, gave a liquid product (2.49 g.), b.p. 113°–114° C. at 13 mm., n_D^{20} 1.4412, $[\alpha]_D^{24} +0.2^\circ$ (c , 4.2, water). Calculated for $C_6H_{14}O_2$: C, 60.98%; H, 11.94%. Found: C, 60.70%; H, 11.89%. Periodate oxidation of a small aliquot

yielded only propionaldehyde in about 90% of the calculated amount (as 3,4-hexanediol). Both the *p*-nitrobenzoate and the 3,5-dinitrobenzoate (obtained in poor yield) were products having a very wide melting range. Repeated recrystallizations finally yielded a *p*-nitrobenzoate of m.p. 162°–164° C. Calculated for $C_{20}H_{20}N_2O_8$: C, 57.69%, H, 4.84%; N, 6.73%. Found: C, 57.87%; H, 4.57%; N, 6.76%. It would, therefore, appear that the liquid fraction is composed mainly of DL-3,4-hexanediol.

Fraction 6 yielded a liquid product (2.60 g.) which solidified partially on cooling. Fractional crystallization from petrol (b.p. 64°–66° C.) gave a major portion (about 65%) of *meso*-3,4-hexanediol, m.p. 88.5°–89.5° C. The residue was impure DL-3,4-hexanediol.

Fraction 8 contained a large amount of an alcohol with $R_f = 0.98$ (benzene-ethanol-water solvent). This compound was obtained readily by a three stage countercurrent distribution. The infrared spectrum was indicative of a hexanediol having a primary hydroxyl group. Since the compound did not react with periodic acid to any large extent, it could be purified by treatment with an aqueous solution of periodic acid. The aqueous solution was extracted three times with chloroform and the extract dried over anhydrous sodium sulphate. The solvent was evaporated and the residual liquid distilled *in vacuo*, giving a clear, colorless liquid, b.p. 120°–125° C. (air bath) at 12 mm., n_D^{20} 1.4515, d_4^{20} 0.9818, $[\alpha]_D^{24} +0.3^\circ$ (*c*, 4.0, water) (Glacet (6) reports for 1,4-hexanediol b.p. 127.5°–127.7° C. at 13 mm., $n_D^{16.3}$ 1.4530, $d_4^{16.3}$ 0.982, phenylurethane, m.p. 71° C., b.p. of the diacetate 120.2°–120.4° C. at 12 mm., $n_D^{16.5}$ 1.4282). Calculated for $C_8H_{14}O_2$: C, 60.98%; H, 11.94%; MR, 32.96. Found: C, 60.62%; H, 12.08%; MR, 32.45. The phenylurethane, m.p. 67°–70° C., was obtained only in poor yield, whereas the *p*-nitrobenzoate was obtained in excellent yield, m.p. 123°–124° C. after two recrystallizations (depressed by an authentic sample of di-*p*-nitrobenzoyl-1,6-hexanediol, m.p. 119°–120° C.). Calculated for $C_{20}H_{20}N_2O_8$: C, 57.69%; H, 4.84%; N, 6.73%. Found: C, 57.63%; H, 4.95%; N, 6.71%.

1,2-Propanediol, Ethanediol, and Glycerol

Analysis by paper chromatography showed that these three polyols were present in practically all but the last fraction, but large amounts were found only in fractions 2, 3, 8, 9, and 10.

Aliquots of the aqueous solutions obtained by countercurrent distribution were analyzed by the chromatographic method of Dal Nogare (3). The same procedure was employed, except that after elution of ethanediol the column was eluted further with *n*-butanol containing ethanol (20%) and finally with aqueous ethanol (50%). The identity of 1,2-propanediol, ethanediol, and glycerol was confirmed by periodate oxidation and colorimetric determination of the formaldehyde (9) and acetaldehyde (4) formed. Glycerol was confirmed by Feigl's spot test (5).

n-Hexanol

Fraction 1 was composed mainly of *n*-hexyl acetate, which yielded on deacetylation and redistillation *n*-hexanol, b.p. 155°–157° C. at 720 mm., n_D^{20} 1.487. The 3,5-dinitrobenzoate was obtained in good yield, m.p. 56°–58° C. (undepressed by an authentic sample of *n*-hexyl 3,5-dinitrobenzoate, m.p. 57.5°–58.0° C.). *n*-Hexanol was also present in small amounts in the solvent mixture obtained during the evaporation and drying of the hydrogenolysis product.

Compounds of Unknown Structure

Fractions 2, 3, and 4 contained a large amount of material which dissolved readily in the chloroform phase when countercurrent distribution was applied. The material thus obtained did not react with periodic acid to any large extent and was, therefore, purified further by treatment with an aqueous solution of periodic acid and, after extraction and drying, by distillation *in vacuo*.

Fraction 2 yielded a colorless liquid (about 75% of the fraction), b.p. 93° C. at 13 mm. Found: C, 57.67%; H, 9.68%; methoxyl, 0.65%. (Calculated for $C_7H_{14}O_3$: C, 57.51%; H, 9.65%.) This compound formed a mono-*p*-nitrobenzoate in excellent yield, m.p. 95°–96° C. Calculated for $C_{14}H_{11}NO_5$: C, 60.20%; H, 6.14%; N, 5.02%; saponification equivalent, 279.28. Found: C, 59.44%; H, 5.94%; N, 4.93%; saponification equivalent, 276. The infrared spectrum indicated that the compound was a cyclic alcohol, having possibly a 1,4-dioxane structure.

Fractions 3 and 4 yielded a colorless liquid (about 30% and 50% respectively), b.p. 90°–91° C. at 13 mm., and n_D^{20} 1.4489. Found: C, 59.11%; H, 10.16%. (Calculated for $C_5H_{10}O_2$: C, 58.80%; H, 9.87%.) The compound did not form a solid *p*-nitrobenzoate, nor was its infrared spectrum identical with that of tetrahydrofurfuryl alcohol.

ACKNOWLEDGMENT

The authors are indebted to Mr. M. Granat for technical assistance, to Mr. J. A. Baignee for the microanalyses, to Miss Agnes Epp for the infrared analysis, and to Dr. A. S. Perlin for the interest shown in this work.

CHROMATOGRAPHY OF WASTE SULPHITE LIQUOR¹

A. C. SHAW AND M. DIGNAM

ABSTRACT

Waste sulphite liquor was studied by chromatographic and ion exchange techniques. A series of chromatographically homogeneous phenolic compounds, which appear to be lignin sulphonate fragments, were separated. Xylose, arabinose, galactose, and rhamnose were isolated and identified by preparation of solid derivatives.

INTRODUCTION

Polysaccharides, sugars, and lignin sulphonates form the main organic constituents of waste sulphite liquor. A more detailed knowledge of these constituents should assist in the search for uses for this waste material. Investigation of the polysaccharide fraction has already been reported (21). The present investigation deals with application of chromatographic techniques to the problem of separating and characterizing constituents of the lignin sulphonate and sugar fractions.

Adequate criteria for the purity of lignin sulphonate fractions are lacking, and with the usual fractionation procedures, e.g., dialysis and precipitation (15, 16), the boundaries between fractions are dependent upon arbitrary selection of experimental conditions. In such experiments, the lignin sulphonates behave as a group of closely related compounds whose molecular weight, physical properties, and chemical properties vary through a continuous range of values. In general, individual compounds are not isolable. However, Bailey (2) described the separation of butanol lignins into zones on paper chromatograms, and reported that chemical differences existed between lignins of different zones. Similarly a methanol lignin examined by Bland and Gatley (4) showed the presence of six constituents, but only the lowest R_f fraction had ultraviolet absorption spectra characteristic of lignin.

The sugar fraction of waste sulphite liquor has been the subject of a number of investigations. Yorston (26) separated a carbohydrate fraction from waste sulphite liquor by sorption of the sugars on a strongly basic ion exchange resin followed by elution with carbonic acid, but recoveries were less than 70%. He isolated crystalline xylose from this fraction.

The presence of glucose, mannose, xylose, galactose, and arabinose in waste sulphite liquor has been demonstrated by paper chromatographic studies (5, 23) as well as by less direct methods such as the measurement of dissociation constants of the sugar bisulphites (20, 24) and fermentation studies (20). McCarthy and co-workers isolated a lignin-free carbohydrate fraction from waste sulphite liquor (17). Constituent sugars were separated by partition chromatography and identified by partition coefficient, but were not isolated in crystalline form. Simple sugars accounted for the total reducing power of the carbohydrate fraction, but reducing substances, calculated as glucose, accounted for only 84% of the solids content of the fraction.

RESULTS AND DISCUSSION

Phenolic Materials Separated by Chromatography

Chromatograms of waste sulphite liquor exhibited a blue fluorescence under ultraviolet light from R_f 0.0 to 0.25 and in the vicinity of R_f 0.75 (*n*-butanol-water development),

¹Manuscript received December 11, 1956.

Contribution from the Department of Chemistry, Ontario Research Foundation, 43 Queen's Park, Toronto 5, Ontario.

and contained areas reducing to ammoniacal silver nitrate which contained no sugars detectable by aniline phthalate. The substances responsible for these phenomena could not be isolated, free of carbohydrates, in amounts large enough for analyses, but the studies described here permitted some conclusions concerning their nature.

The chromatographic mobility of these compounds indicated solubility in organic solvents. Alcohol precipitation in combination with dialysis was therefore used to concentrate these compounds in an alcohol-soluble fraction (fraction I, Fig. 4). Although this fraction contained all of the original sugars, the data of Table I show that it had sulphur and methoxyl contents only slightly below those of the original liquor.

TABLE I
ANALYTICAL DATA OF FRACTIONS FROM DIALYSIS AND SOLVENT PRECIPITATION

	% of original solids	% methoxyl in solids	% of original methoxyl	% sulphur in solids
Original waste				
sulphite liquor	100	7.70	100	
Dialyzate	59.9	5.11	39.7	
Non-dialyzable material	35.2	12.18	55.6	
Fraction A	30.7	4.59	18.3	6.27
Fraction B	3.9	6.13	3.1	7.49
Fraction I	24.6	6.88	22.0	6.14
Calcium sulphate	4.8			
% recovery	99.2		99.0	

Substances which remain on the starting line of a paper chromatogram (fraction C) were removed from fraction I by column chromatography. The fraction II remaining contained the fluorescent reducing materials which move on a paper chromatogram, in mixture with the carbohydrates. These fluorescent materials and all of the methoxyl-, sulphur-, and ash-bearing compounds were removed from fraction II by anion exchange. About 53% of the solids content of the fraction, equivalent to 5.5% of the original liquor solids, was bound by the resin, and thus contained either phenolic or other acidic groups. From the data of Table II, the calculated methoxyl content of the material bound by the resin was 15.4%. The molar ratio of calcium to sulphur was 0.18 as compared with 0.50 for calcium lignin sulphonate. Thus 64% of the sulphur is not present as the calcium salt.

TABLE II
ANALYTICAL DATA OF FRACTIONS SEPARATED BY CHROMATOGRAPHY ON CELLULOSE COLUMNS

	Fraction C	Fraction II	% recovery based on fraction I
% original solids	14.2	10.4	
% of fraction I	57.7	42.3	99.8
% methoxyl in solids	4.18	8.16	85.3
% sulphur in solids	8.29	3.51	101.8
% sulphated ash in solids	20.0	2.7	98.6

Evidence for the presence of phenolic groups was provided by the observation that the fluorescent reducing materials could be detected on paper chromatograms by reaction with diazonium salts or with ferric ferricyanide. Both are general reactions of phenols

(3, 8). It is noteworthy that both reagents give color reactions with lignin (6, 9). Chromatograms of waste sulphite liquor, when sprayed with diazotized sulphanilic acid, gave a series of pink and brown spots, designated by letter R_f value and color in Table III. Essentially, the same series of spots was obtained from liquors from three different cooks.

TABLE III
LIST OF PHENOLIC MATERIALS SEPARATED BY PAPER CHROMATOGRAPHY

Spot	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>	<i>h</i>	<i>i</i>	<i>j</i>
R_f (butanol-water)	0.0	0.04	0.085	0.137	0.148	0.175	0.19	0.25	0.72	0.76
R_f (butanol-ethanol-water)	0.0	0.15	0.30	0.39	0.41	0.45	0.48	0.56	0.78	0.85
Color with diazotized sulphanilic acid	Brown	Red-br.	Red	Brown	Red	Red	Red	Pink	Orange	Red

If the compounds which give rise to these spots are ionized in solution then their R_f values should be changed by change in pH. A sample of fraction I was acidified by cation exchange and its chromatographic behavior compared with that of untreated fraction I. After ion exchange treatment the R_f values of spots *c*, *d*, *e*, *f*, and *g* were almost doubled. Only spots *i* and *j* appeared to be unaffected. Spots *a*, *b*, and *h* were too ill-defined to permit definite conclusions. That the change effected by ion exchange treatment was reversible was shown by the fact that the original R_f values were obtained when acidified fraction I was chromatographed on paper impregnated with calcium carbonate (Fig. 1). Phenolic groups or other chromophores were not involved in the reversible change because no shift in the ultraviolet spectrum followed acidification of fraction I. It was concluded that spots *c*, *d*, *e*, *f*, and *g* are formed by phenolic compounds carrying acidic groups stronger than carbonic acid.

The ultraviolet absorption spectra in acidic and basic solution of materials isolated from each spot as well as the "difference spectra", according to Aulin-Erdtman (1), are shown in Fig. 3. Spot *c* was divided into subfractions based on differences in intensity of fluorescence within the spot.

The spectra of all fractions were similar. All except *i* and *j* showed maxima at 280 $m\mu$, which shifted to 290 $m\mu$ in alkaline solution. The *i* and *j* maxima occurred at 274 $m\mu$ in acid solution. All preparations showed indications of a band at 230 $m\mu$ which in basic solution was intensified to a definite inflection or maximum and shifted to 245 $m\mu$. According to Patterson and Hibbert (18) compounds containing the vanilloyl or veratroyl group absorb at 230, 280, and 306 $m\mu$. The difference spectra of all preparations except *i* and *j* showed maxima at 250 and 300 $m\mu$ typical of lignin and of guaiacyl compounds which do not contain conjugated unsaturation in the side chain (1). The *i* and *j* fraction had a maximum at 245 $m\mu$ and showed higher absorption at the 230 $m\mu$ minimum and towards the longer wave lengths.

Alkaline nitrobenzene oxidation of material from spots *d* and *g* yielded vanillin, confirming the conclusions drawn from studies of ultraviolet spectra. Insufficient material was available for more complete oxidation studies.

It might be expected that calcium salts of strong acids would be separable by ion exclusion on columns of cation exchange resins in the calcium form (25). Thus carbohydrates would be distributed uniformly between water within and water surrounding the resin particles, whereas ionized calcium salts would be excluded from the zone of high

FIG. 1. Chromatograms of phenolic material in acidic and neutral solutions.

FIG. 3. Absorption curves of phenolic materials in acidic solution (solid lines) and in basic solution (dotted lines) and their difference curves (broken lines).

calcium concentration within the resin by a Donnan membrane equilibrium. Chromatograms of the effluents from the ion exclusion of fraction I are shown in Fig. 2 and results are summarized in Table IV.

Spots *a*, *b*, *c*, *e*, *g*, and possibly *f* appeared in the effluent before any significant quantities of sugars were eluted. This supports the contention that these compounds are calcium

TABLE IV
COMPOSITION OF FRACTIONS SEPARATED BY ION EXCLUSION

Fraction	Phenols in order of decreasing concn.	Carbohydrates	% of fraction I
1	<i>a</i> , <i>b</i>	Nil	20.4
2	<i>c</i> , trace <i>a</i> , <i>b</i>	Nil	21.5
3	<i>e</i> , <i>c</i> , <i>g</i>	Trace	10.8
4	<i>e</i> , <i>g</i> , <i>c</i>	Abundant	40.8
5	<i>d</i> , <i>g</i> , trace of <i>h</i> , <i>i</i>	Nil	14.3

salts of strong acids, probably sulphonic acids. Higher sulphonic acid contents and consequent higher polarities should favor lower R_f values and more complete exclusion from within the resin. It was observed that such a correlation did exist; with the exception of spot *d*, the phenols were eluted from the resin approximately in the order of their increasing R_f values. Spots *d*, *h*, *i*, *j*, and to some extent *g*, were adsorbed by the resin. More than 2 liters of water was required to elute spot *j*.

It is apparent that the *i* and *j* compounds differ from the others. Their chromatographic and ion exclusion behavior gives no indication of the presence of sulphonic acid groups. Their absorption maxima occur at slightly lower wave lengths. They are probably a mixture of simple guaiacyl compounds of the type isolated by Kvasnicka and McLaughlin from waste sulphite liquor (14).

The properties and behavior of the remaining compounds suggest that they are low molecular weight degradation products of lignin sulphonates. As starting material for further study of the lignin sulphonates, they offer the advantages of simpler molecules which can be obtained in a chromatographically pure form. Ion exclusion appears to be the most practical method of accumulating workable quantities of these materials.

Carbohydrates

Lignin sulphonates were stubbornly retained by the carbohydrate fraction through a variety of fractionation procedures (dialysis, chromatography, precipitation with amines). No anion exchange resins were found capable of removing all of the lignin sulphonates from waste sulphite liquor. Presumably most of the lignin sulphonate molecules are too large to diffuse to the reactive sites within the resin particle. However, the colored sulphur- and methoxyl-bearing impurities remaining in fraction I after dialysis and solvent precipitation were completely and irreversibly sorbed by the highly permeable resins Dowex 1-X2 and Dowex 2-X2.

In the hydroxide form, there was some evidence that these resins caused changes in the carbohydrates; column eluates contained substances not present in the original liquor, with R_f values 0.196 and 0.316, tentatively identified as mannose (R_f 0.196), and ribose (R_f 0.33) (13) from epimerization of arabinose. It has been reported that sugars may be degraded to organic acids on strongly basic ion exchange resins (19).

Difficulties did not arise when the resin was used in the carbonate form. No qualitative changes in the carbohydrate constituents could be detected by paper chromatography, and experiments with known xylose solutions showed no sorption or destruction of reducing substance by the resin. After removal of acidic materials with Dowex 1-X2 carbonate, the carbohydrate fraction III remained, in a yield of 9.08% of the liquor solids, as a colorless sirup, free of methoxyl, sulphur, and ash, which became partially crystalline on drying.

Refractionation with rejection of intermediate fractions was necessary in order to obtain chromatographically homogeneous fractions (1-5) from the carbohydrate fraction III by column chromatography. No attempt was made to obtain quantitative recoveries. The sugars were separated as white powders by triturating chromatographically pure sirups with ethanol.

Fraction 1 failed to yield any crystalline derivative. This material was subsequently shown to be a mixture of polysaccharides (21). Galactose in fraction 2 was probably contaminated with polysaccharides since on treatment with 1-phenyl-1-methylhydrazine an oil which failed to crystallize was obtained. It is improbable that the mucic acid

obtained by nitric acid oxidation of the fraction was formed from a galactose-containing polysaccharide since subsequent work showed that the highest R_f polysaccharide did not contain galactose.

Solid derivatives of arabinose and xylose were prepared from fractions 3 and 4 respectively. Rhamnose in fraction 5 was contaminated with a reducing substance which was probably not a sugar since it failed to yield a colored condensation product when heated with aniline phthalate. The mixture could not be resolved by column chromatography. Separation was carried out on paper sheets. The non-sugar reducing material was a water-soluble oil which could not be crystallized. It was not identified.

The percentage composition of the carbohydrate fraction (Table V) was calculated from gravimetric estimations of constituents separated by paper chromatography of the fraction in two different solvent systems. The greater resolving power of multiple development paper chromatography (12) as compared to column chromatography permitted quantitative separation of the simple sugars in these experiments. Simple sugars were identified by their position on the chromatogram, but, as a check, the identification of xylose was confirmed by preparation of the crystalline dibenzylidene derivative.

TABLE V
COMPOSITION OF THE CARBOHYDRATE FRACTION

Constituent	Butanol solvent		Ethyl acetate solvent	
	Distance travelled, cm.	% of fraction	Distance travelled, cm.	% of fraction
Polysaccharide	0-2	6.3	0-1	4.4
Polysaccharide	3.2	8.9	2.2	8.9
Polysaccharide	5.4	4.9	3.7	5.7
Polysaccharide	6.6	6.8	4.7	6.6
Polysaccharide	7.5	5.2	5.9	10.8
Polysaccharide and galactose	10.4-11.7	13.7	7.3	12.5
Arabinose	14.2	10.2	8.7	13.6
Xylose	16.4	31.2	11.7	29.8
?	20.6	6.5	14.2	5.6
Rhamnose	22.6	6.8	16.8	8.0
Reducing non-sugar	26.4	14.6	18.0	9.5

EXPERIMENTAL

Chromatograms were developed by descending flow. Where the object of the experiment was to isolate material, chromatograms were run on Whatman No. 3 MM paper. Whatman No. 1 was used for other chromatograms. The solvent systems used were (1) water-saturated *n*-butanol, (2) *n*-butanol:ethanol:water, 20:3.5:8, (3) ethyl acetate:acetic acid:water, 3:1:3. Phenolic materials were detected with sprays of diazotized sulphanilic acid followed by sodium carbonate (11), and with equal parts of 1% solutions of ferric chloride and potassium ferricyanide (3). Aniline phthalate and ammoniacal silver nitrate sprays were used to locate the sugars.

Preparation of Fraction I

A waste sulphite liquor* from a soft cook of mixed spruce and balsam, and commercially fermented with a strain of *Saccharomyces cerevisiae*, was submitted to batch dialysis against distilled water through cellophane membranes for 10 days. Water was changed

*Kindly supplied by the Ontario Paper Co., Thorold, Ontario.

FIG. 4. Flow sheet for the preliminary fractionation of waste sulphite liquor.

on the 3rd and 6th day. The dialyzate, concentrated to about 50% solids, was fractionated by addition in a thin stream to large volumes of vigorously stirred ethanol. Details of the procedure are shown in Fig. 4. Reprecipitations were continued until sugars could no longer be detected in the precipitate by chromatography.

Preparation of Fraction II

Fraction I (10 ml. of 62.3% aqueous solution) was added to a 25 mm. column packed to a depth of 20 cm. with 20–80 mesh screenings of Whatman No. 1 filter paper and previously conditioned with water-saturated butanol. On development with water-saturated butanol, colored low R_f material moved slowly down the column in a uniform brown band with a well defined leading edge. Development was continued until the effluent was free of sugars and the brown band was within an inch of the bottom of the column. Fraction II was obtained by evaporation of the eluates. Fraction C was washed from the column with water.

Ion Exchange of Fraction II

A 2.8×28 cm. column of Dowex 1-X2, 50–100 mesh,* was treated with 200 ml. of 5% sodium carbonate solution and washed to an effluent pH of 5.5. Fraction II (100 ml. of 10% solution) was passed through the column followed by 1000 ml. of wash water. All of the sugars appeared in the first 200 ml. of effluent. The solids content of the combined effluents was 4.68 g. The resin was capable of absorbing about 0.6 g. of lignin acids per ml. of resin.

Isolation of Phenolic Material (Spots a to j)

Fraction I was applied to sheets of Whatman No. 3 paper about 14 in. long, in 0.01 ml. spots of 25% solution spaced 3/4 in. apart, and developed with water-saturated *n*-butanol. Guide strips at either edge of the sheet were cut off, and spots located with diazotized sulphanilic acid. Location of zones of resolved material was aided by examina-

*Kindly donated by the Dow Chemical Co. of Canada, Ltd.

tion of the sheet under ultraviolet light. Zones were then cut from the sheet and eluted by a method analogous to normal chromatographic development using water as the developing solvent. A total of 0.11 g. of fraction I solids was separated in this way.

Ultraviolet Spectra of Spots a to j

The ultraviolet spectra of material from spots *a* to *j* were measured with a Beckman DU spectrophotometer in 1 cm. cells. Solid curves (Fig. 3) were measured in solution acidified with one drop of 10% sulphuric acid in 5 ml.; dotted curves were measured in solution containing 0.1 ml. of 4% sodium hydroxide in 5 ml. Because the preparations were contaminated with unknown amounts of carbohydrates, extinction coefficients could not be calculated. Values were reported as the optical densities of solutions containing the material isolated from 0.1 g. of fraction I solids in 100 ml.

Alkaline Nitrobenzene Oxidation

About 100 mg. each of spots *d* and *g* were oxidized with alkaline nitrobenzene by the method of Stone and Blundell (22). Chromatograms of the oxidation liquors sprayed with 2,4-dinitrophenylhydrazine showed the presence of vanillin.

Ion Exclusion

To a column 70 cm. in height containing 120 ml. of Dowex 50-X2, 100-200 mesh in the calcium form, 1.0 ml. of 10% solution of fraction I was added and followed with wash water at the rate of 0.5 ml./minute. Effluents were collected in 3 ml. fractions and appropriately combined in five fractions with volumes 18, 15, 12, 36, and 70 ml. respectively. Chromatograms of the effluents were prepared on Whatman No. 1 paper and developed with water-saturated butanol for 23 hours.

Isolation of Sugars

A 10% solution of fraction I, containing 31.9 g. of solids, was passed in three batches through 2.8×28 cm. columns of Dowex 1-X2 carbonate, 50-100 mesh. Column eluates plus wash water (about 2 liters) were evaporated under nitrogen to yield fraction III containing 10.8 g. of non-acidic solids.

Fraction III (9.55 g.) was applied in three batches to a 4.5×120 cm. cellulose column and developed with water saturated *n*-butanol. Eluates containing maximum concentrations of one component were combined and rechromatographed on cellulose columns. Intermediate fractions were rejected. The five fractions obtained in this way were concentrated to sirups and repeatedly triturated with absolute ethanol and evaporated in a stream of air. Fraction 1, $R_f < 0.03$, yielded 0.53 g. of white powder $[\alpha]_D -5^\circ$ ($c = 10$, water) which proved to be polysaccharides. Other fractions contained simple sugars.

Galactose

Fraction 2, $R_f 0.06$, yielded 0.35 g. of hygroscopic white powder. Allowed to stand with 1-phenyl-1-methylhydrazine solution as described by Hirst (10), this powder (0.1 g.) yielded only an oil which failed to crystallize.

A solution of 0.20 g. of powder, 1 ml. of nitric acid (sp. gr. 1.42), and 1 ml. of water, heated at 100° for 30 minutes and cooled overnight, deposited 0.027 g. of mucic acid, m.p. 213° C.

Arabinose

The 0.26 g. of crystals which separated from fraction 3, $R_f 0.100$, was heated for 1 hour at 85° with an equal weight of *p*-nitrophenylhydrazine in 4 ml. of ethanol. The resulting

precipitate crystallized in yellow platelets from water and melted at 180° C. alone or in admixture with arabinose *p*-nitrophenylhydrazone.

Xylose

Two crops of xylose $[\alpha]_D +19.2^\circ$ ($c = 10$, water) weighing 1.61 and 0.57 g. were obtained from fraction 4, R_f 0.125. The *p*-nitrophenylhydrazone, prepared as above, melted at 152–153° C. alone or in admixture with xylose *p*-nitrophenylhydrazone.

Rhamnose

Fraction 5, R_f 0.22, failed to deposit any crystalline material. Paper chromatography of the fraction showed the presence of a sugar, and another substance of slightly higher R_f value which did not give a color with the sugar spray reagents (aniline phthalate, *p*-anisidine hydrochloride) but which was strongly reducing to ammoniacal silver nitrate. Accordingly, 0.20 g. of fraction 5 was applied to eight 20-cm. wide sheets of Whatman No. 3 filter paper and developed with butanol, ethanol, water solvent. Zones containing the sugar were cut out, eluted with water, and the water evaporated. A small amount of crystalline material and a non-crystallizing sirup was obtained when the concentrate was triturated with absolute ethanol and evaporated. Crystals (0.05 g.) in 0.50 ml. of water were treated with 0.045 ml. of phenyl hydrazine and refrigerated overnight. The precipitate was washed with ethyl ether, and after two crystallizations from water melted at 156° C. A sample of rhamnose phenylhydrazone melted at 158° C.; the mixed melting point was 157.5° C.

The sirup (0.050 g.) was heated at 100° C. for 15 minutes with 0.050 g. of *p*-nitrophenylhydrazine in 0.6 ml. of ethanol. The precipitate which separated after 24 hours melted at 180° C., which was raised to 183.5° C. by one crystallization from ethanol. Insufficient material was available for further purification. A sample of rhamnose *p*-nitrophenylhydrazine prepared in a similar manner melted at 185° C. The mixture melted at 184° C.

Paper Chromatography of Fraction III

A total of 0.1043 g. of fraction III solids was applied to starting lines 36 cm. from the bottom of four sheets of Whatman No. 3 filter paper (23×44 cm.). Guide spots were applied at both edges of the sheets. Sheets were twice developed (12) with butanol, ethanol, water (20:35:8), the guide strips cut off, and sugars located with aniline phthalate and ammoniacal silver nitrate. Zones were marked, cut out, eluted with water, and the eluates freeze-dried and weighed (Table V).

In a similar experiment 0.1290 g. of fraction III solids on four sheets of Whatman No. 3 filter paper was twice developed with ethyl acetate, acetic acid, water (3:1:3).

Material from the xylose spot (0.0754 g.) treated with dry methanolic hydrogen chloride and benzaldehyde according to Breddy and Jones (7) gave 0.0499 g. of the dibenzylidene derivative of xylose, m.p. 209–210° C.

ACKNOWLEDGMENT

Grateful acknowledgment is made to Drs. J. E. Milks and S. G. Reid for preliminary work leading up to this investigation, and to Dr. H. B. Marshall for many helpful suggestions. This work was supported by a research grant made to the Ontario Research Foundation by the Government of Ontario.

VEGETABLE IVORY AS A SOURCE OF A MANNAN POLYSACCHARIDE¹

T. E. TIMELL

ABSTRACT

Native vegetable ivory has been found to contain in addition to the mannose also glucose residues together with minor amounts of galactose, arabinose, xylose, and rhamnose units. No pectin could be detected. The native material was very non-uniform and was composed of two major portions (mannans A and B) which differed considerably in their average molecular weight and polymolecularity. Alkaline extraction of the untreated product followed by purification via the copper complex offers the best means for obtaining a pure mannan polysaccharide.

The endosperm of the seed of the tagua palm (*Phytelephas macrocarpa*), commonly referred to as vegetable ivory, is the best source available for isolation of a true mannan polysaccharide. This product has been shown to be composed of 45% mannan A, 25% mannan B, and 7.5% cellulose, the remainder constituting a material removed by treatment with sodium chlorite (7, 9). The nature of the latter component is unknown. It has been tentatively suggested that it is a pectic material (9) but it has also been referred to as a lignin (3). Mannans A and B have recently (3) been found to differ mainly in molecular size, exhibiting degrees of polymerization of 10 and 40, respectively. Both are apparently composed of 1,4-linked mannopyranose units, although a few 1,6-linkages are presumably also present.

In connection with a study of a glucomannan from wood (14) it became necessary to prepare a pure mannan polysaccharide from vegetable ivory. It was soon noticed that the technique usually adopted for this purpose (3, 9) was not the most suitable one and that the general composition of vegetable ivory needed further investigation.

EXPERIMENTAL

Material

Vegetable ivory nuts were polished with quartz sand in a ball mill and reduced to thin shavings on a lathe, after which they were extracted with ethanol-benzene (1:2 v/v). A part of the shavings was converted to a 40-60 mesh meal in a Wiley mill. This material, however, proved less satisfactory than the shavings.

Methods

Analytical Procedures

The ivory nut shavings were converted to the corresponding mixture of sugars by the method of Saeman and co-workers (11). The monosaccharides were separated on Whatman No. 1 filter papers using the ethyl acetate - acetic acid - water (9:2:2) and the *n*-butanol-pyridine-water (10:3:3) solvent systems. After elution from the paper with water, the sugars were determined in triplicate analyses by the spectrophotometric *o*-aminodiphenyl method of Timell, Glaudemans, and Currie (12). A portion of the hydrolyzate was treated with baker's yeast for elimination of mannose and glucose. After removal of the yeast by filtration through Celite, the relative amounts of sugars were

¹Manuscript received October 24, 1956.

Contribution from the Department of Chemistry, McGill University, and the Wood Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Que.

estimated as above. Nitrogen analyses were carried out by a semimicro Kjeldahl procedure (13). Standard methods indicated the absence of Klason lignin and methoxyl groups in the native product (9).

Reduced viscosities were measured in 1 *M* cupriethylenediamine and extrapolated to zero concentration with Martin's equation (10). The constant *K* in the latter was determined as 0.16. Nitrate viscosities were estimated in acetone, a value of 0.20 being found for *K* in this case. Both measurements were performed with Cannon-Fenske viscometers. The relationship $D.P. = 100 [\eta]$ was used for converting the intrinsic viscosities of the nitrates to degrees of polymerization.

Identification of Monosaccharides

Glucose, xylose, and rhamnose were identified chromatographically. The sugar mixture obtained after fermentation of the hydrolyzate was separated on large sheets of Whatman No. 1 filter papers with the butanol solvent system. Galactose was identified as the *N*-methyl *N*-phenylhydrazone (4), m.p. and mixed m.p. 190° C. Arabinose was characterized by the benzoylhydrazone (4), m.p. and mixed m.p. 190° C. The xylose component failed to give a crystalline dibenzylidene dimethyl acetal derivative. Mannose was identified in the original hydrolyzate as the phenylhydrazone, m.p. and mixed m.p. 198° C.

Treatment with Sodium Chlorite

Ivory nut shavings (94.7 g.) were treated at 70° C. with 4000 ml. of an aqueous solution containing 30 g. of sodium chlorite and 20 ml. of glacial acetic acid, fresh amounts of the latter two reagents being added every hour (16). After a total time of eight hours, the remaining material was isolated by filtration, washed with distilled water, and dried to give 78.0 g., corresponding to a yield of 79.2%.

Extraction with Ammonium Oxalate

Ivory nut shavings (9.4 g.) were treated at 70° C. for 3 hours with 600 ml. of a 0.5% solution of ammonium oxalate in water. Unextracted material amounted to 7.55 g., corresponding to a yield of 80%. Only a small portion of the extract could be recovered by addition of acidified ethanol.

Nitration and Fractionation

Ivory nut shavings (19.0 g.) were nitrated at +17° C. for 4 hours with 700 ml. of a mixture containing nitric acid, phosphoric acid, and phosphorus pentoxide in the ratio 64:26:10 (1). After removal of the spent acids by filtration, the product was washed with distilled water for two days and finally dried *in vacuo* at 60° C., giving 28.1 g. of a nitrate containing 14.1% nitrogen, corresponding to a yield of 80.5%. Other materials were nitrated in a similar way.

Ten grams of the above product was dissolved in 1400 ml. of reagent grade acetone containing 8% of water. Acetone was slowly removed with a current of air until the formation of a precipitate was indicated by the appearance of a slight opalescence. After equilibration for 10–15 minutes, the precipitate was removed by centrifuging and the supernatant solution was subjected to further fractionation. The fraction was isolated by evaporation of the solvents. In this way a total number of 45 fractions was obtained, most of them ranging in weight between 150 and 250 mg. Intrinsic viscosities were determined for all of them and a few were also denitrated with 20% aqueous ammonium hydrosulphide for subsequent sugar analysis.

RESULTS AND DISCUSSION

The absence of any methoxyl groups as well as the failure to isolate any Klason lignin from vegetable ivory on treatment with strong sulphuric acid suggested that no lignin was present. Uronic acids could not be detected in the sugar mixture obtained after hydrolysis, thus indicating that pectin was probably also absent. In addition to mannose, glucose, galactose, arabinose, xylose, and rhamnose were identified. All sugars were separated on paper chromatograms and quantitatively determined, mannose and glucose having been removed from one hydrolyzate by fermentation. The results are given in Table I. The hydrolyzate of native vegetable ivory apparently contains noticeable

TABLE I

Xylose	0.33	9.4
Rhamnose	Trace	—

quantities of glucose besides the major mannose constituent, and in addition there are also present minor amounts of galactose, arabinose, xylose, and rhamnose. Fifty years ago pentoses and methylpentoses were reported to be present in vegetable ivory (5) but this observation was not corroborated by subsequent experience (15). Pentosans are sometimes detected together with the main galactomannan constituent of the endosperm from legumes (2) but are more often absent (2, 8). Xylose units have been found to accompany the mannan portion of a seaweed, *Porphyra umbilicalis* (6).

Although the absence of any uronic acid groups as well as the complete solubility of ivory nut shavings in cupriethylenediamine, which does not dissolve pectin, suggested the absence of any pectic material, additional evidence was deemed desirable. A known amount of material was converted to the corresponding sugar mixture, the total monosaccharide content of which was determined. In a parallel experiment a mixture containing the same relative amounts of sugars as the ivory nut was also subjected to treatment with sulphuric acid and subsequently analyzed. Comparison between the results showed that 98.8% of the ivory nut consisted of reducing sugar units. A similar experiment, where ribose was added as a reference sugar, gave a value of 98.7%. The only constituents in vegetable ivory are accordingly the sugar residues indicated in Table I and neither lignin nor pectin seem to be present.

Treatment with acidified sodium chlorite and with dilute aqueous ammonium oxalate corroborated the above results. The latter reagent, which is a good solvent for pectin, removed almost the same amount of material as did the chlorite treatment, as can be seen from Table II. However, in both cases the composition of the material remaining after completed extraction was nearly the same as that of the original product.

Mannan has hitherto been prepared from vegetable ivory by alkaline extraction of the material after a prior treatment with chlorite (3, 9). Yield and composition of the

products obtained by alkaline extraction of untreated ivory nut shavings are given in Table III. The corresponding values noted with a material previously digested with sodium chlorite are also presented in Table III. The composition of the various mannans

17.5+4% H ₃ BO ₃	91.8	2.3	1.5	96.2

is evidently almost the same throughout. The higher yield obtained with the product treated with chlorite is undoubtedly due to the much lower average chain-length of the latter (cf. Table II). The best method for isolating a relatively unchanged mannan polysaccharide from vegetable ivory is therefore to extract the untreated material with 5–10% aqueous sodium hydroxide in an atmosphere of nitrogen. Two or three purifications of the crude mannan via its copper complex (3) result in a product containing only traces of anhydrogalactose and glucose units.

When untreated ivory nut shavings were nitrated with a non-degrading acid mixture and the material was dissolved in acetone and subsequently precipitated into water, only half of the material was recovered, as is seen in Table IV. The composition was

†Fraction precipitated into water from acetone solution.

also different from that of a nitrate that had not been reprecipitated. The higher glucan content in the former case indicates that this product contained relatively more cellulose because the low-molecular-weight mannan had not been recovered completely. This conclusion is also supported by the higher intrinsic viscosity of the precipitated portion.

The nitrate obtained in the higher yield was subjected to a fractional precipitation procedure, 45 fractions being isolated in a one-stage experiment using the system acetone-water. Intrinsic viscosity of the fractions was determined in acetone, and seven of them were also denitrated, hydrolyzed, and analyzed for sugar constituents. The weight frequency distribution thus obtained is presented in Fig. 1. The material apparently con-

FIG. 1. Weight frequency distribution of nitrated, native vegetable ivory.

sisted of two distinct portions. One of them, comprising 60% of the total, contained oligosaccharides with 5-7 sugar units whereas the remainder was polymolecular and showed degrees of polymerization extending from 300 up to 1200. The data presented in Table V indicate that the first few fractions contained more anhydrogalactose and glucose units than the following ones. The main part of the material forming the first maximum in the distribution curve consisted of slightly more than 90% of mannose residues. The greater part of the chains within the second peak contained somewhat more anhydroglucose units. The last fraction was a glucan, accompanied by some anhydro-mannose units. This material was probably a cellulose, contaminated by occluded mannan.

It is evident that native ivory nut is a very non-uniform material as regards both chemical composition and chain-length distribution. Extraction of untreated ivory nuts with alkali leaves only a negligible residue undissolved. Precipitation of the extract into acidified ethanol gives, however, a yield of only 60-70%, the low-molecular-weight portion remaining in solution. The chemical constitution of the mannan forming the high-molecular-weight part has been elucidated, albeit only partially (3). Information concerning the major, low-molecular-weight moiety is still lacking. Considering the composition of other endosperms, it does not appear impossible that both glucomannans and galactomannans might be present besides the mannan component.

INTERNAL ROTATION

IX. THE INFRARED AND RAMAN SPECTRA OF LIQUID NORMAL ALKYL BROMIDES¹

T. YOSHINO² AND H. J. BERNSTEIN

ABSTRACT

The ratio of the Raman intensity of the trans to gauche bands and also the optical density ratio, for *n*-alkyl bromides, has been examined in liquid, dilute solution, and vapor (for *n*-propyl bromide) and the temperature dependence of the Raman intensity ratio obtained over the range -80° to $+80^{\circ}$ C. for the liquids. Both Raman and infrared ratios become constant for the higher members of the series but are measurably different for *n*-butyl and *n*-propyl bromide. The results are consistent with a very small difference in energy between gauche and trans forms in liquid, solution, or vapor, and can be interpreted semiquantitatively by assuming appropriate trans-gauche energy differences in the carbon chain.

The normal alkyl bromides may have various configurations due to the trans-gauche rotational isomerism about each C—C bond except the terminal one ending in a CH₃ group. For simplicity hereafter we shall call the molecule which has a trans or gauche configuration with respect to the C—C bond adjacent to the C—Br bond a *T* or *G* type molecule respectively.

The infrared and Raman spectra of propyl bromide have been investigated recently and the bands at 645 and 565 cm.⁻¹ were assigned to the C—Br stretching vibration of the trans (*T*) and gauche (*G*) forms respectively (2, 3, 5). The *T* and *G* type isomers for the *n*-alkyl bromide are shown schematically in Fig. 1. Here R is a normal alkyl

FIG. 1. Rotational isomers of *n*-alkyl bromide.

group or CH₃ for *n*-propyl bromide. There may also be trans and gauche configurations due to rotations about the various C—C bonds in the alkyl group. In these chains three different configurations are possible with respect to rotation about each C—C bond. We denote by *t* the trans configuration, by *g*⁺ the gauche configuration obtained by a clockwise rotation, and by *g*⁻ the gauche configuration obtained by a counterclockwise rotation. A particular isomer of a *n*-alkyl bromide can then be expressed by a combination of symbols such as

$$G^+tg^-g^-tg^+.$$

Since in all the *n*-alkyl bromides investigated the CBr bands due to the *T* and *G* type configurations remain approximately at 645 cm.⁻¹ and 565 cm.⁻¹ and no other fundamental

¹Manuscript received January 7, 1957.

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 4250.

²National Research Laboratories Postdoctorate Research Fellow 1955-.

mode is expected in these regions, we may regard the band at 645 cm^{-1} as a superposition of C—Br stretching bands from all *T* type configurations and that at 565 cm^{-1} as due to the CBr bands from all *G* type configurations.

Let the intensities of the Raman bands belonging to the *i*th configuration of a *T* type isomer and the *j*th configuration of a *G* type isomer be denoted by I_T^i and I_G^j respectively. The observed intensity ratio is given then by

$$[1] \quad \frac{I_{645}}{I_{565}} = \frac{I_T}{I_G} = \frac{\sum_i I_T^i \exp(-\Delta F_T^i/RT)}{\sum_j I_G^j \exp(-\Delta F_G^j/RT)}$$

Here ΔF_T^i and ΔF_G^j are the free energies of the *i*th trans configuration and the *j*th gauche configuration referred to the standard configuration in which all orientations are trans (i.e., the completely staggered or zigzag configuration, *Tttt*...); *R* and *T* have their usual meaning and the summation is over all *i* trans and *j* gauche configurations. If I_T^i and I_G^j are assumed constant, equation [1] becomes

$$[2] \quad \frac{I_T}{I_G} = \frac{I_T^i \sum_i \exp(-\Delta F_T^i/RT)}{I_G^j \sum_j \exp(-\Delta F_G^j/RT)}$$

If the infrared optical density *D* is used, equation [2] may be written for the ratio of the density of the 645 cm^{-1} band to the 565 cm^{-1} band as

$$[3] \quad \frac{D_{645}}{D_{565}} = \frac{D_T}{D_G} = \frac{D_T^i \sum_i \exp(-\Delta F_T^i/RT)}{D_G^j \sum_j \exp(-\Delta F_G^j/RT)}$$

I_T/I_G and D_T/D_G give relative values of the *T/G* mole ratio in the series of homologous compounds.

EXPERIMENTAL

All compounds were Eastman Kodak chemicals once distilled. The infrared spectra were obtained with a Perkin Elmer Model 12C spectrometer with KBr optics (slits $\sim 4\text{ cm}^{-1}$). The same cell (1 mm.) was used throughout and the concentration of the *n*-alkyl bromide in the solvent (cyclohexane) was the same (0.2 *M*) for all molecules. In a separate experiment on *n*-butyl bromide it was determined that the ratio of the optical density of the trans band to that of the gauche band was independent of concentration. Areas under the band contours $\pm 20\text{ cm}^{-1}$ about the peak were measured to obtain optical densities. The results are shown in Table I. The error in the ratio D_T/D_G is estimated to be $\pm 10\%$. The infrared spectra of gaseous *n*-propyl bromide at 22° and 206°C . were obtained in a heated cell previously described (1) and are shown in Fig. 2.

FIG. 2. Infrared spectra of the *T* and *G* bands of *n*-propyl bromide at two temperatures.

grated intensities for the trans and gauche bands, I_T and I_G , are given in arbitrary units and the ratio I_T/I_G has been corrected for convergence error and given in the last column. Two runs are shown for *n*-propyl and *n*-hexyl bromide to indicate the reliability of the measured intensity ratios. The error in the ratio I_T/I_G is estimated to be about $\pm 10\%$.

In order to investigate the temperature dependence of the ratio I_T/I_G the Raman tube was enclosed in an outer jacket through which thermostatically controlled cold or hot liquid could be circulated. The values of I_T/I_G obtained at different temperatures for some of the *n*-alkyl bromides are shown in Table III. Since the depolarization ratios for the 645 and 565 cm.⁻¹ bands of the various molecules are constant within the experimental error, the ratio I_T/I_G will be used in discussing the results.

In Fig. 3 the average value of the ratio I_T/I_G from Table III has been plotted against the number of C atoms in the molecule. In the case of *n*-hexyl and *n*-decyl bromide the values from Table II have been used.

 FIG. 3. The dependence of I_T/I_G on the number of carbon atoms in n -alkyl bromide.

DISCUSSION

From Table III it is evident that there is no temperature dependence for the liquids within the experimental error. The average energy difference* between trans and gauche forms is then very nearly zero in the liquid.

The dielectric constant of the lower members of the alkyl bromides is higher than that of the higher members (8). One might expect therefore that the reaction field of lower members would change by dilution in non-polar solvents. This gives no appreciable changes of trans-gauche energy difference nor trans-gauche mole ratio, since the dipole moments of gauche and trans forms are expected to be very nearly the same (6).

The ratio I_T/I_G for n -propyl bromide was measured also for cyclohexane solutions of concentrations between 1 and 0.1 mole ratio and it was found that dilution had no effect on the value of I_T/I_G . We may consider therefore that the mole ratios of the alkyl bromides are the same for liquid and solution.

The mole ratio of n -alkyl bromide given by D_T/D_G is very nearly the same for vapor and solution and again this is to be expected because of the nearly equal dipole moments of the trans and gauche forms (6). It is evident from Fig. 2 that the energy difference between trans and gauche n -propyl bromide in the vapor is also practically zero. We may conclude therefore that the energy difference in the gas phase for the n -alkyl bromide is nearly zero.

*The definition of the average energy difference appears later in equation [5].

The ratio D_T/D_G shows the same trend as in Fig. 3 for the Raman intensity ratio but the change is not as great from *n*-propyl bromide through to the higher members of the series.

We shall try to interpret the results of Tables I and II and Fig. 3, by taking into account the fact that isomers of the *g* type (where rotations about C—C bonds in the alkyl chain are involved) may have different populations because of different relative stabilities. For example, in a molecule of the type G^+g^- the distance between the terminal carbon atom and the bromine atom is nearly the same as that between the first and fifth carbon atoms of the cyclohexane molecule. The repulsive forces between the terminal methyl group and bromine atom make this form unstable compared to the form G^+g^+ . Furthermore it is reasonable to assume that the configuration denoted by $G^+g^-g^+$ does not actually exist, since here the distance between the terminal carbon and the bromine atom is about the same as that between the 1 and 6 positions of cyclohexane. Such highly unstable forms are more frequently encountered in the *G* type configurations than in the *T* type.

The energy differences between *t* and *g* forms contribute to ΔF_T^i and ΔF_G^j . If the large contributions to ΔF_T^i and ΔF_G^j due to configurations described above were neglected and if ΔF_T^i and ΔF_G^j could be estimated by simply adding *t*-*g* energy differences, then the *T/G* mole ratio

$$[4] \quad r = \frac{\sum_i \exp(-\Delta F_T^i/RT)}{\sum_j \exp(-\Delta F_G^j/RT)}$$

would be constant for all the alkyl bromides. This is so because the abundance ratio of any of the *T* type configurations to the configuration which is the same except for the replacement of *T* by *G* is equal to twice the ratio (*r*) for *n*-propyl bromide. As seen from Fig. 3, *r* is not constant so that it is necessary to introduce energy differences of *g* forms, corresponding to situations described above for G^+g^- , G^+g^+ , etc., for example. To interpret the experimental results the ratio *r* was calculated on the basis of the following assumptions:

(i) If a molecule has *n* pairs of non-bonded carbon atoms separated by the distance corresponding to the 1 and 4 positions of the cyclohexane ring, the configuration is weighted by $(\frac{1}{4})^n$. The factor of $\frac{1}{4}$ corresponds approximately to $\Delta E = +0.8$ kcal., which is the experimental value found for the trans-gauche energy difference in *n*-butane (7).

(ii) If a molecule has *n* pairs of non-bonded atoms in the skeleton separated by the distance nearly corresponding to the 1 and 5 positions of the cyclohexane ring, the configuration is weighted by $(\frac{1}{8})^n$.

(iii) If a molecule has a pair of non-bonded atoms in the skeleton separated by the distance nearly corresponding to the 1 and 6 positions of the cyclohexane ring, the configuration is neglected.

In (i) and (ii) ΔF is assumed to be equal to ΔE .

The calculated *T/G* mole ratios (*r*) for the *n*-alkyl bromides and isoamyl bromide are shown in Table IV referred to *n*-propyl bromide. The calculated values are compared with those observed for I_T/I_G and D_T/D_G normalized so that the constant I_T/I_G ratio of 0.75 (from Fig. 3) is made equal to 1.17 and the constant D_T/D_G ratio of 1.03 (see Table II) is also made equal to 1.17. Since the experimental error in the ratio I_T/I_G and D_T/D_G is $\sim \pm 10\%$, the relative ratios may be in error by as much as $\pm 20\%$ although this seems an overestimate.

TABLE IV
 RELATIVE MOLE RATIOS OF TRANS TO GAUCHE

Molecule	Trans/gauche, calc.	Observed	
		I_T/I_G	D_T/D_G
<i>n</i> -Propyl	1	0.7	1
<i>n</i> -Butyl	1.17	0.9	1.1
<i>n</i> -Amyl	1.16	1.1	1.3
<i>n</i> -Hexyl	1.17	1.2	1.2
<i>n</i> -Heptyl	1.17	1.2	1.2
<i>n</i> -Octyl	1.17	1.2	1.2
<i>n</i> -Nonyl	1.17		1.2
<i>n</i> -Decyl	1.17	1.2	1.2
<i>n</i> -Undecyl	1.17		1.2
<i>n</i> -Osoamyl	1.95	1.5	1.8

We discuss the temperature dependence of the mole ratio by differentiation of [4] with respect to T and obtain

$$[5] \quad \frac{T}{r} \frac{\partial r}{\partial T} = \frac{\sum_i x_i \exp(-x_i)}{\sum_i \exp(-x_i)} - \frac{\sum_j x_j \exp(-x_j)}{\sum_j \exp(-x_j)} = \frac{\epsilon}{RT},$$

where $x_i = \Delta F_i^\ddagger/RT$ and $x_j = \Delta F_j^\ddagger/RT$. The average energy difference ϵ as defined by [5] has been calculated at 300° K. for some alkyl bromides on the same assumptions as for the calculation of r and referred to *n*-propyl bromide as zero. It was found that ϵ for *n*-butyl, *n*-amyl, *n*-hexyl, and isoamyl bromides is -64, +70, +78, and -97 cal./mole respectively.

Since $\partial r/\partial T$ is equal to $r\epsilon/(RT^2)$, it is evident that the change in r with temperature is very small. Even in the case of isoamyl bromide with the largest r and ϵ the calculated $\partial r/\partial T$ is too small to give a measurable temperature dependence of r . This was checked experimentally from 0° to 80° C. and the change in I_T/I_G was found to be within the range of the experimental error.

The experimental results have been adequately explained on the assumption that the Raman and infrared intensities of the C—Br band for different kinds of molecules of the T or G type configuration and for different trans and gauche configurations of the same molecule have remained constant. If the observed ratio I_T/I_G for *n*-propyl bromide is really different from that calculated on the above consideration (viz. 0.7 ± 0.2 compared with 1) it seems that the Raman intensities of the T and G bands here are not the same as for the other bromides.

ACKNOWLEDGMENT

The Raman spectra of the liquids were obtained and measured by Dr. J. C. Evans while a Postdoctorate Research Fellow 1954 and some of the infrared spectra were obtained by Dr. K. Ito while a Postdoctorate Research Fellow 1954.

ORGANIC DEUTERIUM COMPOUNDS

XVI. SYNTHESIS OF α -DEUTERATED ALKYL NITRILES¹

L. C. LEITCH

ABSTRACT

A method of preparing α -deuterated alkyl nitriles by a base-catalyzed exchange with deuterium oxide is described. The products are convenient starting materials for the preparation of α -deuterated acids and alkyl bromides.

Base-catalyzed exchange with deuterium oxide has been used in several instances to deuterate compounds containing labile hydrogen. Thus trichloroethylene-*d* (3), nitromethane-*d*₃ (4), and nitroethane-1,1-*d*₂ (2) have been prepared from the protium compounds in this manner. It seemed desirable to determine whether nitriles would equilibrate rapidly enough to make feasible the preparation of α -deuterated nitriles by this method. In nitriles, however, exchange may be accompanied by hydrolysis to the amide or acid. In 1938 Reitz (6) examined the relative rates of exchange and hydrolysis of acetonitrile and found that at 80° C. exchange was about 40 times as rapid as hydrolysis. However the data were obtained using deuterium oxide only slightly enriched in isotopic hydrogen.

It has now been found that acetonitrile exchanges rapidly when heated with a suspension of calcium deuterioxide in heavy water. After five exchanges a product containing 93.4 mol. % CD₃CN and 4.4 mol. % CHD₂CN was obtained.

Propionitrile underwent no significant exchange under the same conditions but at 125° C. appreciable equilibration took place. At higher temperatures, viz. 140° C., considerable amounts of ammonia were formed owing to hydrolysis. *n*-Butyronitrile was exchanged in the same manner to give *n*-butyro-1,1-*d*₂-nitrile. No significant exchange took place elsewhere in the molecule. Acrylonitrile exchanged rapidly when heated under reflux with the exchange medium but a part of the nitrile polymerized under these conditions. Mass analysis of the product after two exchanges revealed that only one hydrogen atom had been replaced by deuterium, presumably that on the α -carbon atom.

α -Deuterated nitriles are useful starting materials for the synthesis of other deuterated compounds. They are hydrolyzed quantitatively in the presence of hydrogen ions without loss of deuterium by exchange. When nitric acid is used for hydrolysis the organic acid may be recovered in excellent yield as the silver salt. The α -deuterated acids can, of course, also be prepared by decarboxylation of the corresponding deuterated malonic acid (1). However, nitriles are generally more readily available than alkyl malonic acids. The α -deuterated acids undergo brominative decarboxylation to the α -deuterated alkyl bromides (5). These reactions are not particularly useful in the case of acetonitrile because these derivatives are more readily prepared by other methods. However, propionitrile-1,1-*d*₂ is conveniently converted into ethyl-1,1-*d*₂ bromide by this means.

EXPERIMENTAL

Acetonitrile- d_3

A mixture of acetonitrile (50.0 ml.), deuterium oxide (40 ml.), and calcium deuteroxide (10.0 g.) was heated under reflux for 12 hours under a Stedman column and still head. The exchanged nitrile was distilled over as an azeotrope, b.p. 76° C. The distillate was dried over anhydrous potassium carbonate. Yield: 45.0 ml. It was exchanged twice more with fresh portions of deuterium oxide and calcium deuteroxide, and finally distilled on a vacuum manifold through a U-tube filled with phosphorus pentoxide. The yield of product which showed a small Raman band due to CHD_2CN but none due to CH_3CN or CH_2DCN was 35.0 ml.

A final exchange was carried out with 15 ml. of this product in a sealed tube with a re-entrant joint using 25 ml. of deuterium oxide (99.6%) and 1.0 g. of calcium deuteroxide. After the tube had been heated in a rocking furnace for 12 hours at 85° C., it was opened by means of a magnetic hammer while attached to the vacuum manifold. The nitrile was distilled through a tube containing phosphorus pentoxide and condensed in a trap on the line. The yield of product analyzing 93.4 mol.% CD_3CN was 12.0 ml.

Propionitrile-1,1- d_2

A mixture of propionitrile (25.0 ml.), deuterium oxide (25.0 ml.), and calcium deuteroxide (5.0 g.) was heated in the rocking furnace at 120° C. for 12 hours. When the cold tube was opened no odor of ammonia was apparent; the supernatant layer of exchanged nitrile was distilled off in a vacuum manifold into a trap which contained anhydrous potassium carbonate. Yield: 22.0 ml.

The exchange was repeated until the bands due to CHD and CH_2 stretching vibrations in the Raman had disappeared.

n-Butyronitrile-1,1- d_2

This compound was prepared as described for propionitrile-1,1- d_2 .

Acrylonitrile-1- d

A mixture of acrylonitrile (25.0 ml.), deuterium oxide (40.0 ml.), and calcium hydroxide- d_2 (5.0 g.) was heated for 6 hours under reflux with stirring. The nitrile was distilled over as an azeotrope with water, b.p. 70–72° C. The distillate was saturated with anhydrous potassium carbonate and the supernatant layer of nitrile distilled on the vacuum line through a U-tube containing phosphorus pentoxide. Yield: 15.0 ml. (60%). The residue from the azeotropic distillation contained a considerable amount of insoluble polymer. A second exchange gave acrylonitrile- d analyzing 96 atom %.

Silver Propionate-1,1- d_2

Propionitrile-1,1- d_2 (8.6 g.) was heated under reflux on the steam bath overnight with 15 ml. of concentrated nitric acid diluted with an equal volume of water. The solution was further diluted to 100 ml. with water and neutralized with 20% aqueous sodium hydroxide. A solution of 35.0 g. of silver nitrate in 125 ml. of water was then added gradually with stirring. After the solution had been left for half an hour the thick white precipitate of silver propionate was filtered off and washed with water. The yield of slightly gray salt after drying in the air in the dark was 22.0 g. (78%).

ACKNOWLEDGMENT

The author is indebted to Dr. W. Cockburn of Defence Research Chemical Laboratories for the analysis of deuterated acrylonitrile and to Dr. H. J. Bernstein of these laboratories for the infrared and Raman spectra.

ORGANIC DEUTERIUM COMPOUNDS

XVII. A SYNTHESIS OF DEUTERATED METHYL CHLOROFORM¹

J. E. FRANCIS AND L. C. LEITCH

ABSTRACT

1,1,1-Trichloroethane-*d*₃ has been synthesized from trichloroethylene in four steps via trichloroethylene-*d*, 1,1,1,2-tetrachloroethane-*d*₂, and 1,1-dichloroethylene-*d*₂.

The recent interest of spectroscopists in methyl chloroform (1) seemed to justify the preparation of its deuterated analogue. Deuteromethyl chloroform was therefore prepared by the series of reactions outlined below:

Apart from trichloroethylene-*d*, which was reported earlier by one of us (6), the compounds or their mode of preparation are new. After three equilibrations with alkaline deuterium oxide trichloroethylene-*d* showed no C—H absorption in either the Raman or the infrared. 1,1,1,2-Tetrachloroethane-*d*₂ was formed when trichloroethylene-*d* was stirred under an atmosphere of deuterium chloride, in the presence of aluminum chloride. Dehalogenation of the tetrachloroethane with zinc dust in ethanol gave 1,1-dichloroethylene-*d*₂, which had been reported previously (8) but without any mention of the manner in which it was prepared.

Since the addition of hydrogen chloride to 1,1-dichloroethylene had been reported only in patents (3, 7), it appeared desirable to reinvestigate this reaction before exposing easily polymerized deuterated dichloroethylene to the combined action of deuterium chloride and anhydrous aluminum chloride. Contrary to reports in the patent literature (2, 4), 1,1-dichloroethylene could not be prepared by dehydrochlorination of 1,1,1-trichloroethane. However, the isomeric 1,1,2-trichloroethane reacted smoothly with aqueous calcium hydroxide to give a satisfactory yield of 1,1-dichloroethylene.

Hydrogen chloride added without too much difficulty to 1,1-dichloroethylene in the presence of anhydrous aluminum chloride. The addition of deuterium chloride to 1,1-dichloroethylene-*d*₂ carried out in the same manner gave a moderate yield of 1,1,1-trichloroethane-*d*₃ or deuterated methyl chloroform.

In the belief that it would also be of interest to obtain the semideuterated compounds CHDCICCl₃ and CHD=CCl₂, the addition of deuterium chloride to trichloroethylene was carried out under the same conditions. The Raman spectrum of the product indicated it was a mixture of all three tetrachloroethanes—CH₂ClCCl₃, CHDCICCl₃, and CD₂ClCCl₃. Apparently, the presence of anhydrous aluminum chloride had catalyzed hydrogen-

deuterium exchange as well as addition to the double bond. In the aromatic series this reaction is known, having been employed by Klit and Langseth (5) to prepare benzene- d_6 from benzene and deuterium chloride. However its occurrence with olefins is not believed to have been noted before.

EXPERIMENTAL

Trichloroethylene-d

A mixture of trichloroethylene (25 ml.), deuterium oxide (25 ml.), and calcium deuterioxide (4.0 g.) (or an equivalent amount of freshly calcined calcium oxide) was heated with stirring under gentle reflux for 12 hours in a 100 ml. round-bottomed flask surmounted by a Vigreux column and still head. In some experiments the desiccant in the tube attached to the still head was blown out and a deposit of carbon was formed in the column. This was probably produced by the spontaneous combustion of traces of chloroacetylene formed by dehydrochlorination of the trichloroethylene. The exchanged trichloroethylene was then distilled off as an azeotrope, collected in a separatory funnel. After it was dried over anhydrous potassium carbonate the exchange was repeated with fresh portions of deuterium oxide and calcium deuterioxide (or calcium oxide). After three exchanges the trichloroethylene- d , n_D^{20} 1.4771, contained only traces of the normal compound, n_D^{20} 1.4776 according to its nuclear magnetic resonance spectrum. The yield was nearly quantitative.

The deuterium oxide recovered from each exchange was re-used to enrich a second run of trichloroethylene.

Deuterium Chloride

The gas was generated by adding deuterium oxide dropwise to phosphorus pentachloride in an evacuated round-bottomed flask. It was freed of phosphorus halides by being cooled to -78°C . in a spiral trap immersed in dry ice and acetone and collected in a 2 l. evacuated gas bulb. The entire apparatus was flushed out once with deuterium chloride to remove hydrogen adsorbed as water on the walls.

1,1,1,2-Tetrachloroethane- d_2

Trichloroethylene- d (25 ml.) and anhydrous aluminum chloride (2.0 g.) were placed in a 100 ml. round-bottomed flask, a small magnetized bar sealed in glass was introduced for stirring, and the flask was attached to the deuterium chloride generator by an adapter. After cooling and evacuating, stirring was started and deuterium chloride introduced from the gas bulb until the pressure was nearly one atmosphere. Addition of deuterium chloride took place slowly over 2 days, a total of about 4 l. being consumed.

The reaction mixture was connected to a stock trap cooled to -78° on a vacuum line and distilled. The distillate (24.5 ml.) was fractionated in a column packed with glass helices. The pure product, b.p. $128-129^\circ\text{C}$., n_D^{20} 1.4815, amounted to 23.0 g. (58% of the theoretical amount). Its Raman spectrum showed only very faint absorption in the C—H region.

1,1-Dichloroethylene

Dehydrochlorination of 1,1,1-trichloroethane by means of calcium hydroxide was unsuccessful. A suspension of 20 g. of the trichloroethane in 50 ml. of water to which 5.0 g. of calcium oxide had been added was heated under reflux for 5 hours without obtaining a trace of 1,1-dichloroethylene. With 1,1,2-trichloroethane, however, yields of

75–80% 1,1-dichloroethylene were readily obtained. The product was dried by distillation through a U-tube containing phosphorus pentoxide on the vacuum line. To prevent polymerization the monomer was treated with a few crystals of hydroquinone.

1,1,1-Trichloroethane

1,1-Dichloroethylene (5.0 ml.) and 0.05 g. of anhydrous aluminum chloride were stirred in a 100 ml. round-bottomed flask under an atmosphere of hydrogen chloride at 20° C. After 1½ hours no more hydrogen chloride was absorbed. The product was distilled out into a trap on the vacuum line. Yield: 7.5 g. Fractional distillation in a column packed with glass beads gave 5.0 g. of 1,1,1-trichloroethane, b.p. 72–74° C., n_D^{20} 1.4384.

1,1-Dichloroethylene- d_2

To a boiling stirred suspension of 28 g. of zinc dust in 50 ml. of 95% ethanol in a 250 ml. round-bottomed flask with a reflux condenser to which was attached a spiral trap cooled in dry ice and acetone to –78° C. was added dropwise over a period of 2 hours 24.8 g. of 1,1,1,2-tetrachloroethane- d_2 . After addition of the halide the dichloroethylene was swept out of the apparatus by a slow current of nitrogen. The product in the spiral trap was distilled through a tube containing phosphorus pentoxide on the vacuum line. The yield of pure product was 12.8 g. (89%).

1,1,1-Trichloroethane- d_3

In a 500 ml. round-bottomed flask were placed a magnetized bar and 107 mg. of pulverized anhydrous aluminum chloride. The flask was pumped out thoroughly and then 6.2 ml. at 0° C. of 1,1-dichloroethylene- d_2 was distilled into the flask from a trap. One atmosphere of deuterium chloride was then introduced and stirring started. After a short induction period absorption began. The flask was immersed in water at 18° C. to prevent polymerization. After about 1 hour absorption of deuterium chloride ceased; the reaction mixture was purple. The product was distilled *in vacuo* as described for the light compound. Yield: 8.5 g. (78%). It was purified by fractional distillation in a column packed with glass helices, b.p. 73–74° C., n_D^{20} 1.4370. Yield: 4.7 g.

1,1,1,2-Tetrachloroethane- d

Deuterium chloride was reacted with trichloroethylene as described for the synthesis of the dideuterated compound. The Raman spectrum of the product showed absorption due to CH_2 and CD_2 groups as well as the CHD group.

SOME ACENAPHTHENE COMPOUNDS¹

E. H. CHARLESWORTH, H. CAMPBELL, J. J. CONN, C. T. ELSTON, AND D. L. STACHIW

ABSTRACT

A new geometric isomer of 1,2-dichloroacenaphthene has been isolated among the reaction products of acenaphthylene and hypochlorous acid. Some new derivatives of acenaphthenone and acenaphthenol are reported.

INTRODUCTION

A number of students have worked at times in these laboratories in attempts to make the chlorohydrin and epoxide of acenaphthylene (I). This work has not met with success, but a number of compounds containing the acenaphthene nucleus have been prepared, which have been thought worthy of record. In attempts to make the chlorohydrin by treatment of acenaphthylene with hypochlorous acid by the method of Detoeuf (2), a new dichloroacenaphthene, m.p. 64° C., has been isolated. This is undoubtedly a geometric isomer of the 1,2-dichloroacenaphthene of melting point 115° C. prepared by Campbell (1) by the direct chlorination of acenaphthylene in carbon tetrachloride.

The presence of the chlorine in the 1,2-positions of the 64° melting compound has been established by oxidation with dichromate to naphthalic anhydride. Attempts to establish the configuration of these two isomeric 1,2-dichloroacenaphthenes (II and III) have been unsuccessful. Both the isomers on hydrolysis gave a mixture of the two corresponding glycols. Although the configuration of the glycols has been established by Jack and Rule (8), we have not been able to prepare either of the chlorides from the glycols with the usual agents such as zinc chloride – hydrochloric acid, phosphorus trichloride, or thionyl chloride. Both the dichloroacenaphthenes on treatment with potassium acetate and acetic acid were converted to the monoacetate of the *cis*-glycol.

A study of the methylene group in acenaphthenone (IV) has been undertaken by a series of condensations with aromatic aldehydes under alkaline (Claisen-Schmidt) and acid conditions. This reaction has been studied previously by two groups of workers, de Fazi (3) in Italy and Sircar and Gopalan (10, 11, 12) in India. In several cases, as shown in Table I, there is disagreement between these authors on the melting point of the isolated product. This suggested that geometric isomers (V and VI) may have been isolated.

In attempts to clarify the situation, we have always isolated, with one exception, one of the described forms only, no matter whose directions we followed. When *o*-nitrobenzaldehyde was employed, both the described condensation products were isolated,

TABLE I

COMPOUNDS FROM ACENAPHTHENONE AND R·CHO

R—C=CH	Melting point	
	Literature	This investigation
<i>p</i> -Nitrobenzal	202–203° (3) 239–240° (12)	— 241°
<i>o</i> -Nitrobenzal	241–243° decomp. (3) 157° (11)	242–244° 163–165°
<i>p</i> -Methoxybenzal (anisal)	95–98° (1) 126–127° (12)	95–96° —
<i>o</i> -Hydroxybenzal (salicylal)	168° (1) 186–187° (10)	— 185–186°
Cinnamal	167–168° (12) 214–215° (1)	163–165° —
<i>o</i> -Methoxybenzal	Not listed	192–192.5°
5-Nitrosalicylal	Not listed	242–243° decomp.
<i>p</i> -Hydroxybenzal	Not listed	215–216°

the higher melting under alkaline conditions and the lower melting under acid conditions. That the two products were geometric isomers and not polymorphic forms was shown by the difference in the ultraviolet absorption curves. The characteristic peak at 281–282 mμ of the 164° melting compound was missing in the 245° melting compound.

The expected condensation products have been obtained from the three new aldehydes listed in Table I. Naphthalic acid or its anhydride, or biacenone (VII), was the only isolated product, when condensations were carried out with *p*-methylbenzaldehyde, *m*-methylbenzaldehyde, and *m*-methoxybenzaldehyde. Biacenone also resulted when aliphatic aldehydes were employed. This is quite in agreement with the work of Graebe and Gfeller (6), who reported the formation of naphthalic acid by boiling acenaphthenone with sodium hydroxide solution, and of Graebe and Jequier (7), who reported the formation of biacenone from self-condensation of acenaphthenone in alcoholic sodium hydroxide even at room temperature. Phloroglucinaldehyde does not react with acenaphthenone under the normal conditions, but condenses with itself. However, using 2-O-benzoylphloroglucinaldehyde, the pyrylium salt (VIII) was produced.

The semicarbazone of acenaphthenone, which does not seem to have been previously reported, was prepared in the usual manner. A number of characterization derivatives of acenaphthenol, the 3,5-dinitrobenzoate, the *p*-nitrobenzoate, and the α -naphthylurethan, have been prepared.

EXPERIMENTAL

Acenaphthenol acetate, acenaphthenol, and acenaphthenone were prepared as described by Fieser and Cason (4). Acenaphthene (Reilly Tar and Chemical Corporation) was oxidized with lead tetracetate. Alkaline hydrolysis of the resulting acetate gave acenaphthenol, which on oxidation with chromic oxide and acetic acid yielded crude acenaphthenone. It was purified by steam distillation and finally by crystallization from ethanol, as colorless needles which melted at 121° C.*

Acenaphthylene

This substance was prepared essentially as described by Flowers and Miller (5) by passing acenaphthenol acetate vapors and nitrogen through a quartz tube heated to 520° by a nichrome heating element. The crude reddish solid pyrolysis product was washed well with water to remove acetic acid and crystallized several times from ethanol (charcoal). It was thus obtained as lemon yellow plates, m.p. 92° C. in 80% yield. The purification of the crude product could also be somewhat simplified by distillation *in vacuo*, using hydroquinone as a polymerization inhibitor and collecting the fraction boiling at 135–140° (15 mm.). The yields are somewhat lower owing to partial polymerization of the acenaphthylene.

The optimum rate of flow of the acetate through the pyrolysis tube appeared to be when the issuing vapors were thin and pale orange in color. If the vapors were heavy and bright yellow in color, it indicated that unpyrolyzed acetate was passing through the tube. On the average about 2 hours were required to put each 100 g. of the acetate through the tube. The efficiency of the tube was reduced somewhat by carbonaceous material and for best results it should be cleaned after every run of 200 g. To prevent oxidation and photochemical polymerization, the acenaphthylene was stored in amber glass stoppered bottles and kept in the dark.

1,2-Dichloroacenaphthene (m.p. 64°) (II or III)

A variety of unsuccessful attempts were made to obtain acenaphthylene chlorohydrin by the action of hypochlorous acid on acenaphthylene under a variety of conditions.

*Melting points have been determined by the capillary tube method and are uncorrected.

In several cases the above compound of melting point 64° was isolated. A description follows of the method that seemed to give the largest amount of this substance.

Acenaphthylene (25 g.), monochlorourea solution (250 ml., 9.9% in hypochlorous acid, prepared by the method of Detoef (2)), and glacial acetic acid (15 ml.) were placed in a flask (500 ml.) and stirred mechanically. The reaction proceeded very slowly; after 24 hours a gummy solid had collected on the walls of the flask and the loss in hypochlorous acid was about 10% greater than the spontaneous decomposition of the acid. After 5 days the hypochlorous acid concentration was nil. The contents of the flask were then extracted with ether and washed with water and a 5% solution of sodium bicarbonate. The brown oil left after drying and removal of the ether was distilled *in vacuo*. A light yellow oil (14.7 g.) was collected at $170-180^{\circ}$ (15 mm.). After the oil had been left for several days in the ice chest, a crop of light yellow crystals (4.8 g.) was obtained. On recrystallization from ethanol these were obtained as fine white needles which melted sharply at 64° C. Found: Cl, 31.83%. Calculated for $C_{12}H_8Cl_2$: Cl, 31.79%. It would seem that this substance is a geometric isomer of the 1,2-dichloroacenaphthene, melting point 115° C., prepared by Campbell (1) by the chlorination of acenaphthylene in carbon tetrachloride solution.

The residue oil, from which the 64° melting crystals were obtained, was distilled *in vacuo*. The yellow oil, b.p. $165-170^{\circ}$ (14 mm.), did not crystallize. Found: Cl, 19.93%. Calculated for $C_{12}H_7Cl$: Cl, 19.02%. It would seem that this oil was probably identical with 1-monochloroacenaphthylene, which Campbell (1) prepared by treatment of the 115° melting dichloride with an alcoholic solution of sodium ethylate. With a saturated solution of picric acid in ethanol, the oil gave an orange picrate, m.p. $152-153^{\circ}$. A mixed melting point of this picrate and a sample of the picrate, m.p. $151-152^{\circ}$, prepared from a sample of Campbell's oil gave no depression.

Oxidation of the Dichloroacenaphthene

The 64° melting dichloroacenaphthene (2.0 g.) and sodium dichromate (10 g.) were dissolved in glacial acetic acid, 30 ml., and refluxed for 4 hours. The mixture was diluted with water (150 ml.) and the resulting precipitate filtered off. It was triturated with sodium bicarbonate solution and filtered. The filtrate was decolorized with charcoal and acidified with hydrochloric acid. The resulting precipitate was further purified by a repetition of the process and finally crystallized from ethanol. There was thus obtained a white, halogen-free, crystalline solid which melted at $268-270^{\circ}$ and which gave a blue fluorescence in concentrated sulphuric acid. This substance proved to be naphthalic acid and its isolation can be accepted as proof that the halogens in the dichloro compound are in the 1,2-positions. The 115° melting isomer also produced naphthalic acid on oxidation.

Acenaphthylene Glycols

Authentic samples of the two glycols, the *cis*, m.p. $206-208^{\circ}$, and the *trans*, m.p. $155-156^{\circ}$, were prepared by the hydrolysis of the 115° melting 1,2-dichloroacenaphthene according to the directions of Jack and Rule (8). Some of the *cis*-glycol was also prepared by the oxidation of acenaphthene with selenium dioxide following the method of Monti (9).

Hydrolysis of the 64° melting dichloroacenaphthene gave both the *cis*- and *trans*-glycols.

The 64° melting dichloro compound (1.0 g.) was added to a solution of potassium acetate (2 g.) in glacial acetic acid (4 ml.). After the mixture was refluxed for 1 hour it was diluted with water. The resulting solid was crystallized three times from ethanol (charcoal) and gave fine white needles, m.p. 123° C. These were identical with the monoacetate of the *cis*-glycol. The 115° melting dichloro compound on being subjected to similar treatment yielded the same monoacetate of the *cis*-glycol.

Attempted Reactions of Glycols with Halogenating Agents

Various attempts to form the corresponding halogen compounds from the known glycols with agents such as concentrated hydrochloric acid and zinc chloride, phosphorus trichloride, and thionyl chloride (with and without pyridine) failed to yield the halogen compounds or any other identifiable material.

Derivatives of Acenaphthenol and Acenaphthenone

3,5-Dinitrobenzoate

This was prepared by treatment of acenaphthenol in pyridine with 3,5-dinitrobenzoyl chloride in the usual manner. On crystallization from acetone (charcoal) the product was obtained as small pale yellow needles which melted at 166° C. Found: C, 62.4; H, 3.30%. Calculated for $C_{19}H_{12}O_6N_2$: C, 62.6; H, 3.32%.

p-Nitrobenzoate

This ester was prepared in the same manner and crystallized from ethanol (charcoal) in fine pale yellow needles, m.p. 117–118° C. Found: C, 71.5; H, 4.13%. Calculated for $C_{19}H_{13}O_4N$: C, 71.4; H, 4.10%.

α-Naphthylurethan

α-Naphthyl isocyanate was allowed to react with acenaphthenol dissolved in dry pyridine. On crystallization from pyridine, the urethan was obtained as long colorless prisms which melted at 206° with decomposition. Found: C, 81.2; H, 5.06%. Calculated for $C_{23}H_{17}O_2N$: C, 81.4; H, 5.05%.

Acenaphthenone Semicarbazone

Acenaphthenone was allowed to react in the usual manner in hot alcoholic solution with semicarbazide hydrochloride and sodium acetate. The crude yellow semicarbazone which separated was recrystallized twice from ethanol (charcoal) and was obtained as a white fluffy solid, m.p. 241–243°, with decomposition. Found: N, 18.6%. Calculated for $C_{13}H_{11}ON_3$: N, 18.7%.

o-Methoxybenzalacenaphthenone

Acenaphthenone (1 g.) and *o*-methoxybenzaldehyde (0.81 g.) were dissolved in ethanol (50 ml.) and a solution of sodium hydroxide (5 g. in 5 ml. of water) was added slowly over a period of 2 hours. A yellow precipitate started to form during the addition of the alkali. After 24 hours at room temperature, the precipitate was filtered off, washed with ethanol, and crystallized from a mixture of chloroform and ethanol. It separated in yellow prisms (1.2 g.) which melted at 192–193° C. Found: C, 83.8; H, 4.96%. Calculated for $C_{20}H_{14}O_2$: C, 83.9; H, 4.93%.

5-Nitrosalicylalacenaphthenone

This was prepared according to the above directions. The crude dark red solid was crystallized from acetic acid (charcoal) and gave fluffy orange crystals, m.p. 242–243°

with decomposition. Found: C, 71.6. H, 3.53%. Calculated for $C_{19}H_{11}O_4N$: C, 71.9; H, 3.50%.

p-Nitrobenzalacenaphthenone

(1) When this was prepared as described above, which is the method of de Fazi (3), it was obtained as fine yellow needles, m.p. 242° C. This was the melting point of the product made by Sircar and Gopalan. The product of melting point 202–203° described by de Fazi was not obtained.

(2) If prepared according to the directions of Sircar and Gopalan (10, 11, 12) using 10% alcoholic potassium hydroxide as condensing agent, the product again melted at 241° C. Even with variation in temperature of condensation from –20 to +80° C. this product was always obtained under alkaline conditions.

(3) Acenaphthenone (1 g.) and *p*-nitrobenzaldehyde (0.95 g.) were dissolved in glacial acetic acid (10 ml.) and dry hydrogen chloride gas was passed through the mixture at room temperature over a period of 1 hour. The yellow condensation product started to precipitate immediately on the addition of the gas. At the end of the reaction it was filtered off, washed with dilute acetic acid, and crystallized from glacial acetic acid. It again melted at 241° C.

o-Nitrobenzalacenaphthenones

When produced by either of the alkaline condensation conditions described above, it was obtained as very fine yellow needles, m.p. 242–244°. When they were cooled and remelted there was no change in the melting point.

When formed by condensation with hydrogen chloride, yellow needles, m.p. 163–165°, resulted, which, after being cooled, remelted without change. That the two substances were geometric isomers and not polymorphic forms was indicated by the ultra-violet absorption curves. The peak at 281–282 $m\mu$ exhibited by the lower melting compound was not present in the higher melting. Both had the same sort of peak at 231–232 $m\mu$.

Attempts to convert the lower melting isomer to the higher by use of ultraviolet light, iodine, heat, or palladized charcoal resulted in recovery of the starting material in the first two cases, and a dark uncrystallizable oil in the latter two. The low melting form if allowed to stand with alcoholic potash yielded, after acidification, naphthalic anhydride.

p-Hydroxybenzalacenaphthenone

This product resulted from both alkaline and acid condensations. It was recrystallized from acetic acid and melted at 215–216° C. Found: C, 83.7; H, 4.16%. Calculated for $C_{19}H_{12}O_2$: C, 83.8; H, 4.43%.

Salicylalacenaphthenone

Alkaline condensations gave the product melting at 185–186° C.

p-Anisalacenaphthenone

The product of melting point 95° was isolated by either of the alkaline methods of condensation. Nothing was isolated under the acid conditions.

Attempted Condensations

Normal condensations failed to occur with acenaphthenone under alkaline conditions and the following substituted benzaldehydes, *m*-methoxy-, *m*-methyl-, and *p*-methyl-

In the first two cases either naphthalic acid or its anhydride was isolated and in the latter case self-condensation of the acenaphthenone gave yellow crystals of biacenone, m.p. 260° C. Found: C, 90.3; H, 4.43%. Calculated for $C_{24}H_{14}O$: C, 90.5; H, 4.43%. Biacenone was the only isolated product when acenaphthenone was treated with aliphatic aldehydes (propionic and butyric).

Acenaphthylene-1',2',3,5-benzoyloxy-7-hydroxybenzopyrilium Chloride

Acenaphthenone (1 g.) and 2-O-benzoylphloroglucinaldehyde (1.5 g.) were dissolved in anhydrous ethyl acetate (5 ml.) and a few drops of glacial acetic acid (to effect complete solution of the aldehyde). Dry hydrogen chloride gas was passed into the mixture for an hour. The solution, which assumed a deep red coloration, was placed in an ice box for 4 or 5 days. A red powdery material separated which melted at 140–141°. To recrystallize this material, it was dissolved in a little absolute ethanol and the solution was again saturated with hydrogen chloride gas. Found: C, 68.3; H, 4.00; Cl, 7.29; loss at 110° *in vacuo* over phosphoric anhydride 6.45%. Calculated for $C_{26}H_{15}O_4Cl \cdot 1.5H_2O$: C, 68.9; H, 3.98; Cl, 7.84; H_2O , 5.97%.

AN OXYGENATED FATTY ACID FROM THE SEED OIL OF HIBISCUS ESCULENTUS¹

MARY J. CHISHOLM AND C. Y. HOPKINS

ABSTRACT

The fatty acids of okra seed oil (*Hibiscus esculentus* L.) were examined. Acetylation of the oil, followed by saponification and separation of the acids, gave 12,13-dihydroxyoleic acid. From this and other evidence it is concluded that 12,13-epoxyoleic acid is present as a constituent of the glycerides. An oxygenated acid has not been identified previously in seed oils of this plant family (Malvaceae). 9-Hexadecenoic acid was also found. The total fatty acid composition was determined by distillation of the methyl esters and analysis of the distilled fractions. The percentages of the acids identified were estimated as follows: 9-hexadecenoic 0.6, palmitic 29, linoleic 39, oleic 23, stearic 2, 12,13-epoxyoleic 3, arachidic <1. Myristic, eicosenoic, and trienoic acids were not detected and, if present, are judged to have been in amounts less than 1% of the total.

INTRODUCTION

Various plants of the family Malvaceae produce oleaginous seeds but only the cottonseed (*Gossypium* sp.) is utilized commercially for its oil. However, okra (*Hibiscus esculentus* L.) has been proposed as an oilseed crop since it can be grown in areas that are unsuitable for cotton.

The fatty acids of okra seed oil have been examined by several groups of workers (3, 4, 6, 7, 10) and it is agreed that the major components are palmitic, oleic, and linoleic acids. In addition, it was observed by Clopton, Roberts, and Jeskey (3) that their sample of okra oil contained an unusual acid, apparently of greater chain length than C₁₈. They estimated that this acid constituted 8% of the total fatty acids and suggested that it was probably an unsaturated 20-carbon acid. Accordingly, the present work was undertaken to determine whether this might have been eicosenoic acid, particularly as there has been no other indication that eicosenoic acid occurs in any species of Malvaceae.

EXPERIMENTAL

Properties of the Oil

Okra seed was obtained from commercial seed houses. Two varieties were examined, viz. White Velvet and Perkins Mammoth Long Pod. The seeds were ground in a Wiley mill, the moisture content of the meal was determined, and the oil was extracted with petroleum ether. The yields of oil and the analytical values are shown in Table I.

The oil of the Perkins variety was examined in detail. A portion was saponified and the total fatty acids were freed from unsaponifiable matter. Their ultraviolet absorption, before and after alkali isomerization, is shown in Fig. 1.

The content of conjugated acids before isomerization was quite small and the total content of triene acid was negligible.

Examination of the Methyl Esters

The oil (Perkins variety) was converted to methyl esters by methanolysis with dry hydrogen chloride as catalyst. The glycerol was removed by washing with water and

*Method of Swern (11).

FIG. 1. Ultraviolet spectrum of okra oil fatty acids freed of unsaponifiable matter. A, before isomerization; B, after isomerization (in glycerol 45 minutes at 180°).

FIG. 2. Distillation of methyl esters: 1, esters made from the whole oil; 2, esters freed of oxygenated acid; 3, esters from oil freed of oxygenated acid and hydrogenated.

the esters were dried. The mixed esters (318 g.) were distilled through a Podbielniak Heli-Grid column at a pressure of 0.5 mm., with the addition of a heavy petroleum fraction as a chaser. The usual C_{16} and C_{18} fractions were collected but the subsequent fractions were abnormal. A considerable portion distilled at a temperature between that of the ordinary C_{18} and C_{20} esters (Fig. 2, distillation 1). (This was doubtless the fraction that led the earlier workers (3) to suspect the presence of a C_{20} acid.) This fraction had an appreciable acetyl value and accordingly was thought to contain an oxygenated acid.

A fresh lot of okra oil was therefore treated by the procedure of Gunstone (5) to remove any epoxy or hydroxy acids by acetylation, hydrolysis, and solvent partition. The remaining mixed acids were esterified with methanol and distilled. Only the usual C_{16} and C_{18} esters distilled and there was no abnormal fraction (Fig. 2, distillation 2).

A further quantity of the oil was freed of oxygenated acids, hydrogenated, converted to methyl esters, and distilled through a spinning band column (distillation 3). The percentage composition of the non-oxygenated acids, by chain length, was estimated from this distillation as follows: C₁₆, 30%; C₁₈, 65%; undetermined, 5%.

TABLE II
DISTILLATION OF METHYL ESTERS
(Freed of oxygenated acid)

Fraction	Temp., °C. (0.5 mm.)	Weight, g.	Chain length	Iodine value	Refractive index, 25°

The data from distillation 2 are given in Table II. A number of the fractions were examined individually to identify the component acids. These are shown in Table III. Identity of the acid or its derivative was confirmed by mixed melting point in each case.

TABLE III
IDENTIFICATION OF ACIDS

Fraction	Acid	Identified as:	M.p., °C.
1	9-Hexadecenoic	9,10-Dihydroxypalmitic	124-125
3	Palmitic	Palmitic	62-62.5
8	Linoleic	Diepoxystearic	78-79
11	Oleic	Dihydroxystearic	129-130
13	Stearic	Stearic	69-70
—	12,13-Epoxyoleic	See text	Equiv. wt. 285
15	Arachidic	Methyl arachidate	45.5-46.5

Fractions 1 and 2 were combined and recrystallized from acetone at -40°. The crystals were saponified giving palmitic acid. The ester from the filtrate was saponified and hydroxylated by alkaline permanganate, giving 9,10-dihydroxypalmitic acid. Thus the low-boiling material consists mainly of esters of hexadecenoic and palmitic acids. Myristic acid was not identified although there was a small forerun. Fractions 3, 4, and 5 were almost pure methyl palmitate.

Fraction 8 was mainly methyl linoleate. On being saponified and treated with peracetic acid, it gave diepoxystearic acid, m.p. 78-79°. Oleic acid was identified in fraction 11 and stearic acid in fraction 13.

Fraction 15 was recrystallized from acetone at -10° and again from ethanol, giving methyl arachidate. The acetone filtrate was examined but did not yield any eicosenoate, nor did fraction 16. It is estimated that any eicosenoic acid in excess of 1% of the total fatty acids would have been found in this procedure. Examination of the distillation residue indicated the presence of minor amounts of higher saturated acids ($>C_{20}$).

Isolation of an Oxygenated Acid

Freshly-extracted okra seed oil (125 g.) was refluxed with five volumes of glacial acetic acid for 6 hours (5). The acetic acid was distilled off under reduced pressure and the residual oil was saponified by alcoholic potassium hydroxide. Most of the alcohol was removed and replaced by water. The solution was extracted with petroleum ether to remove unsaponifiable matter and then acidified to liberate the fatty acids.

The mixed acids were dissolved in petroleum ether and shaken with successive portions of aqueous methanol (four volumes CH_3OH : one volume H_2O). From the methanol extracts there was obtained 5.3 g. of crude oxygenated fatty acid. It was recrystallized from 60 ml. of acetone at -30° (yield 3.0 g.) and then from petroleum ether:ethyl ether (3:1) at room temperature. The product (2.5 g.) melted at $53.5-54.5^{\circ}$ and gave the following analysis: equivalent weight 316.4; OH, 10.85, 10.65; C, 68.99; H, 11.05 (calc. for dihydroxyoctadecenoic acid, $C_{18}H_{34}O_4$: equivalent weight 314.4; OH, 10.82; C, 68.75; H, 10.89). The iodine value was 103.0, somewhat higher than calculated for one double bond; there is evidently some absorption of iodine by reaction with the OH groups.

The analysis shows, therefore, that the substance is almost certainly a dihydroxy-octadecenoic acid.

Determination of Structure

The acid was split by oxidation with potassium permanganate in acetic acid. A solution of 2.9 g. of the dihydroxyoctadecenoic acid in 30 ml. of glacial acetic acid was held at $40-50^{\circ}$ while 8 g. of powdered $KMnO_4$ in portions was added with stirring. The mixture was kept at 50° for a further 3 hours. The resulting products, isolated by the usual procedures, were azelaic acid, m.p. $104-106^{\circ}$, and hexanoic acid, the latter identified as the *p*-phenylphenacyl ester, m.p. $64-65^{\circ}$. These melting points were not changed by admixture with known samples.

Another portion of the dihydroxyoctadecenoic acid was hydrogenated in methanol with Adams' catalyst, giving dihydroxystearic acid, m.p. $96.5-97^{\circ}$, from ethyl acetate. Oxidative fission by permanganate-periodate (8) gave dodecanedioic acid, m.p. 127° ; equivalent weight, 115.8 (theory 115.2).

The original dihydroxy acid is therefore 12,13-dihydroxy-9-octadecenoic acid (12,13-dihydroxyoleic acid). Its identity was subsequently confirmed by mixed melting point with a sample kindly supplied by Dr. F. D. Gunstone. The identity of the 12,13-dihydroxy stearic acid was confirmed in the same way.

A portion of the original dihydroxyoleic acid was hydroxylated by alkaline permanganate and gave tetrahydroxystearic acid, m.p. 164° . This proved, by mixed melting point, to be identical with the erythro-9,10-threo-12,13-tetrahydroxystearic acid of Bharucha and Gunstone (1).

Identification of the Epoxy Group by Nuclear Magnetic Resonance Spectra

9,10-Epoxy stearic acid and 12,13-epoxyoleic acid were prepared by the action of peracetic acid on oleic and linoleic acids, respectively. The 12,13-epoxyoleic acid was

freed from diepoxy acid by fractional crystallization from acetone at low temperature. It had neutralization equivalent 297.3 (theory 296.4).

The proton magnetic resonance spectra of okra seed oil, oleic acid, and the two monoepoxy acids were obtained with a Varian NMR spectrometer at 40 megacycles; the samples were in solution in chloroform, with the exception of the oleic acid which was examined in the pure liquid form. The results are shown in Figs. 3 and 4.

The signal in the vicinity of 60 cycles per second, referred to the main CH_2 signal as

FIG. 3. Proton magnetic resonance spectra of okra seed oil (Perkins variety). Signals are assigned as follows: *A*, double bond; *B*, glyceryl residue; *C*, epoxy group; *D*, methylene groups adjacent to double bond and to carbonyl; *E*, all other CH_2 groups; *R*, chloroform reference signal.

FIG. 4. Significant bands observed in the proton resonance spectra of okra seed oil and comparison compounds. Signals are assigned as in Fig. 3. Differences in intensities are not indicated. The signal of the acid proton is not shown.

zero, is attributed to the epoxy group. It is clearly evident in the spectrum of okra seed oil, thus confirming the presence of the epoxy group in the oil.

In contrast, coconut oil gave a negligible signal in this region. The seed of *Vernonia colorata* gave a strong signal at 66 c.p.s. This oil was found by chemical analysis to have a high content of epoxyoleic acid (unpublished data), resembling *Vernonia anthelmintica* in this respect.

Halphen Test

Okra seed oil is known to give a positive red color in the Halphen test and this was confirmed with both samples used in the present study. In order to determine whether the epoxy group affects the Halphen reagent (CS_2), several substances were tested. 12,13-Epoxyoleic acid, prepared from linoleic acid, gave a light brown color, not regarded as a positive reaction. Epoxystearic and diepoxystearic acids produced a yellow color, while 12,13-dihydroxyoleic acid gave no color. The oil of *Vernonia colorata* gave only a light yellow color with the Halphen reagent.

Composition of the Total Fatty Acids

The yield of dihydroxyoleic acid, after one recrystallization, was about 2.5% of the weight of the oil. (The White Velvet variety gave a larger yield, 3.8%.) If its precursor is epoxyoleic acid, as believed, the content of epoxyoleic acid in the Perkins variety is estimated to be about 3% of the total fatty acids of the oil. By calculation from the epoxy value of the whole oil, the epoxyoleic acid content is 3.9%.

The proportions of the other acids, including only those actually identified, were calculated from the distillation and analytical data and are shown in Table IV.

No dihydroxyoleic acid was obtained from the whole oil by the solvent partition procedure when the acetylation step was omitted.

TABLE IV
ESTIMATED FATTY ACID COMPOSITION
(Per cent of total fatty acids)

Acid	%
9-Hexadecenoic	0.6
Palmitic	29
Linoleic	39
Oleic	23
Stearic	2
12,13-Epoxyoleic	3
Arachidic	<1
Undetermined	3

DISCUSSION

Although a small amount of a C_{20} acid (arachidic) was found in our sample of okra seed, we did not detect any eicosenoic acid. It is judged that C_{20} acids make up a very minor proportion of the total glycerides. The unusual acid detected by Clopton and co-workers (3) was very probably epoxyoleic acid or reaction products thereof. As already known (5), the oxirane ring in this acid is quite reactive and is opened either during saponification of the glycerides or during esterification of the acids. Thus the distilled methyl ester fractions contain esters of hydroxy or methoxy acids having a chain length of 18 carbon atoms. These distill somewhat higher than the esters of ordinary C_{18} acids

and were observed during our distillation 1. Gunstone's procedure converts the epoxyoleic acid to dihydroxyoleic acid which is readily removed by solvent partition and so does not appear in the distillation.

The identity of dihydroxyoleic acid obtained in the present work from okra oil has been fully established by oxidative scission and by comparison with the same acid obtained by Gunstone and Bharucha from *Vernonia anthelmintica* (5) and *Cephalocroton cordofanus* (2). Although the reactivity of the epoxy group has prevented the isolation of epoxyoleic acid itself from these oils, there can be little doubt that they contain epoxyoleic acid as glyceride. Quantitative determination of the oxirane content of the oils agrees with the amounts of dihydroxyoleic acid isolated. In the present work, further evidence has been obtained by proton magnetic resonance spectra. Oils that yield dihydroxyoleic acid (after acetylation) exhibit a proton resonance signal corresponding to that given by the epoxy group of pure epoxyoleic and epoxystearic acids (Fig. 4).

This is the first instance to be reported of epoxyoleic acid occurring in a seed oil of the Malvaceae family. The amount is small (3%) in comparison with the proportion found in *Vernonia* and *Cephalocroton* oils (about 70%).

Although okra oil gives the Halphen test, neither epoxyoleic nor dihydroxyoleic acids give the test. Presumably, therefore, the acid responsible for the Halphen test is present in okra oil in addition to the other acids so far reported. The "Halphen" acid, believed to contain a three-carbon ring, has been found in three species of Malvaceae (9). It seems doubtful whether there is any relation between the Halphen acid and epoxyoleic acid.

In addition to the acids already known to occur in okra oil, the present work has demonstrated that 12,13-epoxyoleic and 9-hexadecenoic acids are present. Myristic acid was not detected in our sample, nor was eicosenoic acid. It is concluded that the amounts of these two acids, if present, were not more than 1% of the total. Singh and Dutt (10) reported 0.8% of myristic acid.

The estimated proportions of the major acids, palmitic, oleic, and linoleic, confirm the more recent analyses (4, 6).

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES

IV. FURTHER DEGRADATIONS OF REDUCING DISACCHARIDES TO 2-O-GLYCOSYL-GLYCEROLS¹

A. J. CHARLSON,² P. A. J. GORIN,² AND A. S. PERLIN

ABSTRACT

The configuration of glycosidic linkages in a number of reducing disaccharides has been determined by converting each compound to the corresponding 2-O-glycosyl-glycerol, the configuration of which was readily established. Compounds examined include 3-O-β-D-galactopyranosyl-D-galactose, 3-O-α-D-galactopyranosyl-L-arabinose, 3-O-β-D-arabopyranosyl-L-arabinose, 2-O-β-D-xylopyranosyl-L-arabinose, 3-O-α-D-xylopyranosyl-L-arabinose, and 4-O-β-D-xylopyranosyl-D-xylose, all of which were derived by partial hydrolysis of polysaccharides. 2-O-α-L-Arabopyranosyl-glycerol has been synthesized via the Koenigs-Knorr condensation.

A previous paper in this series (3) describes a novel method for determining the configuration of glycosidic linkages in reducing disaccharides containing a hexopyranose non-reducing end-unit. According to this method the reducing end-unit of the disaccharide is degraded selectively by successive lead tetraacetate oxidations and sodium borohydride reductions to a 2-O-substituted glycerol. The resulting 2-O-glycopyranosyl-glycerol is one of two possible anomeric glycosides the configurations of which are designated by Hudson's nomenclature (9) according to their relative specific rotations.

Studies on the oxidation of reducing disaccharides by lead tetraacetate (4) indicate that many kinds of disaccharides can be degraded to give 2-O-glycosyl-glycerols. With the current paper the method has now been applied to each type of disaccharide represented in Fig. 1; the 1,2- and 1,4-aldohexose disaccharides were considered earlier (3). Most of the disaccharides examined had been isolated by other workers through partial hydrolysis of polysaccharides, but many had only tentatively been characterized. Included in the study are several pentopyranosyl disaccharides, and these have furnished three of the four possible 2-O-L-arabopyranosyl- and 2-O-D-xylopyranosyl-glycerols necessary as reference compounds. The fourth of these was synthesized.

Degradation of the various compounds is summarized by the series of reactions listed below, in which lead tetraacetate is represented by "O" and sodium borohydride by "H". Non-crystalline products were characterized as derived benzoates.

A. 3-O-β-L-Arabopyranosyl-L-arabinose (11), from a partial hydrolyzate of larch ε-galactan

B. 3-O- α -D-Xylopyranosyl-L-arabinose (1), from an autohydrolyzate of golden apple gum

C. 4-O- β -D-Xylopyranosyl-D-xylose (22) from a partial hydrolysis of wheat flour pentosan (14)

D. 2-O- β -D-Xylopyranosyl-L-arabinose (21) from a partial hydrolyzate of hemicellulose-B of corn cobs

- E. 3-*O*- α -D-Galactopyranosyl-L-arabinose (17), from a partial hydrolyzate of gum acacia

- F. 3-*O*- β -D-Galactopyranosyl-D-galactose (6, 17), from a partial hydrolyzate of gum acacia

- G. 5-*O*- α -D-Glucopyranosyl-D-fructose (leucrose) (19), from sucrose by enzymic synthesis with *Leuconostoc mesenteroides*

2-*O*- α -L-Arabopyranosyl-glycerol was synthesized in the following way: 2,3,4-tri-*O*-acetyl- β -L-arabopyranosyl-bromide was condensed with 1,3-*O*-benzylidene-glycerol using the procedure of Carter (2). The crystalline (1',3'-*O*-benzylidene)-2-*O*- α -L-arabopyranosyl-glycerol thus formed gave a crystalline tribenzoate. Removal of the benzylidene group by catalytic hydrogenolysis (18) afforded sirupy 2-*O*- α -L-arabopyranosyl-glycerol, which was characterized by conversion to its pentabenzoate. The properties of this and other new glycosyl-glycerols and of their respective benzoate derivatives are listed in Table I. The majority of these benzoates appear to be amorphous. However, they have good melting points, give correct analyses, and are readily distinguishable by their specific rotations and infrared absorption spectra.

The results of the present and earlier studies in this series on determining configuration (3, 5) generally agree with those obtained previously by other workers for the same disaccharides. The sole exception is 2-*O*- β -D-xylopyranosyl-L-arabinose, which originally was thought to possess the α -configuration (20). For most of these disaccharides the assignment of configuration had been made by reference to the equilibrium specific rotations of the compounds. This practice has developed as an extension of Hudson's Rules of Isorotation (10), but its correctness has not been rigidly established, chiefly because the rotatory contribution of the reducing end-unit in the equilibrium mixture is not readily assessed. The current results, therefore, characterize more definitively those compounds examined for which configurations had been assigned previously from equilibrium rotation values. Moreover, because of the generally good agreement between the two methods, they provide support for the validity of the polarimetric method.

It appears likely that the configuration of yet other types of reducing disaccharides can be determined by the present procedure. For example, the reducing end-unit of an aldobiuronic acid may be degraded (4) and the carboxyl group of the uronic acid residue reduced to a carbinol group, giving a 2-*O*-glycosyl-glycerol. When glycosyl-glycerols required as reference compounds are not obtainable, e.g., when the related disaccharides

TABLE I
 PROPERTIES OF 2-O-GLYCOSYL-GLYCEROLS AND DERIVATIVES

are unknown, at least one of the anomers may frequently be synthesized. This procedure is likely to prove more simple than synthesis of the disaccharide itself since it involves a condensation with readily available 1,3-disubstituted glycerols, rather than with possibly a rare sugar derivative having one particular hydroxyl group free.

EXPERIMENTAL

Optical rotations were measured at 27° C. Sugars produced by hydrolysis of disaccharides were characterized by paper chromatography. Chromatograms were prepared using Whatman No. 1 filter paper and *n*-butanol-ethanol-water (40:11:19, v/v) as solvent. Non-reducing and reducing sugars were detected with ammoniacal silver nitrate (13) and *p*-anisidine hydrochloride sprays (8), respectively. Solutions were concentrated at 40° C. under reduced pressure. Infrared absorption spectra were prepared by the potassium bromide window technique (16).

Disaccharides obtained by partial hydrolysis of polysaccharides were isolated by chromatographic methods. In a typical preparation, wheat flour pentosan (14) (50 g.) was hydrolyzed with 0.1 *N* sulphuric acid (250 ml.) for 5 hours on the steam bath. The products were fractionated on a charcoal column, mono-, di-, and tri-saccharides being separated with varying concentrations of ethanol in water (20). The disaccharide fraction was refractionated on a cellulose column (7) using *n*-butanol half saturated with water as solvent, and the material corresponding to xylobiose (1.0 g.) was recovered. Recrystallized from aqueous methanol it had m.p. 183-185° C., undepressed on admixture with authentic 4-O-D-xylopyranosyl-D-xylose.

Some of the disaccharides were sirups, in accordance with the description of these products by other workers. As a check on the isolation procedure, therefore, the component sugars of the compounds were characterized after hydrolysis, and linkage positions determined by lead tetraacetate oxidation (4).

For the sake of brevity, the techniques used in lead tetraacetate oxidations and sodium borohydride reductions are described in full only the first time they are reported. Benzoates were recrystallized from ethanol at -30°C .

2-O- β -L-Arabopyranosyl-glycerol from 3-O- β -L-Arabopyranosyl-L-arabinose

Sirupy 3-O- β -L-arabopyranosyl-L-arabinose (718 mg.) was dissolved in water (2 ml.), and acetic acid (150 ml.) was then added. The solution was treated with lead tetraacetate (1.2 g., 1.1 molar equivalents) and after 10 minutes the divalent lead was removed from solution by addition of 10% oxalic acid in acetic acid. The suspension was stirred for 0.5 hour, then filtered, and the filtrate was evaporated to dryness. The material obtained was dissolved in water (50 ml.) and deionized with a mixture of Amberlite IR-120 and Dowex-1 resin. Sodium borohydride (0.5 g.) was then added and after 15 minutes excess reagent was decomposed with acetic acid. The solution was treated with Amberlite IR-120 resin and evaporated to a crust, which was dissolved in methanol. The solution was evaporated in order to remove the excess boric acid. This procedure was repeated three times to give sirupy 2-O- β -L-arabopyranosyl-L-erythritol (415 mg.) with $[\alpha]_{\text{D}} +135^{\circ}$ (c , 1.70, water).

The erythritol derivative (22 mg.) was benzoylated (procedure described under "2-O- α -L-arabopyranosyl-glycerol"). Two recrystallizations of the product from ethanol gave the hexabenzoate as white needles (41 mg.) with m.p. $131\text{--}134^{\circ}\text{C}$. and $[\alpha]_{\text{D}} +114^{\circ}$ (c , 1.0, 2,4-lutidine). Calculated for $\text{C}_{51}\text{H}_{42}\text{O}_{14}$: C, 69.69%; H, 4.82%. Found, C, 70.03%; H, 4.84%.

The arabopyranosyl-erythritol (304 mg.) was oxidized with lead tetraacetate (590 mg.) in acetic acid (60 ml.) containing water (1 ml.). After the oxidation was completed the reaction mixture was worked up and the product reduced in the usual way with sodium borohydride. A mixture of compounds was produced and these were fractionated on a cellulose column using n -butanol half saturated with water as the mobile phase. The 2-O- β -L-arabopyranosyl-glycerol (83 mg.) crystallized and was twice recrystallized from ethanol. The product (64 mg.) had m.p. $154\text{--}155^{\circ}\text{C}$. and $[\alpha]_{\text{D}} +204^{\circ}$ (c , 1.2, water). Calculated for $\text{C}_8\text{H}_{16}\text{O}_7$: C, 42.85%; H, 7.19%. Found: C, 43.04%; H, 7.20%. Hydrolysis of the material produced arabinose and glycerol. The infrared absorption spectrum of the compound differed from that of its α -anomer.

The glycerol derivative was converted to the pentabenzoate, which had m.p. $48\text{--}50^{\circ}\text{C}$. and $[\alpha]_{\text{D}} +164^{\circ}$ (c , 0.8, 2,4-lutidine). Calculated for $\text{C}_{43}\text{H}_{36}\text{O}_{12}$: C, 69.35%; H, 4.87%. Found: C, 69.47%; H, 4.43%.

2-O- α -D-Xylopyranosyl-glycerol from 3-O- α -D-Xylopyranosyl-L-arabinose

Sirupy 3-O- α -D-xylopyranosyl-L-arabinose (452 mg.) was dissolved in water (2 ml.), and acetic acid (100 ml.) was added followed by lead tetraacetate (990 mg.). After 15 minutes the reaction mixture was worked up as described above and the product was reduced with sodium borohydride to give sirupy 2-O- α -D-xylopyranosyl-L-erythritol (338 mg.), which had $[\alpha]_{\text{D}} +91^{\circ}$ (c , 0.9, water).

The erythritol derivative (42 mg.) was benzoylated and the product recrystallized three times from ethanol. It (60 mg.) had m.p. $64\text{--}67^{\circ}\text{C}$. and $[\alpha]_{\text{D}} +98^{\circ}$ (c , 1.1, 2,4-lutidine). Calculated for $\text{C}_{51}\text{H}_{42}\text{O}_{14}$: $\text{C}_6\text{H}_5\text{CO}$, 71.7%. Found: $\text{C}_6\text{H}_5\text{CO}$, 71.5%.

2-O- α -D-Xylopyranosyl-L-erythritol (209 mg.) was oxidized with lead tetraacetate (400 mg.) in acetic acid (75 ml.) containing water (1.5 ml.). After the oxidation was completed the reaction mixture was worked up and the product reduced with aqueous

sodium borohydride. The resulting 2-*O*- α -D-xylopyranosyl-glycerol was contaminated with a little of the erythritol derivative and the mixture was fractionated on a cellulose column using *n*-butanol, one-third saturated with water, as solvent. The purified sirup had $[\alpha]_D +95^\circ$ (*c*, 1.5, water) and gave xylose and glycerol on hydrolysis.

The glycerol derivative (61 mg.) was converted to its pentabenzoate, three recrystallizations from ethanol yielding a product with m.p. 51–55° C. and $[\alpha]_D +51^\circ$ (*c*, 1.1, 2,4-lutidine). Calculated for $C_{43}H_{36}O_{12}$: C_6H_5CO , 70.6%. Found: C_6H_5CO , 70.9%.

2-O- β -D-Xylopyranosyl-glycerol from 4-O- β -D-Xylopyranosyl-D-xylose

The xylobiose (428 mg.) was dissolved in water (2 ml.), and acetic acid (100 ml.) and lead tetraacetate (1.35 g.) added. After 3 hours the 2-*O*- β -D-xylopyranosyl-D-glyceraldehyde was isolated and converted by sodium borohydride reduction to sirupy 2-*O*- β -D-xylopyranosyl-glycerol (200 mg.) with $[\alpha]_D -37^\circ$ (*c*, 1.1, water). Hydrolysis of the material gave xylose and glycerol.

The glycerol derivative (90 mg.) was benzoylated to give the pentabenzoate, which after three recrystallizations from ethanol had m.p. 51–53° C. and $[\alpha]_D -36^\circ$ (*c*, 0.9, 2,4-lutidine). Yield 33 mg. Calculated for $C_{43}H_{36}O_{12}$: C, 69.35%; H, 4.87%. Found: C, 69.62%; H, 4.83%. The infrared absorption spectrum differed from that of the α -anomer.

2-O- β -D-Xylopyranosyl-glycerol from 2-O- β -D-Xylopyranosyl-L-arabinose

Sirupy 2-*O*- β -D-xylopyranosyl-L-arabinose (465 mg.) was reduced to crystalline 2-*O*- β -D-xylopyranosyl-L-arabitol using sodium borohydride. The product was recrystallized twice from methanol–ethanol and had m.p. 185–187° C. and $[\alpha]_D -33^\circ$ (*c*, 1.2, water). Yield 235 mg. Calculated for $C_{10}H_{20}O_9$: C, 42.25%; H, 7.09%. Found: C, 42.45%; H, 7.15%.

The arabitol derivative (152 mg.) was oxidized in water (0.4 ml.) and acetic acid (40 ml.) with lead tetraacetate (0.59 g.) for 18 hours. The resulting glyceraldehyde derivative was reduced with sodium borohydride to sirupy 2-*O*- β -D-xylopyranosyl-glycerol (135 mg.) having $[\alpha]_D -30^\circ$ (*c*, 1.3, water). The infrared absorption spectrum was identical with that of an authentic specimen. The material gave xylose and glycerol on hydrolysis.

The glycerol derivative (72 mg.) was converted to its pentabenzoate, which after three recrystallizations from ethanol had m.p. 51–53° C., undepressed on admixture with an authentic specimen of 2-*O*- β -D-xylopyranosyl-glycerol pentabenzoate; $[\alpha]_D -35^\circ$ (*c*, 1.2, 2,4-lutidine). Yield 41 mg. Calculated for $C_{43}H_{36}O_{12}$: C, 69.35%; H, 4.87%. Found: C, 69.67%; H, 4.50%. The material had an infrared absorption spectrum identical with that of authentic 2-*O*- β -D-xylopyranosyl-glycerol pentabenzoate and different from that of the α -anomer.

2-O- α -D-Galactopyranosyl-glycerol from 3-O- α -D-Galactopyranosyl-L-arabinose

3-*O*- α -D-Galactopyranosyl-L-arabinose (1.84 g.) was oxidized with lead tetraacetate (2.5 g.) for 10 minutes in acetic acid (250 ml.) containing water (4 ml.). The reaction product was converted by sodium borohydride reduction to 2-*O*- α -D-galactopyranosyl-L-erythritol, which on recrystallization from aqueous ethanol had m.p. 156–158° C. and $[\alpha]_D +145^\circ$ (*c*, 1.0, water). Yield 1.0 g. Calculated for $C_{10}H_{20}O_9$: C, 42.25%; H, 7.09%. Found: C, 42.16%; H, 7.11%.

The erythritol derivative (560 mg.) was oxidized for 3 hours with lead tetraacetate (860 mg.) in acetic acid (100 ml.) containing water (2 ml.). The reaction mixture was

worked up and the product reduced with aqueous sodium borohydride to give a mixture of unchanged material and 2-*O*- α -D-galactopyranosyl-glycerol. These were separated on a cellulose column using *n*-butanol half saturated with water as solvent. The glycosyl-glycerol (250 mg.) was recrystallized from ethanol and had m.p. 131–132° C., undepressed on admixture with an authentic specimen of 2-*O*- α -D-galactopyranosyl-glycerol (12); $[\alpha]_D +164^\circ$ (*c*, 0.7, water). Calculated for $C_9H_{18}O_8$: C, 42.52%; H, 7.14%. Found: C, 42.55%; H, 7.17%. The infrared absorption spectra of the product and of the authentic α -anomer were identical.

2-O- α - and 2-O- β -D-Galactopyranosyl-glycerol Hexabenzoates

2-*O*- α -D-Galactopyranosyl-glycerol (46 mg.) was benzoylated to give its hexabenzoate (76 mg.) having m.p. 156–157° C. and $[\alpha]_D +120^\circ$ (*c*, 1.4, 2,4-lutidine) after two recrystallizations from ethanol. Calculated for $C_{51}H_{42}O_{14}$: C, 69.69%; H, 4.82%. Found: C, 69.24%; H, 4.73%.

The β -anomer (46 mg.) was benzoylated yielding, after four precipitations from ethanol, an amorphous powder (53 mg.) which had m.p. 61–63° C. and $[\alpha]_D +25^\circ$ (*c*, 0.6, 2,4-lutidine). Calculated for $C_{51}H_{42}O_{14}$: C, 69.69%; H, 4.82%. Found: C, 69.20%; H, 5.37%. The two anomeric hexabenzoates had readily distinguishable infrared absorption spectra.

2-O- β -D-Galactopyranosyl-glycerol from 3-O- β -D-Galactopyranosyl-D-galactose

3-*O*- β -D-Galactopyranosyl-D-galactose (500 mg.) was dissolved in acetic acid (100 ml.) containing water (1 ml.) and oxidized with lead tetraacetate (900 mg.). After 20 minutes the reaction mixture was worked up and reduced with sodium borohydride to give 4-*O*- β -D-galactopyranosyl-D-arabitol (2-*O*- β -D-galactopyranosyl-D-lyxitol (390 mg.), which was recrystallized twice from ethanol to give a material with m.p. 177–179° C. and $[\alpha]_D -7^\circ$ (*c*, 0.6, water). Calculated for $C_{11}H_{22}O_{10}$: C, 42.03%; H, 7.06%. Found: C, 41.99%; H, 7.06%.

The disaccharide (310 mg.), thus obtained, was oxidized with lead tetraacetate (860 mg.) for 2 hours in acetic acid (50 ml.) containing water (0.8 ml.). The product was reduced with aqueous sodium borohydride to give a mixture which contained 2-*O*- β -D-galactopyranosyl-glycerol. This was fractionated on a cellulose column using *n*-butanol half saturated with water as the mobile phase. The D-galactosyl-glycerol (100 mg.) could not be induced to crystallize. Therefore a portion (41 mg.) was converted to its hexabenzoate, which after two successive precipitations from ethanol had m.p. 56–59° C., undepressed on admixture with authentic 2-*O*- β -D-galactopyranosyl-glycerol hexabenzoate, and $[\alpha]_D +36^\circ$ (*c*, 0.7, 2,4-lutidine). Calculated for $C_{51}H_{42}O_{14}$: C, 69.69%; H, 4.82%. Found: C, 69.53%; H, 4.83%. The infrared absorption spectrum was identical with that of the β -galactose hexabenzoate derivative and differed from that of the α -anomer.

2-O- α -D-Glucopyranosyl-glycerol from 5-O- α -D-Glucopyranosyl-D-fructose

5-*O*- α -D-Glucopyranosyl-D-fructose (225 mg.) was oxidized with lead tetraacetate (580 mg.) in acetic acid (50 ml.) containing water (1 ml.). After 3 hours' reaction time the product was reduced using sodium borohydride to give a mixture of materials from which 2-*O*- α -D-glucopyranosyl-glycerol (85 mg.) was isolated by chromatography on a cellulose column using *n*-butanol half saturated with water as solvent. It had $[\alpha]_D +119^\circ$ (*c*, 0.7, water), an infrared absorption spectrum identical with that of the α -anomer but

different from that of the β -anomer, and gave glucose and glycerol on acid hydrolysis.

The glycerol derivative was converted to its hexabenzoate, which was recrystallized twice from ethanol. It had m.p. 137–138° C., unchanged on admixture with authentic 2-*O*- α -D-glucopyranosyl-glycerol hexabenzoate, and $[\alpha]_D +94^\circ$ (*c*, 0.8, CHCl₃); it gave an infrared absorption spectrum identical with that of 2-*O*- α -D-glucopyranosyl-glycerol hexabenzoate, but unlike the β -anomer. Calculated for C₅₁H₄₂O₁₄: C, 69.69%; H, 4.82%. Found: C, 69.82%; H, 4.80%.

2-O- α -L-Arabopyranosyl-glycerol

A mixture of tri-*O*-acetyl- β -L-arabopyranosyl-bromide (8.4 g.), 1,3-*O*-benzylidene-glycerol (7.5 g.), silver carbonate (20 g.), and Drierite (50 g.) in benzene (125 ml.) was shaken for 3 hours at 55° C. It was then refluxed for 15 minutes, the solution was filtered, and chloroform (200 ml.) was then added to the filtrate followed by sodium methoxide (0.5 g.) in methanol (20 ml.). After 18 hours at room temperature the solution was evaporated to a sirup which was fractionated on a cellulose column. Benzene eluted unchanged 1,3-*O*-benzylidene-glycerol, and benzene-ethanol-water (3:1:trace, v/v) eluted (1',3'-*O*-benzylidene)-2-*O*- α -L-arabopyranosyl-glycerol (3.1 g.). The product crystallized and was recrystallized twice from methanol-ether, m.p. 121–122° C. and $[\alpha]_D +4^\circ$ (*c*, 1.1, ethanol). Calculated for C₁₅H₂₀O₇: C, 57.68%; H, 6.40%. Found: C, 57.73%; H, 6.48%.

The product (46 mg.) was dissolved in chloroform (0.30 ml.) containing pyridine (0.20 ml.) and benzoyl chloride (0.12 ml.). After 18 hours the reaction mixture was dissolved in chloroform to which a little methanol was added, and the solution was washed successively with 1% sulphuric acid, aqueous sodium bicarbonate, and water, then dried with magnesium sulphate, filtered, and evaporated to a sirup which crystallized. Three recrystallizations from ethanol gave a product softening at 160–165° C. and melting at 170–172° C., with $[\alpha]_D +114^\circ$ (*c*, 0.9, 2,4-lutidine). Calculated for C₃₆H₃₂O₁₀: C, 69.22%; H, 5.16%. Found: C, 69.47%; H, 5.18%.

The 1,3-benzylidene-L-arabinosyl-glycerol (28 mg.) was dissolved in ethanol (25 ml.) and the solution was shaken with palladium oxide (80 mg.) in an atmosphere of hydrogen for 18 hours. The product, obtained as a sirup by filtration and evaporation of the solution, had $[\alpha]_D +5^\circ$ (*c*, 1.0, water).

2-O- α -L-Arabopyranosyl-glycerol Pentabenzoate

The L-arabopyranosyl-glycerol (93 mg.) was benzoylated and the product, after three recrystallizations from ethanol, had m.p. 53–57° C. and $[\alpha]_D +93^\circ$ (*c*, 0.9, 2,4-lutidine). Yield 61 mg. Calculated for C₄₃H₃₆O₁₂: C₆H₅CO, 70.6%. Found: C₆H₅CO, 70.8%.

ACKNOWLEDGMENT

The authors gratefully thank Dr. W. G. C. Forsyth, Colonial Microbiological Research Institute, Port of Spain, for a sample of golden apple gum, Dr. J. R. Nunn, University of Cape Town, for a specimen of 2-*O*- α -D-galactopyranosyl-glycerol, and Dr. Frank H. Stodola, Northern Utilization Research Branch, Peoria, for a sample of leucrose. Thanks are also due to Mr. J. A. Baignée for carbon and hydrogen micro-determinations, Mr. J. W. L. C. Christ for technical assistance, and Miss A. Epp for infrared studies.

A RECORDING VACUUM THERMOBALANCE¹

J. G. HOOLEY

ABSTRACT

A recording quartz spring balance is described, with which weight changes up to 1000 mg. can be followed linearly on a millivolt recorder for samples weighing up to 10 g. During the recording operation the sample may be under vacuum or pressure and may be heated or cooled. The maximum practical sensitivity is about 20 millivolts per milligram and the over-all error in reading the record is about 1 millivolt. The temperature coefficient of fused quartz springs is reported to be $-(1.25 \pm 0.02) \times 10^{-4}$ per degree centigrade in the range 20° to 35° C.

The device could be readily adapted for heavier loads and greater weight changes by using less sensitive springs and could be used for measuring dimensional changes of solids with a maximum sensitivity of at least 2000 mv. per millimeter.

INTRODUCTION

Various recording thermobalances are described in the literature. Some use beams supported by metal wires or conventional knife edges, but operate only at atmospheric pressure. In these a continuous record of weight is supplied by an optical system (1) or by an electronic circuit (3, 5). Others use the twisting or bending of a quartz fiber to measure the weight change. These balances can be enclosed in a vacuum and can be made recording by an electronic circuit (6). They are of low capacity and very subject to external vibrations. On the other hand, they are extremely sensitive and are indispensable for the weighing of small amounts of material.

The quartz spring balance can also operate at any pressure and can handle a much heavier load than a torsion balance (6). To date, however, it has not been made recording. This article describes a recording spring balance of simple and economical construction, whose sensitivity can be easily varied. The essential parts are illustrated in Figs. 1 and 2. The quartz spring *C* supports the steel core *E* of a linear variable differential transformer *F* and below it the sample *M*, whose weight is to be followed. The transformer has one primary and two secondaries in opposition to one another. As the core moves in response to the changing weight of the sample, the net output voltage varies. This is amplified, converted to direct current, and fed into a millivolt recorder.

DETAILS OF DESIGN AND OPERATION

Spring and Circuit Adjustments

In Fig. 1, *B* is a piece of sheet Pyrex held in a vertical position by four projections on the inside of the enveloping tube. In the setting up of the balance, *B* is first suspended outside and to it is hooked a spring, a quartz fiber *D*, and the quartz enclosed transformer core *E*. The whole is lowered into the tube, which is then capped and sealed at *A*. The fiber *L* is hooked to the core and to the quartz pan *M* containing a weighed sample. The six levelling screws in the base of the instrument are then adjusted so that the core-fiber-pan system rides freely in space. The lateral position of the core is not critical.

The recorder is next adjusted to read 50 mv. at zero voltage, i.e. when shorted. This will later correspond to having the core in the vertical center of the transformer. Vertical

displacement from this position produces a positive or negative voltage, depending on the direction of motion. The magnitude of this voltage increases with displacement and with primary voltage. The latter must therefore be constant for a given run. It is supplied by a divider across a 6.3 volt Sola constant voltage transformer. Each potential can be used with either the 20 db. or 40 db. setting of the amplifier. The particular combination chosen is determined by the desired sensitivity. If this sensitivity is such that the subsequent weight change moves the recorder pen off the scale, it can be brought back by the scale shifter between the amplifier and the converter. This is a variable source of constant a-c. voltage from a divider across a 1:1 transformer fed by the same 6.3 volt Sola transformer that feeds the primary circuit.

The height of the transformer *F* is next adjusted so that the recorder pen is at zero or 100, depending on whether the weight change will move it up or down. This is accomplished by coarse and fine adjustments to the height of the wooden clamp holding the transformer. The length of the fiber *D* was initially chosen so that this adjustment could be made. The tube *N* is now placed in position and tubes *K* and *H* are used to control

FIG. 1. The balance and the recording circuit.

FIG. 2.

the atmosphere and its pressure. A thermocouple in tube *J* is used to measure the temperature. A tube furnace or cold bath may be placed around *N*. The millivolt record is converted to milligrams by using the predetermined sensitivity.

During the operation of the balance, the spring may begin to oscillate, in which case it may be several minutes before it has died down sufficiently so that the record is again a smooth line. This time may be reduced to a few seconds by the glass fiber *G* which extends across the center of the tube. The oscillating fiber *L* is brought into light contact with *G* by adjustment of the levelling screws in the base of the instrument.

Transformer-support Temperature Control

The temperature coefficient of an unfavorable support design may be as high as 1 milligram per degree. If, however, the transformer is supported as shown in Fig. 1, then the expansion of the two 7.5 cm. brass bolts equals that of the 42 cm. of Pyrex tubing between the lower clamp and the suspension *B*. The coefficient is thereby reduced to zero if the tube and support are at the same temperature. Actually, the thermostated spring tube is seldom at room temperature and a correction must be applied for the difference.

Spring Temperature Control

The temperature coefficient of the spring may be as high as -2 mg. per degree. Water from a thermostated bath is therefore circulated through the jacket around the spring tube. This jacket and the special transformer support are not shown in Fig. 2.

PERFORMANCE AND CALIBRATION

Reproducibility

For a constant load, sensitivity, and temperature, the record was constant over a period of 8 hours. If everything was then turned off and on again the following day, the record was the same within 1 mv. after an initial warm-up period. At sensitivities over 10 mv. per mg. the pen did follow the temperature variation of $\pm 0.05^\circ \text{C.}$ of the water bath.

Linearity

The millivolt record was found to be a linear function of the weight added if the core displacement was less than 0.20 cm. from its central position. Within this range the deviation of the points from a straight line was always less than 1 mv. This region of linearity corresponds to a weight change of 1000 mg. for a class *C*₂ spring down to 250 mg. for a class *E* spring. This is illustrated in Fig. 3 for spring *D*₁ with a linear range of 400 mg.

Sensitivity

This was determined by measuring the slope of the straight line through at least six points in the plot of millivolt output against weight added. In Fig. 4 its value for spring *D*₁ is plotted against primary voltage as measured by a vacuum tube voltmeter. Values for the other springs were also measured and can be calculated from the sensitivities in cm. g.⁻¹ listed in Table I. It was shown that for a given primary voltage, the standard deviation from the average sensitivity was always less than 1%. This applied to averages of values taken at temperatures from 15° to 35° C. and for total loads from 10 to 15 g.

FIG. 3. The linear region for spring D_1 .

FIG. 4. Sensitivity as a function of voltage.

TABLE I
SPRING CHARACTERISTICS

Spring	Sensitivity, cm. g. ⁻¹	Weight of spring, g.	Total load,* g.	Number of helices	Fiber diameter, cm.	Fractional temperature coefficient per °C. × 10 ⁴
C_1	0.463	1.310	11.364 13.349 15.279	61	0.0535	-1.27 -1.28 -1.27
C_2	0.403	0.342	16.290	27	0.0421	-1.24
D_1	1.001	1.700	11.209 11.219 15.969	95	0.0494	-1.24 -1.23 -1.21
D_2	1.120	1.408	11.828 15.823	89	0.0464	-1.26 -1.23
E	1.532	1.012	11.125 14.625	88	0.0410	-1.25 -1.24 -1.25
				Average		±0.02
Sheft and Fried	7.30	0.84	1.696 2.088	80	0.035	-1.18 -0.96

*Includes connecting fibers and half the weight of the spring.

Sensitivities up to 50 mv. mg.⁻¹ were obtainable, but the record was too much affected by building vibrations and temperature variation of the spring to be useful. The upper practical limit was about 20 mv. mg.⁻¹ for spring D_1 , which is equivalent to 5000 Å per mv.

*Temperature Coefficient**(a) The Transformer Support*

As mentioned above, the relative lengths of the brass bolts and the Pyrex tube above the clamp can be adjusted so that their total expansions per degree are equal. When the temperature of the whole assembly changes, there is therefore no change in the relative position of the core with respect to the transformer, neglecting for now any contribution by the spring itself. However, the jacketed spring tube and the support are usually at different temperatures. The correction to be applied was determined in two ways. In each the air around the support and up to the jacket was thermostated by passing heated air through an insulated polythene bag fitted around that section. In the first method, the temperature of the jacket was held constant and the millivolt record was noted as a function of air temperature and converted to centimeters. In the range 22° to 32° C. a coefficient of -8.5×10^{-5} cm. per ° C. was obtained. The minus sign is used to show that the core moved down relative to the transformer as the air temperature increased relative to the jacket temperature. In the second method, a silica fiber was used in place of a spring. The air temperature was held constant and the millivolt record noted as a function of jacket temperature. A coefficient of -7.7×10^{-5} cm. per ° C. was obtained. When this is corrected for the expansion of the 30 cm. silica fiber, a value of -9.2×10^{-5} cm. per ° C. is obtained for the Pyrex tube itself. In actual runs there is present a length of silica fiber D which varies from 5 to 20 cm. A uniform value of -8.5×10^{-5} cm. per ° C. was therefore used as a correction factor.

(b) The Spring

Thermometers were placed at the inlet and outlet of the water jacket. During operation these showed a temperature difference of less than 0.02° C. and a variation with time of $\pm 0.05^\circ$ C. When the temperature setting was changed, the record became constant again within 2 minutes after the new temperature was reached.

Coefficients were measured as follows: Millivolt readings were taken for several weights at four temperatures. For each temperature a straight line was drawn through the plot of voltage against added weight. The weight values at 50 mv. were then corrected for the difference between the temperatures of the transformer support and the tube jacket. These corrected weights were plotted against temperature and in all cases a straight line fitted the data to $\pm 0.1\%$. The temperature coefficient and its value divided by the total load (including half the weight of the spring) is listed in Table I for five springs at various total loads. The average value is $-(1.25 \pm 0.02) \times 10^{-4}$ per centigrade degree. The data show it to be independent of fiber diameter, the number of coils, and the diameter of the coils, which varied from 1.28 cm. for E to 1.39 cm. for C_1 .

DISCUSSION

The springs used in this work limited the sample weight to a maximum of 10 g. and the weight change for a linear voltage response to 1 g. Both these maxima could easily be increased by using less sensitive springs.

The apparatus could also be used to measure dimensional changes of solids under various conditions of temperature, pressure, and atmosphere. The only requirement is that it must be possible to hook the sample into the system in place of the quartz spring. The maximum sensitivity would be at least 2000 mv. per millimeter. This is equivalent to the practical upper limit of 20 mv. mg.⁻¹ observed for spring D_1 .

The temperature coefficient of quartz springs should be equal in magnitude and opposite in sign to the temperature coefficient of the torsional modulus of quartz (2). This latter value, as determined for quartz fibers in the range 15° to 100° C. by Horton (4), is 1.235×10^{-4} per centigrade degree. This is within the experimental error of the value predicted by the work reported in this paper.

The temperature coefficient of a quartz spring has been determined by Sheft and Fried (7) using an optical system for measurement of length. Their two values of -2×10^{-4} per centigrade degree do not include any of the weight of the spring or connecting fibers. These weights were obtained by private communication and when used to recalculate their values to conform to those in the present paper gave the coefficients listed in Table I. The two new values of -1.18 and -0.96×10^{-4} are to be compared with the value of $-1.25 \pm 0.02 \times 10^{-4}$ reported in this paper. The greater spread and the difference may well be the result of the lower sensitivity of the optical method of observation.

Theoretically, the sensitivity in units of extension per unit load is inversely proportional to the torsional modulus. The temperature coefficient of the sensitivity should therefore be -1.25×10^{-4} per centigrade degree. Hence for the 20 degree range of temperature used in this work, the sensitivity should change by 0.24%. This is less than the observed standard deviation of 1% and was therefore not detected.

APPENDIX

The main components came from the following suppliers:

Springs—Houston Technical Laboratories.

Transformer—Type 060 S-LB from Schaevitz Engineering, Camden 1, N.J.

Amplifier—Model 450 A from Hewlett-Packard Co., Palo Alto, Calif.

Converter—Brown type from Minneapolis-Honeywell.

Recorder—Model G 10 from Varian Associates of Canada, Georgetown, Ont.

ACKNOWLEDGMENT

Advice regarding the electronic circuit was kindly provided by Dr. J. Brown and Mr. W. Corfield of the Departments of Physics and Chemistry respectively.

VISCOSITY OF NATURAL RUBBER SOLUTIONS AT VERY LOW RATES OF SHEAR¹

MORTON A. GOLUB

ABSTRACT

The shear dependence of viscosity of benzene solutions of natural rubber was studied at rates of shear from about 500 down to less than 1 sec.⁻¹. Measurements involved following the change of pressure head with time of the various solutions flowing in a capillary, U-tube viscometer. Curvature in the plots of the logarithm of pressure head versus time indicated non-Newtonian flow. From such curves, reduced viscosity data over the above-mentioned shear range were readily derived. As a check, data over the range 100–500 sec.⁻¹ were also obtained with a five-bulb viscometer of the Krigbaum-Flory type, and these data overlapped those obtained with the U tube. The reduced viscosity increased very sharply with decrease in gradient, making extrapolation to the viscosity axis quite unreliable. However, a theoretical relation proposed by Bueche fitted the composite data rather well. This work furnished a nice technique for determining the zero shear reduced viscosity $(\eta_{sp}/c)_0$ without the necessity of performing an uncertain extrapolation: evaluate the parameters of the Bueche formula which best satisfies the experimental data over a fairly wide range of shear rates, and then calculate $(\eta_{sp}/c)_0$ directly.

INTRODUCTION

In a previous paper (3) describing reduced viscosity measurements on Alfin polyisoprene over the fairly wide range of shear rates 100–20,000 sec.⁻¹, it was shown that a theoretical relation proposed by Bueche (1) to account for the non-Newtonian flow of high polymer solutions fitted the experimental data rather well, at least up to about 12,000 sec.⁻¹. Beyond this point, the Bueche plot fell steadily below the experimental points. Inasmuch as his theoretical expression was derived by dropping terms which become important only at large shear rates, it appeared that the Bueche equation, when modified to incorporate some of these terms, would fit the over-all data quite well even up to about 20,000 sec.⁻¹. At the same time, the revised equation would have to take into consideration the ultimate asymptotic levelling-off of the reduced viscosity at very high gradients.

As recommended by Bueche and indicated in the earlier paper, there is a definite need to obtain further data at shear rates well below 100 sec.⁻¹ in order to ascertain the reliability of the Bueche relation in the very low shear range. Since the gradient enters to the one-half power in the equation at low shear rates, this relation implies a virtually infinite slope of the reduced viscosity – shear curve at the ordinate. Previous work (3), however, over the range 100–500 sec.⁻¹ showed the reduced viscosity to increase in an approximately linear fashion with decrease in rate of shear. Consequently, the exact shape of the reduced viscosity – shear plot at the smallest possible gradients deserves renewed attention.

Chang and Morawetz (2) have recently described a procedure for determining the shear dependence of viscosity at very low rates of shear. This involves following the change of pressure head with time of a liquid flowing in a capillary U-tube viscometer. Curvature in the plots of the logarithm of pressure head versus time indicates non-Newtonian behavior. By means of this procedure, measurements could be readily extended down to shear rates somewhat below 1 sec.⁻¹. This is about the lower practical limit of shear rate attainable in a capillary viscometer for a liquid with a viscosity of about 10 to 20 centipoises.

Contribution from the B. F. Goodrich Company Research Center, Brecksville, Ohio. Presented at the Seventh Canadian High Polymer Forum, Sarnia, Ontario, November, 1956.

In connection with attempts at investigating microstructural differences in polymers through differences of the shear effects, recent attention in these laboratories has been focussed on the natural rubber molecule. It has been observed, for example, that the shear dependence of intrinsic viscosity for the polyisoprene molecule—be it the natural all-*cis*, or the predominantly *trans* Alfin polymer—is pretty much the same for the two substances (4). For an examination of the Bueche equation at very small gradients, natural rubber was consequently selected for study. This paper reports the results obtained from reduced viscosity measurements on *Hevea* solutions at rates of shear from about 500 down to less than 1 sec.⁻¹, using the method of Chang and Morawetz

EXPERIMENTAL

Two U-tube viscometers were used in this work, one covering the shear range 100 down to less than 1 sec.⁻¹ (MV-2), the other covering the wider range 0–500 sec.⁻¹ (MV-4). Each arm of the former viscometer contains a 25 cm. length of precision bore capillary (radius 0.025 cm.) for a total capillary length of 50 cm. A 14 cm. length of precision bore capillary (radius 0.020 cm.) is contained in each arm of the latter viscometer. These instruments are essentially continuously varying pressure head viscometers. Identical cylindrical working volumes in the two arms of each viscometer are assured by the use of precision bore tubing above the capillaries (0.6 cm. I.D.; height 20 cm. in MV-2, 31 cm. in MV-4). To avoid having a curved capillary in the U tubes, the arms are joined at the bottom by a piece of tubing of about 6 mm. inside diameter. The over-all heights of both viscometers are about 47 cm. They were firmly supported in a vertical position in a constant temperature bath set at 25±0.01° C. The bath was an aquarium type with plate glass sides suitable for viewing the menisci with a cathetometer.

The procedure involved first adjusting the liquid levels above the capillaries so that a driving pressure of about 3–5 cm. of benzene in MV-2, or about 13–16 cm. in MV-4, was established. Then measurements were made of the levels in the viscometer arms at various time intervals, as the liquid flowed through the capillary under its own weight, until the driving pressure fell to about 2 or 3 mm. From the definition of viscosity η , it may be seen that for Newtonian flow

$$[1] \quad \ln h/h_0 = -(gR^4d/4a^2\eta l)t = St,$$

where h and h_0 are the actual differences in liquid levels at time t and at the outset of a run respectively, d is the density of the liquid, R and l are the capillary radius and length, a is the radius of the cylindrical working volume, and g is the gravitational constant. Fig. 1 shows the linear plots of $\log h/h_0$ vs. t for a Newtonian liquid, such as benzene, in the low shear viscometers. The good agreement between the measured slopes of the lines² (-3.20×10^{-3} and -2.32×10^{-3} sec.⁻¹ for MV-2 and MV-4, respectively) and the corresponding values for S calculated from the approximate instrumental dimensions and known constants of benzene (-3.08×10^{-3} and -2.25×10^{-3} sec.⁻¹) using equation [1] is evidence for the reliability of this approach. Obviously this procedure could serve as an absolute method for determining the viscosity of a Newtonian liquid.

Curvature in the $\log h/h_0$ vs. t plot indicates non-Newtonian behavior. If S is the slope of such a plot for a solution at some particular value of h , and S_0 the slope for the solvent, then the relative viscosity of the solution at the rate of shear corresponding to the given head is simply S_0/S . By drawing tangents at a number of points in each of the experi-

²Based on the corresponding natural logarithm plots.

mental curves and evaluating S_0/S for the respective gradients, reduced viscosity data over the range of shear rates mentioned above for the two viscometers were readily derived for the various natural rubber solutions.

No kinetic energy corrections were applied to the flow data in this work since these were considered negligible under the given experimental conditions. Mock and Marshall (6) have recently discussed the kinetic energy correction for this type of viscometer.

As a further check on the reliability of the data obtained by the above method, viscosity measurements over the range 100–500 sec^{-1} were also made with a five-bulb viscometer of the Krigbaum–Flory type. The procedure followed with this viscometer has been described before (3).

The maximum rate of shear, D , at the wall was calculated by means of the relation [2]

$$D = Rghd/2\eta l.$$

The natural rubber was a sample of pale crepe, having a viscosity average molecular weight of about 2,100,000. Viscosity measurements were carried out on gel-free benzene solutions varying in concentration from about 0.05 to 0.5 g./dl. The rubber solutions contained tetramethylthiuram disulphide to the extent of 1% on polymer for stabilization.

FIG. 1. Plots of $\log h/h_0$ vs. time for a Newtonian liquid (benzene) in the two low shear viscometers.
 FIG. 2. Effect of rate of shear on the reduced viscosity of natural rubber in benzene at 25°C. The various points were obtained with the five-bulb viscometer (O), and U-tube viscometers MV-2 (X) and MV-4 (A) respectively. The lines were derived from the Bueche equation.

RESULTS AND DISCUSSION

Typical flow data for various concentrations of natural rubber in benzene, obtained in the MV-2 viscometer, are shown as the points joined by the solid lines in Fig. 3. The dotted lines are tangents to the curves at the onset of flow in the U-tube viscometer. The slopes of these tangents, S , divided by that for benzene, S_0 , give the relative viscosities for the several solutions corresponding to the initial hydrostatic heads (and hence mean shear gradients). These solutions were also run in the five-bulb viscometer (see Fig. 2) in which the lowest rate of shear was higher than the highest in the MV-2 viscometer. Significantly, the initial reduced viscosity values, η_{sp}/c , obtained in the latter instrument as described above are all larger than corresponding values obtained in the five-bulb viscometer, and moreover are approximately the values which would be predicted by extrapolation of the nearly linear plots of the five-bulb data. Now, in

FIG. 4. Plots of $\log h/h_0$ vs. time for four non-Newtonian solutions (natural rubber in benzene) in viscometer MV-4.

determining the remaining viscosity-shear points with MV-2, tangents were drawn to the solid lines at various places and their slopes were used to calculate η_{sp}/c values. The mean gradients were calculated from the heads at the points of tangency. The method of arriving at the shear dependence of viscosity using the Chang-Morawetz approach is illustrated by the results presented in Table I for a typical run in the low shear viscometer. Finally, η_{sp}/c values were plotted against D as in Fig. 2.

† S_0 (benzene) = -3.204×10^{-3} sec.⁻¹.

It should be pointed out that although the curvature in the various $\log h/h_0$ vs. t plots appears slight, the reduced viscosities are nevertheless changing quite rapidly with drop in hydrostatic head. This curvature, of course, becomes progressively less pronounced as the concentration of the rubber solution is diminished. For a concentration of 0.055 g./dl. the plot is so nearly linear that it is quite hazardous to draw tangents to the line, and hence this was not done. However the five-bulb data show that this solution is likewise non-Newtonian. Since the experimental technique is quite simple and inherently capable of a high degree of accuracy, each point in the $\log h/h_0$ vs. t plot must be treated as fully accurate and a smooth line permitted to pass through the various points. The difficulty in this method lies in having to draw tangents to the curves at the various points, and this results in some uncertainty in the particular value calculated for the reduced viscosity at a given gradient. However, there is no uncertainty in the trend of sharply increasing viscosity with reduction in rate of shear, which behavior is in accord with some recent observations of other investigators (5, 7, 8).

Fig. 4 shows typical flow data for several concentrations of natural rubber in benzene obtained in the wider shear range MV-4 viscometer. From these curves η_{sp}/c values at various gradients were calculated in the manner outlined above and plotted in Fig. 2, where they are seen to overlap data obtained with both the MV-2 and five-bulb viscometers. This overlapping strengthens our confidence in the reliability of these results.

An attempt to fit the composite data to the Bueche equation is indicated by the solid lines in Fig. 2. As is clearly seen the agreement is very good. Since this equation was previously shown (3) to represent the reduced viscosity data rather well over the very wide range of 100 to 12,000–20,000 sec.⁻¹, the present work has provided therefore experimental confirmation of the correctness of this formula down to extremely small

rates of shear. Moreover, it has furnished a nice technique for evaluating the zero shear reduced viscosity without the necessity of performing an uncertain extrapolation. Essentially, it requires the determination of the parameters of the Bueche formula, which best satisfies the experimental data over a fairly wide range of shear rates. Calculation of the zero shear reduced viscosity from such a derived expression is then immediately possible. An example will illustrate this point. For our purposes, the Bueche equation may be expressed simply as

$$[3] \quad \frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c} \right)_0 \left[1 - k \left(\frac{\eta_{sp}}{c} \cdot D \right)^{\frac{1}{2}} \right]$$

where η_{sp}/c and $(\eta_{sp}/c)_0$ are the reduced viscosities at shear rates D and zero, respectively, and k is a constant embracing a number of molecular parameters. Several experimental values of η_{sp}/c and D are substituted into the relation to give an average value of k , and also an approximate value for $(\eta_{sp}/c)_0$. Using these values for k and $(\eta_{sp}/c)_0$, a set of reduced viscosities are then calculated for the different gradients, and compared with the experimental viscosities. These values for k and $(\eta_{sp}/c)_0$ are then varied somewhat and the process repeated until as good a fit as possible of the equation to the data can be found. The value for $(\eta_{sp}/c)_0$ which makes the Bueche equation fit the data best may then be considered as the true zero shear reduced viscosity. Although this point may be open to question, in the absence of any other method for uniquely determining the zero shear reduced viscosity, it is the author's view that the present approach should be adopted as a regular method for obtaining $(\eta_{sp}/c)_0$. This has the obvious advantage of avoiding an unreliable extrapolation in a gradient range where the viscosity is very shear dependent. Typical results obtained by this method are shown in Table II, where

the calculated and experimental values for η_{sp}/c are indeed in close agreement. Although this work emphasized the Chang-Morawetz procedure, it is not essential to use it in order to arrive at a reasonable value for $(\eta_{sp}/c)_0$. Actually the data from the five-bulb viscometer are sufficient for this purpose, since in all cases the Bueche plot passes through these experimental points, and hence the zero shear reduced viscosity can be recovered from such viscosity-shear data in the manner outlined above.

ACKNOWLEDGMENTS

The assistance of Mrs. Corinne Bonar with the experimental work is gratefully acknowledged. It is a pleasure to acknowledge also helpful discussions with Dr. R. A. Mock.

STRUCTURE OF A HEMICELLULOSE FROM MAPLE WOOD PREVIOUSLY EXTRACTED BY LIQUID AMMONIA¹

L. G. NEUBAUER² AND C. B. PURVES

ABSTRACT

The extraction of maple wood meal with anhydrous liquid ammonia under pressure near 20° altered the wood in such a way that an additional small amount of lignin could be extracted with ethanol, and 1.9% of crude hemicelluloses with hot water. An additional 0.25% of nitrogen was retained, apparently as insoluble amides, by the residual wood. After elimination of pectic material by acetylation, the three subfractions of the hemicellulose acetate had identical specific rotations of $-61 \pm 1^\circ$ in chloroform; all three corresponded in composition to a combination of one methylglucuronic anhydride to six anhydroxylose units. A conventional study by the methylation method suggested that the hemicellulose was a branched-chain structure averaging four anhydroxylose units linked 1—4, with one also substituted in the second position, and another linked 1—3.

INTRODUCTION

The observation (32) that nearly anhydrous (99.5%) liquid ammonia under pressure at room temperature extracted most of the acetyl groups in maple wood flour as acetamide (4) suggested that any other type of ester group in the wood might also have been cleaved to an acid amide. If such were the case, then components of the wood that had not been removed in the exhaustive preliminary extractions with alcohol, ether, and

water might have acquired solubility in one or other of these liquids. The present research originated in attempts to explore this possibility.

Two samples of the same wood meal were analyzed in an air-dry condition before and after the extraction with liquid ammonia (Fig. 1), the actual work being performed by Yan and by one of the writers in different years. As Table I shows, the residual wood

meals were slightly deficient in Klason lignin, markedly deficient in acetyl groups, and had acquired additional nitrogen. This additional nitrogen was probably not attributable to retained acetamide, because exhaustive extractions of the second wood sample with alcohol and then with hot water failed to remove it, although they did remove 0.8% of a lignin and 1.9% of a crude hemicellulose. When samples were distilled with dilute aqueous sodium hydroxide, however, the surplus nitrogen was removed as ammonia, and therefore was present in the wood residue as an amide or an ammonium salt. The latter possibility was improbable because boiling aqueous magnesium hydroxide expelled no more ammonia from the residue than did boiling water (22). The simplest interpretation to put upon the data was that some of the uronic acid groups in the wood were transesterified with other constituents; cleavage of these ester groups by liquid ammonia made it possible to extract small additional quantities of lignin and carbohydrate material by the renewed use of alcohol and water, while the insoluble amides remained in the residue. Rogers, Mitchell, and Ritter (27) found 4.36% of uronic acid, or 0.25 milliequivalents per gram, in a maple wood which contained only 0.24% of ash. Even the unlikely assumption that all this ash was sodium carbonate failed to raise the calculated ash alkalinity above 0.045 milliequivalent per gram. Since wood is nearly neutral in reaction, much of the uronic acid must have been neutralized in a way not dependent on salt formation. The transesterification hypothesis would explain this anomaly also. Other reasons led Anderson and co-workers (1) to conclude that pectic substances in woods might be partly esterified with other plant constituents, while Foster, Schwerin, and Cohen (11) formed the same opinion about the uronic anhydride units in *Eucalyptus regnans*.

Concentration of the combined aqueous extract (Fig. 1), followed by dilution with ethanol, caused the precipitation in 1.9% yield of a gray powder which consisted essentially of uronic anhydride and pentosan units. A long series of fractional precipitations from aqueous alcohol tended to concentrate the pentosan in the more soluble portion, but analytical constancy in successive subfractions was never attained. Selective absorption on carbon was equally unsatisfactory. Finally, subfractions were combined in the three groups, *M*, *X*, and *Y*, whose divergent analyses were recorded in Table II.

**Also 36% of acetate insoluble in acetone and in water.

Each of these groups was then acetylated with pyridine as catalyst, and dilution of the acetylation mixture precipitated acetates of the same composition and optical rotation but in differing yield. The composition of the unprecipitated portion approximated that of a polyhexuronic acid diacetate, and the isolation of mucic acid by the hydrolysis and oxidation of the original polysaccharide showed that the polyhexuronic acid was pectic acid. Hirst and Jones (15) discovered that pectic acid could be separated in the same way, or by methylation, from plant gums and crude pectins. Anderson and his collaborators (1) isolated up to 3% of pectic material from various woods, and showed that it was a contaminant in an aspen hemicellulose extracted by alkali (2).

The analyses of the uniform acetate were those required by the acetate of a hemicellulose averaging six pentosan units to one of methoxyhexuronic anhydride. If it was assumed that the fractions *M*, *X*, and *Y* consisted only of this hemicellulose and of pectic acid, then the percentage amount of the latter could be calculated from their uronic acid contents (Table II, column 6). These percentages in turn made it possible to correct the observed consumption of periodic acid by the fractions *M*, *X*, and *Y* for the amount consumed by their content of pectic acid. The results (right hand column) indicated that the repeating unit of the hemicellulose reduced 4 moles of periodic acid rapidly with the production of no formaldehyde and probably of no formic acid. A sample

of fraction *M* was hydrolyzed with boiling 3% sulphuric acid until the copper reducing power attained a maximum value equivalent to the liberation of 63.7% of xylose. The amount of crystalline xylose isolated from the hydrolyzate and carefully identified was 56.3%, and no other sugar could be detected. These observations strongly suggested that all of the pentosan in fraction *M* was xylan, and that the hydrolysis yielded 4 moles of xylose and 1 mole of an aldotriuronic acid which was not isolated.

When fraction *M* was thoroughly methylated by standard methods, the product was readily separated into a chloroform-soluble portion with the composition required by the above hemicellulose when completely substituted, and a chloroform-insoluble portion which appeared to be a methylated salt of pectic acid. Oxidation of the fully methylated polysaccharide with nitric acid yielded a pale yellow sirup which was esterified with methanolic hydrogen chloride and then fractionally distilled. The methyl ester of 2,3,4-tri-*O*-methyl saccharolactone crystallized spontaneously from the distillate. When the methanolic mother liquors were saturated with ammonia gas the diamides of the optically active 2,3-di-*O*-methylxyloglutaric and of the internally compensated 3-*O*-methylxyloglutaric acid were recovered in a crystalline condition and suitably identified. The final mother liquors yielded an uncrystallized substance which gave a negative Weerman (30) test for α -hydroxy acids, and which had the composition of a di-*O*-methylxyloglutaramide. This substance appeared to be the internally compensated 2,4-isomer. Although the distillation of the original mixture of methyl esters was not quantitative, the percentage amounts of the above four compounds actually isolated were in close agreement with those required by a molar ratio of 1:4:1:1.

Both anhydroxylose and anhydroglucuronic acid appear to occur in natural polysaccharides invariably with pyran cyclic structures. If X and G, respectively, represented these structures, then the results of the methylation and hydrolysis just described were compatible with the branched-chain formula

This formula was not unique because the anhydroxylose units could be interchanged, and the branch lengthened or shortened, in various ways consistent with the experimental data. The four anhydroxylose units linked 1—4 each retained unsubstituted hydroxyl groups in the second and third positions, and would account for the observed consumption of 4 moles of periodate by the structure shown in the formula. This inference suggested that the anhydroglucuronic acid G did not react with periodate and therefore did not contain adjacent hydroxyl groups in the second, third, and fourth positions. The assumption that the methyl group in the hemicellulose was present in the third position of the anhydroglucuronic unit satisfied this requirement (9) and was also consistent with the repeated failure to find unmethylated saccharolactone among the oxidation products of the hemicellulose.

Previous investigations on the hemicelluloses from maple wood appear to be restricted to the preliminary fractionations and group analyses of Haas (12) and of Ritter and his colleagues (21, 27). The ratio of six anhydroxylose to one methylglucuronic acid residue now found has been encountered among the more soluble fractions of hemicelluloses derived from oak (24), jute (28), and other plants. To judge from a recent review (14), a branched chain hemicellulose is not unusual, and glucuronic acid residues are usually

present either as such or as the 4-*O*-methyl derivative. Since 3-*O*-methylglucuronic acid residues have been thought to be present only in the isolated case of jute hemicellulose (7, 8), the presence of this isomer in the product from maple requires to be confirmed by a more direct method than the one used in the present research.

EXPERIMENTAL

Materials

The wood meal, of 40 to 80 mesh, was prepared from the log of sugar maple (*Acer saccharum* Marsh) used in the previous research (32) and was exhaustively extracted with distilled water, ethyl ether, and ethanol in succession. Little or no "native lignin" was removed by the last two liquids. After being dried in the air, the meal was extracted for 5 hours at room temperature with five times its weight of nearly anhydrous liquid ammonia in the apparatus constructed for that purpose (32). Acetamide was separated in 85% of the theoretical yield from the extract, together with a lignin and a polyuronide in yields amounting to 1.1% and 1.2%, respectively, of the wood.

The air-dry, ammonia-extracted wood meal, 2.25 kg., was thoroughly extracted in a Soxhlet apparatus with ethanol, and after being dried once more in the air, each 500 g. was extracted three times with 3 liter volumes of distilled water at 95–97° for 2 hours. Residual wood meal, 2.25 kg., saved from the earlier work was treated in the same fashion. After being evaporated, the combined ethanol extracts from the 4.5 kg. of wood yielded 41 g. of a dark brown, resinous material which gave a positive test for angiosperm lignin in the Mäule reaction. The aqueous extracts from each 500 g. batch were centrifuged to remove turbidity, were combined, and were evaporated *in vacuo* to 750 ml. Two volumes of ethanol were then added, and the resulting precipitate was recovered by filtration, solvent-exchanged through ethanol and ether, and dried *in vacuo* at 50° over phosphoric anhydride. Total yield of crude hemicelluloses, 91.5 g. or 1.9% of the wood. A pale brown solid, 11.4 g., was recovered from the mother liquors.

The analyses of the residual wood meal at various stages of extraction were summarized in Table I. Acetyl groups were determined after steam distillation of a solution of the sample in 72% sulphuric acid (19); total nitrogen by the Gunning (3) modification of the semimicro-Kjeldahl method; amide nitrogen by distillation of 0.5 g. samples with 20 cc. of 0.001 *N* sodium hydroxide; and ammonium salt nitrogen by distillation with water containing 0.3 g. of magnesium oxide (22). In the last three cases the ammonia was distilled into a suitable amount of standard hydrochloric acid, and the whole was back-titrated to a methyl red end point with 0.01 *N* alkali.

Examination of the Hemicellulose (Fig. 1 and Table II)

The pale gray powder, 91.5 g., was precipitated several times from aqueous solution by two volumes of ethanol, but the composition of the product showed no signs of becoming constant and its solution in water was still too turbid to permit an optical rotation to be determined. Absorbent carbon, 25 g., was added to a solution of the less soluble portion of the product, 75 g., in 3 liters of hot water, but only 28.9 g. of a very pale gray powder was recovered from the filtrate. After being fractionated from aqueous ethanol, the less soluble portion was six times reprecipitated in the same way, and yielded 11.6 g. of the less soluble subfraction X. The more soluble portion, Y, 6.6 g., was a white powder. Since the portion of the hemicellulose that remained adsorbed on the carbon

could not be eluted with water, this operation was carried out, although with difficulty, by extraction with cold 1% sodium hydroxide. The eluate was neutralized with dilute hydrochloric acid, and then diluted with two volumes of ethanol to precipitate 28.1 g. of a pale gray powder. The product was combined with several minor fractions and twice reprecipitated to yield 24.8 g. of fraction *M*. McCready, Swenson, and Maclay's semi-micro method (20) was used to determine uronic anhydride, and that of Klein and Acree (18) for furfural. The percentage of the latter was reduced by 21.5% of the percentage of uronic acid found (23) and the result when multiplied by the factor 1.557 was accepted as per cent anhydroxylose units.

Samples, 1 g.–1.3 g., of the three fractions *X*, *Y*, and *M* were separately acetylated by adding 20 cc. of acetic anhydride to a suspension previously swollen in pyridine. The mixtures were kept at room temperature for 24 hours, then near 100° for 4 hours, and were poured into 400 ml. volumes of ice and water. The precipitates were extracted with acetone, any small residue being removed by filtration, and after being concentrated the extracts were diluted with water. When dried *in vacuo* at 60° over phosphorus pentoxide, the hemicellulose acetates were hard, white powders. Clark's semimicro method (6) was used to determine acetyl content, and the values given in Table II were not increased by reacetylating the acetates. The aqueous residues from the above acetylations on evaporation yielded three gray powders containing 10–47% of ash which was apparently silica. When corrected for this ash, the yields were 35%, 9%, and 16% from fractions *X*, *Y*, and *M*, respectively; their uronic anhydride content was 62.5–69.7%; anhydroxylose, 2.0–3.2%; and acetyl, 24.9–31.5%. Calc. for pectic acid diacetate; uronic anhydride, 67.7; acetyl, 33.1%.

A 0.04 *N* solution of sodium metaperiodate was used to oxidize 0.3 g. samples of the three unacetylated hemicellulose fractions, the consumption of oxidant being followed by the arsenite (10) method, and the production of formic acid by titration to the original pH of the solution with standard alkali. None of the fractions yielded enough formaldehyde to be detected by the dimedon reagent (26). By extrapolating the later, nearly linear portions of the plots to zero time, the rapid initial reactions were found to consume 5.5, 4.7, and 4.53 moles of periodate per 1000 g. of fractions *X*, *Y*, and *M*, respectively, and to produce 0.43, 0.27, and 0.23 moles of formic acid. In the case of 1000 g. of fraction *M*, the 101 g. of pectic acid this amount was assumed to contain (Table II) would reduce 1 mole of periodate per galacturonic anhydride unit (base mol. wt. 176) or 0.57 mole. By attributing the production of 0.23 moles of formic acid to a rapid secondary oxidation of the pectic material, the latter consumed a further 0.46 mole of periodate. The consumption attributable to 899 g. of hemicellulose was therefore (4.53 – 0.57 – 0.46) 3.5 moles, or 3.9 moles for the base molecular weight of 982 g. assumed for the hemicellulose. The corresponding values given in Table II for fractions *X* and *Y* were estimated in the same way.

A portion of fraction *M*, 3.38 g. (ash-free), was hydrolyzed near 97° in 250 cc. of 3% sulphuric acid until the Shaffer–Hartmann–Somogyi (29) copper reducing power reached a maximum corresponding to 2.16 g. of xylose (63.5%) after 160 minutes. After filtration from 0.11 g. of a dark material, a 5 cc. aliquot of the filtrate was neutralized with sodium hydroxide and was found to be unfermented by yeast; added glucose was later fermented readily. Glucose, fructose, and mannose were therefore absent. The remainder of the hydrolyzate was neutralized with barium carbonate, and the filtrate, now free of sulphate

ion, was concentrated and diluted with 10 volumes of ethanol. A light brown precipitate (0.12 g.) which formed was isolated and oxidized with nitric acid according to Wise and Peterson (31). The yield of 0.035 g. of insoluble white crystals melted at 217°, undepressed by admixture with authentic mucic acid of melting point 217°. When the filtrate from the above brown precipitate was evaporated *in vacuo*, 2.81 g. of a pale yellow, dextro-rotatory, partly crystalline solid remained. A 0.37 g. portion when analyzed for xylose by the method of Breddy and Jones (5) yielded 0.32 g. of the dimethyl acetal of dibenzylidene-D-xylose with the correct specific rotation of $[\alpha]_D^{20} -8.5^\circ$ in chloroform and melting at 210°. A mixed melting point with an authentic sample was at 211°. This quantity of acetal was equivalent to 56.3% by weight of xylose. Tests on 0.3 g. samples for arabinose, rhamnose, and galactose by the method of Hirst, Jones, and Woods (16) were completely negative.

Heidelberger and Goebel's method (13) was used to oxidize 1.17 g. (ash-free) of fraction X with 50 cc. of boiling *N* hydrobromic acid containing 0.5 cc. of bromine. After being kept 24 hours under reflux, the liquor was evaporated, finally over solid potassium hydroxide, to 3 ml., and 0.315 g. of mucic acid was removed and identified. The mother liquor was neutralized with potassium hydroxide and concentrated to a sirup. No crystals of acid potassium saccharate could be obtained when this sirup was diluted with glacial acetic acid, although as little as 40 mg. of the salt could be readily isolated by the procedure used.

Methylation and Hydrolysis of Fraction M

Following the procedure of Hirst and Jones (15), 3.31 g. (ash-free) of the hemicellulose *M* was mixed with 30 cc. of 4 *N* thallous hydroxide; the precipitate which immediately formed was separated and dried at 35° *in vacuo*, was crushed to a pale yellow powder, 10.3 g., and was warmed under reflux with 25 cc. of methyl iodide for 18 hours. The methyl iodide was then evaporated, and the residue remethylated in the same way. The third methylation involved the use of 20 cc. of anhydrous ethanol and 50 cc. of *N* thallous ethylate in benzene (25), and the fourth, with 50 ml. of the thallous ethylate solution, failed to increase the methoxyl content of the product. Exhaustive extraction of this product with chloroform removed 2.75 g. of a very pale yellow resin. Found: uronic anhydride 15.0, 15.0; methoxyl, 39.3, 39.4; ash, 0.1%. Calc. for the methyl ester of the fully methylated hemicellulose, $6C_6H_8O_4 \cdot C_6H_8O_6 \cdot 15CH_2$ (mol. wt. 1178): uronic anhydride, 14.9; methoxyl, 39.5%. The residue, insoluble in chloroform, on re-extraction with hot water, yielded 0.38 g. of a gray powder. Found: uronic anhydride, 51.4, 51.5; methoxyl, 28.6, 28.7; ash, 20.1, 20.2%.

Simultaneous oxidation and hydrolysis of the chloroform-soluble product, 2.29 g., was by solution at 80° for 6 hours in 35 cc. of 32% nitric acid (17). The clear, pale orange solution was evaporated with the simultaneous addition of water until the acidity was reduced to pH 6, and was then concentrated to a sirup. After being esterified by 8 hours' boiling with 35 cc. of 3% methanolic hydrogen chloride, the ether-soluble, neutral, almost colorless esters, 1.74 g., were distilled at 0.1 mm. pressure; fractions 1, 2, and 3 weighed 0.22, 0.69, and 0.39 g., and boiled at 110–129°, 130–145°, and 146–160°, respectively. The still residue, 0.31 g., was dark brown.

Fraction 3 partly crystallized on standing, and fraction 2 when triturated with ethanol-ether-ligroin (1:1:2 vol.). After one recrystallization from ether, both crops melted at 106–107° and both melting points were undepressed by admixture with the authentic

methyl ester of 2,3,4-tri-*O*-methylsaccharolactone (prepared from β -glucosan (1,4) (1,5)), m.p. 109°. Total yield from 1.3 g. of distillate, 0.15 g. or 11.5%. The mother liquors from the two crops were separately evaporated to dryness and the residues redissolved in 5 to 8 cc. of anhydrous methanol saturated with dry ammonia gas. The two crystalline crops that separated after 2 days at 0°, 0.06 and 0.07 g., were recrystallized from aqueous methanol and both melted at 161–162° (dec.), a mixed melting point being undepressed. These crystals had the methoxyl and nitrogen contents required by a mono-*O*-methyl xyloglutardiamide, were optically inactive, and gave a positive Weerman (30) test for α -hydroxy acid amides. They consisted of 0.13 g. (10%) of 3-*O*-methyl xyloglutardiamide. The original mother liquors from the two crops were each evaporated to one-half volume and left for 3 days at 0°. Each deposited identical crystals melting at 140° after recrystallization from aqueous methanol; yields 0.10 g. and 0.39 g., respectively. These crystals gave a positive Weerman test, had a specific rotation $[\alpha]_D^{20} +28^\circ$ in water (c , 0.8), and had the methoxyl and nitrogen contents of a di-*O*-methyl xyloglutardiamide. They were therefore the 2,3-di-*O*-methyl isomer.

A solution of fraction 1 in 3 cc. of methanol saturated with ammonia gas deposited 0.04 g. of dimethoxysuccinamide melting correctly at 290° (dec.) after one recrystallization from water, and with the correct methoxyl content. After a further 6 days at 0°, the methanolic mother liquor deposited a further 0.14 g. of 2,3-di-*O*-methyl xyloglutardiamide (m.p. and mixed m.p. 139–140°), the total yield of which was therefore 0.63 g. or 48.5%. No further crystallization occurred in the final mother liquors from the three fractions of the original distillation. When combined and evaporated, they yielded 0.14 g. (11%) of a brown sirup which gave a negative Weerman test. Found: OCH_3 , 29.0; N, 13.8%. Calc. for $\text{C}_7\text{H}_{14}\text{O}_5\text{N}_2$: OCH_3 , 30.1; N, 13.6%. The sirup was probably 2,4-di-*O*-methyl xyloglutardiamide.

SOME OXIDATION REACTIONS OF DELCOSINE¹

RAGINI ANET,² D. W. CLAYTON,² AND LÉO MARION

ABSTRACT

The alkaloid delcosine was oxidized by chromic acid in acetic acid, and also by the Oppenauer reaction, to dehydodelcosine in which the carbonyl was shown by infrared absorption to be in a pentatomic ring. Oxidation of the alkaloid with silver oxide gave two products: (a) N-desethyldelcosine, which could be N-acetylated or converted back to the original base by ethylation, thus proving the presence of an N-ethyl group; (b) a compound, $C_{24}H_{37}O_7N$, the properties of which agreed best with those of an internal ether, i.e., anhydrohydroxydelcosine. The action of N-bromosuccinimide on the alkaloid produced the same two compounds as silver oxide, plus a derivative, $C_{22}H_{35}O_7N$, that proved to be N-desethyl-anhydrohydroxydelcosine. Potassium permanganate oxidized delcosine to a product, $C_{22}H_{31}O_7N$, that had lost the N-ethyl group, contained the internal ether, and also a carbonyl in a five-membered ring. This same product was obtained on similar oxidation of N-desethyl-anhydrohydroxydelcosine. Oxidation of delcosine with mercuric acetate gave N-desethyl-delcosine and N-desethyl-anhydrohydroxydelcosine, together with a compound that was very soluble in water and proved to be the carbinolamine formed by hydroxylation of the methylene in the N-ethyl group. These results are discussed in terms of a structure that is tentatively advanced for delcosine.

Delcosine is a monoacidic base with an empirical formula that has been previously established as $C_{24}H_{39}O_7N$ (12). Of its seven oxygens three are known to be present in methoxyl groups and four in hydroxyls. Two of the hydroxyls are readily acetylated, but the remaining two are not (12), and are probably tertiary alcoholic groups. It does not take up any hydrogen in the presence of Adams' catalyst, thus indicating the absence of unsaturation. The ultraviolet spectrum of the bases, like that of lycoctonine (4), shows only end absorption and is similar to that of sparteine, which contains no unsaturation. As with lycoctonine, the end absorption is due to the basic nitrogen, with some contribution from hydroxyls and methoxyls (4). The infrared spectrum of delcosine does not contain any absorption band characteristic of a double bond. Delcosine must, therefore, possess a structure made up of six rings and, further, it has been shown by Goodson (7) probably to contain an N-ethyl group.

The behavior of delcosine towards various oxidizing agents has been investigated, and the results together with their interpretation in terms of a tentative structure are now reported.

Oxidation of delcosine with chromic acid in acetic acid or in dilute sulphuric acid gave a ketone $C_{24}H_{37}O_7N$ (I) in poor yield. The ketone formed mixed crystals with delcosine, but could be separated by paper chromatography or by countercurrent distribution. Its infrared spectrum (band at 1755 cm^{-1} , no C—H stretching absorption at $2600\text{--}2800\text{ cm}^{-1}$) revealed it to be a five-membered ketone. It formed a monoöxime showing no carbonyl absorption in the infrared. Hence one of the hydroxyls in delcosine must be secondary and present in a five-membered ring. Attempts to condense the ketone I (dehydodelcosine) with piperonal failed and, hence, it is probable that no methylene groups are present adjacent to the carbonyl. The same dehydodelcosine was obtained by Oppenauer oxidation but the yield was also low and attempts to improve it by varying the conditions (cf. 13) proved fruitless.

²National Research Council of Canada Postdoctorate Fellow.

Delcosine was found to be inert to silver oxide under conditions which gave hydroxylycoctonine from lycoctonine (4). If, however, the reaction was carried out at 80° in ethanol for 68 hours, two products were obtained. One of these, $C_{22}H_{35}O_7N$ (II), was sparingly soluble in benzene; it contained five active hydrogens and was a stronger base (pK_a 7.9) than delcosine (pK_a 6.49). With acetic anhydride and pyridine it formed a neutral acetyl derivative showing an amide carbonyl absorption peak at 1643 cm^{-1} in the infrared. The acetyl derivative on hydrolysis gave back the basic product II, which must therefore be a secondary base. The base II was shown to be N-desethyldelcosine by treatment with ethyl iodide in dimethylformamide, which converted it to delcosine, thus firmly establishing the presence of an N-ethyl group in the alkaloid.

The second product of the silver oxide oxidation, $C_{24}H_{37}O_7N$ (III), was a much weaker base than the first (pK_a 4.2). Its infrared absorption spectrum showed no carbonyl nor double bond absorption, but contained sharp peaks at 1000 and 900 cm^{-1} which were absent in the spectrum of delcosine. As the pK_a of III showed a sharp drop of 2.29 units from that of delcosine, a change in the environment of the nitrogen such as the formation of a carbinolamine was suspected. (Lycoctonine on conversion to hydroxylycoctonine shows a drop in pK_a of three units.) The analysis, however, which showed that III contained the same number of oxygens as delcosine, and the fact that the compound formed a perchlorate that was not an anhydronium salt, provided evidence that compound III was not a simple carbinolamine.

If, on the other hand, it were assumed that one of the hydroxyls in the molecules was placed suitably to react with the carbinolamine formed initially, there could then arise an internal ether as indicated in the following partial formulae, and this would be in agreement with the pK_a of the compound and its analytical figures. In fact, compound III contained only three active hydrogens, thus substantiating the assumption. Cyclic carbinolamine internal ethers are not unknown in the field of alkaloids (cf. 11).

Reduction of compound III with sodium borohydride gave back delcosine, thus showing that no change had taken place in the stereochemistry of the molecule. Although

compound III was inert to hydrogenation in neutral medium, it rapidly took up 1 mole of hydrogen in aqueous perchloric acid in the presence of Adams' catalyst to give delcosine. There is thus no doubt that the net result of the oxidation was the abstraction of two hydrogens. Hence the reaction can be rationalized only on the basis of an internal ether formed from an intermediate carbinolamine.³ Thus compound III is anhydrohydroxydelcosine (see partial formulae above).

N-Bromosuccinimide is known to oxidize secondary alcohols to ketones (6), and has been used in such a reaction by Cookson and Trevett (2) in their study of delpheline. Delcosine when oxidized with this reagent in buffered solution gave three products. One was identical with anhydrohydroxydelcosine (III) described above. The second product, $C_{22}H_{33}O_7N$ (IV), had a pK_a 4.6 and contained four active hydrogens. On treatment with ethyl iodide in dimethyl formamide it gave rise to III. Hence compound IV was clearly the internal ether of N-desethyl delcosine, i.e., N-desethyl-anhydrohydroxydelcosine. Reduction of IV with sodium borohydride gave N-desethyl delcosine (II), which was also obtained as the third product of the oxidation. The oxidation with N-bromosuccinimide was thus not specific, but attacked two carbon atoms vicinal to the nitrogen.

Oxidation of delcosine with potassium permanganate in acetone gave intractable material and some neutral product which could not be purified. On the other hand, potassium permanganate in N-potassium hydroxide at room temperature oxidized delcosine to two products. One was N-desethyl-anhydrohydroxydelcosine IV also obtained in the oxidation of delcosine with N-bromosuccinimide. The other was a high melting compound, $C_{22}H_{31}O_7N$ (V), the infrared absorption spectrum of which in nujol contained a band at 1741 cm^{-1} which shifted in chloroform solution to 1751 cm^{-1} indicating the presence of a five-membered cyclic ketone. In addition, the spectrum in nujol contained bands at 1000 and 900 cm^{-1} which were present in the spectra of III and IV, but absent in the spectra of delcosine, dehydrodelcosine (I), and N-desethyl delcosine, and can be considered as characteristic of the internal ether. Brief treatment with sodium borohydride reduced compound V quantitatively to N-desethyl-anhydrohydroxydelcosine IV. Hence the compound V was N-desethyl-anhydrohydroxy-dehydrodelcosine.⁴

N-Desethyl-anhydrohydroxydelcosine IV could be oxidized in over 60% yield to the corresponding ketone V. This increased yield indicated that in the oxidation of delcosine to the ketonic compound V, the formation of IV is the controlling factor. This oxidation is significant since secondary alicyclic alcohols do not give ketones in good yield under these conditions. The relatively high yield obtained may indicate that the secondary hydroxyl involved in the reaction is flanked on either side by quaternary carbons or, alternatively, by carbons located at bridgeheads, so that the ketone once formed cannot enolize.

The N-desethyl ketone V when ethylated with ethyl iodide gave rise to a new ketone,

³It is possible to explain the analysis and the active hydrogen on the basis of hemiketal structure but the basic strength of compound III is incompatible with this. Furthermore, the infrared spectrum of the compound does not contain the absorption bands characteristic of such a structure (I), which is, therefore, very unlikely.

⁴The high melting point of V and the shift in carbonyl frequency in its infrared spectrum may be due to considerable hydrogen bonding. In fact, the infrared showed a strongly bonded NH.

$C_{24}H_{35}O_7N$ (VI) (infrared band at 1752 cm^{-1}), still containing the internal ether (infrared bands at 1005 and 900 cm^{-1}), which, therefore, must be anhydrohydroxy-dehydrodelcosine. Compound VI proved to be identical with a product obtained in minute quantity in the oxidation of delcosine with chromium trioxide – pyridine complex (9). It tended to form a hydrate and was difficult to extract.

In order to investigate whether the hydroxyl group oxidized by chromic acid or by the Oppenauer oxidation to give the ketone I was the same as that involved in the formation of compound V in the oxidation of IV, attempts were made to reduce selectively the ether system. For this purpose the ethylated derivative VI was used, but all attempts proved unsuccessful. An indication that the hydroxyl involved in both cases was the same can be obtained by a comparison of the pK_a values of the various compounds. The decrease in pK_a in going from delcosine (pK_a 6.49) to dehydrodelcosine I (pK_a 5.75) and from N-desethyl-anhydrohydroxydelcosine (IV) (pK_a 4.6) to the corresponding ketone V (pK_a 4.0) is small in both cases, i.e., 0.74 and 0.6 units respectively. The hydroxyl, therefore, does not seem to have been in close proximity to the nitrogen since Cookson and Trevett (3) have shown that in delpheline (pK_a 7.6) oxidation of a hydroxyl close to the nitrogen to give dehydrodelpheline (pK_a 5.5) caused a decrease in pK_a of 2.1 units.

Silver acetate oxidation of delcosine gave anhydrohydroxydelcosine III together with some N-desethyldelcosine (II). Oxidation with mercuric acetate in acetic acid gave a mixture of N-desethyl-anhydrohydroxydelcosine (IV), N-desethyldelcosine (II), and a compound which was very soluble in water and was not isolated. The aqueous solution containing this compound was acidified and some of the water distilled off. The distillate contained acetaldehyde which was isolated as its *p*-nitrophenylhydrazone. The remaining acid aqueous solution was rendered basic with ammonia and on extraction yielded a further quantity of N-desethyldelcosine II. The water-soluble compound which could not be isolated as such must, therefore, have been the carbinolamine of delcosine formed by hydroxylation of the methylene in the ethyl group which was subsequently split by acid to N-desethyldelcosine and acetaldehyde. A similar oxidation in delpheline was observed by Cookson and Trevett (3).

Delcosine ($C_{24}H_{39}O_7N$), lycoctonine ($C_{25}H_{41}O_7N$), and delpheline ($C_{25}H_{39}O_6N$) are three *Delphinium* alkaloids, and the first two occur together in some species. If their substituents be replaced by hydrogen, all three can be represented by the common saturated empirical formula $C_{21}H_{33}N$, which is that of a hexacyclic structure. It is, therefore, legitimate to assume that the three alkaloids possess closely related structures.

The chemical investigation of lycoctonine has led to a partial elucidation of its structure (5) while an X-ray crystallographic analysis has made it possible to advance a total structure VII (10) which can also be written in the diterpenoid form VIII.⁵ In order to accommodate the chemistry of delpheline which parallels that of lycoctonine, Cookson and Trevett (3) have recently suggested the same ring structure for delpheline in which, however, some of the substituents are different although similarly located. The behavior of delcosine towards oxidizing agents described above and the acylation results described previously (12) can be rationalized by assuming for delcosine a structure IX with the same ring arrangement as that proposed for lycoctonine. The difference between delcosine, lycoctonine, and delpheline would then rest with the oxygenated substituents and with the different orientation of the substituent at the asterisked position in IX.

To account for the formation of N-desethyl-anhydrohydroxy-dehydrodelcosine V, which contains both an internal ether and a five-membered ketone, it is necessary that the substituent on the five-membered ring remote from the nitrogen should be a secondary hydroxyl. Also that a hydroxyl be present in the pentatomic ring adjacent to the heterocyclic ring instead of the methoxyl present in lycoctonine, and that its orientation be opposite to that obtaining in lycoctonine. It is this particular orientation of the hydroxyl that accounts for the formation of an internal ether instead of a lactam. Lycoctonine (4) and delpheline (2) both form lactams on oxidation, and the latter contains a hydroxyl in the same position as that marked with an asterisk in IX. This hydroxyl in delpheline just like the methoxyl in lycoctonine must, therefore, be oriented away from the α -position to the nitrogen. On the basis of structure IX the compound V (N-desethyl-anhydrohydroxy-dehydrodelcosine) can be represented as shown by the partial formula V, which also shows the internal ether.

In the course of the isolation of the various oxidation products described, no acidic material was isolated, and it is concluded that no primary alcoholic group is present in the alkaloid. The presence of a vicinal triol system in delcosine should be detectable by oxidation with periodate, but this oxidation gave anomalous results, and up to 5 moles of oxidant were consumed in 120 hours. On the other hand, anhydrohydroxydelcosine (in which one of the hydroxyls is bound in an internal ether) on similar oxidation consumed 1 mole of periodate, thus indicating the presence of vicinal hydroxyls in that compound. The results of the periodate cleavage studies will be reported later.

Although the size of the heterocyclic ring, and many features paralleling lycoctonine chemistry still have to be proved, we tentatively propose to represent delcosine by structure IX on the basis of which all the known facts can be rationalized.

⁵We feel that the representation VII of the structure of lycoctonine used heretofore by this group is a better illustration of the spatial model produced by X-ray crystallography than the diterpenoid representation. Further, the diterpenoid formula gives a distorted aspect to the rings, and does not lend itself as well to the illustration of the various rearrangements undergone by lycoctonine. Since, however, most of the workers in this field of alkaloid chemistry are using the diterpenoid representation, we are adopting it in spite of its shortcomings, in order to avoid confusion in the literature.

EXPERIMENTAL

All the infrared spectra were measured in nujol mulls (unless otherwise mentioned) on a Perkin-Elmer double-beam spectrometer model 21B, using a sodium chloride prism. The specific rotations were measured in chloroform solutions (accuracy $\pm 1.5^\circ$) and the pK_a were determined in 50% ethanol by electrometric titration.

Oxidation of Delcosine with Chromic Acid in Acetic Acid (Dehydodelcosine I)

To a solution of delcosine (1.35 g.) in glacial acetic acid (10 ml.) chromium trioxide (0.505 g.) was added portionwise. The solution was set aside for 24 hours at room temperature, and then refluxed for 90 minutes. The solvent was removed under reduced pressure and the residue partitioned between dilute sulphuric acid and chloroform (100 ml.). The chloroform layer was washed with a fresh quantity of dilute acid, and the combined acid extract and washings brought to pH 10 with aqueous 40% sodium hydroxide. This alkaline solution was extracted with chloroform and the extract on evaporation left 0.926 g. of a gummy basic product. The chloroform layer separated from the dilute sulphuric acid solution yielded acidic and neutral material (0.139 g.) but no crystalline product could be obtained from this fraction.

The gummy basic product was dissolved in benzene and chromatographed on a column of grade V alumina. Elution with the first 100 ml. of benzene gave a gum, whereas the next 100 ml. gave a partially crystalline material (259 mg.). This was recrystallized from ethanol, m.p. 199–200°. Mixture with delcosine depressed its melting point. Its infrared absorption spectrum in nujol showed a band at 1755 cm^{-1} . The further eluates from the chromatogram yielded unchanged delcosine.

Paper chromatography, by the descending technique on Whatman No. 1 paper buffered to pH 4.78 (8) with butanol saturated with water as solvent, showed that the crystalline product consisted of a mixture of delcosine (R_f 0.546) and a ketonic substance (R_f 0.725). The spots were made visible with Dragendorff's reagent.

In a second experiment, delcosine (6.75 g.) dissolved in acetic acid (50 ml.) was oxidized with chromic acid (2.525 g.) at room temperature. After the products were worked up as above, the acid fraction obtained weighed 1.07 g. It was amorphous, and chromatography on alumina or celite failed to yield a crystalline substance. On the other hand, the basic fraction (4.406 g.) when chromatographed on grade II alumina gave 1.23 g. of a mixture of gummy and crystalline material. This mixture when chromatographed again on alumina and eluted with 300 ml. of benzene containing 20% of chloroform yielded the ketonic product (0.357 g.). This was crystallized from a mixture of benzene and petroleum ether from which it separated as colorless prisms. Five recrystallizations from dilute ethanol furnished an analytical sample of dehydodelcosine, m.p. 212.5–213.5°. Found: C, 63.58; H, 8.10. Calc. for $\text{C}_{24}\text{H}_{37}\text{O}_7\text{N}$: C, 63.83; H, 8.26%. The pK_a was 5.75 and the molecular weight 457 (calc. 451). The infrared absorption spectrum contained a strong band at 1755 cm^{-1} . A paper chromatogram of the pure dehydodelcosine gave one spot (R_f 0.725).

In a later experiment, it was found more convenient to purify the ketone by counter-current distribution. The crude mixture of basic products (3.0 g.) was distributed in 12 transfers between benzene (100 ml. in each tube) and a buffer (100 ml.) pH 4.92, made by mixing 55 volumes of *M* dipotassium acid phosphate and 45 volumes of 0.5 *M* citric acid. When the distribution was complete, the aqueous solutions were made alkaline with aqueous 40% sodium hydroxide (13 ml.) and the organic solutes driven into

the benzene layers. Delcosine (1.52 g.) was contained in tubes 11 and 12 whereas dehydrodelcosine was found in tubes 7, 8, and 9 (568 mg.). No crystalline product was isolated from the other tubes although a peak occurred in tube 3.

Dehydrodelcosine Oxime

Hydroxylamine hydrochloride (58 mg.) and dehydrodelcosine (95 mg.) were dissolved in ethanol, and the pH of the solution brought to 9 by addition of 10% sodium hydroxide. After the solution had refluxed for 3.5 hours the solvent was evaporated under reduced pressure and the residue dissolved in water. The pH was adjusted to 7 and the solution extracted with chloroform. Evaporation of the chloroform extract gave the crystalline oxime, which, after recrystallization from ethanol, consisted of colorless needles, m.p. 229.5–230.5°. Found: C, 62.03; H, 8.44; N, 6.09. Calc. for $C_{24}H_{38}O_7N_2$: C, 61.78; H, 8.21; N, 6.00%. The infrared absorption spectrum contained no band in the carbonyl region.

Oppenauer Oxidation of Delcosine

A solution of aluminum isopropoxide (7.26 g.) in dry benzene (100 ml.) was added in the course of 30 minutes to a refluxing solution of delcosine (1.35 g.) in dry benzene (60 ml.) containing cyclohexane (40 ml.). The mixture was refluxed for 4 hours, left overnight at room temperature, and refluxed for a further 5 hours. It was acidified with glacial acetic acid and steam distilled to remove the volatile solvents. After cooling, the residual aqueous solution was brought to pH 1 with 3 *N* sulphuric acid and extracted with chloroform. The pH was then adjusted to 10 by the addition of 40% sodium hydroxide and the solution extracted with chloroform. This chloroform extract, on evaporation, left a gummy residue, 1.24 g., which was dissolved in ethanol. On cooling, delcosine (0.33 g.) crystallized. The residual basic material recovered from the mother liquor was dissolved in benzene and chromatographed on grade V alumina. The eluate yielded the mixture of delcosine and dehydrodelcosine, m.p. 199–200°, wt. 181 mg., previously described.

Reduction of Dehydrodelcosine

Dehydrodelcosine (10 mg.) and sodium borohydride (30 mg.) were added to methanol containing a few drops of water (3 ml.) and the mixture left at room temperature for 15 minutes. The solution was then heated on the steam bath for 1 hour, diluted, and allowed to cool. Colorless, glistening hexagons separated out, m.p. 201–203°, either alone or mixed with delcosine.

Silver Oxide Oxidation of Delcosine

Freshly prepared silver oxide (from 7.4 g. of silver nitrate) was added to a solution of delcosine (2.86 g.) in ethanol (150 ml.) and water (150 ml.). The mixture was kept at 80° with vigorous stirring for 68 hours, then cooled and filtered. The residue of metallic silver and silver oxide was washed well with ethanol and the combined filtrate and washings was evaporated to a sirup under reduced pressure. This sirup was partitioned between 3 *N* sulphuric acid and chloroform, and the aqueous layer separated and extracted with three 50 ml. portions of chloroform. The combined chloroform extract was back extracted with 3 *N* sulphuric acid, washed with water, and evaporated to dryness. It left a brown residue (30 mg.) which was not further investigated.

The combined acid liquor and washings was made alkaline with ammonia and extracted with chloroform. Evaporation of the chloroform extract gave a colorless residue (2.326 g.). This, on trituration with benzene (5 ml.), left a crystalline compound (0.679 g.), m.p. 230–232°, which, after recrystallization from ethanol (charcoal), melted at 240–241° (dec.) (N-desethyltelcosine II), pK_a 7.9, $[\alpha]_D^{22} +79.5^\circ$ (c , 0.88). Found: C, 62.13; H, 8.24; N, 3.36; act. H (in dioxane), 1.05. Calc. for $C_{22}H_{35}O_7N$: C, 62.09; H, 8.29; N, 3.29; 5 act. H, 1.18%.

The benzene liquor left after filtration of N-desethyltelcosine was diluted with benzene and chromatographed on grade V alumina. It was eluted with benzene and the first 125 ml. of eluate contained a base, 0.602 g., m.p. 187–188°. Further elution with benzene (325 ml.) and then with benzene containing 1% ethanol (100 ml.) yielded a further 0.258 g. of the same product. Continued elution with benzene containing 1% ethanol (300 ml.) gave N-desethyltelcosine, 0.155 g., m.p. 240–241° (dec.).

The product melting at 187–188° (anhydrohydroxytelcosine III) had pK_a 4.2 and $[\alpha]_D^{22} +74.6^\circ$ (c , 1.4). Found: C, 63.92; H, 8.04; N, 3.35; act. H, 0.56. Calc. for $C_{24}H_{37}O_7N$: C, 63.83; H, 8.26; N, 3.10; 3 act. H, 0.66%. Its infrared absorption spectrum showed no carbonyl nor double bond absorption but contained two sharp bands at 1000 and 900 cm^{-1} .

Anhydrohydroxytelcosine Perchlorate

A solution of anhydrohydroxytelcosine (161 mg.) in methanol (5 ml.) was made just acid by the cautious addition of 70% perchloric acid. Dropwise addition of ethyl acetate with cooling and stirring caused the salt to separate as colorless needles (141 mg.). Recrystallized from methanol–ether containing a trace of perchloric acid, it melted at 216–217° (dec.). Found: C, 51.94; H, 7.07; N, 2.52. Calc. for $C_{24}H_{37}O_7N.HClO_4$: C, 51.90; H, 6.90; N, 2.52%. The infrared absorption spectrum of the salt contained no absorption bands in the region 1550–1800 cm^{-1} . The perchlorate is therefore not an anhydronium salt.

Ethylation of N-Desethyltelcosine

N-Desethyltelcosine (35 mg.), sodium carbonate (39 mg.), and dimethylformamide (250 mg.) containing ethyl iodide (79 mg.) were heated on the steam bath for 6.5 hours. The solution was cooled, acidified with dilute sulphuric acid, and extracted with chloroform. It was then rendered basic with ammonia and again extracted with chloroform. This second extract, on evaporation, gave colorless rhombs, m.p. 197–202°, which on recrystallization from dilute methanol, separated as hexagons, m.p. 201–202°, either alone or mixed with telcosine.

Acetylation of N-Desethyltelcosine

A mixture of N-desethyltelcosine (141 mg.), pyridine (two drops), and acetic anhydride (2.5 ml.) was left at room temperature for 20 hours. A sufficient quantity (15 ml.) of aqueous sodium carbonate to produce a basic solution⁶ was added. Extraction with chloroform gave a colorless gum (153 mg.) that could not be crystallized, and was possibly a mixture of O,N-diacetate and O,O,N-triacetate. It was hydrolyzed with aqueous sodium carbonate on the steam bath for 5 hours and, after cooling, the solution was extracted with chloroform. The extract, on evaporation, left a crystalline residue, m.p. 221–225°, which in admixture with N-desethyltelcosine melted at 190–220°.

⁶It is important to keep the aqueous solutions basic throughout, otherwise the product cannot be crystallized.

N-Acetyl-N-desethyldecosine, after crystallization from acetone, consisted of colorless needles, m.p. 221–225°. Found: C, 61.78; H, 8.17; N, 3.07. Calc. for $C_{24}H_{37}O_2N$: C, 61.65; H, 7.98; N, 3.00%. The infrared absorption spectrum showed no band at 1730 cm^{-1} characteristic of an acetoxy group, but contained a band at 1643 cm^{-1} characteristic of an amide carbonyl.

Hydrolysis of N-Acetyl-N-desethyldecosine

The N-acetyl derivative (50 mg.) was hydrolyzed by being heated on the steam bath with 20% aqueous potassium hydroxide for 2 hours. Extraction of the cooled solution with chloroform gave N-desethyldecosine, m.p. 239–241°, either alone or mixed with an authentic sample.

Reduction of Anhydrohydroxydecosine

(a) Anhydrohydroxydecosine (258 mg.) was dissolved in 50% aqueous methanol (5 ml.), and sodium borohydride (50 mg.) was added to the solution. The solution was left standing at room temperature for 18 hours, and subsequently heated on the steam bath for 1 hour. After cooling, the solution was extracted with chloroform, and the extract, on evaporation, left a residual white powder, m.p. 196–200°, wt. 236 mg. This was purified by chromatography on alumina and crystallized from dilute methanol from which it separated as colorless hexagons, m.p. 201–203° either alone or mixed with decosine.

(b) Anhydrohydroxydecosine (54.6 mg.) was hydrogenated in aqueous perchloric acid in the presence of Adams' catalyst (33 mg.) at atmospheric pressure and room temperature (26°). One mole of hydrogen was absorbed smoothly in 30 minutes, but no further uptake of hydrogen was observed within the next 2 hours. The solution was diluted with water and the catalyst filtered and washed with dilute ethanol. The combined filtrate and washings was made alkaline with ammonia and extracted with chloroform. Evaporation of the extract left a crystalline residue (45 mg.), m.p. 199–201° and, in admixture with decosine, m.p. 200–203°.

Oxidation of Decosine with N-Bromosuccinimide

Decosine (500 mg.) was dissolved in aqueous acetone (4 acetone:1 water, 10 ml.) containing a few drops of glacial acetic acid. Sodium acetate (450 mg.) and N-bromosuccinimide (1.75 equivalents) were added at room temperature. On addition of the latter the solution turned yellow, and the color disappeared in 30 seconds as some heat was evolved. The solution was diluted with water (30 ml.) and allowed to stand at room temperature for 20 hours. Dilute sulphuric acid was added to bring the solution to pH 2, and the acidic and neutral material was removed by extraction with chloroform. The aqueous solution was then made alkaline with ammonia and again extracted with chloroform. The basic product (350 mg.) left after evaporation of this chloroform extract was dissolved in benzene and chromatographed on grade V alumina. Elution with benzene-ether (1:1) gave anhydrohydroxydecosine III (197 mg.), which crystallized from acetone-petroleum ether as colorless prisms, m.p. 188–189°, identical with the compound obtained from the silver oxide oxidation. Further elution with benzene containing 10% ethanol gave N-desethyldecosine II (138 mg.), which after crystallization from ethanol melted at 239–240°. Mixture with N-desethyldecosine obtained in the silver oxide oxidation failed to alter the melting point, and comparison of the infrared absorption spectra confirmed the identity.

In a second experiment, delcosine (578 mg.) was dissolved in acetone and oxidized with N-bromosuccinimide (358 mg.) in the presence of sodium carbonate (480 mg.). The solution (pH 8–9) was diluted with water and left at room temperature for 20 hours. When worked up as above, anhydrohydroxydelcosine (80 g.) was obtained. The N-desethyl-delcosine fraction, however, was accompanied by a compound separating as needles which was very soluble in acetone. It was readily separated from N-desethyl-delcosine, which is sparingly soluble in acetone. The new product crystallized from acetone–petroleum ether as needles, m.p. 218–219°, which proved to be N-desethyl-anhydrohydroxydelcosine IV. It had pK_a 4.6 and $[\alpha]_D^{25} +132^\circ$ ($c = 0.75$). Found: C, 62.60, 62.47; H, 7.82, 7.97; N, 3.85. Calc. for $C_{22}H_{33}O_7N$: C, 62.39; H, 7.85; N, 3.31%.

Ethylation of N-Desethyl-anhydrohydroxydelcosine

N-Desethyl-anhydrohydroxydelcosine (70 mg.) was added to a solution of sodium carbonate in freshly distilled ethyl iodide (275 mg.) and dimethylformamide (350 mg.) and heated on the steam bath for 5 hours. The solution was cooled overnight, during which silky needles were deposited. The crystalline hydriodide was dissolved in water, and the solution made basic with sodium hydroxide and extracted with chloroform. The product obtained from the extract consisted of anhydrohydroxydelcosine (50 mg.), which after purification by chromatography melted at 187–188° either alone or in admixture with an authentic sample. Comparison of the infrared absorption spectra which were superimposable confirmed the identity.

Reduction of N-Desethyl-anhydrohydroxydelcosine

The compound (88 mg.) was dissolved in 50% aqueous methanol and sodium borohydride (23 mg.) was added to the solution which was kept at room temperature for 20 hours, subsequently heated on the steam bath for 10 minutes, and allowed to cool. On standing, crystals of N-desethyl-delcosine (20 mg.) separated. Chloroform extraction of the mother liquor yielded a further 35 mg. of the same compound. After recrystallization the melting point was raised to 240–241° and was undepressed by mixing with an authentic sample of N-desethyl-delcosine.

Oxidation of N-Desethyl-anhydrohydroxydelcosine with Potassium Permanganate

N-Desethyl-anhydrohydroxydelcosine (194 mg.) was dissolved in 5% aqueous potassium hydroxide (10 ml.) and a 1% solution of potassium permanganate in 5% aqueous potassium hydroxide (30 ml.) was added gradually over an hour at room temperature. The solution was then diluted and warmed on the steam bath to complete the reaction. The manganese dioxide was filtered off and the excess permanganate reduced with a concentrated solution of sodium sulphite. The liquor was then extracted with chloroform and the extract evaporated to dryness. There was left a crystalline residue (122 mg.), m.p. 275–293°. Repeated recrystallization from acetone–petroleum ether and from ether–petroleum ether raised the melting point to 298°. Its pK_a was 4.0. Found: C, 62.61; H, 7.99; N, 3.48. Calc. for $C_{22}H_{31}O_7N$: C, 62.69; H, 7.41; N, 3.32%. The analytical figures agree with those required by N-desethyl-anhydrohydroxy-dehydrodelcosine and the infrared absorption spectrum contained the two bands at 1000 cm^{-1} and 900 cm^{-1} typical of the internal ether and a sharp band at 1743 cm^{-1} indicating a five-membered cyclic ketone.

Reduction of N-Desethyl-anhydrohydroxy-dehydrodelcosine

The keto compound (12 mg.) was reduced with sodium borohydride by heating (12 mg.) in aqueous methanol on the steam bath for 1 hour. Chloroform extraction of

the reaction mixture gave the product (11 mg.) as needles, m.p. 213–215°. Recrystallized from acetone–petroleum ether, it consisted of colorless needles, m.p. 216–218°, either alone or in admixture with N-desethyl-anhydrohydroxydelcosine.

Ethylation of N-Desethyl-anhydrohydroxy-dehydrodelcosine

A mixture of N-desethyl-anhydrohydroxy-dehydrodelcosine (50 mg.), ethyl iodide (1 ml.), dimethylformamide (20 mg.), and sodium carbonate (20 mg.) was heated on the steam bath for 5 hours. The reaction mixture was evaporated to dryness, and the residue triturated with hot dry acetone and filtered. The filtrate was evaporated to dryness, the residue taken up in dry benzene containing a little acetone, and the solution filtered and evaporated to dryness. The residual anhydrohydroxy-dehydrodelcosine was crystallized from alcohol–ether from which it separated as needles, m.p. 192–193°. $[\alpha]_D^{23} +34.9^\circ$ ($c = 1.46$). Found: C, 63.95; H, 7.95; N, 3.14. Calc. for $C_{24}H_{35}O_7N$: C, 64.12; H, 7.85; N, 3.12%.

Oxidation of Delcosine with Potassium Permanganate⁷

Delcosine (231 mg.) was dissolved in *N* potassium hydroxide and the solution cooled to 0°. A solution of 1% of potassium permanganate in *N* potassium hydroxide was added dropwise to the stirred solution of delcosine. The addition was continued until the permanganate color persisted and during the addition the temperature was allowed to rise to room temperature. The excess permanganate was destroyed with sodium sulphite, the solution filtered, and the filtrate extracted with chloroform. Evaporation of the extract left a crystallized residue (65 mg.), m.p. 210–280°. Fractional crystallization from a mixture of chloroform, ether, and petroleum ether gave a compound separating as needles (44 mg.), m.p. 280–285°, that proved to be identical with N-desethyl-anhydrohydroxy-dehydrodelcosine (see above), and also a smaller quantity (17 mg.) of N-desethyl-anhydrohydroxydelcosine, m.p. 218°.

Oxidation of Delcosine with Silver Acetate

Delcosine (405 mg.) and silver acetate (1.445 g.) were refluxed in 3% acetic acid (50 ml.) for 40 minutes. The hot solution was filtered from the metallic silver, and filtered again, after cooling, from the silver acetate that had crystallized. Dilute sulphuric acid was added to the filtrate and the acid solution extracted with chloroform. The aqueous solution was then made alkaline with ammonia and again extracted with chloroform. The gum left after evaporation of the chloroform was dissolved in benzene and chromatographed as usual. It yielded anhydrohydroxydelcosine (230 mg.), m.p. 187–188°, undepressed by mixture with the sample obtained by silver oxide oxidation. No other pure product could be isolated from the reaction.

Oxidation of Delcosine with Mercuric Acetate

Delcosine (3.0 g.) was dissolved in 3% acetic acid (65 ml.), and mercuric acetate (16.8 g.) was added. The solution was heated on the steam bath for 60 minutes. The precipitated mercurous acetate was filtered off and the filtrate extracted with chloroform. Evaporation of the chloroform extract left a mixture of N-desethyl-delcosine and N-desethyl-anhydrohydroxydelcosine which was directly reduced with sodium borohydride to give N-desethyl-delcosine (1.9 g.). The aqueous solution that had been extracted was acidified with dilute hydrochloric acid, and an aliquot (25 ml.) distilled at atmospheric pressure to about half volume. The aqueous distillate was treated with an acetic acid solution of *p*-nitrophenylhydrazine containing a few drops of hydrochloric acid. Yellowish

⁷This oxidation was first carried out by Dr. W. E. Wallis in this laboratory.

brown needles separated, m.p. 127–130.5°. Recrystallization from aqueous methanol raised the melting point to 130–130.5°, and this was undepressed by mixing with an authentic sample of acetaldehyde *p*-nitrophenylhydrazone.

The acidic solution from which the aliquot had been taken was hydrolyzed on the steam bath, cooled, made alkaline with ammonia, and extracted with chloroform. The extract on evaporation yielded a further quantity of N-desethyldelecosine.

ACKNOWLEDGMENT

The authors wish to express their indebtedness to Dr. O. E. Edwards for many valuable discussions, and to Mr. R. Lauzon for taking the infrared absorption spectra.

THE STRUCTURE OF ANNOTININE¹

M. MARTIN-SMITH,² R. GREENHALGH,² AND LÉO MARION

ABSTRACT

Annotinine is hydrolyzed by aqueous barium hydroxide to annotininic acid, $C_{16}H_{23}O_4N$, which with diazomethane forms methyl annotininate. Treatment of this ester (or of annotinine) with potassium methoxide in methanol produces epimerization and gives rise to methyl epiannotininate, also produced by methanolysis of annotininic acid. Whereas under the action of barium hydroxide methyl annotininate regenerates annotininic acid, methyl epiannotininate is converted to annotinine hydrate. Hydrolysis of annotinine with dilute sulphuric acid gives rise to annotinine diol, which is oxidizable to an amino acid, whereas the isomeric annotinine hydrate on oxidation gives rise to a hydroxyketo lactone. This corroborates the evidence already in the literature indicating that the γ -lactone ring in annotinine hydrate is not the same as that originally present in the alkaloid. The relevant chemical reactions of annotinine are reviewed in the light of a tentative structure suggested for annotinine.

It has been established previously that annotinine ($C_{16}H_{21}O_3N$) is a tertiary base containing a γ -lactone and a cyclic ether (6) that MacLean and Prime (5) have later shown to be an epoxide. The same authors have also established the position of the epoxide system relative to the nitrogen as

Annotinine reacts with alcoholic alkali giving rise to annotinine hydrate (6), a substance containing a γ -lactone and two hydroxyls. Henderson, Stonner, Valenta, and Wiesner (4) were the first to suggest that the γ -lactone of annotinine hydrate was not that originally present in the alkaloid, but a new γ -lactone formed by relactonization of the carboxyl with one of the hydroxy groups originating from the oxide ring. Wiesner and his collaborators (8) by a study of the reactions of annotinine anhydrochlorolactam, formed by dehydration of the lactam chlorohydrin, have supplied evidence supporting such a suggestion. The same authors have also suggested a number of tentative structural formulae for the alkaloid.

In this paper we wish to record a number of experiments supplying more evidence pointing to a different relactonization in the formation of annotinine hydrate, and also to suggest a tentative structure for the alkaloid that seems to accommodate all the chemical evidence.

It was reported by Henderson, Stonner, Valenta, and Wiesner (4) that annotinine on prolonged treatment with boiling dilute sulphuric acid led to a derivative, m.p. 75° , whose empirical formula $C_{16}H_{23}O_4N$ differed from that of annotinine by the addition of the elements of water. Careful repetition of this work failed in our hands to give a compound of that melting point, but gave rise to three products. One was present only in traces while the other two were annotinine hydrate (8%) and the isomeric annotinine diol, m.p. $190-192^\circ$. This last compound formed a diacetyl derivative, m.p. 168° , which is obviously the same as that prepared by Henderson, Stonner, Valenta, and Wiesner (4) from their material. It is probable that annotinine diol is a substance in which the γ -lactone is the same as that present in the alkaloid.

When annotinine was boiled for several hours with aqueous barium hydroxide it gave rise to a trihydroxy acid which on treatment with 25% sulphuric acid was also converted to annotinine diol. Oxidation of this diol with barium permanganate gave rise to the same amino acid, $C_{14}H_{19}O_4N$, previously obtained from "unsaturated lactone A" (see below) (1) and from annotinine anhydrochlorolactam (4). On the other hand, oxidation of annotinine hydrate has been shown (7) to give rise to a hydroxyketo lactone ($C_{16}H_{21}O_4N$).

When annotinine was treated with boiling aqueous barium hydroxide for 40 minutes, there resulted a good yield of a hydroxy acid, $C_{16}H_{23}O_4N$. It is proposed to designate this acid, which still contains the epoxide ring intact, annotininic acid. The infrared spectrum of the acid did not show absorption at a normal carboxyl frequency but instead contained a diffuse peak at $1575\text{--}1568\text{ cm}^{-1}$. Such absorption is typical of an amino acid existing as a zwitterion. On treatment with diazomethane, annotininic acid was smoothly converted to its methyl ester, m.p. $132.5\text{--}134^\circ$. Boiling methyl annotininate with aqueous barium hydroxide regenerated annotininic acid. Treatment of methyl annotininate with potassium methoxide in absolute methanol converted it into an isomeric methyl ester, m.p. $163\text{--}164^\circ$. This ester (methyl epiannotininate) also resulted when annotinine was treated with an equivalent of potassium methoxide in methanol at room temperature. The action of barium hydroxide on this ester converted it to annotinine hydrate in contrast with the action of the same reagent on methyl annotininate, which regenerated the acid.

Methyl epiannotininate had previously been reported by Henderson, Stonner, Valenta, and Wiesner (4), who prepared it by the action of methanolic potassium hydroxide on annotinine, followed by methylation with diazomethane. This sequence masked the essential nature of the reaction, which is a methanolysis of the lactone accompanied by an epimerization. Such a transesterification had been observed with the naturally occurring lactones picrotin and picrotoxinin (3) under the influence of potassium hydroxide in absolute methanol (such a solution containing a high concentration of methoxide ions). Further, it seems highly improbable that epiannotininic acid could be isolated as such since it passes extremely readily into annotinine hydrate.

A similar transesterification with epimerization was observed by Wiesner and collaborators (4, 8) when methanolic potassium hydroxide was allowed to react with unsaturated lactamic derivatives of annotinine.

Annotinine lactam itself underwent the same transesterification to form methyl epiannotininate lactam, which was also obtained by oxidation of methyl epiannotininate.

It has been shown by MacLean and Prime (5) that the lactam obtainable from annotinine can be converted to a lactam chlorohydrin ($C_{16}H_{20}O_4NCl$), which in turn can be dehydrated to an anhydrochlorolactam ($C_{16}H_{18}O_3NCl$). Later, Henderson, Stonner, Valenta, and Wiesner (4) described the oxidation of this last compound to an amino acid, $C_{14}H_{19}O_4N$, still containing a γ -lactone ring, which must be that initially present in the alkaloid. Subsequently, Anet and Marion (1) showed that this same amino acid could be obtained by oxidation of the "unsaturated lactam A" produced by mild treatment of annotinine chlorohydrin with chromous chloride (7). The methyl ester of this amino acid underwent transesterification under the influence of potassium methoxide and gave rise to a diester. Anet and Marion (1) have also shown that in the presence of palladium at 250° , the amino acid is readily dehydrogenated to an acid, $C_{14}H_{15}O_3N$, that no longer contains a lactone ring, but contains a lactamic carbonyl as well as a free carboxylic group. Furthermore, this acid can be decarboxylated to a neutral compound,

$C_{13}H_{15}ON$. The structure originally advanced for the neutral compound (1) is erroneous and Valenta, Wiesner, Bankiewicz, Henderson, and Little (9) have established its structure and that of the lactam acid by synthesis to be I and II respectively.

None of the sequence of reactions involved in going from annotinine to the acid II and the neutral compound I is of a drastic nature, with the possible exception of the palladium dehydrogenation. Since, however, the product of this dehydrogenation has retained all its atoms, and its asymmetric center has retained its optical activity, it seems legitimate to assume that no deep-seated rearrangement can be involved in the formation of these compounds and of the amino acid. Any structure suggested for annotinine should, therefore, be such as to permit of the easy formation of these derivatives. It should contain a $C-CH_3$ group and also account for the formation of 8-*n*-propylquinoline (2) and of 7-methylquinoline (1), which were obtained in small yield from the alkaloid under dehydrogenating conditions. It should contain an epoxide ring (5, 6) and a γ -lactone with the carboxyl so located as to be capable of relactonization to a new γ -lactone with one of the hydroxyl groups obtainable by hydrolysis of the epoxide.

We now wish to suggest the tentative structure III for annotinine. It contains the requisites mentioned above, and supplies a basis for all the chemical transformations of annotinine so far observed. On the basis of this structure the "unsaturated lactone A" would be represented by IV and the oxidation of IV would give V, which must be the

structure of the amino acid $C_{14}H_{19}O_4N$. The passage from V to the lactam acid II on heating in the presence of palladium would involve, first, the rupture of the $O-C$ bond, then rupture of the bond that is marked in the four-membered ring, aromatization of the six-membered carbon ring, and lactamization of the liberated carboxyl with the secondary amino group. Methyl annotininate and methyl epiannotininate would be represented by partial formulae VI and VII respectively.

In two short communications Wiesner and his co-workers (10, 11) have recently reported that the hydroxy ester of annotinine $C_{17}H_{22}O_4NCl$ (obtained by methanolysis of anhydrochloro annotinine lactam), when refluxed in xylene with phosphorus pentoxide, gave rise to two isomeric esters $C_{17}H_{20}O_3NCl$. One was simply an anhydro product while the other (isolated as the free acid) showed the spectroscopic features of an α -pyridone (10), and had undergone scission in one ring with formation of a double bond (11). The anhydro ester product when heated in the presence of palladium-charcoal produced a quinolone acid VIII ($R = CO_2H$) which could be decarboxylated to the quinolone VIII ($R = H$). Wiesner, Valenta, Ayer, and Bankiewicz (11) consider that the production of these quinolone derivatives limits the structure of annotinine to IX in which an additional connection has to be made between $*C$ and C(1), C(2), or C(3), of which they deem a $*C-C(2)$ bond preferred.

We consider that our tentative formula III permits the rationalization of these reactions equally well and furthermore makes the derivation of compounds such as I and II much more obvious than does structure IX.

On the assumption of structure III the hydroxy epiester derived from the anhydrochlorolactam can be represented by X and the anhydro ester by XI. A concerted rearrange-

ment involving a contraction of the seven-membered ring in XI, a wandering of a carboxyl group, and aromatization and elimination of the side chain results in the formation of VIII ($R = CO_2H$).

EXPERIMENTAL

The infrared absorption spectra were taken in nujol mulls with a Perkin-Elmer double beam spectrometer Model 21B with a sodium chloride prism.

Hydroxylactone and "Unsaturated Lactone A"

The preparation described previously (7) was not entirely satisfactory and the following procedure gave better yields of the two compounds. Annotinine (4.0 g.) was refluxed for

90 minutes with concentrated hydrochloric acid (40 ml.) and water (60 ml.). At the end of this period chromic chloride hexahydrate (35 g.) was added to the hot mixture, which now contained a considerable quantity of crystalline annotinine chlorohydrin hydrochloride. Water (150 ml.), concentrated hydrochloric acid (10 ml.), and zinc powder (25 g.) were also added to the mixture, which was refluxed under nitrogen for 5 hours.

The mixture was cooled, the zinc filtered out and washed with water, and the filtrate made alkaline with a large excess of ammonia with constant swirling to render the precipitated chromium salts granular. The mixture was extracted with ether in a continuous extractor and the extract evaporated to dryness. There was left an amorphous solid (4.0 g.), which was dissolved in benzene and chromatographed on alumina (Grade III). Benzene, and then ether, were used as eluants. Unsaturated lactone A (2.03 g.) m.p. 132°, and hydroxylactone (1.1 g.), m.p. 174°, were obtained from the eluants (cf. 7).

Annotininic Acid

Annotinine (1.0 g.) was refluxed for 40 minutes with barium hydroxide octahydrate (6.0 g.) and water (30 ml.). The alkaloid was completely dissolved in *ca.* 30 minutes. The solution was cooled and an excess of carbon dioxide was bubbled through it to precipitate the barium. The barium carbonate was filtered and washed well with water. The combined filtrate and washings was evaporated to dryness under reduced pressure, and the white solid residue was dissolved in methanol. This solution was concentrated on the steam bath until it began to deposit crystals and was then allowed to cool. Colorless, glistening prisms (500 mg.) were obtained by filtration, and a further crop (275 mg.) by concentration of the mother liquor. After recrystallization from methanol, the product consisted of hard glistening prisms, becoming powdery on exposure to air, m.p. 258–259° (dec.). Found: C, 65.80; H, 7.76; N, 4.57. Calc. for $C_{16}H_{23}O_4N$: C, 65.51; H, 7.90; N, 4.78%. The acid is nearly insoluble in ether, sparingly soluble in ethanol, and readily soluble in methanol and in water. The infrared absorption spectrum showed a diffuse peak at 1575–1568 cm^{-1} typical of an ionic carboxylic group and a strong hydroxyl peak at 3330 cm^{-1} . Surprisingly, there was a small but well-defined peak at 3020 cm^{-1} suggestive of a double bond. No uptake of hydrogen was observed, however, when the acid in aqueous acetic acid was treated with hydrogen in the presence of Adams' catalyst. The ultraviolet spectrum of the acid in water showed continuous transmission from 220 $m\mu$ to 350 $m\mu$. Attempts to decarboxylate the acid failed.

Annotinine Chlorohydrin from Annotininic Acid

Annotininic acid (200 mg.) was refluxed with concentrated hydrochloric acid (3 ml.) and water (4 ml.) for 90 minutes. After the solution had cooled, addition of a seed crystal of annotinine chlorohydrin hydrochloride initiated crystallization. The chlorohydrin was liberated from the hydrochloride (190 mg.) by the addition of ammonia to its aqueous solution. Annotinine chlorohydrin thus obtained melted at 190° either alone or in admixture with an authentic specimen.

Methyl Annotininate

Finely ground annotininic acid (800 mg.) was added to an ethereal solution of diazomethane. Very little reaction was apparent, but on addition of a little methanol there was a vigorous evolution of nitrogen and nearly all the acid dissolved. The reaction ceased after 10 minutes. A little unchanged material was removed by filtration and the filtrate was evaporated to dryness. The residual colorless oil was digested with several

portions of ether and the combined ether extracts concentrated until crystallization began. The ester separated as hard rectangular colorless prisms, m.p. 132–134°, 604 mg. After one recrystallization from ether, m.p. 132.5–134°. Found: C, 66.49; H, 8.30. Calc. for $C_{17}H_{25}O_4N$: C, 66.42; H, 8.20%. The infrared absorption spectrum of the ester in a nujol mull contained a hydroxyl band at 3460 cm^{-1} and an ester peak at 1732 cm^{-1} . In carbon disulphide solution, the hydroxyl peak had a lower intensity and was at 3580 cm^{-1} while the ester carbonyl peak was broadened but still occurred at 1732 cm^{-1} .

The methyl ester, on saponification by refluxing with aqueous barium hydroxide for 35 minutes, regenerated annotininic acid, m.p. 256–258°.

Methyl Epiannotininate

(a) From Methyl Annotininate

Methyl annotininate (90 mg.) was dissolved in a solution of potassium (100 mg.) in methanol (20 ml.) and allowed to stand at room temperature for 2 days. The solvent was then evaporated under reduced pressure at room temperature and the residue extracted with ether. When concentrated, the ethereal solution deposited a crystalline material, m.p. 163–164°, either alone or in admixture with methyl epiannotininate prepared as described below.

(b) From Annotinine

Annotinine (900 mg.) was added to a solution of potassium (1 g.) in absolute methanol (30 ml.). The solution in a stoppered flask was allowed to stand at room temperature for 72 hours; it was then evaporated in an air stream. The residue was washed with a little water and dissolved in ether. The ethereal solution was dried over sodium sulphate and concentrated. It deposited colorless pyramidal prisms, wt. 765 mg. A sample was recrystallized from ether for analysis, m.p. 163–164°. Found: C, 66.64; H, 8.37. Calc. for $C_{17}H_{25}O_4N$: C, 66.42; H, 8.20%. The infrared absorption spectrum in nujol mull showed a sharp hydroxyl band at 3510 cm^{-1} with an ester carbonyl peak at 1725 cm^{-1} . In carbon disulphide solution, the hydroxyl peak is greatly diminished in intensity and occurs at 3580 cm^{-1} , while the ester carbonyl peak shows a shoulder at 1738 cm^{-1} and is shifted at 1733 cm^{-1} .

Annotinine Hydrate from Methyl Epiannotininate

(a) By the Action of Acetic Acid

Methyl epiannotininate (300 mg.) was dissolved in acetic acid (10 ml.) and the solution allowed to stand at room temperature for 24 hours. The solvent was evaporated under reduced pressure and the residual oil crystallized from ether, m.p. 220–224°, wt. 270 mg. Mixing with an authentic specimen of annotinine hydrate did not depress the melting point.

(b) By the Action of Barium Hydroxide

Methyl epiannotininate (200 mg.) was refluxed for 40 minutes with barium hydroxide octahydrate (1 g.) in water (15 ml.). The solution was cooled and carbon dioxide bubbled into the solution to precipitate all the barium. Barium carbonate was filtered off and the clear filtrate evaporated to dryness under reduced pressure. The residue, on crystallization from ethanol, yielded colorless hard prisms, wt. 147 mg., m.p. 227°, either alone or mixed with annotinine hydrate.

Trihydroxy Acid

Annotinine (1 g.) was refluxed for 18 hours with barium hydroxide octahydrate (6.0 g.) in water (30 ml.). To the cooled solution dilute sulphuric acid was cautiously added until precipitation of the barium sulphate was complete. The mixture was filtered and the filtrate evaporated to dryness under reduced pressure. The residual gum was extremely soluble in water and methanol, soluble in ethanol, but insoluble in acetone, ether, and ethyl acetate. Passage of an aqueous solution of the gummy sulphate through an amberlite 400-OH column failed to yield the trihydroxy acid in solid form. It was crystallized as the sulphate from absolute ethanol. The sulphate was extremely hygroscopic and, consequently, the analytical figures obtained were slightly outside the experimental limits usually accepted. Found: C, 52.80; H, 7.51. Calc. for $(C_{16}H_{25}O_5N)_2 \cdot H_2SO_4$: C, 53.32; H, 7.27%.

Annotinine Chlorohydrin from the Trihydroxy Acid

The trihydroxy acid sulphate (800 mg.) was refluxed for 90 minutes with concentrated hydrochloric acid (12 ml.) and water (16 ml.). The solution initially went bright yellow but as the reaction proceeded the intensity of the color lessened considerably. The solution was concentrated to *ca.* half volume and neutralized with aqueous sodium carbonate. This produced a precipitate that was removed by extraction with ether. The material obtained by evaporation of the ether extract was dissolved in benzene and chromatographed on alumina (Grade IV). Elution with benzene gave annotinine chlorohydrin (520 mg.) identical (m.p., mixed m.p., and I.R. spectra) with an authentic sample. Further elution with chloroform gave an oil (170 mg.) that could not be induced to crystallize.

*Annotinine Diol**(a) From the Trihydroxy Acid*

The trihydroxy acid sulphate (1.0 g.) was refluxed with 25% sulphuric acid (30 ml.) for 3 hours. The solution was then made strongly basic with ammonia and extracted with ether in a continuous extractor for 36 hours. Evaporation of the ether extract left a residual, slightly yellow, oil which was dissolved in methanol; the solution was treated with norite and filtered. To the filtrate 2 drops of concentrated hydrochloric acid were added, and the solution diluted with ether. The crystalline hydrochloride that separated was recrystallized several times from methanol-ether, m.p. 231–233° (dec.). Found: C, 56.69; H, 7.59. Calc. for $C_{16}H_{23}O_4N \cdot HCl \cdot \frac{1}{2}H_2O$: C, 56.71; H, 7.44%. The anhydrous salt melted at 295° (see below).

The perchlorate of annotinine diol was prepared from the hydrochloride by treating a methanolic solution of the latter with perchloric acid and diluting with ether. The perchlorate that separated was recrystallized from ethanol-ether, m.p. 243–244°. Found: C, 48.79; H, 6.14. Calc. for $C_{16}H_{23}O_4N \cdot HClO_4$: C, 48.62; H, 6.06%.

(b) From Annotinine

Annotinine (1.0 g.) in 25% sulphuric acid (5 ml.) was refluxed gently for 25 hours. The cooled solution was made basic with ammonia and extracted with chloroform. The chloroform extract was concentrated and allowed to stand. It deposited a crystalline substance (261 mg.), which after recrystallization from chloroform melted at 192–193°. Its infrared absorption spectrum showed strong hydroxyl absorption at 3440 cm^{-1} and a

lactone carbonyl band at 1750 cm^{-1} . Found: C, 65.68; H, 7.89; N, 4.79. Calc. for $\text{C}_{16}\text{H}_{23}\text{O}_4\text{N}$: C, 65.51; H, 7.90; N, 4.78%.

A sample of the crystalline annotinine diol thus obtained was converted to the hydrochloride, which was recrystallized from methanol-ether. The colorless crystals melted at $295\text{--}296^\circ$, either alone or mixed with the anhydrous hydrochloride (m.p. 295°) mentioned above. Found: C, 56.15; H, 7.03. Calc. for $\text{C}_{16}\text{H}_{23}\text{O}_4\text{N}\cdot\text{HCl}$: C, 58.27; H, 7.33%. This salt on exposure to air became hydrated and then melted at $231\text{--}233^\circ$ as the salt already described.

The chloroform mother liquor from which the annotinine diol had crystallized was evaporated to dryness and the residual dark tar (650 mg.) dissolved in benzene and chromatographed on alumina (grade IV). Benzene and chloroform were used as eluants. The first eluates yielded 80 mg. of colorless prisms, m.p. $227\text{--}228^\circ$, either alone or in admixture with authentic annotinine hydrate. A mixture of annotinine hydrate and annotinine diol melted at $169\text{--}177^\circ$. The remaining eluates yielded a reddish oil (510 mg.); this was dissolved in methanol and the solution neutralized with a few drops of hydrochloric acid. After the addition of a little ether the solution deposited colorless needles, m.p. $294\text{--}296^\circ$, identical with that of annotinine diol hydrochloride. The yield of annotinine hydrate was 8%, that of annotinine diol 67%.

Annotinine diol on being heated with acetic anhydride and fused sodium acetate formed a diacetyl derivative, m.p. $165\text{--}167^\circ$, as previously reported (4). Found: C, 63.81; H, 7.12. Calc. for $\text{C}_{20}\text{H}_{27}\text{O}_6\text{N}$: C, 63.64; H, 7.21%.

Oxidation of Annotinine Diol

Annotinine diol (536 mg.) in aqueous solution was oxidized with barium permanganate (984 mg.). At the end of the reaction the excess permanganate was reduced by the addition of a little alcohol. The manganese dioxide was filtered and washed repeatedly with water; it was suspended in water and dissolved by passing sulphur dioxide into the solution. Both this solution and the filtrate were worked up separately. After the barium had been removed with sulphuric acid, the product of the oxidation was isolated as the sulphate, m.p. $233\text{--}235^\circ$ (dec.), either alone or in admixture with the amino acid sulphate obtained previously by oxidation of "unsaturated lactone A" (1), wt. 291 mg. The two sulphates were also identified by comparison of their infrared absorption spectra. Methylation of the acid with diazomethane gave rise to the methyl ester, m.p. 124° (4). Acetylation of the methyl ester with acetic anhydride and fused sodium acetate gave a neutral N-acetyl ester, m.p. 135° . Found: C, 63.01; H, 6.74. Calc. for $\text{C}_{17}\text{H}_{23}\text{O}_5\text{N}$: C, 63.53; H, 7.21%.

Methanolysis of the Methyl Ester of the Amino Acid

The methyl ester (354 mg.) was dissolved in anhydrous methanol (18 ml.), and potassium (50 mg.) dissolved in methanol (1 ml.) was added. The solution was kept in the dark at room temperature for 3.5 days. The solvent was then evaporated in a stream of air, the residual yellow oil dissolved in water (5 ml.), and the solution extracted with ether, acidified with sulphuric acid, and extracted with chloroform. The acid solution was alkalinized with sodium carbonate and extracted with ether. This last ether extract on evaporation left a clear oil, 98 mg., that a paper chromatogram showed to be homogeneous. It was chromatographed on alumina (Grade IV) and eluted with ether-benzene. It was then distilled, b.p. $115\text{--}122^\circ$ at 10^{-4} mm. Found: C, 62.12; H, 8.12. Calc. for $\text{C}_{16}\text{H}_{25}\text{O}_5\text{N}$: C, 61.71; H, 8.09%.

Treatment of Annotinine Lactam with Potassium Methoxide in Methanol

Annotinine lactam (640 mg.) was allowed to stand at room temperature for 3 days with a solution of potassium metal (1 g.) in methanol (25 ml.). The solvent was removed by evaporation in a stream of air, and the residue extracted with ether. The ethereal solution on evaporation left a colorless oil that slowly crystallized. Recrystallized from ether, it consisted of colorless prisms (30 mg.), m.p. 192–193°. Found: C, 63.53; H, 7.21. Calc. for $C_{17}H_{23}O_5N$: C, 63.40; H, 7.22%. The infrared absorption spectrum showed a sharp hydroxyl peak at 3375 cm^{-1} , an ester carbonyl peak at 1723 cm^{-1} , and a lactam carbonyl peak at 1636 cm^{-1} .

The residue, which was not soluble in ether, was dissolved in water, and the solution was acidified with hydrochloric acid and allowed to stand a week at room temperature. It was then extracted continuously with ether for 36 hours. The extract, on evaporation, yielded a gum which after several crystallizations from water consisted of colorless prisms (380 mg.), m.p. 246–248°. Found: C, 62.75; H, 7.09. Calc. for $C_{16}H_{21}O_5N$: C, 62.62; H, 6.88%.

Oxidation of Methyl Epiannotinate

The ester (150 mg.) was oxidized with chromic oxide (100 mg.) in pyridine at room temperature for 16 hours. It yielded a product which, after recrystallization from ether, consisted of colorless prisms, m.p. 192–193° either alone or in admixture with the methyl epiester of annotinine lactam described above.

ACKNOWLEDGMENT

We wish to express our gratitude to Mr. R. Lauzon of these laboratories for preparing all the infrared absorption spectra.

NOTES

AN AMPEROMETRIC TITRATION OF TITANIUM¹R. P. GRAHAM AND E. VANDALEN²

A few years ago it was shown (1) that *m*-nitrophenylarsonic acid is suited to the amperometric titration of thorium(IV), zirconium(IV), tin(IV), and uranium (as uranyl ion). With titanium(IV), however, the results were non-reproducible under all the conditions investigated, and the conclusion was drawn that an amperometric determination of titanium by means of this arsonic acid is not feasible. Recent work in this laboratory (3) on the reaction of *m*-nitrophenylarsonic acid (MNPA) with titanium (IV) has led to knowledge of conditions under which the amperometric titration of titanium with this reagent is possible.

Precipitation of Titanium(IV) with MNPA

For titanium to be precipitated quantitatively as a *m*-nitrophenylarsonate the pH of the solution must be controlled carefully. If the pH is unduly low, titanium is not precipitated quantitatively or even not at all; if the pH is unduly high, titanium (though it still may be precipitated quantitatively) is in part precipitated as the hydrous oxide or as a basic salt. Moreover, the nature and concentration of the anions in the solution have an important bearing on the choice of the proper pH for precipitation, as the data of Table I show.

TABLE I
EFFECT OF ANIONS ON THE OPTIMUM pH FOR THE
PRECIPITATION OF TITANIUM *m*-NITROPHENYLARSONATE
(Ti ~ 0.04 MG./ML.)

Anion	Concentration (M)	Optimum pH*
Chloride	35×10^{-3}	1.2
Perchlorate	24×10^{-2}	0.80-1.60
Sulphate	1.1×10^{-3}	1.20-1.50
	4.1×10^{-3}	1.62-1.80
	36×10^{-3}	2.25-2.35

*During precipitation, as would be expected, the pH fell slightly from the preadjusted value of the titanium and reagent solutions (adjusted to the same desired value before mixing). The pH was recorded as the mean of the "before" and "after" values, which differed by 0.1 pH units or less. Measurements were made with a Beckman Model G pH meter.

The greater ease with which titanium precipitates in a perchlorate medium, as compared to a sulphate medium, can be associated with the lesser tendency of perchlorate to complex with titanium. The complexing effect of sulphate is reflected, too, in the dependence of the degree of completeness of the precipitation on the concentration of sulphate in the solution. Absorptiometric tests on the filtrates using a Tiron method (4) showed that, although titanium is quantitatively (>99.9%) precipitated throughout

the pH ranges given in Table I for the three concentrations of sulphate, the precipitation is more complete the lower the concentration of sulphate.

The range of pH over which a fixed amount of titanium reacts with a constant amount of MNPAA (Table I) was determined by analyzing, for excess MNPAA, the filtrates and washings from the filtered precipitates by a polarographic method described elsewhere (3), or by a related method in which the filtered and washed precipitates were dissolved.

From these findings the following procedure for the amperometric titration of titanium with MNPAA was developed.

Procedure

About 35 ml. of a titanium solution, containing 5 to 20 mg. of titanium in the presence of chloride and perchlorate, was put into a titration cell. This consisted of a beaker into which dipped a potassium chloride - agar bridge connected to a saturated calomel reference electrode, a bubbling tube through which nitrogen could be led to the bottom of the beaker, and a dropping-mercury electrode. The pH of the solution was adjusted to 1.2 ± 0.1 by the careful addition of 2.5 *M* ammonia or 2.5 *M* perchloric acid. Five milliliters of a 2.0 *M* solution of sodium perchlorate, which had been adjusted to a pH of 1.2 with perchloric acid, was added as supporting electrolyte. This solution also contained methyl red (at a concentration of 10 mg./l.), which functions as a maximum suppressor. The titrant was an aqueous solution of MNPAA prepared by dissolving the reagent (Distillation Products Industries, Rochester, N.Y.) in water to make a 0.8% solution, adjusting the pH to 1.2 with 60% perchloric acid, and, after 24 hours, filtering the solution.

Oxygen-free nitrogen was bubbled through the solution for 5 minutes before the first addition of titrant. After each addition of titrant (from a 10-ml. burette graduated to 0.05 ml.) the solution was stirred, by passing nitrogen through it, for 3 minutes if the equivalence point had not been reached or for 1 minute if the equivalence point had been passed. (Experiments had shown that these waiting periods were sufficient to allow for substantially complete reaction.) After each bubbling, an additional 1-minute period was allowed for the re-establishment of quiet solution conditions before the galvanometer

FIG. 1. Typical amperometric titration curve of titanium (0.0065 *M*), in a sodium perchlorate - perchloric acid medium of pH 1.2, with *m*-nitrophenylarsonic acid (~ 0.032 *M*) at pH 1.2.

deflection was recorded. The deflection, at an applied potential of -0.70 volts* vs. S.C.E., was read from the visual scale of a Sargent Model XI polarograph. Four or five readings on each side of the equivalence point were taken and the data, after correction for the dilution effect, were plotted. Fig. 1 is a typical titration graph.

The results of some titrations are shown in Table II. Multiplicate determinations had a precision of about $\pm 0.5\%$; over a fourfold spread in titanium concentration the average deviation from the mean value was $\pm 0.6\%$. These results are very satisfactory

TABLE II
RESULTS OF AMPEROMETRIC TITRATIONS

Titanium taken (mg.)	Volume of titrant (ml.)	Ml. of titrant per mg. of Ti
5.22	3.20	0.613
10.44	6.33*	0.606
15.66	9.46†	0.604
20.88	12.75	0.611

*Average of three determinations: 6.35, 6.28, 6.35.

†Average of four determinations: 9.48, 9.42, 9.50, 9.43.

for an amperometric titration in this concentration range ($\sim 0.005 M$). Nevertheless, the method has rather limited practical application because of the restrictiveness of the conditions under which satisfactory titrations may be performed.

*Composition of Titanium *m*-Nitrophenylarsonate*

We have analyzed precipitates of titanium *m*-nitrophenylarsonate obtained by bringing together, under conditions similar to those obtaining in the amperometric titration described above, solutions of titanium and MNPAA in amounts corresponding to those prevailing both very close to the equivalence point and somewhat beyond it. The precipitates were filtered, washed appropriately, and dissolved in a $0.35 M$ solution of sodium tartrate. The solutions were analyzed polarographically (3) for MNPAA using a Sargent Model XX polarograph and absorptiometrically for titanium, with hydrogen peroxide, using a Coleman Model 11 spectrophotometer. The MNPAA for the calibration was obtained by purifying the commercial product, referred to earlier, by the method of (2) and the standard titanium solutions were prepared from titanium dioxide supplied by the National Bureau of Standards, the solutions being analyzed by a standard gravimetric procedure.

The average of analyses of eight precipitates was 0.94 moles of reagent for every mole of titanium. Thus, under these conditions of precipitation, a monoarsonate is formed and the reaction is probably, as suggested by Kolthoff and Johnson (1),

where H_2R is MNPAA, $\text{NO}_2\text{C}_6\text{H}_4\text{AsO}(\text{OH})_2$.

When, however, a very considerable excess of reagent is present, a diarsonate is formed. This was demonstrated by experiments in which known amounts of titanium in a perchlorate medium were precipitated by MNPAA at pH 1.2 under conditions that had been shown to precipitate the titanium quantitatively, and with about 20 moles of reagent present for each mole of titanium. The precipitates were dissolved as before and

*Subsequent work indicated that -0.50 volts would have been a more suitable setting.

analyzed polarographically for MNPAA, the calibration being done using a purified sample of the reagent. The average value from seven determinations of the number of moles of reagent per mole of titanium was 2.02 (with an average deviation of ± 0.03 from this average). It is clear that when the monoarsonate reacts with excess reagent a diarsonate, TiR_2 , is formed and not a compound of formula $\text{TIR}_{1.5}$, as has been suggested (1).

THIAZOLES

III. INFRARED SPECTRA OF METHYLTHIAZOLES^{1,2}

ALFRED TAURINS,³ J. G. E. FENYES, AND R. NORMAN JONES

ABSTRACT

The infrared absorption spectra of thiazole, all three monomethylthiazoles, and two dimethylthiazoles have been measured in the liquid phase.

The infrared absorption spectra of substituted thiazoles have been studied only to a limited extent. Randall, Fowler, Fuson, and Dangel (4) measured the infrared absorption of 4,5-dimethyl-2-mercapto- (I), 2-amino- (II), 2-mercapto-4-phenyl- (III), and 2-amino-4-(*p*-biphenyl)thiazole (IV) in the range of 3510 to 1200 cm^{-1} , and in each case attributed two bands of the spectrum to absorption by the thiazole ring:

compound I 1623 cm^{-1} (6.16 μ) and 1479 cm^{-1} (6.76 μ),
compound II 1626 cm^{-1} (6.16 μ) and 1515 cm^{-1} (6.60 μ),
compound III 1570 cm^{-1} (6.37 μ) and 1493 cm^{-1} (6.70 μ),
compound IV 1634 cm^{-1} (6.12 μ) and 1538 cm^{-1} (6.50 μ).

The infrared spectra of several *N*-acetyl derivatives of 2-amino-alkylthiazoles and the sulphonic acid of 2-amino-4-methylthiazole have been investigated by Bogomolov, Sheinker, and Postovskii (1).

We studied for the first time the infrared absorption spectra of thiazole (V) and the 2-methyl, 4-methyl, 5-methyl, 2,4-dimethyl, and 2,5-dimethyl derivatives (VI-X). These compounds were synthesized by known methods (2), purified by fractional dis-

tillation, dried over barium oxide, and redistilled immediately prior to use. The spectra, shown in Figs. 1-6, were measured on the liquid samples using a Perkin-Elmer double beam spectrophotometer (Model 21) with sodium chloride prism. The positions of the absorption maxima are listed in Table I. Different preparations of the same compound

showed broad absorption of varying intensity in the region between 3650 and 3300 cm^{-1} ; this was attributed to traces of residual moisture in the samples, and is indicated by dashed lines in the figures.

Comparison of spectra of thiazole and methylthiazoles with those of benzene and alkylbenzenes (3) show a general similarity, since both contain aromatic ring systems. The absorption bands of thiazole (V) and methylthiazoles (VI-X) can be classified as follows:

(a) *The Region 3110-3050 cm^{-1}*

Thiazole and five methylthiazoles, like aromatic hydrocarbons, exhibit C—H stretching vibrations in this region.

(b) *The Region 2980-2810 cm^{-1}*

These bands are given by symmetric and asymmetric vibrations of the methyl groups. Thiazole itself has no bands in this region.

(c) *The Region 2750-1755 cm^{-1}*

There are a few bands in the spectra of thiazole and 2-methylthiazole in this region. These bands are weak and could be studied to greater advantage at greater sample thickness. It is probable that bands in this region arise from overtone and combination tone vibrations.

(d) *The 1690-1480 cm^{-1} Region*

These bands may be assigned to skeletal vibrations of the thiazole ring. They have been found in spectra of four substituted thiazoles (I-IV) (4), and are similar to bands observed in the infrared spectra of aromatic hydrocarbons.

(e) *The Region 1445-1375 cm^{-1}*

Usually, bands at 1458 and 1376 cm^{-1} arise by antisymmetric and symmetric deformation vibrations of the methyl group C—CH₃. The absorption in this spectral region is

†vs = very strong; s = strong; ms = medium strong; m = medium; w = weak; vw = very weak.

shown not only by methylthiazoles, but by thiazole as well (strong band at 1385 cm.⁻¹). It must be concluded that bands at 1445 and 1435 cm.⁻¹ arise only by absorption of CH₃ groups, but that bands at 1375–1385 cm.⁻¹ are given by the thiazole skeleton in addition to the methyl groups.

(f) *The Region 1340–1175 cm.⁻¹*

Since the absorption bands of this region, with the exception of bands 1192–1175 cm.⁻¹, are present in the spectra of all thiazoles, they must be assigned to skeletal vibrations

of the thiazole ring. The bands at 1192–1175 cm^{-1} may be attributed to the skeletal $\text{CH}_3\text{—C}$ vibrations.

(g) *The 1160–930 cm^{-1} Region*

The bands of this region are characteristic thiazole ring vibrations.

(h) *The Low Frequency (900–640 cm^{-1}) Region*

The more prominent of these bands are probably associated with out-of-plane bending vibrations of the C—H groups of the thiazole ring. The number of absorption maxima varies from three (for VIII, IX, and X) to four (V) to five (VII) and six (VI). There is no correlation between the number of unsubstituted H atoms attached to the thiazole ring and number of bands.

ACKNOWLEDGMENT

Grateful acknowledgment is made to Mr. R. Lauzon for his help in taking the infrared spectra.

THE RATE CONSTANT OF THE REACTION BETWEEN FERROUS IONS AND HYDROGEN PEROXIDE IN ACID SOLUTION¹

T. J. HARDWICK

ABSTRACT

Identical values of the bimolecular rate constant of the ferrous ion-hydrogen peroxide reaction were obtained from intercomparisons of the methods previously used in following this reaction. In perchloric acid the bimolecular rate constant is unaffected by acid concentration; in sulphuric acid it increases slightly in acid concentrations above 10^{-2} N. The results agree with and explain the differences between those obtained by Baxendale and by Dainton, but are only in marginal agreement with those recently reported by Weiss.

INTRODUCTION

In acid solution ferrous ions react with hydrogen peroxide in a two step process:

All side reactions are eliminated if the equivalent concentration of hydrogen peroxide is less than that of ferrous ion and if the solutions are free from organic contaminants (1). Reaction [2] is rapid; reaction [1] is the rate-controlling step. Under these conditions the reaction is second order. The rate of disappearance of hydrogen peroxide is equal to one half the rate of ferric ion production:

$$[A] \quad -d[\text{H}_2\text{O}_2]/dt = \frac{1}{2}d[\text{Fe}^{+++}]/dt = k_0[\text{Fe}^{++}][\text{H}_2\text{O}_2].$$

In the integrated form this equation becomes

$$[B] \quad k_0 t = [2.303/(a-2b)] \log [2b(a-x)/\{a(2b-x)\}],$$

where

- a is the initial concentration of ferrous ion,
- b is the initial concentration of hydrogen peroxide,
- x is the concentration of ferric ion produced in time t ,
- k_0 is the bimolecular rate constant.

Experimental values of k_0 obtained in various investigations differ considerably, and some disagreement exists as to the value of the activation energy. A summary of published values is given in Table I; comments on these experiments are made below.

Haber and Weiss (5) used large volumes of solution (~ 2 liters) and quenched the reaction by the addition of acid permanganate. The extent of the reaction was calculated from the amount of permanganate reduced. At the reactant concentrations used ($[\text{Fe}^{++}] = 3 \times 10^{-3}$ M, $[\text{H}_2\text{O}_2] = 5 \times 10^{-4}$ M) the reaction time before quenching was usually about fourteen seconds, at which time about one half of the hydrogen peroxide had disappeared. Since complete mixing of volumes of this magnitude requires several seconds, it is likely that there is considerable error in estimating the reaction time.

Baxendale, Evans, and Park (2) followed the reaction by measuring the disappearance of ferrous ion. At a given time the reaction was quenched by the addition of a solution

containing acetate buffer, $\alpha\alpha'$ -dipyridyl, and fluoride ion. The ferrous ion was chelated by the $\alpha\alpha'$ -dipyridyl at pH 4-7, forming a stable complex whose color is suitably intense for colorimetric analysis, while the fluoride ion formed a complex with the ferric ion, inhibiting the slow reduction of ferric ion by hydrogen peroxide.

Barb *et al.* (1) repeated this work later (1951) using the same experimental technique, but covering a much wider range of acid and reactant concentrations. The value of the bimolecular rate constant at 20° C. was found to be about 20% lower in the later work. Baxendale explained this by remarking that the importance of the complete exclusion of organic materials was not fully appreciated in his early work. Since rigorous purification procedures were used in the 1951 experiments more confidence was put in the later value.

Dainton and Sutton (4) measured k_0 in 0.8 *N* sulphuric acid. They followed the reaction (a) by measuring the ferrous concentration after quenching with acetate buffer and *o*-phenanthroline (cf. $\alpha\alpha'$ -dipyridyl) and (b) by adding excess ceric ion which oxidized both ferrous ion and hydrogen peroxide. In the latter case, the amount of ferric ion produced may be calculated from the measured decrease in ceric ion concentration. Within experimental error the same value of k_0 was obtained by both methods. This value agrees with Baxendale's 1946 value.

Taylor and Weiss (8) and Rigg, Taylor, and Weiss (6, 7) carried out the reaction in a spectrophotometer cell, maintained at constant temperature, and measured directly the ferric ion produced. As these authors point out (6, 7, 8) this method of following the reaction should give the most reliable results. The results in reference (8) were later (6, 7) found to be in error. The value of k_0 found by Rigg, Taylor, and Weiss at 20° C. agrees with that found by Baxendale (2); however, the activation energy observed (8640 cal.) was somewhat lower than that reported by Baxendale (2).

Throughout these experiments it had been accepted that the type or concentration of acid (sulphuric or perchloric) has no effect on the value k_0 or the activation energy. There is in fact only limited experimental support for this view (2, 7). While no effect of acid concentration has been found in perchloric acid solutions (2), a systematic study of the effect of acid concentration has not been made in sulphuric acid solutions.

From the evidence presented in the above papers, there seems to be no reason why the various methods of following the reaction should give different values of the bimolecular rate constant. In an attempt to resolve these discrepancies, the reaction of ferrous ion with hydrogen peroxide in acid solution has been investigated along the following lines.

1. An intercomparison of the various methods of following the reaction has been made, using the same initial ferrous ion and hydrogen peroxide solutions.
2. Values of the bimolecular rate constant k_0 were measured as a function of temperature and acid concentration in both sulphuric acid and perchloric acid. The reaction was followed by the method considered most suitable from the results of the first series of experiments.

EXPERIMENTAL

Three methods of following the reaction have been investigated—quenching by chelation, quenching with ceric ion, and direct optical observation of the rate of ferric ion formation. These are described in detail below with suitable comment on the technique.

The reaction vessel, shown in Fig. 1, was carefully cleaned and dried. A 20 ml. volume of ferrous ion solution was pipetted into the smaller compartment, while 25 ml. of

FIG. 1. Mixing vessel.

hydrogen peroxide solution was pipetted into the other. The vessel was placed in a constant temperature water bath and allowed to come to temperature. The reactants were mixed by rapidly pouring the solution from one compartment to the other.

Methods of Following the Reaction

I. Quenching by Chelation

The quenching solution contained 3 *M* ammonium acetate, 0.2 *M* ammonium fluoride, and sufficient *o*-phenanthroline to chelate all the ferrous ion. Ammonia was present in sufficient amount to neutralize approximately the acid in the reacting solution.

To stop the reaction, 5 ml. of the quenching solution was added to the reacting solution from a plunger pipette. This method has the advantage that the resultant solution is suitably colored (ferrous *o*-phenanthroline complex) for colorimetric analysis.

The amount of ferrous ion present was determined by measuring the light absorption of the solution at 510 $m\mu$ in a Beckman Spectrophotometer. The extinction coefficient for the complex was determined in separate experiments and was found to be 11,250. Although this value is 1% higher than the accepted value of 11,110 (3), the same result was obtained repeatedly using different sources of two primary standards, viz., ferrous ammonium sulphate and potassium dichromate.

Normally optical measurements were made using 1 cm. cells, but where necessary, cells of longer path length were used. This was the case for reactions in 1 *N* perchloric acid, where it was found that the ferrous *o*-phenanthroline color faded on standing in strong perchlorate ion solutions. In this particular case, the 50 ml. of solution was diluted with water to 500 ml. (where the color was stable) and optical measurements were made with 10 cm. cells.

The initial ferrous ion concentration was measured against a blank consisting of the acid plus the buffer. For other solutions, a method of differential spectrophotometry was used. Here the quenched *reacting* solution was used as a "blank" and the "quenched" *initial* solution (ferrous ion plus 25 ml. of appropriate acid) used as the "unknown".

In this way a direct measure of the ferrous ion disappearance, i.e., ferric ion production, was made. The initial amount of hydrogen peroxide was measured by allowing the reaction to go to completion before "quenching". Its concentration is equal to one-half of the total ferrous ion disappearance. In all cases initial ferrous ion and hydrogen peroxide determinations were made in triplicate. Suitable arithmetical corrections were made to relate the measured concentration of ferrous ion to that in the reacting solution.

II. Quenching with Ceric Ion

The quenching solution was ceric ion in 1 *N* sulphuric acid. The ceric ion concentration was such that 1 ml. of solution gave a 5% stoichiometric excess of ceric ion over the initial ferrous ion plus hydrogen peroxide. After quenching, 20 ml. of the original ferrous ion was added to reduce the ceric ion and give an excess of ferrous ion. A 5 ml. volume of the buffer solution described in method I was added, and the concentration of ferrous *o*-phenanthroline complex measured spectrophotometrically as before. The difference between the ferrous ion concentration of the reacting solution and the initial solution after similar treatment for analysis was measured directly. Suitable arithmetical corrections were made for the dilution. The amount of ferric ion produced in this system is equal to one-half the difference in ferrous ion concentration. Initial concentrations of hydrogen peroxide and ferrous ion were determined by method I.

III. Direct Measurement of the Ferric Ion Concentration

(a) *In sulphuric acid.*—The temperature of a spectrophotometer cell compartment was controlled to $\pm 0.05^\circ\text{C}$. by circulating water. The reactant solutions were brought to this temperature, mixed, and poured into a 1 cm. optical cell. The absorption of light at $320\text{ m}\mu$ was measured at 30 second intervals for about five minutes. At this wavelength, light absorption is entirely due to ferric ion. The initial concentrations of hydrogen peroxide and ferrous ion were determined by method I. The extinction coefficient of ferric ion under the experimental conditions was found by allowing the reaction to go to completion (t_∞). This extinction coefficient is equal to the optical density at t_∞ divided by twice the initial hydrogen peroxide concentration.

(b) *In perchloric acid.*—The rate of ferric ion production in perchloric acid solutions was measured by a continuously recording ultraviolet spectrophotometer. No facility existed for thermostating solutions in the cell compartment, so several runs were made at the prevailing room temperature ($19\text{--}21^\circ\text{C}$.). The values of k_0 obtained were normalized to one temperature assuming $E = 9500\text{ cal}$.

Measurements were made at a wavelength of $235\text{ m}\mu$ where the light absorption is due to ferric ion only. Initial concentrations of hydrogen peroxide and ferrous ion were found by method I. The extinction coefficient of ferric ion was determined in the same manner as in method III-a.

Reagents

Perchloric acid: Merck Reagent perchloric acid was vacuum distilled at 100°C . The middle 60% was retained.

Sulphuric acid: Nichol's chemically pure sulphuric acid was used.

Hydrogen peroxide: Merck 30% Superoxol was suitably diluted with water or acid.

Ferrous ion solutions:

(a) in sulphate solutions: Reagent ferrous ammonium sulphate was dissolved in dilute sulphuric acid;

(b) in perchlorate solutions: Johnson, Matthey, Mallory spectrographically pure iron was dissolved in excess perchloric acid.

Water: All water, including that used for final rinsing of the apparatus, was distilled from alkaline permanganate.

Ceric ion solutions: Ceric ammonium sulphate was dissolved in 1 *N* sulphuric acid to give the desired ceric ion concentration.

o-Phenanthroline: G. Frederick Smith *o*-phenanthroline was dissolved in 95% ethanol and added to the quenching solution.

Ammonium acetate, ammonium fluoride, and ammonia were all reagent grade.

RESULTS

Comparison of the Methods

Preliminary experiments in sulphuric acid solution, using method III-*a*, confirmed that the reaction was first order with respect to both hydrogen peroxide and ferrous ion. For the remainder of the experiments the following initial concentrations were chosen: $[\text{Fe}^{++}] = 100\text{--}120 \mu\text{M./l.}$, $[\text{H}_2\text{O}_2] = 20\text{--}25 \mu\text{M./l.}$ With these initial concentrations the half-life of the reaction was about three minutes at room temperature.

In all cases a plot of $\log [2b(a-x)/\{a(2b-x)\}]$ vs. t gave a straight line passing through the origin. Usually six determinations were made for each such plot. The error in k_0 is estimated to be $\pm 2\%$, 1% for the determination of the slope of the second order plot, and 1% for the determination of the absolute value of $1/(a-2b)$.

Values of k_0 in 0.1 *N* perchloric acid and 0.8 *N* sulphuric acid were determined at 20.2° C. using all three methods of following the reaction. The same initial solutions were used for each acid medium ($[\text{Fe}^{++}] \cong 120 \mu\text{M./l.}$, $[\text{H}_2\text{O}_2] \cong 20 \mu\text{M./l.}$). The results are reported in Table II. There is no significant difference in the results obtained by the three methods.

TABLE II
VALUES OF k_0 DETERMINED BY THE THREE METHODS
 $T = 20.2^\circ \text{C.}$

	k_0 (l. mol. ⁻¹ sec. ⁻¹)	
	In 0.1 <i>N</i> HClO ₄	In 0.8 <i>N</i> H ₂ SO ₄
Method I	41.3	50.4
Method II	41.7	50.6
Method III- <i>a</i>		51.6
III- <i>b</i>	41.8, 40.7	

The choice of method of following the reaction will depend on the convenience of analysis and the accuracy required. Method I is generally the most convenient and accurate method provided the ferrous ion concentration is less than ten times that of hydrogen peroxide. Method II is capable of greatest sensitivity, and is recommended where the concentrations of both reactants are below $10^{-5} M$. Method III is in principle the most widely applicable, since ferric ion is the only light-absorbing material under the conditions used. However, the extinction coefficient of ferric ion varies with the type of acid and its concentration and temperature, and in practice must be determined in separate experiments.

The Effect of Variables on the Bimolecular Rate Constant k_0

In the experiments reported below, method I was used.

The value of k_0 was determined for a series of acid concentrations over a range of temperature (0–40° C.) in both sulphuric acid and perchloric acid solutions. Activation energies were calculated from the usual plot of $\log k_0$ vs. $1/T$. The values of E and of k_0 at 20° C. are recorded in Table III. Additional experiments showed that the presence of chloride ion in millimolar concentrations had no effect on either the rate or the activation energy.

FIG. 2. Plot of $\log k_0$ vs. $1/T$ for the ferrous ion - hydrogen peroxide reaction in perchloric acid.
○ Present experiments ● Baxendale (1951)

In agreement with the results of Baxendale (2), we find that in perchloric acid solutions the rate is independent of the acid concentration above 10^{-3} M acid. At lower acid concentrations side reactions are probably present (2), and this may account for the higher value of both E and k_0 in 5.3×10^{-4} M acid. (See Table III.)

Assuming this independence of acid concentration, mean values of k_0 in perchloric acid solutions were calculated at each temperature. Fig. 2 is a plot of $\log k_0$ vs. $1/T$ for these data, together with the data reported by Baxendale. The two sets of data are clearly in close agreement, and in perchloric acid solutions the rate equation is

$$k_0 = 5.3 \times 10^8 e^{-9450/RT} \text{ l. mol.}^{-1} \text{ sec.}^{-1}.$$

TABLE III
VALUES OF E AND k_0 (20° C.) IN VARIOUS ACID MEDIA

Acid concentration, equiv./l.	E , cal.	k_0 (20° C.), l. mol. ⁻¹ sec. ⁻¹
In sulphuric acid		
0.80	9750	51.4
0.10	9650	49.3
0.0105	9850	42.6
0.0014	9850	42.6
Mean 9750		
In perchloric acid		
1.00	9450	44.6
0.10	9450	41.5
0.011	9400	42.3
0.00167	9600	42.6
0.00053	10330	55.0

$$k_0 \text{ (in HClO}_4\text{)} = 5.3 \times 10^8 e^{-9450/RT}$$

FIG. 3. Plot of $\log k_0$ vs. $1/T$ for the ferrous ion - hydrogen peroxide reaction in 0.8 N sulphuric acid.
○ Present experiments ⊗ Baxendale (1946) ● Dainton and Sutton (1953)

In sulphuric acid solutions the activation energy appears to be independent of the sulphuric acid concentration. The value of k_0 (20° C.) increases with acid concentration, and this is interpreted as an increase in the temperature independent factor. At present, we can offer no explanation for this behavior.

At low acid concentrations at room temperature $k_0(\text{H}_2\text{SO}_4)$ is fortuitously equal to $k_0(\text{HClO}_4)$, and this observation led Baxendale to assume the rate to be independent of the acid medium, and hence independent of sulphuric acid concentration. Fig. 3 shows a plot of $\log k_0$ vs. $1/T$ for 0.8 *N* sulphuric acid. We have included on this graph data from Dainton and Sutton (4) and also from Baxendale, Evans, and Park (2). Although the latter group used 1 *N* sulphuric acid as the medium, little change in k_0 is expected between 0.8 and 1.0 *N* sulphuric acid.

An examination of Fig. 3 shows that the results of previous workers and the present work are in reasonable agreement. Although previously obtained data lie below the straight line, this discrepancy is probably due to differences in analytical calibrations. This difference will not affect the slope of the line. Baxendale's results of 1946 are not anomalous, but are in agreement with values obtained in the same concentration of sulphuric acid. In 0.8 *N* sulphuric acid the rate expression is

$$k_0 = 9.6 \times 10^8 e^{-9750/RT} \text{ l. mol.}^{-1} \text{ sec.}^{-1}.$$

The rate expression in 0.5–0.8 *N* sulphuric acid reported by Weiss (6, 7) is $\bar{k}_0^* = 1.05 \times 10^8 e^{-8460/RT} \text{ l. mol.}^{-1} \text{ sec.}^{-1}$. In the temperature range 15–25° C. the values of k_0 calculated from Weiss' rate expression agree within $\pm 4\%$ of the present work; at 40° C. there is a difference of 14%. These values result in differences in both the activation energy and the temperature independent factor.

THE KINETICS OF THE OXIDATION OF FERROUS ION BY HYDROGEN PEROXIDE IN THE PRESENCE OF DISSOLVED HYDROGEN AND CARBON MONOXIDE¹

T. J. HARDWICK

ABSTRACT

An expression has been derived for the rate of ferric ion production in the ferrous ion - hydrogen peroxide reaction in aqueous solution containing dissolved hydrogen and oxygen. It involves the relative value of the rate constants for the intermediate reactions

The effects of side reactions involving the intermediate hydroperoxyl radical are considered. The rate calculated from the derived expression agrees with that measured experimentally ($\pm 2\%$). When carbon monoxide is used instead of hydrogen, the kinetic scheme and rate expression are the same. The agreement between experimental and calculated rates is within $\pm 2\%$.

INTRODUCTION

It has been known for some time that the amount of ferric ion produced in the ferrous ion-hydrogen peroxide reaction in air-saturated solution (Fenton reaction) is increased by the presence of dissolved organic materials (4). Dainton and Hardwick (2) have studied such systems in detail and were able to explain their results quantitatively on the basis of competition for hydroxyl radicals between the organic substrate and ferrous ion.

A parallel but simpler case also studied by Dainton and Hardwick is that of the Fenton reaction in the presence of dissolved hydrogen gas. In this system the reactions are as follows:

In one reaction cycle the disappearance of one hydrogen peroxide molecule by reaction [0] produces two ferric ions and regenerates a smaller amount of hydrogen peroxide. The hydrogen peroxide thus formed will of course react in the same manner as that originally present. The final result is an increase in the total amount of ferric ion produced.

By measuring the *total* ferric ion produced with and without added hydrogen, Dainton and Hardwick (2) determined the value of the ratio f_1/f_2 , where f_1 and f_2 are the fractions of hydroxyl radicals reacting with hydrogen and ferrous ion respectively. Since

$$[A] \quad f_1/f_2 = k_1[\text{H}_2]/(k_2[\text{Fe}^{++}]),$$

the relative value of the rate constants (k_1/k_2) may be found.

It follows from the results in this last paper that the *rate* of ferric ion production should be increased in the presence of dissolved hydrogen since the net rate of hydrogen

¹Manuscript received December 3, 1956.

Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 425.

peroxide disappearance is smaller. It is the purpose of the present paper to derive a mathematical expression for the increase in reaction rate, and to compare such derived values with experimental results.

In the simple bimolecular reaction between ferrous ion and hydrogen peroxide, the rate of ferric ion production is

$$[B] \quad dx/dt = 2k_0(F-x)(P-\frac{1}{2}x),$$

where x is the concentration of ferric ion at time t ,

F is the initial concentration of ferrous ion,

P is the initial concentration of hydrogen peroxide,

k_0 is the bimolecular rate constant.

Values of k_0 have been determined for a variety of conditions (4).

In the presence of dissolved hydrogen, when one molecule of hydrogen peroxide disappears by reaction [0] two ferric ions will be produced: one by reaction [0], and the second either by reaction [2] or by the reaction sequence [1], [e], [3]. At the same time f_1 hydrogen peroxide molecules will be regenerated. The net number of hydrogen peroxide molecules disappearing for each ferric ion formed will be $\frac{1}{2}(1-f_1) = \frac{1}{2}f_2$.

The rate expression then becomes

$$[C] \quad dx/dt = k_0(F-x)(2P-f_2x).$$

Since

$$[D] \quad f_2 = [\text{Fe}^{++}] / \{ (k_1/k_2)[\text{H}_2] + [\text{Fe}^{++}] \} = (F-x) / \{ (k_1/k_2)[\text{H}_2] + F-x \},$$

we write the rate expression as

$$[E] \quad dx/dt = k_0(F-x) \{ 2P - (F-x)x / (C+F-x) \},$$

where $C = (k_1/k_2)[\text{H}_2]$. C will be a constant for any set of initial conditions.

Solution of Equation

In integrating equation [E],

$$[F] \quad k_0 \int dt = \int \frac{C+F-x}{(F-x)[2P(C+F) - (F+2P)x + x^2]} dx,$$

the integral on the right-hand side may be written

$$[G] \quad \int \left[\frac{M}{F-x} + \frac{N+Rx}{A+Bx+x^2} \right] dx,$$

where $A = 2P(C+F)$,

$B = -(F+2P)$,

M, N, R are terms to be evaluated.

Multiplying out the numerator of equation [G] and equating this to $C+F-x$, we find on equating coefficients and solving

$$M = R = 1/2P, \quad N = 0;$$

thus we have

$$[H] \quad k_0 \int dt = \frac{1}{2P} \left[\int \frac{dx}{(F-x)} + \int \frac{x dx}{A+Bx+x^2} \right],$$

$$[J] \quad k_0 t = \frac{1}{2P} \left[2.303 \log \frac{F}{F-x} - \frac{2.303}{2} \log \frac{A}{A+Bx+x^2} - \frac{B}{\sqrt{q}} \left\{ \tan^{-1} \frac{B+2x}{\sqrt{q}} - \tan^{-1} \frac{B}{\sqrt{q}} \right\} \right],$$

where $q = 8PC - (F - 2P)^2$.^{*} The expression in square brackets will be defined as $\phi(x)$. If the kinetic scheme is correct, a plot of $\phi(x)$ versus time will give a straight line passing through the origin, the slope of which is equal to $2Pk_0$. Experimentally, we shall measure the amount of ferric ion produced after various periods of reaction. The calculated value of $\phi(x)$ for each measurement will be plotted as a function of time and compared with the theoretical straight line $\phi(x) = 2Pk_0 t$.

Values of k_1/k_2 were determined using the method outlined in the previous paper (2). From other work, k_0 at 20.2° C. in 0.1 *N* perchloric acid was taken as 41.5 l. mol.⁻¹ sec.⁻¹ (4). Initial concentrations of ferrous ion, hydrogen peroxide, and hydrogen were known.

Carbon monoxide also reacts with hydroxyl radical in aqueous solution:

When the Fenton reaction is carried out in the presence of dissolved carbon monoxide, the sequence of reactions occurring will be identical with those when hydrogen is present with the exception that reaction [1] is replaced by reaction [1a]. It follows that the kinetics of the two systems will be identical.

Rate experiments with dissolved carbon monoxide were carried out. Since the value of k_{1a}/k_2 (CO) is about 30 times larger than k_1/k_2 (H₂) at room temperature the use of carbon monoxide in place of hydrogen permits a more rigorous test of the kinetic scheme. There will be more peroxide cycles in the carbon monoxide experiments; consequently the magnitude of deviations between experimental and calculated values due to incorrect values of k_1/k_2 , or to side reactions not considered in the kinetic scheme, will be increased.

EXPERIMENTAL

Perchloric acid: Merck Reagent perchloric acid was vacuum distilled at 100° C. The middle 60% was retained.

Ferrous ion: Spectrographically pure iron was dissolved in dilute perchloric acid.

Hydrogen peroxide: Merck 30% Superoxol was suitably diluted.

Water: Distilled water was redistilled from alkaline permanganate. This was also used for the final rinsings of all glassware.

***o*-Phenanthroline:** G. Frederick Smith *o*-phenanthroline was dissolved in 95% ethanol.

Ammonium acetate and ammonium fluoride were reagent grade.

Determination of k_1/k_2

The reaction vessel is shown in Fig. 1. A 20 ml. volume of ferrous ion solution (500 μM./l.) was pipetted into one chamber, while 25 ml. of hydrogen peroxide solution (20 μM./l.) was pipetted into the other. The atmosphere above the solution was removed (water pump) and replaced by a known synthetic mixture of hydrogen plus air to a

^{*}If q is negative the last term becomes

$$\frac{B}{\sqrt{-q}} \left\{ \tanh^{-1} \frac{B+2x}{\sqrt{-q}} - \tanh^{-1} \frac{B}{\sqrt{-q}} \right\}.$$

FIG. 1. Reaction vessel.

pressure of about 780 mm. The vessel was placed in a constant temperature bath for 10 minutes. At the end of this period it was shaken vigorously to equilibrate the gas and liquid. The gas was momentarily vented to the atmosphere and the vessel shaken again. Reaction was started by tipping the vessel in such a manner that both solutions mixed rapidly in the connecting chamber. The cell was then replaced in the bath and the reaction allowed to go to completion (about 1 hour). At the end of this time, 5 ml. of 3 *N* sulphuric acid was added to the solution, and the light absorption of the solution was measured at 310 $m\mu$ in a Beckman Spectrophotometer, using 10 cm. cells. At this wavelength light is absorbed by ferric ion only.

A set of experiments was carried out similar in all respects to those described above except that the solutions were air saturated. In both cases suitable blanks were made to determine the ferric ion present in the initial solutions. In all cases experiments were carried out in quadruplicate.

For the determination of k_1/k_2 one requires only a ratio of the amount of ferric ion produced with and without hydrogen (2). This quantity may be determined from the ratio of the optical densities of the two solutions; an accurate knowledge of the extinction coefficient is unnecessary. Experimentally, at 20.2° C. in 0.1 *N* perchloric acid the value of k_1/k_2 was found to be 0.116.

Determination of k_{1a}/k_2 (CO)

The procedure for the determination of k_1/k_2 was repeated, using a suitable mixture of carbon monoxide and air for equilibration instead of hydrogen plus air. At 20.2° C. in 0.1 *N* perchloric acid the value of k_{1a}/k_2 was found to be 3.79.

The solubilities of hydrogen and carbon monoxide in 0.1 *N* perchloric acid have been taken equal to that in water at the same temperature. Any errors in the values of k_1/k_2

and k_{1a}/k_2 resulting from this approximation will be cancelled when these values are inserted in the rate expression.

Kinetic Experiments

The method of preparing the solutions, equilibrating with the selected gas mixture, and initiating reaction was identical with that used in the determination of k_1/k_2 . The initial concentrations of the ferrous ion and hydrogen peroxide solutions were 132 and 22 $\mu\text{M./l.}$, respectively.

The method of following the reaction has been described in detail previously (method I, Ref. 3). Briefly, the reaction was quenched by the addition of a chelating agent for ferrous ion. The concentration of ferric ion produced was determined from the measured decrease in the ferrous ion concentration.

Rate experiments were carried out using both hydrogen and carbon monoxide as dissolved gases. The conditions are shown in Table I.

RESULTS AND DISCUSSION

Effect of the Reduction of Ferric Ion

Since ferric ion is produced in this system, the reaction

will take place. As a result, (a) the measured amount of ferric ion will be less than twice the amount of hydrogen peroxide which has disappeared by reaction [0] and (b) less hydrogen peroxide will have been regenerated via reaction [3]. It is therefore necessary to determine the extent to which reaction [4] has occurred during the over-all reaction.

In the first case the extent of the ferric ion reduction must be calculated and a correction made to the measured ferric ion production. In our experiments such corrections were usually about 3% and never exceeded 7% of the ferric ion concentration. In the second case such a small correction to the hydrogen peroxide concentration will affect the rate of ferric ion production only slightly and deviations from the calculated values should occur only in the later stages of the reaction.

Correction for Ferric Ion Reduction by Reaction [4]

Reaction [4] is of course in competition with reaction [3], and the relative extent of each reaction will change as the ferrous ion/ferric ion ratio changes. Previous workers

have found that the ratio of the rate constants of reactions [3] and [4], k_3/k_4 , is somewhat dependent on acid concentration (1). From their data it is estimated that the value of k_3/k_4 at 20° C. is 14 in 0.1 *N* acid and 40 in 0.3 *N* acid.

The amount of ferric reduction which occurs during a run may be calculated as follows: We shall define f_3/f_4 as the fraction of HO_2 radicals reacting with ferrous ions (reaction 3) divided by that fraction reacting with ferric ions (reaction 4). It follows that

$$[K] \quad \frac{f_3}{f_4} = \frac{k_3 [\text{Fe}^{++}]}{k_4 [\text{Fe}^{+++}]}$$

As the ratio of ferrous ion to ferric ion changes during the reaction, so will the value of f_3/f_4 . We require to know the mean value of f_3/f_4 for each experiment as the ferric ion concentration increases from 0 to x .

Mean values of the ratio f_3/f_4 were calculated from equation [K] for successive small ($5 \mu\text{M./l.}$) intervals of ferric ion concentration, using the average concentrations of ferrous and ferric ions within each interval. These values were plotted against the ratio ferric ion/ferrous ion. For any concentration of ferric ion x , the area under the curve is the fraction of the total ferric ion which has been reduced. The corrected ferric ion concentration will be $x/(1 - \text{area})$. Values of the measured ferric ion concentration thus corrected for ferric ion reduction have been used in the calculation of $\phi(x)$.

Effect of Increase in Regenerated Hydrogen Peroxide on the Rate of Ferric Ion Production

In principle it is possible to include such a correction in the rate equation [B]. Since this would complicate the integration considerably we have limited ourselves to indicating that the measured amount of ferric ion would be slightly less than the calculated value in the later stages of reaction. An examination of Figs. 2 and 3 (particularly 2a,

FIG. 2. Ferric ion production in the presence of dissolved hydrogen. For initial conditions, see Table I.

2b, 3a, and 3b, where such effects are largest) shows that a small deviation in the expected direction does indeed occur.

Comparison of Calculated and Measured Values of $\phi(x)$

Figs. 2 and 3 show plots of $\phi(x)$ versus time. The value of $\phi(x)$ was calculated from the measured amount of ferric ion which had been corrected for ferric ion reduction by reaction [4]. These values are represented by circles. The straight line is drawn

FIG. 3. Ferric ion production in the presence of dissolved carbon monoxide. For initial conditions, see Table I.

through the origin with a slope equal to $2Pk_0$. The conditions for each set of experiments are listed in Table I. In all cases 300 seconds represents about 75% of the total reaction.

The agreement between calculated and experimental values is better than $\pm 2\%$. This agreement is unaffected by variations in the ferric ion concentration (runs 3 and 5, Table I), in the reacting gas concentration (runs 1 and 2, 3 and 4), and in the acid concentration (runs 3 and 6) although each of these variables changes the rate of ferric ion production.

The results of this paper show that the relative values of the rate constants k_1 and k_2 may be justifiably applied to kinetic systems involving hydroxyl radical reactions in acid solutions. In addition, one can correct for complications due to the side reactions involving HO_2 radicals, using values of rate constants reported in the literature.

A NOTE ON UREIDO DERIVATIVES ISOLATED AS BY-PRODUCTS IN AMINO ACID SYNTHESIS¹

P. D. BURLAND² AND J. D. CHRISTIAN³

ABSTRACT

Approximately 10–20% yields of alpha-ureidopropionamide and alpha-ureidoisovaleramide were obtained as major by-products in the synthesis of 5-methylhydantoin and 5-isopropylhydantoin, respectively, by the Gaudry (3) technique. The two compounds can be hydrolyzed to their corresponding amino acids, DL-alanine and DL-valine, in alkaline solution or recycled to their corresponding hydantoins with mineral acid.

INTRODUCTION

In an attempt to improve the yields and to establish the generality of the Gaudry (3) amino acid synthesis, two homologous compounds were isolated, only one of which has been previously reported in the literature (2).

The reaction between acetaldehyde cyanohydrin and a water solution of ammonium carbonate at 55° C. in addition to the major product 5-methylhydantoin (I) produces 10–20% yields of alpha-ureidopropionamide (II). Similarly, isobutyraldehyde cyanohydrin and ammonium carbonate produce about the same yields of alpha-ureidoisovaleramide (IV). Both ureido derivatives presumably are formed as partial ammonolysis products of their corresponding hydantoins. Alpha-ureidoisovaleramide has previously been unreported in the literature.

Although the alternative mechanism involving an ammonium carbamate equilibrium must also be considered (Eqs. 3 and 4), the ammonolysis mechanism (Eqs. 1 and 2) seems to be the more logical course for the side reaction.

¹Manuscript received December 19, 1956.

Contribution from the Monsanto Chemical Company, Texas City, Texas.

²Present address: Development Department, Lion Oil Division, Monsanto Chemical Company, Luling, Louisiana.

³Present address: Research Department, Grace Chemical Company, Memphis, Tennessee.

This ammonolysis seems to occur during the time the reaction mixtures of corresponding cyanohydrin and $(\text{NH}_4)_2\text{CO}_3$ are being boiled to decompose excess $(\text{NH}_4)_2\text{CO}_3$ and to concentrate the hydantoin prior to crystallization. Alpha-ureidopropionamide first isolated melted at 192°C^* and after three crystallizations from water melted at $199\text{--}200^\circ\text{C}$. The compound was isolated from the third (last) crystallization of 5-methylhydantoin mother liquor resulting from the original reaction. The material was characterized according to the method of Franchimont and Klobbie (2) by cyclization to 5-methylhydantoin in 10% HCl. Dakin (1) also cyclized hydantoic acid to hydantoin in a similar manner. A portion of the ureidoamide was hydrolyzed to DL-alanine with $\text{Ba}(\text{OH})_2$.

Franchimont and Klobbie (2) in 1888 reported the isolation of (II) from a reaction mixture of acetaldehyde, NH_3 , KCN, KCNO, and H_2SO_4 . An uncorrected melting point of 196°C . is reported. Since that time, only references to hydantoic acids appear in the literature and no mention is made of the corresponding amides.

Alpha-ureidoisovaleramide (IV), m.p. 240°C . (decomp.), was isolated in the same manner as its previously described homologue from the mother liquor of the original reaction. It was cyclized to 5-isopropylhydantoin in the manner outlined above. A portion of the ureidoamide was also hydrolyzed with $\text{Ca}(\text{OH})_2$ to DL-valine.

Although alpha-ureidoisovaleramide is more soluble in water than 5-isopropylhydantoin, recrystallization from aqueous solution is not too effective for purification. The solubility relationship of these two compounds, however, is reversed in methanol, presenting a convenient method for purifying fractions of the ureidoamide contaminated with hydantoin.

Infrared spectra of the two ureidoamides and their corresponding hydantoins are shown in Fig. 1. They were prepared by the KBr disk technique (4, 5).

The yields of DL-alanine and valine, by a minor variation of the method of Gaudry (3), produced 90% over-all yields of both amino acids. In either instance, this was accomplished by proceeding directly from the aldehyde to the amino acid without isolation of the intermediates.

EXPERIMENTAL

Acetaldehyde Cyanohydrin (Lactonitrile)

Liquid HCN (1 mole, 27.0 g.) was introduced into a flask maintained at ice bath temperature ($0\text{--}10^\circ\text{C}$.) followed by 2 ml. of 10% NaOH added as catalyst. Acetaldehyde (1 mole, 44.0 g.) was then added dropwise to the mixture with stirring over a period of 30 minutes. The bath was maintained at $0\text{--}10^\circ\text{C}$. during the addition and then removed. With continued stirring the temperature was allowed to rise to 25°C . and maintained for 1 hour. At the end of this period, the reaction was complete (6).

5-Methylhydantoin (I), Alpha-ureidopropionamide (II)

Lactonitrile (1 mole, 71.0 g.) was added to a solution of ammonium carbonate (2 moles, 192.0 g.) in water (400 ml.) and stirred at 55°C . for 1 hour in a water bath. The temperature of the bath was then raised rapidly to the boiling point to decompose the excess ammonium carbonate. The boiling was continued until the volume was reduced

*Melting points are all corrected unless otherwise indicated.

FIG. 1. Infrared spectra of hydantoin, 5-methylhydantoin, 5-isopropylhydantoin, α -ureidopropionamide, and α -ureidoisovaleramide.

to about 250 ml. The solution was then cooled; 5-methylhydantoin (I) crystallized and was filtered. The filtrate was evaporated again to a small volume and a second crop of crystals was obtained. Total, 93.1 g. (82% yield). The third crystallization (18.3 g., 14% yield based on hydantoin) containing the crude ureidoamide melted at 191–193° C., which, after two crystallizations from water, melted at 199–200° C. Found for $C_4H_9N_3O_2$ (Kjeldahl): N, 31.64%. Calc. for $C_4H_9N_3O_2$: N, 32.04%.

Two grams of the pure alpha-ureidopropionamide were dissolved in 100 ml. of concentrated HCl and the mixture refluxed for 2 hours. The mixture was cooled, evaporated to a small volume, and crystallized (m.p. 144–145° C.). After two recrystallizations from water the resultant compound melted at 145° C. Literature m.p. for 5-methylhydantoin 145° C. (7), 150° C. (3) (uncorrected).

DL-Alanine from Alpha-ureidopropionamide (II)

The remaining crude alpha-ureidopropionamide (16.3 g., 0.1 mole) was dissolved in 600 g. of water and slurried with $Ba(OH)_2 \cdot 8H_2O$ (103 g., 0.33 mole). This mixture was placed in a steel pressure bomb, heated at 150–160° C. with continuous agitation for 4–5 hours, and then cooled. The mixture was removed from the bomb and evaporated to about 500 ml. About 50 g. of $(NH_4)_2CO_3$ were added to the cooled mixture to remove excess $Ba(OH)_2$. $BaCO_3$ was filtered off and the solution evaporated until alanine began to crystallize on the surface of the solution. Two volumes of methanol were added to the warm mixture and then cooled to ice bath temperature. Alanine was filtered off, washed with cold methanol, dried, and weighed. Total alanine recovery 8.4 g., m.p. 295° C. (decomp.).

Isobutyraldehyde Cyanohydrin

This material was prepared in the same manner as lactonitrile with the exception of the catalyst. One milliliter of concentrated ammonia was added per mole of cyanohydrin formed instead of 2 ml. of 10% NaOH. This technique resulted in a cyanohydrin which was neither discolored by HCN polymer during the course of the reaction nor during storage for several weeks.

5-Isopropylhydantoin (III), Alpha-ureidoisovaleramide (IV)

Two moles of a 28% water solution of NH_4OH (34 g. as NH_3) were added to a round-bottom flask equipped with stirrer, thermometer, gas-inlet tube, and a 0–10° C. ice bath. With continued stirring, carbon dioxide (44.8 liters, 2 moles) was passed into the solution of NH_3 while the temperature was being maintained at 0–10° C. The gas inlet tube was then removed and 1 mole (99 g.) of previously prepared isobutyraldehyde cyanohydrin was added to the flask slowly, the temperature being allowed to rise to 55° C. The 1-mole addition took place over a 15-minute period. The reaction mixture was allowed to stir for another 45 minutes at 55° and then raised to boiling to decompose unreacted $(NH_4)_2CO_3$. Alternate evaporation and crystallization yielded the crops of product shown in Table I.

Subsequent treatment of fractions 4–6 and the residue with 10% HCl yielded 6.0 g. of pure (III) resulting in 98% corrected yield of (III), m.p. 147.5–148.5° C. (corrected).

The high-melting fractions from a repeat run of the above synthesis were combined and recrystallized 8 to 10 times from methanol to isolate pure (IV). The resulting material, m.p. 240° C. (corrected), analyzed as follows: C = 45.16%, H = 8.71%, N = 26.33%. Calculated for (IV) $C_6H_{13}N_3O_2$: C = 45.25%, H = 8.23%, N = 26.41%.

TABLE I

Crystallization	Weight, g.	M.p. (uncorrected), ° C.
1	82.1	147-148
2	35.5	147-149
3	19.2	147-149
4	3.6	145-160
5	2.2	145-160
6	1.7	160-185
Dry residue	2.0	—
Total	143.3	
Per cent of theory = 101		

A 1 g. sample of pure (IV) was heated in 15 ml. of 10% aqueous HCl and dissolved. The solution was refluxed for about one hour and allowed to cool. The crystals which deposited on cooling melted at 146-147° C. The melting point was not depressed by a 1:1 mixing of an authentic specimen of (III) with the material in question.

DL-Valine from Alpha-ureidoisovaleramide (IV)

Alpha-ureidoisovaleramide (IV) (10.59 g., 0.0667 mole) was charged to a 2 liter pressure autoclave along with 600 ml. of H₂O and 9.9 g. (0.1334 mole) of Ca(OH)₂. The mixture was heated at 155° C. for 4 hours with continuous stirring and then allowed to cool. Insoluble Ca(OH)₂ was filtered off and dissolved calcium precipitated with excess (NH₄)₂CO₃. After a second filtration, the filtrate was evaporated to about 50 ml. and cooled in an ice bath. Cold methanol (100 ml.) was then added to the solution and the mixture allowed to crystallize at 0-5° C. for 1 hour.

A 7.0 g. yield of crystals was obtained on one crystallization. The residue when evaporated to dryness contained about 1.0 g. of crude product. The theoretical yield of DL-valine from 10.59 g. of (IV) is 7.8 g. Nitrogen analysis found: 11.94%. Calculated for C₅H₁₁NO₂: 11.96%.

ARSENIDES OF TRANSITION METALS: THE ARSENIDES OF IRON AND COBALT¹

R. D. HEYDING AND L. D. CALVERT

ABSTRACT

Alloys of cobalt and arsenic containing up to 60% As by weight have been studied by means of room temperature and high temperature Debye-Scherrer diagrams. Two compounds exist at room temperature, Co_2As and CoAs , both of which undergo crystallographic transformations at higher temperatures, the former between 400° C. and 500° C., the latter at about 950° C. A third compound, probably Co_3As_2 , is formed by the reaction of Co_2As with CoAs above 940° C. The structures of these compounds are compared with the structures of the corresponding compounds in the iron/arsenic system. These results indicate the necessity of slight revisions to the Co/As diagram, and raise serious questions in respect of the validity of decomposition pressure data reported recently for cobalt arsenides.

As part of a program designed to investigate the chemistry of cobalt speiss, we have undertaken studies of the Debye-Scherrer diagrams of the alloys of iron, cobalt, and nickel containing up to 60% arsenic by weight. The interpretations of the powder diagrams for the iron/arsenic and cobalt/arsenic systems are discussed here, and the nickel/arsenic system will be reported in a later paper.

The constitution of the Fe/As phase diagram in the 0-56% As region is well understood. Friedrich's diagram (3), modified by Hägg (6, 7), shows the presence of two compounds, Fe_2As and FeAs , at room temperature, and a third, Fe_3As_2 , which is stable only above 795° C. Fe_2As crystallizes in an end-centered tetragonal lattice (2), while FeAs forms an orthorhombic cell in which the atoms are only slightly displaced from the positions of nickel and arsenic in hexagonal NiAs (5, 7). No structure has been assigned to Fe_3As_2 .

The corresponding region in the Co/As system has not been subjected to a similar comprehensive crystallographic investigation. Of the four compounds recorded in the phase diagram (4), Co_5As_2 , Co_2As , Co_3As_2 , and CoAs , only the last has been studied by Debye-Scherrer techniques (5), and Fylking's conclusion that it is isostructural with FeAs rather than NiAs has been questioned in view of the poor resolution of the powder diagram at high orders (16).

Kochnev has employed the Knudsen effusion principle to measure the arsenic vapor density over cobalt alloys of composition corresponding to these four compounds (10, 11). These data were subsequently expanded to yield values for the thermodynamic functions associated with the thermal dissociation of these compounds (12, 13).

The unique feature of Kochnev's results was the appearance of "anomalous breaks" in the curves obtained by plotting the dissociation pressures against the temperature. These discontinuities, in the form of either a sharp maximum or a sharp minimum, or both, were found to occur at temperatures in the region of the "ignition temperature" of the alloys, and were interpreted as being the result of polymorphic transitions in the compounds. If this conclusion is correct, two transitions should be observed in the powder diagrams of CoAs in the 780°-890° C. region, three in Co_3As_2 , four in Co_2As , and three in Co_5As_2 . These transitions are not shown on Friedrich's phase diagram.

It should be emphasized that during the thermal analysis of this system Friedrich observed a great tendency of the alloys to supercool, and interpretation was correspondingly uncertain. Hansen has criticized Friedrich's analysis in this respect (8). There is a further indication of the type of error which might be expected in the Co/As phase diagram, in that in the Fe/As system, the compound Fe_3As_2 , which according to thermal analysis was expected to exist at room temperature, was found by X-ray analysis to decompose below 795°C . In view of the marked similarity of the phosphides of iron and cobalt, and the apparent isomorphism of FeAs and CoAs, it is difficult to appreciate why four arsenides should form in the cobalt system as compared to two in the iron system, and why so many modifications of these four compounds should exist while apparently none were observed among the iron arsenides.

EXPERIMENTAL

Iron and cobalt sponges, the former containing less than 1 p.p.m. impurities, mainly as nickel, and the latter 0.8 p.p.m., mainly as iron, were obtained from Johnson Matthey & Co. Similar high purity nickel was used to make the nickel arsenides used in substitutional solid solution studies. Each of these metal powders was soaked in hydrogen for 2 to 3 hours at $670\text{--}700^\circ\text{C}$., immediately prior to mixing the components, to reduce the surface oxide.

Commercial "Pure" metallic arsenic was purified by double vacuum sublimation, eliminating all heavy metals and reducing the antimony content to less than 50 p.p.m. The crystals were ground in air and stored *in vacuo*.

To prepare the alloys, arsenic and the appropriate metal powder were weighed into pyrex tubes, which were evacuated, sealed, and heated at $500\text{--}550^\circ\text{C}$. for 48 hours.² The products were removed, reground, and melted in either of two ways depending on the size of the sample. Larger quantities (10–15 g.) were melted by induction and chill cast under argon in the furnace described by Craw and Henry (1). This method relied on rapid melting and chilling to minimize the loss of arsenic as vapor and the subsequent alteration in the composition of the alloy. The results were satisfactory for cobalt-rich alloys; at higher arsenic concentrations, however, the decomposition pressures at the melting point are appreciable and significant losses were incurred.

To prepare alloys within narrow concentration limits, smaller samples (2–3 g.) were sealed in small silica ampoules under vacuum, and melted by slowly lowering the ampoule through the narrow hot zone in a small vertical Gobar resistance furnace. Conditions were then such that when the alloys were moved out of the hot zone they solidified while the temperature gradient prevented the condensation of arsenic on the walls about the void space. Analysis showed that alloys prepared in this manner were within 0.03 weight per cent units of the original mixture.

Alloys were annealed in evacuated pyrex or quartz ampoules in the usual manner. To quench samples from the melt, the ampoule was suspended by a fine quartz fiber from a brass weight slightly smaller in diameter than the central tube of the vertical resistance furnace. With the whole system filled with argon, the ampoule containing the molten alloy and the weight were allowed to fall freely into a brass receiver containing water at 0°C . In all instances the ampoule was shattered before solidification of the alloy could occur.

²At this point the majority of alloys showed evidence of fusion indicating a rather high negative enthalpy of formation. If the products were ground and reheated *in vacuo* at 700°C . for a similar period, the reactions were found to be essentially complete, but the powder diagrams lacked definition at high orders.

Room temperature powder diagrams were taken in 11.46 cm. Norelco cameras with CoK_α radiation. Patterns at higher temperatures were obtained in a 19 cm. Unicam high temperature camera. Since the silica specimen tubes used in this camera were attacked, particularly by those alloys rich in cobalt, it was necessary to minimize as far as possible the time required to obtain a series of powder diagrams of any given alloy. To this end we chose to use CuK_α radiation in spite of the loss in clarity on the film due to fluorescence. In general, camera and specimen were allowed to equilibrate for 8 hours at each temperature and 12–14 hour exposures were made overnight.

RESULTS AND DISCUSSION

Our conclusions with respect to the compounds existing in the Fe/As system at room temperature are in complete agreement with the results of Hägg (2, 7) and Fylking (5). In view of Hägg's thorough study, we did not attempt any comprehensive investigation at higher temperatures.

There is considerable similarity between this system and the Co/As system, and it is convenient to discuss them simultaneously in terms of the compounds formed.

The $M_5\text{As}_2$ Compounds

No compound exists in the Fe/As system.

Powder diagrams of cobalt alloys containing 22 to 35% As by weight show the presence of two phases, the α solid solution of As in Co, and the compound Co_2As , regardless of the heat treatment of the samples. This is not conclusive evidence that Co_5As_2 does not exist, since a fast peritectic or peritectoid decomposition at high temperature might not have been quenched by our techniques. Investigations of alloys with the composition of this compound in the high temperature camera were only partly successful owing to attack of the silica specimen capillaries at temperatures above 700°C . Nevertheless in the few photographs which were obtained up to 800°C ., there is no indication that a new phase is formed. Therefore, if the compound Co_5As_2 exists, it is stable only at high temperature and at some temperature above 800°C . must decompose to Co_2As and the solid solution of As in Co.

The $M_2\text{As}$ Compounds

Fe_2As is end-centered tetragonal, space group $P4/nmm$, (D_{4h}^{7h}), with unit cell dimensions $a = 3.627 \text{ \AA}$ and $c = 5.981 \text{ \AA}$, in good agreement with Hägg's values of $3.627 \text{ \AA}$ and $5.973 \text{ \AA}$. The interplanar spacings, indices, and observed intensities of the powder diagram are recorded in Table I.

The corresponding cobalt compound at room temperature is not isostructural with Fe_2As , nor does it exhibit the hexagonal Fe_2P or the orthorhombic Co_2P structure. Between 400° and 500°C . the room temperature modification, $\alpha\text{Co}_2\text{As}$, undergoes a slow transition to a second crystal form, $\beta\text{Co}_2\text{As}$. When the camera temperature was increased by 30 – 50° increments from 340°C . at 24-hour intervals, the diffraction pattern of $\beta\text{Co}_2\text{As}$ appeared between 490° and 520°C ., and was replaced by the $\alpha\text{Co}_2\text{As}$ pattern between 402° and 388°C . when the compound was cooled.

The high temperature modification is hexagonal and apparently isostructural with Fe_2P . In Table II the intensities of the reflections are compared with the intensities of the corresponding reflections of Fe_2P (9) and isostructural Ni_2P (14). The agreement is satisfactory, particularly when allowance is made for the obvious difference in relative exposure times of the Fe_2P and the Co_2As patterns.

*Intensities of the reflections from corresponding planes in Fe_2P and Ni_2P

Fe_2P $a = 5.85$ Å, $c = 3.45$ Å;

Ni_2P $a = 5.86$ Å, $c = 3.37$ Å.

The structure of $\alpha\text{Co}_2\text{As}$ is closely related to the structure of the β form. A hexagonal cell, very similar in dimensions to the hexagonal unit cell of $\beta\text{Co}_2\text{As}$, is readily obtained when the diffraction pattern is subjected to analysis, and the majority of reflections are of comparable intensity with the corresponding reflections of the high temperature modification. However, one reflection at $d = 1.91$ Å cannot be indexed using this cell. This broad reflection, weak in intensity, occurs in all patterns of this phase, and is not diminished or enhanced in intensity or clarity by annealing at 300°C . for 4 weeks,

or by chilling from 400° C. Its relative intensity is not decreased by doubling the thickness of the beta filters, so it does not appear to result from beta radiation. It is not likely to be the result of "double internal diffraction" because it appears regardless of the wavelength of the radiation. It cannot be indexed if c of the pseudohexagonal cell is doubled, but may be if a is doubled, although it seems unlikely that an order-disorder transformation which might be suggested to justify doubling this dimension would lead to such a marked change in dimensions on transformation to the β (disordered) form. We conclude that Co_2As is pseudohexagonal, true symmetry unknown.

For purposes of identification, the diffraction pattern of $\alpha\text{Co}_2\text{As}$ is recorded in Table III. The unit cell dimensions of $\beta\text{Co}_2\text{As}$ and the pseudohexagonal $\alpha\text{Co}_2\text{As}$ cell at various temperatures are given in Table IV.

*Pseudohexagonal $\alpha\text{Co}_2\text{As}$.

The $M_3\text{As}_2$ Compounds

None of our iron/arsenic alloys quenched from temperatures above 800° C. showed any indication of a compound in this region. Hägg's evidence for the stability of Fe_3As_2 above 795° C. is such that we did not attempt to repeat his study.

Alloys of cobalt and arsenic in the corresponding concentration region at room temperature showed only the patterns of $\alpha\text{Co}_2\text{As}$ and CoAs regardless of heat treatment. In the high temperature camera, these patterns were observed at temperatures up to 920° C., the lines due to $\alpha\text{Co}_2\text{As}$ being replaced by those of $\beta\text{Co}_2\text{As}$ between 400° and 500° C. At 940° C. a new pattern was obtained which had no lines in common with either the $\beta\text{Co}_2\text{As}$ or the CoAs patterns at the same temperature. There was no indication

in the diffraction pattern or in the state of the specimen recovered from the camera that a liquidus phase had been formed.

Since only two alloys were studied (44.2 and 45.8% As), the exact composition of the compound formed between 920° and 940° C. cannot be precisely defined; but the complete absence of $\beta\text{Co}_2\text{As}$ and CoAs reflections in the X-ray diagram indicates that the stoichiometric formula is very close to Co_3As_2 (45.87% As).

The quality of the powder diagram at 940° C. was poor, with 10 lines visible in the low order region and none at higher orders. These lines could not be indexed on simple cubic, hexagonal, or tetragonal cells, and we do not feel justified in proposing a unit cell of large dimensions or a cell of symmetry less than tetragonal.

The MAs Compounds

Iron arsenide, FeAs, crystallizes in the orthorhombic system, space group $Pnma$ (V_h^{16}), with unit cell dimensions $a = 3.372 \text{ \AA}$, $b = 6.023 \text{ \AA}$, and $c = 5.432 \text{ \AA}$, with an uncertainty of $0.002 \text{ \AA}$. These values are in good agreement with those reported by Hägg: 3.366, 6.016, and 5.428, in kX units.

Cobalt arsenide, CoAs, is isostructural with FeAs, with the dimensions $a = 3.458 \pm 0.002 \text{ \AA}$, $b = 5.869 \pm 0.005 \text{ \AA}$, and $c = 5.292 \pm 0.006 \text{ \AA}$. Not only are the systematic extinctions consistent with the $Pnma$ space group, but the intensity of any given reflection is comparable to the intensity of the reflection from the same plane in FeAs. A column giving the intensities of the corresponding reflections in the FeAs powder diagram is given in Table V, which lists the first 10 lines of the CoAs pattern, and subsequently all lines with relative intensity of 20 or greater.

*Intensity of reflection from corresponding plane in powder diagram of FeAs.

The parameters of the cobalt and arsenic positions in CoAs are probably not much different than the parameters of iron and arsenic in FeAs. For both compounds, the distortion from the more symmetrical hexagonal NiAs structure is small, the ratio b/a for FeAs being 1.786, and for CoAs 1.684, as compared to 1.732 for an orthohexagonal cell. Both compounds expand anisotropically with increasing temperature in such a way that these ratios approach the orthohexagonal value as shown in Fig. 1. Between

FIG. 1. Effect of temperature on the ratio b/a for the orthorhombic unit cells of FeAs and CoAs.

FIG. 2. Lattice dimensions a and c for the solid solutions of Co in hexagonal NiAs and Ni in orthorhombic CoAs.

944° and 960° C. orthorhombic CoAs undergoes a transformation to β CoAs which is hexagonal and isostructural with NiAs. It is possible that FeAs undergoes a similar transition below its melting point, but we were unable to obtain satisfactory patterns above 900° C. owing to attack of the silica specimen capillaries.

Orthorhombic unit cell dimensions at various temperatures are recorded in Table VI, and the approximate mean thermal expansion coefficients in the 25°–900° C. range, along the three axes, in Table VII.

As might be expected, substitutional solid solutions of Co in NiAs are formed over a considerable concentration range; for alloys annealed at 700° C. and chilled to room temperature, the NiAs structure is retained even when 80% of the nickel atoms have been replaced by cobalt (see Fig. 2). The substitution of Ni for Co in the CoAs lattice is correspondingly limited. Between the concentrations equivalent to $\text{Ni}_{0.15}\text{Co}_{0.85}\text{As}$ and $\text{Ni}_{0.05}\text{Co}_{0.95}\text{As}$ two solid solutions are represented in the powder diagrams.

above and below the compositions of these compounds indicates that unlike NiAs and many compounds with the NiAs structure, FeAs and CoAs do not exist over any appreciable concentration range.

CONCLUSIONS

This limited study is sufficient to show the marked similarities in the Fe/As and Co/As systems. Both exhibit M_2As and MAs compounds at room temperature and an M_3As_2 compound stable only at high temperatures. The MAs compounds are isostructural. Accepting our hypothesis that β Co₂As has the Fe₂P structure, Co₂As and Fe₂As are also closely related. The difference in these two structures is most readily described in terms of the co-ordination of the metalloid atoms; while the arsenic atoms in Fe₂As are surrounded by nine iron atoms in two groups of four atoms at 2.4 Å and 2.6 Å, and one other atom at 2.5 Å, the Fe₂P structure is such that the nine metal atoms are arranged in two groups of three at *ca.* 2.5 Å in β Co₂As, and three at 2.3 Å. The planes of nearly close-packed metal atoms occurring in the Fe₂As structure do not occur in the Fe₂P structure.

It may be remarked that while there is considerable similarity between these two compounds, there is virtually no difference between the hexagonal Co₂As (Fe₂P) structure and the orthorhombic Co₂P (PbCl₂) structure, the pseudohexagonal nature of the latter being very well defined.

We were able to find no crystallographic explanation for the discontinuities observed by Kochnev in the decomposition pressures of Co₂As and CoAs. The determination of vapor pressures by the Knudsen effusion method is technically difficult, particularly at high temperatures, and it may be that insufficient allowance was made for experimental uncertainty.

The fact that alloys corresponding in composition to the compound Co_3As_2 gave decomposition pressures lower than CoAs at temperatures where, according to our observations, the alloy consists of a mixture of CoAs and Co_2As would seem to indicate that equilibrium was not attained in the Knudsen cell. This argument is also applicable to the vapor pressure data on the mixtures corresponding in composition to Co_5As_2 , and consequently must be extended to include the possibility that equilibrium conditions were not obtained even for the single phase alloys Co_2As and CoAs.

It is a basic prerequisite of the application of the Knudsen equation to weight loss data of this type that equilibrium exist on the high pressure side of the orifice, that is, that the liquid or solid be able to supply the vapor at a rate much greater than the rate of effusion through the orifice. Strictly speaking, of course, even under the most ideal conditions removal of vapor disturbs the equilibrium and introduces a finite error. Nevertheless the method has been used recently by Searcy and his co-workers with great success in measuring vapor pressures at very high temperatures. It is interesting to note that for one compound, Mo_3Ge , the method was unsatisfactory because equilibrium was not established over the solid (15). To eliminate this possible source of error from the Co/As decomposition pressure data it may be necessary to repeat the experiments with the object of determining the dependence of the decomposition pressure on orifice area.

ACKNOWLEDGMENTS

We wish to express our thanks to Mrs. M. Beck who obtained and measured the great majority of the diffraction patterns, and to Dr. W. G. Henry who assisted greatly in the preparation of the alloys in his chill casting apparatus.

THE DIELECTRIC PROPERTIES OF METHANOL AND METHANOL-*d*¹

D. W. DAVIDSON

ABSTRACT

The dielectric properties of methanol and methanol-*d* were examined between liquid nitrogen and room temperature at frequencies between 40 and 10^6 cycles per second. In addition to the large increase in the dielectric constant within solid CH_3OH at 159.6°K ., there is evidence of a further, gradual transition at about 155°K . Similar changes in CH_3OD occur at 163.2° and about 157°K . Dispersion processes within the solid are discussed in terms of misaligned crystallites and polarization at the interfaces between crystallites and between regions of solid and liquid. Conductance maxima near 130°K . are tentatively related to the methanol-water eutectic. Static dielectric constants of liquid CH_3OD are a little lower than those of CH_3OH , while relaxation times over a limited temperature range above the freezing point are some 35% higher; the activation energies for dielectric relaxation of the two molecules in the liquid state are approximately the same (3.5 kcal./mole).

INTRODUCTION

Smyth and McNeight (24) have shown that the transition at 160°K . from the monoclinic (α) to the orthorhombic (β) form of solid methanol is accompanied by an increase in dielectric constant. In view of the discovery by Staveley and Hogg, in a recent dilatometric investigation (26), of a second transition some three degrees below the principal transition temperature, and in view of the uncertainty about the exact nature of the dispersion that occurs at audio-frequencies in the β phase, a new, more thorough investigation of the dielectric properties of solid methanol seemed justified. The results of the present work on solid methanol in general confirm those of Denney and Cole (8), which appeared while the present work was underway, but are in some respects a little more detailed.

The dielectric properties of CH_3OD are reported here for the first time. As for CH_3OH the presence of a second transition within the solid state of CH_3OD is suggested by the dilatometric data (6) and by specific heat anomalies in the vicinity of the α - β transformation (25).

The effect of deuterium substitution in the hydroxyl group on the relaxation times for the primary dispersion of liquid alcohols appears to have been investigated only in the case of *n*-octanol (4) where, at temperatures where the data are most reliable, deuterium substitution raises the relaxation time by less than 10% (17). In the present work the relaxation times of liquid CH_3OH and CH_3OD have been estimated from the absorption conductance measurements over a temperature range extending 35° above the freezing points.

EXPERIMENTAL METHODS AND MATERIALS

Measurements were made, using the substitution method, with a General Radio 716-C Capacitance Bridge and 716-P4 Guard Circuit over a frequency range extending from 40 cycles to 1 megacycle per second.

Two three-terminal stainless steel sample cells were used. In Cell 1 the parallel plate electrode assembly consisted of an upper circular electrode and a surrounding guard ring both mounted on a Teflon block connected to the shaft of a micrometer screw head and a

¹Manuscript received January 4, 1957.

Contribution from the Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada. Issued as N.R.C. No. 4293.

lower electrode held in a Teflon block fixed to the bottom of the stainless steel can which formed the body of the cell. The effective electrode diameter was 2 in. and the inter-electrode distance was variable between 0 and 0.5 in.

Cell 2, modelled after the cell of Gross and Taylor (11), was of the coaxial cylindrical electrode type and had an air capacitance of $\sim 5 \mu\text{mf}$. The measured capacitance was independent of sample volume between 10 and 13 ml.

To avoid condensation within the cell of water from the atmosphere, cell 2 was enclosed in an air-tight chamber, the main features of which are indicated in Fig. 1. The cell fitted snugly into the copper can which formed the bottom of the cell chamber and the electrode

FIG.1. Cell chamber.

and thermocouple leads were brought out through the Pyrex top in the manner shown. In order that samples of low volatility could be heated to 300° C., Teflon was the insulating material in the connecting cable and all electrical joints in the lower part of the chamber were made with silver solder. The cable was sufficiently flexible that the excess length (not shown) could be folded within the upper part of the chamber when the ball-and-socket joint was assembled.

The thermostat consisted of an aluminum block into which fitted the cell chamber containing cell 2 to a height of a few inches above the copper-Pyrex seal. Cell 1 sat in a similar block. In either case, the block was wound with a heater, heavily lagged with asbestos, and placed in a large copper can which was mounted in a wide-mouthed 5-gallon Dewar flask. Liquid nitrogen in the latter was held to an approximately constant level by means of a Dekhotinsky-type thermoregulator which controlled the flow of nitrogen into the Dewar flask from the external tank. The block heater was controlled by a thermistor placed in a hole drilled in the block. The thermistor formed one arm of a Wheatstone bridge, in the usual manner. Because, however, of the high resistance acquired by the thermistor at low temperatures, it was found necessary to amplify considerably the unbalance current of the Wheatstone bridge. The output from the amplifier was fed into a sensitive (50 microampere) d-c. relay which controlled the heater circuit. Temperature control to at least $\pm 0.05^\circ$ C. was realized to below 120° K.

Temperature was measured by means of two copper-constantan thermocouples, one within the cell and the other within the block. These had been calibrated to at least 0.2° C. down to liquid nitrogen temperature.

Because of the tendency of β phase methanol to persist to low temperatures, a thermal conditioning procedure was followed before each run was begun (26). This involved cooling the sample to 120° K., heating slowly to about 153°, where the sample was kept for several hours, and then recooling to the starting temperature for the run. Preliminary heating runs on CH_3OH , with no thermal conditioning, showed a drop in the value of the dielectric constant near 150° K., an effect which did not recur on cooling or on cooling and reheating. Most runs were made with increasing temperature, some with temperature allowed to increase continuously (heating rate 2° per hour or less), but most with discrete jumps in temperature from one thermostat setting to another. In the latter case, at least 3 hours was allowed for new thermal equilibrium to be established.

Baker's Analyzed Reagent Grade Absolute Methanol was distilled over aluminum amalgam to give a product which had a conductivity less than 10^{-7} ohm $^{-1}$ cm. $^{-1}$. This conductivity invariably increased initially over a period of days in the cell, probably because of the dissolution of small quantities of metallic ions from the cell walls since the Fischer reagent indicated no increase in water content.

Two samples of methanol- d were provided by Dr. L. C. Leitch of the Pure Chemistry Division. Initial attempts to dry CH_3OD with aluminum amalgam resulted in significant reduction in the deuterium content. Calcium oxide, freshly dried at 600° C., was finally used as drying agent. The infrared spectrum of the CH_3OD used indicated less than 1% CH_3OH .

Densities of the driest samples of CH_3OH and CH_3OD were determined with the quartz pycnometer previously mentioned (7). These were, for CH_3OH , $d_4^{20} = 0.79141$ (the ICT value is 0.79134) and for CH_3OD , 0.81252 (compared with 0.81269 given by Staveley and Gupta (25)).

RESULTS

Within the low temperature α phase (except for a region extending a few degrees below the α - β transition) the radio-frequency dielectric constants of CH_3OH and CH_3OD are the same within experimental reproducibility, and this is also the case for the high temperature β form. Within the liquid phase, the values of the static dielectric constants of CH_3OD are slightly lower than those of CH_3OH at the same temperatures, although these values are practically identical if compared at the freezing points. The β phase of CH_3OD exists over a 10-degree range of temperature in comparison with the 15 degrees covered by this phase in CH_3OH .

Phase Transitions

Fig. 2 shows the region of the solid-solid transitions of CH_3OH . The unbroken curve represents the constant value (ϵ_1) of the dielectric constant measured at frequencies of

FIG. 2. Solid CH_3OH .

about 100 kc./sec. and higher. That frequency-independent values of ϵ' in the β phase are reached in this frequency range has been pointed out by Denney and Cole (8). There is a small and gradual increase in ϵ_1 in the vicinity of 155° K. which probably has the same origin as the gradual increase in molar volume observed by Staveley and Hogg near 156° K. (26). This will be called the α '- β "transition" below. The value of ϵ_1 jumps abruptly at the α '- β transition and continues to rise slightly with increasing temperature in the β phase until it turns sharply upward near the melting point.

The lower broken curve of Fig. 2 illustrates the behavior of the dielectric constant at fixed audio-frequency for the same sample as the unbroken curve. Dispersion for this sample is thus evident at temperatures considerably lower than the transition points.

Whereas the lower two curves refer to measurements in which the sample was in thermal equilibrium with the thermostat, the upper broken curve shows the behavior at 1 kc./sec. of a sample which was continuously heated. The dielectric constant passes through a peak at the temperature of the principal transition. This is probably a result

of Maxwell-Wagner polarization during the coexistence of the two phases. There is a pronounced conductance maximum at the same time. The same curve shows the drop in dielectric constant below 150° K. always noticed for samples which were not thermally-conditioned. This effect is attributed to the disappearance of some β phase methanol which was "frozen in" during the original cooling of the sample.

Fig. 3 shows ϵ_1 for CH_3OD in the transition region (solid curve) together with values of the dielectric constant measured at a fixed frequency (dashed curve). The dotted curve

FIG. 3. Solid CH_3OD .

refers to values of ϵ_1 obtained with a sample containing 0.2 weight per cent D_2O . There is a gradual but pronounced rise in ϵ_1 for the dry sample near 157° K. which tends to be obscured in the presence of water. The dilatometric results show the α - α' transition to occur at about 158° K. for this molecule. The change in ϵ_1 at this transition in CH_3OD appears to be greater than in CH_3OH . There is again an abrupt rise in ϵ_1 at the α' - β transition which occurs at 163.2° K. for CH_3OD .

Dispersion in the Solid

Fig. 4 shows a series of dispersion curves obtained for solid CH_3OH at a number of temperatures. Numbers beside points are measurement frequencies in cycles/sec. All the unbroken curves refer to the same sample. There is no indication of a significant change in the nature of the dispersion in the region of the gradual transition. However, such a change does occur at the α' - β transition, as indicated by the difference between the plots obtained at 158.4° and 160.4° K. It is evident that the value of ϵ'' obtained at a given frequency passes through a maximum at this transition temperature. The loss exhibited by the orthorhombic modification subsequently increases rapidly with increasing temperature.

In the β phase there was considerable variation in the dispersion behavior of different samples. This variation is shown in its extreme form by the difference between the solid curves and the two broken curves in Fig. 4. The first of the latter (at 170.9° K.) forms

For CH₃OD the dispersion curves followed much the same sequence with increasing temperature as for CH₃OH (Fig. 5). In CH₃OD the arc was usually better defined before it turned upward at low frequencies. At the α' - β transition there was again a marked fall

FIG. 4(c). Cole-Cole plots for solid CH_3OH .

in ϵ'' . Within the β phase, some samples showed evidence of two or more overlapping dispersion processes (see, for example, the locus at 169.2°K).

Low Temperature Conductance Anomaly

All samples of CH_3OH showed a small conductance maximum at low audio-frequencies near 130°K , although the magnitude varied from one sample to another and tended to decrease for a given sample with time. Fig. 6(a) illustrates this effect for two samples, one of which was taken through this temperature several times. The peak occurred with both increasing and decreasing temperature. As shown in Fig. 6(b) there seems to be a slight increase in dielectric constant in the same region. A similar conductance peak was observed at about 132°K in most samples of CH_3OD . For both methanols the temperature at which the peak occurs appears to be independent of frequency for the low frequencies at which the effect could be detected. A few degrees higher the conductance begins to increase rapidly.

Liquid Measurements

Some values of the dielectric constants of liquid CH_3OH and CH_3OD , together with a few values of τ , are given in Table I. The latter are the observed, rather than the "Lorentz-field corrected", relaxation times and were obtained from the absorption conductance

$$k_{\text{abs}} = k_{\text{obs}} - k_{\text{d-c.}} = 3.496 \times 10^{-12} f^2 \tau (\epsilon_0 - \epsilon_1)$$

by a least squares treatment. Here f is the frequency of measurement and the k 's are specific conductances. ϵ_1 was evaluated at each temperature by assuming the constancy of $(\epsilon_1 - 1)V/(\epsilon_1 + 2)$ (in which V is the molar volume) and that $\epsilon_1 = 6.0$ at 20°C . (20) for both molecules. The resulting values of ϵ_1 are larger than those obtained with ϵ_1 at 20°C . taken as 5.3, the value recently reported by Poley (19), and smaller than those

FIG. 5. Cole-Cole plots for solid CH_3OD .

given by Denney and Cole (8), which are presumably based on extrapolations in temperature and composition of experimental values for methanol-*n*-propanol solutions at lower temperatures.

Use of the equation above for the determination of the relaxation time from the absorption conductance assumes that a single relaxation time is adequate to describe the principal dispersion process. That this is so for liquid methanol is suggested, *inter alia*, by the microwave data of Saxton (20) on methanol at higher temperatures and by detailed investigations of the nature of the dispersion in other alcohols that lend them-

FIG. 6. Conductance (a) and dielectric constant (b) anomalies in CH_3OH near 130°K . (frequency = 500 cycles/sec.). The arrows in (b) indicate the temperatures of the conductance peaks in (a).

selves to supercooling to low temperatures where their behavior may be conveniently examined at radio and audio frequencies (5, 7, 13).

The accuracy of the τ 's reported is limited primarily by the necessity of subtracting large values of the d-c. conductance from the observed conductance and by the restriction of the experimental frequencies to a range considerably lower than the critical frequency, $(2\pi\tau)^{-1}$.

DISCUSSION

The dielectric properties of solid methanol are not qualitatively affected by substitution of deuterium in the hydroxyl group. On the whole, the calorimetric, dilatometric, and dielectric studies of CH₃OH and CH₃OD establish the same sequence of "phases". The transitions occur at temperatures which differ by only a few degrees in the two molecules.

 α - α' Transition

As in the dilatometric studies, this "transition" appears as a gradual one in the dielectric measurements. The anomalous rise in ϵ_1 is centered near 155° and 157° K. for CH₃OH and CH₃OD, respectively, in each case a degree lower than the temperature at which the coefficient of expansion reaches its maximum value. In neither method, however, is it easy to estimate these temperatures accurately. The change in polarization is not great, but despite the complications produced by the presence of the much more pronounced α' - β transition only a few degrees higher, the effect seems to be rather greater than would be expected from the volume changes alone (that is, the reduction in air gaps produced by sample expansion), especially for the deuterated alcohol. Beyond the indication of a slight increase in polarization, the dielectric results do not affect substantially the uncertainties connected with the origin of this transition which have been discussed elsewhere (26, 6).

 α' - β Transition

The present dielectric results indicate that this transition occurs in CH₃OH at 159.6° and in CH₃OD at 163.2° K. In each case it marks the change from the low temperature monoclinic to the high temperature orthorhombic modification of the solid. The increase in ϵ_1 at this transition is at least 10 times the effect to be expected from reduction of the size of the air gaps in the solid sample alone, although this factor makes some contribution. Moreover, the difference between ϵ_1 and the square of the refractive index, which provides a measure of the contribution to the polarization on the part of orienting molecules

(together with atomic polarization), jumps at the transition from a value of about 1 to more than 3. The observation that the magnitude of ϵ_1 in the β phase is not significantly changed by deuteration suggests that any explanation of the high value of ϵ_1 that is based on perturbation by the applied field of the equilibrium positions of the hydrogen atoms of the hydroxyl group must be ruled out.

Low Temperature Conductance Maxima

There appears to be an interesting correlation between the conductance maximum observed at 130° K. (Fig. 6) and an incipient peak detectable in the heat capacity results of Staveley and Gupta (25) at about the same temperature. Fig. 7 is a reproduction of

FIG. 7. Heat capacity curve of Staveley and Gupta (25) for CH_3OH . (Reproduced by permission of Dr. Staveley and the editor of the *Transactions of the Faraday Society*.)

a figure in their article. Both effects are tentatively interpreted as marking the appearance of a small quantity of liquid phase at the eutectic temperature of the methanol-water system. Baumé and Borowski (1) report the eutectic temperature of the water-methanol system to occur at approximately 134° K., but there is wide variation in the values of this temperature reported in the literature (9). It should be pointed out, however, that the high density reported in the paper by Staveley and Gupta (25) ($d_4^{20} = 0.79216$), which could be taken to indicate $\sim 0.25\%$ water, is a misprint and should read 0.79126. (We are indebted to Dr. Staveley for drawing this to our attention.) This density, which was carefully determined, gives no evidence of appreciable water content.

Visual examination of methanol to which some water has been added shows that as the temperature rises between the eutectic and the melting point, drops of liquid rise and collect above the solid. The conductance peak may thus arise from the interfacial polarization between well-dispersed liquid regions and the solid, since the polarization conductance would be expected to fall temporarily as patches of liquid coalesce and grow in size. It is, however, difficult to account for the appearance of the peak with decreasing temperature on this basis.

Some additional evidence for connecting the conductance anomaly with the eutectic temperature is provided by the appearance of a large second peak in the vicinity of 123° K. when a sample containing added water is rapidly cooled in liquid nitrogen. This peak may arise at the eutectic temperature of supercooled β phase methanol since this temperature must be lower than that for the α phase. This second peak disappears when the sample is "annealed" to ensure the absence of the β form.

A few degrees above the peak the conductance again begins to increase, as does the

value of ϵ_1 . The effect of adding a known amount of water is to increase ϵ_1 in this temperature region by an amount rather larger than one calculates for a simple model consisting of a layer of liquid in parallel with a solid methanol layer.

A similar explanation is advanced for the 132° K. conductance peak in CH_3OD .

If the present explanation of the conductance peaks is correct it would appear that the measurement of conductance offers a sensitive method of investigating eutectic phenomena, at least when the liquid phase is relatively highly conducting.

Dispersion Effects in the Solid

The variability in the results shown in the β phase by different samples and by the same sample with different thermal histories suggests that the dominant dispersion in this phase arises from the existence of crystal inhomogeneities, in particular from the presence of interfaces between anisotropic crystallites oriented in different directions (as suggested by Denney and Cole (8)) and perhaps between solid regions and patches of liquid resulting from the presence of a small quantity of water in the sample. It is worth noting that the dispersion in the β phase seems to be more dependent on the thermal history of the sample than on water content (provided this is low) and the dielectric loss was sometimes higher for drier samples, whereas the opposite is true for the α phase.

Such plots as the dashed curves of Fig. 4 for CH_3OH and those shown for β phase CH_3OD (Fig. 5) may indicate the presence of true bulk polarization, but this question cannot be settled with certainty until it is possible to make measurements on macroscopic single crystals of methanol (8).

For bulk dispersion arising from dipolar relaxation, different sample histories may well change the measured values of the complex dielectric constant since these are compounded of contributions from microcrystalline regions whose axes are irregularly orientated with respect to the direction of the electric field. However, misaligned crystallites will also give rise to Maxwell-Wagner dispersion effects at the interfaces if the ratio of conductivity to dielectric constant is significantly different along the different crystal axes. It is possible that a proton transfer mechanism is responsible for an abnormally high conductance in the planes containing the hydrogen bonds. Such an explanation has been suggested to account for the high dielectric loss observed over a range of temperature below the melting points of long-chain alcohols (14, 15) where the existence of an unstable phase in which the hydroxyl groups lie in parallel planes has been postulated.

The high values of ϵ_1 in the β phase strongly suggest the existence of a dispersion region at frequencies considerably above 1 Mc./sec. It is possible that this dispersion is related to the secondary dispersion reported for several liquid alcohols at frequencies much higher than the principal dispersion region. It has been suggested by Saxton (20) that the high frequency dispersion-absorption at millimeter wave lengths in liquid methanol at room temperature may be due to a resonance absorption, but for other alcohols the characteristics of secondary dispersions of this kind have been analyzed and interpreted as true relaxation effects involving the reorientation of C—O bond moments (12, 5, 8). The possibility that the methyl group possesses some freedom, in the high temperature form of solid methanol, to take up new positions with respect to the hydroxyl group finds some support in the large amplitudes of thermal motion of atoms out of the plane of the hydrogen bonds, as reported by Tauer and Lipscomb (27), and in the

FIG. 8. Static dielectric constants of liquid CH_3OH and CH_3OD .FIG. 9. Relaxation times of liquid CH_3OH and CH_3OD .

negligible effect of deuterium-substitution on the value of ϵ_1 . Measurements at much higher frequencies are clearly desirable.

Effects of Deuteration on the Properties of Liquid Methanol

In Fig. 8 values of the static dielectric constants (ϵ_0) of CH_3OH and CH_3OD are plotted against $1/T$. Within experimental uncertainty, the data for each molecule fall on a straight line and the slopes of the two lines are the same. This implies that the values of the Kirkwood correlation parameter (18) do not depend greatly upon the temperature and are very nearly the same for the two molecules. ϵ_0 for CH_3OD is smaller by about one unit than for CH_3OH over the experimental temperature range. Part at least of this difference may be related to the larger molar volume of CH_3OD (6). The dielectric constant of D_2O is likewise less than that of H_2O in the liquid (28) while the molar volume is greater.

Plots of $\log \tau$ vs. $1/T$ over the limited temperature range for which the relaxation times could be estimated with the present apparatus are shown in Fig. 9, together with some values for CH_3OH from the work of Denney and Cole (8). Within experimental error, these plots are linear, with identical slopes. The activation energy derived directly from the slope is 3.5 kcal./mole.

The relaxation times of methanol-*d* are some 35% higher than those of methanol. Absolute reaction rate theory (10) predicts that $\tau = h/(kT)\exp(\Delta F^\ddagger/RT)$, that is, that isotopic substitution can affect only the exponential factor in the rate equation. In the present instance, even if the above expression is assumed to be adequate, it is uncertain whether the main effect of deuteration is to change the entropy or the energy of activation. A difference of the order of 100 cal./mole between the activation energies of the two

FIG. 10. Reciprocal rate plots for liquid CH_3OH . Units: τ , 10^{-9} sec.; τT , 10^{-7} sec.-deg.; η , centipoise; $1/k$, 10^9 ohm-cm.

molecules could alone account for the difference between the relaxation times, and the present data are not sufficiently accurate to rule out a difference of this magnitude. Moreover, the validity of the absolute reaction rate theory is especially doubtful for dielectric relaxation in strongly hydrogen-bonded liquids, in which the relaxation processes, although related to the breaking of hydrogen bonds, appear to involve the co-operation of a large number of molecules (8, 21).

The increase in relaxation times produced by deuterium-substitution in water (3) and in methanol, together with the increase in molar volumes, strongly suggests the existence in the deuterated molecules of slightly more extensive and more regular hydrogen bonding, subject to less frequent thermal disruptions.

As for other liquid alcohols at low temperatures (7, 22), the temperature-dependence of the dielectric relaxation rate is similar to that of other rate processes in methanol at temperatures not far above the freezing point. In Fig. 10 the behavior of the relaxation time over the temperature range between room temperature and the freezing point is compared with that of the viscosity η (16) and $1/k$ (where k is the direct-current conductance as measured for a particular methanol sample). These quantities may be considered as reciprocals of rate constants. The value of the relaxation time at 20° C. (5.8×10^{-11} sec.) is the one obtained by Saxton (20) from a compilation of the results of a number of workers at different frequencies in the microwave range. Cole and Cole (2) obtained a value of 5.9×10^{-11} sec. at 19° C. from the data of Slevogt (23). Despite the absence of data over a large temperature interval, $\log \tau$ appears to maintain its linear dependence on $1/T$ over the whole temperature range. This is not so for the viscosity and the d-c. resistance, which at low temperatures have slopes very similar to the slope for the relaxation time, but undergo a decrease in slope over the range between 190° and 200° K. to a value which then remains constant to room temperature and corresponds to an activation energy of 2.5 kcal./mole. Thus the rate-determining mechanism may well be the same for the three processes at low temperatures, but ionic mobility and viscous flow appear not to be limited by the factors responsible for dipolar orientation at higher temperatures. For other alcohols the linearity between $\log \tau$ and $1/T$ is not maintained at low temperatures, especially in the supercooled state (5, 7, 13).

There is some reason to believe (from, for example, the rate equation above) that the substitution of τT for τ in the rate plot should lead to a "better" value of the energy of activation for dielectric relaxation. The plot of τT in Fig. 10 is likewise linear, with a slope that is slightly smaller than before. Agreement with the resistance and viscosity slopes at low temperatures is now not quite as good.

The d-c. conductance of CH_3OD shows much the same behavior as that of CH_3OH except that now the change of slope occurs between 195° and 210° K.

ON FLAME PROPAGATION IN EXPLOSIVE MIXTURES OF GASES

IV. ON THE DECOMPOSITION FLAME OF OZONE IN MIXTURES RICH IN OZONE¹

ROBERT SANDRI²

ABSTRACT

The theory of flame propagation in ozone-oxygen mixtures developed in earlier papers of the author is applied to mixtures containing 50%-100% ozone. The formulae are modified to allow for comparatively high concentration of atomic oxygen. The results are found to be in very good agreement with experimental values which have recently become available.

In an earlier paper (3), the general theory of flame propagation developed by the author (2) has been applied to the decomposition flame of ozone. Numerical examples were calculated and good agreement between theory and experimental results was found to exist in mixtures of ozone and oxygen containing up to 50% ozone. In the meantime, experimental data have become available for mixtures rich in ozone and even for pure ozone (4) so that it seems to be interesting to apply the theory also to these mixtures.

Some simplifying assumptions have been made in the paper quoted, which were based upon the fact that for ozone contents up to 50% the flame temperature is not very high so that dissociation of molecular oxygen in the "burned" gas is negligible. This is no longer true for rich mixtures. For instance, decomposition of pure ozone produces a flame temperature near 2700° K. and the equilibrium concentration of atomic oxygen at this temperature is about 3.5% (volume) of the mixture. The question arises how this affects the formulae derived for the concentrations of the components in the flame zone and for the flame velocity.

In the first place, the assumption was made that only two reaction rates in the system of possible reactions were significant, namely*

$$[1] \quad U_{-}^{(1)} = 10.56 \times 10^{12} n^2 \sqrt{T} y_3 e^{-24140/RT},$$

$$[2] \quad U_{+}^{(2)} = 7.15 \times 10^{13} n^2 \sqrt{T} y_1 y_3 e^{-6000/RT},$$

where n is the total concentration of the mixture, and y_1 and y_3 are the molar fractions of atomic oxygen and ozone. Numerical checks show that this assumption still holds when dissociation is no longer quite negligible, i.e., for comparatively high values of y_1 . The above rates correspond to the reactions

Further, the conclusion was drawn that, since the concentration of atomic oxygen was very small, its rate of formation had to be near zero so that

$$[3] \quad U_{-}^{(1)} - U_{+}^{(2)} \approx 0.$$

This is no longer true when y_1 is not very small, i.e., for high flame temperatures, and a closer investigation becomes necessary.

To calculate the flame velocity, an expression is needed for the heat Q produced by chemical reactions per unit of space and time. Evidently

¹Manuscript received January 28, 1957.

*Because of a printing error, n appears instead of n^2 in formulae [1], [2], and [3] in the paper quoted.

$$\begin{aligned}
 [4] \quad Q &= -q_1 U_-^{(1)} + q_2 U_+^{(2)}, \\
 \text{where} \quad q_1 &= 24,140 \text{ cal./mole}, \\
 q_2 &= 93,210 \text{ cal./mole}.
 \end{aligned}$$

The expression for $U_-^{(1)}$ contains only y_3 and is therefore determined by the choice of y_3 . In order to determine $U_+^{(2)}$, we use the equation of the general theory

$$z \frac{d}{dT} \left(\frac{\delta_1}{m} z \frac{dy_1}{dT} - \frac{y_1}{m} \right) + \frac{\lambda}{V_0^2 \rho_0^2 c_p} U_1 = 0,$$

where U_1 is the rate of production of atomic oxygen. Hence

$$U_1 = U_-^{(1)} - U_+^{(2)}$$

or

$$[5] \quad U_+^{(2)} = U_-^{(1)} + \frac{V_0^2 \rho_0^2 c_p}{\lambda} z \frac{d}{dT} \left(\frac{\delta_1}{m} z \frac{dy_1}{dT} - \frac{y_1}{m} \right).$$

Here λ is the thermal conductivity, c_p the specific heat per gram of the mixture, and ρ_0 the specific mass of the cold mixture. The constant δ_1 (the reduced diffusion coefficient of atomic oxygen) does not differ much from unity and can be placed equal to unity, since it only appears in a correction term. Likewise, the molecular weight m of the mixture can be considered as constant. The variable z can be determined from the differential equation of the general theory

$$[6] \quad z \left(\frac{dz}{dT} - 1 \right) = - \frac{\lambda Q}{V_0^2 \rho_0^2 c_p^2}.$$

For the evaluation of equation [5], a mathematical expression for y_1 is needed. Since y_1 is present only in the second term on the right-hand side, which is small compared to the first, we can use a rough approximation for it which can be calculated from formula [3] although this formula is not exactly correct. So we find

$$[7] \quad y_1 \approx 1.474 e^{-18140/RT} = 1.474 e^{-A/T}.$$

Substituting this in [5] and utilizing equations [6] and [4], we find

$$[8] \quad Q \approx (q_2 - q_1) U_-^{(1)} + \frac{q_2}{m c_p} \frac{A}{T^2} y_1 \left[\frac{V_0^2 \rho_0^2 c_p^2}{\lambda} z^2 \left(\frac{A}{T^2} - \frac{2}{T} \right) - (q_2 - q_1) U_-^{(1)} \right].$$

This formula can be used for calculating corrected values of the flame velocity as follows. The second term is at first disregarded and an approximate heat development Q^* is computed:

$$Q^* = (q_2 - q_1) U_-^{(1)}.$$

Using Q^* and placing

$$[9] \quad y_3 = y_{30} \frac{T_f - T}{T_f - T_0} = y_{30} \eta$$

we can compute an approximate value V_{0H} for the flame velocity by means of the formulae of the general theory

$$[10] \quad V_{0H}^* = \frac{1}{1 - \eta_m} \left[\int_0^1 F^*(\eta) d\eta \right]^{\frac{1}{2}},$$

$$[11] \quad F^*(\eta) = \frac{\lambda Q^*}{\rho_0^2 c_p^2 (T_f - T_0)} = \frac{\lambda (q_2 - q_1)}{\rho_0^2 c_p^2 (T_f - T_0)} U_-^{(1)},$$

where η_m is the value of η corresponding to the maximum of $F^*(\eta)$.

Likewise, approximate values for z can be calculated by replacing Q by Q^* in equation [6] and integrating step by step. Substituting V_{0H}^* for V_0 and substituting for y_1 from formula [7], we can therefore compute Q as a function of T (or η). These improved values for Q are then substituted in equations [10] and [11] whereby a better value V_{0H} is obtained for the flame velocity.

Actually, the difference between V_{0H}^* and V_{0H} is small, V_{0H}^* being about 5% larger than V_{0H} for the 100% ozone gas, while for 50% ozone or less the two quantities are virtually identical.

In the earlier paper, V_{0H} was defined as the flame velocity found for constant enthalpy in the flame zone because for mixtures of low ozone contents our formula [9] corresponds to approximately constant enthalpy. For mixtures rich in ozone, however, this is not so and V_{0H} is simply the value obtained for a linear decrease of y_3 in the entire flame zone. An improved value V_0 can be computed from V_{0H} by dropping assumption [9], as shown in the earlier paper.

Table I shows the values of V_0 as computed by the methods described here, for an initial temperature $T_0 = 298^\circ \text{K}$. (The results for lower ozone contents have been incorporated for the sake of completeness.) The flame temperatures T_f were computed by thermodynamical methods. The table also shows experimental results obtained by Streng and Grosse (4) and by Lewis and von Elbe (1). The results of Streng and Grosse satisfy the linear equation

$$V_0 = 563y_{30} - 88.8 \text{ cm./sec.}$$

TABLE I
FLAME VELOCITIES IN OZONE-OXYGEN MIXTURES

Initial temperature $T_0 = 298^\circ \text{K}$.								
y_{30}	0.25	0.40	0.50	0.60	0.70	0.80	0.90	1.00
T_f ($^\circ \text{K}$.)	1250	1687	1934	2155	2333	2475	2587	2677
V_0^a (cm./sec.)	41	139	214	290	349	386	411	430
V_0^b (cm./sec.)	50	136	190	249	307	362	418	474

T_f ($^\circ \text{K}$.)	1172	1610	1867	2090	2279	2430	2552	2650
V_0^a (cm./sec.)	17.1	70	119	164	204	232	250	260

^a Calculated by the author for $\delta = 0.94$.

^b Calculated from the empirical relation found by Streng and Grosse.

^c Measured by Lewis and von Elbe.

^d $T_0 = 300^\circ \text{K}$, $y_{30} = 0.2466$.

^e $T_0 = 301^\circ \text{K}$, $y_{30} = 0.4005$.

^f $T_0 = 302^\circ \text{K}$, $y_{30} = 0.496$.

It should be mentioned here that the constants in formulae [1] and [2], in particular the energy appearing in the exponent in formula [1], should undergo some modification for the higher flame temperatures. No such adjustments were made in the calculations of Table I because complete experimental kinetic data are not available. The corrected values of V_0 would be a few per cent lower than those shown.

Table I also shows flame velocities calculated by the same method for an initial temperature $T_0 = 195^\circ \text{K}$. (temperature of dry ice).

OXIDATION OF THE ANALYTICAL REAGENT "TIRON" (DISODIUM-4,5-DIHYDROXYBENZENE-1,3-DISULPHONATE)¹

G. F. ATKINSON AND W. A. E. MCBRYDE

ABSTRACT

The analytical reagent "tiron" undergoes oxidation in alkaline solution by the oxygen of the atmosphere to a yellow-colored substance, which is assumed to be the corresponding quinone. In certain circumstances the reagent may be oxidized with production of a green substance believed to be a semiquinone. Interference in the colorimetric determination of iron by means of this reagent may occur in alkaline solution owing to the overlap of the iron III derivative and of the oxidation product. Alkaline solutions of tiron react with iron II salts even in the rigorous absence of oxygen to form the iron III tironate FeR_3^{-9} . Oxygenated solutions of tiron in alkali fail to produce this compound with iron III salts, but do so with iron II salts.

Disodium-4,5-dihydroxybenzene-1,3-disulphonate has been proposed by Yoe and co-workers as a colorimetric reagent for the determination of iron (27), titanium (26), and molybdenum (24), and by these workers has been assigned the trivial name "tiron". It has more recently been proposed as a polarographic reagent in alkaline media for iron (3, 5), vanadium (14), and uranium (4).

The stoichiometry of the reaction with iron III has been investigated by Harvey and Manning (8), by Schwarzenbach and Willi (16), and by Vareille (18) using his ingenious method of isobestic points (17). A magnetic study of the complexes has been reported by Jones and Yeatts (10), and the effect of very high pH on the complex has been discussed by Kuznetsov (11).

The present investigation owes its origin to our observation that in alkaline solutions the same colored species is formed from tiron and iron salts whether the latter are added as iron II or iron III. This observation contradicts the statement by Yoe and Jones (27) that iron II does not interfere in the colorimetric determination of iron III. Our observations suggest that tiron in alkaline solution is suitable for the determination of total iron, and that conditions may be found for the determination of iron III only by the same reagent in more acidic solutions. The latter proposal will not be dealt with in this report beyond noting that the solution constituents present in iron III - tiron solutions in acidic media vary greatly with ionic strength of the solution as well as with pH, as has already been reported (18, 27).

We have endeavored to establish the cause of the yellowing of tiron solutions at high pH which has been reported by Kuznetsov (11) and by Yoe and co-workers (24, 26), and to determine its relationship to the phenomena mentioned above, as well as to other behavior of these solutions.

EXPERIMENTAL

Tiron was obtained from both the LaMotte Chemical Products Co. and Winthrop-Stearns of Canada, Ltd., and was used without further purification. Iron II sulphate was prepared by dissolving a known weight of pure (99.99%) iron wire in hot sulphuric acid in a nitrogen atmosphere. A stock solution was made by dilution with air-free water and stored under nitrogen. Iron III solutions were prepared either by dilution of a

¹Manuscript received November 9, 1956.

Contribution from the Department of Chemistry, University of Toronto, Toronto 5, Ontario.

gravimetrically standardized solution of iron III perchlorate, or by oxidation of a known weight of iron II ammonium sulphate in solution by bromine, followed by boiling with sulphuric acid to expel the bromine. Water was boiled vigorously for five minutes to expel dissolved gases, and either cooled and used fresh, or cooled with nitrogen bubbling through it and stored under a nitrogen atmosphere. Other reagents were used with no special treatment, and solutions were prepared in accordance with standard analytical procedures (21) and with appropriate degrees of precision.

Spectrophotometric studies were made on Beckman Model DU and Model DK-1 spectrophotometers with 1-cm. silica cells, with sensitivity 50 and the small aperture on the DK-1, and with constant sensitivity on the DU. Potentials were measured with a Cenco student potentiometer and Beckman calomel and platinum electrodes. Measurements of pH were made with a Beckman Model G pH meter.

The Yellowing of Tiron Solutions

In a 0.08 *M* aqueous tiron solution yellow color became visible in one or two days, but the color had grown very little more intense after several weeks. The same observations were made on a 0.01 *M* solution having a pH slightly above 5.

When tiron solution was placed in buffers of various pH values so as to give final solutions 0.008 *M* in tiron, those of pH 4 or less remained colorless for several weeks; in less acid buffers up to neutrality a color similar to that of aged stock solution appeared in a short time, and then remained with little change.

In alkaline solutions, especially above pH 9, an intense yellow color formed very rapidly. An absorption spectrum of a yellow solution (0.008 *M*) at pH 12.4 is shown in Fig. 1, together with the curve showing the decrease in transmission of light at 425 μ as the yellow color intensified in the solution.

Alkaline Solutions in Rigorous Absence of Air

Dry tiron and potassium hydroxide were placed in a test tube, and several grams of pyrogallol were spread in the bottom of a vacuum flask in which the test tube was then supported. The flask was repeatedly evacuated with an aspirator pump, and filled to 10 cm. excess pressure with prepurified nitrogen (less than 20 p.p.m. oxygen), which entered through three Fieser towers and one pyrogallol tower. A quantity of air-free 2 *M* potassium hydroxide solution was then added to the pyrogallol through a funnel tube, and the evacuation and filling cycle repeated several times more. Finally, air-free water was forced by nitrogen pressure into the test tube. An almost colorless solution was obtained which remained so for weeks.

The Color Formed with Iron II and III

When the above experiment was repeated with iron II ammonium sulphate also present in the test tube, a blood-red color appeared.

When equivalent amounts of iron II and III salts were respectively added to two portions of alkaline tiron solution, an identical red color appeared in each sample. The absorption spectra were confirmed as being the same both in potassium hydroxide medium of pH 12, and in Yoe's alkaline buffer system of pH about 8.5 (27). The same red color was also formed when base was added to solutions of tiron with iron II and III initially at low pH, and in this case the final red colors were the same although the original solutions were respectively colorless and blue. In another experiment, solutions of the same total

FIG. 1. Absorption spectrum of oxidation product. Curve λ —absorbance of 0.008 M solution. Curve T—growth of absorption peak at 425 $m\mu$.

iron concentration variously apportioned between iron II and III salts were buffered to the same low pH, and the spectra of their various intensities of blue color obtained; they were then uniformly diluted with base and found to give superposable spectra from their identical red colors.

Dissolution of Iron III Hydroxide

When tiron as solid or solution was added to an alkaline solution containing a precipitate of iron III hydroxide, the precipitate dissolved and a red color appeared.

Treatment of Tiron Solutions with Oxygen

Oxygen gas was bubbled through a 0.08 M solution of tiron in 2 M potassium hydroxide for several hours. The yellow solution turned orange, and then red, although thin layers still appeared yellow. Spectra of this final solution diluted 1:2 and 1:5 with alkali showed no new absorption peaks compared to yellow alkaline solutions not treated with oxygen, but merely a broadening of the peaks.

The solution treated with oxygen gave scarcely any color with iron III salts, but the familiar deep red color with iron II salts.

FIG. 2. Charge passed vs. light transmission at 650 m μ . Solid line—immediate measurements. Broken line—delayed measurements.

FIG. 3. Reduction potential vs. pH for tiron solutions.

Anodic Electrolysis of Tiron Solutions

A solution of 0.01 *M* tiron, brought to pH 10 by addition of alkali, was electrolyzed in a bridge-type cell at a 1 in. $\times$ 1 in. cylindrical platinum gauze electrode with very small current. The anolyte, which had been previously treated by bubbling with nitrogen, was stirred with a magnetic stirrer, and portions for spectrophotometric examination were taken at intervals.

The solutions, initially somewhat yellow, changed to a clear green color, related to the appearance of an absorption peak at 650 $m\mu$ and accompanied by a general decrease in transmission throughout the visible range. The smallest transmission at the peak occurred at the point in the electrolysis corresponding to 1 faraday/mole.

Further electrolysis produced a color change to a final golden yellow, and the peak at 650 $m\mu$ vanished.

On standing, solutions having undergone more than 1 faraday/mole of electrolytic oxidation tend to be unstable and to proceed to the final color. Thus, samples from the latter portion of an electrolytic experiment for which spectrophotometric measurements were delayed show higher transmission at 650 $m\mu$. See Fig. 2.

In solutions of pH 13, neither color change nor spectral change was produced by electrolysis at the anode.

FIG. 4. Potentials produced by titration of iron into alkaline tiron solutions.

Effect of pH on Reduction Potential

Three samples of 1.37 millimoles of tiron were taken. To these were added respectively no iron, 0.25 millimole of iron II, and 0.25 millimole of iron III salts, and each was made up to 50 ml. with water. Potassium hydroxide solution was added to each from a burette, and reduction potential and pH were measured at intervals. These results are shown in Fig. 3.

In another series of experiments, known weights of tiron dissolved in potassium hydroxide were individually titrated with iron II and iron III solutions, and the resulting potentials recorded. These are shown in Fig. 4.

Miscellaneous Experiments

The addition of 0.1 *N* potassium permanganate solution to alkaline tiron solution produced precipitation of manganese dioxide. After aspiration of the liquid phase through a filter stick into a clean vessel, it was seen to have a green color. Spectrophotometric study showed the rise and subsequent fall of an absorption peak at 650 m μ as the precipitation and aspiration were several times repeated.

The addition of 30% hydrogen peroxide to the green solution produced by electrolysis resulted in a momentary red color followed by the golden-yellow color. The addition of this same reagent to the original yellow solution decolorized this, however, rather than producing the colors described above.

When an alkaline tiron solution of pH 10 was titrated with 0.1 *N* potassium hexacyanoferrate III solution, the solution gradually became green, and displayed steady potentials at noble metal electrodes until one equivalent of oxidant had been consumed. Then the reduction potential drifted rapidly to more positive values and the solution became yellow. When the drift ceased, very little further oxidation was possible.

DISCUSSION

It is of interest to compare the reactions of tiron (I) with those of the similar and simpler substance pyrocatechol (*o*-dihydroxybenzene).

Pyrocatechol is a powerful reducing agent, especially in alkaline media (23), reducing oxygen at pH 8.5 (20). It can be cautiously oxidized to give *o*-benzoquinone (23). It reacts with iron III to form 1:1, 2:1, and 3:1 complexes in acidic, neutral, and alkaline media, giving respectively green, violet, and red solutions (2). From a polarographic study of the pH - half-wave potential curve for the system *o*-benzoquinone-pyrocatechol, an estimate of E° for this system has been obtained (6). Vaubel has discussed the oxygen uptake of pyrocatechol solutions, and noted that this is approximately constant in strongly alkaline solutions (19). This author states that the final quinone that is produced is yellow, but that complicated intermediates of darker red color may form. Suggested explanations of these intermediates are offered by various authors (1, 7). The general behavior of quinone systems is discussed in several well-known sources (12, 15, 22).

As might be expected, tiron exhibits many similarities to pyrocatechol. It forms 1:1, 2:1, and 3:1 chelate complexes with iron III in particular regions of pH, and the colors of these are blue-green, violet, and red respectively (16). Its solution becomes increasingly reducing at high pH, and absorbs oxygen from the air to become yellow. Oxygen gas bubbling through the alkaline solution produces a dark reddish color.

We believe that the yellow color of alkaline or aged tiron solutions is produced by the

formation of a quinone (III) and that under appropriate conditions this may be formed via a green semiquinone intermediate (II).

When a tiron solution is made alkaline, oxidation being carefully prevented, we expect this reaction to take place immediately:

If oxidation is then permitted to proceed, the following reaction will ensue:

And if conditions favor a process via a semiquinone the latter reaction may alternatively be represented as:

For the more usual yellowing on addition of base, we can write overall:

for which the Nernst equation is:

$$E = E^\circ + \frac{1}{2} \times 0.059 \log \left[\frac{(\text{Bz}^{-2})}{(\text{H}_2\text{Bz}^{-2})} \right] - 0.059 \text{ pH}.$$

Now inspection of the pH-potential curve of tiron from pH 8 to 11 (Fig. 3) shows its slope to be -60 mV/pH unit, but since it was not practicable to obtain an estimate of the concentration ratio involved, no value for E° could be obtained. It may at least be said that this ratio is constant in the region under discussion. The constancy of this ratio in this range is analogous to Vaubel's finding (19) that the oxygen uptake of pyrocatechol is independent of hydroxyl ion concentration. Further, the lower limit of this range is interestingly similar to that reported by Vlcek *et al.* for the oxidation of pyrocatechol by oxygen (20).

The reduction half-reaction accompanying quinone formation is presumably:

Combining [4] and [5] then gives:

In considering the green solutions produced by anodic oxidation during the electrolysis of tiron, it is necessary to invoke reactions [3a] and [3b] rather than [4]. The green semiquinone is formed by the passage of the first equivalent of charge, then converted to the yellow quinone by the passage of the second equivalent. The characteristic spectral feature of the semiquinone species is a prominent peak at $650 \text{ m}\mu$. The fact that the green

color does not appear at pH 13 accords with Remick's statement (15) of the upper limit of pH for semiquinone formation. At this pH, even air accomplishes the two-electron step at once, whereas at less alkaline pH values the two one-electron steps can still be successively carried out.

Since rigorous exclusion of air is necessary to permit the preparation of colorless alkaline solutions, the yellow species is confirmed as being an oxidation product. Thus it appears that tiron when in alkaline media is oxidizable by oxygen but not by water.

Examination of the spectra obtained leads to the conclusion that oxidation with permanganate ion also proceeds via the semiquinone. The reaction of hydrogen peroxide with green solutions forms the quinone, with the momentary red color likely a peroxy-intermediate.

The cyanoferrate III titration parallels the electrolytic experiments in that the addition of one equivalent forms semiquinone, but then this unstable semiquinone spontaneously proceeds by air oxidation to form quinone, and so causes a drifting potential.

Consider now solutions with iron present.

Since the same spectrum is displayed by solutions formed by addition of iron II or III to alkaline tiron solution, these presumably contain the same solution constituent. This conclusion is supported by the spectra of mixed solutions made alkaline being identical regardless of the original iron II to iron III ratio. Also, since the red color with iron II appeared in the rigorous absence of air, oxygen need not be involved in its formation.

The question to be decided, then, is whether the red-colored constituent in these solutions is formed by iron II or iron III. Although it might be supposed that in the strongly reducing medium of an alkaline tiron solution iron III would be reduced, it is more reasonable to interpret the red color in terms of the iron III complex. This must form, in the case of iron II salts where air is carefully excluded, by reduction of water, viz.,

Reaction [7] will be driven forward by the exceptionally large formation constant of the 3:1 complex (16). Concerning the red-colored complex, reference may be made to the work of Jones and Yeatts (10), who concluded from magnetic studies that the complex was one of iron III, and of Williams (25), who noted that its absorption peak occurs at a wave-length in common with a number of other iron III complexes. On this assumption we explain the fact that oxygenated tiron reacts with iron II but not with iron III by the following reactions:

followed by:

There is an unexplained inconsistency between our results and an observation made by Dolezal and Adam (3) in connection with polarographic measurements with tiron. These authors state that in 1 *N* sodium hydroxide solution iron II is completely oxidized in the presence of tiron in 80 seconds. Despite the most careful exclusion of oxygen we observed the instantaneous formation of the red iron III complex when alkaline tiron and iron II salts were mixed.

A slightly alkaline solution of iron-tiron red complex shows a characteristic absorption peak at 480 μ . Now subtracting this spectrum at every point from that of a similar

FIG. 5. Spectra of various iron concentrations in alkaline tiron solutions.

sample at high pH gives a difference curve of the form characteristic of yellow oxidized tiron solutions. So it appears that although high pH does not greatly alter the visible color, and although the red chelate complex still forms in the solution, its useful analytical peak at $480\text{ m}\mu$ is badly masked by the absorption from oxidized reagent. Fig. 5 shows spectra of high pH samples containing various amounts of iron.

The change of electrode potential resulting from addition of iron to alkaline tiron solution (Fig. 4) may be explained thus: addition of iron III presents no possibility of reaction with the already oxidized tiron, so the potential is not altered. Iron II is oxidized with reduction of the quinone form (preferentially to the reduction of water) to tironate ion, and then iron III and tironate react according to reactions [9], [10], and [11]. As this system is established, the potential falls, and then becomes steady.

For the pH-potential curves (Fig. 3), this explanation is offered: with iron III present, the 2:1 complex exists before tiron oxidation begins. As oxidation proceeds slowly in slightly alkaline solution, the complex easily obtains a third unoxidized ligand. When formation of 3:1 complex is complete, the solution will behave like one containing only the excess amount of tiron. Note for example the parallel linear regions. With iron II present, no complex forms until the alkalinity of the system permits reaction [7] accompanied by [8], or [6] followed by [10]. The sharp drop in reduction potential at near

neutral pH, corresponding to the drop shown in Fig. 4, indicates the onset of this process.

The implications of this investigation may be briefly mentioned. It will be apparent that iron II does interfere in the absorptiometric determination of iron III in alkaline tiron solutions, and that this interference cannot be prevented even by the most rigorous exclusion of oxygen. Moreover, there may also be interference due to the formation of an oxidation product of the excess reagent. The formation of this occurs gradually in alkaline solutions, and the more quickly the higher the pH. The presence of this oxidation product will not necessarily be apparent from visual examination of solutions containing the red-colored iron complex, but will add to the light absorption at 480 m μ . Since the procedure for the colorimetric determination of iron by this reagent at pH 8.5 is the more sensitive of the two described by Yoe and Jones (27), it is apt to be the more frequently used, and therefore these interferences should be clearly understood.

If our conclusions regarding the oxidation of tiron in alkaline solutions are correct, some questions are raised concerning the polarographic determination of iron in molar sodium hydroxide proposed by Dolezal and Adam (3). These authors noted that under these conditions a rapid oxidation of iron II occurred (though not instantaneous, as we have mentioned). It seems possible, in view of our observations, that the process taking place at the polarographic cathode is not the reduction of "ferric tironate" to "ferrous tironate", but rather a process involving the quinone-hydroquinone reactions of tiron. Prior to our knowledge of the work of these authors we made a number of polarographic measurements in alkaline tiron solutions, recording waves at about -0.75 and -1.15 v. (vs. S.C.E.), the heights of which gradually increased as the solutions stood longer in air.

Kuznetsov (11) has reported the appearance of a yellow color in iron III-tiron solutions, which he attributes to a change in the intramolecular bonding of the ligand ring. From the evidence in this investigation it may be concluded that this yellow color is due only to oxidized reagent. Similarly, other systems of complexes formed by reagents that undergo oxidation in alkaline solution may exhibit colors that belong to the oxidized ligand rather than to metal-ligand compounds. For instance, Howsmon (9) reported yellow coloring in the system iron III-benzenehydroxamic acid for pH's higher than those at which a red complex formed. Since the work of Page (13), Williams (25), and others suggests that red, violet, and blue should be the characteristic colors of iron III complexes, the appearance of yellow color may indicate that oxidation has occurred in this case also.

LIGHT ABSORPTION STUDIES

PART VII. CONCERNING THE RELATION BETWEEN THE INFRARED CARBONYL STRETCHING BANDS AND ULTRAVIOLET SPECTRA (B-BANDS) IN RING SUBSTITUTED ACETOPHENONES¹

W. F. FORBES AND W. A. MUELLER

ABSTRACT

The B-bands of a number of ring substituted acetophenones were determined. The observed changes are discussed in relation to the nature and position of the substituent group and are compared with the corresponding changes observed in the infrared carbonyl stretching bands.

INTRODUCTION

Infrared absorption spectra, if considered in conjunction with ultraviolet absorption spectra, are of special interest since information may thus be obtained concerning the postulated electronic excited state in transitions resulting in the ultraviolet absorption spectra. This follows, because infrared spectra are conditioned by ground states alone, whereas ultraviolet absorption spectra involve transitions between ground and excited states.

With this in mind, a recent investigation (21) of the positions, integrated absorption intensities, and widths of the carbonyl stretching bands in carbon tetrachloride solution has indicated that it is possible to rationalize the observed behavior of most of these spectra in an ad hoc fashion, by considering the effect of the following factors on the distribution of electrons in and around the C=O linkage:

- (a) Mesomeric effects;
- (b) Inductive effects and electrical field effects;
- (c) Steric effects;
- (d) Hydrogen bonding and other environmental factors.

The inherent difficulties and limitations of this treatment were then stated, and although these are clearly of the greatest importance, they will not be discussed again at this stage.

The present paper is intended to develop the basic discussion initiated in the previous investigation, using not only carbonyl stretching frequencies, but also the data obtained for B-bands in ultraviolet absorption spectra. In the following discussion, the above-mentioned factors will be treated separately, together with the information deducible from each of the electronic interactions.

MESOMERIC EFFECTS IN INFRARED AND ULTRAVIOLET ABSORPTION SPECTRA

In the B-bands of ultraviolet spectra definite shifts to longer wavelength are consistently obtained on introducing a substituent in the benzene molecule, or on introducing a parasubstituent in a monosubstituted benzene derivative. These shifts are generally in the order of the mesomeric effects of the substituents (cf. Table I). Further, mesomeric interactions have been postulated to affect the B-bands mainly by altering the energy level of the electronic excited state (9, 16).

¹Manuscript received December 5, 1956.

Contribution from the Memorial University of Newfoundland, St. John's, Newfoundland.

This led to the observation that the mesomeric (or resonance) effects of the halogens may well be in the order $-\text{I} > -\text{Br} > -\text{Cl} > -\text{F}$ (16). The apparent lack of consistent variation in a number of other data (for example, dipole moment data) describing the different para halogen-substituted compounds was ascribed to these data being conditioned by ground states alone. Consequently the insensitivity of the carbonyl band* (ν_{max}) to para halogen substituents provides an additional example of this kind and suggests that in the ground state there is some compensatory action to the operation of the mesomeric effect, and/or that the latter effect is of less importance in the ground state than in the electronic excited state. These hypotheses are illustrated in Table I, which shows that the carbonyl bands for para halogen-substituted acetophenones are similar to each other and to the parent compound.

TABLE I

¹Ref. 21.

On the other hand, the same halogen derivatives show significant intensity differences in the carbonyl band, with the intensity decreasing in the sequence

Since integrated absorption intensities are apparently related to resonance energies (1), this again suggests that the mesomeric effect is strongest for iodine and weakest for fluorine.

More generally, a decreased carbonyl stretching frequency, for example in the *p*-amino and *p*-methyl derivatives, is often paralleled by a similar increase in the intensity of the carbonyl band, and *qualitatively* the B-band in the ultraviolet region also shows a comparable shift, i.e. a bathochromic shift accompanied by increased absorption intensity. Further, as the carbonyl stretching frequency is raised, as in the extreme example of *p*-nitroacetophenone, this is accompanied by a reduced intensity in the carbonyl band. However, the ultraviolet absorption of *p*-nitroacetophenone is shifted to *longer* wavelength and is intensified (see Table I), presumably because resonance contributions *lower* the electronic excited state, whereas the energy of the ground state is raised.

The different effect in the two bands, which is not confined to this one example, illustrates the lack of even semiquantitative correlation between the carbonyl stretching

*The band due to the infrared carbonyl stretching frequency will be referred to as the "carbonyl band" throughout this paper.

frequencies, the intensities of the carbonyl band, the B-band in the ultraviolet, and its absorption intensity (see the four columns in Tables I and II). An explanation consistent with the observations may be provided by the following considerations:

(i) Carbonyl stretching frequencies are determined by a number of factors (see Introduction), which probably interact with one another in a complex manner (cf. 21).

(ii) The intensities of the carbonyl bands suggest a more promising approach since these are apparently predominantly determined by the resonance energy of conjugation in the ground state, and this hypothesis may be extended to explain the anomalously low intensities of *m*-fluoro-, *o*-methyl-, and *m*-chloro-acetophenones (21). Also Table II shows that integrated absorption intensities of para and ortho compounds are greater than for the corresponding meta isomers except for nitroacetophenones, where the reverse effect is observed. This is consistent with Barrow's contention that the carbonyl band intensity is related to the resonance energy of conjugation.

(iii) The maxima of the B-bands in ultraviolet spectra may be correlated, as a first approximation, by considering only mesomeric interaction in the electronic excited state and steric effects. Apparently inductive and electrical field effects do not appreciably alter the wavelength of maximal absorption. (For example, an *o*-fluoro substituent generally does not appreciably affect the B-band maximal wavelength.) Hydrogen bonding and solvent-solute interactions also are normally only of little importance in

determining the maximal wavelength, and will frequently alter only the intensity values (17).

(iv) This sensitivity of intensity values in the B-band of ultraviolet spectra, as well as their sensitivity to small steric effects (12, 13, 14), indicates that intensity values (ϵ) also will not be directly proportional to the other values discussed.

It may be concluded that a direct relation between the four parameters would not be expected, nor is in fact observed. Nevertheless, in extreme examples, for instance in the presence of powerful mesomeric interactions, some correlation between the four parameters may well be obtained.

INDUCTIVE AND FIELD EFFECTS IN INFRARED AND ULTRAVIOLET ABSORPTION SPECTRA

It was implied in the previous section that inductive effects determined by nuclear charges acting along bonds, and electrical field effects associated with charges acting across space, are both of less importance in determining B-bands in ultraviolet spectra than in determining carbonyl bands. If this is correct it should follow that certain changes, mostly in the immediate environment of the carbonyl group, which hardly affect the ultraviolet spectrum, may occasionally alter appreciably the carbonyl band. This type of change is in fact apparent for a number of examples. Thus, comparing the ultraviolet and infrared spectra for series of compounds $C_6H_5.CO.X$ and $C_6H_5.CO.CH=CH.X$, Fuson, Josien, and Shelton (18, cf. also 3) found that in a number of examples, the carbonyl bands were shifted by different amounts, whereas the ultraviolet spectrum remained almost identical.

This hypothesis is also consistent with the following observations:

(i) A nitro group in either the meta or para position brings about a significant change in the carbonyl band (see Table II). This change is ascribed to the nitro group deactivating the benzene ring so that the carbonyl stretching frequency is increased to 1700 cm.^{-1} , near to that of an aliphatic ketone. Since the deactivation is almost identical in both para and meta isomers as indicated by the similar location of the carbonyl bands and incidentally also by similar melting points (see experimental section), the deactivation is probably—at least partly—inductive in character. Certainly the effect of the interaction on the B-band in the ultraviolet is quite different, as would be anticipated if the B-band were less dependent on inductive type interactions. This interpretation also explains why the absorption intensity of the carbonyl band of *p*-nitroacetophenone is low (namely because of deactivation decreasing the percentage of dipolar forms in the ground state), whereas the absorption intensity in the B-band of the ultraviolet (which depends primarily on the energy requirements in the electronic excited state) is high.

(ii) The decreased absorption intensity in the carbonyl band of *m*-fluoro- and *m*-chloroacetophenone may be explained in terms of what is essentially a field effect (17), and this explanation may also account for the low intensity of the carbonyl band in *o*-methylacetophenone. Consequently the hypothesis of decreased importance of inductive and field effects in the ultraviolet spectrum indicates why some of the above-mentioned effects are not as readily detected in the B-band.

STERIC EFFECTS IN INFRARED AND ULTRAVIOLET ABSORPTION SPECTRA

Resonance interactions are known to operate more effectively if the substituents at the double bonds lie in the same plane. Hence it would be expected that steric interactions,

especially those associated with van der Waals repulsions between vicinal non-bonded atoms, also influence both spectra. Further, since mesomeric interactions are of greater importance in the B-band of ultraviolet spectra, steric effects would be expected to contribute to a greater extent in these spectra.

This is actually observed and it has also been noted that steric effects in the B-band of ultraviolet absorption spectra can conveniently be classified into three types (6, 12, 13, 14). Using this classification it was shown that a small steric effect frequently causes only a change in absorption intensity (ϵ). This was ascribed to the energetically most favorable interplanar angle of the ground state being altered, without affecting the energy levels of either ground or excited state (or at least those sections thereof which are involved in the transitions) (6, 14). An identical effect (i.e. loss of absorption intensity) would clearly be produced if only the most favorable interplanar angle of the excited state alters, with the energy levels again remaining approximately the same. The two possibilities are illustrated in Fig. 1, and infrared spectra should, in theory at least, help to distinguish between them.

A similar uncertainty, namely whether the energy changes caused by steric effects

FIG. 1. Schematic representation of electronic transitions between ground and excited states; with (Top) steric hindrance affecting chiefly the ground state and (Bottom) steric hindrance affecting chiefly the excited state.

occur mainly in the ground or excited state, applies to larger steric effects. In the B-band of ultraviolet absorption spectra these steric interactions cause wavelength changes accompanied by changes in the absorption intensity. This type of steric effect also occurs most frequently (13), and usually the energy level of the excited state is raised more than the energy level of the ground state, thus causing a hypsochromic shift. However, if the energy level of the ground state is raised more than that of the excited state, or if the energy level of the electronic excited state is lowered relative to the ground state, then a bathochromic shift will be observed.

Infrared spectra should again help to distinguish between these possibilities and should similarly help to confirm the interpretation of large-type steric effects in which conjugation is apparently completely inhibited and the molecule absorbs as two distinct entities. This may be steric inhibition of π - π conjugation, for example, in 2,3,5,6-tetramethylacetophenone; or steric inhibition of π - σ or π - p conjugation, as for example in certain orthosubstituted compounds, where the orthosubstituent has no appreciable effect on the B-band of the ultraviolet spectrum (cf. 13, 17).

Proceeding now to actual examples, the effect of slight steric interactions on both carbonyl bands and B-bands has recently been investigated. Braude and Timmons (7) showed that for a number of alicyclic ethylenic ketones, the carbonyl stretching frequency increased roughly in proportion to the loss of absorption intensity (i.e. the steric hindrance) as shown from ultraviolet spectra (see Table III).

This relation may be explained by assuming that steric interactions alter the energetically most favorable interplanar angle in the ground state (cf. 14) and consequently only some vibrational states in the hindered molecules (those in planar or near-planar conformations) contribute to the observed ultraviolet absorption intensity, whereas al

²In carbon tetrachloride solution; unfortunately the carbonyl stretching frequencies are not determined under identical conditions, and this clearly introduces some uncertainty. However, the argument as developed in the text is hardly affected by this.

the vibrational states contribute to the observed carbonyl band. Therefore, although the mean transition energy for allowed transitions leading to the ultraviolet absorption remains approximately constant, the transition probability decreases with increased steric interaction. Further, the different vibrational ground states (which include those sufficiently hindered so as not to lead to transitions to electronic excited states) will cause the observed carbonyl stretching frequency to vary as the percentage of coplanar conformations decreases. It should be noted that the data could *not* be explained in terms of steric hindrance, which would predominantly affect the interplanar angle of the excited state. The latter hypothesis could account for the ultraviolet absorption, but should lead to a similar carbonyl stretching frequency for the four compounds listed in Table III (see also Fig. 1).

In compounds which give rise to larger steric effects (wavelength shifts) in the ultraviolet (see Table II and also Table IV, example i), a corresponding carbonyl band shift (i.e. to higher frequency) is also frequently observed. Further, if in the ultraviolet an almost complete inhibition of conjugation occurs, the observed carbonyl stretching frequency tends towards that of a saturated carbonyl group (see Table IV, example iii).

The following additional observations concerning steric interactions in the two bands may also be noted:

(i) The frequent similarity in the effects produced in both spectra is not unexpected because effective interference radii are often sufficiently large (cf. 15) to cause an appreciable interplanar angle between the two parts of a molecule in conjugation. This angle reduces conjugation in the ground state and, since the interplanar angle does not alter

⁴Carbon tetrachloride solution (see Table II).

during electronic excitation from the ground to excited state (Franck-Condon principle), it also reduces conjugation in the electronic excited state. Further, in the excited state the attaining of a similar interplanar angle usually requires more energy, and consequently the steric effect is normally enhanced in the ultraviolet region.

(ii) The few examples mentioned do not rule out the possibility that examples may exist where steric interactions affect mainly the most favorable interplanar angle in the electronic excited state (see Fig. 1); however, this is unlikely.

(iii) Examples occur in a number of $\alpha:\beta$ -unsaturated ketones where the change from a five- to a six-membered ring compound is accompanied by *either* a hypsochromic *or* a bathochromic shift (30). The question then arises, if on passing from a five- to a six-membered ring compound, the carbonyl frequency change may be in the reverse order from the changes occurring in the B-band of the ultraviolet spectrum. This question cannot as yet be decided, since few examples are available. One possible example is suggested in Table IV, example ii, but since the readings were determined under different conditions, no generalization is justified at this stage. (The possible changes are also illustrated in Fig. 2.)

FIG. 2. Schematic representation of hypothetical electronic transitions in ring compounds.

Further possible examples are provided by the spectra of more rigid systems (cf. 2, 30, 33), where it might be anticipated that occasionally the infrared band is moved towards shorter wavelength (higher frequency) whereas in the ultraviolet a shift to longer wavelength is observed (see Fig. 2).

(iv) Certain steric interactions in the ultraviolet give rise only to intensity changes. These effects are useful in determining permitted planar conformations in solution (14), and cannot so readily be detected in the carbonyl bands. Also, loss of conjugation appears to be more readily discernible in the ultraviolet, because in the ground state there is usually some residual conjugation even if the interplanar angle is large. For example, the carbonyl band of 2,3,5,6-tetramethylacetophenone (1704 cm^{-1} in carbon tetrachloride solution), although indicating considerable hindrance, has still not attained the frequency of a

saturated ketone ($1717 \pm 3 \text{ cm}^{-1}$ in carbon tetrachloride solution (18)). This follows, since transitions to excited states in the ultraviolet are no longer possible once the interplanar angle in the ground state exceeds a certain critical value and hence the B-band will show apparently complete loss of conjugation (see Fig. 1).

From this, one may conclude that steric effects may frequently be more easily identified in ultraviolet spectra. More generally, although carbonyl bands have the inherent advantage that consideration of the ground state only is necessary, steric effects are less easily detected in the carbonyl band because more interactions contribute to what determines the absorption of the ortho isomer. Thus the frequency of the carbonyl band in ortho isomers has been shown to give rise to a variety of effects (21) and the simpler pattern of the B-band is no longer evident. Intensity changes in the carbonyl band are also affected by steric interactions, but again other interactions are clearly evident (see below).

THE EFFECT OF HYDROGEN BONDING AND OTHER ENVIRONMENTAL FACTORS IN INFRARED AND ULTRAVIOLET ABSORPTION SPECTRA

Under this heading we may briefly discuss the effect of inter- and intra-molecular hydrogen bonding as well as the effect of solvent-solute interactions on the four parameters under discussion (i.e. the positions of the two absorption bands and their respective intensities).

It will be shown in a separate communication that intermolecular hydrogen bonding frequently affects the intensity but not the location of the maximal wavelength in the B-band (17). In the absorption intensity of the B-band this effect is very pronounced and there is some evidence that a similar interaction also occurs in infrared spectra, that is, a decreased force constant causing a lower frequency in the carbonyl band corresponding to the higher intensity in the B-band (cf. 18, 19, 27). The effect of intermolecular hydrogen bonding on the intensity of the carbonyl band does not appear to have been investigated. However, since this type of interaction sometimes almost doubles the absorption intensity of the B-band (17), it is possible that intermolecular hydrogen bonding or association accounts for some of the "anomalous" intensity values of the carbonyl band (for example, the relatively high value of *p*-methylacetophenone).

This suggestion also seems probable because *intramolecular* hydrogen bonding appears to be normally more pronounced for the carbonyl band than for the B-band. This can be illustrated from the data in Table II, where for two examples, *o*-methylbenzaldehyde and *o*-aminoacetophenone—presumably because of intramolecular hydrogen bonding—the frequency of the carbonyl band is considerably lowered compared to the para isomer (cf. also 29). In contrast, for the B-band the frequency of the ortho isomer is consistently raised (i.e. the wavelength is lowered) and the absorption intensity is decreased compared to the corresponding para isomer.

Lastly, general solvent-solute interaction may affect all the parameters, but again there is some evidence that the changes produced are normally more pronounced for the carbonyl band than for the B-band. For example, the carbonyl band of acetophenone occurs in chloroform solution at 1685 cm^{-1} with an integrated absorption intensity of 2.7 units, whereas the corresponding value for carbon tetrachloride solution is 1692 cm^{-1} with an integrated absorption intensity of 2.1 units (1, cf. also 18). Although the actual comparable values for the ultraviolet are not available, it seems improbable that a similar degree of change would occur for the B-band on changing the solvent in a similar manner.

CONCLUDING REMARKS

One of the aims of correlating frequency (wavelength) shifts and intensity changes in absorption spectra is to establish how different electronic interactions affect any particular absorption band. As a result of this and previous studies we may conclude that the wavelength changes in the B-band of ultraviolet absorption spectra are normally caused mainly by steric and mesomeric interactions, since inductive and hydrogen bonding effects are in general relatively less important. Consequently for para-disubstituted benzene derivatives, where in addition steric effects will be small, mesomeric interactions will usually be mainly responsible for the observed changes. Therefore the position of the B-band in ultraviolet spectra appears to be a good measure of mesomeric effects, that is of effects associated with electron mobility acting along systems of conjugated bonds.

A number of corollaries follow from this. Firstly, the mesomeric effect of the halogen atoms is probably, as previously suggested, in the order $-I > -Br > -Cl > -F$, and this is also supported independently from the intensity values of the carbonyl band. Secondly, the values of the mesomeric effects thus obtained from ultraviolet spectra should relate at least semiquantitatively for different series of compounds (e.g. acetophenones, nitrobenzenes, and other compounds). Thirdly, since the change in *p*-methylacetophenone is greater than the change in *p*-fluoroacetophenone (both compared to acetophenone) it suggests that the wavelength change due to the methyl group in the B-band of the ultraviolet spectrum is caused predominantly by a hyperconjugative effect.

The relatively lesser importance of mesomeric interactions on the frequency of carbonyl bands is readily illustrated since parasubstituents methyl, fluorine, chlorine, bromine, and iodine do not appreciably affect the carbonyl stretching frequency in acetophenone. There is some evidence that mesomeric interactions affect the intensities of the carbonyl bands, but the changes obtained are not proportional to those in the ultraviolet spectra, because the former are caused entirely in the ground state, whereas the latter are determined predominantly in the electronic excited state.

It may also be noted that the intensities of the carbonyl bands, the wavelength of maximal absorption in the B-band, and to a lesser extent the carbonyl stretching frequencies all support the concept of spectra in terms of resonance theory. Molecular orbital theory provides a slightly different picture, but the over-all results are qualitatively similar as has previously been noted by Nagakura (26).

Steric effects occur in both types of spectra, but the interactions are usually more evident in the B-band of ultraviolet spectra. This follows because although the ground state determines the interplanar angle, the repulsion energy set up between vicinal atoms is normally greater in the electronic excited state. There is also some evidence that for orthosubstituted acetophenones, in the carbonyl band, the inductive effect, field effects, and hydrogen bonding play a more important part.

The steric effects, as shown in the spectral properties, are also evident in some of the reactions employed in the preparation of compounds. For example, yields of ortho derivatives in halogen-substituted acetophenones are smaller (see Table V). Further, the refractive indices for fluoro- and chloro-acetophenones also indicate an order para > meta > ortho, and it seems probable that this order is conditioned by steric effects, at least to some extent.

EXPERIMENTAL

The ultraviolet absorption spectra were determined in quartz cells of 1 cm. path-length using a Unicam SP 500 spectrophotometer. For each compound at least two independent sets of observations were made. Some of the spectra have already been described in previous parts of this series.

The physical constants, after purification, of compounds not previously reported in this series are listed in Table V.

TABLE V
PHYSICAL CONSTANTS OF CARBONYL COMPOUNDS

Carbonyl compound	Melting point, or boiling point and refractive index	Yield	Reported value of physical constants
<i>o</i> -Methylbenzaldehyde	B.p. 55°, 3 mm., $n_D^{22.5}$ 1.5480	40%	B.p. 94°, 10 mm., n_D^{19} 1.549 (20)

o-Methylbenzaldehyde was prepared from *o*-tolyllithium and dimethylformamide by the method of Sicé (31). *p*-Methylbenzaldehyde was prepared by the standard Gattermann-Koch reaction. Both benzaldehydes were purified by vacuum distillation.

o-Methylacetophenone was prepared by the method previously described (12).

The fluoroacetophenones, *o*-chloroacetophenone, and *o*-bromoacetophenone were prepared from the corresponding acid chlorides by treatment with an excess of dimethylcadmium (cf. 8). Purification was effected by distillation *in vacuo*.

m-Chloroacetophenone was obtained by diazotization of *m*-aminoacetophenone, followed by the standard Sandmeyer procedure. The compound was purified by vacuum distillation.

p-Bromo- and *p*-iodoacetophenones were obtained by Friedel-Crafts acetylation of the halogen-substituted benzenes using acetyl chloride and aluminum chloride. Purification was effected by crystallization and vacuum sublimation.

o-Aminoacetophenone was obtained by reduction of *o*-nitroacetophenone with tin and hydrochloric acid, and purified by vacuum distillation.

The remaining acetophenones were purified from the commercially available compounds. *m*-Nitro- and *p*-nitroacetophenones were vacuum sublimed, and *p*-chloroacetophenone was purified via the semicarbazone.

ORGANIC DEUTERIUM COMPOUNDS

XVIII. ADDITION PRODUCTS OF HYDROGEN AND DEUTERIUM BROMIDES TO 1,1-DICHLOROETHYLENE¹

J. E. FRANCIS AND L. C. LEITCH

ABSTRACT

The addition of hydrogen bromide to 1,1-dichloroethylene under ultraviolet illumination gave two products identified as 1-bromo-2,2-dichloroethane and 1-bromo-2,2,4,4-tetrachlorobutane. With deuterium bromide, the corresponding deuterated halides were formed. 1-Chloroethene-1-*d* was prepared from 1-bromo-2,2-dichloroethane-2-*d*.

In connection with the synthesis of deuterium-labelled vinyl chloride it became necessary to investigate the addition of hydrogen bromide to 1,1-dichloroethylene. Under ultraviolet irradiation, reaction took place readily to give two compounds. The chief product was 1-bromo-2,2-dichloroethane, which was identified by its conversion into vinyl chloride on treatment with zinc dust in ethanol. A second compound, which sometimes comprised up to 30% of the yield, was isolated from the residue by distillation under reduced pressure. The high boiling point, density, and index of refraction of the by-product indicated it might be a polyhalobutane. Its proton magnetic resonance spectrum revealed the presence of two non-adjacent methylene groups. Structure I is consistent with this observation.

I

It is conceivable that the by-product might be formed by the following homolytic mechanism:

It is consistent with Haszeldine's observation that CF_3 radicals always add to the CH_2 end of $\text{RCH}=\text{CH}_2$ when $\text{R} = \text{CH}_3, \text{Cl}, \text{F}, \text{CO}_2\text{CH}_3, \text{CF}_3$, or CN (4). Also, one of us has already reported that the addition of hydrogen bromide to trichloroethylene is very slow (5).

Proof of the structure I was obtained by the following series of degradations. Dehalogenation with zinc dust in ethanol proceeded vigorously to give a compound with the physical constants of a trichlorobutene—provisionally $\text{CH}_2=\text{CClCH}_2\text{CHCl}_2$. When the latter was stirred with 80% sulphuric acid it dissolved with evolution of copious fumes of hydrogen halide. On dilution of the reaction mixture with water a solid separated which, after purification, melted at 160–161° C. It was neutral and contained no halogen. Comparison with 1,3,5-triacetylbenzene prepared as in reference (3) showed the two substances were identical.

Addition of HBr to CH₂=CCl₂

1,1-Dichloroethylene (20.0 ml., 24.2 g.) was distilled on the vacuum line into a 500 ml. round-bottomed Pyrex flask containing a magnetized stirring bar. Hydrogen bromide (6.0 ml., 16.6 g.) was distilled into the line until the pressure was nearly one atmosphere. Absorption of hydrogen bromide took place only after the reaction flask was irradiated with ultraviolet light, and then only at the rate of about 1 ml. of liquid hydrogen bromide (measured at -78°C.) per hour. After 18 hours' irradiation, absorption ceased. Unreacted hydrogen bromide and dichloroethylene were then pumped off. The reaction mixture was diluted with 30 ml. of methylene chloride, washed with 5% sodium bicarbonate, and dried over anhydrous potassium carbonate. The product was distilled in a column filled with glass helices. After the methylene chloride was distilled off, the temperature rose rapidly to 134°C. The yield of product, b.p. $134\text{--}135^{\circ}\text{C.}$, n_{D}^{25} 1.5054, was 22.4 g. (61.5%).

The residue was distilled under reduced pressure in a short Vigreux column. It came over almost entirely between 56° and 57°C. under 0.25 mm., n_{D}^{20} 1.5349, n_{D}^{25} 1.5325. The yield was 16.2 g. (31.6%). Calc. for $\text{C}_4\text{H}_5\text{BrCl}_4$: C, 17.4%; H, 1.82%. Found: C, 17.0%; H, 1.86%.

In later experiments the reaction was carried out in a 500 ml. round-bottomed quartz flask. Addition of hydrogen bromide took place much more rapidly but the yield of high-boiling by-product was much lower. Slow addition of hydrogen bromide appears to favor a higher yield of the halobutane.

Degradation of I

The compound (4.0 g.) was stirred under a reflux condenser in 15 ml. of ethanol with 2.0 g. of zinc dust. In a minute or two a vigorous reaction took place. After it had been stirred for half an hour longer the alcohol and other volatile material were pumped off and condensed in a stock trap cooled to -78°C. in dry ice and acetone. The distillate was poured into 50 ml. of water and the oil extracted with 10 ml. of methylene chloride. After the solution had been dried over calcium chloride to remove alcohol and water the solvent was evaporated and the residue distilled into a trap on the vacuum manifold under 0.1 mm. pressure. The yield of distillate, b.p. $125\text{--}127^{\circ}\text{C.}$, n_{D}^{20} 1.4770, was 1.7 g.

The product was shaken at intervals with 5.0 ml. of conc. sulphuric acid diluted with 1 ml. of water. Copious fumes of hydrogen halide were evolved. After a day the dark sirupy liquid was diluted to 20 ml. with water and allowed to stand in the refrigerator. The pale yellow precipitate that separated was filtered off and recrystallized from dilute ethanol, using carbon black to decolorize the solution. Small white plates, m.p. $160\text{--}161^{\circ}\text{C.}$, separated on cooling. The substance was neutral and gave a negative Beilstein test.

1,3,5-Triacetylbenzene

The compound was prepared as described in Organic Syntheses (3) scaled down to 1/50. The product melted at $160\text{--}161^{\circ}\text{C.}$ alone and on admixture of the degradation product derived from I. The latter is therefore almost certainly 1-bromo-2,2,4,4-tetrachlorobutane.

Oxidation of the Trichlorobutene

Trichlorobutene (2.7 g.) was stirred with 100 ml. of 2% aqueous potassium permanganate at room temperature. Solid potassium permanganate was added in small portions (1.0 g.) until the purple color persisted after the stirring had been continued for half an hour.

Excess permanganate was destroyed by adding a drop or two of the chloro compound and again stirring. The manganese dioxide was filtered off and the filtrate evaporated nearly to dryness under reduced pressure. The residue was acidified with 12 *N* sulphuric acid and extracted with 50 ml. of ether. The ether solution was dried over anhydrous sodium sulphate and then freed of solvent. When the last traces of ether had been removed under reduced pressure the yellowish residue crystallized. It was purified by recrystallization from petroleum ether, m.p. 54° C., yield: 0.5 g.

The neutralization equivalent of the acid was determined by titrating 0.2080 g. with *N*/10 sodium hydroxide using phenolphthalein as indicator. The volume of alkali consumed was 14.3 ml. Neutralization equivalent, 145. Calc. for $\text{CHCl}_2\text{CH}_2\text{CO}_2\text{H}$, 143.

β,β -Dichloropropionic acid is reported to melt at 56° C. (7). The chloro-olefin is therefore 2,4,4-trichloro-1-butene, $\text{CH}_2=\text{CClCH}_2\text{CHCl}_2$.

Addition of DBr to $\text{CH}_2=\text{CCl}_2$

The experiment was carried out essentially as described for the light compound. 1-Bromo-2,2-dichloroethane-2-*d* was isolated in 64% yield. The deuterated halobutane was also isolated from the reaction mixture as already described.

1-Chloroethene-1-d

1-Bromo-2,2-dichloroethane-2-*d* (4.7 ml., 6.0 g.) was added slowly dropwise to a boiling suspension of zinc dust (10 g.) in 40 ml. of ethanol. The vinyl chloride evolved from the condenser was condensed in a spiral trap cooled to -78° with dry ice and acetone. The yield was 2.3 g. Its Raman spectrum was examined by Evans and Bernstein (1).

ACKNOWLEDGMENTS

We wish to thank Dr. H. J. Bernstein for examining and interpreting the magnetic resonance spectrum of one compound and Mr. H. Seguin for its analysis.

THE INFRARED CARBONYL STRETCHING BANDS OF RING SUBSTITUTED ACETOPHENONES¹

R. NORMAN JONES, W. F. FORBES, AND W. A. MUELLER²

ABSTRACT

An examination has been made of the carbonyl stretching bands in the infrared spectra of acetophenone derivatives substituted in the aromatic nucleus. The positions, integrated absorption intensities, and widths of the bands have been measured in carbon tetrachloride solution. The variation of these quantities is discussed in relation to the nature and position of the substituent group.

INTRODUCTION

The C=O stretching band in the infrared spectra of carbonyl compounds occurs normally between 1850 and 1650 cm^{-1} . Its position in this range depends primarily on the force constant of the C=O bond, and only to a lesser extent on the masses attached to the carbon atom. The C=O force constant is determined by the distribution of electrons in and around the linkage. At present it is not possible to evaluate this electron distribution accurately by quantum mechanics, although some studies directed to this end have been made (4). Experimentally some insight into the problem can be gained by comparison of the bands in series of related compounds, and pending the development of an adequate quantum mechanical treatment we can discuss the influence of small changes in molecular structure on the C=O frequency in terms of the following factors:

- (a) Mesomeric effects associated with electron mobility acting along systems of conjugated bonds.
- (b) Inductive effects determined by nuclear charges acting along the bonds.
- (c) Electrical field effects associated with nuclear charges acting on the C=O bond across space.
- (d) Steric effects, especially those associated with van der Waals repulsions between vicinal non-bonded atoms.
- (e) Hydrogen bonding.
- (f) Other environmental factors, notably solvent-solute interactions in solution and lattice forces in crystals.
- (g) Mass effects of α -substituents.

It is convenient to treat these factors as though they acted independently on the carbonyl group, but they must, in fact, interact with one another in a complex manner.

This paper is concerned with the spectra of acetophenone derivatives substituted at the ortho, meta, and para positions. The positions of the absorption maxima, the integrated absorption intensities, and the widths of the C=O stretching bands have been measured in carbon tetrachloride solution; the effects of the type and position of the substituent on these quantities are analyzed qualitatively in terms of the factors (a)-(g) outlined above.

EXPERIMENTAL

The spectra were measured in carbon tetrachloride solution in a 1 mm. cell using a Perkin-Elmer Model 112 double pass single beam spectrometer. A calcium fluoride prism was used providing a computed spectral slit width (S') of 1.6 cm^{-1} (11(a)). The values reported for ν_{max} are accurate to $\pm 1 \text{ cm}^{-1}$. The integrated absorption intensities (A) are reported in units of $\text{mole}^{-1} \cdot \text{liter} \cdot \text{cm}^{-2} \times 10^4$ and were calculated from the equation

$$A = K(1/cl) \log_{10}(T_0/T)_{\text{max}} \cdot \Delta\nu_{\frac{1}{2}} \times 2.303 \times 10^{-4}$$

where c is the concentration in moles per liter, l the cell length in cm., $\log_{10}(T_0/T)_{\text{max}}$ the optical density at the absorption maximum, and $\Delta\nu_{\frac{1}{2}}$ the band width in cm^{-1} at half maximal intensity. K is a constant dependent on the ratio $S'/\Delta\nu_{\frac{1}{2}}$. Ramsay has shown (10, 12) that for bands which conform to a Lorentz curve shape K may be taken as $\pi/2$, provided $S'/\Delta\nu_{\frac{1}{2}} < 0.2$. In these spectra the narrowest band width was 8.6 cm^{-1} (Table IV) giving a ratio of 0.187 for $S'/\Delta\nu_{\frac{1}{2}}$. It was therefore assumed that the finite slit effect could be neglected and A was computed on the basis of $K = \pi/2$. In a few compounds (*o*-nitro, *o*-chloro, and *o*-bromo derivatives) the band was resolved into a doublet and the intensities were computed by numerical integration following Ramsay's Method II (10, 12). Intensities were computed separately for three solutions of each compound, and both the individual and mean results are given in the tables. A Perkin-Elmer heated cell assembly was used to obtain the spectra of the liquids at elevated temperatures.

The compounds, if not commercially available, were prepared at the Memorial University of Newfoundland by standard methods described in the literature, and purified by fractional crystallization, vacuum distillation, vacuum sublimation, or combinations of these techniques. Sample purity was checked by refractive index measurements.

RESULTS AND DISCUSSIONS

The compounds investigated contained methyl, fluoro, chloro, bromo, iodo, nitro, and amino groups. For acetophenone the maximum was observed at 1691 cm^{-1} with intensity 2.20 units. This is in good agreement with Barrow (2), who reported 1692 cm^{-1} for ν_{max} and 2.1 units for the intensity. Soloway and Friess (13) and Fuson, Josien, and Skelton (8) have also measured the band positions for several *m*- and *p*-substituted acetophenones, but no studies of the band intensities have been previously reported.

Parasubstituted Acetophenones

The values for ν_{max} and A obtained for the parasubstituted compounds are given in Table I. The lowest frequency is observed for the *p*-amino group and the highest for the *p*-nitro group. Para halogenation has little effect on the band position. In Fig. 1, ν_{max} is plotted against the Hammett reactivity constant (σ_p) and the linearity of this relationship agrees with similar observations of earlier investigators (3, 8, 13) in demonstrating that the same combination of factors is responsible for both the shift in C=O stretching frequency and the reactivity. This is presumably the over-all electronegativity of the substituent, i.e. the algebraic sum of the mesomeric and inductive effects. Substituents like the *p*-amino group which force electrons into the benzene ring to stabilize the quinonoid structure I will reduce the double bond character of the C=O bond and lower the frequency.

FIG. 1. Plot of $\nu_{\max}$ against Hammett's σ_p for parasubstituted acetophenones. 1—NH₂; 2—CH₃; 3—H; 4—F; 5—Cl; 6—Br; 7—I; 8—NO₂.

The shift of -4 cm.⁻¹ produced by the *p*-methyl group must be due to inductive and/or hyperconjugative effects, and the shift of $+9$ cm.⁻¹ for the nitro group to mesomeric and inductive effects reinforcing to withdraw electrons from the ring. The inductive and mesomeric effects of the halogen substituents are of opposite sign and the insensitivity

of the C=O frequency to these substituents must result from this compensatory action.

Comparison of the maximal frequencies and the intensities in Table I does not suggest that there is any simple relation between the intensity and frequency shifts. It is notable that the halogen derivatives show significant intensity differences among themselves, the band in the *p*-iodo compound being 0.22 unit stronger than the *p*-fluoro band, with the intensity increasing in the sequence $F < H < Cl \sim Br < I$.

The failure of the band intensities to vary in the same sequence as the band frequencies must indicate that they are subject to a different combination of controlling effects. For the band positions we have evidence from the parallelism with the Hammett constants that the over-all electronegativity ($M + I$ effect) of the substituent is mainly involved. Barrow (2) has pointed out that for conjugated ketones the C=O stretching band intensity varies directly with the resonance energy of conjugation, and this, according to Bellamy (3), depends on the mesomeric effect alone. This reasoning leads to the conclusion that the band intensity may be determined by the mesomeric effect alone and the band position by the combined mesomeric and inductive effects. This however is no more than an unconfirmed hypothesis and will be reconsidered in the concluding section of this paper. It should be noted here that if we accept this hypothesis we must infer that the combined mesomeric and inductive effects for all four halogens are very similar, but the mesomeric effect is strongest for iodine and weakest for fluorine. This differs from the sequence usually accepted (cf. Forbes and Ralph (7) and the references cited therein).

Metasubstituted Acetophenones

The data for the metasubstituted acetophenones are given in Table II. In Fig. 2 the peak frequencies are plotted against the Hammett σ_m constants and show an excellent linear relationship. At the meta position the inductive effect will presumably be the major factor determining the C=O frequency shift, and it is consistent with this hypothesis that the *m*-amino group causes very little band displacement whereas the shift is large for the *p*-amino group. The nitro group produces a comparable displacement at

(Carbon tetrachloride solution)

Compound	$\nu_{\max}$ (cm. ⁻¹)	Integrated absorption intensity (mole ⁻¹ . liter. cm. ⁻² × 10 ⁻⁴)		$\epsilon_{\max}^{(a)}$ Mean
		Individual measurements	Mean	
<i>m</i> -Aminoacetophenone	1689	2.09, 2.20, 2.15	2.15	540
Acetophenone	1691	2.18, 2.26, 2.18	2.20	650
<i>m</i> -Chloroacetophenone	1696	1.82, 1.93, 1.94	1.90	616
<i>m</i> -Fluoroacetophenone	1696	1.69, 1.64, 1.64	1.66	533
<i>m</i> -Nitroacetophenone	1701	1.97, 1.99, 2.11	2.02	645

both the meta and para positions which indicates that at the para position there is probably an appreciable inductive contribution to the over-all electron withdrawal process. Data for the meta halogens are limited to the chloro and fluoro groups and both show the same displacement of +5 cm.⁻¹.

The meta compounds all exhibit weaker bands than the corresponding para isomers, except in the case of the nitro group. This is in qualitative accord with Barrow's views associating the band intensity with the resonance energy of conjugation (2, 3). The substituents which have a positive mesomeric effect (i.e. push electrons into the ring) will enhance the band intensity from the para position while the negative mesomeric effect of the *p*-nitro group will diminish it.

It would be naïve, however, to expect that the substitution effects can be described entirely in these simple terms. They provide no explanation for the extremely low band intensities in the *m*-fluoro and *m*-chloro compounds, or the high intensity in the *p*-methyl compound.

Orthosubstituted Acetophenones

The spectra of the orthosubstituted acetophenones are summarized in Table III. At the ortho position mesomeric and inductive effects will both be strong, and in addition there can be direct field effects (dipole-dipole interaction) between the substituent and

the acetyl group. Steric effects and field effects may both act to stabilize preferentially one or other of the two planar conjugations II, III, or non-planar configurations in which the acetyl group is rotated with respect to the benzene ring.

In the *o*-methyl compounds the substituent is large and steric factors are dominant. The C=O maximum for *o*-methylacetophenone is at 1690 cm^{-1} but in 2,3,5,6-tetramethylacetophenone $\nu_{\max}$ is increased to 1704 cm^{-1} . In the tetramethyl compound strong van der Waals repulsions between the *o*-methyl groups and the acetyl methyl cause the acetyl group to take up a non-planar configuration; the position of minimum potential energy is probably close to perpendicular to the plane of the ring, since the C=O frequency is near to that of an aliphatic ketone. In acetophenone and *o*-methylacetophenone the position of the C=O maximum is practically the same, from which we may infer that *o*-methylacetophenone can accommodate itself in a planar *s-cis* configuration (III). The same argument has been advanced to account for differences between the ultra-violet spectra of these compounds (4, 5); it does not explain however why the intensity of the *o*-methylacetophenone band is so low.

FIG. 3. C=O stretching band in infrared spectrum of *o*-chloroacetophenone (CCl₄ soln.).

FIG. 4. C=O stretching band in infrared spectrum of *o*-bromoacetophenone (CCl₄ soln.).

The spectra of the *o*-chloro, *o*-bromo, and *o*-nitro derivatives are of particular interest, as they all exhibit two maxima in carbon tetrachloride solution. (Figs. 3-5.) These doublets are probably associated with an equilibrium between the *s-trans* and *s-cis* isomers, similar to that observed by Allen and Bernstein for furfural (1). The effect of temperature change on the spectra of the liquid *o*-bromo and *o*-nitro derivatives is shown in Figs. 6 and 7. The *o*-chloro compound proved to be too volatile for similar study. The satellite band occurs on the low frequency side of the main peak in the *o*-bromo and *o*-nitro compounds, and is not as well resolved for the pure liquids as for carbon tetrachloride solutions; nevertheless, the presence of the second band is demonstrated in Figs. 6 and 7 by reflecting the higher frequency part of the band envelope

FIG. 5. C=O stretching band in infrared spectrum of *o*-nitroacetophenone (CCl₄ soln.).

about an ordinate through the absorption maximum, and subtracting the image from the observed curve. The resultant differential curve does not necessarily provide a true quantitative representation of the secondary component band, but it does demonstrate that the contribution of this component diminishes with increasing temperature in a reversible manner. To assure that the curve asymmetry is genuine these spectra were obtained by scanning both from low to high and from high to low frequency when no difference in the curve shape was observed.

In the *s-cis* form (III) the C=O and C-X dipoles will be aligned in the same direction, resembling the arrangement in the equatorially α -halogenated cyclohexanones, where the halogen is known to raise the C=O frequency (9, 11(b)). This would suggest that the higher frequency maximum is to be assigned to the *s-cis* isomer (III). The temperature dependence measurements would then indicate greater thermodynamic stability for the *s-trans* isomer (II) since the low frequency band augments as the temperature falls.

In addition to this electrostatic charge effect, a purely steric factor may also play a part in determining the energetics of this equilibrium. Although the chlorine and bromine atoms are smaller than the methyl group, they may still be large enough to exert signi-

FIG. 7. Effect of temperature on C=O stretching band in infrared spectrum of *o*-nitroacetophenone (pure liquid). (See Fig. 6.)

significant van der Waals repulsion with the acetyl methyl group in the *s-trans* configuration II. The equilibrium between the two species in the cases where $X = \text{Cl}, \text{Br}, \text{NO}_2$ must depend on the approximate equivalence of the $X \cdots \text{CH}_3$ repulsive force associated with II (largely steric), and the $X \cdots \text{O}$ repulsive force associated with III (largely electrostatic).

These arguments would suggest that *o*-fluoroacetophenone might also exhibit a doublet spectrum, but there is no evidence for this. In this compound the electrostatic repulsion between the fluorine and oxygen atoms in the *s-cis* configuration III will be greater than that associated with the heavier halogen atoms, whereas the steric repulsion in II will be less because of the smaller atomic radius. The combination of these factors may suffice to reduce the equilibrium concentration of the *s-cis* isomer to negligible proportions. The C=O maximum for *o*-fluoroacetophenone is at 1692 cm^{-1} , suggesting a correspondence with the lower frequency band in the *o*-chloro and *o*-bromoacetophenone spectra. In this connection we may note also that the band of lower frequency is the more intense in the *o*-chloro compound, but the higher frequency component is stronger in the

o-bromo compound. This is consistent with the above arguments in indicating increasing stabilization of the *s-cis* configuration with increasing size of the halogen atom.

It has been tacitly assumed above that both the *s-cis* and *s-trans* configurations are truly planar. This of course need not be so; the balance of the van der Waals and electrostatic forces in either configuration may be such as to produce wells of minimum potential energy associated with torsional displacements of the acetyl group from the planar configurations of II and III. If these torsional displacements differ appreciably for the quasi *s-cis* and quasi *s-trans* structures, the conjugation between the carbonyl group and the ring will be modified and this will provide an additional factor influencing the C=O frequency.

The C=O frequency for *o*-aminoacetophenone occurs down at 1653 cm.⁻¹ and this compound probably exists as the *s-cis* isomer, stabilized by internal hydrogen bonding (IV).

Band Widths

The band widths at half maximal intensity are listed in Table IV. The variation among the meta and para derivatives is small (8.6–9.8 cm.⁻¹) except for the amino compounds.

^aDetermined at a computed spectral slit width of 1.6 cm.⁻¹.

^bDoublet spectrum.

The ortho compounds have wider bands, and we can recognize two likely causes. Cases may arise where the *s-cis* and *s-trans* stereoisomers occur in equilibrium, but with insufficient frequency separation to allow of resolution into two bands. Band broadening could also occur through torsional displacement of the acetyl group; this may produce excited molecules for which C=O frequency would be slightly displaced. Since the energy associated with such torsional excitation would be small, these excited states would be appreciably populated at room temperature. If the molecule is planar in the ground state this type of excitation should induce asymmetry only on the high frequency side of the band envelope.

CONCLUSIONS

While it is possible to rationalize the observed behavior of most of these spectra in an ad hoc fashion, it is difficult to generalize from such observations, as several variables are involved, none of which can be evaluated separately. This problem cannot be resolved until a more rigorous evaluation of the C=O force constant is achieved. The C=O frequency shifts associated with meta and para substitution are clearly determined by the same combination of factors that control chemical reactivity, insofar as this can be identified with the Hammett constants. The orthosubstituted acetophenones demonstrate the existence of *s-cis* *s-trans* stereoisomers and an analysis of the band displacements suggests that the infrared spectra may provide a means of distinguishing between these.

The band intensities are variable, but the total range of variation from 1.4 to 2.9 is small when compared with the range from 0.1 to 18.4 observed by Thompson and Steel for the $\text{—C}\equiv\text{N}$ stretching band in similarly substituted benzonitriles (15).³ In a qualitative fashion the C=O band intensities are consistent with Barrow's contention that the intensity is related to the resonance energy of conjugation. However, attempts to formulate this quantitatively have been unsuccessful. There is no suggestion of regularity when C=O band intensities for the parasubstituted acetophenones are plotted against $\sigma_p - \sigma_m$, although this quantity might be expected to provide an approximate index of the contribution of mesomerism to the over-all electronegativity of the parasubstituent. Plots of the band intensities against the functions σ^* , $(\sigma_p - \sigma')$, and $(\sigma_m - \sigma')$ derived by Taft, Roberts, and Moreland (14) all failed to exhibit significant linearity, although σ^* should be proportional to the inductive effect of the substituent, and $(\sigma_p - \sigma')$ and $(\sigma_m - \sigma')$ to the mesomeric effect.

Thompson and Steel (15) observed a linear relationship when $\log A$ was plotted against the Hammett σ functions for the substituted benzonitriles, but a similar plot of our acetophenone data showed a wide scatter.

ACKNOWLEDGMENTS

Two of the authors (W.F.F. and W.A.M.) are indebted to the National Research Council of Canada and the Research Corporation of New York for financial assistance in support of this investigation.

We also wish to thank Dr. C. Angell, who carried out the temperature differential studies, and Mrs. M. A. MacKenzie for assistance with the measurement of the spectra.

³The units of intensity used by Thompson and Steel differ from ours by a factor of 3×10^{10} .

NOTES

THE PREPARATION OF METHYL BISNORCHOLANATE¹

D. J. WHITTINGHAM² AND R. NORMAN JONES

Considerable ambiguity exists in regard to the characterization of bisnorcholanolic acid (I) and its methyl and ethyl esters.

The first preparation of these substances was reported by Wieland, Schlichting, and Jacobi (9). These investigators described no less than five distinct isomers of bisnorcholanolic acid, viz.

- (i) α -Bisnorcholanolic acid, m.p. 214° C.; $[\alpha]_D -7.5^\circ$. Ethyl ester, m.p. 106–107° C.
- (ii) β -Bisnorcholanolic acid, m.p. 242° C.; $[\alpha]_D +23^\circ$. Ethyl ester, an oil.
- (iii) γ -Bisnorcholanolic acid, m.p. 210–211° C.; $[\alpha]_D$ indefinite. Ethyl ester, m.p. 82–83° C.; methyl ester, m.p. 117° C.
- (iv) δ -Bisnorcholanolic acid, m.p. 184° C.; $[\alpha]_D +32^\circ$. Methyl ester, m.p. 99° C.
- (v) ϵ -Bisnorcholanolic acid, m.p. 181° C.; $[\alpha]_D +14^\circ$. Methyl ester, m.p. 123° C.

Subsequently Hollander and Gallagher (5) described two compounds obtained by the oxidation of Δ^{22} -norcholenyl methyl ketone which they identified with Wieland's β and ϵ isomers.

In connection with a systematic study of the infrared spectra of bile acid derivatives we have recently prepared methyl bisnorcholanate from methyl 3 α -hydroxycholanate by the two independent routes outlined below; both methods give an identical product, and under no circumstances have we been able to induce isomerization.

¹Issued as N.R.C. No. 4301.

²N.R.L. Postdoctorate Fellow.

Our compound is characterized by the infrared spectrum shown in Fig. 1 and has m.p. 126–127° C.; $[\alpha]_D +11^\circ$. The final step in our preparation by Method I involved a Wolff-Kishner reduction, i.e. treatment with alkali at 200° C., yet the product obtained is the same as that by Method II, where the final stage is the Barbier-Wieland degradation of methyl norcholanate. Furthermore, our methyl bisnorcholanate failed to epimerize under a variety of alkaline conditions. The bisnorcholanate obtained on hydrolysis of our methyl ester had m.p. 190–195° C.; $[\alpha]_D +5.5^\circ$ C.; and differs from any of the five products reported by Wieland.

FIG. 1. Infrared spectrum of methyl bisnorcholanate. (Perkin-Elmer Model 21 spectrophotometer; CS₂ solution; 1 mm. path length; 12.3 mg. per ml.)

A sample of one of the bisnorcholanate acids (m.p. 196–201°; $[\alpha]_D +19.5^\circ$) isolated by Hollander and Gallagher was available from these investigators. The infrared spectra in carbon disulphide and chloroform solutions were very weak and in no respect comparable with the spectrum of the product described in our investigation. A sample of the methyl ester, m.p. 65–66°, prepared by Hollander and Gallagher, while it exhibited absorption at 1739 cm.⁻¹, could not be compared with the product obtained in the present investigation because the amount of material was so small that only a very weak spectrum was obtained.

These observations led us to conclude that the products described by the earlier investigators were not bisnorcholanate acids.

EXPERIMENTAL

All melting points have been corrected. The specific rotations were determined in chloroform solution unless otherwise stated; the concentrations in grams per 100 ml. of solution are indicated in parenthesis.

Method I

3 α -Hydroxycholanolic acid (100 g.) was esterified by the Fischer-Speier method. The crude ester was treated with 700 ml. of boiling methanol and the product filtered while hot to remove insoluble impurities. When cooled the filtrate deposited 76.5 g. of methyl 3 α -hydroxycholanate, m.p. 128–129° C.

Methyl 3 α -hydroxycholanate (58.0 g.) was degraded to 3 α -hydroxynorcholanolic acid by the method of Hoehn and Mason (4) with the exception that benzene was used as solvent in the oxidation stage, in place of chloroform. Esterification of the acid yielded 24.0 g. of methyl 3 α -hydroxynorcholanate. A sample recrystallized from methanol-water melted at 137–137.5° C.; $[\alpha]_D +36^\circ$ (*c*, 1.13). Sawlewicz and Reichstein (8) report a melting point of 117–118° C., and Reindel and Niederländer (7) report one of 99–100° C.

Methyl 3 α -hydroxynorcholanate (24.0 g.) was degraded to 12.3 g. of 3 α -hydroxybisnorcholanolic acid in exactly the same manner as described above for the degradation of methyl 3 α -hydroxycholanate.

3 α -Hydroxybisnorcholanolic acid (5.0 g.) was oxidized by Fieser's method (3) to give the 3-keto derivative, which after esterification, chromatography on alumina, and three recrystallizations from methanol yielded 796 mg. of methyl 3-ketobisnorcholanate, m.p. 164–164.5° C.; $[\alpha]_D +22^\circ$ (*c*, 1.42). Anal. Calc. for C₂₃H₃₆O₃: C, 76.62; H, 10.07. Found: C, 76.27; H, 9.91.

Crude 3 α -hydroxybisnorcholanolic acid (4.6 g.) was oxidized as described heretofore, and the 3-ketobisnorcholanolic acid so obtained was subjected to a Wolff-Kishner reduction as modified by Huang-Minlon (6). Esterification with diazomethane, chromatography on alumina, and four recrystallizations from ethanol gave 610 mg. of methyl bisnorcholanate, m.p. 126–127° C.; $[\alpha]_D +11^\circ$ (*c*, 1.16). Anal. Calc. for C₂₃H₃₈O₂: C, 79.71; H, 11.05. Found: C, 79.88, 79.70; H, 11.01, 11.29.

Method II

Methyl 3 α -hydroxycholanate (50.0 g.) was oxidized to methyl 3-ketocholanate (1), and the latter compound yielded 41.0 g. of methyl cholanate after a modified Wolff-Kishner reduction (6) and esterification with 1% hydrogen chloride in methanol.

Successive Barbier-Wieland degradations (2, 9), of methyl cholanate and methyl norcholanate, produced 2.8 g. of crude bisnorcholanolic acid. After esterification with diazomethane, chromatography on alumina, and three recrystallizations from ethanol, the compound melted at 124–125.5° C.; $[\alpha]_D +10^\circ$ (*c*, 1.44). On admixture with a specimen of methyl bisnorcholanate prepared by Method I, the melting point was 125–126.5° C.; the infrared spectra of the two preparations were identical.

Attempted Isomerization Experiments

(i) Methyl bisnorcholanate, 350 mg., was dissolved in 100 ml. of absolute methanol, to which was added 3 ml. of 1 *N* sodium methoxide. The solution was allowed to stand at room temperature for 2.5 hours; acidification with dilute sulphuric acid, dilution with water, extraction with ether, and recrystallization from ethanol gave 228 mg. of compound, m.p. 124–126° C. A mixed melting point determination with authentic

methyl bisnorcholanate showed no depression; the infrared spectrum was identical with that of the original ester.

(ii) Methyl bisnorcholanate, 350 mg., was heated under reflux for 2 hours in 30 ml. of absolute methanol containing 3 ml. of 1 *N* sodium methoxide. The reaction mixture was worked up as described in Experiment (i), 299 mg. of a compound being obtained m.p. 124–125.5° C. This compound was identical with methyl bisnorcholanate as was shown by a mixed melting point determination and by a comparison of the infrared spectra.

(iii) Methyl bisnorcholanate, 235 mg., was allowed to stand at room temperature for 2 hours in 15 ml. of 95% ethanol containing 1 ml. of 3 *N* sodium hydroxide. The solution was then heated under reflux for 2 hours; the isolation procedure was the same as that described in Experiment (i). Again the product (252 mg.; m.p. 123–124° C.) was identical with the starting material as was shown by a mixed melting point determination and by a comparison of the infrared spectra.

Bisnorcholanic Acid

Methyl bisnorcholanate was heated under reflux for 7 hours in the presence of alcoholic base. The product was recrystallized four times from acetic acid–water and a fifth time from ethanol, m.p. 190–195° C.; $[\alpha]_D +5.5^\circ$ (*c*, 1.10 in 95% ethanol). Re-esterification with diazomethane gave the original ester in quantitative yield, m.p. 124–125.5° C. (no depression of melting point on admixture with authentic methyl bisnorcholanate; identical infrared spectra).

ACKNOWLEDGMENTS

We are very grateful to Dr. T. F. Gallagher for providing samples of his preparations for comparative purposes. We also wish to thank Mr. R. Lauzon for assistance with the measurements of the infrared spectra, and Mr. H. Seguin for the carbon and hydrogen analyses.

SOME ARALKYL AND ARYL ALKYL SULPHIDES AND DISULPHIDES¹

MARSHALL KULKA AND F. G. VAN STRYK

ABSTRACT

Sixty sulphides and disulphides have been prepared from mercaptans and alkyl and alkylene halides for testing as insecticides.

In a co-operative program of insecticide research, a series of sulphides and disulphides were synthesized in this laboratory and screened for aphicide action at the Ontario Agricultural College by Professor A. J. Musgrave and Mr. I. Kukovica (10). This paper describes the preparation and some reactions of these compounds.

The method of Patterson and du Vigneaud (12), which comprises heating the mercaptan (I) in the presence of alkali with a large excess of ethylene dichloride, was employed in the preparation of the aralkyl 2-chloroethyl sulphides (II) listed in Table I:

Aralkyl 3-bromopropyl sulphides could not be obtained by this method from 1,3-dibromopropane because at some stage during the reaction with the benzyl mercaptan (I) dehydrohalogenation occurred and the aralkyl allyl sulphide formed. When two moles of the mercaptan (7) and one mole of the alkylene dichloride were allowed to react the product was the disulphide (III) (Table V):

It is known that sodium alkoxides react with trichloroethylene to give α,β -dichlorovinyl ethers (6). Also Cusa and McCombie (4) have provided evidence that the reaction product of thiophenol and trichloroethylene has the α,β -dichlorovinyl sulphide structure (IV).

On this basis it was concluded that the reaction products of benzyl mercaptans (I) and trichloroethylene recorded in Table IV are α,β -dichlorovinyl benzyl sulphides (IV) and not the β,β -dichlorovinyl sulphides.

2-(*p*-Chlorophenylmercapto) cyclohexanone (V), which was readily obtained from *p*-chlorothiophenol and 2-chlorocyclohexanone, proved to be a good source for ω -*p*-chlorobenzenesulphonylhexanoic acid (VII). The sulphone VI, obtained by hydrogen

EXPERIMENTAL

Preparation of 2-Chloroethyl Aryl and Aralkyl Sulphides (Table I)

To a solution of sodium (0.2 mole) in methanol (50 ml.) was added the mercaptan (RSH, R = aralkyl) (0.2 mole). The resulting solution was cooled, ethylene dichloride (300 ml.) was added, and the reaction mixture heated under reflux for $\frac{1}{2}$ hour. The reaction was only slightly exothermic. The reaction mixture containing precipitated sodium chloride was washed with water, the excess ethylene dichloride removed, and the residue distilled. Methanolic potassium hydroxide may be used instead of sodium and methanol with equally good results.

Preparation of the Bis-(aryloxyethyl) and Bis-(arylmercaptoethyl) Sulphides

($RYCH_2CH_2SCH_2CH_2YR$) (XI) from Bis-(2-chloroethyl) Sulphide (Table III)

To a solution of sodium (0.2 mole) in methanol (200 ml.) was added the phenol or the thiophenol (0.2 mole) followed by bis-(2-chloroethyl) sulphide (0.1 mole), and the reaction mixture was heated under reflux for 3 hours. The methanol solution was decanted

from the precipitated salt, the solvent removed, the residue dissolved in benzene, and the benzene solution washed with aqueous sodium hydroxide and with water. The solvent was removed from the benzene solution and the residue crystallized from methanol or benzene.

Preparation of the Sulphides Listed in Table IV

These sulphides were prepared by the same method as were the 2-chloroalkyl aralkyl sulphides (II) of Table I (above) using excess alkyl halide where possible. In those cases where the boiling point of the alkyl halide was over 100° an excess was not used. Instead, benzene or methyl ethyl ketone was employed as solvent. With less reactive halides such as trichloroethylene the reaction time had to be extended to 5 hours.

Preparation of the Disulphides from Alkylene Dihalides (Table V)

The method used here was essentially the same as that employed in the preparation of 1,3-bis-(*p*-chlorophenylmercapto)-2-propanol except that distillation of the final product was not necessary (see p. 526).

p-Chlorobenzyl 2-Chloroethyl Sulphide

To a solution of *p*-chlorobenzyl 2-chloroethyl sulphide (5 g.) (Table I) in acetic acid (15 ml.) was added 30% hydrogen peroxide (15 ml.) and the solution heated on the steam bath for $\frac{1}{2}$ hour with occasional cooling in order to keep the temperature below 100°. The resulting solution was diluted with a few milliliters of water and allowed to cool. White needles (5.4 g. or 95%) precipitated and melted at 119–120°. Anal. calc. for $C_9H_{10}O_2Cl_2S$: C, 42.69; H, 3.96. Found: C, 42.60, 43.17; H, 3.91, 4.11.

p-Chlorobenzyl α,β -Dichlorovinyl Sulphide

This was prepared in poor yield by the above method from *p*-chlorobenzyl α,β -dichlorovinyl sulphide (Table IV), m.p. 70–72°. Anal. calc. for $C_9H_7O_2Cl_3S$: C, 37.83; H, 2.45. Found: C, 37.97, 38.15; H, 2.63, 2.90.

2-p-Chlorobenzenesulphonylcyclohexanone (VI)

This could not be prepared by the above method because the reaction in this case was very exothermic and could not be controlled. To a cold solution of 2-*p*-chlorophenylmercaptocyclohexanone (V) (Table IV) (10 g.) in acetic acid (50 ml.) was added 30% hydrogen peroxide (25 ml.) and the resulting solution was allowed to stand at room temperature for 3 days with occasional cooling on the first day in order to keep the temperature below 30°. The product was worked up as above and when recrystallized from aqueous methanol it melted at 78–80°. The yield was 70%. Anal. calc. for $C_{12}H_{13}O_3ClS$: C, 52.94; H, 4.78. Found: C, 53.25, 53.29; H, 5.07, 4.88.

ω -*p*-Chlorobenzenesulphonylhexanoic Acid (VII)

To a solution of sodium hydroxide (3 g.) in water (50 ml.) was added 2-*p*-chlorobenzenesulphonylcyclohexanone (1 g.) and the reaction mixture heated on the steam bath for 1 hour. The resulting solution was cooled, acidified with concentrated hydrochloric acid, and the white precipitate (0.80 g. or 78%) filtered, washed, and dried, m.p. 109–110°. It is soluble in aqueous sodium bicarbonate. Anal. calc. for $C_{12}H_{15}O_4ClS$: C, 49.58; H, 5.16. Found: C, 50.00, 49.98; H, 5.22, 5.33.

p-Chlorobenzyl 2-Chloropropyl Sulphide

This was prepared in 90% yield from *p*-chlorobenzyl 2-hydroxypropyl sulphide (Table IV) and thionyl chloride in the usual manner. The colorless liquid boiled at 165°

at 13 mm. pressure, $n_D^{20} = 1.5692$. Anal. calc. for $C_{10}H_{12}Cl_2S$: C, 51.06; H, 5.11. Found: C, 51.29, 51.69; H, 5.07, 5.35.

p-Chlorobenzyl 2,3-Dichloropropyl Sulphide

This was prepared in 90% yield from *p*-chlorobenzyl 2-hydroxy-3-chloropropyl sulphide (Table IV) and thionyl chloride. The colorless liquid boiled at 135–137° at 0.2 mm. pressure, $n_D^{20} = 1.5845$. Anal. calc. for $C_{10}H_{11}Cl_3S_2$: C, 44.53; H, 4.08. Found: C, 44.96; H, 4.29.

p-Chlorobenzyl 2-Thiocyanatopropyl Sulphide

A solution of *p*-chlorobenzyl 2-chloropropyl sulphide (10 g.), sodium thiocyanate (4 g.), and ethanol (75 ml.) was heated under reflux for 2 hours. The ethanol was distilled off, benzene and water were added to the residue, and the whole shaken. The benzene layer was washed, the solvent removed, and the residue distilled, b.p. (0.1 mm.) = 151–153°, yielding 9 g. of colorless liquid, $n_D^{20} = 1.6010$. Anal. calc. for $C_{11}H_{12}NCIS_2$: C, 51.26; H, 4.66. Found: C, 51.23; H, 4.76.

1,3-Bis-(*p*-chlorophenylmercapto)-2-propanol (X)

To a solution of potassium hydroxide (24 g.) in methanol (100 ml.) was added *p*-chlorothiophenol (58 g.), benzene (100 ml.), and 1,3-dichloro-2-propanol (26 g.) and the reaction mixture was heated under reflux for 5 hours. Water was then added, the benzene layer separated and washed with water, the solvent removed, and the residue distilled. The fraction boiling at 205–208° at 0.5 mm. pressure was collected and allowed to solidify. It was pulverized, washed with petroleum ether (b.p. 30–60°), and dried. The white powder (42 g. or 61%) melted at 46–47°. Anal. calc. for $C_{15}H_{14}OCl_2S_2$: C, 52.18; H, 4.05. Found: C, 51.90, 51.93; H, 3.86, 3.81.

1,3-Bis-(*p*-chlorophenylmercapto)-2-chloropropane (IX)

A solution of 1,3-bis-(*p*-chlorophenylmercapto)-2-propanol (X) (20 g.), thionyl chloride (20 ml.), and dry benzene (50 ml.) was heated under reflux for 3 hours. The excess thionyl chloride and benzene were removed *in vacuo* and the residue distilled at 195–220° at 0.5–1 mm. pressure. The distillate on crystallization from methanol yielded white needles (13 g. or 60%) which melted at 86–87° alone or in admixture with the product obtained from 1,2,3-trichloropropane and *p*-chlorothiophenol (Table V).

MECHANISM OF GUANIDINE NITRATION

II. TETRAETHYLNITROGUANIDINE¹

M. W. KIRKWOOD AND GEORGE F. WRIGHT

ABSTRACT

The preparation of *sym*-tetraethylnitroguanidine now shows that a ketimino group can be nitrated directly. The mode of nitration has been evaluated first by determination of the ionization of guanidine bisulphate (prepared anew) and tetraethylguanidine in nearly-anhydrous sulphuric acid by means of an improved cryoscope, and by comparison of these ionizations with those of substances the ionizing behavior of which may be reliably predicted. Subsequent studies show that the stronger base, *sym*-tetraethylguanidine, is nitrated more slowly than guanidine, both reactions being reversible. Detailed kinetic studies were not made because of the irreversible side-reaction yielding tetraethylurea. This irreversible reaction, which is suppressed by sodium bisulphate but not by nitric acid, is presumptive for the existence of an intermediate nitrotetraethylguanidinium salt out of which the tetraethylnitroguanidine or tetraethylurea may arise.

In the first paper of this series (33) it was suggested that nitration of a guanidine occurs at the imino rather than a primary amino nitrogen. In order to test this hypothesis we have examined *sym*-tetraethylguanidine in which only the imino nitrogen is available for replacement of hydrogen by a nitro-group. Nitration does not occur in a nitric acid – acetic anhydride system, but in a nitric acid – sulphuric acid system a 61% yield of *sym*-tetraethylnitroguanidine is obtained. The substance has been characterized by analysis and by alkaline hydrolysis to yield tetraethylurea.

This authentic nitrimine resembles nitroguanidine in many respects. Thus its absorption maximum at 268 m μ is near to that of nitroguanidine (265 m μ), though different from a previous specification of nitrimine absorption (20). The infrared spectra of tetraethylnitroguanidine and nitroguanidine are not comparable because the principal absorption (6.8–7.0 μ) found for the new compound as a supercooled liquid is masked by the mineral oil used for the mull of nitroguanidine (16). However both substances behave similarly by negative Franchimont tests for the nitramine linkage (9). Finally the electric moment of 7.64 D., determined in dioxane at 20°, is higher than that of nitroguanidine (μ = 6.95 D.) (15) by about the contribution that would be expected from the effect of four ethyl groups tetrahedrally disposed at the amino nitrogens. These similarities tend to confirm the nitrimino structure which has been proposed for nitroguanidine (1).

Thus the nitration of tetraethylguanidine seems to resemble that of guanidine, but the rate of nitration is slower. Insofar as imine nitration is thought to resemble secondary amine nitration this result would not be unexpected if tetraethylguanidine were more strongly basic than guanidine (8). Since direct evaluation of electron-donation is of questionable significance in strong sulphuric acid, we have examined instead the extent of salt dissociation by cryoscopic means.

For this cryoscopic evaluation we have prepared the hitherto-unknown guanidine bisulphate, an easily purified anhydrous salt. A salt of tetraethylguanidine satisfactory for cryoscopic study could not be found so the carbonate-free amine was used for the purpose. We have included comparative studies with benzoic acid, trinitrotoluene, dimethylsulphone, and *p*-tolyltrimethylammonium bisulphate. Surprisingly we have

¹Manuscript received January 15, 1957.

Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

found the latter salt to be satisfactory for cryoscopic studies although Williams and his co-workers (18) reported unworkable hygroscopicity. Possibly they encountered the sulphate salt.

In common with other workers (10, 12) we have found that freezing point determinations in absolute sulphuric acid lead to i values (Δ° found/ Δ° calc. from molecular weight of solute) which depend on the amount of solute present. Typical is the behavior of benzoic acid, the first item in Table I, using Gillespie's cryoscopic constant ($5.98^\circ/\text{g. mole}^{-1}$, kg.) for absolute sulphuric acid. The freezing point depressions in the first two determinations are smaller than would be expected if benzoic acid dissociates in absolute sulphuric acid according to equation (i):

but the expected result according to equation (i) is obtained (determination 3) when the concentration of solute is increased further.

This behavior has been explained (10, 12) as due to alteration, by the bisulphate ion generated according to equation (i), of the autoprotolysis of sulphuric acid

since a shift of (ii) to the left would reduce the particle concentration. According to this explanation the mass effect should decrease with increasing amounts of solute.

The validity of this argument may be questioned, and indeed it has been shown that indiscriminate addition of bisulphate salts leads to ambiguous results (5). Actually the i values for benzoic acid are consistent over a series of concentrations of solute (determinations 4–9 inclusive) when the sulphuric acid is 0.03 molar in water. But this inclusion, which has been thought to contribute sufficient hydronium bisulphate to compensate reaction (ii), causes an apparent dissociation which exceeds that expected of reaction (i). This discrepancy has been evaluated by examination of other substances the dissociations of which are thought to be known.

It has been demonstrated spectroscopically (4) that trinitrotoluene does not react with anhydrous sulphuric acid. We have examined this substance in anhydrous sulphuric acid as well as that containing 0.03 mole per liter of water (determinations 10–21 inclusive, Table I) and find that the i values are essentially the same in both media although they are higher than the expected value of unity. This discrepancy may be due to the use of Gillespie's freezing point constant in a system to which it is not applicable.

A further test of this constant has been made by study of dimethylsulphone upon the assumption that it does not undergo salt formation in absolute, or nearly-absolute, sulphuric acid. However the determinations (22–27 inclusive, Table I) do not confirm this assumption. It may be seen that increasing concentration of solute in absolute sulphuric acid causes increasing i values, the maximum of which is about the same as that observed for all solute concentration in sulphuric acid 0.03 molar in water. This might be considered as evidence of partial ionization in the systems.

It was hoped that an examination of trimethyl-*p*-tolylammonium bisulphate would specify the freezing point constant since this quaternary ammonium salt might be expected to be so completely dissociated in sulphuric acid that the system would be characterized by an i value of 2. This hope has not been realized. Determinations 28–30 inclusive (Table I) show increasing i values with increasing concentration despite the use of a sulphuric acid which is not anhydrous. Furthermore the maximum i value,

2.13, exceeds the theoretical value of 2 by approximately the same discrepancy that has been observed for the three other test substances which were examined. This (so-called) discrepancy cannot be a function of time, at least for determination 30, Table I, because the difference ($10.308^\circ - 9.905^\circ$) was reproducible within 0.001° 12 hours after the original measurement.

In view of these results we are inclined to agree with Wyatt (34), and indeed to extend his opinion to electrolytes, that the cryoscopic method is inaccurate as an evaluation

of basic strength. Nevertheless comparison with the same type of substance ought to be qualitatively valid, and this we have done with guanidine and tetraethylguanidine.

Upon the basis of freezing point lowering caused by guanidine carbonate in absolute sulphuric acid Hantzsch and Geidel (13) considered this amidine to be triprotonated. However, decomposition of the carbonate added an equivalent of water so that the medium was about 0.03 molar in water. Recalculation of Hantzsch's data with use of Gillespie's cryoscopic constant reduces the i value to about 2.8.

Other workers (31) have studied the behavior of the benzoate, perchlorate, and benzenesulphonate of guanidine in sulphuric acid about 0.03 molar in water and have arrived at an i value of about 2.4. It may be seen (determinations 35–38 inclusive, Table I) that our values obtained from guanidine bisulphate in nearly-anhydrous sulphuric acid are in agreement. In absolute sulphuric acid we observe the same i value increase with increasing concentration which is characteristic of the other solutes that we and others have examined.

(A) Nitric acid added to give mole ratio of HNO₃/STENG equal to 5.25.(B) Sodium bisulphate added to give mole ratio of NaHSO₄/STENG equal to 4.20.

We would have preferred to examine *sym*-tetraethylguanidine exactly like guanidine but we were unable to prepare a sulphate salt of the tetraethyl homologue which was sufficiently non-hygroscopic for freezing point determination. However the base itself was amenable to use in nearly-anhydrous sulphuric acid. As Table I (determinations 39-44 inclusive) shows, the compound is a stronger proton acceptor than guanidine in sulphuric acid, in conformity with its lesser rate of nitration.

Similarly with guanidine (28, 32) the nitration of tetraethylguanidine is reversible. Solutions of 0.09 g. of the nitro compound in 1 g. of 96.6% and 95.0% sulphuric acids after 60 minutes gave precipitates of nitron nitrate equivalent to 12.6% and 1.7% of denitration respectively. On the other hand no nitron nitrate could be detected after 60 minutes in 92.8% sulphuric acid. The denitration is thus critically dependent on the alteration of the system by water.

A detailed study of the nitration of *sym*-tetraethylguanidine (STEG) and the denitration of *sym*-tetraethylnitroguanidine (STENG) has been accomplished by separation of STEG and STENG from the reaction system by means of ion-exchange resins with subsequent evaluation of each by ultraviolet absorption intensities. Comparative reactions have been carried out in 95%, 91.2%, and 83.8% sulphuric acid.

The data of Expts. 2, 4, and 6, Table II, in which a ratio of nitric acid to STEG slightly greater than 1 is maintained, show that the maximum reaction rate occurs when the water content of the medium is about 10-15%. This phenomenon has been observed in the nitration of amides (27), amidines like guanidine (26), and aromatic nitro-compounds (19, 3, 30). Since the rate maximum is approximately the same for nitration of these several types it is evident that the behavior is principally a function of the properties of the sulphuric acid medium. An adequate explanation, which has not yet been forthcoming, must await a new insight into the nature of this common, yet little-understood, substance called sulphuric acid.

Inspection of Expts. 1 and 3 (less apparent, 5) shows that the yield of tetraethylnitroguanidine (STENG) with respect to time is only temporarily maximal. This evidence of a side reaction, indicated also by the per cent of tetraethylguanidine (STEG) not accounted for by the analytical method, has been confirmed by examination of a system in 95% sulphuric acid which was allowed to proceed to completion. The identification of tetraethylurea and nitrous oxide shows that this side reaction is an irreversible decomposition of the desired product, STENG, and the kinetic data show that this decomposition is faster in stronger sulphuric acid.

This irreversible decomposition has been confirmed by treatment of the desired nitration product, STENG, with aqueous sulphuric acid containing 95, 91.2, and 83.8% of the acid. Experiments 7, 8, and 9 show that the rapid reversible denitration reaction is followed by a slower irreversible reaction which must be the decomposition of *sym*-tetraethylnitroguanidine (STENG) to tetraethylurea and nitrous oxide. It is shown (Expt. 10) that this irreversible decomposition is not affected appreciably by excess of nitric acid, although, as might be expected, the nitric acid represses the reversible denitration. On the other hand it is of interest to note that the addition of sodium bisulphite (Expt. 11) has little effect on the reversible denitration but it retards profoundly the irreversible decomposition in which tetraethylguanidine disappears from the system.

Assuming that this bisulphate salt operates by protonic capture, one may formulate the following reaction series to explain these phenomena:

According to this concept, nitration proceeds by coordination of nitronium ion with STEG to give the ammononitronium ion I. This ion may be converted reversibly to either STEG, the tetraethylguanidine, or else the nitration product STENG with loss of a proton. An excess of nitric acid forces the equilibrium from STEG to STENG without decreasing the concentration of the intermediate ion I whereas sodium bisulphate, by inactivation of both nitronium and hydrogen ion (or its solvated equivalent), reduces the concentration of I. But the complex ion I may also decompose irreversibly by loss of nitrous oxide to yield ephemerally the tetraethylisourea cation II which, by loss of hydrogen ion or its equivalent, appears as *sym*-tetraethylurea, STEU.

Such a concept has been shown to be untenable in the instance of, say, toluene nitration (21, 2), where the absence of an isotope effect precludes an equilibrium between complex nitronium ion and product, which would be shifted by presence of bisulphate ion. However the difference in coordinative power between toluene and tetraethylguanidine is profound, and a significant concentration of ammononitronium ion I is not unexpected. In the present instance it is of interest to examine a nitratable compound, the cation acceptance of which is intermediate between STEG and toluene.

The nitration of guanidine, which falls into this category, has been studied by Williams and Simkins (32). There is no detectable tendency in this reaction to form the urea as a by-product, at least at the lowest temperature (15°) which these workers employed. In order to establish a basis for comparison with tetraethylguanidine we have nitrated guanidine (as the carbonate) at 0° in sulphuric acid initially containing 16.2% of water (see Table III). We find that the reaction is almost complete within 5 minutes, and no decomposition of the product occurs. Comparison of this nitration rate with that of tetraethylnitroguanidine under the same conditions (Table II) shows that nitroguanidine is formed about 700 times as fast as its tetraethyl homologue. Since the nucleophilicity

TABLE III
NITRATION OF GUANIDINE IN 83.8% SULPHURIC ACID AT 0°
Initial moles guanidine carbonate: moles HNO₃ = 0.411 mole/liter: 0.569 = 1.38

Time, min.	5	20	60	240	600
Conc. nitroguanidine, moles/l.	0.378	0.389	0.401	0.378	0.389

of guanidine is less than that of tetraethylguanidine (STEG, Table I) it would seem that the nitration rate was dependent on a balance between acquirement of alternative ions, exemplified in the formulation above as nitronium and hydrogen ions. Essentially this is the behavior of secondary amines with respect to nitration, thus justifying a formal relationship between R_2NH and R_2CNH (6, 8).

We believe that the general tendency of the nitroguanidines toward decomposition into nitrous oxide and the analogous ureas also supports the concept of the intermediacy of complex nitronium salts during nitration of amines. Although nitroguanidine itself does not undergo this decomposition in the acid reaction media at 25° (32) it is unstable in this respect at higher temperatures (14). This decomposition might have occurred via a primary nitramino group in nitroguanidine but this path obviously is impossible for *sym*-tetraethylnitroguanidine. Insofar as the two guanidines are analogous the nitration may be considered to operate through a complex cation such as I, which ought to behave toward excess nitric acid and toward sodium bisulphate in the manner which we observed during nitration of STEG.

EXPERIMENTAL*

sym-Tetraethylnitroguanidine, STENG

To a solution of 1.71 g. (0.01 mole) of *sym*-tetraethylguanidine (24, the final Grignard reaction should stand for 10 hours prior to hydrolysis) in 14.7 g. (0.15 mole) of 100% sulphuric acid at 0° C. was added with stirring over a period of 20 minutes, 3.15 g. (0.05 mole) of 99.9% nitric acid. The colorless reaction system was maintained at 0° C. for 60 minutes and then was dripped slowly onto 25 g. of crushed ice. The drowned reaction system was then neutralized by addition of solid sodium carbonate and the amber oil which separated was collected by three 25-ml. extractions with chloroform. The combined extract, dried by magnesium sulphate, was distilled, first at 25° C. (20 mm., 1.65 g.), and then at 0.01 mm., to yield 0.01 g., b.p. 55° C. (identified as tetraethylurea by conversion to its chloroplatinate), and then 1.33 g. (61%), b.p. 141–142° C., solid at 30° C. Low temperature crystallization from ethyl acetate gave a melting point of 37.3–38.0° C. Calc. for $C_9H_{20}O_2N_4$: C, 50.0; H, 9.32; N, 25.9. Found: C, 49.8; H, 9.07; N, 26.0. The substance showed an absorption band at 268 $m\mu$ (molar extinction coefficient, 1.195×10^4) as contrasted to tetraethylguanidine with a band at 227 $m\mu$ where the nitro compound again absorbed strongly. The infrared spectrum is recorded in μ at K_e , 2.95 [0.921], 3.35 [6.12], 3.45 [6.10], 6.50 [1.171], 6.68 [0.968], 6.85 [1.302], 6.95 [1.378], 7.25 [0.798], 7.48 [0.635], 7.67 [0.783], 7.80 [0.916], 8.05 [2.931], 8.75 [0.744], 8.90 [0.724], 9.05 [0.761], 9.26 [0.798], 9.85 [0.607], 10.10 [0.654], 10.50 [0.519], 10.60 [0.548], 10.75 [0.611], 12.10 [0.394], 12.45 [0.494], 12.65 [0.536], 12.85 [0.494], 13.40 [0.616], 13.50 [0.629]. The electric moment in dioxane at 500 kc. at 200° C. is 7.64 D., calculated by the method of Halverstadt and Kumler (11); P (total) = 1290 cc.; MR_D calc.: 61.1 cc., found from n_D^{20} 1.51880 and d_4^{20} 1.037 using supercooled liquid: 63.2. However, if the atomic polarization determined for nitroguanidine from the dielectric constant of solid pellets (22) at maximum density ($P_a = P_{e+a} - MR_D = 30.4 - 23.2 = 7.2$ cc.) applies to the tetraethyl analogue, then μ for STENG = 7.61 D. STENG does not give a true Franchimont test for secondary nitramines although a green color develops on the zinc surface in diethylaniline – acetic acid. The X-ray diffraction pattern, determined with Cu K_α radiation (Ni filtered), is reported as intensities $[I/I_1]$ at spacings

*Melting points have been corrected against reliable standards (Can. J. Technol. 34, 89 (1956)).

Tetraethylurea

a. By Decomposition of Tetraethylnitroguanidine in Alkali

A mixture of 0.50 g. (0.0025 mole) of tetraethylnitroguanidine and 5 ml. of 20% aqueous sodium hydroxide (0.025 mole) was heated under reflux for 150 minutes. The cooled two-phase system was twice extracted with chloroform and the 20 ml. of extract, dried with magnesium sulphate, was vacuum-evaporated. The residue (0.31 g.) was distilled, b.p. 90–91° C. (9 mm.), 0.16 g. (40%); the chloroplatinate did not depress the melting point of an authentic sample.

b. By Decomposition in 96% Sulphuric Acid

A mixture of 0.669 g. (0.0031 mole) of tetraethylnitroguanidine and 5 ml. of 96% sulphuric acid was stirred magnetically at 20° C. for 1 day while the evolved gas was collected over water. By combustion with hydrogen this gas was found to contain 18.4 cc. of nitrous oxide (27%). The remaining liquid was poured onto ice and diluted to 100 ml. with water. Threefold extraction with ether followed by processing as described above gave a 51% yield of authentic tetraethylurea.

c. From Diethylamine and Phosgene

This product, prepared by the method of Michler (23), did not give the chloroplatinate (m.p. 134° C. but not analyzed) reported previously (25) but instead a chloroplatinate with m.p. 98–99° C. Calc. for $(C_2H_5N_2O)_2H_2PtCl_6$: Pt, 25.9. Found: Pt, 26.6.

Guanidine Bisulphate

To 13 ml. (0.25 mole) of 100% sulphuric acid in a flask protected from air was added in small quantities 15.1 g. (0.08 mole) of guanidine carbonate. Upon cooling to 20° C. the system became a white slush which was triturated seven times with 100-ml. volumes of diethyl ether in order to remove the excess sulphuric acid. Subsequently the ether-insoluble portion was filtered off and dried to constant weight *in vacuo*, 23.6 g. (89%), m.p. 101.0–101.5° C. after two crystallizations from hot acetic acid. Calc. for $CH_7O_4N_3S$: N, 26.7; SO_4 , 61.1. Found: N, 26.2; SO_4 , 60.9. The picrate prepared from this salt melted at 325–330° C.; admixture with authentic guanidine picrate did not depress this melting point.

p-Tolyltrimethylammonium Bisulphate

A solution of 15.0 g. (0.054 mole) of *p*-tolyltrimethylammonium iodide (prepared from *p*-dimethyltoluidine and methyl iodide in anhydrous diethyl ether) in 200 ml. of 95% ethanol was treated with small quantities of freshly-precipitated silver oxide until the formation of silver iodide was no longer evident. The silver salts were then filtered off and washed well with 95% ethanol. Filtrate and washings, combined, were chilled to 0° C. Then 96% sulphuric acid was added slowly until the pH of the system reached about 2. After vacuum evaporation of the solvent the amber gummy solid was redissolved in 125 ml. of absolute ethanol and this solution was decolorized by Norit. Subsequent addition of 150–200 ml. of absolute diethyl ether gave 9.61 g. (72%) of white leaflets, m.p. 133–136° C. This crude bisulphate was purified by solution in absolute ethanol followed by precipitation with absolute ether, m.p. 132.5–133.3° C. Calc. for $C_{10}H_{17}O_4NS$:

SO₄, 38.9. Found: SO₄, 38.9. The melting point of the picrate prepared from this salt (m.p. 197–198° C.) was not depressed by admixture with an authentic sample (29).

Dimethyl Sulphone

This substance, prepared by hydrogen peroxide oxidation of dimethyl sulphide (7), was dissolved in 80 ml. of saturated aqueous sodium sulphate and this solution was continuously extracted with chloroform. The extract, dried over sodium sulphate, was vacuum-evaporated and the 3.1 g. (47%), m.p. 107–110° C., was twice crystallized from hot chloroform (10 ml. per g.), m.p. 109.3–110.0° C. (soft 108.5° C.). The literature reports a melting point of 109° C. (17).

Analytical Procedure for Kinetic Studies

In order to separate tetraethylguanidine and tetraethylnitroguanidine from nitric and sulphuric acids, and from each other, the drowned aliquots were passed through a 15×2 cm. column containing Amberlite IR-4-B ion exchange resin (Dowex-2 was too basic and destroyed the nitration product) to retain as much of the mineral acids as possible. Thence the eluate was passed through a column 2 cm. by 0.8 cm. containing Dowex-50 in order to remove tetraethylguanidine. Since this base is stronger than the IR-4-B resin, the eluate from the Dowex-50 contained some sulphuric acid which was subsequently removed by a third column, 5 cm. by 1.5 cm., containing IR-4-B.

The eluate from the three tandem columns contained only tetraethylnitroguanidine. The amount was ascertained by comparison of the absorption spectrum with those of standard solutions via identical columns (see Table IV).

TABLE IV
DETERMINATION OF MOLAR EXTINCTION COEFFICIENT AT 268 mμ OF *sym*-TETRAETHYLNITROGUANIDINE IN AQUEOUS SOLUTION

Conc., mole/l. × 10 ⁻⁵	1.027	2.054	3.081	4.108	5.135	6.162	7.189
Molar extinction coefficient × 10 ⁴	1.199	1.207	1.198	1.184	1.197	1.188	1.213

The tetraethylguanidine was recovered by inverting the Dowex-50 column and washing it with 4 *N* sulphuric acid. The eluted salt in aqueous acid was evaluated by comparison of the absorption spectrum with those of standardized solutions via identical columns (see Table V).

TABLE V
DETERMINATION OF MOLAR EXTINCTION COEFFICIENT AT 227 mμ OF *sym*-TETRAETHYLGUANIDINE IN 4 *N* SULPHURIC ACID

Conc., mole/l. × 10 ⁻⁵	1.43	2.86	4.29	5.72
Molar extinction coefficient × 10 ³	9.16	9.19	9.12	9.13

Mixtures of known composition comprising the two compounds were found to be 96–100% recoverable according to spectroscopic analysis, while the presence of tetraethylurea interfered neither with the separation nor with the subsequent spectrometry since the urea is transparent in the spectral regions involved in the analysis.

Kinetic Procedure

The nitration of *sym*-tetraethylguanidine in sulphuric acid, and the subsequent analyses, were carried out as follows. A weighed quantity of tetraethylguanidine was added to the appropriate medium containing sulphuric acid. A solution of absolute

nitric acid in sulphuric acid of the same strength was prepared at 0° C. and the two solutions were mixed at 0° C. and made up rapidly to a volume of 10 ml. by addition of more of the sulphuric acid medium, then shaken rapidly at 0° C. for 1 minute and thereafter maintained at this temperature. Periodically 1-ml. samples were withdrawn and drowned on 20–25 g. of ice. These aliquots were made up to 100-ml. volumes with distilled water and then were passed successively through the ion-exchange columns. Subsequently the three tandem columns were washed with 350 ml. of water. The combined eluates were made up to a 500-ml. volume with distilled water and then diluted appropriately (usually 2 ml. to 25 ml.) for optical density determination at 268 $m\mu$ to indicate the amount of tetraethylnitroguanidine.

The Dowex-50 columns were inverted and eluted with 250 ml. of 4 *N* sulphuric acid. The eluates, made up to 300 ml. with the same acid and usually diluted (2 ml. to 25 ml.), also with 4 *N* sulphuric acid, were examined for optical density at 227 $m\mu$ for the amount of tetraethylguanidine.

Nitration of Guanidine

A solution of guanidine carbonate in sulphuric acid of known concentration was prepared at 0° C. To this solution was added a solution of 99.9% nitric acid in sulphuric acid of the same known concentration and the whole at 0° C. was made up quickly to 10 ml. with this sulphuric acid. Periodically 1-ml. aliquots were drowned on 20–25 g. of ice, then diluted to about 100 ml. with distilled water and passed through a 15×2 cm. column of Amberlite IR-4-B resin. This column was washed with water until the combined eluates equalled 500 ml., of which 2 ml. diluted to 25 ml. was usually used for optical density measurement at 264 $m\mu$, where guanidine is transparent. The molar extinction coefficient of nitroguanidine at this wavelength was determined with solutions of concentration 5.30, 2.65, and 7.95×10^{-5} mole/liter as 1.56, 1.54, 1.55×10^4 , or an average of 1.55×10^4 . Similar solutions of known concentration were passed through the IR-4-B columns to prove by optical density measurement that recoveries of 98.7–99.6% were effected.

Cryoscopy in Sulphuric Acid

A. The Cryostat

In the apparatus shown in Fig. 1 the stainless-steel stirrer is driven by a cam which is rotated by a variable-speed motor. The temperature is measured by means of a Western Electric Type 14-A thermistor (R at 0° C. 3.5×10^5 ohms, at 50° C. 3.5×10^4 ohms), which is a part of the Wheatstone bridge shown in Fig. 2. Calibration with respect to a U.S. Bureau of Standards thermometer by plotting the logarithm of resistance of the variable arm of the bridge against the reciprocal of absolute temperature at the thermistor shows that the variation is linear and sensitive to 0.001° C.

For operation, the Wheatstone bridge is balanced at approximately 9° C. by adjustment of the variable resistance arm with respect to the galvanometer and then is switched to the Leeds and Northrup Speedomax recorder, the chart paper width of which covers a temperature range of about 0.35° C., thus facilitating readings to at least 0.001° C. In order to cover the range 9.0–10.4° C. four range settings are necessary, and these are available by means of the variable resistance arm of the bridge, which is adjusted to return the recorder pen to the origin at each step. In practice the recorder is connected when a deflection on the table galvanometer shows that solidification is commencing.

FIG. 1.

FIG. 2. Electrical circuit for measuring temperature changes in cryostat No. 2.

B. Procedure

Between 25 and 35 g. of absolute sulphuric acid is pipetted into the lower extremity of the cryostat, which previously has been flamed during passage of dry nitrogen through it. An air jacket with an inlet tube is then fitted around the lower extremity of the cryostat and the assembly is immersed in a bath of crushed ice. The sulphuric acid is then stirred under a slight positive pressure of nitrogen at the rate of 90 to 95 strokes per minute of the stainless-steel stirrer (Fig. 1). It is essential to the success of the experiment that the lowest extremity of the stirrer scrapes the wall of the cryostat during the entire stroke.

When the temperature of the sulphuric acid is about 2° C. above the freezing point a piece of dry ice (2 cm. by 0.5 cm. by 0.5 cm.) is passed along the lateral inlet tube of the air jacket and is pressed against the wall of the cryostat for 45 seconds. The seeds of sulphuric acid which form on the interior wall are dispersed through the medium by the action of the stirrer as it scrapes along the wall of the cryostat. In this manner supercooling of anhydrous sulphuric acid is avoided entirely and a time-temperature cooling curve is obtained without the necessity for corrections (10).

The solute, weighed into a very-thin-walled glass tube, is introduced into the cryostat through the 19/38 joint (Fig. 1) and is crushed manually against the wall of the cryostat with the aid of the stirrer in order to ensure uniform distribution throughout the cryoscopic medium. The freezing point is then determined from the chart record by reference to the calibration curve for the thermistor used in the bridge circuit. The results are reproducible to at least 0.003° C. if, and only if, current has been passed through the thermistor for about 12 hours prior to the determination.

ACKNOWLEDGMENTS

The authors are grateful to Messrs. Myers and Bedard of the Defence Research Board for the infrared spectrum and to Mrs. Liselotte Westland for the dipole moment determination. Also they are grateful to the Defence Research Board and the National Research Council for financial aid in support of this investigation.

ION-EXCHANGE METHODS FOR THE QUANTITATIVE SEPARATION OF THE ALKALINE EARTHS, AND THEIR APPLICATION TO THE DETERMINATION OF Sr^{90} IN MILK ASH¹

GWEN M. MILTON AND W. E. GRUMMITT

ABSTRACT

A study has been made of the effects of column loading and eluting agent on the cation-exchange separation of the alkaline earths—beryllium, magnesium, calcium, strontium, barium, and radium. The principal eluting agents tested were ammonium lactate, ammonium citrate, and hydrochloric acid. Dowex-50 resin (Ion X, 300–400 mesh) was used throughout the investigation, and the column temperature was maintained at approximately 80° C. Under optimum conditions, involving the use of 0.25 g. of resin per milliequivalent of sample and with ammonium lactate eluant (0.55 *M* at pH 5 for beryllium, and 1.5 *M* at pH 7 for magnesium, calcium, strontium, barium, and radium), a quantitative separation of all six elements in a single sample is possible in 5 hours. This procedure has been applied to the routine analysis of Sr^{90} in bulk milk ash samples, containing 20 mg. of strontium carrier, with yields of 85–95%. By the same method trace amounts of strontium naturally occurring in milk have also been determined.

INTRODUCTION

In recent years many investigators have reported separations of neighboring pairs of alkaline earths by methods other than precipitation procedures, e.g. paper chromatography (6, 11), anion-exchange (13), and numerous cation-exchange procedures utilizing such eluting agents as ammonium citrate (15), ammonium lactate (10), ammonium acetate (8); ethylenediamine tetraacetic acid (1, 4), and hydrochloric acid (2, 3). The cation-exchange method has been used almost exclusively in the few papers which have reported quantitative data (2, 10), and this technique would appear to be the most promising one for quantitatively separating millimoles of alkaline earth phosphates.

An estimation of the degree of separation obtained between two elements can be made by calculating the ratio of their distribution coefficients (D = milliliters of eluate to peak less one interstitial column volume/weight of resin in grams (12)). Using 1.2 *M* ammonium lactate eluant at room temperature, Lerner and Rieman (10) obtained the ratios $\text{Sr}/\text{Ca} = 1.5$, $\text{Ba}/\text{Sr} = 2.5$, and although millimole quantities of strontium and calcium were quantitatively recovered under these conditions, a greater separation would seem desirable for rapid or routine analysis. Campbell and Kenner (2) obtained data which give a ratio of distribution coefficients $\text{Ca}/\text{Mg} \geq 3$, using 1.07 *M* and 1.21 *M* hydrochloric acid eluant, also at room temperature. No mention was made of extending this method to include strontium and barium separations, but a recent study by Diamond (3) of alkaline earth distribution factors in hydrochloric acid indicated the feasibility of good separations between these two elements.

The purpose of this investigation was to determine whether milligram quantities of beryllium, magnesium, calcium, strontium, barium, and trace amounts of radium could be recovered quantitatively from a single sample in a few hours, and, by a study of various eluting agents at elevated temperature and the effects of column loading, to determine the optimum conditions for such a separation.

Following this work a severe test of the flexibility of the separation using 1.5 *M* ammonium lactate eluant was made by applying it to the analysis of milk and bone

ash. Ion-exchange techniques have previously been used to determine the alkali metals in these substances (14, 5); in this paper the new data were applied to the analysis for other constituents in the following two cases: (a) the recovery of calcium-free strontium, barium, and radium from bulk samples (15–17 g.) containing 2.5 g. (approx.) of calcium, and 20 mg. of added strontium, in order to measure Sr^{90} levels in milk routinely; (b) the determination of 70–130 p.p.m. of strontium in samples containing 16% of calcium (the composition of the average milk ash).

EXPERIMENTAL

The column used for most of the separations was a 1.1 cm. i.d. by 10 cm. long sinter funnel, packed with Dowex-50 (Ion X, 300–400 mesh) to a height of 8 cm. above the sinter. In addition two other sizes were employed; a 1.0 cm. i.d. by 2.0 cm. bed was used for some of the barium–radium separations to obtain smaller elution volumes and a 2.8 cm. i.d. by 10 cm. column, packed to a height of 9 cm. with approximately seven times the weight of resin in the original column, was required for the larger milk ash samples (15 g.).

Although improved separations are obtained at elevated temperatures in most instances (9), the operation of a column at 80–100° C. is not universal because of the complexity of the apparatus required and the associated troubles arising from the release of gas in the resin. Both of these objections have been satisfactorily overcome by the method adopted here. The packed column was surrounded by an air jacket, electrically heated to $78^{\circ} \pm 5^{\circ}$ C. Constant temperature was maintained throughout the column at normal flow rates (0.2 to 2 ml./min.) by the ethanol preheater attached to the eluant intake tube, provided the length of the reflux tube was not less than 25 cm. When used with the 2.8 cm. diameter apparatus, the size of the preheater and the current passing through it were both increased to maintain the temperature at the higher flow rate (5 ml./min.). Normally the elements were separated at 1.0 ml./min. when the smaller columns were employed, though a rate of 0.5 ml./min. was used with 6 *M* hydrochloric acid owing to the lower temperature (60° C.) required to prevent gas evolution.

A. The Separation of Milligram Amounts of the Alkaline Earths

Samples containing less than 40 mg. of each of the alkaline earths to be separated were dissolved in a minimum volume of the eluting agent to be used, at pH 2–4. Calcium–magnesium and calcium–strontium separations were attempted first, using 0.75 *M*, 1.0 *M*, and 1.5 *M* ammonium lactate at pH 7. The somewhat erratic results obtained initially were traced to the practice of degassing solutions before use by boiling, causing increases in the lactate concentration of as much as 25%. More efficient removal of dissolved air was obtained by degassing for 2 minutes, cold, with a filter pump, and the elution volumes became reproducible.

Trial runs were made to determine the position of the peak and the width of the elution band for each element, using precipitation and tracer techniques for identification. Subsequently, the separation was extended to include all six elements, eluting beryllium with 0.55 *M* lactate at pH 5, and the remainder with 1.5 *M* lactate at pH 7, though occasionally the radium was stripped off with 6 *M* hydrochloric acid. The percentage recovery of radium was determined from the α -disintegration rates before and after separation. Other elements were recovered as beryllium oxide, magnesium ammonium phosphate, calcium carbonate, strontium sulphate, and barium sulphate, using standard procedures (7).

Comparative separations of most of the foregoing elements were made using ammonium lactate, ammonium citrate, and also hydrochloric acid, as eluting agents. Similar attempts with versene and the ammonium citrate-versene mixtures used by Farabee (4) had to be discontinued, as no method of satisfactorily operating a column with these eluants at elevated temperatures and flow rates of approximately 1 ml./min. could be found.

B. The Separation of the Alkaline Earths Present in Milk Ash Samples

Preliminary experiments were done with 2.5 g. samples of milk ash (containing 16% calcium, 2% magnesium, and 35% phosphate), dissolved in 6 *M* hydrochloric acid. Strontium carrier (20 mg.) was added to the solution before it was evaporated just to dryness. The residue from this evaporation was taken up in a minimum of 1.5 *M* lactic acid, pumped free of air, and run onto the column at the rate of 1 ml./min.

During subsequent elution with 1.5 *M* ammonium lactate, ammonium oxalate was added to the eluate fractions to identify the calcium band, and at the first sign of a marked decrease in the calcium oxalate precipitate the next 50 ml. were collected as the strontium fraction. Following this, the barium and radium were stripped off together with 6 *M* hydrochloric acid. After the 50 ml. strontium fraction had been evaporated to 10–15 ml. the strontium was recovered as the sulphate, and any calcium carried with it removed by metathesis to the carbonate followed by a fuming nitric acid precipitation of strontium nitrate.

Following these tests both the sample and column size (but not the amount of strontium carrier added) were increased in order to obtain a measurable amount of fallout Sr^{90} activity in the separated strontium. In addition, recoveries were simplified by eluting the strontium with 6 *M* hydrochloric acid following the ammonium lactate separation of calcium.

RESULTS

A. The Separation of Milligram Amounts of the Alkaline Earths

(i) Ammonium Lactate Eluant

Preliminary measurements showed that calcium and magnesium were easily separable using ammonium lactate, and so this pair was chosen for a series of tests of the effects of concentration changes on the separation factor. In Fig. 1 the equilibrium distribution for each element (volume of eluate to the peak less the interstitial volume/weight of resin in grams) is plotted as a function of the ammonium lactate concentration. As shown in this figure, at three different molarities the ratio of Ca to Mg distribution coefficients remained essentially constant, despite the rapid change in equilibrium distributions at the higher molarities.

An upper limit to the molarity of the eluant is set by the requirement that the eluate volume to the first peak must be greater than the resin interstitial volume in order to prevent overlapping of adjacent bands. In the case of magnesium the ammonium lactate upper limit is 1.5 *M*. The separation of five elements at this concentration is shown in some detail in Fig. 3. The apparent improvement in ratios of distribution coefficients over those indicated by Lerner and Rieman (10) (see Table I) is attributed to the use of a higher elution temperature. Fig. 2 shows a typical elution curve for beryllium and magnesium. Here the limits of the lactate concentration for a complete, rapid separation are 0.55 *M* and 0.75 *M*. The unexpected broadness of the magnesium band in both

FIG. 1. The variation of distribution coefficient with concentration of ammonium lactate.

TABLE I
EFFECT OF ELUTING AGENT ON DISTRIBUTION COEFFICIENTS

Eluting agent	Ratios of distribution coefficients				
	Mg/Be	Ca/Mg	Sr/Ca	Ba/Sr	Ra/Ba
0.55 M amm. lactate pH 5	3.7				
0.75 M amm. lactate pH 7		2.8			
1.0 M amm. lactate pH 7		2.7			
1.2 M amm. lactate pH 7			1.5*	2.5*	
1.5 M amm. lactate pH 7		2.8	3.1	3.2	2.1
1.07 M HCl		~3†			
1.5 M HCl	2.3	4.0	<2.0	>3.0	
2.0 M HCl			1.8		
2.5 M HCl		3.3			
4.0 M HCl			2.3	3.0	
6.0 M HCl					1.1
5% amm. citrate pH 5.4		1.7	1.8	3.4	

*Calculated from the data of Lerner and Rieman (10).

†Calculated from the data of Campbell and Kenner (2).

these figures is a result of the relatively large quantity of that element present in these samples (milliequivalents of magnesium = $8 \times$ milliequivalents of strontium).

Yields measured under the conditions specified in Figs. 2 and 3 have been tabulated in Table II. It is apparent that quantitative separation of all six elements is possible within 5 hours, with one change of eluant required during that time. If preferred, the radium can be stripped off the column with 6 M hydrochloric acid immediately following the barium elution. The difference in the strontium recovery for samples containing 100 mg. of calcium (99.5%) and 400 mg. of calcium (88%) indicates the extent of column loading permissible in quantitative separations of this kind. These weights correspond

to a calcium uptake of 1.3 and 5 milliequivalents/g. of resin respectively, hence the column was completely in the calcium form in the second instance.

FIG. 2. The separation of beryllium and magnesium with ammonium lactate eluant—0.55 *M* at pH 5. 1.1 × 8 cm. column, flow rate 1.0 ml./min., *T* = 78° C. (In this and all succeeding figures one interstitial volume has been subtracted from the eluate volume before plotting.)

(ii) *Hydrochloric Acid Eluant*

Fig. 4 shows a separation of beryllium, magnesium, calcium, strontium, and barium using 1.5 *M* hydrochloric acid as eluant, and Fig. 5 a separation of calcium, strontium, and barium using 4 *M* acid. The Mg/Ca and Ba/Sr ratios of distribution coefficients are slightly better than those for ammonium lactate, and the elements are more easily recovered quantitatively from the hydrochloric acid solutions. Diamond's (3) plot of distribution coefficient versus hydrochloric acid molarity indicates that the calcium-strontium separation should improve with increasing strength of the acid, to a maximum at 6 *M*. Despite the Sr/Ca distribution coefficient ratio increase from 1.8 in 2 *M* to 2.3 in 4 *M* acid, however, some overlapping of the fractions still occurs. This overlap and a similar one in the beryllium-magnesium separation in 1.5 *M* acid are partially the result of too fast flow rates (~1 ml./min.) for the lowered elution temperatures (60° C.), plus inadequate temperature control in these two cases, causing broadening of the elution bands. By reducing the column load, maintaining the temperature at 60° and the flow rate at 0.5 ml./min., the overlapping has been decreased, but the bands are still appreciably broader than those obtained with ammonium lactate or ammonium citrate eluant.

FIG. 3. The separation of magnesium, calcium, strontium, barium, and radium with ammonium lactate eluant—1.5 *M* at pH 7. 1.1×8 cm. column, flow rate 1.0 ml./min., *T* = 78° C.

FIG. 4. The separation of beryllium, magnesium, calcium, and strontium with 1.5 *M* hydrochloric acid eluant. 1.1×8 cm. column, flow rate ~1.0 ml./min., *T* ~ 60° C.

FIG. 5. The separation of calcium, strontium, and barium with 4 *M* hydrochloric acid eluant. 1.1×8 cm column, flow rate ~1.0 ml./min., *T* ~ 60° C.

(iii) Ammonium Citrate Eluant

In order to achieve as rapid a separation of magnesium, calcium, strontium, and barium using ammonium citrate as with 1.5 *M* ammonium lactate, it was necessary to use a 5% citrate solution at pH 5. At that concentration the strontium-barium separation was the best obtained with any of the eluants, but it can be seen from Fig. 6 that some

FIG. 6. The separation of magnesium, calcium, strontium, and barium with ammonium citrate eluant—5% at pH 5. 1.1×8 cm. column, flow rate 1.0 ml./min., $T = 78^{\circ}\text{C}$.

overlapping is present in the calcium-magnesium and strontium-calcium fractions. However, the ratios of distribution coefficients are sufficiently high that the suggested methods for the development of a quantitative hydrochloric acid separation are equally applicable to the use of this eluant.

B. Calcium-Strontium Separations in Milk Ash Samples

In order to analyze milk and bone ash samples for strontium, barium, and radium, which are present in amounts of <0.025% of the calcium, it is necessary to use an eluant effecting as large a separation of these elements from calcium as possible. As a result of the foregoing comparative study ammonium lactate was chosen as the most promising.

Fig. 7 shows the separation achieved with a 2.5 g. sample of ash on the small column. Phosphate is not held by the resin at all, appearing after the first column volume of eluate. At this extent of overloading both the magnesium and calcium appear in the eluate before all the sample is on the resin. This effect can be reduced somewhat by dilution of the sample solution, but since the end point of the calcium fraction and the beginning of the strontium appear to be unaffected by the overloading, the dilution seems unnecessary. The strontium yield for this separation was 88%, and the calcium present in this strontium fraction was less than 0.05 mg.

From these data for a column loaded to capacity (5 milliequivalents of calcium/g. of resin),¹ it became obvious that approximately seven times the weight of resin in this column would be required to separate satisfactorily 20 mg. of strontium from a 15–17 g. sample of ash. Fig. 8 shows a typical elution curve of a 15 g. sample from the larger column. The strontium yield of 84% from the 300–650 ml. fraction contained 0.24 mg. of calcium. Another 6% of the strontium was recovered from the last 20 ml. of the calcium fraction, containing 1.5 mg. of calcium. Since the increase in volume of eluate

FIG. 7. The separation of magnesium, calcium, and strontium from 2.5 g. of milk ash, with ammonium lactate eluant—1.5 *M* at pH 7. 1.1×8 cm. column, flow rate 1.0 ml./min., *T* = 78° C. (The arrow indicates the volume of the sample solution.)

to the strontium peak in Fig. 8 over that in Fig. 3 (70 ml. to 350 ml.) can be accounted for by the increase in area of column (factor of 5), it may be inferred that the decrease in strontium yield was a result of the broadening of the calcium peak until an appreciable overlap of the two fractions existed. However, by a further increase in the amount of resin used, this overlap has been eliminated, and over 35 routine analyses have now been made with this column, with strontium recoveries varying between 85 and 95%.

The method has also been applied to the determination of much smaller quantities of strontium in bulk amounts of milk ash. Traces of strontium ranging from 0.6 to 2 mg. have been separated from samples containing approximately 2.5 g. of calcium and

0.3 g. of magnesium, and the total strontium present in these samples (70–130 p.p.m.) calculated by utilizing the percentage recovery of known amounts of strontium activity (see Table III). The reliability of the method when used in such determinations is demonstrated by the nearly quantitative recovery of added activity in sample 2 (a), while in the other samples the yield was deliberately lowered by repeated chemical purifications to ensure the constant specific activity of the strontium precipitate.

FIG. 8. The separation of magnesium, calcium, and strontium from 15 g. of milk ash, with ammonium lactate eluant—1.5 M at pH 7. 2.8×9 cm. column, flow rate 5.0 ml./min., $T = 78^\circ \text{C}$. (The arrow indicate the volume of the sample solution.)

TABLE III
DETERMINATION OF NATURALLY OCCURRING STRONTIUM IN MILK

Sample	Weight (g.)	Strontium activity added (dis./min.)	Strontium activity recovered (dis./min.)	Weight strontium recovered (mg.)	Total strontium in sample (mg.)	p.p.m. strontium in sample	Ca/Sr in sample
1	15	24	13.5	0.6	1.07	71	2240
2 (a)	17	198	180	1.99	2.2	130	1140
2 (b)	17	198	105	1.03*	2.0	120	1250

*Sample 2 (b) is the result of subjecting sample 2 (a) to repeated chemical separations to test the purity of the strontium carbonate precipitate, and hence the yield is very low.

THE POLYMERIZATION OF METHACRYLONITRILE AT ELEVATED TEMPERATURES¹

S. BYWATER

ABSTRACT

The photosensitized polymerization of methacrylonitrile has been investigated at temperatures above 100° C. A study of the kinetics suggests that at these temperatures the reverse (depropagation) reaction is important. From the experimental data, the heat and entropy change for the polymerization has been calculated.

INTRODUCTION

Dainton and Ivin (5) have indicated the reversible nature of polymerization and shown how heats and entropies of polymerization may be obtained from 'ceiling temperature' phenomena. Heats and entropies of polymerization may be obtained in this way for methyl methacrylate (2, 7, 10). Further information on other monomers would be of interest in order to obtain more data on heats and entropies of polymerization. It is desirable to choose a monomer where the reverse reaction yields predominantly monomer rather than larger fragments. Kern and Fernow (8) have reported an 85% yield of monomer in the depolymerization of polymethacrylonitrile so this compound is suitable for a study of reversible polymerization.

EXPERIMENTAL

The apparatus used was identical with that described previously (2). *o*-Dichlorobenzene was not used as solvent in this case since, although it is an efficient photosensitizer for methacrylonitrile, the polymer precipitates. Benzonitrile was found to be suitable for use as solvent since the polymer is soluble in this solvent. It does not, however, function as a photosensitizer and it was necessary to add one which is thermally stable to 150° C. Benzoin appears to fulfill these requirements (10) and was used throughout these experiments at a concentration of 0.0089 molar. Light from the mercury arc was filtered through an 0-52 Corning filter in order to remove the shorter wavelength radiation where benzoin has a strong absorption (3). C. P. benzoin was recrystallized twice from benzene before use. Methacrylonitrile was supplied by the Shell Development Co. and distilled under nitrogen before use. Benzonitrile (Eastman Kodak white label) was distilled prior to use. Methacrylonitrile was estimated in 1 ml. samples by the mercaptan addition method of Beesing *et al.* (1); since, however, mercaptans add to methacrylonitrile more slowly than to acrylonitrile, the analysis solutions were left standing 40 minutes in a thermostat bath at 35° before titration. Blank experiments showed that methacrylonitrile could be analyzed successfully by this method.

RESULTS

The rate of polymerization was studied at four temperatures, 110.6°, 121.0°, 132.2°, and 144.5°, as a function of monomer concentration. Methacrylonitrile shows very slow rates of polymerization (4) compared to other monomers so it was not possible to show

¹Manuscript received January 25, 1957.

Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.

that at high conversions the monomer concentration tends to an equilibrium value as was done previously for methyl methacrylate. Rates of monomer disappearance were studied up to 15% conversion, the plots being slightly curved. Initial rates were plotted as a function of monomer concentration and are shown in Figs. 1 and 2. The figures show that initial rates of polymerization are first order with respect to monomer concentration

FIGS. 1 and 2. Initial rates of polymerization as a function of initial monomer concentration at four temperatures.

but as the temperature increases, an increasing intercept is found on the x -axis corresponding to a monomer concentration at which the polymerization rate falls to zero. The slopes of the lines were plotted against reciprocal temperature in Fig. 3 giving an activation energy of 5.4 kcal.

FIG. 3. Slopes of the plots of Figs. 1 and 2 versus reciprocal temperature.

DISCUSSION

The scheme of polymerization given by the present author (2) substituting benzoin for the solvent as photosensitizer should hold for the present polymerization. This yields the rate expression

$$-d(M)/dt = k_p f(I_0)^{1/2} k_t^{-1/2} \{ [M]_0 - [M]_e \}$$

in the non-integrated form since we are dealing with initial rates only. Here $[M]_0$ is the initial monomer concentration, $[M]_e$ an equilibrium monomer concentration, k_p and k_t the rate constants for chain propagation and termination respectively, and $f(I_0)$ some function of the incident light intensity and the benzoin concentration. This relation requires that at each temperature the initial rates should be first order in monomer concentration but the rate should fall to zero as the monomer concentration is reduced to the equilibrium value $[M]_e$, which is the critical concentration at which the velocity of chain propagation becomes equal to that of depropagation or 'unzipping' of the chain. The experimental data conform to this equation, enabling $[M]_e$ values to be obtained. The slopes of the first order plots should be a function of $k_p k_t^{-1/2}$ according to the above equation, and making the reasonable assumption that $f(I_0)^{1/2}$ is temperature independent the activation energy from Fig. 3 should correspond to $E_p - \frac{1}{2}E_t = 5.4$ kcal. Grassie and Vance (6) obtained a value of 6.5 kcal. for this ratio at lower temperatures where depropagation is negligible.

The equilibrium monomer concentration is related to the standard Gibbs free energy of polymerization by the relation (2)

$$-\Delta G_{ss}/RT = \ln(1/[M]_e)$$

where ΔG_{ss} is the Gibbs free energy change in the polymerization at a standard state of 1 mole per liter.

Thus $\Delta G_{ss}/RT$ can be computed from the intercepts of the lines in Figs. 1 and 2 (Table I). $\Delta G_{ss}/RT$ is plotted against $10^3/T$ in Fig. 4. The slope of this line (corresponding to ΔH_{ss}) is equivalent to -15.3 kcal. Substitution of this value into ΔG_{ss} gives $\Delta S_{ss} = -34$

TABLE I

T ($^{\circ}$ K.)	$[M]_e$ (moles/liter)	$-\Delta G_{ss}/RT$
394.2	0.09	2.40
405.4	0.15 _s	1.87
417.7	0.27	1.31

e.u. It is estimated that the uncertainty in these determinations amounts to ± 1 kcal. in ΔH and ± 2 e.u. in ΔS . No direct calorimetric data on the heat of polymerization of methacrylonitrile exist but Tong and Kenyon (12) report a heat of polymerization of acrylonitrile (liquid monomer-solid polymer) of -17.3 kcal. α -Methyl substitution lowers the heat of polymerization by several kilocalories; thus the heat of polymerization of the most closely similar monomer, acrylic acid, is lowered by 2.8 kcal. on α -methyl substitution. Thus the present value for the heat of polymerization appears reasonable. The entropy of polymerization is slightly larger than that reported for methyl methacrylate (2) ($\Delta S_{ss} = -29.5$ e.u.) but not greatly different. Calculations of ΔH_{1e} and ΔS_{1e} (2) have not been carried out since benzonitrile is not reported (9) to be a 'good' solvent for

polymethacrylonitrile and hence the μ value characterizing polymer-solvent interaction required for the correction term is not easily estimated. This can be done should more data become available on the thermodynamics of solutions of this polymer.

There undoubtedly exist side reactions in this type of polymerization. Talât-Erben and Bywater (11) have indicated abnormal steps in the propagation steps and the fact that the yield of monomer in degradation is not 100% (8) suggests that side reactions

FIG. 4. $\Delta G_{ss}/RT$ as a function of reciprocal temperature.

also may occur in the depropagation steps. The kinetics however clearly indicate that both chain propagation and the reverse (depropagation) steps occur in methacrylonitrile above 110° C. and it seems doubtful whether the effect on the measured ΔH and ΔS values for the process could be much larger than the estimated error in their determination.

CONSTITUTION OF A WATER SOLUBLE HEMICELLULOSE FROM AMERICAN BEECHWOOD (*FAGUS GRANDIFOLIA*)¹

G. A. ADAMS

ABSTRACT

Extraction of beechwood chlorite holocellulose with hot water yielded a hemicellulose in 13.4% yield (based on original extractive-free wood) containing D-xylose 72%, D-galactose 11.0%, and uronic acid 13.2%. Purification of the crude hemicellulose by complexing with Fehling's solution yielded a chemically homogeneous fraction containing D-xylose 83% and 4-O-methyl-D-glucuronic acid 15.5%. Hydrolysis of the fully methylated hemicellulose yielded 2,3,4-tri-O-methyl-D-xylose, 2,3-di-O-methyl-D-xylose, 3-O-methyl-D-xylose, and 3-O-methyl-2-O-(2,3,4-tri-O-methyl-D-glucopyranosyluronic acid)-D-xylose in a molar ratio of 2:35:3:5. On the basis of the methylation data, periodate oxidation, reducing power determinations, and weight average molecular weight values a possible structure for the hemicellulose is proposed.

Existence of a xylan in beechwood was established by Wheeler and Tollens in 1889 (16) by identification of D-xylose in an acid hydrolyzate of beechwood sawdust. Later O'Dwyer (12) isolated hemicelluloses A and B from beechwood by extraction with sodium hydroxide and showed them to differ in physical and chemical properties. A recent investigation of the structure of hemicellulose A (3) showed it to be a straight chain of about 70 1 → 4 linked β-D-xylopyranose residues to which a terminal 4-O-methyl-D-glucopyranuronic acid residue is linked through C₍₂₎ to every 10th xylose unit. On the basis of fractionation experiments with hemicellulose A acetates, O'Dwyer (13) has suggested that this material may contain as many as three separate hemicelluloses; this suggestion is not improbable considering the complexities usually found in most polysaccharides of plant origin. The present study was undertaken to investigate the possibility of preparing a hemicellulose from beechwood by the use of a milder solvent than 4% sodium hydroxide. The constitution of a hemicellulose extracted by water forms the main subject of the investigation.

The starting material was holocellulose prepared by chlorite delignification of American beechwood (*Fagus grandifolia*). Although Timell and Jahn (15) have shown that the polysaccharides of birch undergo degradation during this treatment, there is also evidence that the degradation is neither extensive (17) nor selective (7). Extraction with heated water (94° C.) produced an extracting medium which was slightly acid (pH 5.1) and hence may have had a degrading effect on the hemicelluloses, thereby increasing their solubility in water. That such an effect was minimal was demonstrated by the fact that there was no change in the viscosity of the isolated hemicellulose after it was heated for 24 hours in aqueous solution (final pH 5.1). Chromatographic examination of the heated solution showed no evidence of cleavage products. Hence it may be concluded that the water extraction removed a pre-existent hemicellulose component from the holocellulose.

The isolated hemicellulose (13.4% yield) contained xylose and a monomethyl uronic acid as the major constituents; a small amount of galactose was also present. Purification by complexing with Fehling's solution removed the galactose and yielded a hemicellulose containing D-xylose 83%, uronic acid 15.5%, and having $[\alpha]_D^{25} - 75^\circ$ (in water).

The uronic acid was separated from the neutral sugars after hydrolysis as an aldobiouronic acid. Its constituents were determined by reducing its methyl ester methyl

¹Manuscript received January 24, 1957.

glycoside with lithium aluminum hydride to the corresponding disaccharide, methyl-*O*-(4-*O*-methyl-D-glucopyranosyl)-D-xyloside. Acid hydrolysis yielded D-xylose and 4-*O*-methyl-D-glucose and hence the acid constituent was identified as 4-*O*-methyl-D-glucuronic acid. The high positive rotation of the aldobiouronic acid (+79°) indicated an α -configuration for the glycosidic bond.

The hemicellulose was methylated and fractionally precipitated from chloroform solution by petroleum ether to give one main fraction having theoretical methoxyl content. Methanolysis and hydrolysis yielded the following products: (I) methylated uronic acid, (II) 3-*O*-methyl-D-xylose, (III) 2,3-di-*O*-methyl-D-xylose, and (IV) 2,3,4-tri-*O*-methyl-D-xylose; the molar ratio of these fractions was approximately 5:3:35:2.

The linkage between the D-xylose residue and the 4-*O*-methyl-D-glucuronic acid was established by examination of the methylated aldobiouronic acid Fraction I. Reduction of its methyl ester methyl glycoside with lithium aluminum hydride followed by hydrolysis of the disaccharide yielded 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose. These results showed that the uronic acid was glycosidically attached to the D-xylose unit through C₍₂₎ or C₍₄₎. The exact point of attachment was established by reducing the original aldobiouronic acid with lithium aluminum hydride to the corresponding disaccharide, 4-*O*-methyl-D-glucosyl-D-xylose. The disaccharide was then fully methylated and on hydrolysis yielded 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose. These results proved that the attachment of the uronic acid moiety was to C₍₂₎ of the xylose unit. Therefore the aldobiouronic acid derived from the hemicellulose by acid hydrolysis was 2-*O*-(4-*O*-methyl- α -D-glucopyranosyl uronic acid)-D-xylopyranose.

The 2,3,4-tri-*O*-methyl-D-xylose represented the terminal xylopyranose units in the original methylated hemicellulose and the amount indicated that there was one non-reducing end group present for every 25 sugar residues. The relatively large proportion of 2,3-di-*O*-methyl-D-xylose proved that the main chain of the hemicellulose was composed of xylopyranose units linked through C₍₁₎ and C₍₄₎. The change in rotation of the methylated polysaccharide on hydrolysis from negative (−102°) to positive (26°) indicated that the xylose units were mainly in the β -configuration. The 3-*O*-methyl-D-xylose in the hydrolyzate from the methylated hemicellulose indicated branch points in the molecule. The amount of 3-*O*-methyl-D-xylose exceeded the amount of 2,3,4-tri-*O*-methyl-D-xylose originating from the non-reducing end groups and it must be concluded that not all of the monomethyl pentose was structurally significant. It was considered likely that incomplete methylation and demethylation on hydrolysis contributed partly to the production of the monomethyl sugar. Its possible origin from cleavage of the methylated aldobiouronic acid was discounted, as no free methylated glucuronic acid was found in the hydrolyzate from the methylated hemicellulose.

On the basis of the methylation data it is possible to propose a structure for the hemicellulose consisting of 45 D-xylopyranose units linked 1 $\rightarrow$ 4 by β -glycosidic bonds. The xylan chain contains one branch point at C₍₂₎ of a xylose unit and hence the molecule has two non-reducing end groups and one reducing end group. Five units of 4-*O*-methyl-D-glucuronic acid are joined as single terminal side chains to the xylose units of the main structure by α , 1 $\rightarrow$ 2 glycosidic bonds. The distribution of the uronic acids units along the xylan chain is unknown except that they cannot be attached to the units forming the branch point or the non-reducing end. Periodate oxidation data provided confirmation of the structure as proposed from the methylation data. The proposed structure should consume 1.08 moles of periodate and produce 0.08 moles of formic acid

per mole of anhydropentose unit; actual consumption of periodate was 0.98 moles and formic acid production was 0.09 moles per sugar unit. On the basis of formic acid production (assuming two non-reducing ends) the molecule would contain 44 sugar units. The foregoing evidence was supported further by an estimate of reducing power, which indicated one reducing group per 47-51 sugar residues. Viscosity measurements of the hemicellulose, which yield weight average molecular weight values, were made in 0.1 *M* sodium chloride and in cupriethylenediamine and gave values of 46 and 47 respectively. Although the viscosity data as calculated from Staudinger's equation may be slightly anomalous owing to a branched molecule, the presence of one branch point is not likely sufficient to affect the general order of the result.

This hemicellulose isolated from American beechwood by aqueous extraction differed in some respects from the European beechwood studied by Aspinall *et al.* (3). While the constituents are the same, the American beechwood hemicellulose was a smaller molecule and was singly branched. The hemicellulose of the European beechwood was prepared by alkaline extraction of the wood (11) and may have included a water soluble hemicellulose similar to that isolated from American beechwood. The presence of branched material in the hemicellulose studied by Aspinall *et al.* (3) might have accounted in part for the presence of the monomethyl xylose formed on methanolysis of the methylated hemicellulose. A singly branched xylan containing a terminal D-glucuronic acid residue has been isolated from pear cell wall (5), but unlike the beechwood xylan, had the uronic acid attached to C₍₃₎ of the xylose unit. As pointed out previously (1) the presence of a methyl ether substituent on C₍₄₎ of D-glucuronic acid is associated with glycosidic linkage attachment to C₍₂₎ of the xylose residue. However, a recent investigation (4) of Monterey pine (*Pinus radiata*) has shown the presence of a small amount of 3-O- α -(4-O-methyl-D-glucuronosyl)-D-xylose along with the usual 2-O-(4-O-methyl-D-glucuronosyl)-D-xylose, and the authors have predicted that the former acid may be a fairly common acidic constituent of wood hemicelluloses.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated and melting points are corrected.

Paper Chromatography

The following solvents (v/v) were used to separate the sugars and their derivatives: (A) ethyl acetate:pyridine:water (2:1:2), (B) methyl ethyl ketone:water (2:1), (C) ethanol:benzene:water (47:200:15), (D) *n*-butanol:ethanol:water (40:11:19), and (E) ethyl acetate:acetic acid:formic acid:water (18:3:1:4). Separations were performed by the descending technique on Whatman No. 1 filter paper. A 3% solution of *p*-anisidine in ethanol was used as the spray reagent. The *R_f* values are mobilities relative to 2,3,4,6-tetra-O-methyl-D-glucose.

Preparation of Hemicellulose

Shavings were prepared from a mature American beechwood log (*Fagus grandifolia*) and were ground in a Wiley mill. The fraction passing 20 mesh and retained on 60 mesh was successively extracted with benzene-ethanol (2:1) and ethanol. Pectic substances were removed by extraction with ammonium oxalate (0.5%) at 85° C. for two periods of 3 hours each; the residue was thoroughly washed with water at 85° C. Holocellulose was prepared from the extractive-free wood by the acid chlorite method (18) in 80.5%

yield. Holocellulose (600 g.) was suspended in 35 liters of water and stirred continuously for 24 hours at 94° C. The pH of the solution was initially 5.5 and decreased over the 24 hour period to 5.1. The extract was filtered through cloth, centrifuged to remove cellulosic fibers, and concentrated 10-fold at 25° C. in a Majonnier evaporator. The concentrated solution was poured into 4 volumes of ethanol and after it had been left overnight the precipitated hemicellulose was recovered by filtration. Drying with ethanol and ether yielded a fine white powder, yield 13.4% (based on extractive-free wood), ash 6.5%, moisture 8.4%. Determination of uronic acid (6) required substantially ash-free material and the ash content was reduced to <0.1% by the following procedure: hemicellulose (2 g.) was dissolved in 100 ml. of water to which were added *N* hydrochloric acid (10 ml.) and 95% ethanol (25 ml.). The mixture was kept at 5° C. for 1.5 hours with frequent shaking. The hemicellulose was precipitated into 420 ml. of absolute ethanol and washed free of acid, after which it was taken up in water and freeze-dried. Analysis showed that the hemicellulose was composed of uronic acid 13.2%, xylose 72.0%, and galactose 11.0%.

Purification of the Water Soluble Hemicellulose

Hemicellulose (50 g.) was dissolved in 4% sodium hydroxide (3500 ml.) and mixed with Fehling's solution (3000 ml.). The copper complex which formed was filtered off, decomposed with hydrochloric acid in acetone (25:600 v/v), and the polysaccharide was washed free of acid with acetone:water (60:40 v/v) and dried *in vacuo*. Chromatographic examination of the product after acid hydrolysis showed that xylose was the only neutral sugar present. Anal.: xylose 83.8%, uronic acid 15.5%, ash 0.35%, $[\alpha]_D^{25} -75^\circ \pm 2^\circ$ (c, 1.0% in 1% sodium hydroxide).

Preparation of Uronic Acids from the Hemicellulose

Hemicellulose (100 g.) was stirred overnight in *N* sulphuric acid (2000 ml.) at room temperature; during this time the solution became dark brown. Heating at 98° C. for 7 hours hydrolyzed the polysaccharide to a constant reducing value. The solution was brought to pH 6.0 by the addition of barium hydroxide, filtered free of barium sulphate, and the cations were removed by passage through a column of Amberlite IR-120. The solution and washings were concentrated to about one-quarter of their volume at 30° C. The uronic acid components were absorbed on a column of Dowex 1-X⁴ (HCO₃⁻) (20×150 mm.). The column was washed with water until free of sugars by the anthrone test. Uronic acids were displaced from the resin by addition of excess 0.1 *N* sodium hydroxide and cations were removed from the solution by Amberlite IR-120. The acidic solution was concentrated to a sirup and freeze-dried, yield 11.34 g. Chromatographic examination in solvent E showed the presence of five components with *R_z* values (movement relative to xylose) as follows: 0.09, 0.27, 0.35, 0.70, and 1.30 (Fractions 1, 2, 3, 4, and 5); of these, Fraction No. 4 (*R_z* 0.70) was the largest component. Fraction No. 5 was chromatographically identical with 4-*O*-methyl-D-glucuronic acid.

The uronic acid fractions (6.7 g.) were separated chromatographically on sheets of Whatman No. 1 filter paper (18½×11½ in.) using solvent E. The acid fractions were eluted with water, concentrated at 30° C., and dried *in vacuo* to constant weight.

Examination of the Uronic Acid Fractions

Samples of Fractions 1, 2, 3, and 4 (approximately 20 mg. each) were hydrolyzed in sealed tubes with *N* sulphuric acid for 18 hours at 110° C. Considerable decomposition

occurred. Neutralization with barium carbonate and clarification with charcoal followed by chromatographic examination in solvents A and E showed xylose and 4-*O*-methyl-D-glucuronic acid to be the main components of all fractions; traces of glucose were also present. Fractions 1 and 2 contained a small amount of galacturonic acid which was thought to have its origin in a pectic contaminant. Since all fractions had essentially the same components, Fraction 4, being the largest, was chosen for further examination.

Uronic Acid Fraction 4

This material was an aldobiouronic acid, acid equivalent 347 (calculated for $C_{12}H_{19}O_{11}$, acid equivalent 340), $[\alpha]_D^{25} +79^\circ \pm 2^\circ$ (in water), R_x 0.66–68 (solvent E). Identification of the constituents of this acid was made as follows: the methyl ester methyl glycoside of the acid was prepared by refluxing the aldobiouronic acid in 2% methanolic hydrogen chloride for 8 hours. The product (354 mg.) was dissolved in dry tetrahydrofuran (20 ml.) and added dropwise to a suspension of lithium aluminum hydride (0.7 g.) in tetrahydrofuran (35 ml.) over a period of 1 hour. The reaction mixture was then refluxed gently for an additional hour, cooled, and excess lithium aluminum hydride was decomposed by addition of ethyl acetate and then water. The precipitated salts were filtered off and the solution was deionized by a mixture of Amberlite IR-120 and IR-4B. The recovered disaccharide weighed 284 mg. Hydrolysis with 0.5 *N* sulphuric acid for 8 hours at 100° C. yielded a sirup which on qualitative chromatographic examination using solvent C showed spots corresponding to D-xylose and 4-*O*-methyl-D-glucose. The sugars were separated chromatographically on large sheets of Whatman No. 1 paper using solvent C. Elution with water yielded D-xylose (91 mg.), m.p. and mixed m.p. 145° C., $[\alpha]_D^{25} +18^\circ \pm 0.5^\circ$ (*c*, 0.8% in water), and sirupy 4-*O*-methyl-D-glucose (111 mg.). Anal.: calculated for $C_7H_{14}O_6$: OCH_3 16.0%; found: OCH_3 15.4%.

The osazone of the 4-*O*-methyl-D-glucose was prepared by heating the sugar (90 mg.) with water (3.5 ml.), acetic acid (0.3 ml.), and phenylhydrazine (0.5 ml.) for 2.5 hours at 90° C. The recovered 4-*O*-methyl-D-glucosazone was recrystallized from ethanol containing a small amount of water and had a melting point of 157–158° C., unchanged on admixture with an authentic sample.

Methylation of Hemicellulose

Hemicellulose (15 g.) was methylated with dimethyl sulphate and sodium hydroxide by a method previously described (2). Two methylations were applied successively, after which the crude product was recovered by neutralization, dialysis, and evaporation. After a total of 10 methylations the product was soluble in methyl iodide and was subjected to four methylations by Purdie's reagents. The recovered product had a methoxyl content of 37.5%. Methylation with diazomethane increased the methoxyl content to 38.1%, a value which was not increased by further methylation. The infrared spectrum showed no hydroxyl band at 3500 cm^{-1} . The fully methylated hemicellulose was a porous yellow solid, yield 13.6 g., OCH_3 38.1% (theoretical value for dimethyl xylan 38.7%), $[\alpha]_D^{25} -102^\circ \pm 1^\circ$ (*c*, 0.9% in chloroform).

Fractionation of Methylated Hemicellulose

The methylated hemicellulose (13.0 g.) was dissolved in chloroform solution, clarified by centrifuging, and fractionally precipitated by the addition of petroleum ether (b.p. 30°–60° C.). With the exception of small head and tail fractions, the main bulk

of the hemicellulose precipitated as one fraction, yield 12.5 g., OCH_3 38.2%, $[\alpha]_D^{25} -102^\circ \pm 1^\circ$ (c , 1.0% in chloroform).

Methanolysis

The fully methylated hemicellulose (50 mg.) was heated with 8% methanolic hydrogen chloride (5.0 ml.) in a boiling-water bath for 12 hours. Solvent was removed, 0.5 *N* hydrochloric acid (5 ml.) was added, and the methyl glycosides were hydrolyzed for 8 hours at 100° C. to yield a mixture of methylated sugars, $[\alpha]_D^{25} +26^\circ \pm 1^\circ$. The sugars were recovered and chromatographed in solvent B, using *p*-anisidine as the indicating spray. Authentic samples of 3-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2,3,4-tri-*O*-methyl-D-xylose were used as reference compounds. A total of four spots appeared on the chromatogram and the following tentative identifications were made, based on mobility of the substances relative to the reference compounds: methylated uronic acid (I), a monomethyl pentose corresponding to 3-*O*-methyl-D-xylose (II), a dimethyl pentose corresponding to 2,3-di-*O*-methyl-D-xylose (III), and a trimethyl pentose corresponding to 2,3,4-tri-*O*-methyl-D-xylose (IV). The yield of Fraction I was determined by isolation as described later. Quantitative chromatography of the sugars on paper, elution with water, and analyses by the alkaline hypiodite method (5) showed Fractions I, II, III, and IV to be present in a simple molar ratio of 5:3:35:2.

Separation of Methylated Sugars

The fully methylated hemicellulose (6.7 g.) was refluxed with methanolic hydrogen chloride (8%) for 10 hours, when the rotation became constant. After neutralization of acid with silver carbonate and recovery of glycosides and uronosides by the usual method, the latter were converted to their barium salts by heating at 65° C. for 2 hours with a saturated solution of barium hydroxide (80 ml.). Excess barium hydroxide was removed by carbon dioxide.

The fully methylated glycoside fraction was recovered by continuous extraction with *n*-pentane (yield 0.469 g.). The aqueous residue was freed of cations by Amberlite IR-120 and the uronic acid glycoside was absorbed on Amberlite IR-4B (acetate form). Thorough washing of the resin yielded the sugar glycosides (5.82 g.). The acid fraction was recovered by elution with 0.1 *N* formic acid, yield 0.84 g. Hydrolysis and chromatography showed that the trimethyl glycoside fraction contained some dimethyl glycosides and also that the uronic acid fraction contained some monomethyl glycoside. The various glycoside fractions were hydrolyzed to reducing sugars by 0.5 *N* hydrochloric acid and these were separated on Celite columns (10) using butanol saturated with water as solvent. Butanol saturated with 0.25% ammonium hydroxide was used when uronic acid was separated from sugars. The uronic acid fraction was recovered by eluting the column with water. A total of four separate fractions was recovered, which corresponded to Fractions I, II, III, and IV as found on the paper chromatograms previously described.

Examination of the Methylated Sugar Fractions

Fraction I.—This material was a methylated aldobiouronic acid which gave a cherry red spot with *p*-anisidine spray on a paper chromatogram, OCH_3 38.8%, acid equivalent 412 (calculated for $\text{C}_{16}\text{H}_{28}\text{O}_{11}$: OCH_3 39.2%, acid equivalent 396). Identification of the constituents of the aldobiouronic acid was made as follows: The aldobiouronic acid (422 mg.) was converted to its methyl glycoside methyl ester by refluxing for 6 hours with 8% methanolic hydrogen chloride (25 ml.). The acid was neutralized with silver

carbonate, silver salts were removed by filtration, and the solvent was removed by evaporation. The product was dissolved in dry ethyl ether (25 ml.) and the solution was added dropwise over a period of 1 hour to a stirred suspension of lithium aluminum hydride (0.9 g.) in ether (55 ml.). The reduction and recovery procedures were carried out as previously described and the glycoside of the neutral disaccharide was recovered as a porous solid (358 mg.). Hydrolysis with *N* sulphuric acid (10 ml.) on a boiling-water bath yielded two sugars, a monomethyl pentose and a trimethyl hexose as shown by chromatographic examination in solvents B and C. The sugars were separated on a Celite column using butanol saturated with water as the solvent.

Identification of 3-O-methyl-D-xylose.—The R_f value of the monomethyl pentose in solvent B corresponded to that of an authentic sample of 3-O-methyl-D-xylose. Anal.: calculated for $C_6H_{12}O_5 \cdot OCH_3$ 19.9%; found: OCH_3 18.6%. The sirup, which did not crystallize, had $[\alpha]_D^{25} +18^\circ \pm 1^\circ$ (c , 1.0% in water), reported value $+19^\circ$ (9). Preparation of the osazone yielded crystalline 3-O-methyl-D-xylosazone, m.p. 170° – 171° C. (reported value 172° C. (3)).

Identification of 2,3,4-tri-O-methyl-D-glucose.—The trimethyl hexose (233 mg.) had the same R_f values (0.78 and 0.53) in solvents B and C respectively as an authentic sample of 2,3,4-tri-O-methyl-D-glucose, and $[\alpha]_D^{25} +68^\circ \pm 2^\circ$ (c , 1.0% in water), reported value $+66.8^\circ$ (14). Anal.: calculated for $C_6H_{12}O_6 \cdot 3OCH_3$ 41.9%; found: OCH_3 41.6%. The trimethyl glucose (95 mg.) was oxidized with nitric acid (10 ml.; d , 1.2) for 2.5 hours at 90° C. After removal of solvents by distillation with water and ethanol, the recovered sirup was converted to the corresponding lactone by heating for 3 hours at 90° C. *in vacuo* and to the methyl ester by refluxing with 2% methanolic hydrogen chloride for 6 hours. The methyl ester of the lactone (89 mg.) was distilled and 2,3,4-tri-O-methyl-D-glucosaccharo-1,5-lactone-6-methyl ester was recovered, yield 47 mg., b.p. (bath temperature) 140° – 150° C. at 0.01 mm. The product crystallized readily on nucleation, m.p. 105° – 106° C., unchanged on admixture with an authentic sample, and had $[\alpha]_D^{25} +54^\circ \pm 2^\circ$ in 20 hours (c , 1% in methanol). Anal.: calculated for $C_{10}H_{16}O_7 \cdot OCH_3$ 50.0%; found: OCH_3 50.4%.

Fraction II.—This sirup had the same R_f values (0.59–0.60 and 0.67–0.68) in solvents D and A respectively as an authentic sample of 3-O-methyl-D-xylose. This sirup crystallized, and recrystallization from methanol yielded 3-O-methyl-D-xylose, m.p. 103° – 104° C., unchanged on admixture with an authentic sample, $[\alpha]_D^{25} +18^\circ \pm 1^\circ$. Anal.: calculated for $C_6H_{12}O_5 \cdot OCH_3$ 18.9%; found: OCH_3 18.6%.

Fraction III.—This material was recovered from the Celite column as a clear, white sirup which had $[\alpha]_D^{25} +23^\circ \pm 1^\circ$, η_D^{25} 1.4732, OCH_3 34.8% (calculated for $C_7H_{14}O_5 \cdot OCH_3$ 34.8%). The R_f value in solvent B (0.67–0.68) was identical with that of an authentic sample of 2,3-di-O-methyl-D-xylose. The crystalline aniline derivative, 2,3-di-O-methyl-N-phenyl-D-xylosylamine, was prepared having m.p. and mixed m.p. 123° – 124° C.

Fraction IV.—This sirup partially crystallized on standing. Recrystallization from ethyl ether containing a small amount of petroleum ether yielded 2,3,4-tri-O-methyl-D-xylopyranose, m.p. 89° – 90° C., unchanged on admixture with an authentic sample, $[\alpha]_D^{25} +21^\circ \pm 1^\circ$ (c , 1.0% in water), OCH_3 48.1% (calculated for $C_8H_{16}O_5 \cdot OCH_3$ 48.4%). The R_f value (0.86–0.88) in solvent C was identical with that of 2,3,4-tri-O-methyl-D-xylose.

Further Examination of Uronic Acid Component

A portion of the main uronic acid fraction (678 mg.) as isolated earlier was converted

to its methyl glycoside methyl ester by refluxing with 2% methanolic hydrogen chloride (25 ml.) for 8 hours. The methyl glycoside methyl ester of the aldobiouronic acid (654 mg.) in tetrahydrofuran (45 ml.) was reduced by dropwise addition to a solution of lithium aluminum hydride (700 mg.) in tetrahydrofuran (35 ml.). The glycoside of the neutral disaccharide was recovered as foamed solid (583 mg.).

Methylation of the Disaccharide

The 4-*O*-methyl-D-glucosyl-D-xylose (583 mg.) was dissolved in 20% sodium hydroxide (10 ml.) and methylated by the simultaneous dropwise addition of 40% sodium hydroxide (55 ml.) and dimethyl sulphate (30 ml.) at room temperature. The methylation was repeated once. The solution was heated at 95° C. for 1 hour, cooled, acidified with 2 *N* sulphuric acid to pH 5.0, and extracted continuously with chloroform for 24 hours. Evaporation of the chloroform yielded a sirup (430 mg.). Two further methylations with Purdie's reagents (silver oxide 10 g., and methyl iodide 30 ml.) yielded a clear sirup (391 mg.), $[\alpha]_D^{25} + 112^\circ \pm 1^\circ$ (*c*, 1.0% in chloroform). The infrared spectrum indicated that there were no free hydroxyl groups. Anal.: calculated for $C_{18}H_{34}O_{10}$: OCH_3 52.9%; found: OCH_3 51.2%.

Hydrolysis of fully methylated disaccharide and recovery of sugar components.—The methylated disaccharide (391 mg.) was hydrolyzed by heating for 18 hours in 8% methanolic hydrogen chloride (25 ml.), and after removal of the solvent, by further heating for 10 hours at 100° C. with 0.5 *N* hydrogen chloride. The hydrolyzate was neutralized by silver carbonate, deionized by Amberlite IR-120 and Amberlite IR-45, and concentrated to a sirup (280 mg.). Chromatographic examination of the sirup in solvent B showed two sugars corresponding to 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose. The sugars were separated on a Celite column (10) using butanol saturated with water as the solvent to give 3,4-di-*O*-methyl-D-xylose (90 mg.) and 2,3,4,6-tetra-*O*-methyl-D-glucose (123 mg.).

Identification of 3,4-di-O-methyl-D-xylose.—The colorless sirup had $[\alpha]_D^{25} + 19^\circ \pm 1^\circ$ (*c*, 1.4% in water). On chromatographic examination in solvent C it had an R_f value of 0.38 and thus was distinguishable from 2,3-di-*O*-methyl-D-xylose (R_f 0.31) and 2,4-di-*O*-methyl-D-xylose (R_f 0.27). Anal.: calculated for $C_7H_{14}O_5$: OCH_3 34.8%; found: OCH_3 34.8%. A solution of the 3,4-di-*O*-methyl-D-xylose (75 mg.) in water (1.2 ml.) containing barium carbonate (60 mg.) was oxidized by bromine (0.6 ml.) in the dark for 60 hours. The bromine was removed by aeration with nitrogen, and the solution was acidified by *N* hydrochloric acid, filtered, and extracted continuously with chloroform for 72 hours. The recovered sirup from the chloroform extraction was heated *in vacuo* at 90° C. for 3 hours to lactonize the acid. On seeding with 3,4-di-*O*-methyl-D-xylo- δ -lactone, crystallization took place. Recrystallization from ether containing hexane yielded 3,4-di-*O*-methyl-D-xylo- δ -lactone, m.p. 66°–67° C., $[\alpha]_D^{25} - 22^\circ \pm 1^\circ$ (*c*, 1.1 in water).

Identification of 2,3,4,6-tetra-O-methyl-D-glucose.—The sugar as recovered from the Celite column crystallized spontaneously on removal of solvent. Recrystallization from ether–petroleum ether solution yielded white needles, $[\alpha]_D^{25} + 82^\circ \pm 2^\circ$ (in water), m.p. and mixed m.p. 96° C. The 2,3,4,6-tetra-*O*-methyl-D-glucose (90 mg.) in methanol (3 ml.) containing aniline (3 ml.) was refluxed for 2.5 hours. On removal of solvent the anilide crystallized at once. Recrystallization from ethanol yielded 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 116°–117° C., $[\alpha]_D^{25} + 205^\circ \pm 1^\circ$ (*c*, 1.1% in acetone).

Estimation of Degree of Polymerization

Viscosity measurements.—Viscosity determinations were made on solutions of beechwood hemicellulose in 0.1 M sodium chloride and cupriethylenediamine. Solution concentrations were within the range 0.20–1.00% and measurements were made in Oswald-Cannon-Fenske viscometers in a water bath at $25^{\circ} \pm .02^{\circ}$ C. Weight average molecular weights were calculated by substituting limiting viscosity number $[\eta]$ values in Staudinger's equation using 5.0×10^{-5} as the value for K_m as proposed by Husemann (8). The molecular weights obtained for the hemicellulose in both solvents were 6000–6200, which corresponds to a D.P. of 46–47.

Reducing power.—Samples of the beechwood hemicellulose (50 mg.) were oxidized by alkaline hypiodite according to the method of Chanda *et al.* (5). Number average molecular weights based on reducing power of the hemicellulose gave values between 6200 and 6700, which corresponds to one reducing end group for each 47–51 sugar units.

Periodate oxidation.—Beechwood hemicellulose (100 mg.) was oxidized by 1% sodium metaperiodate (100 ml.) in the dark at 16° . Analyses for periodate consumption and formic acid production were made at 24 hour intervals (5). The results showed that the oxidation was essentially complete in 144 hours and that 0.98 moles of periodate had been consumed per mole of anhydropentose unit and 0.09 moles of formic acid had been produced per mole of sugar.

MECHANISM OF THE DECOMPOSITION OF ETHYLENE WHEN PHOTOSENSITIZED BY METAL VAPORS¹

E. WHALLEY

ABSTRACT

A detailed mechanism of the molecular split of ethylene into acetylene and hydrogen, which occurs when ethylene is photosensitized by $\text{Hg}(^3\text{P}_1)$, is presented. It is suggested that the triplet ethylene molecule which is first formed isomerizes to a molecule of uncertain lifetime in which two hydrogen atoms act as "bridges" between the two carbon atoms. The hydrogen molecule which splits from the ethylene molecule is formed when these two atoms leave simultaneously. The experimental observations on the decomposition of ethylene when photosensitized by $\text{Cd}(^1\text{P}_1)$ or $\text{Zn}(^1\text{P}_1)$ are consistent with the primary interaction of the excited metal atom with either a C-H group or with the π electrons.

1. INTRODUCTION

Electronically excited metal atoms are quenched by olefins very much more readily than by paraffins (10).² In olefins there are three kinds of electrons involved in chemical bonding, viz. $\sigma_{\text{C-C}}$, $\sigma_{\text{C-H}}$, and $\pi_{\text{C-C}}$. Paraffin hydrocarbons contain $\sigma_{\text{C-C}}$ and $\sigma_{\text{C-H}}$ electrons, and have very low quenching cross-sections; hence, it is provisionally concluded that the interaction of the $\pi_{\text{C-C}}$ electrons with the excited metal atom is responsible for the large quenching by olefins. The primary process is

where M represents the metal atom, and the superscript asterisk denotes a state excited electronically or vibrationally (this includes rotational excitation) or in both modes.

The fate of the activated molecule C_2H_4^* depends upon the properties of the excited atom M^* , particularly on its multiplicity and its energy. These properties determine the properties of C_2H_4^* , particularly whether either the electronic or the vibrational degrees of freedom, or both, are excited (7). If M^* is $\text{Na}(^2\text{P})$ and M is $\text{Na}(^2\text{S})$, C_2H_4^* is a vibrationally excited molecule in its electronic ground state. It has insufficient energy to react and it loses its energy by collisions until it reaches thermal equilibrium. If M^* is $\text{Cd}(^3\text{P}_1)$ or $\text{Zn}(^3\text{P}_1)$ and M is $\text{Cd}(^1\text{S}_0)$ or $\text{Zn}(^1\text{S}_0)$ the excited ethylene must be in its first triplet state according to the Wigner-Witmer correlation rules and reasonable speculations about the energy of the first triplet state (see Ref. 7). It also appears to have insufficient energy to decompose (10), and it loses its electronic and vibrational energy at an unknown rate by collisions.

If M^* is $\text{Hg}(^3\text{P}_1)$ and M is $\text{Hg}(^1\text{S}_0)$ the resulting excited ethylene is again a vibrationally excited triplet, presumably in the same electronic state as that from $\text{Cd}(^3\text{P}_1)$ or $\text{Zn}(^3\text{P}_1)$, but with more vibrational energy. It now has sufficient energy to decompose, and the total reaction is

It is well verified that this reaction occurs via an excited molecule, and a detailed mechanism for the reaction is proposed in this paper. If M^* is $\text{Cd}(^1\text{P}_1)$ or $\text{Zn}(^1\text{P}_1)$ and M is $\text{Cd}(^1\text{S}_0)$ or $\text{Zn}(^1\text{S}_0)$ it is not known whether or not an excited molecule mechanism is followed, and possible mechanisms are briefly discussed.

2. ETHYLENE

We first consider the structure of the excited ethylene molecules. Those obtained from triplet atoms are in the first excited triplet state. This almost certainly is obtained by the uncoupling of the spins of the π electrons and their localization, one on each carbon atom. The structure of this molecule has been discussed by Walsh (11) and he concludes that the carbon valencies are pyramidally directed, and the ground state is staggered, thus:

More detailed calculations (6, 8) confirm that the methyl radical is probably pyramidal, but almost planar, and this is confirmed spectroscopically by Herzberg and Shoosmith (5). This indirectly confirms the structure of triplet C_2H_4 . The energy transferred from the $Hg(^3P_1)$ is $471 \text{ kJ. mole}^{-1}$ ($112.6 \text{ kcal. mole}^{-1}$). The energy absorbed in the excitation of ethylene from its ground state to its first triplet state is not known, but it is likely to be not more than about $100\text{--}200 \text{ kJ. mole}^{-1}$ ($20\text{--}40 \text{ kcal. mole}^{-1}$). The triplet ethylene has, therefore, considerable vibrational energy.

It seems to be well verified that the excited molecule decomposes homogeneously and intramolecularly. The claim of Darwent (4) that a large amount of decomposition occurs at the wall appears to be incorrect (2). Cvetanović and Callear (3) have shown conclusively by using ethylene labelled with deuterium that the reaction occurs completely intramolecularly, and this has been confirmed by Lossing *et al.* (9) by mass spectrometry. Darwent (4) and Callear and Cvetanović (1) have shown that the kinetics are not in accordance with the simple reaction mechanism (10)

and Callear and Cvetanović show that they do agree with a mechanism in which the triplet ethylene which is first formed cannot decompose directly to acetylene and hydrogen but must first isomerize to another excited ethylene $C_2H_4^{**}$ which can so decompose. The complete scheme is

The isomerization of $C_2H_4^{**}$ to $C_2H_4^*$ was not included in the original scheme and we shall show that the measured rates indicate that it has little influence on the course of the reaction.

It is possible to invent more elaborate sets of reactions with more rate constants, and so to improve agreement with experiment by introducing more parameters; the set above appears to be the simplest. A steady state treatment of the above reactions shows

that the rate of production of hydrogen R_{H_2} depends upon the intensity of light absorbed I_a and the partial pressure of ethylene p , in the manner

$$[1] \quad I_a/R_{H_2} = 1 + Ap + Bp^2,$$

where

$$[2] \quad A = \left(1 + \frac{k_3}{k_6}\right) \frac{k_4}{k_2} + \frac{k_5}{k_6},$$

$$[3] \quad B = \frac{k_4}{k_2} \frac{k_5}{k_6}.$$

Callear and Cvetanović (1) have shown that if $R_{H_2}^{-1/2}$ is plotted against p a nearly straight line is obtained. This means that approximately

$$[4] \quad A^2 = 4B.$$

Equations [2], [3], and [4] contain five unknowns, viz. A , B , $k_3/k_6 = x$, $k_4/k_2 = y$, and $k_5/k_6 = z$. There are therefore two degrees of freedom. It is a rather remarkable property of these equations that there is only one possible value of x consistent with the condition that x , y , and z must be real, positive numbers. By inserting equation [2] and [3] into [4] we find that

$$[5] \quad (1+x)^2 y^2 - 2z(1-x)y + z^2 = 0.$$

Solving for y we find that

$$[6] \quad \frac{y}{z} = \frac{(1-x) \pm 4(-x)^{1/2}}{(1+x)^2}.$$

Since x , y , and z must be real and positive, the only possible solution of [6] is

$$x = 0, \quad y = z.$$

Hence the kinetics show that

$$[7] \quad \begin{aligned} k_3/k_6 &\ll 1, \\ k_4/k_2 &= k_5/k_6 \text{ very nearly.} \end{aligned}$$

This means that $C_2H_4^{**}$ decomposes much faster than it isomerizes to $C_2H_4^*$. Conditions [7] were suggested by Callear and Cvetanović.

We know the probable structure of $C_2H_4^*$ and the question immediately arises, what is the nature of $C_2H_4^{**}$? Callear and Cvetanović (1) showed that when *cis*- $C_2H_2D_2$ was photosensitized by $Hg(^3P_1)$ it isomerized to both *trans*- $C_2H_2D_2$ and *anti*- $C_2H_2D_2$ in at least one of the deactivation processes. This must occur by migration of at least two hydrogen atoms. The migrations can occur either separately or together. If one hydrogen atom migrates to the other carbon, triplet ethylidene CH_3CH is produced. The two unshared, unpaired electrons on one carbon atom repel one another more than they would if they were on different atoms and so the electronic energy of CH_3CH is higher than that of CH_2CH_2 . To produce this extra electronic energy an equivalent amount of vibrational energy must be concentrated in those modes which lead to a shift of one hydrogen atom. Less vibrational energy need be converted to electronic energy if two hydrogen atoms move simultaneously. Also it would be quite strange if ethylidene were to split off a hydrogen molecule; it would be more likely that a C—H split would occur as for example occurs in the mercury photosensitized decomposition

of substituted ethylenes (9, 10). It is quite easy to see, as we show below, how a molecular split can occur if two hydrogen atoms move together. We conclude therefore that simultaneous migration is more likely than consecutive migration.

The state halfway along this simultaneous shift of the H atoms is

and it is proposed that this molecule is $C_2H_4^{**}$. Each C—H—C bond in the bridge is a three electron three center bond, and it is not likely to be very stable. The hydrogens in the bridge will interact with one another as indicated by the dotted lines joining them. The same structure can be considered as a hydrogen molecule embedded in the π electrons of triplet acetylene. It is immediately evident that it will have a strong tendency to decompose to a hydrogen molecule and a triplet acetylene molecule. The kinetics indicate that it decomposes, and is deactivated by collisions, but that it rarely isomerizes spontaneously to $C_2H_4^*$.

The mechanism of the $Cd(^1P_1)$ or $Zn(^1P_1)$ photosensitized reaction is not so clear cut. The main reaction is undoubtedly a split of a C—H bond to give an H atom and a C_2H_3 radical (10). There are two possible mechanisms, corresponding respectively to interaction of the excited metal atom with either the σ_{C-H} or the π_{C-C} electrons. These may be written

and

The experimental evidence is insufficient to decide between these two mechanisms. Quenching is not observed, but this may be because the lifetime of $C_2H_4^*$ is short compared with the time between collisions even at the highest pressures studied.

Laidler (7) has suggested in effect that the primary interaction is with the σ_{C-H} electrons, the first mechanism above, because it appeared to be difficult otherwise to account for the difference between the molecular and the radical decomposition of the excited molecules. It is not wholly satisfactory to postulate that $Cd(^1P_1)$ and $Zn(^1P_1)$ interact with σ_{C-H} electrons while $Na(^2P)$, $Cd(^3P_1)$, $Zn(^3P_1)$, and $Hg(^3P_1)$ interact with the relatively much more extensive π_{C-C} electrons. There is no other evidence for this, and it is possible, as we show below, to account for the different modes of decomposition of the excited molecules. Consequently, the experimental evidence is consistent with an excited molecule mechanism, but an interaction with σ_{C-H} is not excluded.

If an excited ethylene molecule is produced by interaction with $Cd(^1P_1)$ or $Zn(^1P_1)$ it must be in a singlet state, and since there is no excited singlet level with sufficiently low energy, it must be in its electronic ground state. The energy transferred from the

excited metal atom must be converted to vibrational energy. The structure is, therefore,

and it will be relatively difficult for this molecule to reach the singlet state of the bridge structure; consequently conditions are not favorable for an intramolecular split of a hydrogen molecule. The relative probability of the alternative mode, a split of a C—H bond, is therefore increased, and little, if any, molecular decomposition occurs.

It is interesting that at temperatures of about 300° there is evidence that triplet ethylene obtained by photosensitization with $\text{Hg}(^3\text{P}_1)$ decomposes to a small extent by a C—H split. Evidently the higher vibrational energy which the molecule possesses increases somewhat the chance of a C—H split.

NOTES

THE KINETICS OF THE THERMAL DECOMPOSITION OF DIMETHYL-2,2'-BIS-AZO-ISOBUTYRATE¹J. S. MACKIE² AND S. BYWATER

The kinetics of the thermal decomposition of bis-azo-nitriles has received much attention in late years. Less work has been presented on the decomposition of the corresponding azo esters. The kinetics of the thermal decomposition of dimethyl-2,2'-bis-azoisobutyrate has been followed gasometrically by Lewis and Matheson (3) and by Ziegler *et al.* (5). The final products are described by Bickel and Waters (1).

EXPERIMENTAL

Dimethyl-2,2'-bis-azoisobutyrate (AIB) was prepared from 2,2'-bis-azoisobutyronitrile (Westville Laboratories) by the method reported by Thiele and Heuser (4). It was purified by recrystallization from ether to a melting point of 30°. The solvent used was 2,2,5-trimethylhexane (Phillips Petroleum Co., purity >95%). This was freed from polar and unsaturated compounds by passage through a silica gel column until optically clear to 250 m μ . The kinetic measurements of the rate of decomposition were made using the technique previously reported (1) using measurements of optical density at 390 m μ . The purified azo compound was found to have a symmetrical absorption band with maximum at 360 m μ ; $E_{\max} = 18.0$. Measurements of change in optical density with time were also made at 270, 280 m μ where the absorption of the azo compound is negligible.

RESULTS

The thermal decomposition in purified nitrogen (2) was followed at 70°, 80°, 90°, and 100° C. and normally at concentrations of 0.03, 0.06, and 0.10 molar azo compound. The decomposition followed first order kinetics as far as the reaction was measured (normally over 90% decomposition). The first order constants were independent of initial concentration of AIB. Rate constants obtained are shown in Table I.

TABLE I

T (° C.)	70	80	90	100
$k_1 \times 10^4$ (sec. ⁻¹)	0.223	0.786	2.59	8.45

The experimental results are best fitted by the relation k_1 (sec.⁻¹) = $1.31 \times 10^{15} \exp(-31.1/RT)$. Lewis and Matheson (3) report $k_1 = 1.09 \times 10^{-4}$; $E = 35.8$ (xylene, 80°). Ziegler, Deparade, and Meye give $k_1 = 1.04 \times 10^{-4}$ (undecane, 80°); $k_1 = 1.61 \times 10^{-4}$ (nitrobenzene, 80°); $k_1 = 17.3 \times 10^{-4}$ (nitrobenzene, 100°); $E = 30.9$. There are no indications in either paper that measurements were made at enough temperatures for an accurate activation energy assessment.

¹Issued as N.R.C. No. 4324.²N.R.L. Postdoctoral Fellowship holder, 1954-56.

At 270, 280 $m\mu$ the optical density *increased* with time to an almost steady value at 70° and 80°, and at higher temperatures increased to a maximum and then slowly decreased. This is similar to the observations on the azonitrile (2). The optical density values are such that this cannot be accounted for by any of the reported products (1) and must indicate the formation of some other compound, thermally unstable at higher temperatures.

THE INTRINSIC VISCOSITIES OF AQUEOUS SOLUTIONS OF SMALL MOLECULES

J. T. EDWARD

For finite concentrations of neutral spheres suspended in a liquid, the Einstein equation for specific viscosity η_{sp} is modified to the power series

$$[1] \quad \eta_{sp}/\phi = \alpha_0 + \alpha_1\phi + \dots,$$

where ϕ is the volume fraction occupied by the spheres, and α_0 and α_1 are constants equal to 2.5 and about 13 respectively (3, 7, 8, 11, 12, 19). While this equation is derived from classical hydrodynamic principles, and hence has no necessary validity for solutions in which the size of the solute approaches that of the solvent molecule, Vand (19) found it applicable to aqueous solutions of sucrose if one assumed some hydration of the sucrose molecule. However, in default of any means of estimating the volume of the sucrose molecule, Vand's treatment was indirect and involved.

Recently a simple means of estimating the van der Waals volume V_w of a molecule has been described (5). In aqueous solution this volume will be multiplied by a hydration factor H , and hence the volume fraction occupied by the hydrated molecules in a solution having a concentration of c g./100 ml. will be given by

$$[2] \quad \phi = cNV_wH/100M,$$

M being the molecular weight of the solute and N Avogadro's number. The intrinsic viscosity $[\eta]$ of the solution will then be given by

$$[3] \quad [\eta] = \lim_{c \rightarrow 0} \eta_{sp}/c = \alpha_0NV_wH/100M.$$

In applying this equation to actual molecules, it is necessary to take some account of their shapes, since for all non-spherical shapes $\alpha_0 > 2.5$. For solute particles having ellipsoidal shapes, α_0 may be calculated from the ratios of the axes of the ellipsoids by

conformations of the molecule were possible, by rotation about single bonds, the most extended conformation was chosen (1, 10). The effect of hydration on the shape of the molecule was ignored.

The hydration factors (H_η) calculated from equation [3] using these values of α_0 are shown in Table I. The intrinsic viscosities of aqueous solutions of compounds 1-7 have been given by Polson (13), those of compounds 8-12 were obtained from plots of η_{sp}/c against c , using data from the literature. Except in the case of glycerol, there was a fairly wide scatter of the experimental points from a straight-line plot, and hence the values of H_η for these compounds must be accepted with reserve.

The values of the hydration factor obtained in this way are of the same magnitude as the values (H_D in Table I) obtained from diffusion coefficients D in water by use of the modified Stokes-Einstein equation (6):

$$[4] \quad \nu = \frac{kT}{5\pi\eta_0} \left(\frac{f_0}{f} \right) \left(\frac{4\pi}{3V_w H} \right)^{\frac{1}{3}},$$

where k is Boltzmann's constant, T is the temperature, η_0 the viscosity of water, and (f/f_0) the frictional ratio (4) to correct, where necessary, for the non-spherical shape of the molecule. The values of H_η and H_D have not in all cases been calculated for the same temperature, but the differences are too small to affect grossly the comparison (1). Consequently, it would appear that equation [1] is applicable to the specific viscosities of quite small molecules in aqueous solution. However, it should be emphasized that equations [1] and [4] have empirical validity only, and that no precise meaning should be attached to the hydration factors, which probably measure several different solvent effects.

A knowledge of the hydration factor enables one to calculate ϕ for a given concentration of solute by equation [2]. A plot of η_{sp}/ϕ against ϕ for glycerol (15), using $H = 1.54$, gave a good straight-line curve from which a value of 6.75 for α_1 in equation [1] was

obtained. This value is considerably lower than that found in studies of aqueous suspensions of polystyrene latex particles (diameter $\approx 2600 \text{ \AA}$) (3) and of glass spheres (diameter $\approx 50,000 \text{ \AA}$) (11). However, Vand (19) has given reasons for expecting this constant to decrease as the suspended particles approach molecular dimensions.

I am most grateful to Dr. D. A. I. Goring for a discussion of this topic.

IODINE COMPLEXES IN INERT SOLVENTS. VII. THERMODYNAMIC CONSTANTS
AND SPECTROSCOPIC DATA FOR THE REACTION $2I_2 \rightleftharpoons I_4$ IN CARBON
TETRACHLORIDE

P. A. D. DE MAINE*

Some workers (2, 7) have reported that the weak absorption band, with center near $2800 \text{ \AA}$, found for iodine dissolved in carbon tetrachloride arises from contributions by two absorption bands. One is due to I_2 (with center near $2775 \text{ \AA}$), and the other is due to I_4 (with center near $2880 \text{ \AA}$ (7) or $2935 \text{ \AA}$ (2)). These workers have used an approximate method for estimating $K\epsilon_{I_4}$ (K is the equilibrium constant for the reaction $2I_2 \rightleftharpoons I_4$; ϵ_{I_4} is the molar extinction coefficient for I_4). The heat of formation of I_4 in carbon tetrachloride ($\Delta H = -1.0$ (7) or -1.96 (2) kcal. per mole) has been estimated in both cases from $K\epsilon_{I_4}$ with the assumption that ϵ_{I_4} does not alter with changes in temperature.

de Maine, de Maine, and Goble (5) have used an exact method to obtain K , ϵ_D , and ϵ_M (D is dimer; M is monomer) for the reaction

where the MeNO_2 and the dimer bands are superimposed, in carbon tetrachloride. These

IODINE COMPLEXES IN INERT SOLVENTS. VII. THERMODYNAMIC CONSTANTS
AND SPECTROSCOPIC DATA FOR THE REACTION $2I_2 \rightleftharpoons I_4$ IN CARBON
TETRACHLORIDE

P. A. D. DE MAINE*

Some workers (2, 7) have reported that the weak absorption band, with center near $2800 \text{ \AA}$, found for iodine dissolved in carbon tetrachloride arises from contributions by two absorption bands. One is due to I_2 (with center near $2775 \text{ \AA}$), and the other is due to I_4 (with center near $2880 \text{ \AA}$ (7) or $2935 \text{ \AA}$ (2)). These workers have used an approximate method for estimating $K\epsilon_{I_4}$ (K is the equilibrium constant for the reaction $2I_2 \rightleftharpoons I_4$; ϵ_{I_4} is the molar extinction coefficient for I_4). The heat of formation of I_4 in carbon tetrachloride ($\Delta H = -1.0$ (7) or -1.96 (2) kcal. per mole) has been estimated in both cases from $K\epsilon_{I_4}$ with the assumption that ϵ_{I_4} does not alter with changes in temperature.

de Maine, de Maine, and Goble (5) have used an exact method to obtain K , ϵ_D , and ϵ_M (D is dimer; M is monomer) for the reaction

where the MeNO_2 and the dimer bands are superimposed, in carbon tetrachloride. These

*Present address: Chemistry Department, University of Ottawa, Ottawa, Canada.

authors found that a system of this kind is described by the following exact equations:

$$[1] \quad D_{\text{obs}}/(C_A - C) = 2K\epsilon_D(C_A - C) + \epsilon_M,$$

$$[2] \quad C_A^2/D_D = 1/2K\epsilon_D + (2C_A - C)/\epsilon_D,$$

$$[3] \quad C = [1 + 4KC_A - (1 + 8KC_A)^{1/2}]/4K,$$

where C_A is the total concentration of nitromethane (as MeNO_2), $C/2$ is the concentration of $(\text{MeNO}_2)_2$, D_{obs} is the measured optical density, and D_D is the optical density of the dimer species.

D_{obs} and C_A were measured, and exact values for K , ϵ_D , and ϵ_M were obtained from equations [1], [2], and [3] by a method of successive approximations.

The exact method just described has been applied to data for the carbon tetrachloride-iodine solutions ($C_A = 12 \times 10^{-3}$ to 0.8×10^{-3} moles per liter) near 17°C ., to obtain accurate values for K ($= 2.28$ liters/mole), ϵ_D , and ϵ_M . Molar extinction coefficients for I_2 (ϵ_M) and I_4 (ϵ_D) in carbon tetrachloride at 17°C . are given in Table I. The values

for ϵ_M are also compared to the approximate values reported earlier (2). The shapes of both molar extinction curves, calculated by the exact method, are given in Fig. 1.

FIG. 1. Shapes of the molar extinction curves for I_2 and I_4 in carbon tetrachloride at 17°C . and 21°C .

The shapes of the curves are not appreciably different from the corresponding first-approximation curves (Ref. 2, Fig. 2). This means that the band centers reported earlier (2) are correct. It was also found that the I_4 absorption band, with center near 2935 Å, does not extend to the longer wavelength side of 3700 Å.

The accurate value obtained for the equilibrium constant ($K = 2.28$ liters/mole at 17° C.) corresponds to a free energy change of $\Delta F = -1.81$ kcal. per mole at 25° C. Corresponding ΔS values, calculated by means of the equation $\Delta F = \Delta H - T\Delta S$, using $\Delta H = -1.96$ (2) or -1.0 (7) kcal. per mole, are given in Table II. These values for

TABLE II

ΔF AND ΔS FOR THE REACTION $2I_2 \rightleftharpoons I_4$ IN CCl_4 (25 IS THE REFERENCE STATE); $\Delta F = -RT \ln K_x$, $\Delta F = \Delta H - T\Delta S$, WHERE K_x IS THE EQUILIBRIUM CONSTANT IN MOLE FRACTION UNITS

ΔF , kcal.	ΔS , e.u.	ΔH , kcal.	K at 25° C., liters/mole

-1.84	+2.81	-1.0	2.16

ΔF , ΔH , and ΔS , together with the corresponding values for the iodine complexes with pyridine (10), diethyl ether, methanol, or ethanol (3), do not fit the empirical relationships of Andrews and Keefer (1). This supports the author's view (3) that the linear relationship between ΔF and ΔS or ΔH applies only for donor molecules with similar molecular shapes.

Comparison of the extinction coefficients at the absorption maximum ($\epsilon_{\max}$), and the heat of formation (ΔH) or equilibrium constant (K) for the reaction $2I_2 \rightleftharpoons I_4$, with corresponding constants for some other complexes of iodine in carbon tetrachloride (Table III) shows that there is no simple relation between the constants. Mulliken's

Donor	λ_0	ϵ_0	λ_{vis}	ϵ_{vis}	ΔF	ΔH	ΔS	K
I_2	2935	390	—	—	-1.81	-1.96	-0.50	21.3
MeOH ³	2428	8360	4400	973	-0.91	-1.90	-3.32	4.6
EtOH ³	2433	10802	4430	1082	-0.83	-2.10	-4.09	4.0
Et ₂ O ³	2490	4700	4680	873	-1.31	-4.30	-9.86	8.7

"charge-transfer" theory (8) predicts that $\epsilon_{\max}$ (or more exactly the integral extinction for the band) should increase with ΔH or K , and that K should increase with ΔH . The lack of the expected correlation cannot be attributed to neglect of activities of the reaction components (4). Finally Mulliken's new "charge-transfer - contact charge-transfer" theory (9), which is based on the experimental work of Evans (6) with iodine-saturated paraffin solutions, cannot explain why the visible absorption band is located nearer the ultraviolet when K and ΔH are smaller for the iodine-oxygenated compound complexes (4). It is therefore concluded that neither the simple "charge-transfer" nor the new "charge-transfer - contact charge-transfer" theory explains all the experimental data for the iodine complexes mentioned.

The author is deeply indebted to Professor W. C. Price of King's College for providing facilities for the experimental work and calculations. Attention should again be drawn to the fact that the method used in the analysis was developed by the author from a method suggested by Dr. E. W. Kosower through a private communication.

THE DECOMPOSITION OF 1-BUTENE AND 1-BUTENE-4- d_3 INDUCED BY METHYL RADICALS

PAUL KEBARLE AND W. A. BRYCE

The effect of the addition of mercury dimethyl on the rates of decomposition of 1-butene and 1-butene-4- d_3 has been investigated as part of a detailed study of the pyrolysis of these two compounds. The reactions were carried out in a static system in a quartz reactor at temperatures around 500° C. The composition of the reaction mixture was determined at various time intervals by gas chromatography. In the studies with 1-butene-4- d_3 , the reaction products separated by gas chromatography were collected and analyzed in a 90° Nier-type mass spectrometer to determine the distribution of deuterium in the various isomeric products.

The principal products of the 1-butene pyrolysis were methane, propylene, ethylene, ethane, and a number of C_5 to C_7 unsaturated hydrocarbons mostly with cyclic structures. The addition of 5% by volume of mercury dimethyl to the 1-butene was found to accelerate greatly the formation of practically all reaction products. The concentrations of the C_1 to C_3 hydrocarbon products for the normal and sensitized decomposition of 1-butene at 492° C. as a function of reaction time are shown in Fig. 1. The initial pressure of the reactant was 200 mm. of mercury in each experiment. The C_1 to C_3 hydrocarbons accounted for approximately 70 to 80% by volume of the total reaction products at the above temperature. The effect of the sensitizer on the rate of formation of the C_1 to C_3 decomposition products can be seen in a comparison of the concentration of each substance at 1 minute reaction time in the sensitized and unsensitized decompositions under similar reaction conditions. These results are given in Table I.

At the temperature of the experiment mercury dimethyl undergoes rapid decomposition resulting in the formation of free methyl radicals. Thus, the acceleration of the butene decomposition in the sensitized reaction is certainly due to "forced" free radical reactions brought about by the methyl radicals. The fact that the addition of methyl radicals

THE DECOMPOSITION OF 1-BUTENE AND 1-BUTENE-4- d_3 INDUCED BY METHYL RADICALS

PAUL KEBARLE AND W. A. BRYCE

The effect of the addition of mercury dimethyl on the rates of decomposition of 1-butene and 1-butene-4- d_3 has been investigated as part of a detailed study of the pyrolysis of these two compounds. The reactions were carried out in a static system in a quartz reactor at temperatures around 500° C. The composition of the reaction mixture was determined at various time intervals by gas chromatography. In the studies with 1-butene-4- d_3 , the reaction products separated by gas chromatography were collected and analyzed in a 90° Nier-type mass spectrometer to determine the distribution of deuterium in the various isomeric products.

The principal products of the 1-butene pyrolysis were methane, propylene, ethylene, ethane, and a number of C_5 to C_7 unsaturated hydrocarbons mostly with cyclic structures. The addition of 5% by volume of mercury dimethyl to the 1-butene was found to accelerate greatly the formation of practically all reaction products. The concentrations of the C_1 to C_3 hydrocarbon products for the normal and sensitized decomposition of 1-butene at 492° C. as a function of reaction time are shown in Fig. 1. The initial pressure of the reactant was 200 mm. of mercury in each experiment. The C_1 to C_3 hydrocarbons accounted for approximately 70 to 80% by volume of the total reaction products at the above temperature. The effect of the sensitizer on the rate of formation of the C_1 to C_3 decomposition products can be seen in a comparison of the concentration of each substance at 1 minute reaction time in the sensitized and unsensitized decompositions under similar reaction conditions. These results are given in Table I.

At the temperature of the experiment mercury dimethyl undergoes rapid decomposition resulting in the formation of free methyl radicals. Thus, the acceleration of the butene decomposition in the sensitized reaction is certainly due to "forced" free radical reactions brought about by the methyl radicals. The fact that the addition of methyl radicals

results in the accelerated formation of all products already formed in the unsensitized decomposition suggests that the normal decomposition also proceeds by a radical mechanism in which methyl radicals play an important part.

The free radical decomposition of 1-butene involving the primary step [1] has been detected at high temperatures (1000 °C.) with the mass spectrometer (3):

The activation energy and frequency factor of reaction [1] have been determined with the toluene carrier technique for the temperature range 650–770° C. (5). However, the

FIG. 1. The effect of sensitization by mercury dimethyl (5% by volume) on the rate of formation of light hydrocarbons in the pyrolysis of 1-butene. 1—Methane. 2—Propylene. 3—Ethylene. 4—Ethane.

lack of inhibiting effect by nitric oxide on the thermal decomposition at lower temperatures (550° C.) (4) has been considered as an indication that, at these temperatures, the decomposition proceeds by a molecular mechanism (2). As was pointed out above, the results of the mercury dimethyl sensitized reaction suggest that, at these lower temperatures also, the reaction proceeds by a free radical mechanism. This is further borne out in the results from the 1-butene-4- d_3 experiments.

TABLE I

Compound	Concentration ratio, sensitized to unsensitized reaction (after 1 minute)
CH_4	13.3
C_2H_6	11.4
C_2H_4	7.1
C_3H_6	9.7

In preliminary experiments, the thermal decomposition of the 1-butene-4- d_3 was compared with that of undeuterated 1-butene. No significant differences were found in the rates of decomposition and rates of product formation for the two compounds.

The deuterium distribution in the C_1 to C_4 reaction products from the normal and mercury dimethyl sensitized decomposition of the 1-butene-4- d_3 at 492° C. for 1 minute reaction time is shown in Table II. For the sensitized reaction, the concentrations of the

C ₃ H ₆	0.16	7.5	47
C ₄ H ₈	—	27.0	

compounds are given in mole per cent of the initial 1-butene-4- d_3 . The reactant 1-butene-4- d_3 contained 9% 1-butene-4- d_2 as an impurity (1). The mass spectrometric analysis of the deuterium compounds was facilitated by the complete separation of the methanes from the ethanes, the ethanes from the ethylenes, etc., by means of gas chromatography. However, the lack of published spectra for some of the deuterioisomers, particularly the deuterioethanes, for which measurements of the molecular (parent) masses at low electron energies are also not applicable, resulted in some uncertainties in the concentration data given in Table II. These data should be considered as having a semiquantitative significance only.

The results in Table II show that deuterium mixing has occurred to a surprisingly large extent. In the non-sensitized decomposition of the 1-butene-4- d_3 , only approximately 1% of the reactant had decomposed. For this case, the effect of secondary reactions involving stable reaction products should be insignificant. Therefore, the large extent of deuterium mixing is probably the result of a complex free radical mechanism.

It is interesting to note that, in the sensitized reaction, a relatively large quantity (2.7%) of undeuterated butene was formed. This product was not observed in the normal decomposition of the 1-butene-4- d_3 . The mechanism proposed to explain the formation of undeuterated butene is the following:

In addition to explaining the formation of undeuterated butene, the mechanism provides CD₃ radicals, which should account to a large extent for the increased rate of formation of CD₃H and CD₄ (and possibly other products containing CD₃ groups) in the sensitized reaction. A similar reaction has been suggested in the reaction of methyl radicals with propylene (6).

Addition of the methyl radical to the secondary carbon of the double bond in 1-butene-4- d_3 could result in alternative modes of decomposition of the $C_5H_8D_3$ radical:

Reaction [6] would result in an increased rate of formation of both propylene and CH_3CD_3 , in qualitative agreement with the results given in Table II.

The possible occurrence of reactions [3] to [6] indicates that, in the temperature range studied, free radical addition to the double bond of an olefin is not necessarily inactive for the mechanism, i.e. the addition product does not exclusively decompose to yield back the original radical and olefin. The newly formed bond in the addition may be retained and the addition product may decompose with the splitting of a different bond leading to the formation of a new olefin and a new radical. Such disproportionation reactions might be of considerable importance in mechanisms for the thermal decomposition of olefins.

A full account of the results obtained in the investigation of the pyrolyses of 1-butene and 1-butene-4- d_3 will be published.

We are grateful to Dr. L. C. Leitch of the National Research Laboratories, Ottawa, for the synthesis of the 1-butene-4- d_3 , to the Defence Research Board for financial support (D.R.B. Project No. D44-50-01-10), and to Mr. S. A. Ryce for assistance with the gas chromatographic analysis.

THE ATTEMPTED SYNTHESIS OF TWO HEXOSE PHOSPHONATE ESTERS¹

F. C. G. HOSKIN²

ABSTRACT

The synthesis of glucose-1-methylphosphonate and isopropyl glucose-1-methylphosphonate has been attempted. Although the intermediates were successfully prepared, deacetylation failed to give the desired products.

The formation of biologically important phosphate derivatives of lipids, carbohydrates, and other substances is well known. However, it has recently been shown that under circumstances where hexose phosphate esters are enzymatically produced from phosphate, no analogous esters are formed from methylphosphonate (5).

The present report describes the attempted chemical synthesis of barium or potassium glucose-1-methylphosphonate and of isopropyl glucose-1-methylphosphonate. Although intermediates analogous to those encountered in the chemical preparation of glucose-1-phosphate were synthesized without difficulty, neither acid nor alkaline treatment (3, 8) gave the two desired compounds from the corresponding acetylated intermediates. In repeated attempts, white solids were obtained which proved to be either inorganic salts or rather impure glucose.

EXPERIMENTAL

Phenyl Methylphosphonochloridate

Equimolar amounts of phenol and methylphosphonyl dichloride (7) were allowed to react in a manner analogous to that described for the reaction of phenol with phosphorus oxychloride (2). After degassing and the removal of unreacted methylphosphonyl dichloride at about 90° C. (temperature of distillation flask) and 8–10 mm. pressure, the material distilling at 60–80° C. and 0.01–0.02 mm. was collected. A rather large non-volatile fraction probably represented diphenyl methylphosphonate. The crude material was redistilled and, except for a small forerun and residue, was collected at 67–69° C. and 0.01 mm.; $n_D^{27} = 1.5234$; final yield 49%. Calc. for $C_7H_8O_2ClP$: C, 44.12; H, 4.23. Found: C, 43.84; H, 4.52.

Silver Phenyl Methylphosphonate

Phenyl methylphosphonochloridate (80 g., 0.42 mole) was poured over 200 g. ice with shaking. When all of the ice had melted, the cloudy aqueous mixture was extracted several times with ether, the combined ether extracts were back-extracted once with water, and the ether solution was dried with anhydrous magnesium sulphate. After filtration the ether was evaporated and the remaining oily material was dried *in vacuo*

¹Manuscript received January 21, 1957.

Contribution from the Suffield Experimental Station, Defence Research Board, Ralston, Alberta.

²Present address: Defence Research Kingston Laboratories, Box 123, Kingston, Ontario.

at about 65° C. A portion was heated in a distilling apparatus to 200° C. at 0.005 mm. but no distillate was obtained. On cooling, the material showed only slight discoloration but had become quite viscous. Probably a considerable amount of phenyl methylphosphonic anhydride, $(\text{CH}_3\text{P}(\text{O})\text{OC}_6\text{H}_5)_2\text{O}$, had been formed.

The remaining impure phenyl methylphosphonic acid was converted to its silver salt by being heated on a steam bath with an excess of freshly prepared silver oxide suspended in a large volume of hot water. After being heated for 15 minutes, the slurry was filtered hot and the filtrate was evaporated to dryness. Following vacuum desiccation the yield of crude silver phenyl methylphosphonate was nearly quantitative. A hot aqueous solution of this salt was treated with norite, filtered, recrystallized by reduction of the solvent volume and cooling, and was desiccated *in vacuo* over silica gel. Yield was 82% based on phenyl methylphosphonochloridate, allowance being made for the fraction used for the attempted distillation. The silvery white platelets darkened slightly at about 150° C. and melted sharply at 221° C. with decomposition. Calc. for $\text{C}_7\text{H}_5\text{O}_3\text{AgP}$: C, 30.13; H, 2.89. Found: C, 30.34; H, 3.11.

2,3,4,6-Tetraacetylglucose-1-methylphosphonate Phenyl Ester

A total of 9.5–10 g. (approximately 0.035 mole) of silver phenyl methylphosphonate was reacted with 10.0 g. (0.0243 mole) acetobromoglucose (6) according to the directions of Posternak (8) for the reaction of silver diphenyl phosphate and acetobromoglucose. The resulting sirup crystallized readily. The product was recrystallized twice from anhydrous ether – absolute ethanol, treated with norite, and recrystallized once more. The resulting white crystalline powder was readily soluble in ethanol and only slightly soluble in ether or water giving a neutral solution in the latter which yielded no precipitate on addition of silver nitrate. Yield 39%; m.p. 89–93° C. without elevation on subsequent recrystallizations, $[\alpha]_D -7.5^\circ$ (*c*, 0.4, ethanol–water).^{*} Calc. for $\text{C}_{21}\text{H}_{27}\text{O}_{12}\text{P}$: C, 50.20; H, 5.42. Found: C, 50.15; H, 5.53.

2,3,4,6-Tetraacetylglucose-1-methylphosphonic acid

2,3,4,6-Tetraacetylglucose-1-methylphosphonate phenyl ester (4.2 g., 0.008 mole) was exhaustively hydrogenated in absolute ethanol in the presence of 0.4–0.5 g. platinum oxide catalyst (1). The uptake of hydrogen was complete within the first hour. The alcoholic solution was filtered hot to remove catalyst. The filtrate was cooled and the product crystallized readily. The product, after filtration, was washed several times with anhydrous ether, recrystallized from absolute ethanol, and desiccated *in vacuo* over silica. Yield 87%; needles, m.p. 152° C., $[\alpha]_D -4.7^\circ$ (*c*, 0.4, water). Calc. for $\text{C}_{15}\text{H}_{23}\text{O}_{12}\text{P}$: C, 42.26; H, 5.44. Found: C, 42.28; H, 5.62.

Silver Isopropyl Methylphosphonate

The silver salt of isopropyl methylphosphonic acid, referred to briefly in a previous publication (4), was synthesized and purified by reactions analogous to those described for the synthesis of silver phenyl methylphosphonate. Isopropyl methylphosphonic acid was collected at 80° C. and 0.008 mm.; $n_D^{25} = 1.4232$. Calc. for $\text{C}_4\text{H}_{11}\text{O}_3\text{P}$: C, 34.78; H, 8.03. Found: C, 34.66; H, 7.95. The silvery white platelets of silver isopropyl methylphosphonate darkened slightly at about 120° C. and melted with decomposition at 210–220° C. Calc. for $\text{C}_4\text{H}_{10}\text{O}_3\text{AgP}$: C, 19.61; H, 4.11. Found: C, 19.62; H, 4.17.

^{*}A small-bore, 4 dm. polarimeter tube was used for this and subsequent determinations.

2,3,4,6-Tetraacetylglucose-1-methylphosphonate Isopropyl Ester

A total of 8.5–9 g. (approximately 0.035 mole) of silver isopropyl methylphosphonate was reacted with 10.0 g. (0.0243 mole) acetobromoglucose. After thorough drying the resulting sirup crystallized with some difficulty on addition of petroleum ether. The product was recrystallized twice from ether – petroleum ether and desiccated *in vacuo* over silica. The fine white crystals were readily soluble in ether, ethanol, or water, giving a neutral solution in the latter which yielded no precipitate on addition of silver nitrate. Yield, 60%; m.p. 73–75° C. Calc. for $C_{18}H_{29}O_{12}P$: C, 46.15; H, 6.24. Found: C, 46.43; H, 6.34. Successive recrystallizations finally gave a product melting at 77–79° C., $[\alpha]_D -4.2^\circ$ (c, 3.1, ethanol–water). Found: C, 46.34; H, 6.56.

Attempted Deacetylation

Repeated attempts to deacetylate 2,3,4,6-tetraacetylglucose-1-methylphosphonic acid with hydrochloric acid in methanol (3) or with dilute sodium hydroxide (8) according to the methods described for the preparation of glucose-1-phosphate led only to inorganic salts which, when subjected to qualitative tests, appeared to be either barium chloride or potassium sulphate, depending on the method employed. Similar attempts to deacetylate 2,3,4,6-tetraacetylglucose-1-methylphosphonate isopropyl ester and to isolate a neutral product yielded a white amorphous substance. Elemental analysis and optical rotation indicated that the product was rather impure glucose.

ACKNOWLEDGMENTS

For the general methods of preparation of methylphosphonic acids and their silver salts from the corresponding methylphosphonohalides, I have drawn on unpublished results of Mr. A. H. Ford-Moore. Analyses were performed by Mr. Tom Stewart of the Suffield Experimental Station, Ralston, Alberta.

THE GROWTH OF BUTADIENE POPCORN POLYMER IN THE PRESENCE OF METHYL METHACRYLATE MONOMER¹

GLENN H. MILLER² AND ABOLFATH KHAN BAKHTIAR

ABSTRACT

The rate of growth of butadiene popcorn polymer seed in the presence of methyl methacrylate monomer vapor was found to be logarithmic with time and very sensitive to the presence of hydroquinone in the monomer. The resulting butadiene-methyl methacrylate graft polymer was homogeneous in appearance. No satisfactory kinetic mechanism can be presented at this time.

Butadiene popcorn polymer will propagate itself when placed in the presence of various monomers such as styrene, methyl methacrylate, butyl acrylate, etc. (4, 6). The growths of these graft polymers are known to be rapid, but little attention has been given to the actual rates. A logarithmic rate has been demonstrated for the cases of butadiene popcorn seed in the presence of butadiene (5) and styrene (4) monomers in the vapor phase. The following investigations represent one of several series of experiments designed to determine the generality of this logarithmic growth rate phenomena.

EXPERIMENTAL

The methyl methacrylate was obtained from the Borden Co. Even though all the experiments were carried out in the vapor phase, it was found necessary to remove the 0.06% hydroquinone inhibitor by vacuum distillation of the monomer.

The 11th generation butadiene popcorn polymer seeds used in these experiments were from the same original source as those used in previous experiments and were handled in the manner previously described (3). The average activity of the seeds used varied from 25 to 89%, i.e., the weight per cent increase in 5 days when the seeds were incubated above butadiene monomer at 60°.

The general experimental procedure has been described (4). A weighed amount of butadiene seed was placed on a weighed tuft of glass wool in an 18 mm. O.D. tube above the methyl methacrylate monomer. The monomer was then solidified at dry-ice temperature and the tube evacuated and sealed. Following the desired length of time in the darkness of an oil bath at 60°, plus or minus 0.5°, the tube was opened and the polymer evacuated at room temperature until a constant weight was obtained.

Soluble polymer was extracted from the graft polymer in a Soxhlet extractor. Sintered-glass extraction thimbles were used and the extractions were carried out for 24 hour intervals in an inert atmosphere of nitrogen using benzene as a solvent.

RESULTS

The results of preliminary experiments are presented in Fig. 1, where the final weights of methyl methacrylate-butadiene graft polymers are plotted versus time at 60°. Since the butadiene seeds were placed in the vapor phase it was believed that, owing to its low vapor pressure, the 0.06% hydroquinone contained in the methyl methacrylate would have no effect on the growth of the popcorn. In the case of analogous experiments

¹Manuscript received March 4, 1957.

Contribution from the Department of Physical Sciences, University of California, Santa Barbara College, Goleta, California.

²National Research Council Postdoctorate Fellow, 1956-1957.

using styrene (4) the authors found it advantageous to leave the inhibitor in the monomer so that the bulk polymerization would be retarded, thus permitting the growth of the popcorn to be observed for a longer period of time. Curve 2, Fig. 1, however, shows that

FIG. 1. Effect of hydroquinone on growth of methyl methacrylate-butadiene popcorn polymer.

in the present case inhibited and rather erratic growth occurred when 0.06% hydroquinone was present in the monomer. To further verify the inhibition as being due to hydroquinone, experiments were performed in which the methyl methacrylate was saturated with hydroquinone. The negligible growth rate obtained is shown as curve 3.

FIG. 2. Growth of butadiene popcorn in the presence of methyl methacrylate vapor.

FIG. 3. Rate of growth of insoluble popcorn and benzene soluble polymer on butadiene popcorn in methyl methacrylate vapor.

Curve 1, Fig. 1, represents the results obtained when no hydroquinone is present in the monomer.

The growth rate of methyl methacrylate – butadiene popcorn graft polymer is shown in Fig. 2. A plot of the growth time in hours at 60° versus the logarithm of the final seed weight in grams was found to be linear. The slopes of the curves varied with the activity of the seed. The rate of popcorn growth in the vapor phase is independent of the amount of methyl methacrylate used as long as some monomer is present. Owing to the bulk polymerization of the monomer, however, the rate of popcorn growth ceases when the vapor pressure of the monomer becomes negligible. For this reason the growth rate could only be followed for less than 30 hours.

Solvent extraction of several samples of graft polymer indicated the presence of various amounts of soluble polymer. In view of this, additional experiments were performed in which larger initial seed samples were used and in which all samples of the resulting solid polymer were extracted with benzene. Fig. 3 shows the linear growth rate observed for the soluble polymer as well as the logarithmic growth of the insoluble popcorn.

The graft polymer was homogeneous in appearance. When samples of the unextracted popcorn were allowed to stand exposed to air they oxidized and became light yellow in color. The color was quite uniform in many samples, but in the majority of cases the portion at the top of the tube did not oxidize as readily as the lower portion where the butadiene seed was initially located, i.e., there was a gradation of color from top to bottom. This variation in oxidation rate can undoubtedly be explained by the presence of the non-popcorn, linear polymer which probably formed to a somewhat greater extent at the top of the sample and thus prevented uniform oxidation. Oxidation of extracted polymer proceeded uniformly in all samples. However, even after 6 months of air exposure small portions of white, non-oxidized masses were uniformly distributed throughout the polymer.

From the curves of Fig. 2 it is apparent that the rate of popcorn growth depends on the initial growth activity of the seed. The difference in slopes observed for curves 2 and 3 can be attributed to variations in initial seed activity, approximately 25% and 37%, respectively, while for curves 1 and 2 (both from the same seed source) the difference is due to variations in monomer purity with regard to the hydroquinone content. The monomer source was redistilled following the collection of curve 1 data and prior to the data of curves 2, 3, and 4. Regardless of these variations, however, the growth rate appears to be proportional to the mass of polymer present at any given time. Within the limits of the experimental method used, no induction period was noted for the growth of the popcorn or for the soluble polymer which formed on the popcorn. These data do not conform to the mechanism of popcorn formation, as previously presented by Devins and Winkler (1).

The results obtained reaffirm the previously published conclusion (2, 3) that the growth of popcorn is not dependent on the decomposition of hydroperoxide linkages on the seed.

Whitby (6) has stated that the extent to which the growth of popcorn polymer will proceed is determined by the extent of unsaturation in the seed polymer. It is difficult, however, to explain why the growth of a monomer being grafted onto an unsaturated seed should not slow down as these centers of unsaturation are utilized. The present work of the authors does not yet warrant a kinetic treatment or theory to explain the growth mechanism.

ADDITION OF ETHYL RADICALS TO ETHYLENE¹

J. A. PINDER² AND D. J. LE ROY

ABSTRACT

The addition of ethyl radicals to ethylene has been studied in the temperature range 58° to 123° C. The radicals were produced by the mercury photosensitized decomposition of hydrogen in the presence of ethylene, and the rate of the addition reaction was measured in terms of the rate of formation of *n*-hexane by the combination of ethyl and butyl radicals. Corrections were made for the non-uniformity of radical concentrations in the reaction zone. Assuming a negligible activation energy for the combination of two ethyl radicals, the activation energy for the addition reaction is 5.5 kcal. per mole; the steric factor, relative to the square root of the steric factor for ethyl radical combination, is 5.0×10^{-5} .

Although it is generally assumed that the activation energies for the addition of free radicals to olefins are small, relatively few quantitative data are available because of the complexity of the over-all processes and the lack of suitable "reference" reactions. Raal and Danby (7, 8) have studied the addition of methyl radicals to a number of olefins using the photolysis of acetaldehyde as the source of radicals and the abstraction of H atoms from acetaldehyde by methyl radicals as the reference reaction. Mandelcorn and Steacie (6) have used the photolysis of acetone as the source of methyl radicals and the combination of methyl radicals as the reference reaction.

In the present work we have studied the rate of addition of ethyl radicals to ethylene, to form butyl radicals, by measuring the rate of formation of hexane and assuming that this substance is formed exclusively by the combination of ethyl with butyl radicals. The ethyl radicals were produced by the mercury (³P₁) photosensitized decomposition of hydrogen in the presence of ethylene.

It has been established (4) that at temperatures below 200° C. the main features of the reaction can be interpreted in terms of the following mechanism:

At low pressures anomalous variations in the ratio of ethane to butane occur which suggest that under such conditions these compounds are not formed simply by bimolecular reactions of ethyl radicals (1, 9). At the pressures used in the present work these effects are relatively unimportant and the ratio of the rate of formation of ethane to that of butane is in good agreement with the values of k_4/k_3 obtained by other methods (9). As the pressure of ethylene is raised, small but increasing amounts of a product with a molecular weight greater than butane are found. In the present work this product was shown, by gas chromatography, to be *n*-hexane. It was assumed to be formed by the following reactions:

¹Manuscript received March 19, 1957.

Contribution from the Department of Chemistry, University of Toronto, Toronto, Ont.

²Present address: Canadian Celanese Limited, Kingston, Ont.

On the assumption that all butyl radicals formed in [5] disappear by [6] it is evident that the rate of formation of hexane would be given by the expression,

$$d(\text{C}_6\text{H}_{14})/dt = k_5(\text{C}_2\text{H}_5)(\text{C}_2\text{H}_4). \quad [\text{i}]$$

Assuming, further, that butane is formed only in reaction [3], it follows that,

$$[d(\text{C}_6\text{H}_{14})/dt]/[d(\text{C}_4\text{H}_{10})/dt]^{\frac{1}{2}} = (k_5/k_3^{\frac{1}{2}})(\text{C}_2\text{H}_4). \quad [\text{ii}]$$

The errors which would arise if these two assumptions are not valid will be considered in the Discussion.

Equation [ii] applies to *local* rates. In order to utilize the measured amounts of hexane and butane formed in an experiment to evaluate $k_5/k_3^{\frac{1}{2}}$ it is necessary to apply a correction term which takes into account spatial variations in the ethyl radical concentration throughout the reaction vessel. This correction has been discussed in detail by Cvetanović and Whittle (2); it is of some importance in the present instance because of the large extinction coefficient of mercury vapor.

EXPERIMENTAL

The general procedure was similar to that used previously (3). An improved form of circulating pump was used, having a capacity of approximately $2000 \text{ cm}^3 \text{ min}^{-1}$. Before they entered the reaction vessel the gases were saturated with mercury vapor at 10°C . The quartz reaction vessel was 4.6 cm. in diameter and 11 cm. long; the total volume of the system, including a buffer volume, was 1910 cm^3 .

The ethylene was Phillips Research Grade. Commercial hydrogen was purified as described previously (3). The C_6 hydrocarbons used as reference standards in the chromatography were obtained from the United States Bureau of Standards. The *n*-butane and other gases were supplied by the Ohio Chemical and Manufacturing Company.

The products were analyzed by both low temperature distillation (5) and by gas-liquid partition chromatography using a 7-ft. column containing Octoil-S supported on Celite with helium as the carrier gas. Excellent agreement was obtained between the two methods; the latter served to establish that the C_4 fraction contained only *n*-butane, and that the higher boiling fraction contained only *n*-hexane. With the high ethylene pressures and low conversions used in the present work no other olefins and no odd-numbered paraffins were found.

In order to take account of the spatial variations in the ethyl radical concentration it was necessary to determine the extinction coefficient of mercury vapor for $2537 \text{ \AA}$. This quantity is strongly dependent on wave length, even within the narrow range of wave lengths which constitute the resonance "line" emitted by a mercury-rare gas lamp of the type used in the present experiments. As a result, for a given value of the mercury concentration (Hg) the extinction coefficient q depends on the distance L through which the light has passed as well as on the particular lamp used and its operating conditions.

Values of q were obtained in a separate series of experiments using three cells, C_1 , C_2 , and C_3 , having internal path lengths of 0.185, 0.994, and 10.0 cm., respectively. The cells were mounted in a temperature-controlled bath containing distilled water; a parallel beam of light from the lamp entered the bath through a fused quartz window and traversed the three cells. The cross section of the beam was somewhat smaller than that of the cell windows. Each cell was filled with approximately 300 mm. of Phillips Research Grade propane and isolated with a mercury cutoff. Mercury in a side arm on each cell

was allowed to reach its saturation pressure over a period of 16 hours before illumination. The period of illumination was approximately 24 hours. The non-condensable gases were removed with a liquid air trap and the hydrogen formed in each cell was measured. The average decomposition in any one experiment was of the order of 0.1%.

The arrangement of the three cells is shown schematically in Fig. 1. It was necessary to take into account the fraction of light reflected, R , and the fraction transmitted, T , at the windows W_2 and W_3 . Each of these windows consisted of two glass-gas interfaces and two glass-water interfaces. For clarity the incident beam I_0 is shown entering the first cell at an angle to the perpendicular; the various transmitted and reflected beams from which appreciable absorption takes place are indicated. The amount of light transmitted through the rear window of cell C_3 was negligible under the conditions used.

FIG. 1. Arrangement of cells used to determine the extinction coefficient of mercury vapor.

If G_1 , G_2 , and G_3 are the amounts of hydrogen produced in C_1 , C_2 , and C_3 and α_1 and α_2 are the fractions of light transmitted in a single passage through cells C_1 and C_2 it can be shown that

$$1/\alpha_2 - R_3\alpha_2 = 1 - R_3 + T_3G_2/G_3$$

and

$$1/\alpha_1 - \alpha_1(R_2 + T_2^2 R_3\alpha_2^2) = 1 - R_2 - T_2^2 R_3\alpha_2^2 + (1 - \alpha_2 + R_3\alpha_2 + T_3\alpha_2 - R_3\alpha_2^2) T_2G_1/(G_2 + G_3).$$

The values of R and T were calculated from Fresnel's law and the known properties of the window materials. Extinction coefficients were calculated from the expression

$$\alpha = e^{-q(\text{Hg})L}.$$

The mercury concentration was varied from 1.6×10^{-3} to 9.3×10^{-3} mm. by changing the bath temperature. In Fig. 2 the values of q are plotted against L' , the equivalent path length for a saturation temperature of 25° C. A smooth curve can be drawn through the values for α_1 ($L' < 1.0$ cm.) and α_2 ($L' > 1.0$ cm.), indicating that adequate corrections were made for reflection and absorption by the windows.

The kinetic experiments were made with a cell 11 cm. long and a mercury saturating temperature of 10° C.; this corresponds to a path length of less than 3 cm. at 25° C. The value of q used was 15×10^{-15} cm.² molecule⁻¹.

RESULTS

The production of butane and hexane was studied at four temperatures in the range 58.4° to 123.1° C. using a constant hydrogen pressure of approximately 640 mm. (at 22° C.). At each temperature the ethylene pressure was varied by a factor of about 2.5. The effect of hydrogen pressure was also studied. The results are shown in Table I.

The concentrations of hexane and butane are expressed in mm. of mercury in the

FIG. 2. Dependence of the extinction coefficient of mercury vapor on the equivalent path length for saturation at 25°C.

* , † In these two experiments the hydrogen pressure was 215 mm. and 397 mm., respectively; in all of the others it was approximately 640 mm. at 22°C.

system (1910 cm.³) at 22° C.; the concentration of ethylene is the average of the initial and final pressures in the system at the reaction temperature. Using the units given in Table I, the uncorrected values of $k_5/k_3^{1/2}$ given in column six were obtained from the expression

$$k_5/k_3^{1/2} = \frac{7.93 \times 10^{-12} T (\text{C}_6\text{H}_{14})}{(\text{C}_2\text{H}_4)_{\text{av.}} (\text{C}_4\text{H}_{10})^{1/2} t^{1/2}} \quad [\text{iii}]$$

In column eight are given the values of the correction term δ by which the uncorrected values of $k_5/k_3^{1/2}$ are multiplied to obtain the corrected values in column seven.

FIG. 3. Arrhenius plot for the addition of ethyl radicals to ethylene.

The quantity δ is a rather complicated function of two parameters, β and s (2). In the present instance these are given by the expressions:

$$\beta = q(\text{Hg})L, \quad [\text{iv}]$$

in which q is the extinction coefficient of mercury vapor to base e , (Hg) is the concentration of mercury vapor in the reaction vessel, and L is the length of the light path (ca. 11 cm.);

$$\text{and} \quad s = \frac{4(k_3 + k_4) q(\text{Hg}) \phi I_0}{k_5^2 (\text{C}_2\text{H}_4)^2} \quad [\text{v}]$$

On the assumption that $k_4/k_3 = 0.15$ (9), the quantity $(k_3 + k_4)$ in [v] can be equated to $1.15 k_3$. The value of ϕI_0 , the effective incident light intensity in quanta cm.⁻² sec.⁻¹, was calculated on the assumption that the effective number of quanta absorbed per second, $\phi I_0(1 - e^{-\beta})A$, was equal to the number of molecules of hydrogen consumed per second, i.e., to the number of molecules of ethane, butane, and hexane formed per second. The average value of ϕI_0 calculated in this way was 8.2×10^{13} quanta cm.⁻² sec.⁻¹ $\pm 6.5\%$.

An Arrhenius plot of the corrected mean values of $k_5/k_3^{1/2}$ for each temperature is shown in Fig. 3. The least squares value of $E_5 - \frac{1}{2}E_3$ is 5.5 kcal. per mole; the steric factor ratio, $p_5/p_3^{1/2}$, is 5.0×10^{-5} , assuming a mean collision diameter of 4.0 Å.

DISCUSSION

It was considered worth while to evaluate the correction term δ for these experiments because of the uncertainty, arising from the large extinction coefficient, which has been associated with quantitative deductions from mercury photosensitization experiments. It was an obvious advantage, in this regard, to saturate the reagents with mercury vapor at 10° C. rather than at some higher temperature and to use a lamp with a somewhat broadened emission line.

Possible sources of error arise from the assumptions that all butyl radicals are consumed by reaction [6] and that butane is formed exclusively by reaction [3]. If the rate constants were of the same magnitude for the combination of two ethyls, an ethyl and a butyl, and for two butyls, one would expect appreciable amounts of *n*-octane to be formed at the higher ethylene concentrations, particularly at the higher temperatures. There is no evidence for this, in the form of lower values of $k_5/k_3^{1/2}$ under these conditions. It has already been pointed out that no compound of higher molecular weight than hexane was found by gas chromatography. Also, the uncorrected value of $E_5 - \frac{1}{2}E_3$ based on analytical data obtained by gas chromatography differed from the value based on low temperature distillation by less than 0.3 kcal. per mole.

If any of the butyl radicals formed in [5] had undergone disproportionation reactions with ethyl radicals the calculated values of $k_5/k_3^{1/2}$ would be in error.

Assuming that any butene formed in [7] was measured as butane, it can be shown that the right hand side of equation [ii] would have to be multiplied by the term

$$[1 - (R_7 + R_8)/R_B]^{1/2} \cdot R_6/(R_6 + R_7 + R_8),$$

in which R_B is the rate of formation of butane plus that of butene, and R_6 , R_7 , and R_8 are the rates of the corresponding reactions. It can be easily shown that if $R_7 + R_8$ were comparable in magnitude to R_6 the values of $k_5/k_3^{1/2}$ obtained by applying this correction would be strongly dependent on the ethylene pressures, in disagreement with the experimental results. It seems justifiable to conclude that reactions [7] and [8] can be of only minor importance.

There do not appear to be any quantitative data in the literature to compare with the present results on the addition of ethyl radicals with ethylene. However, Mandelcorn and Steacie (6) have discussed their own data and those of other workers on the addition of methyl radicals to ethylene and other unsaturated compounds. They obtained a relative rate constant, $k_{\text{addition}}/(k_{\text{combination}})^{1/2}$, of 11×10^{-12} at 144° C. for the addition of methyl radicals to ethylene. From our data $k_5/k_3^{1/2}$ would be equal to 1.8×10^{-12} at that temperature. Since there is little difference between the rate constant for the combination of two methyl radicals and that for the combination of two ethyls, it is evident that the rate constants for the addition of methyl and ethyl radicals to ethylene do not differ greatly, at least at 144° C. where the results of the three methods used by Mandelcorn and Steacie agree most closely. It is also of interest that the activation energy for the addition of ethyl radicals to ethylene obtained by us falls between the value obtained by Mandelcorn and Steacie (7.0 kcal. per mole) and the corrected value of Raal and Danby (4.6 kcal. per mole) (7, 6) for the addition of methyl radicals to ethylene.

4-O-METHYL-D-GLUCURONIC ACID AND 4-O-METHYL-D-GLUCOSE¹

P. A. J. GORIN

ABSTRACT

A novel method for the preparation of 4-O-methyl-D-glucuronic acid is described. This sugar and 4-O-methyl-D-glucose were obtained in good yield by two different series of reactions from 2-O-(4-O-methyl-D-glucopyranuronosido)-D-xylose, an acid hydrolysis product of the hemicellulose of *Populus tacamahacca* Mill.

The extension of configurational studies in oligosaccharides to O-methyl-aldobiuronic acids required 4-O-methyl-D-glucuronic acid and 4-O-methyl-D-glucose for synthesis of reference 2-O-glycosyl glycerols. The most ready source of these sugars appeared to be wood hemicellulose which yields 2-O-(4-O-methyl-D-glucopyranuronosido)-D-xylose. However, the hydrolysis of unmodified aldobiuronic acids proceeds only with difficulty and may require 4% acid at 120° C. for 10 to 24 hours for complete scission (15). Under these conditions the free uronic acid monosaccharide is unstable and liable to decarboxylation rendering its over-all yield small. This is true of the hydrolysis of aspen wood hemicellulose to 4-O-methyl-D-glucuronic acid (9). The present paper describes a technique for liberating 4-O-methyl-D-glucuronic acid from the above aldobiuronic acid.

The starting material for the preparation of the expected aldobiuronic acid was *Populus tacamahacca*. Extractive free splinters were acid hydrolyzed by the method of Gorrod and Jones (4) to give a sugar mixture containing the aldobiuronic acid. Fractionation of the hydrolyzate on a charcoal column (14) using ethanol-water mixtures afforded the aldobiuronic acid in good yield. The fact that the compound consumed lead tetraacetate only slowly (2), thus indicating a 1,2-glycosidic linkage, together with subsequent reactions characterized the disaccharide as 2-O-(4-O-methyl-D-glucopyranuronosido)-D-xylose.

Bromine oxidation of the aldobiuronic acid in the presence of calcium benzoate buffer (8) gave the calcium salt of 2-O-(4-O-methyl-D-glucopyranuronosido)-D-xylonic acid (I). The salt of the aldonic acid was treated with two molar equivalents of lead tetraacetate to yield presumably the corresponding L-glycerotriuronic acid derivative (II) since the 4-O-methyl-D-glucuronosido residue is relatively resistant to lead tetraacetate oxidation (11). Hydrolysis of this substance with 10% acetic acid (3) on a steam bath for 3 hours produced the required 4-O-methyl-D-glucuronic acid (III) in 51% yield based on aldobiuronic acid. The material appeared to be free from other sugars on paper chromatograms (10) but was passed through a cellulose column (6) to remove extraneous material. The uronic acid was treated under reflux with methanolic hydrogen chloride and the resulting α,β -methyl-4-O-methyl-D-glucopyranuronoside methyl ester reduced with sodium borohydride (16) to α,β -methyl-4-O-methyl-D-glucopyranoside. Hydrolysis of the glucoside with acid gave the free sugar which was characterized as its crystalline phenylosazone (12). From the above observations it would appear that degradation of an aldobiuronic acid to the component uronic acid is possible, providing it contains a 1,2-glycosidic linkage. This type of reaction has been used previously for the degradation of a neutral oligosaccharide (3). It is noteworthy that disaccharides of most other linkage

¹Manuscript received April 1, 1957.

Issued as N.R.C. No. 4349 and as Paper No. 244 on the Uses of Plant Products.

types can be degraded to a suitable 1,2-disaccharide by oxidation of the reducing end with lead tetraacetate (1).

The methyl ester of 2-*O*-(4-*O*-methyl-D-glucopyranuronosido)-D-xylose, obtained by the action of diazomethane on the free acid, was reduced to sirupy 2-*O*-(4-*O*-methyl-D-glucopyranosyl)-D-xylitol. Methanolysis of the disaccharide afforded a mixture of sirupy α,β -methyl-4-*O*-methyl-D-glucopyranoside and xylitol. These two substances were readily separable on a cellulose column, the glucoside being eluted by *n*-butanol and

FIG. 1.

characterized after acid hydrolysis by conversion to 4-*O*-methyl-D-glucose phenylosazone. The sirupy xylitol column fraction was warmed with formaldehyde in concentrated hydrochloric acid to yield crystalline 2,4,3,5-di-*O*-methylene-DL-xylitol (5).

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper using ethyl acetate-acetic acid-water (9:2:2 v/v) as solvent. Melting points are corrected. Evaporations were carried out under reduced pressure at 40° C. Optical rotations were measured at 27° C.

2-*O*-(4-*O*-Methyl-D-glucopyranuronosido)-D-xylose

Extractive free splinters of *P. tacamahacca* (500 g.) were digested in 2 *N* sulphuric acid (4 l.) at 65° C. for 7 days. The mixture was then filtered and the filtrate neutralized with barium hydroxide followed by barium carbonate. After filtration the solution was treated with Amberlite IR-120 and the sugar mixture then fractionated on a charcoal column. Water eluted the monosaccharides and 10% ethanol eluted the aldobiuronic acid together with traces of xylobiose and xylotriose detected chromatographically on paper using the *p*-anisidine hydrochloride spray (7). The solution which contained the aldobiuronic acid was evaporated to a sirup (8.9 g.) having $[\alpha]_D^{25} +88^\circ$ (*c*, 2.3, water).

2-*O*-(4-*O*-Methyl-D-glucopyranuronosido)-D-xylonic Acid (Calcium Salt)

The aldobiuronic acid (3.0 g.) in water (60 ml.) containing calcium benzoate (3.4 g.) was oxidized with bromine (0.90 ml.) for 2 days. Excess bromine was then removed by aeration, the solution filtered, and the filtrate treated with Amberlite IR-120. Benzoic

acid was removed by extracting the solution three times with equal volumes of chloroform. The aqueous portion was treated with calcium carbonate (4.0 g.) and heated at 100° C. for 14 hours. The solution was filtered and added to methanol and a precipitate of the required calcium salt of the aldonic acid was formed. Yield 2.9 g.

4-O-Methyl-D-glucuronic Acid

The calcium salt (1.65 g.) was dissolved in water (8 ml.) and added to acetic acid (175 ml.). Lead tetraacetate (3.7 g.; 2 molar equivalents) was added with stirring and after 18 hours the mixture was treated with 10% oxalic acid in acetic acid (8.2 ml.). Water (300 ml.) was added to the suspension, the solution filtered, and the filtrate treated with Amberlite IR-120. The solution was evaporated to a sirup which was then dissolved in water (90 ml.) containing acetic acid (10 ml.) and was heated at 100° C. for 3 hours. The hydrolyzate was evaporated to a sirup (1.07 g.) which produced on a paper chromatogram a bright red spot, with a rate of 0.9 compared to rhamnose, with the *p*-anisidine hydrochloride spray and a brown spot in the same position using the silver nitrate – sodium hydroxide – acetone dip (13).

The sirup was put on to a cellulose column which was developed with ethyl acetate–acetic acid – water (9:2:1 v/v). The required 4-*O*-methyl-D-glucuronic acid (0.63 g.) with $[\alpha]_D +48^\circ$ (c , 1.3, water) was eluted. Yield, based on aldobiuronic acid, 51%.

4-O-Methyl-D-glucose Phenyllosazone from 4-O-Methyl-D-glucuronic Acid

4-*O*-Methyl-D-glucuronic acid (0.62 g.) was heated under reflux for 1 hour in 5% methanolic hydrogen chloride (10 ml.), the solution cooled, neutralized (silver carbonate), filtered, and evaporated to sirupy α,β -methyl-4-*O*-methyl-D-glucopyranuronoside methyl ester (0.45 g.).

A portion of the ester (0.22 g.) in water (10 ml.) was treated with sodium borohydride (0.10 g.) in water (5 ml.). After 16 hours the solution was treated with acetic acid and then shaken with Amberlite IR-120. It was then evaporated to dryness and dissolved in methanol which was boiled off to remove boric acid. This process was repeated three times and the resulting sirup was treated with Amberlite IR-4B in aqueous solution to remove any α,β -methyl-4-*O*-methyl-D-glucopyranuronoside. Evaporation of the solution yielded sirupy α,β -methyl-4-*O*-methyl-D-glucopyranoside (0.17 g.).

The glucoside was hydrolyzed in *N* sulphuric acid (5 ml.) at 100° C. for 18 hours, and the solution was neutralized (barium carbonate), filtered, and evaporated to a sirup (148 mg.) with $[\alpha]_D +61^\circ$ (c , 0.7, water). The 4-*O*-methyl-D-glucose thus formed corresponded on a paper chromatogram to the authentic material using the *p*-anisidine hydrochloride spray.

The aldose (0.14 g.) was heated for 2 hours at 100° C. in water (20 ml.) containing phenylhydrazine (0.40 ml.) and acetic acid (1 ml.). The precipitate which formed on cooling was recrystallized twice from benzene to give yellow needles (21 mg.) with m.p. 154–157° C. and $[\alpha]_D +30^\circ \rightarrow 0^\circ$ (constant value) (c , 0.5, EtOH). Calculated for $C_{19}H_{24}O_4N_4$: $-\text{OCH}_3$, 8.3%. Found: $-\text{OCH}_3$, 8.3%.

2-O-(4-O-Methyl-D-glucopyranosyl)-D-xylitol

2-*O*-(4-*O*-Methyl-D-glucopyranuronosido)-D-xylitol (2.55 g.) in methanol (200 ml.) was neutralized with ethereal diazomethane. The solution was evaporated to a sirup which was dissolved in water (100 ml.) and added to sodium borohydride (1.5 g.) in water (10 ml.). The reaction mixture was left for 16 hours and then worked up by the method

described previously. The product was a sirup (2.32 g.) with $[\alpha]_D +86^\circ$ (c , 0.8 in 50% ethanol).

4-O-Methyl-D-glucose

The 2-O-(4-O-methyl-D-glucopyranosyl)-D-xylitol (1.92 g.) was heated under reflux in 5% methanolic hydrogen chloride (20 ml.) for 10 hours. The hydrolyzate was then neutralized (silver oxide), filtered, and evaporated to a sirup (1.88 g.). This was fractionated on a cellulose column. *n*-Butanol eluted sirupy methyl 4-O-methyl-D-glucopyranoside (0.71 g.) and *n*-butanol half saturated with water eluted sirupy xylitol (0.55 g.).

The xylitol was characterized as its 2,4,3,5-di-O-methylene derivative (5), m.p. and mixed m.p. 199–200° C. Calculated for $C_7H_{11}O_5$: C, 47.72%; H, 6.87%. Found: C, 47.95%; H, 6.84%.

Methyl-4-O-methyl-D-glucopyranoside (0.24 g.) was hydrolyzed as described previously to 4-O-methyl-D-glucose (0.22 g.) with $[\alpha]_D +58^\circ$ (c , 0.8 in water). The sirupy product (0.11 g.) was converted to 4-O-methyl-D-glucose phenylosazone (27 mg.) with m.p. 154–156° C. and $[\alpha]_D +30^\circ \rightarrow 0^\circ$ (constant value) (c , 0.5 in EtOH). Calculated for $C_{19}H_{24}O_4N_4$: $-\text{OCH}_3$, 8.3%. Found: $-\text{OCH}_3$, 8.3%.

PREPARATION OF SOME PURE POLYOXYETHYLENEGLYCOL ETHERS. PART I¹

B. A. GINGRAS AND C. H. BAYLEY

ABSTRACT

The Williamson ether synthesis has been applied to the preparation of polyoxyethylene-glycol mono- and di-ethers. These were obtained by reacting the mixed potassium salts of hexaoxyethyleneglycol with alkyl or aryl halides. Hexaoxyethyleneglycol monoethers of the type $R.O(CH_2CH_2O)_6H$, ($R = n-C_{10}H_{21}$, $n-C_{12}H_{25}$, $n-C_{14}H_{29}$, and *p*-*iso*- $C_8H_{17}.C_6H_4.O.CH_2CH_2$) and diethers of the type $R.O(CH_2CH_2O)_6R$, ($R = n-C_{10}H_{21}$, $n-C_{12}H_{25}$, and $n-C_{14}H_{29}$) have been prepared in pure state and some of their properties determined.

Polyoxyethyleneglycol ethers of the type $R.O(CH_2CH_2O)_nH$ ($R = H$, alkyl, or aryl) are usually prepared by polymerization reactions of ethylene oxide with itself or with the appropriate alcohol or phenol (2, 5, 9, 11, 13),

The polymerization is carried out at relatively high temperature and is catalyzed by alkalis. It has been shown that the reaction is a random one, giving a mixture of closely related materials in which the number of molecules of varying sizes is represented by Poisson's distribution formula (3). The separation of such polymeric mixtures into pure constituents is not as yet feasible. Mayhew and Hyatt (7) report two experiments in which two polyoxyethylated alkyl phenols were distilled separately, using a molecular still, and fractions of various molecular weights were obtained in each case. They point out that it would be extremely difficult to isolate a single molecular species by this method.

In an attempt to prepare certain of these ethers in a pure state for other work, use has been made of a direct method of synthesis which has been found to give chemically pure products in satisfactory yields. The method is similar to that used by Hibbert and co-workers (4, 10) for the preparation of the higher polyoxyethylene glycols. It involves the preparation of hexaoxyethyleneglycol monopotassium salt (V) and its subsequent reaction with an alkyl halide as illustrated in the following scheme:

¹Manuscript received January 16, 1957.

Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4352.

The reaction of diethyleneglycol (I) with sodium methylate gives the monosodium salt (II). Addition of *bis*(2-chloroethyl) ether (III) to (II) yields hexaoxyethyleneglycol (IV), which reacts with metallic potassium to give a mixture of the mono- (V) and the di-potassium (VI) salts. These, with an alkyl halide, give hexaoxyethyleneglycol monoalkyl ether (VII) and diether (VIII) respectively. In this way, hexaoxyethyleneglycol monoethers ($R = n\text{-C}_{10}\text{H}_{21}$, $n\text{-C}_{21}\text{H}_{43}$, $n\text{-C}_{14}\text{H}_{29}$, and $p\text{-iso-C}_8\text{H}_{17}\cdot\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_2\text{CH}_2$) and diethers ($R = n\text{-C}_{10}\text{H}_{21}$, $n\text{-C}_{12}\text{H}_{25}$, and $n\text{-C}_{14}\text{H}_{29}$) have been prepared.

In preparing the *isooctylphenyl* ether sought, i.e., *p*-(1,1,3,3-tetramethylbutyl)phenyl, *p-isooctylphenyl* chloride could not be used as starting material, since the chlorine atom, when attached directly to the benzene ring, does not react under the conditions employed. Hence use was made instead of *p-isooctylphenyl-β-chloroethyl* ether (XII) prepared by the method of Clemo and Perkin (1) for introducing the chloroethyl group into phenols, alcohols, and amino compounds. This method comprises reacting *β-chloroethyl*toluene-*p*-sulphonate (X) with the appropriate phenol in the presence of alkali, the main products being the *β-chloroethyl* derivative of the phenol and sodium *p*-toluene sulphonate (XI). In the present instance *p-isooctylphenol* (IX) was used and *p-isooctylphenyl-β-chloroethyl* ether (XII) was obtained. This chloroether (XII) was then reacted with the monopotassium salt of hexaoxyethyleneglycol (V), and there were obtained heptaoxyethyleneglycol mono-*p-isooctylphenyl* ether (XIII), and a product (XIV) which is believed to have been formed by a Wurtz-type reaction between two molecules of the chloroether (XII) and potassium and is not as yet positively identified. In this case, the reaction proceeded somewhat differently, since the expected *bis-p*-(1,1,3,3-tetramethylbutyl)phenyl octaoxyethyleneglycol ether (XV) was not formed.

The results of elementary analysis of compound (XIV) are in conformity with the following structure, $p\text{-C}_8\text{H}_{17}\cdot\text{C}_6\text{H}_4\cdot\text{O}(\text{CH}_2)_4\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{C}_8\text{H}_{17}\text{-}p$. Infrared spectra provide further evidence in support of this structure, showing the absence of free hydroxyl groups, the presence of aromatic groups at 6.2μ , and a strong band at 12.2μ indicative of a *p*-substituted phenyl ring. There are no aliphatic ether bands in the 9μ region but two bands at 8 and 9.6μ indicate aromatic ether groups.

The polyoxyethyleneglycol ethers prepared have not been previously reported in the literature and are listed, together with their properties, in Tables I and II.

The monoethers listed in Table I are liquids at room temperature or low-melting solids. They are all soluble in water and, like the corresponding products prepared by polymerization, their solubility decreases with increasing temperature, i.e., they have a "cloud point", which is the temperature at which a dilute aqueous solution becomes turbid. The free hydroxyl group reacts normally with the usual alcohol reagents, and several attempts have been made to prepare solid derivatives, but all were liquids. It

is of interest to note that trityl chloride, which has been used to prepare solid derivatives of several glycol ethers (12), gave products that were liquids at room temperature.

Infrared spectra confirm the assigned structures for these ethers, showing the characteristic stretching frequencies of the hydroxyl group in the $3\ \mu$ region, a broad band in the $9\ \mu$ region indicative of aliphatic ether, and a medium band at $13.9\ \mu$ due to $—CH_2—$ deformation frequencies in an aliphatic long chain. The spectrum of hepta-oxyethylene-glycol mono-*p*-isooctylphenyl ether (XIII) shows, besides the already mentioned absorptions, the characteristic $C=C$ stretching of the aromatic nucleus at $6.25\ \mu$ and strong absorptions at $12.1\ \mu$, indicative of a *p*-substituted phenyl ring, and at $7.30\ \mu$ owing to the deformation frequencies of the CH_3 in *t*-butyl groups from the isooctyl chain.

The trityl ethers have infrared spectra similar to those of the free alcohols, but they also show the typical bands due to the aromatic rings and a particularly strong absorption at $14.25\ \mu$ indicative of monosubstituted phenyl rings. They showed no bands in the OH ($3\ \mu$) region.

The dialkyl ethers listed in Table II are not soluble in water. Their behavior resembles that of aliphatic hydrocarbons, and they are soluble in all the hydrocarbon and most usual organic solvents. Their infrared spectra are also of requisite character, being very similar to those of the corresponding monoalkyl ethers except in the $3\ \mu$ region where they show no hydroxyl group bands.

EXPERIMENTAL

Hexaoxyethyleneglycol was prepared according to the method of Hibbert and co-workers (4). An atmosphere of dry nitrogen was maintained in the reaction vessel during the formation of the metallic salts of the glycol and their condensation with the halides. The fractional distillations were carried out with a Vigreux-type column (20 cm. $\times$ 1 cm.). In the case of the trityl derivatives, where quantities less than 1 gram were used, distillations were made in a Späth tube. The solid products were recrystallized to constant melting points, which were taken with a Fisher-John apparatus, and are corrected.

Preparation of Hexaoxyethyleneglycol Monodecyl and Didecyl Ethers

Hexaoxyethyleneglycol (94 g., 0.33 M.) was covered with a layer of petroleum ether (b.p. $60-75^\circ$) and 12.9 g. (0.33 g-atom) of metallic potassium was added in small portions. After 15 hours' stirring, the temperature was raised slowly to 135° while the salt formation was completed. Then, *n*-decyl chloride (69.6 g., 0.39 M.), η_D^{20} (found) 1.4380, η_D^{20} (reported in literature) 1.43799 (6), was added dropwise with stirring over a 2 hour period, the stirring being continued for a further 3 hours at the same temperature. The mixture was then neutral to litmus. The potassium chloride was removed by filtration and the residue distilled under reduced pressure to give two volatile fractions A and B and a residue C.

Fraction A was the unreacted *n*-decyl chloride (25 g., b.p. 88° at 1.3 mm. Hg). Fraction B was the recovered hexaoxyethyleneglycol (40 g., b.p. 160° C. at 0.01 mm. Hg). The dark brown residue weighed 62.8 g. A sample (9.67 g.) was chromatographed through a column of silica gel. A mixture of ethyl ether and methyl alcohol (19:1) eluted an oily material which, after another purification by the same process, gave crystals of hexaoxyethyleneglycol didecyl ether (VII, $R = n-C_{10}H_{21}$). Ethyl ether and methyl alcohol (2:1) eluted hexaoxyethyleneglycol monodecyl ether, which could not be crystallized. Successive chromatographic separations gave a total yield of 15.35 g. (8%) of the diether and 44.6 g. (31%) of the monoether.

The monodecyl ether (3.03 g., 0.7 M.) and triphenylchloromethane (1.97 g., 0.7 M.) were dissolved in 10 cc. of pyridine and heated on a steam bath for 1 hour. The solution was then allowed to cool and was poured into a mixture of water and ice containing 11 cc. of concentrated hydrochloric acid. An oil that precipitated out was taken up in ether; the ethereal solution was washed with dilute sulphuric acid, a dilute solution of sodium bicarbonate, and then with water; and the solution was dried over anhydrous sodium sulphate. The solvent was removed by evaporation and the residue (4.26 g.) was chromatographed through silica gel; three products were obtained. Benzene and ethyl ether (19:1) eluted 1.3 g. of triphenyl carbinol (m.p. and mixed m.p. 162°). Ethyl ether eluted

0.98 g. of the monotrityl ether of (VII) while 1.97 g. of VII ($R = n\text{-C}_{10}\text{H}_{21}$) was recovered from the last fraction. The monotrityl ether, $\text{C}_{10}\text{H}_{21}\text{O}(\text{CH}_2\text{CH}_2\text{O})_6\text{C}(\text{C}_6\text{H}_5)_3$ was a yellowish liquid (b.p. 195° at 0.001 mm. Hg, η_D^{20} 1.5207). Calculated for $\text{C}_{41}\text{H}_{60}\text{O}_7$: C, 74.09%, H, 9.10%; found: C, 74.13%, H, 9.31%.

Reaction between Hexaoxyethyleneglycol Monopotassium Salt and 1-Chlorododecane

The reaction was carried out as in the previous case using 28.2 g. (0.1 M.) of the glycol, 3.91 g. (0.1 g-atom) of potassium and 25 g. (0.12 M.) of 1-chlorododecane, η_D^{20} (found) 1.4432, η_D^{20} (reported in literature) 1.44255 (14). The mixture became neutral after 2 hours, acetone was added, and the potassium chloride was removed by filtration. The acetone was evaporated off, and the remaining solution was distilled under reduced pressure. After the excess of reagent had distilled over, there was obtained hexaoxyethyleneglycol monododecyl ether (VII, $R = n\text{-C}_{12}\text{H}_{25}$, 22.4 g., 50%; b.p. 216° at 0.002 mm. Hg). The residue was chromatographed through silica gel and ethyl ether eluted 6.7 g. (10.8%) of crystalline didodecyl ether (VIII, $R = n\text{-C}_{12}\text{H}_{25}$), which was recrystallized from absolute ethyl alcohol; m.p. 33.5° .

The trityl ether from the monododecyl ether was prepared as described before, separated by chromatography, and further purified by distillation; (b.p. 155° at 0.001 mm. Hg, η_D^{20} 1.5188). Calculated for $\text{C}_{43}\text{H}_{64}\text{O}_7$: C, 74.53%, H, 9.31%; found: C, 74.82%, H, 9.36%.

*Preparation of Hexaoxyethyleneglycol *n*-Tetradecyl Ethers*

The reaction was carried out as above using 22.56 g. (0.08 M.) of the glycol, 3.13 g. (0.08 g-atom) of potassium, and 25 g. (0.09 M.) of 1-bromotetradecane, η_D^{20} (found) 1.4602, η_D^{20} (reported in literature) 1.4608 (8). After the mixture had become neutral, it was submitted to fractional distillation under 0.02 mm. Hg. The first two fractions were the unreacted reagents, *n*-bromotetradecane (b.p. 75° at 0.02 mm. Hg) and hexaoxyethyleneglycol (b.p. 156° at 0.02 mm. Hg), and the third fraction was hexaoxyethyleneglycol monotetradecyl ether (VII, $R = n\text{-C}_{14}\text{H}_{29}$, b.p. 195° at 0.02 mm. Hg, 14.3 g., 33.1%), which crystallized on cooling and was recrystallized from acetone; m.p. 35° . The residue from the distillation was fractionated by chromatography through a column of silica gel and there were obtained, from elution with ethyl ether, crystals of the ditetradecyl derivative (VIII, $R = n\text{-C}_{14}\text{H}_{29}$; 8.9 g., 29.2%), which were recrystallized from absolute ethyl alcohol; m.p. 43° .

The trityl derivative from the monoether was prepared as above, separated through a column, and distilled (b.p. 195° at 0.001 mm. Hg). Calculated for $\text{C}_{35}\text{H}_{68}\text{O}_7$: C, 74.9%, H, 9.51%; found: C, 74.0%, H, 9.25%.

*Preparation of *p*-(1,1,3,3-Tetramethylbutyl)phenyl- β -chloroethyl Ether (XII)*

A mixture of *p*-(1,1,3,3-tetramethylbutyl)phenol (IX) (74 g., 0.36 M.), sodium hydroxide (14 g., 0.36 M.), and 30 cc. of water was stirred vigorously and heated at 100° in a water bath for 10 minutes. Dioxane (30 cc.) was then added to dissolve the sodium phenate completely, and β -chloroethyl toluene-*p*-sulphonate (X) (85 g., 0.36 M.) was added slowly over a 2 hour period. After another hour's heating and stirring, enough sodium hydroxide (10%) was added to neutralize completely the *p*-toluene sulphonic acid (XI) formed. The mixture was then distilled with steam. The residue from the steam distillation was extracted with benzene and dried over potassium carbonate. The solvent was evaporated and the residue (96 g.) was distilled under reduced pressure.

There was obtained 90 g. (93%) of *p*-(1,1,3,3-tetramethylbutyl)phenyl- β -chloroethyl ether (XII) as a colorless liquid (b.p. 98° at 0.005 mm. Hg, η_D^{23} 1.5124). Calculated for: $C_{16}H_{25}OCl$: C, 71.50%, H, 9.31%, Cl, 13.2%; found: C, 71.62%, H, 9.32%, Cl, 12.7%.

Its infrared spectrum showed the typical aromatic bands at 6.2 μ (C=C stretching) and the strong band in the 12 μ region indicative of a *p*-substituted phenyl ring, a band at 8 μ corresponding to an aromatic ether, and the typical absorptions of the *t*-butyl groups at 7.35 μ .

Preparation of Heptaoxyethyleneglycol Mono-p-(1,1,3,3-tetramethylbutyl)phenyl Ether (XIII)

The monopotassium salt of hexaoxyethyleneglycol was prepared as described previously using 56.4 g. (0.2 M.) of glycol and 7.8 g. (0.2 g-atom) of potassium. This was condensed with 58.7 g. (0.21 M.) of the chloroether (XII). The potassium chloride was removed by filtration and the excess reagents were distilled under reduced pressure. The residue (20.92 g.) was chromatographed in two portions through silica gel. There was obtained 16.41 g. (16%) of heptaoxyethyleneglycol mono-*p*-(1,1,3,3-tetramethylbutyl)phenyl ether (XIII) as a colorless liquid and 5.74 g. of (XIV) as a semisolid of waxy appearance; calculated for $C_{32}H_{50}O_2$: C, 80.7%, H, 10.5%; found: C, 80.9%, H, 10.5%. The monoether could not be crystallized but was distilled (b.p. 125° at 0.001 mm. Hg).

A monotrityl derivative of (XIII) was prepared in the usual manner. The product was separated by chromatography and distilled twice to give a yellowish liquid (b.p. 230° at 0.001 mm. Hg, η_D^{20} 1.5447). Calculated for $C_{47}H_{64}O_3$: C, 74.60%, H, 8.46%; found: C, 74.46%, H, 8.36%.

MERCURY PHOTOSENSITIZED DECOMPOSITION OF BUTYLENE OXIDE¹

R. J. CVETANOVIĆ AND L. C. DOYLE

ABSTRACT

Mercury photosensitized decomposition of *trans*-2,3-epoxybutane has been studied at 25°. The quenching efficiency of this compound is 1.23 relative to the quenching efficiency of N₂O taken as unity; the quenching cross section is, therefore, 19 Å² (taking 3.6 Å² for the quenching cross section of *n*-butane). The main products formed are isobutanol, C₂H₆, CO, C₂H₄, C₃H₈, CH₃CHO, C₂H₅CHO, CH₃COC₂H₅, CH₄, and H₂. The yields of most of the products decrease with increasing pressure while those of C₂H₆, CH₄, and H₂ remain essentially pressure independent. Possible reaction mechanisms are discussed.

INTRODUCTION

Mercury photosensitized decomposition of different organic and inorganic compounds frequently provides a convenient source of free radicals and atoms and may be of considerable value for the study of elementary chemical reactions. The usefulness of this technique is largely dependent on the knowledge of the primary steps in the process. While important progress has been made in an attempt to draw general conclusions from the available experimental results (14), further advance might be expected from more extensive comparisons between and within different series of compounds, particularly of organic compounds containing different functional groups. More experimental information of this nature, is, therefore, desirable.

In a previous publication the results of a study of the mercury photosensitized decomposition of ethylene oxide were reported (3). The quenching efficiency of this compound was found to be much smaller than of some other oxygen containing compounds as, for example, of acetaldehyde, which is isomeric with it. The major primary process, the splitting of the molecule into CH₃ and HCO radicals, necessarily involved the opening of the epoxide ring and migration of an H-atom prior to the decomposition. The existence of at least one more primary process was established and also a close similarity of the over-all course of the reaction with the reaction of oxygen atoms with ethylene.

The present work was undertaken in an attempt to obtain further information on quenching by epoxides and to establish whether there is in general a similarity between the mercury photosensitized reaction of epoxides and the reaction of oxygen atoms with the corresponding olefins. An epoxybutane was chosen for this purpose since the mechanism of interaction and the products formed when oxygen atoms add to butene are now known (5).

EXPERIMENTAL

The experimental arrangement employed has been described before (3). For the analysis of products use was made of a Le Roy still (12), gas-liquid partition chromatography (GLPC) (2), and infrared and mass spectroscopy.

A sample of *trans*-2,3-epoxybutane was kindly supplied by the Distillers Company, Ltd., Great Burgh, Epsom, Surrey, Great Britain. It was used after repeated bulb to bulb distillation *in vacuo*. No appreciable amounts of impurities were detected by GLPC analysis. Oxygen was produced by heating research grade KMnO₄.

¹Manuscript received February 5, 1957.

Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada.

Issued as N.R.C. No. 4354.

The intensity of the low pressure mercury arc used was determined on the basis of H_2 production from 200 mm. of *n*-butane, for which Bywater and Steacie (1) have found a quantum yield of 0.50 at 25° C.

RESULTS

(a) Quenching Efficiency

The method described previously (4) was used to determine the relative over-all quenching efficiency of *trans*-2,3-epoxybutane. The plots of reciprocal quantum yields

FIG. 1. Plot of the reciprocal quantum yield of nitrogen production against the ratio of the concentrations of *trans*-2,3-epoxybutane and nitrous oxide (100 mm. N_2O , $24 \pm 1^\circ C$., irradiation time 120 minutes, mean I_a 3.54×10^{15} quanta/second).

of nitrogen production for various ratios of *trans*-2,3-epoxybutane and nitrous oxide are given in Fig. 1. The pressure of nitrous oxide in these experiments was 100 mm., the temperature $24 \pm 1^\circ C$., the exposure 120 minutes, and the mean light intensity 3.54×10^{15} quanta/second. The slope to intercept ratio of the plot gives 1.23 as the value of the ratio of the over-all quenching efficiency of the epoxide to that of nitrous oxide. With the previous choice of $3.6 \text{ \AA}^2$ for the quenching cross section of *n*-butane (4) this leads to $18.9 \text{ \AA}^2$ as the quenching cross section of *trans*-2,3-epoxybutane.

(b) Photosensitized Decomposition of *trans*-2,3-Epoxybutane

The main products observed in the mercury photosensitized decomposition of *trans*-2,3-epoxybutane were carbonyl compounds, C_2H_6 , CO, C_2H_4 , C_3H_8 , H_2 , and CH_4 . Smaller amounts of *n*-butane and isobutane were found also, at least at larger conversions, as well as traces of some other compounds. The quantum yields of the various products as a function of the extent of conversion at an initial pressure of 20 mm. are shown in Fig. 2. Notable is the pronounced decline with reaction time in the yields of C_2H_4 and of the carbonyl compounds. The latter compounds have been determined from infrared absorption measurements at a single wave length and on the basis of calibration

with a single carbonyl compound. Since, however, they are mixtures of several compounds there may be some doubt with regard to the absolute values of their quantum yields given in Fig. 2. At an initial pressure of 10 mm. *trans*-2,3-epoxybutane it was possible to analyze for these compounds by GLPC. The results are shown in Fig. 3 together with some values for CO, C₂H₆, C₃H₈, and C₂H₄. At low conversions the main

FIG. 2. Effect of the extent of reaction on the products of the mercury photosensitized decomposition of *trans*-2,3-epoxybutane at an initial pressure of 20 mm.

FIG. 3. Effect of the extent of reaction on the products of the mercury photosensitized decomposition of *trans*-2,3-epoxybutane at an initial pressure of 10 mm.

product is isobutanol. Appreciable amounts of acetaldehyde, propanal, and methyl ethyl ketone are also formed, and perhaps at larger conversions also some acetone (not identified with certainty). There is a rapid decline in the yield of isobutanol with the reaction time and similarly in the yield of ethylene. These experiments have been extended to very high conversions using exposures of up to 16 hours with simultaneous illumination

at both ends of the reaction cell. With such long reaction times small amounts of *cis*-2,3-epoxybutane are also found, as will be discussed later.

The effect of pressure of *trans*-2,3-epoxybutane is shown in Fig. 4 (open circles). The values at 20 and 10 mm. are the extrapolations to zero conversions from Figs. 2 and 3, respectively. Such extrapolations are necessarily somewhat uncertain. The remaining values have been determined at relatively low conversions. After the usually observed initial increase in quantum yields, at still higher pressures the yields of some of the products (C_2H_6 , CH_4 , H_2) appear to remain approximately constant while those of the

FIG. 4. Effect of pressure of *trans*-2,3-epoxybutane (open circles) and of carbon dioxide added to 20 mm. of *trans*-2,3-epoxybutane (filled circles) on the products of the mercury photosensitized decomposition of *trans*-2,3-epoxybutane.

other products decrease. With large amounts of CO_2 added to 20 mm. of *trans*-2,3-epoxybutane (filled circles) the quantum yields had to be calculated after allowing for quenching by CO_2 . This was done on the basis of the literature value (16) for the quenching cross section of CO_2 and the present value for *trans*-2,3-epoxybutane. It should be stressed that the two values have been determined by two widely different methods and the good coincidence of most of the yields corrected for quenching by CO_2 with those obtained with the corresponding pressures of *trans*-2,3-epoxybutane alone may be to some extent fortuitous. With CO_2 added, the quantum yields of CO , evaluated in this manner, are somewhat higher than those obtained with the epoxybutane alone. It is significant, however, that again the yields of CO and C_2H_4 decline with increasing pressure while those of C_2H_6 , CH_4 , and H_2 remain approximately constant. With large amounts of CO_2 added, no attempt was made to analyze for C_3H_8 and the carbonyl compounds.

The effect of large amounts of argon added to 10 mm. of *trans*-2,3-epoxybutane on the yields of the carbonyl compounds, determined by GLPC analyses, is shown in Table I. In the presence of argon the quantum yields of carbonyl compounds show a general decrease, more conspicuous at lower conversions, where it is presumably less masked by secondary effects. On the other hand, the yield of *cis*-2,3-epoxybutane is distinctly *increased*.

*N.d. = not determined.

†The values in parentheses are the corresponding yields in the absence of added gases, based on Fig. 3.

One experiment was carried out in which O₂ was added in the course of the sensitized decomposition of 10 mm. *trans*-2,3-epoxybutane in frequent small doses so that the pressure of O₂ was maintained at about 0.5 mm. The concentration of oxygen had to be kept relatively low in order to avoid appreciable direct quenching by this compound. Some of the results are shown in Table I. A large increase in CO yield was observed and there was a drastic decrease in the yields of the other products. Large amounts of oxygen were consumed ($\phi \approx 1.4$) and methanol, not observed in the absence of O₂, was found to be a major product ($\phi \approx 0.4$). The results thus indicated the important role in this process of free radicals and in particular of methyl radicals. The yield of acetaldehyde remained essentially unaltered in the presence of oxygen although this could not be taken as a positive proof of a direct molecular formation of this compound since it may also be a secondary product in the presence of oxygen. Similarly, the incomplete suppression of CH₄, C₂H₆, etc., should not be taken as a proof of a dual manner of formation of these compounds. With the intermittent replenishment of the oxygen consumed in the process it is possible that during part of the reaction time the concentration of oxygen might have been quite low.

Formation of CH₃ radicals as a major primary product is strongly indicated by the above results. This has been further confirmed by direct detection of these radicals in large amounts in the mass spectrometer in an experiment kindly performed by Dr. F. P. Lossing with the use of an experimental technique recently developed (9).

DISCUSSION

In the reaction of oxygen atoms with either *trans*- or *cis*-butene-2 very little decomposition of the initially formed biradical (I)

takes place and the reaction products consist essentially entirely of the following four compounds (5, 6): *cis*- and *trans*-2,3-epoxybutane, isobutanal, and methyl ethyl ketone. These products are formed by molecular rearrangement of the biradical (I) and not by combination of free radicals. In contrast to the relatively simple course of these reactions, the mercury photosensitized decomposition of *trans*-2,3-epoxybutane is quite complex.

This complexity precludes a quantitative treatment of the experimental results obtained and only a qualitative discussion is possible at present.

The yields of some of the products of the photosensitized decomposition of *trans*-2,3-epoxybutane are strongly suppressed as the pressure is increased while those of the other products, notably of ethane, are affected very little. Methyl radicals undoubtedly play an important role in the process. In view of this it is worth while first to enquire whether an assumption of a predominant but not necessarily exclusive initial formation of methyl radicals, not suppressed by increasing pressure, is sufficient to explain the experimental observations. The decrease of the yields of some of the products at higher pressures would then have to be explained by assuming that the remainder of the molecule, the fragment C_3H_5O , can lose its excess energy on collisions and be stabilized into the radical (II),

while at lower pressures it can readily isomerize into the radical $CH_3\cdot CH\cdot CHO$ (and possibly, to a much smaller extent, into $CH_3\cdot CO\cdot CH_2$) or decompose into C_2H_4 and CHO . The last of these radicals is known to decompose readily into CO and H ; it can also combine with CH_3 and C_2H_5 to give CH_3CHO and C_2H_5CHO , respectively (3). The major product of the process, isobutanol, could be formed by combination of CH_3 and $CH_3\cdot CH\cdot CHO$ and its formation, as well as that of CO , C_2H_4 , C_3H_8 , and of the other carbonyl compounds should, therefore, decrease with increasing pressure, as observed. Propane could result from CH_3 and C_2H_5 and the latter from H and C_2H_4 . Methane and hydrogen are produced in relatively small amounts and the approximate pressure independence of their yields is perhaps due to the fact that H -abstraction from β -butene oxide appears to be quite slow at 25° so that the necessary hydrogen is probably obtained mainly from HCO radicals. It is also possible that CH_4 and H_2 result at least partly from a direct intramolecular rearrangement, as was shown to be the case with H_2 in the photosensitized decomposition of ethylene oxide (3).

The predominantly free radical mechanism just discussed can, therefore, explain qualitatively the main experimental observations. It is also necessary, however, to assume that at higher pressures the stabilized radicals (II) combine largely with CH_3 radicals to regenerate the *trans*-2,3-epoxybutane while the *cis* isomer is formed only in minor amounts. This assumption should be verified by the use of *cis*-2,3-epoxybutane as the initial reactant. In the present work a pronounced *increase* in the yield of the *cis* isomer has been observed on addition of large amounts of argon, although even then the yield was relatively small. The products formed by combination of C_3H_5O radicals between themselves, as would be required by this mechanism, would be of too low volatility to be observed by the methods employed in this work.

It is of interest that Gomer and Noyes (10) and Trotman-Dickenson and Steacie (15) have observed previously a complex behavior of the $CH_2-CH\cdot$ radical, obtained

through hydrogen abstraction from ethylene oxide, which may be regarded as the first member of the series of which the radical (II) represents the next higher member.

An alternative mechanism can be formulated by assuming two distinct and approximately equally important primary steps: (1) formation of a very short lived excited

molecule which always decomposes into radicals or stable molecules, and (2) formation of a second excited molecule which is sufficiently long lived to be capable of collisional deactivation at higher pressures. In view of the pronounced effect of oxygen, the long lived excited molecules would then have to be assumed to be able also to react rapidly with oxygen molecules to give products different from those normally formed.

A comparison of the quenching efficiencies of the two epoxides studied so far with those of the corresponding olefins and paraffins is given in Table II. The quenching

TABLE II

$\begin{array}{c} H_2C-CH_2 \\ \diagdown \quad \diagup \\ O \end{array}$	0.10	$\begin{array}{c} CH_3.CH-CH.CH_3 \\ \diagdown \quad \diagup \\ O \end{array}$	0.59
$H_3C.CH_3$	0.004	$CH_3.CH_2.CH_2.CH_3$	0.12

*Calculated from the data of Darwent, Phibbs, and Hurtubise (Ref. 8).

efficiency of ethylene is taken as unity. The quenching efficiencies of the epoxides lie between those of the paraffins and the olefins and are somewhat closer to the latter. They show a large increase as the molecule becomes larger, and are similar in that respect to the paraffins (7, 8). The primary chemical process, however, is not the rupture of a C—H bond, as in paraffins, but resembles in some ways the processes observed with some olefins and carbonyl compounds.

It is believed that in the interaction of $Hg\ 6(^3P_1)$ atoms with olefins triplet olefin molecules are formed while in the case of paraffins there are no sufficiently low-lying triplet levels for this to occur (11). The energy of 112 kcal./mole available from the $Hg\ 6(^3P_1)$ atoms ought to be well in excess of the energy necessary for the opening of the epoxide ring in *trans*-2,3-epoxybutane. The formation of the triplet biradicals (I), a quenching process which would satisfy the spin conservation rule (11), could then be anticipated. The difference between the behavior of these biradicals and those formed when oxygen atoms add to butene-2 may be explained by the difference in the vibrational excitation in the two cases. If the heat of reaction of oxygen atoms with *trans*-butene-2, to give the biradical (I) is A kcal./mole, then this energy represents approximately the excess vibrational energy possessed by the biradical when formed. This energy is evidently insufficient to decompose the biradical to any extent before it degrades to the four compounds formed as the final product of the reaction. If the same biradical is formed initially from *trans*-2,3-epoxybutane on transfer of 112 kcal. from $Hg\ 6(^3P_1)$ atoms, the excess energy is likely to be $A + 20$ to 30 kcal., i.e., some 20 to 30 kcal. greater.* This excess of vibrational energy might be sufficient to lead to a rapid decomposition of the biradical into a CH_3 and a C_3H_5O fragment or, alternatively, to an internal rearrangement. An analogous explanation can reconcile the various primary processes established recently for some simple olefins by Lossing, Marsden, and Farmer

*The heats of reaction of oxygen atoms with C_2H_4 , C_3H_6 , and *trans*- C_4H_8 -2 to give ethylene oxide, CH_3CHO , C_2H_5CHO , CH_3COCH_3 , and $CH_3COC_2H_5$ are 87, 114, 113, 116, and 114 kcal./mole, respectively.

(13) with an initial interaction of the $\text{Hg } 6(^3\text{P}_1)$ atoms with the CC double bonds in those compounds.

In conclusion it should be emphasized that while the study of the mercury photo-sensitized decomposition of ethylene oxide and *trans*-2,3-epoxybutane has revealed some interesting trends, other members of the epoxide series ought to be investigated before generalizations can be made with certainty.

ACKNOWLEDGMENT

The authors are thankful to Dr. A. W. Tickner for mass spectrometer analyses and to the Analytical Section of this Division for infrared analyses.

REACTIONS OF SULPHONIC ESTERS

VI. THE TEMPERATURE DEPENDENCE OF THE RATE FOR THE HYDROLYSIS OF A SERIES OF ALKYL BENZENESULPHONATES¹

R. E. ROBERTSON

ABSTRACT

Data are presented showing temperature dependence of the rate of hydrolysis of methyl, ethyl, isopropyl, and *n*-propyl benzenesulphonates in water. The heat of activation is shown to be temperature dependent to the extent of -30 to -40 cal./mole deg. Since, in solvolysis, the properties of water favor ionization over nucleophilic displacement, it is suggested that these temperature coefficients, $\Delta C_p^\ddagger$, and the accompanying entropy differences, $\Delta S^\ddagger$, can be rationalized in terms of variations in the reorganization of the solvent about the transition state.

This paper is the first of a series in which we shall examine the changes in the thermodynamic parameters characterizing solvolysis which result from simple structural changes in the ester. Here, we examine the effect of α -methylation in the series methyl, ethyl, and isopropyl benzenesulphonate; stepwise structural changes which should cause each successive ester to react by a mechanism approaching more closely the limiting S_N1 type. Data for the *n*-propyl ester are included for comparison with the α -methylated series and to extend our earlier investigation of straight chain effects in this series (23).

The formation of a quasi-ionic transition state from the unchanged ester will certainly result in a reorganization of solvent molecules, the extent depending on the particular ester and on the degree of charge separation in the transition state. It is reasonable to expect this reorganization to determine, in part, the changes in the values of the thermodynamic parameters which characterize the activation process, particularly in the entropy ($\Delta S^\ddagger$) and the heat capacity ($\Delta C_p^\ddagger$). Theoretical reasons for expecting a change in the heat capacity in such reactions have been given many years ago (22) and experimental evidence showing that

$$d\Delta H^\ddagger/dT \neq 0$$

for solvation reactions has recently been reviewed by Bensley and Kohnstam (1). In every example known, the sign of $\Delta C_p^\ddagger$ for solvolysis of esters is negative and of the same sign and magnitude as found for the analogous ionization of weak acids (7). Since the values of $\Delta C_p^\ddagger$ are so large there seems no reason to doubt that the observed heat capacity changes which characterize both processes arise in large part from the reorganization of solvent molecules, and our consideration of the differences in the kinetic parameter, $\Delta C_p^\ddagger$, will be based on this assumption.

EXPERIMENTAL

The experimental procedures and methods of calculation have already been described in detail (29, 19) and need not be repeated here save to note the introduction of an amplifier (GR-1231-B) into the separate Wagner earthing circuit. This deserved mention, since it permitted a more precise balancing and proved particularly advantageous where several runs were being followed simultaneously.

¹Manuscript received January 18, 1957.

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa. Presented in part at the Spring Meeting of the Chemical Institute of Canada, May 28, 1956, in Montreal.
Issued as N.R.C. No. 4355.

Methyl benzenesulphonate, Eastman White Label, was repeatedly fractionated by fractional freezing to give a product with a constant melting point -4.50°C . Ethyl, *n*-propyl, and isopropyl benzenesulphonates were synthesized by the method of Morgan and Cretcher (26) from purified starting materials and redistilled under vacuum to give products with properties identical with those already published (28).

The initial concentration of the methyl and ethyl esters in kinetic rate studies was about 0.2 g./liter but this was reduced to 0.1 g./liter for the propyl esters because of the lower solubility of the latter. A single stock solution of distilled water containing 0.2 g./liter of benzenesulphonic acid as a supporting electrolyte was used throughout the study. Efforts were made to study the rates over the same average low ionic concentration and similar concentration changes in order to minimize salt effects.

RESULTS

Average rate data from *n* concurrent runs at each temperature are collected for the four esters in Tables I, II, III, and IV. The average deviation of the rates is given in

 SUMMARY OF CONSTANTS FOR EQUATION [1]

Benzenesulphonate	A	B	C
Methyl	-6860.442	-15.81888	57.2186
Ethyl	-7063.212	-16.37588	59.2178
Isopropyl	-7454.790	-19.74238	70.6734
<i>n</i> -Propyl	-6734.056	-14.73970	53.9527

Rates corresponding to the experimental temperatures were calculated from these derived constants according to equation [1] and are included along with the differences ($k_{\text{obs.}} - k_{\text{calc.}}$) in the respective tables. A comparison of the average deviations with the corresponding deviation from the calculated rate shows both deviations are of the same magnitude at a given temperature, thus justifying the use of equation [1] which assumes that

$$d\Delta C_p^\ddagger/dT = 0.$$

Somewhat better agreement would probably be achieved by further refinement of our experimental method but such steps are not warranted at this time.

In order to compare our results with those of Tommila and Lindholm (34, 35) we computed the rates at 25° and 50° C. for the four esters (Table VI). Tommila and Lindholm derive Arrhenius parameters from their data in the range 25° to 60° C. to get values

TABLE VI
 SUMMARY OF DERIVED THERMODYNAMIC QUANTITIES AT 298.16° K.

Benzenesulphonic ester	Methyl	Ethyl	Isopropyl	n-Propyl
$k_1 \text{ sec.}^{-1} \times 10^5$	1.166*	1.016†	26.27	0.785
$\Delta F^\ddagger \text{ cal.}$	5,912	6,730	4,885	6,696
$\Delta H_0^\ddagger \text{ cal.}$	31,391	32,319	34,098	30,813
$\Delta H_{298.16}^\ddagger \text{ cal.}$	21,420	22,080	21,810	21,490
$-\Delta C_p^\ddagger \text{ cal./mole deg.}$	33.4	34.5	41.2	31.3
Standard error in $\Delta C_p^\ddagger \pm$	1.1	1.4	0.5	0.7
$-\Delta S^\ddagger \text{ cal./mole deg.}$	9.29	7.51	1.81	9.87

* Compared to 1.15 and †1.03 Tommila and Lindholm (34).

of $E = 21,030 \text{ cal.}$ and $\log PZ = 10.48$ for the hydrolysis of methyl benzenesulphonate. Corresponding values calculated by the method of least mean squares from data in Table I lead to values of $E = 21,600$ and $\log PZ = 10.8928$ over the range $10^\circ\text{--}70^\circ \text{ C.}$ The value for $\Delta H_{315.66}^\ddagger + RT$ is 21,467 cal. In spite of such agreement the application of the Arrhenius equation must be regarded as but a roughly approximate expression of the temperature dependence of the rate (30) since there it is assumed, contrary to experimental facts, that $d\Delta E/dT = 0$.

The thermodynamic quantities for the hydrolysis of the four esters were computed from the corresponding constants (Table V) where

$$\begin{aligned}
 A &= -(\Delta H_0^\ddagger/2.303 R), \\
 B &= (\Delta C_p^\ddagger/R+1), \\
 C &= (\Delta S_0^\ddagger - \Delta C_p^\ddagger/2.303 R + \log_{10} k/h).
 \end{aligned}$$

Common usage coupled with the practical advantage in connection with the calculation of the entropy led to the adoption of the Eyring transition state nomenclature.*

DISCUSSION

The process of solvolysis for esters of strong acids has frequently been discussed in terms of an intermediate mechanism in which nucleophilic displacement and the factors favoring ionization are complementary (2, 18, 20, 36, 33). While there appears to be no common agreement as to the range of mechanism to be regarded as intermediate it should be obvious that this classification supplements rather than replaces the S_N1 – S_N2 classification of Hughes and Ingold (21). By definition a mechanism is of the limiting S_N1 type where no nucleophilic displacement can be detected in the rate determining step; hence the intermediate mechanism may be regarded as a more detailed description of the older S_N2 classification applicable to those reactions where the tendency toward ionization is significant. It thus serves the useful purpose of emphasizing the contribution of the whole solvent shell to the process of activation rather than concentrating attention on the varying contribution of a single nucleophilic species. This change of emphasis is desirable when discussing the mechanism of solvolysis where the nucleophiles are weak and particularly so in this study of the hydrolysis of benzenesulphonic esters in water.

The low nucleophilicity of water together with its excellent ionizing properties provide

*In this connection we wish to acknowledge discussions with Professor H. C. Brown, Professor J. Halpern, Professor K. J. Laidler, Professor A. Streitwieser, Jr., and Dr. K. O. Kutschke. The values obtained by this method compared with that employed previously (29) are identical for $\Delta H_0^\ddagger$, differ by 2 cal./mole deg. in $\Delta C_p^\ddagger$, while $\Delta S_0^\ddagger$ does not include $\log_{10} k/h$.

the conditions for solvolysis shifted toward the S_N1 type in character. While the usual kinetic tests for nucleophilic participation are not available in the case of solvolysis, the conclusion that those solvent-solute interactions favoring ionization are important in the solvolysis of the benzenesulphonates is supported by the contrast between the relative rates of solvolysis for these esters in ethanol with those in water and acetic acid (Table IX). The small range of rate change through the series in the latter solvents, the increase at isopropyl, and the relatively small difference between methyl and neopentyl all support the above hypothesis. Unfortunately it is not possible at present to measure the relative importance of nucleophilicity and of ionization in such reactions. The correlation equations of Grunwald and Winstein (16, 36) and of Swain, Mosely, and Scott (32) provide approximate answers but are subject to the limitation that they are based on relative rates. A more complete evaluation will require a comparison of not only the rates but of the heat, entropy, and heat capacity of activation and such a correlation will remain incomplete unless due allowance is made for the initial state differences of the esters compared. Since it is implicit that solvation effects will be of importance in solvolysis and particularly so for reactions in water, we shall review the salient features of aqueous solutions which we believe are pertinent to the discussion of results presented here and to be presented in subsequent papers of this series.

Solvation of the Initial State

The large changes in entropy and heat capacity which characterize the formation of aqueous solutions of non-electrolytes are most conveniently explained in terms of some type of "freezing" presumably involving the formation of a type of dynamic water shell about the solute. This structure has been compared to that in a gas hydrate (3, 12) and is frequently referred to as an "iceberg" formed about the solute. Although other hypotheses exist for the nature of aqueous solutions, notably that of Powell and Latimer (27) and of Eucken (5), we have found the iceberg model most useful in this work. This graphic term carries the connotation of greater rigidity than probably exists but evidence that the relative difference between the solvation of the initial and the transition state remains much the same within a given series over a 50–60° range is seen in the relative constancy of the ratio k_{D_2O}/k_{H_2O} for isopropyl and isobutyl benzenesulphonate and for methyl bromide, isopropyl bromide, and benzyl bromide (24, 25). Further evidence is the fact that over a temperature range of 70–80° we have not detected any appreciable temperature change in $\Delta C_p^\ddagger$ for data in this paper or in a previous publication (29). This contrasts with the expectation raised by the findings of Feats and Ives (10) from their study of the ionization of cyanoacetic acid. The latter authors consider their finding

$$d\Delta C_p(\text{ionization})/dT \neq 0$$

to result from an appreciable change in the water structure in the region 30–40° C. We can only conclude that in so far as such changes exist, the effect is small compared to the changes being observed in hydrolysis.

Molecules which interact strongly with water, such as the alcohols, show greater $-\Delta S_{sol}$ than non-polar molecules, an effect which in this instance may be attributed to hydrogen bonding. Thus qualitative evidence pointing to stronger interaction between the sulphonic ester and water than for the corresponding alkyl halides (25) leads to a picture of the initial state in which the solvation shell is attracted, possibly hydrogen bonded, at two points to the sulphonate group. If the solvation shell did in fact resemble

a unit gas-hydrate (12), such interaction would clearly introduce important modifications in the structure of the shell. For the present problem the most obvious consequence of such attraction will be that in the initial state at least two water molecules will be orientated in a position closer to that which they will occupy in the transition state than in the case of the corresponding alkyl halide, and so will require less reorientation on activation. This conclusion is borne out by the value of k_{D_2O}/k_{H_2O} being closer to unity for the benzenesulphonates and other oxygenated anions than for the alkyl halides (24) and this latter work also provides support for the reasonable hypothesis already stated that, within a given series, solvation differences about the seat of reaction in the initial state are small compared with the changes which arise on activation. It is of interest to note in this connection that Swain and co-workers (32) introduce a constant " c_2 " into their correlation equation to take account of the solvent interaction with the anionic part of the ester and further that (31) there is a close correspondence between these " c_2 " values and the " m " values of the Grunwald, Winstein, and Jones equation, which supposedly represents the whole molecule.

Solvation of the Transition State

Major changes in solvation will obviously arise as the result of the formation of two quasi-ions. In contrast to the large positive heat capacities and relatively large negative entropies which characterize the aqueous solutions of non-electrolytes, monovalent ions of comparable volume have somewhat more positive entropies and large negative heat capacities (4, 11). Since the reactions under consideration involve the change from a non-electrolyte into two quasi-ions, it will be useful to cast a comparison noted by Frank and Evans in the form of an equation and to consider the magnitude of the change in $\Delta S_{(\text{solvation})}$ and $\Delta C_{p(\text{solvation})}$ for the hypothetical reaction of argon converting to chloride ion in water

The entropy and heat capacity changes accompanying the solution process (from the gas phase) are given in Table VII and the differences are the approximate changes in

TABLE VII
THERMODYNAMIC PARAMETERS FOR THE HYPOTHETICAL REACTION

	$A \xrightarrow{H_2O} \text{Cl}^-$	
	ΔS (cal./mole deg.)	ΔC_p (cal./mole deg.)
Final state ($\text{Cl}^-_{\text{solvated}}$)	-18.3	-14.5
Initial state (A_{solvated})	-22.6	+43
	$\Delta S^\ddagger$ +4.3	$\Delta C_p^\ddagger$ -57.5

these parameters due to changes in solvation were the above reaction possible. (We assume the transition state and final state to be similarly solvated.) Using the argument of Frank and Evans (11) the net gain in the entropy on the formation of the ion may be attributed to the "depolymerization" of the water in the area which lies beyond the primary tightly bound layer. The large negative heat capacity change associated with the formation of the ion may be accounted for in part by the decrease in $\Delta C_p^\ddagger$ as a consequence of the clamping of a few water molecules by strong electrostatic forces in the

primary solvation layer plus the further loss resulting from the depolymerization phenomenon noted above. While this hypothetical example illustrates the trend to be expected in $\Delta S^\ddagger$ and $\Delta C_p^\ddagger$ for the creation of a quasi-ionic transition state from a neutral ester, some reasons for expecting quantitative differences in the hydrolysis of a series of benzenesulphonic esters are (a) the ions produced are large compared to Cl^- , (b) though the partial charge may be more diffuse, the total charge may be greater, there being two partial ions, (c) charge separation (development) will vary through the series, (d) water molecules hydrogen bonded in the initial state will reduce effect of reorientation, (e) steric effects will vary through the series and may be expected to have a different relative effect in the initial compared to the transition state.

The number of water molecules forming the solvation shell about the non-electrolyte will obviously be a function of the size of the solute molecule—a fact which may be reflected in the magnitude of both the heat capacity and entropy change characterizing the solution process (11, 13). On activation, charge development will be largely though not entirely localized at the seat of reaction; consequently reorientation will be most evident in this area and will *not* necessarily be proportional to the size of the molecule. This observation is illustrated in the recent paper by Laughton and Robertson (24) comparing the relative rates of solvolysis in light and heavy water. Evidence that the character of the solvation shell remains essentially unchanged in the transition state at a distance of two or three saturated carbon atoms from a charge is seen in the small changes in ΔC_p and ΔS for the ionization process of fatty acids (7). If the creation of a charge led to the collapse of the co-ordinate shell (as might be expected if the solvated molecule resembled a unit gas-hydrate) we would expect large incremental changes in ΔS and ΔC_p as the molecular volume increased; in fact differences become negligible as chain length increases. Further evidence that the solvation shell suffers no large change at a distance of two to three carbon atoms from a created charge is the large positive heat capacity which may be attributed to the alkyl chain of sodium octanoate from a calorimetric determination of the heat of solution by Goddard, Hoeve, and Benson of these laboratories (14). This conclusion is in agreement with that reached by Frank and Evans from a consideration of the entropy change associated with solvation and the fluidities of alkylammonium ions (11, also 17).

Effect of α -Methylation

In this section we shall examine changes in the derived parameters from the hydrolysis of the series $\text{Me} \rightarrow \text{Et} \rightarrow \text{i-Pro}$ benzenesulphonates in terms of the general model discussed in preceding sections.

In reactions of the type discussed here, successive α -methylation leads to an increase in steric hindrance to nucleophilic attack and an increase in electron release to the seat of reaction (21). Both of these effects favor a shift in mechanism toward ionization. The observed rate ratio $\text{Me} = \text{Et} < \text{i-Pro}$ (1:1:24), the equality of the derived $\Delta H^\ddagger$, and the relatively small differences in $k_{\text{D}_2\text{O}}/k_{\text{H}_2\text{O}}$ through the series suggest that either the mechanistic differences here are small, as a consequence of the spectrum of reactions being shifted toward $\text{S}_{\text{N}}1$ type and of the possible smaller steric requirements of water as a nucleophile, or that the small differences result from the cancellation of larger effects. Whatever the cause of the small differences, bond making should certainly be greater in the solvolysis of the primary compared to the secondary esters and hence lead to a stiffer transition state and less charge development (15). Considering the nucleophile

and the ester alone, this should result in a more negative $\Delta C_p^\ddagger$ for the methyl ester than for the isopropyl ester, contrary to what is found. Considered as a partial ionization, the differences in solvation arising from differences in size (solvent exclusion) between the methyl and isopropyl quasi-cations would favor a shift in $\Delta C_p^\ddagger$ which is likewise the opposite of that observed. But if our model is correct, charge development is not equal and we are led to the hypothesis that the observed negative shift in $\Delta C_p^\ddagger$ (Table IX) is the result of an even tighter clamping of water molecules in the solvation shell surrounding the transition state of the isopropyl ester than is suggested by the observed $\Delta\Delta C_p^\ddagger$. Such a hypothesis implies that initial state differences within a given series are of less importance than those arising from differences in charge development, and we have already discussed evidence favoring this assumption. Everett has suggested that the opposition of trends in the ΔS and ΔC_p for the ionization of three methylamines may be attributed to differences of initial state solvation (9) but in this case, it will be noted that the ions (corresponding to the transition state) have equal positive charges. An explanation for the positive trend in the entropy between the secondary and primary esters on hydrolysis based on the relative tightness of the nucleophile-ester bond, alone, appears illogical to us if it is necessary to account for the change in $\Delta C_p^\ddagger$ in terms of the clamping down of many water molecules. We have noted above that aqueous solutions of ions are characterized by having more entropy than would be expected; the addition of a charge may even lead to a net increase in entropy (Table VII) though the charge undoubtedly would result in the tighter binding of some of the solvent molecules. Exclusion of solvent from the seat of reaction in the transition state, as suggested by Evans and Hamann (6), is probably a factor but this would also lead to a positive trend in $\Delta C_p^\ddagger$ if this were the controlling factor. In any case evidence from the ratio of solvation rates in light and heavy water suggest that solvation of the cationic part of the transition state is of less consequence than the reorganization of solvent about the forming anion. On the simplest solvation model the latter would lead to a more negative entropy for the isopropyl ester unless we invoke some opposing mechanism such as the depolymerization hypothesis of Frank and Evans, discussed in the previous section. A program of research to explore this possibility and to determine corresponding parameters in other series is now in progress.

n-Propyl Benzenesulphonate

The *n*-propyl benzenesulphonate was studied as an extension of an earlier examination of the effect of lengthening the alkyl chain in hydrolysis (23) and for comparison with the trends in heat capacity and entropy which characterize the dissociation of straight chain weak acids (8). The data in Tables VIII and IX show that while the addition of a β -methyl to ethyl results in but a small change in the rate compared to the second α -methyl, this small change is the result of larger compensating changes in the heat and

entropy of activation. A similar reversal in trend is evident in the heat capacity change. In the dissociation of weak acids, the positive trend in heat capacity was attributed to a chain-stiffening effect resulting from exclusion by the solvent of the alkyl chain from the charge center. This may contribute to the present reversal, but other factors must be considered since the entropy shift found here is the opposite to that required by the chain-stiffening hypothesis.

CONCLUSION

We have considered the above esters to hydrolyze in water by an intermediate mechanism in which ionization forces are important. While nucleophilic attack by a solvent molecule has not been excluded by this study, arguments based on relative rates in solvents of varying nucleophilic and ionizing ability, on the small differences in the rates and derived thermodynamic parameters, and on the similarity between the values of ΔC_p for the ionization of weak acids and value of $\Delta C_p^\ddagger$ observed here all point to a mechanism which approaches an ionization in character. The changes in $\Delta S^\ddagger$ and $\Delta C_p^\ddagger$ have therefore been rationalized in terms of the reorientation of the solvent.

ACKNOWLEDGMENT

We wish to acknowledge the technical assistance of Mr. Alan Relf through part of this work. We are indebted as well to Professors H. S. Frank and P. M. Laughton, and to Dr. J. B. Hyne, for helpful discussions.

REACTIONS OF ARYLSULPHONIC ESTERS

VII. THE HEAT CAPACITY OF ACTIVATION FOR THE ETHANOLYSIS OF METHYL *p*-NITROBENZENESULPHONATE¹

J. B. HYNE² AND R. E. ROBERTSON

ABSTRACT

A conductometric method is described for the determination of rates of solvolyses in non-aqueous media with an accuracy of better than $\pm 0.5\%$ in k . The heat of activation derived from the results so obtained is shown to have a temperature coefficient ($\Delta C_p^\ddagger$) of -21 cal./mole deg.

The utility of the heat capacity of activation as a parameter in the study of reaction mechanisms in solution has already been noted (3, 4) and recently reported experimental work (7, 8) has established the practicability of such determinations. Previous work from this laboratory, however, has been restricted to hydrolysis reactions in water where the high degree of dissociation of the product acids permits a simplification of experimental method. The importance of solvent influence on reaction mechanism in solution made it desirable to extend the study of heat capacities of activation to non-aqueous systems. Such an extension raises many experimental problems. The accuracy required in rate measurements of solvolytic reaction for use in heat capacity computations can be most conveniently attained by conductometric methods. In aqueous solution many systems can be used where the product of the reaction is completely ionized and the conductivity over a considerable range is a linear function of the concentration to a sufficiently high degree of approximation. This is not true in non-aqueous systems, and a calibration technique is required for conversion of conductometric data to concentration units which can then be employed directly in the computation of rates. This additional step has been employed in several instances (1, 2) with a consequent loss in accuracy of rate determinations.

Shiner and Verbanic (10) have recently reported rate data in 90% ethanol-water mixtures determined by the direct conductometric method; these authors claim that the relationship between conductivity and concentration is sufficiently linear under the conditions employed to enable determination of rates reproducible to 0.5%. The relationship was established by "independent measurements" and while the validity of these measurements is not questioned, it is clear that the linearity of the relationship is critically dependent upon both the concentration range over which linearity was established and upon the specific nature of the electrolyte being produced. Shiner and Verbanic found, as we did, that there was no such linearity in pure ethanol and as a consequence did not use this solvent in their work. Since we were particularly interested in the magnitude and sign of the heat capacity of activation in pure solvents, particularly in the alcohol series, there was a need for a method utilizing the extreme accuracy of the conductometric system but capable of application to a wide range of non-aqueous media worthy of investigation.

We describe the development of such a system in some detail and demonstrate its utility by determining the heat capacity of activation for the solvolysis of methyl *p*-nitrobenzenesulphonate in ethanol.

EXPERIMENTAL DETAIL

The basic requirement of the experimental technique is that the conductometric method employed be independent of degree of ionization of the ionic species being produced. This has been achieved by employing the conductivity as a null point indicator.

Two magnetically stirred conductivity cells (Fig. 1) of approximately 100 ml. volume containing identical solutions of the electrolyte to be produced in the reaction are totally immersed in a thermostat controlled to $\pm 0.003^\circ \text{C}$. (7). These cells (*cl*) constitute the two arms of a standard a-c. Wheatstone network (Fig. 2). After thermal equilibrium

FIG. 1.

has been established, the bridge is balanced by adjustment of R_1 and R_2 , the compensating capacitors C_1 and C_2 , and the Wagner grounding circuit. Since the bridge is operated at all times as a null point instrument, stability is the only requirement and inexpensive components may be used. This balance point represents identical ionic concentrations in the two cells and compensates for any difference in the cell constants. The bridge setting remains unaltered throughout the course of any given run. The "titration cell" (Fig. 1, *b*) is connected through a fine capillary to a precision delivery titrimer and a concentrated solution of the electrolyte to be produced in the reaction is pumped from the titrimer to the cell. No change in the balance point of the bridge detector is noted until the solution reaches the stirred cell. At this point the titrimer reading is noted and represents zero volume delivered to the cell.

Approximately 10^{-4} moles of the material to be solvolyzed is now introduced into the "reaction cell" (Fig. 1, *a*) *in situ*. Production of the electrolyte by solvolysis immediately

affects the balance point of the bridge and can be followed qualitatively on the bridge detector. Electrolyte is now added from the titrimer to the titration cell to counter-balance that being produced in the reaction cell. Normally excess electrolyte is added to the titration cell and the reaction cell allowed to "catch up". When the original balance point is regained (equal ionic strengths), a time reading is taken corresponding to the titrimer reading minus the zero volume reading. Successive readings may be taken in a similar manner throughout the course of the reaction.

FIG. 2.

Comments on Method

(1) Since all readings are taken at identical concentrations in the two cells, changes in degree of ionization with concentration are equal in both arms of the bridge and consequently there is no net effect on the balance point of the bridge.

(2) It is essential that changes in concentration in the titration cell be a linear function of the titrimer scale reading, i.e., of volume delivered. This is not strictly the case since, while electrolyte is being produced in the reaction cell without significant change of volume, the change in electrolyte concentration in the titration cell is accompanied by a net change in total volume due to the volume delivered from the titrimer. A correction factor is, therefore, applied to the titrimer reading. This can be easily computed from the volume delivered to the cell at each reading and the original volume of solution in the cell. The factor may be kept small by using a concentrated solution of electrolyte in the titrimer; the total volume delivered to the cell will then be small—of the order of 3 to 5 ml. for the complete run.

(3) The more important technical difficulties which must be overcome are worthy of mention. (a) At higher temperatures with low boiling solvents back pressure in the delivery capillary can be troublesome. All joints must be liquid tight under pressure. This includes the capillary jointing and the piston seals in the titrimer. (b) Back diffusion of solution from the delivery tip in the titration cell can be overcome by adding electrolyte in slight excess *immediately prior* to the taking of the reading. Any diffusion that has taken place between readings will then be accounted for in the volume delivered.

(c) Care is essential in adding the reactant to the reaction cell. The tip of the delivery pipette must be inserted *under* the solvent level to ensure that no reactant adheres to the glass of the injection port and enters the solution *after* readings have begun. All but very insoluble reactants are homogeneously distributed by the stirrer within two to three minutes. (d) In view of the length of the delivery capillary unthermostated it was found desirable to limit fluctuation of the ambient room temperature throughout a given run to $\pm 1.0^\circ \text{C}$.

(4) The titrimeter used in this work was a precision instrument constructed in the workshops of these laboratories and capable of delivering up to 10 ml. with an accuracy of ± 0.001 ml. The vertically mounted barrels were of Teflon and the pistons were precision ground from Hastelloy B alloy. Glass barrels were also used. Glands were fashioned from Teflon. The drive train from the electric motor to the pistons incorporated a three-speed gearbox mainly for convenience in flushing and recharging barrels between runs. With concentrated solutions of electrolytes in contact with the alloy pistons over long periods of time sufficient corrosion was observed to establish intolerable concentration gradients in the solution in the barrel. This was overcome with the electrolytes used by introducing sufficient mercury into the barrel to prevent direct contact between piston and electrolyte.

(5) In addition to achieving the high degree of accuracy attainable by use of the conductometric method without restriction to aqueous media this method also preserves the advantage of following the rates without interfering with the reacting system in any mechanical manner. In the present work it was unnecessary to calibrate the titrimeter units in terms of concentration as the rate constants measured were independent of concentration units. In the many studies where changes in concentration units are required, however, simple calibration would render this instrument a useful experimental tool.

COMPARISON WITH OTHER METHODS

Robertson (7) has reported rates of hydrolysis of methyl benzenesulphonate over a wide range of temperatures using a well established direct conductometric method. From this work the value $k = 31.85 \times 10^{-5} (\text{sec.}^{-1})$ at 54.790°C . can be computed. This system was run in the present apparatus for comparison and a value of $31.84 (\pm 0.03) \times 10^{-5} (\text{sec.}^{-1})$ was obtained.

Robertson (9) has previously reported the rate of ethanolysis of methyl *p*-nitrobenzenesulphonate at 70°C ., determined by a simple aliquot and titration technique, as $k = 65.3 (\pm 0.7) \times 10^{-5} (\text{sec.}^{-1})$ compared with the value obtained in this work $k = 64.53 (\pm 0.1) \times 10^{-5} (\text{sec.}^{-1})$.

RESULTS

A typical solvolytic rate determination in non-aqueous medium, the ethanolysis of methyl *p*-nitrobenzenesulphonate, is shown below. Typical rate plots (Fig. 3) and preparative data are recorded for a determination at 60°C . and rate data for this solvolysis from 40°C . to 75°C . are shown in Table I.

Typical Experiment at 60°C .

Preparative

Methyl *p*-nitrobenzenesulphonate synthesized by the method of Morgan and Cretcher (6) from Eastman White Label *p*-nitrobenzenesulphonyl chloride. Recrystallized from 60–80 petroleum ether to m.p. 53°C . Absolute ethanol dried by the diphtalate method.

Solutions

Backing electrolyte—0.001 *M* *p*-nitrobenzenesulphonic acid in ethanol; titrating electrolyte—0.02 *M* *p*-nitrobenzenesulphonic acid in ethanol; reactant added—0.01 g. methyl *p*-nitrobenzenesulphonate in 1 ml. ethanol.

Guggenheim rate plots for three determinations at 60° C. are shown in Fig. 3. Rates determined from large scale plots were (1) 25.96×10^{-5} , (2) 25.89×10^{-5} , (3) 25.77×10^{-5} sec.⁻¹. This represents a reproducibility of $\pm 0.4\%$ in k comparable with the precision of individual rate determinations.

From the data of Table I values of the constants for the equation (3, 7)

$$\log_{10} k = A/T + B \log_{10} T + C$$

are evaluated by the method of least mean squares. These values are shown in Table II

TABLE II
THERMODYNAMIC CONSTANTS FOR ACTIVATION AND
EQUATION CONSTANTS

$A =$	-5885.3
$B =$	-9.5471
$C =$	$+38.1643$
$\Delta F^\ddagger_{298.16} =$	$+24,557$ cal./mole
$\Delta H^\ddagger_{298.16} =$	$+20,708$ cal./mole
$\Delta S^\ddagger_{298.16} =$	-12.79 e.u.
$\Delta C_p^\ddagger =$	-20.96 ± 3.5 cal./mole deg.

together with the thermodynamic constants for the activation process. These latter can be calculated by identifying A , B , and C with the coefficients of the expanded form of the Eyring equation,

$$\log_{10} k = -\Delta H_0^\ddagger/2.303 RT + (\Delta C_p^\ddagger/R + 1) \log_{10} T + [(\Delta S_0^\ddagger - \Delta C_p^\ddagger)/2.303 R + \log_{10} k/h].$$

The error for ΔC_p is computed from the standard error in coefficient B obtained from the least mean square calculation. The higher error, compared with other data reported from this laboratory, results largely from the smaller temperature range over which the rates were determined.

DISCUSSION

The primary purpose of this investigation was to develop a technique by which we might fully utilize the convenience and precision of the conductometric method in the study of solvolysis in non-aqueous media and thus to determine the respective heat capacities of activation. We believe this aim has been achieved although there are many refinements in the technique yet to be developed, in particular the extension of the temperature range and the attendant problem of back pressure in the system at higher temperatures. It was primarily to avoid this problem that the system methyl *p*-nitrobenzenesulphonate ethanolysis was chosen, since this solvolysis proceeds at a convenient rate at easily accessible temperatures.

The values of the thermodynamic parameters obtained in this initial investigation in non-aqueous medium are, nevertheless, of considerable interest. Clearly the value of the heat capacity of activation is lower than those values already reported (7, 8) for similar systems in water and for the methyl halide hydrolyses (5). It would appear, therefore, as hoped, that the heat capacity of activation is a parameter which shows considerable response to the solvent changes in the system.

Preliminary investigation of the thermodynamic parameters of activation for the methyl *p*-nitrobenzenesulphonate hydrolysis indicates that the $\Delta C_p^\ddagger$ value is in the region -26 to -27 cal./mole deg. which is considerably lower than that for the unsubstituted methyl benzenesulphonate hydrolysis ($\Delta C_p^\ddagger = -33.4$). Interpretation of the value for the *p*-nitro compound ethanolysis ($\Delta C_p^\ddagger = -21$) would, therefore, appear

to be dependent upon a twofold reducing effect relative to the unsubstituted case, the influence of the *p*-nitro group, and the effect of changing the solvent medium. The influence of changing the alkyl group on $\Delta C_p^\ddagger$ has already been observed (9) and it would now appear that variation of substituent on the aromatic anionic fragment is also reflected in the heat capacity change.

More detailed interpretation of the thermodynamic parameters obtained in this work must await further, more exhaustive study of similar systems. This investigation, however, establishes the fact that not only is the method described practical but that the heat capacity of activation has considerable merit as a measurable parameter in the study of solvent effects in non-aqueous as well as aqueous systems.

ACKNOWLEDGMENT

The authors wish to express their indebtedness to the following members of the technical staff of these laboratories without whose assistance construction of the apparatus described would have been impossible: Mr. George Ensell for the cells used and Mr. André Couture and Mr. J. G. Labrèche for their painstaking efforts with the titrimeter.

THE DIPOLE MOMENTS OF MERCURIC CHLORIDE AND MERCURIC BROMIDE IN BENZENE¹

A. R. TOURKY AND H. A. RIZK

ABSTRACT

From dielectric constant measurements in benzene for the two halides mercuric chloride and mercuric bromide, the dipole moments are 1.23 and 0.95 D. respectively. Thus, they apparently possess angular structures.

Kohlrausch (18) gathered from Raman spectral data that mercuric chloride and mercuric bromide might possess linear structures. Bell (3) calculated the moments of these halides from solubility data and the values he obtained were 4.0 and 5.7×10^{-18} e.s.u. cm. respectively. Braekken and Scholten (5) concluded afterwards from X-ray analysis that the molecular configuration of mercuric chloride was linear, whereas that of mercuric bromide was not. Curran and Wenzke (8) determined the dipole moments of these two halides from dielectric constant measurements in dioxane on the opinion that these halides do not form co-ordination compounds with dioxane supported by the experimental fact that diphenyl mercury has the same dipole moment in dioxane as that determined by Hampson (12) in benzene and decalin. This conclusion was criticized by Crenshaw *et al.* (7), who found from vapor pressure measurements that mercuric halides form dioxanates in dioxane solutions. Williams (28) pointed out that the use of dioxane as a solvent in dipole moment studies is limited to compounds with which it does not form addition products. Curran, in an investigation concerning the dipole moments of some organomercuric halides in dioxane (9), concluded that if co-ordination between the dioxane and the mercuric halides took place, a coplanar configuration of the

type $^+O-Hg \begin{matrix} \diagup Cl \\ \diagdown Cl \end{matrix}$ for mercuric chloride dioxanate with 120° valence angles would have

resulted. This complex would have a moment greater than 5 D. The bromide and the iodide dioxanates would have slightly smaller moments. He thus postulated that dioxane does not form co-ordinated bonds with mercuric halides or organomercuric halides but forms dipole-dipole bonds between oxygen and mercury similar to the ion-dipole bonds between oxygen and metal cations in hydrates. In the present investigation, we have been able to study the polarization of mercuric chloride and mercuric bromide in benzene as a solvent. However, in view of the limited solubility of these compounds in benzene, the measurements could not be extended over a wide range of concentration.

EXPERIMENTAL

Mercuric chloride of "AnalaR" grade was crystallized three times from twice redistilled water and the product was dried first at 100° C. in a stream of dry air and then under vacuum. The chloride was finally distilled under vacuum. The crystals obtained were white, long-needled, and completely soluble in water. Mercuric bromide was synthesized according to the method of Baker and Watson (2). The product obtained was distilled under vacuum, thus producing pure white crystals. Benzene of grade "AnalaR", carbon tetrachloride, and nitrobenzene were rigorously dried and purified according to recommended procedures (27).

¹Manuscript received December 7, 1956.

Contribution from the Department of Chemistry, Faculty of Science, University of Cairo, Cairo, Egypt.

The dielectric constant, ϵ , was measured using a resonance circuit in which a frequency of 1.875×10^6 c.p.s. was fixed by a quartz crystal. A specially designed cylindrical platinum cell was used instead of the silvered Sayce-Briscoe cell (25), as in the latter cell chemical interaction with the halides takes place. The measuring cell was rigidly fixed in a jacket that could be connected to an ultrathermostat. The air capacity of the cell was $30 \mu\text{f.}$, the range over which ϵ could be measured was 1.9 to 3.1, and the volume required to fill the annulus was 8 cc. For the calibration of the apparatus, liquids of reliable dielectric constants were used:

	Benzene (13, 19)	Carbon tetrachloride (19)	Nitrobenzene in benzene (17, 20)		
ϵ at 25° C.	2.2725	2.2270	2.2925	2.3000	2.3325
			$f_2 = 0.0008707$	0.001197	0.002612

The uncertainty in ϵ was ± 0.0005 . The density was measured by a pycnometer of the Sprengel-Ostwald type that was filled by the method of Smyth and Morgan (26) and Miller (23). The pycnometer was first calibrated using carbon-dioxide-free redistilled water, and the density of the liquid was corrected for the buoyancy of air. The refractive index for the sodium D line was measured directly by means of a Hilger-Abbé refractometer. The composition of the solutions in weight fraction was determined using the Eley and King method (11). The temperature at which measurements were carried out was $25^\circ \pm 0.002^\circ \text{C.}$

RESULTS AND DISCUSSION

The total specific polarization of each halide, p_s , at different concentrations in benzene was calculated from the modified Clausius-Mosotti-Debye equation applicable to solutions (6, 10). The polarization at infinite dilution, $p_{s\infty}$, was graphically and mathematically determined. In the latter case the Hedestrand method (14) and the Palit-Banerjee method (24) were used. To get the best values of $p_{s\infty}$ the method of least squares was applied; the mean of the values obtained was then taken. The part of the molecular polarization arising from the induced dipoles was calculated from measurements of the refractive index for the sodium D line using the modified form of the Lorenz-Lorentz equation applicable to solutions (21). The molecular refraction was then corrected by applying the dispersion formula $(1 - \lambda_0^2/\lambda^2)R_2$, where $\lambda_0 = 1013 \text{ \AA}$ (23) and $\lambda = 5896 \text{ \AA}$ (1), so as to get the molecular refraction for infinite wave-length, $R_{2\infty}$, which is identical with the electronic polarization, ${}_EP_2$. The deformation polarization, ${}_DP_2$, was taken as $1.10R_{2\infty}$ (29) and the apparent dipole moment, μ , was calculated by the refractivity method. The data obtained are shown in Tables I and II.

It can be seen from these tables that the electronic polarizations of mercuric chloride and mercuric bromide for infinite wave-length, namely 29.65 and 54.99 cc., are lower than the values, 30.36 and 55.30 cc., which were obtained by Bergmann and Engel (4) and applied by Curran and Wenzke (8) by 0.71 and 0.31 cc. respectively. The magnitude of the orientation polarization of mercuric chloride which has been applied in calculating the dipole moment is 21.36 cc., being taken as the difference between the total polarization, 63.97 cc., and 1.10 times the electronic polarization for infinite wave-length, 32.61 cc. On the other hand, Curran and Wenzke's value (8) is $65.03 - 30.36 = 24.67$ cc. The same can be said with regard to mercuric bromide; our orientation term is $79.03 - 60.49 = 18.54$ cc., whereas that given by Curran and Wenzke (8) is $78.63 - 55.30 = 23.33$ cc. It is thus evident that the polarization values of these two halides taking benzene as the

solvent are in agreement with the values obtained by Curran and Wenzke (8) using dioxane. The dipole moment values are 1.23 and 0.95 D. for mercuric chloride and mercuric bromide respectively, whereas those due to Curran and Wenzke (8) are 1.29 and 1.06 D. respectively.

The polarities of these two halides indicate that they possess dissymmetric distribution of charges. Whether the dissymmetry is ascribable to a bent structure or to dissimilar distances of the halogen nuclei from the mercury in a linear molecule must be decided by other measurements. With respect to this point reference can be made to the water molecule, which resembles mercuric halides, being of the type structure XY_2 and having a finite dipole moment value. The rotation spectrum of water as determined by Mecke (22) and the theoretical considerations of Heisenberg (15) and of Hund (16) necessitate a bent structure and not a linear one. Thus, it seems very likely that mercuric chloride and bromide molecules are of angular structures. The decrease in the electric moment from 1.23 to 0.95 D. as we pass from the chloride to the bromide indicates a decrease in the dissymmetry of the charge of the $Hg-X$ bond along the direction of the bond. This can be attributed to the fact that as the electron cloud in the bromide ion is greater than that in the chloride ion, then the induced moment $Hg \leftarrow X$ which opposes the permanent moment will increase to an extent greater than the increase in the permanent moment

due to the increase in the nuclear distance. The decrease in polarity may be also partly ascribed to an increase in the valency angle as a result of the greater repulsion between the two bromide ions; but in order that this view be fully justified, other types of measurements than the dipole moment measurements are needed.

THE HEMICELLULOSES PRESENT IN ASPEN WOOD (POPULUS TREMULOIDES)

PART III. THE CONSTITUTION OF PENTOSAN AND HEXOSAN FRACTIONS¹

J. K. N. JONES, E. MERLER, AND LOUIS E. WISE

ABSTRACT

Extractive-free aspen wood (*Populus tremuloides*) was extracted with water, followed by alkaline solutions of successively increasing concentration, and finally with alkaline borate solution. Hemicellulose fractions (I-IX) were thus obtained, and some of these were further subdivided into components which formed water-insoluble copper complexes (A) and those which did not (B). Analytical data are recorded for each fraction.

One of the fractions (V) represented 19% by weight of the original wood. Hydrolysis of the methylated material gave 2,3,5-tri-*O*-methyl-L-arabinose, 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2- and 3-mono-*O*-methyl-D-xyloses, and three acidic fragments as the major components.

When V was treated with an enzyme preparation, 80% by weight of the material was hydrolyzed to simple sugars, and an enzyme-resistant polysaccharide fraction remained. Methylation of the latter, followed by hydrolysis, afforded, in addition to those methylated sugars described above, 2,3,4,6-tetra-*O*-methyl-D-mannose.

A mannose-rich hemicellulose fraction (VIII A) was also methylated and then hydrolyzed. The major products were 2,3,4,6-tetra-*O*-methyl-D-mannose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3,6-tri-*O*-methyl-D-glucose. The significance of these results is discussed.

INTRODUCTION

In Parts I and II of this series of papers, the hemicellulosic fraction of aspen wood was studied by controlled acid hydrolysis of the crude wood (7, 8). The major products of hydrolysis were shown to be the monosaccharides L-rhamnose, L-arabinose, D-xylose, D-galactose, and 4-*O*-methyl-D-glucuronic acid. In addition, three oligosaccharides, a xylobiose, a xylotriose, and 2-*O*-(4-*O*-methyl- α -D-glucuronosyl)-D-xylose were identified. Since then, Milks and Purves (11) have studied aspen holocellulose by treatment of the wood with wet liquid ammonia, followed by acetylation of the extracted material. Methylation of the acetate, followed by hydrolysis, led to the isolation of 2,3-di-*O*-methyl-D-xylose, and a mixture of 2- and 3-mono-*O*-methyl-D-xyloses.

In the present work, an attempt has been made to fractionate the total carbohydrate fraction of aspen wood. The crude, extractive-free wood was extracted first with cold water, from which a polysaccharide fraction (I) was isolated. Stepwise extraction of the residue with potassium hydroxide solutions of successively increasing concentration then led to the isolation of five hemicellulose fractions (II-VI). Extraction of the residue with alkaline borate solution (9) gave a solution, neutralization of which resulted in the precipitation of another hemicellulose fraction (VII). From the supernatant solution, a further hemicellulose fraction (VIII) was isolated.

The woody residue was then delignified by the method of Wise, Murphy, and D'Addieco (14). By extraction of the remaining material with alkaline borate solution, the former was divided into a hemicellulose fraction (IX) and a cellulose-rich residue.

Each of fractions I-V was hydrolyzed. Chromatographic examination of the products indicated that the major component in each case was xylose, together with smaller amounts of arabinose, glucose, mannose, galactose, rhamnose, fucose, and uronic acids.

¹Manuscript received March 12, 1957.

Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario, and the Institute of Paper Chemistry, Appleton, Wisconsin, U.S.A. This paper represents part of a thesis submitted by E. Merler to the Department of Chemistry, Queen's University, Kingston, Ontario, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

When fractions I-V were subdivided into copper complexing (A) and non copper complexing (B) subfractions, each subfraction was similarly shown to contain the same sugar residues as above, in varying amounts. The fractions and subfractions were analyzed for methoxyl and uronic anhydride content. The results are collected in Table I.

Fraction V represented 19% by weight of the original wood. When subjected to electrophoresis on sheets of glass paper (2), it was shown to be resolvable into two major components. Furthermore, when this fraction was treated with a special enzyme preparation, it was hydrolyzed to the extent of 80%; the remaining 20% represented an enzyme-resistant polysaccharide fraction. When the latter was examined by glass paper electrophoresis, it was observed that one of the original components had largely disappeared. It was therefore considered to be of interest to examine both the original material and the enzyme-resistant material by methylation techniques. Fraction V contained xylose (67 parts), arabinose (2 parts), rhamnose (3 parts), hexoses (2 parts), and uronic anhydride (9 parts) (6) in the proportions indicated. On methylation, followed by hydrolysis, it gave 2,3,5-tri-*O*-methyl-L-arabinose (1 part), 2,3,4-tri-*O*-methyl-D-xylose (1 part), 2,3-di-*O*-methyl-D-xylose (210 parts), 2- and 3-mono-*O*-methyl-D-xyloses (3 parts), and uronic acid fragments (20 parts), together with traces of an unidentified tri-*O*-methyl-hexose (3 parts).

The enzyme-resistant polysaccharide contained xylose (74 parts), arabinose (6 parts), rhamnose (2 parts), hexoses (2 parts), and uronic anhydride (4 parts) (6) in the proportions indicated. Hydrolysis of the methylated material afforded 2,3,5-tri-*O*-methyl-L-arabinose (1 part), 2,3,4-tri-*O*-methyl-D-xylose (1 part), 2,3-di-*O*-methyl-D-xylose (270 parts), 2- and 3-mono-*O*-methyl-D-xyloses (4 parts), and three uronic acid fragments (33 parts), together with traces of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,4-tri-*O*-methyl-L-arabinose. Owing to the difficulties in the fractionations of the sugars losses occurred, particularly of the more volatile portions, and for this reason the proportions quoted are approximate only.

The neutral methylated sugars were all characterized either as the crystalline compounds, or as crystalline derivatives of the compounds. The uronic acid fractions in each case were not easily resolvable by chromatographic means. The mixtures were therefore treated with hot methanolic hydrogen chloride to convert the sugars into their methyl esters and methyl glycosides, and the products reduced with potassium borohydride (10). Hydrolysis of the resulting sirupy materials in each case gave a mixture of 2,3,4-tri-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-glucose which were provisionally identified from a study of the derivatives produced after reduction followed by periodate oxidation of the resultant sugar alcohols. 3,4-Di-*O*-methyl-D-xylose was identified by converting it to 3,4-di-*O*-methyl-D-xylonolactone, and 2- and 3-mono-*O*-methyl-D-xyloses were tentatively identified by means of paper electrophoresis.

The hemicellulose fractions VI-IX were all relatively rich in hexose residues, the principal hexose being mannose, as indicated by chromatographic examination of the hydrolyzed materials. Fraction VIII was especially rich in mannose residues, and after formation of a copper complex, a fraction (VIII A) was isolated which contained residues of D-mannose (18 parts), D-glucose (9 parts), and D-xylose (1 part). Methylation of this fraction, followed by hydrolysis, gave rise to 2,3,4,6-tetra-*O*-methyl-D-mannose (2 parts), 2,3,6-tri-*O*-methyl-D-mannose (24 parts), and 2,3,6-tri-*O*-methyl-D-glucose (12 parts), identified by means of crystalline derivatives and in the approximate proportions indicated. Also, evidence was obtained for the presence of small amounts of 3,4,6-

tri-*O*-methyl-D-mannose, 2,3-di-*O*-methyl-D-xylose, and 2,6-di-*O*-methyl-D-glucose in the hydrolyzate.

From the above work it would appear that the pentosan fraction of aspen wood contains a mixture of polysaccharides which are very similar in their general architecture, this similarity being sufficient to prevent any sharp fractionation into chemically distinct molecular species. The fact that fractionations which are dependent upon the solubility of the polysaccharides, or of their copper complexes, failed to give fractions differing in the kind of sugar residue present implies that the pentosans are highly heterogeneous in both the physical and chemical sense. It may be noted that the xylans from the hardwoods beech (1) and birch (12) are long-chain molecules while that from the softwood western hemlock (3) is highly branched. The latter concept appears to be the most probable explanation for the behavior of the enzyme preparation, since the enzyme-resistant polysaccharide isolated from fraction V contained less than half the uronic acid of the original and three times the arabinose. However, in the absence of knowledge of the exact specificity of the enzymes, it is not possible to draw any positive conclusions. Fractions I-III were totally resistant to enzymic attack, perhaps because they contained acetyl groups, but fraction IV was completely hydrolyzed by the enzyme.

Although the fine structures of the xylans remain obscure, it is clear that they all contain chains of (1 → 4) linked xylose residues, to which are attached, through positions 2 and 3 of a xylose residue, occasional end groups of L-arabofuranose residues and side chains which are terminated by uronic acid residues. It is uncertain whether residues of mannose or rhamnose are incorporated in this structure, or, if they are, by what kind of linkage. The nature of the uronic acid end groups presents an interesting problem. The enzymic hydrolyzate of fraction V was shown to contain 4-*O*-methyl-D-glucuronic acid. The uronic acid fraction isolated after hydrolysis of the methylated xylans, after treatment with methanolic hydrogen chloride followed by reduction, gave a product which was hydrolyzed to yield a mixture of 2,3,4- and 2,3,6-tri-*O*-methyl-D-glucoses. The former probably resulted principally from glucuronic acid or 4-*O*-methyl glucuronic acid residues in the original polysaccharide. The latter must have resulted from neutral glucose residues, which were probably intermediate between a uronic acid end group and a xylose residue. The isolation of 3,4-di-*O*-methyl-D-xylose from the hydrolyzate would suggest that xylose residues are also incorporated in the side chains.

The structure of the glucomannan fraction (VIII A) is less complex. It appears to contain essentially (1 → 4) linked chains of glucose and mannose residues; the non-reducing end groups are mainly mannose residues. Alternatively, this fraction could be a mixture of a (1 → 4) linked mannan and a similarly-linked glucan. While this fraction represents only a small part of the total hemicellulosic fraction of the wood (*ca.* 2%), it is interesting that it resembles the glucomannans which have been found in some softwoods. The xylose residues probably arise from a contaminating xylan. The origin of the 3,4,6-tri-*O*-methyl-D-mannose and 2,6-di-*O*-methyl-D-glucose produced on hydrolysis of the methylated glucomannan fraction is not clear.

All efforts to obtain a residual cellulose which would give only glucose on hydrolysis were unsuccessful. Traces of xylose and mannose were always detected in the hydrolysis products of the residual α -cellulose. However, the amounts of foreign sugars percentage-wise formed on hydrolysis of the α -cellulose were very small. Much further work will be required before it is decided whether these sugars form part of the cellulose molecule or whether they arise from associated xylan and mannan.

EXPERIMENTAL

Paper partition chromatography was carried out on Whatman No. 1 filter paper, with the upper layers of the following solvent systems (v:v): (A) *n*-butanol-ethanol-water-ammonia (4:1:4.9:0.1); (B) benzene-ethanol-water (169:47:15); (C) *n*-butanol-pyridine-water-benzene (5:3:3:1); and with the systems (D) *n*-butanol-pyridine-water (10:3:3); (E) ethyl acetate - acetic acid - formic acid - water (18:3:1:4). Solvents were removed under reduced pressure and at *ca.* 40° C.

Extraction and Fractionation of the Hemicelluloses

Milled aspen wood (370 g.), as received from The Institute of Paper Chemistry, Appleton, Wisconsin, was washed continuously by percolation with the azeotrope of benzene and ethanol. The extractive-free plant tissue (350 g.) was evenly packed in a column, and tap water (30 liters) was percolated slowly through the material until a small sample gave a nearly negative Molisch test. This water extract was concentrated to a small volume which was poured into ethanol containing hydrochloric acid (1% of concentrated acid); the precipitate was redissolved in water and reprecipitated with ethanol, washed with ether, and dried (fraction 1: 7.8 g., 2.1%). The residual plant tissue was extracted with aqueous potassium hydroxide (1%). A portion of this solution was neutralized on contact with the wood; this neutral solution was concentrated, and the concentrate poured into alcoholic-hydrochloric acid (as above) to give fraction 2 (1.8 g., 0.5%). After percolation the alkaline solution was acidified with acetic acid and the precipitate collected at the centrifuge (fraction 3: 2.0 g., 0.5%). The supernatant liquid from fraction 3 was concentrated and the residue poured into alcoholic-hydrochloric acid. The precipitate was redissolved in water and precipitated again with ethanol (fraction 4: 13.6 g., 3.7%). These alkaline extractions of the woody tissue were continued, using successively 10% and 20% potassium hydroxide, and gave respectively fraction 5 (70.0 g., 19%) and fraction 6 (7.8 g., 2.1%).

Fractions 1, 2, 3, 4, and 5 were further subdivided into subfractions *A* and *B* by adding Fehling's solution to solutions of the polysaccharides. Subfractions *A* represent the materials forming insoluble copper-complexes and *B* the materials not forming copper-complexes. The recoveries of material in these experiments ranged from 60% to 85%. Fraction 6 was not investigated further. Altogether 14 fractions were obtained; each, when hydrolyzed, gave mainly xylose with smaller amounts of arabinose, rhamnose, uronic acids, and at least one of the hexoses glucose, mannose, and galactose. The fractions soluble in water also contained small amounts of a sugar moving chromatographically at the same rate as fucose; galactose concentrated in subfractions *B* and fucose in subfractions *A*. Physical constants of the fractions are recorded in Table I. The uronic acid content was estimated on the basis of carbon dioxide formed on heating the polysaccharide with hydrochloric acid (12%) (6). Optical rotations were determined in sodium hydroxide solution (*N*).

Extraction and Fractionation of the Woody Residue after the Previous Extractions

The residue (300 g.), which was rich in cellulose and lignin, was stirred for 72 hours with a solution of potassium hydroxide - borate (2.5 liters, 20:4%) (9). The mixture was filtered through a medium sintered-glass funnel, the filtrate was neutralized with acetic acid, and the woody residue was extracted twice more. The combined neutralized filtrates were dialyzed and the solid which precipitated was removed at the centrifuge (fraction 7: 1.2 g., 0.4%). The supernatant liquid (10 liters) was concentrated and the residue

TABLE I
 PHYSICAL CONSTANTS OF ASPEN WOOD FRACTIONS

Fraction	$[\alpha]_D^{25^\circ}$ (c, 1.0)	Methoxyl, %	Uronic anhydride, %
1	-1	3.4	20.3; 20.1
1A	+2	3.4	21.9
1B	-3	5.2; 5.2	23.0
2	-18	3.6; 3.4	11.2; 11.8
2B	-18	2.3; 2.2	11.2
3	-4	6.7; 6.8	7.6; 7.4
3A	-10	5.0; 5.6	7.5
3B	+15	1.9; 2.1	0.9

5A	-79	1.7	8.5
5B	-74	1.3	4.5

(200 ml.) poured into ethanol (1 liter) to which concentrated hydrochloric acid (10 ml.) had been added. After reprecipitation the material was dried (fraction 8: 3.8 g., 1.2%). The woody residue from the above treatment was delignified by the chlorite method (14) and the residue was shaken overnight with cuprammonium hydroxide (13). The undissolved material was removed at the centrifuge and the ammoniacal supernatant solution was neutralized with hydrochloric acid. The precipitate which formed was separated (centrifuge) and treated at room temperature with the potassium hydroxide-borate solution for 100 hours. The polysaccharide in the extract was isolated as described above. A portion of the residual cellulose (25 g.) was added to sulphuric acid (20 ml., 72%); initially the temperature of the reaction was kept below 10° C. After 12 hours, water was added (1.5 liters) and the solution was heated on the boiling water bath for 24 hours. The solution was cooled and neutralized with barium hydroxide. The barium salts were removed at the centrifuge and the solution concentrated. The residue was composed mainly of glucose, but occurring also were mannose, xylose, and uronic acid residues as indicated by paper chromatography. (The yields are calculated on the basis of non-extracted wood.)

Fraction 8 (9.2 g., 3.0%) was dissolved in sodium hydroxide (2 N) and treated with a slight excess of Fehling's solution. This yielded a copper complex (8A), the supernatant liquid from which gave a precipitate with aqueous acetone (50%). Some polysaccharide remained in solution. With the exception of fraction 8A the various polysaccharides were tested for sugar units after hydrolysis, and were shown to contain varying amounts of all, or some, of the following: mannose, glucose, galactose, xylose, arabinose, fucose, rhamnose, and uronic acids. Fraction 8A (further treatment of which is given below) when hydrolyzed gave largely mannose and glucose with smaller amounts of xylose and uronic acids.

Properties of the Hemicellulose in Fraction 5 (Termed "Xylan")

Hydrolysis of fraction 5 (cf. Table I) with sulphuric acid (N) in a boiling water bath

for 12 hours and estimation of the liberated aldoses by the method of Hirst and Jones (4) indicated the presence of the following sugars (calculated as proportions of sugar in residues in the original xylan): xylose, 67 parts; arabinose, 2 parts; hexoses, 2 parts; and rhamnose, 3 parts. The lignin content (13, p. 369) was 3.4%.

Methylation of the Xylan

The xylan (10 g.) was methylated five times with methyl sulphate and sodium hydroxide. The reaction mixture was carefully acidified and extracted with chloroform to give an oil which solidified (10 g.). The material soluble in chloroform–light petroleum (b.p. 60–80° C.) (3:7) was isolated (7.2 g.), and a portion (5 g.) methylated four more times with methyl sulphate and sodium hydroxide. The methylated polysaccharide (3.3 g.) had $[\alpha]_D^{23} - 58^\circ$ (c , 1.5 in CHCl_3 ; found: OMe, 37.5%).

Hydrolysis of the Methylated Xylan and Identification of the Neutral Sugars

The methylated xylan (3.0 g.) was dissolved in aqueous formic acid (40 ml., 50%) and heated in a boiling water bath for 6 hours to constant optical rotation. The solution was cooled and concentrated to a sirup, which was dissolved in sulphuric acid (30 ml., N) and heated 3 hours on the boiling water bath until the solution had a constant optical rotation. The cooled solution was extracted continuously with chloroform for 2 days. The aqueous layer was neutralized with barium carbonate, the barium salts were removed at the centrifuge and washed with water, and the solvent removed. Since both the chloroform extract and the water fraction contained uronic acid residues (paper chromatography), the two samples were combined and cations were removed by passage through a column of Amberlite IR-120 (acid form) resin. The residue was separated in two portions by chromatography on a column of Amberlite IR-4B (acetate form) resin; thus a neutral fraction (2.311 g.) and an acidic fraction (0.232 g.) were obtained.

The neutral methylated sugars (2.311 g.) were separated into five fractions by partition chromatography on columns of cellulose powder (5), using as eluants light petroleum (b.p. 100–120° C.)– n -butanol (7:3) saturated with water, changing to light petroleum– n -butanol (6:4) saturated with water, than n -butanol saturated with water, and finally water. A part of this chromatographic separation was also made on extractive-free Whatman 3 MM paper. The full details of these separations are omitted because the operations were repeated many times to obtain pure fractions. The fractions finally obtained are termed A–E.

Fraction A.—The sirup (0.010 g.) had $[\alpha]_D^{26} - 22^\circ$ (c , 0.8 in H_2O) and R_f 0.98 in solvent A (found: OMe 47.9%; calc. for $\text{C}_8\text{H}_{16}\text{O}_5$: 48.4%) and was identified as 2,3,5-tri- O -methyl-L-arabinose by conversion into the lactone after oxidation with bromine water, $[\alpha]_D^{26} - 25^\circ$ (c , 0.7 in H_2O) and derived amide, m.p. and mixed m.p. with an authentic sample 135–137° C.

Fraction B.—The sirup (0.015 g.) had $[\alpha]_D^{25} + 20^\circ$ (c , 0.90 in H_2O) and R_f 0.94 in solvent A (found: OMe, 48.2%; calc. for $\text{C}_8\text{H}_{16}\text{O}_5$: 48.4%) and was identified as 2,3,4-tri- O -methyl-D-xylose, m.p. and mixed m.p. 90–92° C., $[\alpha]_D^{26} + 60^\circ \rightarrow +20^\circ$ (equil.) (c , 0.50 in H_2O).

Fraction C.—The sirup (2.09 g.) had $[\alpha]_D^{25} + 24^\circ$ (c , 1.40 in H_2O) and R_f 0.74 in solvent A (found: OMe, 34.4%; calc. for $\text{C}_7\text{H}_{14}\text{O}_5$: 34.4%), m.p. and mixed m.p. with 2,3-di- O -methyl-D-xylose 79–80° C., $[\alpha]_D^{23} + 60^\circ \rightarrow +23^\circ$ (equil.) (c , 1.10 in H_2O).

Fraction D.—The sirup (0.040 g.) had $[\alpha]_D^{25} + 72^\circ$ (c , 1.10 in H_2O) and R_f 0.87 (found: OMe, 42.2%; calc. for $C_9H_{18}O_6$: 41.9%); it solidified and was recrystallized from ether to give needles (0.030 g.), m.p. 137–139° C. In solvent *B* this substance had an R_f value different from that of 2,3,6- or 2,4,6-tri-*O*-methyl-D-glucoses. A small sample, on reduction with potassium borohydride and oxidation with sodium metaperiodate (10), gave a compound having an R_f value of 0.80 chromatographically identical with di-*O*-methyl-threose and another unknown material producing a color with chromic oxide and diphenylcarbazide and having an R_f value of 0.70. Fraction *D* remained unidentified since the melting point of this material is much higher than any recorded melting point of any tri-*O*-methyl derivatives of glucose, mannose, or galactose.

Fraction E.—This proved to be a mixture. The sirup (0.030 g.) had $[\alpha]_D^{25} + 21^\circ$ (c , 1.20 in H_2O) and R_f 0.50 in solvent *A* (found: OMe, 18.6%; calc. for $C_6H_{12}O_5$: 18.5%). A small sample of fraction *E* after methylation with silver oxide and methyl iodide gave only one substance, chromatographically identical with 2,3,4-tri-*O*-methyl-D-xylose. Another sample was examined by paper electrophoresis in a borate buffer of pH 10 and by applying a potential difference of approximately 450 v. between the ends of the paper for 10 hours. Spots corresponding to 3-*O*-methyl-D-xylose and 2-*O*-methyl-D-xylose were noted.

Reduction with Potassium Borohydride of the Acidic Fraction from the Methylated Xylan

The acidic fraction (0.230 g.), which was a mixture, was refluxed with methanolic hydrogen chloride (*N*) for 8 hours. After neutralization with silver carbonate the solution was taken to dryness and the resulting sirup (0.220 g.) was dissolved in water (2 ml.) and added slowly to a solution of potassium borohydride (0.1 g.) in water (2 ml.). After 1 hour the excess borohydride was destroyed by the addition of dilute acetic acid and the reduced oligosaccharides were collected (0.190 g.). The sirup was heated with sulphuric acid (*N*) at 100° C. for 9 hours and the hydrolyzate separated into four components (*A'*, *B'*, *C'*, and *D'*) by chromatography on Whatman 3 MM paper in solvent *A*.

Fraction A'.—The sirup (0.030 g.) had $[\alpha]_D^{22} + 70^\circ$ (c , 0.45 in H_2O) and R_f 0.86 in solvent *A* (found: OMe, 40.9%; calc. for $C_9H_{18}O_6$: 41.9%). Methylation of a portion of fraction *A'* and hydrolysis of the resulting methyl glycoside gave a compound chromatographically identical with 2,3,4,6-tetra-*O*-methyl-D-glucose. The remainder of fraction *A'* was reduced with potassium borohydride and oxidized with sodium metaperiodate (10). Examination of the product on a paper chromatogram revealed two substances, one chromatographically identical with 2,3,4-tri-*O*-methyl-D-xylose and another identical with di-*O*-methyl-threose, indicating that the original material was composed of a mixture of 2,3,6- and 2,3,4-tri-*O*-methyl-glucoses.

Fraction B'.—The sugar (0.030 g.) had $[\alpha]_D^{22} + 22^\circ$ (c , 0.86 in H_2O) and R_f 0.74 in solvent *A* (found: OMe, 34.2%; calc. for $C_7H_{14}O_5$: 34.4%) and was identified as 3,4-di-*O*-methyl-D-xylose by conversion into 3,4-di-*O*-methyl-D-xylonolactone, m.p. and mixed m.p. 62–65° C. and $[\alpha]_D^{25} - 50^\circ \rightarrow -22^\circ$ (equil.) (c , 0.42 in H_2O).

Fraction C'.—The sirup (0.020 g.) had $[\alpha]_D^{22} + 30^\circ$ (c , 0.80 in H_2O) and R_f 0.50 in solvent *A* (found: OMe, 18.2%; Calc. for $C_6H_{12}O_5$: 18.9%) and was found by paper electrophoresis to be a mixture of 2- and 3-mono-*O*-methyl-D-xyloses.

Fraction D'.—This fraction (0.040 g.) had R_f 0.00 to 0.30 in solvent *A* and was a mixture of unmethylated xylose and unreduced methylated uronic acids (paper chromatography). The paucity of acidic material made identifications difficult.

Quantitative Estimation of the Sugars Produced on Hydrolysis of the Methylated Xylan (Fraction 5)

A sample of the methylated xylan (0.170 g.) was hydrolyzed by heating it with aqueous formic acid (50%) followed by sulphuric acid (*N*). After neutralization with barium carbonate, the hydrolyzate was separated on extractive-free Whatman 3 MM paper in solvent *A*. The appropriate sections of the paper were extracted with methanol, the solution was filtered and taken to dryness. The proportions found were: R_f 0.94 (tri-*O*-methyl-pentose), 1; R_f 0.74 (di-*O*-methyl-pentose), 100; R_f 0.50 (mono-*O*-methyl-pentose), 2; R_f 0.00 to 0.30 (uronic acids), 40 (all by weight).

Hydrolysis of Fraction 8A: the Glucomannan

A sample of fraction 8A (0.078 g.), termed "glucomannan", was hydrolyzed by dissolving the polysaccharide in sulphuric acid (72%) at 20° C. After 12 hours water was added and the solution (*N* sulphuric acid) heated at 100° C. for 24 hours. The sulphuric acid was removed as barium sulphate and the residue separated on a cellulose column with *n*-butanol half saturated with water as the eluant. Four fractions were obtained. Fraction 1 (0.0015 g.) had $[\alpha]_D^{26} + 20^\circ$ (*c*, 1.12 in H₂O), its rate of movement relative to galactose (R_{gal}) was 1.9 in solvent *C*, and the osazone derivative had m.p. and m.p. mixed with the osazone of D-xylose 159–162° C. Fraction 2 (0.0272 g.) had $[\alpha]_D^{26} + 13^\circ$ (*c*, 1.24 in H₂O), R_{gal} 1.14 in solvent *C*, and the phenylhydrazone derivative had m.p. and mixed m.p. with the phenylhydrazone of D-mannose 199–202° C. Fraction 3 (0.0137 g.) had $[\alpha]_D^{26} + 54^\circ$ (*c*, 0.62 in H₂O), R_{gal} in solvent *C*, and the osazone derivative had m.p. alone and when mixed with the osazone of D-glucose 210–214° C. Fraction 4 (0.0016 g.), obtained by elution of the cellulose column with water, consisted of barium salts of acidic materials.

Methylation of the "Glucomannan"

The polysaccharide (1.6 g.) was methylated seven times with sodium hydroxide and methyl sulphate. The methylated polysaccharide soluble in chloroform–light petroleum (b.p. 60–80° C.) (1:4) was isolated (1.16 g.) and had $[\alpha]_D^{24} - 9.5^\circ$ (*c*, 1.04 in CHCl₃) (found: OMe, 43.8%).

Hydrolysis of the Methylated Glucomannan and Separation of the Sugars

The methylated material (0.970 g.) was heated at 100° C. in aqueous formic acid (50%) for 6 hours. The solvent was evaporated and the hydrolysis was continued for 24 hours at 100° C. with sulphuric acid (*N*). The sulphuric acid was removed as barium sulphate and the residue separated into four fractions by paper chromatography on sheets of extractive-free Whatman 3 MM paper in solvent *A*.

Fraction A.—The sirup (0.020 g.) had $[\alpha]_D^{26} + 2.4^\circ$ (*c*, 0.75 in H₂O), R_f 1.00 in solvent *A* (found: OMe, 51.9%; calc. for C₁₀H₂₀O₆: 52.5%), and was identified as 2,3,4,6-tetra-*O*-methyl-D-mannose by conversion of part of the sirup (0.018 g.) into the aniline derivative (0.0102 g.), m.p. 144–146° C. (identical when mixed with an authentic sample).

Fraction B.—The sirup (0.510 g.) had $[\alpha]_D^{26} + 10^\circ$ (*c*, 2.0 in H₂O) and R_f 0.80 in solvent *A* (found: OMe, 41.3%; Calc. for C₉H₁₈O₆: 41.9% and for C₇H₁₄O₆: 34.8%). Oxidation of a small sample with sodium metaperiodate revealed components chromatographically identical with 2,3,5-tri-*O*-methyl-arabinose and 2,3,6-tri-*O*-methyl-glucose. Reduction of another sample with potassium borohydride followed by oxidation with sodium metaperiodate revealed components chromatographically identical with 2,3,5-tri-*O*-methyl-arabinose,

di-*O*-methyl-erythrose, and di-*O*-methyl-threose. A portion of the sirup (0.184 g.) was oxidized with bromine water for 32 hours, the solution was aerated to remove the excess of bromine and neutralized with silver carbonate. The solution was filtered, saturated with hydrogen sulphide, and the water removed by distillation under diminished pressure. The residue was extracted with ether; removal of the ether left a sirup which was separated into three fractions B_1 , B_2 , and B_3 by paper chromatography, using extractive-free Whatman 3MM paper in solvent B ; each fraction was purified further by distillation under diminished pressure in a "cold finger" apparatus.

Fraction B_1 .—The sirup (0.0326 g.) had $[\alpha]_D^{26} + 56^\circ \rightarrow 32^\circ$ (equil.) (c , 1.50 in H_2O), R_f 0.82 in solvent B , and was identified as the furanolactone of 2,3,6-tri-*O*-methyl-D-gluconic acid by conversion to the phenylhydrazine derivative, m.p. and mixed m.p. 143–145° C.

Fraction B_2 .—The sirup (0.0756 g.) had $[\alpha]_D^{26} + 68^\circ$ (c , 0.52 in H_2O) and R_f 0.68 in solvent B , crystallized and was recrystallized from benzene–light petroleum (b.p. 60–80° C.) to give needles (0.052 g.) having m.p. and mixed m.p. (with the lactone of 2,3,6-tri-*O*-methyl-D-mannonic acid) 83–85° C. and $[\alpha]_D^{26} + 67^\circ \rightarrow +66^\circ$ (in 72 hours) (c , 0.68 in H_2O). In the mother liquor from the above crystallization the presence of 3,4,6-tri-*O*-methyl-mannonolactone and 2,3-di-*O*-methyl-xylonolactone was indicated chromatographically.

Fraction B_3 .—The sirup (0.0186 g.) had $[\alpha]_D^{26} + 60^\circ \rightarrow +40^\circ$ (equil.) (c , 0.85 in H_2O) and R_f 0.53 in solvent B . The phenylhydrazine derivative was prepared in very low yield and had m.p. 153–155° C. This substance gave an X-ray powder photograph different from that given by the phenylhydrazine derivative of 2,3,6-tri-*O*-methyl-D-gluconolactone.

Fraction C .—The sirup (0.0124 g.) had $[\alpha]_D^{26} + 60^\circ$ (c , 0.25 in H_2O) and R_f 0.55 in solvent A (found: OMe, 29.4%; calc. for $C_8H_{16}O_6$: 29.8%). On oxidation of a sample with sodium metaperiodate and chromatographic analysis, two components were noted, having R_f values 0.37 and 0.80. The component having R_f 0.37 is reported to be (10) methoxymalondialdehyde and is formed by oxidation of a 2,6-di-*O*-methyl-hexose. Demethylation of a small sample with hydrobromic acid (48%) and chromatographic analysis indicated mainly glucose with also smaller amounts of mannose.

Fraction D .—This fraction (0.0127 g.) consisted of mono-*O*-methyl-hexoses and methylated uronic acids (paper chromatography).

The Enzymic Hydrolysis of Hemicelluloses

A commercial preparation of a hemicellulose supplied by the Rohm and Haas Co. of Philadelphia was used. The powder (1 g.) was added to water (100 ml.) and the undissolved residue separated at the centrifuge. The solution was dialyzed against running water for 24 hours and again centrifuged; no reducing sugars were found in this solution (paper chromatography). This product will be called the "purified enzymes".

A solution of the purified enzymes was heated with sodium hydroxide (50 ml., 4 *N*) at 90° C. for 5 hours. The solution was cooled in ice, neutralized with hydrochloric acid, dialyzed against running water for 72 hours, and the water was distilled under diminished pressure. On hydrolysis with sulphuric acid (2 *N*) at 100° C. for 12 hours xylose, galactose, and mannose were indicated (paper chromatography).

Samples of the purified enzymes were heated at 37° C. and 45° C.; different solutions were prepared having pH values 5, 6, and 7. Toluene was added to the solutions and

the samples heated for 28 days. Aliquots were analyzed by paper chromatography and by the iodine consumed on reaction with hypoiodite. In all cases the presence of xylose, galactose, and mannose was indicated. Iodine numbers were nearly equal at the different pH values.

Substrate samples of the disaccharides glucuronosido-xylose, glucuronosido-galactose, and 4-*O*-methyl-glucuronosido-xylose were added to solutions having pH values of 2, 4, and 6. The appropriate amount of enzymes was added and the solutions heated at 45° C. for 72 hours; solutions containing approximately 10 μ g. of purified enzymes per gram of substrate were used. In all cases the disaccharides were hydrolyzed to the component sugars after the first hour (paper chromatography).

Less than 1% of untreated and milled aspen wood, but nearly 20% of the extractive-free and macerated wood, was hydrolyzed by a purified solution of the enzymes. The sugars produced and indicated chromatographically were the hexoses glucose, galactose, and mannose, the pentoses arabinose and xylose, and uronic acids. Nearly 5% of aspen α -cellulose was hydrolyzed; the sugars produced were mannose, glucose, galactose, xylose, and uronic acids. Hemicellulose fractions 1, 2, and 3 (cf. Table I) were resistant to attack by a purified solution of the enzymes; fraction 4 was hydrolyzed completely; and fraction 5 to an extent of 80%.

Enzymic Hydrolysis of Fraction 5

A sample of fraction 5 (10 g.) was suspended in water (2 liters) and the appropriate amount of a solution of the purified enzymes added. Toluene was added and the solution kept at 45° C. for 7 days. Ethanol (200 ml.) was then introduced and the solution placed in a number of dialysis containers. These were immersed in distilled water and the solution was agitated gently; the water was renewed every day for 7 days; a total of 20 liters of solution was collected. The solution inside the cellophane containers was again treated with a purified solution of the enzymes and the cycle repeated four times as before. The residue resistant to hydrolysis by the enzymes (1.5 g.) on hydrolysis with sulphuric acid (*N*) showed the presence of xylose, and traces of arabinose, rhamnose, mannose, glucose, and acidic materials.

The solutions which passed through the membranes were concentrated to a sirup (8.0 g.) which was separated into two fractions by chromatography on a column of Amberlite IR-4B (acetate form) resin: a neutral fraction (6.2 g.) and an acidic fraction (1.7 g.) were obtained. A second larger sample of fraction 5 (80 g.) was hydrolyzed by the enzymes and the reducing sugars isolated as described above.

Identification of the Constituent Sugars of the Neutral Fraction Produced on Enzymic Hydrolysis of Fraction 5

The sirup (6.2 g.) solidified and was recrystallized from aqueous ethanol to give D-xylose (4.7 g.) having m.p. and mixed m.p. 147° C. and $[\alpha]_D^{22} + 19^\circ$ (equil.) (*c*, 1.10 in H₂O). The mother liquor was separated into seven fractions by chromatography on cellulose using first *n*-butanol half saturated with water followed by water as the eluant.

Fraction 1 (0.100 g.) had $[\alpha]_D^{22} + 9^\circ$ (equil.) (*c*, 0.94 in H₂O) and after recrystallization from ethanol had m.p. and mixed m.p. with L-rhamnose hydrate 95° C. Fraction 2 (0.350 g.) had $[\alpha]_D^{22} + 20^\circ$ (equil.) (*c*, 1.19 in H₂O) and after recrystallization from methanol had m.p. and mixed m.p. with D-xylose 147° C. Fraction 3 (0.120 g.) had $[\alpha]_D^{22} + 102^\circ$ (equil.) (*c*, 0.82 in H₂O) and after recrystallization from methanol had m.p. and mixed m.p. with L-arabinose 156–158° C. Fraction 4 (0.093 g.) had $[\alpha]_D^{22} + 13^\circ$ (*c*, 0.22 in H₂O)

and the phenylhydrazone derivative had m.p. and mixed m.p. with the phenylhydrazone derivative of D-mannose 199–201° C. Fraction 5 (0.043 g.) had $[\alpha]_D^{22} + 54^\circ$ (c , 0.10 in H₂O) and the osazone derivative had m.p. and mixed m.p. with the osazone of D-glucose 210–214° C. Fraction 6 (0.050 g.) had $[\alpha]_D^{22} + 26^\circ$ (c , 0.20 in H₂O) and the osazone derivative had m.p. and mixed m.p. with the osazone of xylobiose 210–212° C. Fraction 7 (0.320 g.) was a complex mixture of oligosaccharides. On hydrolysis with sulphuric acid (N) at 100° C. for 7 hours the presence of xylose was indicated (paper chromatography) as the only monosaccharide.

Identification of the Constituent Sugars of the Acidic Fraction Produced on Enzymic Hydrolysis of Fraction 5

The sirup (1.7 g.) was separated into four fractions by chromatography on cellulose using ethyl acetate – acetic acid – water (9:2:1), changing to ethyl acetate – acetic acid – water (9:2:2), to aqueous acetic acid, and finally to water as the eluants. Fraction 1 (0.150 g.) had $[\alpha]_D^{24} + 25^\circ$ (c , 0.60 in H₂O) and R_f 0.66 in solvents A , B , D , and E (found: OMe, 20.2%; E.W., 497), had m.p. 152–154° C., was unstable, and showed an ultra-violet absorption with a maximum at 254 μ (optical density). On hydrolysis with sulphuric acid (N) at 100° C. for 2 hours fraction 1 yielded 4-*O*-methyl-glucuronic acid and an unknown compound having R_f 0.98. Possibly the latter was an aromatic aglycone. Fraction 2 (0.450 g.) had $[\alpha]_D^{24} + 75^\circ$ (c , 0.98 in H₂O); the derived methyl- α -4-*O*-methyl-D-glucuronamide had m.p. 236° C. and $[\alpha]_D^{20} + 150^\circ$ (c , 1.02 in H₂O); the derived methyl- β -4-*O*-methyl-D-glucuronamide had m.p. 236° C. and $[\alpha]_D^{20} - 50^\circ$ (c , 1.04 in H₂O). Fraction 3 (0.108 g.) had $[\alpha]_D^{24} + 18^\circ$ (c , 0.94 in H₂O); on reduction with potassium borohydride and hydrolysis D-glucose was formed having m.p. 145–148° C. and $[\alpha]_D^{22} + 53^\circ$ (equil.) (c , 0.43 in H₂O). The presence of a small amount of galactose was also indicated. Fraction 4 (0.500 g.) was composed of a large number of oligosaccharides; on hydrolysis with sulphuric acid (2 N) at 100° C. for 18 hours the presence of xylose, glucose, rhamnose, and acid residues was indicated.

Properties of the Polysaccharide Resistant to Enzymic Degradation: The Residual "Xylan"

The material had $[\alpha]_D^{24} - 76^\circ$ (c , 1.02 in H₂O), the uronic anhydride content was 4.1% (6), and the lignin 2.9% (13, p. 369). Quantitative estimation, by the method of Hirst and Jones (4), of the sugars produced on hydrolysis with sulphuric acid (N) at 100° C. for 12 hours, indicated the presence of the following (calculated as proportions of sugar residues in the original xylan): xylose (74 parts), arabinose (6 parts), hexoses (2 parts), and rhamnose (less than 1 part).

Methylation of the Residual Xylan and Identification of the Component Sugars

A sample of this material (11 g.) was methylated nine times with sodium hydroxide and methyl sulphate; the methylated polysaccharide was extracted as previously described (8.1 g.) and had $[\alpha]_D^{23} - 66^\circ$ (c , 1.30 in CHCl₃) (found: OMe, 37.5%). The methylated material was hydrolyzed with aqueous formic acid (50%) followed by sulphuric acid (N) and the hydrolyzate was separated on columns of cellulose powder and on paper into six fractions (A – F). Fraction A (0.010 g.) had $[\alpha]_D^{25} + 1.3^\circ$ (c , 0.34 in H₂O), R_f 1.00 in solvent A , and the aniline derivative had m.p. and mixed m.p. (with the aniline derivative of 2,3,4,6-tetra-*O*-methyl-D-mannose) 147–148° C. (found: OMe, 40.3%; calc. for C₁₈H₂₅O₅N: 39.8%). Fraction B (0.020 g.) had $[\alpha]_D^{25} - 20^\circ$ (c , 0.76 in H₂O), R_f 0.98 in solvent A (found: OMe, 47.9%; calc. for C₈H₁₆O₅: 48.4%), and was identified

as 2,3,5-tri-*O*-methyl-L-arabinose by conversion to the amide derivative, having m.p. and mixed m.p. 135–137° C. Fraction *C* (0.020 g.) had $[\alpha]_D^{25} + 21^\circ$ (*c*, 1.0 in H₂O), *R_f* 0.94 in solvent *A* (found: OMe, 48.0%; calc. for C₈H₁₆O₅: 48.4%), and was identified as 2,3,4-tri-*O*-methyl-D-xylose, m.p. and mixed m.p. 90–92° C. Fraction *D* (5.2 g.) had $[\alpha]_D^{25} + 23^\circ$ (*c*, 2.0 in H₂O), *R_f* 0.74 in solvent *A* (found: OMe, 34.1%; calc. for C₇H₁₄O₅: 34.4%), and was identified as 2,3-di-*O*-methyl-D-xylose, m.p. and mixed m.p. 79–80° C. Fraction *E* (0.020 g.) had $[\alpha]_D^{25} + 122^\circ$ (*c*, 0.80 in H₂O), *R_f* 0.80 in solvent *A*. The lactone derivative had $[\alpha]_D^{22} + 140^\circ \rightarrow + 40^\circ$ (equil.) (*c*, 0.42 in H₂O) and was believed to be a derivative of 2,3,4-tri-*O*-methyl-L-arabinose. Fraction *F* (0.070 g.) had $[\alpha]_D^{25} + 20^\circ$ (*c*, 0.62 in H₂O), *R_f* 0.50 in solvent *A* (found: OMe, 18.5%; calc. for C₆H₁₂O₅: 18.9%), which paper electrophoresis indicated to be a mixture of 2- and 3-mono-*O*-methyl-D-xyloses.

The acidic fraction (0.300 g.), which behaved as three components, was reduced with potassium borohydride and treated in a way analogous to that described for the original xylan. A mixture of 2,3,4- and 2,3,6-tri-*O*-methyl-D-glucoses and of 2- and 3-mono-*O*-methyl-D-xyloses was indicated to be present and 3,4-di-*O*-methyl-D-xylose was identified.

After quantitative hydrolysis of the methylated residual polysaccharide resistant to enzymic degradation, the following proportions were found: *R_f* 0.94 (tri-*O*-methyl-pentose) 1 part; *R_f* 0.74 (di-*O*-methyl-pentose) 80 parts; *R_f* 0.50 (mono-*O*-methyl-pentose) 1 part; *R_f* 0.00 to 0.30 (uronic acids) 10 parts. Details are given of the analysis of fraction 5 under the section entitled "Quantitative Estimation of the Sugars Produced on Hydrolysis of the Methylated Xylan (Fraction 5)". It will be observed that enzymic degradation has altered but slightly the relative proportions of sugars.

ACKNOWLEDGMENTS

The authors thank the National Research Council of Canada for the award of a Studentship (to E.M.); The Institute of Paper Chemistry, Appleton, Wisconsin, for financial assistance, and The Rohm and Haas Company for the generous gifts of enzyme preparations. They also thank Mr. T. J. Painter, M.A., for assistance with the manuscript.

POLAROGRAPHIC BEHAVIOR OF THE VIOLOGEN INDICATORS¹

R. M. ELOFSON AND R. L. EDSBERG²

ABSTRACT

The polarographic behavior of 1,1'-dimethyl- and 1,1'-dibenzyl-4,4'-bipyridinium dichloride has been investigated over the pH range of 1 to 13. Reversible reduction waves are obtained for the first single-electron step for both compounds. The second step is electrochemically irreversible but evidence is presented to indicate that the second step is fleetingly reversible at the dropping mercury electrode for methyl viologen but not benzyl viologen. Minor waves due to adsorption of the reduced viologen on the surface of the mercury have been observed.

INTRODUCTION

The viologen indicators (3) (e.g. 1,1'-dimethyl- and 1,1'-dibenzyl-4,4'-bipyridinium chloride I and II) undergo reversible one-electron reduction to produce very intensely colored violet solutions. These colored substances have been definitely shown to be free radicals and may be represented by structures such as III or IV (2, 8). Two-electron reduction results in structures which can be represented by V, a biradical, or VI, in which the electrons have become paired (6). Weitz (10) concluded from the behavior, such

I R = METHYL

II R = BENZYL

III

IV

V

VI

as oxidizability in air, of these latter compounds that he was working with biradicals and that, in fact, he had biammonium radicals, which would be the only structures in which pairing of the electrons would not be likely to occur. However, Mueller (6) by means of magnetic measurements on the benzyl derivative has shown that the product of a single-electron reduction is paramagnetic while that of a two-electron reduction is diamagnetic, which indicates that pairing of electrons has occurred as in VI. Michaelis and Hill (4), during their studies on semiquinones, investigated the first step of the reduction by potentiometric titration. They could only make the titrations at pH greater

¹Manuscript received April 4, 1957.

Contribution from the Research Council of Alberta, Edmonton, Alberta, and the Central Research Laboratory, General Aniline and Film Corporation, Easton, Pa. Presented at the Western Regional Meeting of the Chemical Institute of Canada, Edmonton, Alberta, September, 1956.

²Present address: Research Laboratory, Burroughs Corporation, Paoli, Pa.

than 9 because at lower pH the potentials were so negative as to exceed the overvoltage of hydrogen on platinum. They could not, of course, attempt a study of the second step of the reduction. Mueller (5) investigated the polarographic behavior of methyl viologen and confirmed the expectation that for the first step of the reduction the potentials were independent of pH over the entire pH range.

In the present investigation it has been confirmed that the first step of the reductions for both methyl and benzyl viologen is independent of pH and agrees closely with the potentiometric data. Further, it has been found that the second step of the reduction is also independent of pH. The nature of this second wave and certain other waves has been examined in detail.

EXPERIMENTAL

The polarograph used for the data presented in Tables I and II was built in the laboratories of the General Aniline and Film Corporation, and has been reported previously (1). For this work the dropping mercury electrode had the following characteristics:

$$t = 4.6 \text{ seconds, } m = 1.56 \text{ mg./second, and } h = 92 \text{ cm.}$$

Further studies—the controlled potential electrolyses, the effect of temperature, and the polarogram of Fig. 2—were carried out with a Leeds and Northrup Electrochemograph Model E at the Research Council of Alberta. The buffered solutions were prepared according to Clark and Lubs.

The determinations of half-wave potential were made with increasing and decreasing potentials to minimize the instrumental lag.

Investigation of the effect of height of the mercury column showed that all waves except the adsorption waves mentioned in the text were diffusion controlled.

RESULTS

Fig. 1 shows a polarogram prepared on methyl viologen at pH 9. The first reduction step occurs at $E_{\frac{1}{2}} = -0.680$ o.v. vs. S.C.E., or -0.434 v. vs. N.H.E., which is in satisfactory agreement with the potentiometric value of -0.446 v. (4). In Fig. 3 confirmation of the fact that the first step corresponds to a single-electron reduction is shown by the plot of $\log[i/(i_d - i)]$ vs. E_{de} , which produces a straight line with an inverse slope of 0.061 v. in good agreement with the theoretical value of 0.059 v. for a one-electron reduction. Because the second step of the reduction has a height equal to that of the first, the conclusion is that it corresponds to the second step of the reduction, V or VI.

FIGS. 1 AND 2.

Table I shows the results for methyl viologen over the entire pH range. The first step of the reduction occurs at a constant potential of $0.678 \pm .002$ v. The second step occurs at a potential of -1.038 v. in the pH range 5–13. Below this range the second wave occurs at a potential that decreases with pH, and it is irregular in shape. Because of the discharge of hydrogen, it is not possible to study the wave in this range.

FIG. 3.

Fig. 2 shows a polarogram made on benzyl viologen at a pH of 9. The first step at -0.597 v. vs. S.C.E. (0.331 v. vs. N.H.E.) is in excellent agreement with that found by potentiometric titration of -0.359 v. vs. N.H.E. (4). The second step in the reduction occurs at -0.78 v. vs. S.C.E. but from its shape clearly corresponds to an irreversible process. In addition, two more steps which may correspond to the third and fourth electron steps are observed. However, these latter waves change in height and position with pH. Table II shows that the half-wave potentials of the first two waves are constant over

TABLE I
POLAROGRAPHIC HALF-WAVE POTENTIALS OF METHYL VIOLOGEN VS. S.C.E.
Temp. 25°C ., concn. $4.5 \times 10^{-4} M$

pH		$E_{\frac{1}{2}}$ first wave, volts	$E_{\frac{1}{2}}$ second wave, volts
1.15	0.1 N HCl	-0.678	-0.890
1.55	0.1 N H ₂ SO ₄	-0.676	-0.884
2.1		-0.677	-0.917
3.1		-0.679	-0.934
4.0		-0.677	-0.980
5.0		-0.678	-1.036
5.6	0.1 N NaOH	-0.680	-1.038
8.0		-0.678	-1.033
9.0		-0.680	-1.040
11.5		-0.678	-1.039
		-0.677	-1.043
		Av. -0.678	Av. (pH 5-13)

the entire pH range and equal -0.592 v. and -0.792 v. vs. S.C.E. respectively. The constancy of the potential of the second wave with pH is not as good as for the methyl viologen but this is to be expected of such sharply irreversible waves.

TABLE II
POLAROGRAPHIC HALF-WAVE POTENTIALS OF BENZYL VIOLOGEN VS. S.C.E.
Temp. 25° C., concn. $4.5 \times 10^{-4} M$

pH	$E_{\frac{1}{2}}$ first wave, volts	$E_{\frac{1}{2}}$ second wave, volts
1.15 0.1 N HCl	-0.594	-0.785
2.0	-0.591	-0.793
5.6	-0.589	-0.804
7.0	-0.594	-0.776
9.0	-0.597	-0.787
10.0	-0.591	-0.767
0.1 N NaOH	-0.589	-0.762
	Av. -0.592	-0.782

In addition to these major waves, a small wave occurs at -0.35 v. vs. S.C.E. with benzyl viologen. This wave has been proved to be an adsorption wave by the fact that it does not increase in height with increase in concentration beyond a certain limit and by the fact that its height varies directly with the height of the mercury in the reservoir (2). Only a trace of such a wave occurs in the polarograms on methyl viologen. Since the wave is at a more positive potential than the main wave, it corresponds to adsorption of either the singly or the doubly reduced material at the electrode (2). These waves have been taken into consideration in computing the values of E_0 from Tables I and II.

For methyl viologen the second step of the reduction is the final step at the dropping mercury electrode, whereas with benzyl viologen subsequent steps are observed. While the nature of these has not been investigated in detail, they are dependent on pH and may correspond to further reduction involving hydrogen ions. This may indicate that with methyl viologen the biammonium radical V is temporarily stabilized towards further reduction whereas with benzyl viologen it is not.

The reversibility of the first step of the reduction has been demonstrated polarographically in this investigation by chemical reduction with reducing agents such as sodium hydrosulphite, and zinc and ethyl alcohol. Polarograms on the reduced solutions produced anodic or anodic-cathodic waves at potentials corresponding to the first wave of the reduction. Similar results were obtained by controlled potential electrolyses on both compounds at potentials on the plateaus between the first and second waves.

Quite different results were obtained when attempts were made to show the presence of anodic waves corresponding to the second stage of reduction. Chemicals which are known to produce the products of two-electron reductions (10), such as sodium amalgam, and zinc and sodium hydroxide, were used to reduce the solutions but no anodic waves were produced. Controlled potential electrolyses at the second plateau likewise produced no anodic waves. The passage of oxygen through these cells, however, resulted in the return of the original viologen; therefore the conclusion is that the second step of the reduction is not reversibly active at the electrode although it can be reoxidized by the air. The fact that material corresponding to the second step of the reduction but not to the first has been isolated and maintained in the solid state in air supports this view. Apparently therefore the product of two-electron reduction in solution corresponds to formula VI, which is supported by the magnetic measurements of Mueller (6).

However, the polarograms indicate that, whereas for benzyl viologen the second

step of the reduction is clearly irreversible, the second step of the reduction of methyl viologen may be fleetingly reversible. The evidence for this is:

(1) With the methyl viologen the second wave is symmetrical and corresponds to a reversible one-electron reduction; the second benzyl viologen wave does not.

(2) The $E_{1/2}$ of the methyl viologen wave is nearly independent of temperature, whereas the wave for benzyl viologen has a temperature dependence of -3 mv./°C. (2).

Mueller (7) and others (9) have produced biradicals in such systems by preventing the overlapping and pairing of the π -orbitals by substitution in the ortho-positions to prevent planarity. If such compounds can be prepared, polarographic waves corresponding to the second wave of methyl viologen may be obtained, but it should be possible in addition to obtain corresponding anodic waves.

ACKNOWLEDGMENT

The authors are indebted to Dr. J. H. Sprung of General Aniline and Film Corporation who supplied the methyl and benzyl viologen chloride.

SYNTHESIS IN THE FIELD OF THE ERYTHRINA ALKALOIDS

PART I. THE SYNTHESIS OF HEXAHYDROAPOERYSTRINE¹

B. BELLEAU

ABSTRACT

The synthesis of the complete ring system of the aromatic class of *Erythrina* alkaloids is described. The basic sequence involves reaction of hexahydroindole (whose preparation was studied in some detail) with phenylacetyl chloride to give the ketoamide (VII) which suffered ring closure to the desired ring system (XI) when treated with polyphosphoric acid. Reduction of XI with lithium aluminum hydride gave the corresponding base (XIII). Evidence in support of structure XI is presented. Application of the same sequence with homoveratroyl chloride as starting material led ultimately to the spiroamine (XIV) which proved identical with a sample of natural origin. The stereochemistry of the spiroamines is discussed and the reaction mechanisms involved are critically examined. The new cyclization reaction was successfully applied to the system phenylacetamide-cyclohexanone in an effort to explore its scope.

In 1951, Prelog and co-workers (5) presented convincing evidence that the aromatic class of *Erythrina* alkaloids must be assigned the basic structure I although at that time the exact position of the ring D methoxyl was not established. Most members of this class of alkaloids differ from one another mainly in the nature of the substituents in ring A, and evidence on that point was adduced by the conversion of two important members (namely erysodine and erythraline) to a common base (II), erysotrine. A complete description of the evidence concerning their structure has been reviewed by Boekelheide (4) and more recently by Prelog (13) and it may be only necessary to mention that Prelog and his group (15) have confirmed their previous deductions and elucidated the conformation of erythraline by an X-ray investigation which also revealed the exact position of the ring D methoxyl. Moreover, the stereochemistry of the corresponding tetrahydro derivative (III) of erythraline could be inferred and in all probability possesses a *trans* arrangement about the perhydroindole moiety, a prediction in agreement with the probable course of hydrogenation of the rigid ring system of erythraline. By analogy, hydrogenation of apoerysotrine to hexahydroapoerysotrine (IV) should in all probability lead to a *trans* configuration. The latter base (IV) includes the complete and unrearranged ring system of this class of *Erythrina* bases and appeared more susceptible to approach by synthesis than the native alkaloids. Moreover, it was hoped that such spiroamines as IV might be of pharmacological interest.

At the time the present investigation was initiated, Wiesner and his group (18) described an interesting approach directed at the synthesis of the intact ring system of this class of alkaloids. However, their efforts have not been fruitful as yet, but more significantly they were successful in synthesizing apoerysopine dimethyl ether which proved identical with a sample of natural origin (5). Apoerysopine being related to the natural alkaloids through a rearrangement, the task remained to elaborate synthetically the intact skeleton as present for instance in hexahydroapoerysotrine (IV).

An obvious approach to the desired ring system would involve ring closure of the quaternary Schiff base V to IV, a possibility patterned after Boekelheide's scheme (4)

¹Manuscript received January 11, 1957.

Contribution from the Department of Biochemistry, School of Medicine, Laval University, Quebec, Que. This work was first presented at the Eighth Summer Seminar on the Chemistry of Natural Products held at Grand Manan, N.B., Aug. 5-12, 1956. Preliminary communications have already been published (Refs. 2 and 3).

for the biogenesis of the various *Erythrina* bases. The close analogy of this presumption with the classical Pictet-Spengler ring closure (17) justified the preparation of quaternary salt V in order to test the possibility of cyclization to IV. Intermediate V was readily obtained as a hygroscopic solid from homoveratryl bromide and hexahydroindole, the preparation of which is described in detail later in this paper. However, all attempts at effecting ring closure to IV under a variety of conditions proved fruitless, unchanged starting material being recovered.* In order that these negative results be rationalized and serve as a basis for further discussion, it becomes necessary at this point to examine briefly some of the features of the classical Pictet-Spengler synthesis (P-SS) of tetrahydroisoquinolines (THI) (17). The most remarkable feature of the P-SS lies in its great sensitivity toward minor structural variations about either the carbonyl or the aromatic component. Thus, a brief survey of the literature suffices to see that as the number of substituents on the trigonal carbon of intermediate VI increases, the yield of THI tends to decrease markedly. It is possible to detect a clear-cut detrimental effect of a single alkyl group on the yield of THI and this may be illustrated by the unsuitability of simple aliphatic aldehydes in the P-SS under pseudophysiological conditions provided the aromatic component is activated by alkoxyl groups only. Indeed, under such conditions only formaldehyde is known to lead to important yields of THI and it is necessary to effect condensation in hot concentrated hydrochloric acid if other aldehydes are used as intermediates. Moreover, even under the best experimental conditions, ketones lead only to low yields of cyclized products (8) and it becomes clear therefore that the success of the P-SS is largely dependent upon the number of alkyl groups present on the trigonal carbon of VI. It is of interest that in some instances it is possible to overcome the detrimental effect of alkyl groups by an appropriate increase in activation of the aromatic component. This is illustrated by the successful pseudophysiological condensation of certain aralkylaldehydes with phenethylamines when the activating groups are hydroxyls. It is obvious therefore that a very delicate balance between the electrophilicity of the trigonal carbon of VI and the activation of the aromatic ring is a major characteristic of the P-SS, and small alterations of this balance by alkyl groups are principally ascribable to the inductive effect (+I) of the alkyl groups resulting in a discrete but critical decrease in electrophilicity of the trigonal carbon. These serious limitations to the P-SS contrast sharply with the generality of the Friedel-Crafts alkylation of aromatic nuclei with carbonyl compounds even though both reactions are mechanistically closely related. This marked difference in scope between the two reactions closely parallels the twofold difference in bond moment between the imine and carbonyl double bonds (7), and it can be seen that if the bond moment of the imine or immonium double bond could be increased to approach that of the carbonyl double bond, the scope of the P-SS would then parallel that of the Friedel-Crafts reaction. It was therefore of considerable interest to devise means by which the polarization of the immonium double bond of V would be increased, since it is obvious from the above line of reasoning that the quaternary Schiff base V did not stand a chance to undergo ring closure. One way of accomplishing this would be to introduce a carbonyl group adjacent to the nitrogen atom. It can be predicted that such an amide carbonyl group will increase the electrophilic character of the trigonal carbon in two ways: (a) through its strong $-I$ effect transmitted by the nitrogen to the reactive carbon and (b) through a resonance effect

*In a private communication, Professor Wiesner has informed the author that similar results were obtained in his laboratory.

leading to a hybrid between two extreme forms A and B, the latter being presumably incapable of existence in that form because of the two adjacent positive charges. In this manner, the polarization of the immonium double bond should be considerably increased

and may well approach the state of affairs obtained in the Friedel-Crafts alkylation with carbonyl compounds. The ketoamide (VII) appeared as the best choice* for our purposes since it seemed unlikely that the amide carbonyl group as such would be capable of alkylating either the aromatic ring or other points in the molecule.† This ketoamide (VII) was readily obtained from phenylacetyl chloride and hexahydroindole and heated to 100° for several hours in a 50:50 mixture of phosphorus pentoxide – phosphoric acid to give, in 60% yield, a single crystalline substance analyzing correctly for structure XI and which exhibited strong absorption in the infrared at 6.14 μ , in agreement with a six-membered substituted lactam. The compound proved inert toward acid or alkaline hydrolysis, thus fixing the potential carboxyl and amino groups in close steric proximity as required by a six-membered lactam but not by a higher-membered lactam. Such refractoriness of a six-membered lactam toward hydrolysis is not unique and has been observed before in the morphine series (9). Vigorous oxidation of XI with nitric acid led to the isolation of 4-nitrophthalic acid, thus establishing conclusively that alkylation of the benzene ring had occurred in the anticipated manner. Finally, lithium aluminum hydride reduction of XI gave the corresponding base (XIII), which formed well-crystallized salts.

The success in bringing about cyclization of intermediate IX, which obviously arises from the ketoamide VII in the acid medium, adds considerable weight to the above generalizations and may open a new way to a variety of substituted tetrahydroisoquinolines hitherto inaccessible by the conventional Pictet-Spengler synthesis. Another point of interest in structure XI is the probable configuration about the perhydroindole moiety which is tentatively considered to be “*trans*” on the basis of arguments described below.

From these results, it became apparent that substituting homoveratroyl chloride for phenylacetyl chloride in the above sequence would offer no difficulty and would even facilitate ring closure by virtue of the activating methoxy groups on the benzene ring.‡ Thus, reacting homoveratroyl chloride with hexahydroindole afforded the ketoamide VIII in 93% yield which underwent smooth ring closure to XII in 73% yield when heated for a few hours in a phosphorus pentoxide – phosphoric acid mixture. Subsequent reduction with lithium aluminum hydride gave the corresponding base (XIV) whose dimorphic picrate had an infrared spectrum indistinguishable from that of a sample of hexahydroapoerysotrine picrate kindly supplied by Professor V. Prelog. Resolution of the synthetic base was successfully accomplished through the dibenzoyltartrate salt to give the levorotatory base, $[\alpha]_D^{24} = -43^\circ$ (reported (14): -39°), whose picrate had

*A preliminary account of this work has appeared elsewhere (2).

†Long after this work was first reported, a preliminary report was published by Mondon (11) on the ring closure of the isomeric amide obtainable from homoveratryl amine and 2-oxocyclohexane – acetic acid. It is of interest that Bishler-Napieralsky ring closure does not appear to take place as might have been anticipated with this isomeric amide.

‡A preliminary report covering this portion of the work has already appeared (3).

m.p. 205–207°, not depressed upon admixture with the sample of natural origin (itself melting at 205–206° (14)). Finally, the infrared spectra of the picrates were identical in every respect. Thus, the structural assignments deduced by Prelog from degradative evidence concerning the basic ring system of the aromatic *Erythrina* alkaloids are fully substantiated. From the fact that hexahydroapoerysotrine possesses in all probability a “*trans*” configuration (see above) and that ring closure of ketoamide (VIII) to lactam (XII) is stereospecific in that only one product was obtained (the presence of a second isomer could not be detected), the conclusion must be reached that there exists a mechanistic or conformational barrier to the formation of a “*cis*” isomer during the process of cyclization of the intermediate immonium ion (X). The recent findings of Barnes (1) may have a bearing on the mechanistic aspect of this reaction although conformational restrictions may also be of importance. However, an attempt at such a conformational interpretation clearly leads to the prediction of a “*cis*” configuration for the ring-closed

FIG. 1.

products as can be seen in Fig. 1. Molecular models of the transition state (Fig. 1) show a much smaller degree of hindrance to approach by the phenyl ring on the top of the plane (passing through the four atoms linked to the immonium double bond). Approach from under the plane is hindered by two axial hydrogens. Since a “*trans*” arrangement about the perhydroindole moiety is the most probable one as judged from the investigations of Prelog, it becomes clear that other factors must come into play and a detailed knowledge of the exact mechanism of cyclization would be necessary before this matter could be discussed further. A tentative explanation might be that the immonium ion (Fig. 1), is highly solvated by bulky polyphosphate anions on the top of the plane, thus forcing approach of the phenyl ring from under the plane.

It is of interest to note that, regardless of the configuration, the ready cyclization of X to XII provides so to speak a chemical confirmation of Boekelheide's biogenetic scheme in the sense that the amide carbonyl group serves as the essential activator of the immonium bond and acts as a substitute for enzymatic activation as in the plant.

The success in cyclizing amides of the type of VII raised the possibility of applying this new approach to the synthesis of tetrahydroisoquinoline derivatives that have remained hitherto inaccessible by the P-SS. As an example, an extreme case would involve condensation of a ketone with 2-phenethylamine, the latter being incapable of giving any tetrahydroisoquinolines even with formaldehyde as the carbonyl component. In fact, when equimolar amounts of phenylacetamide and cyclohexanone were heated to 100° for a few hours in excess polyphosphoric acid, there was obtained a 35% yield of a crystalline lactam, formulated as XV on the basis of empirical composition, ultraviolet spectrum (only benzenoid absorption), and refractoriness toward hydrolysis. It may seem therefore that application of this new method may deserve attention wherever the P-SS fails.

CHART I.

The Preparation of Hexahydroindole

The basic starting material hexahydroindole (XVII) was prepared by three different methods, the last one described being preferred for reasons of convenience. King and co-workers (10) were the first to obtain hexahydroindole, which they prepared by hydrogenation of 2-(2'-nitroethyl)cyclohexanone (XVI). The latter nitroketone was obtained in a reported yield of 30% (to be compared with a reported yield of 70% by Reichert and Posemann (16) from 2-dimethylaminocyclohexanone and nitromethane. In our hands, the best yields of pure nitroketone (XVI) never exceeded 15%, a result at variance with those of King *et al.* However, reduction of XVI over Raney nickel proceeded smoothly to give an 80% yield of hexahydroindole which proved resistant to further hydrogenation with that catalyst. In our earlier report (2), the base was arbitrarily assigned an enamine structure which must now be changed to the ketimine structure (XVII) on the basis of a recent infrared investigation by Witkop (20). Structure XVII for the base was confirmed by quantitative hydrogenation over Adams' catalyst in ethanol to *cis*-octahydroindole, whose picrate proved identical with octahydroindole picrate prepared according to Willstätter and Jacquet (19). All attempts to improve the yield of 2-nitroethylcyclohexanone were fruitless. It therefore became necessary to explore other methods of preparation of XVII. Condensation of 2-bromoethylphthalimide with 2-ethoxycarbonylcyclohexanone would be expected to yield XVIII, which on

hydrolysis should lead to XVII. These expectations were realized and the base XVII obtained in 35–40% over-all yield. Unfortunately, this method was not easily adaptable to large-scale preparations and a third but somewhat longer sequence was finally developed which offers the advantage of greater versatility. Thus, condensation of 2-chlorocyclohexanone (12) with ethyl cyanoacetate in the presence of sodium ethoxide in benzene

CHART II.

gave ethyl α-cyano-2-oxocyclohexanecarboxylate (XIX) in 65–70% yield which was partially saponified and decarboxylated to 2-oxocyclohexanecarbonitrile (XX) in 60% yield (based on the ester). The latter was ketalized to XXI in over 90% yield using ethylene glycol followed by lithium aluminum hydride reduction in tetrahydrofuran and mild acid hydrolysis, to yield hexahydroindole in 70% yield (based on XXI). The low pressure catalytic hydrogenation of XX or XXI using Raney nickel as the catalyst also afforded hexahydroindole (XVII) in lower yields.

Recently, Dornow and Fleischmann (6) reported on an alternative preparation of 2-cyanomethylcyclohexanone (XX) which considerably shortens the preceding sequence. They found that dimethylaminocyclohexanone cyanohydrin (XXII) can be converted in 80% yield to XX by simply heating to 150°. In this manner, hexahydroindole becomes available in quantity through relatively few and simple operations.

EXPERIMENTAL*

2-(2'-Nitroethyl)cyclohexanone (XVI)

This was prepared according to Reference 16 with the following modifications: only freshly distilled 2-dimethylaminocyclohexanone (b.p. 60° at 0.5 mm.) was used and vigorous stirring maintained 2-3 days under a stream of nitrogen to sweep out the dimethylamine. In this way, 90 g. of pure 2-dimethylaminocyclohexanone afforded 16.4 g. of crude product, b.p. 153-158° at 16 mm. Care must be taken not to overheat toward the end of the distillation, as vigorous decomposition of the residue takes place. Redistillation gave 13.5 g. of pure nitroketone, b.p. 104-107° at 0.35 mm. (reported (16): 154° at 14 mm.).

 $\Delta^{1(7a)}$ -Hexahydroindole (XVII)

The preceding 13.5 g. of 2-(2'-nitroethyl)cyclohexanone was dissolved in 100 ml. of absolute ethanol and shaken over Raney nickel under 30 lb. p.s.i. of hydrogen. Absorption ceased within 2.5 hours and after removal of the catalyst, the solvent was distilled through a short column. Distillation of the residue *in vacuo* yielded 5.80 g. of colorless base, b.p. 70°-72° at 14 mm. Calc. for $C_8H_{13}N$: N, 11.37. Found: N, 11.28. It gave a picrate separating from methanol as yellow needles, m.p. 132-133° (reported (10): 132-133°). Calc. for $C_{14}H_{16}O_7N_4$: C, 47.72; H, 4.57. Found: C, 47.85; H, 4.45.

cis-Octahydroindole

Hexahydroindole (132 mg.) in 5 ml. of absolute ethanol was hydrogenated over pre-reduced Adams' catalyst (10 mg.) at room temperature and atmospheric pressure. After 75 minutes, 98% of the theoretical amount of hydrogen was absorbed. The catalyst was filtered off, the solvent evaporated, and the base isolated as its picrate, which separated from benzene as yellow prisms, m.p. 135°-137° (19), alone or when admixed with an authentic sample prepared according to the literature (19).

Hexahydroindole (XVII) from XVIII

A solution of 20.8 g. of potassium was prepared in 500 ml. of dry *t*-butyl alcohol followed by the addition of 88.5 g. of 2-ethoxycarbonylcyclohexanone. The alcohol was distilled off, dry toluene added, and the solution distilled to remove the last traces of alcohol. Then, 500 ml. of dry toluene was added followed by 133 g. of 2-bromoethylphthalimide in 200 ml. of hot toluene. The mixture was stirred and heated under reflux for 20 hours. It was cooled, poured into water, and the toluene layer dried and evaporated. The residue was distilled *in vacuo* to yield at 115-125° and 20 mm. 38 g. of unchanged 2-ethoxycarbonylcyclohexanone. The residue was heated under reflux in a mixture of 100 ml. of acetic acid and 250 ml. of concentrated hydrochloric acid for 15 hours. The mixture was cooled and filtered to remove phthalic acid. The filtrate was concentrated to a small volume *in vacuo*, 250 ml. of water added, and the solution made strongly alkaline followed by extraction with ether. The ether was dried and evaporated and the residue distilled *in vacuo* to give 13.4 g. (37% yield based on unrecovered β -ketoester) of material identical with the above hexahydroindole. Attempts to isolate in a state of purity the intermediate alkylation product XVIII were not successful.

*All melting and boiling points are uncorrected. The microanalyses were carried out by the Schwartzkopf Microanalytical Laboratory and Messrs. B. Girard and B. Mercier of our laboratories.

Ethyl α -Cyano-2-oxocyclohexane Acetate (XIX)

To 1500 ml. of absolute ethanol was added in portions 56 g. of sodium, and to the solution was added 275 g. of ethyl cyanoacetate. The alcohol was distilled *in vacuo* and two portions of 300 ml. of benzene distilled from the residue to remove the last traces of alcohol. Two liters of dry benzene was then added and, while stirring, 248 g. of 2-chlorocyclohexanone (12) was added at a rate to maintain gentle reflux. The mixture was stirred and heated under reflux for 4 hours, cooled, and poured into water. The benzene layer was dried and evaporated and the residue distilled; at 158–160° and 2 mm. there was obtained 262 g. of XIX as a yellowish oil with a pleasant honeylike odor. The yield amounted to 66%. Calc. for $C_{11}H_{15}O_3N$: N, 6.69. Found: N, 6.72. If the condensation was carried out in alcohol instead of benzene, only intractable tars resulted. The sodio derivative of ethyl cyanoacetate could also be prepared with sodium hydride in benzene, but on the scale employed, this procedure was found hazardous, the reaction sometimes getting out of control after a long induction period.

2-Oxocyclohexaneacetonitrile (XX)

A solution of 604 g. of the preceding substance (XIX) in 1200 ml. of absolute ethanol was cooled to -15° in an ice and salt bath and, while stirring, a solution of 116 g. of sodium hydroxide in 150 ml. of water was added over a period of 3 to 4 hours. Toward the end of the addition a white crystalline precipitate separated and the solution soon solidified to a white mass. The mixture was allowed to stand at 0° – 5° overnight. It was found disadvantageous to isolate the crystalline salt because of considerable losses reflected in the over-all yield. Instead, the mixture was treated in the cold with a chilled solution of 116 g. of concentrated sulphuric acid in 1 liter of water. The sodium sulphate was removed by filtration and the filtrate concentrated *in vacuo* until most of the alcohol had distilled. The residue was diluted with water and extracted with ether. The ether extract was dried and evaporated to a viscous sirup. It was found somewhat critical at this point to remove all traces of water from the residue to ensure a maximum yield in the next operation. Failure to do that decreased the yield by as much as 20–25%. Thus, benzene was distilled from the sirupy residue until the distillate was clear. About 50 g. of the residue was placed in a 1-liter three-necked flask equipped with a condenser and stirrer. While the residue was being stirred, the flask was heated to 170° whereupon decarboxylation took place; the rest of the sirup, kept at 100° , was added in a thin stream over about 1 hour while a temperature of 170° was maintained in the flask. The brown residue was distilled *in vacuo* to yield 248 g. (63% yield) of colorless 2-oxocyclohexaneacetonitrile, b.p. 137 – 139° at 10 mm.; it solidified to colorless plates, m.p. 25 – 26° (reported (6): 143 – 145° at 12 mm.). Calc. for $C_8H_{11}ON$: N, 10.21. Found: N, 10.30.

2-Oxocyclohexaneacetonitrile Ethylene Ketal (XXI)

The preceding ketonitrile (XX), 231 g., was mixed with 108 g. of pure ethylene glycol, 500 ml. of benzene, and 1 g. of *p*-toluenesulphonic acid (if too small an amount of *p*-toluenesulphonic acid is used, the reaction becomes very sluggish and ketalization is incomplete). The mixture was heated under reflux with a Dean-Stark water separator. Within 2 hours, the theoretical amount of water had separated (about 30 ml.) and the cooled mixture was washed with dilute alkali, and the benzene layer dried and evaporated. Distillation of the residue afforded 290 g. (95% yield) of colorless liquid, b.p. 138 – 140° at 10 mm. Calc. for $C_{10}H_{15}O_2N$: N, 7.76. Found: N, 7.71.

Hexahydroindole (XVII) from XXI

To a solution of 12 g. of lithium aluminum hydride in 250 ml. of dry tetrahydrofuran was added dropwise and while stirring 36 g. of the preceding nitrile-ketal (XXI) in 50 ml. of tetrahydrofuran. The mixture was heated under reflux for 5 hours, after which time the solvent was removed under reduced pressure and replaced by 250 ml. of ether. The excess hydride was decomposed carefully with 13 ml. of water followed by 10 ml. of 20% aqueous sodium hydroxide and then 45 ml. of water. The precipitated salts were removed by filtration and the filtrate extracted with dilute hydrochloric acid. The acid extract was allowed to stand 1 hour, then made strongly alkaline and extracted with ether. The ether was dried and evaporated and the residue distilled *in vacuo* to give 17.0 g. (68% yield) of colorless hexahydroindole, b.p. 62–64° at 9 mm. If ether was used as the solvent for the reduction, the yield dropped to 30%.

Catalytic Hydrogenation of XXI to XVII

A solution of 30.0 g. of 2-oxocyclohexanecarbonitrile ethylene ketal (XXI) in 250 ml. of absolute ethanol was hydrogenated over Raney nickel (2 teaspoonfuls) under 50 lb. p.s.i. of hydrogen. Two molar equivalents of hydrogen was absorbed in 4–5 hours after which time absorption ceased. The catalyst was removed by filtration and the filtrate evaporated to a liquid which was distilled *in vacuo*; at 147–148° at 24 mm. there was obtained 24.0 g. (78% yield) of colorless 2-oxocyclohexanethylaniline ethylene ketal which formed a solid carbonate on standing in air. Its neutral equivalent was 186 (theory requires 185). Calc. for $C_{10}H_{19}O_2N$: N, 7.56. Found: N, 7.50. A solution of 8.90 g. of the amine-ketal was allowed to stand 1 hour in 100 ml. of 5% aqueous hydrochloric acid. The solution was made strongly alkaline and extracted with ether. The ether was dried and evaporated, followed by distillation of the residue to give 5.0 g. (84% yield) of hexahydroindole, b.p. 86° at 24 mm. The over-all yield was 65%.

Catalytic Hydrogenation of XX to XVII

When 2-oxocyclohexanecarbonitrile (IX) was hydrogenated over Raney nickel in ethanol under 50 lb. p.s.i. of hydrogen, absorption was rapid, and when the reaction was allowed to proceed to completion, it was found that hexahydroindole was produced but appeared to be contaminated by octahydroindole from which separation by distillation was not possible. No attempt was made to quantitatively determine the relative proportions of the two although fractional crystallization of their picrates from methanol and benzene (octahydroindole picrate is soluble in methanol but insoluble in cold benzene whereas hexahydroindole picrate is insoluble in cold methanol) served to establish their presence as a mixture.

However, if hydrogenation was stopped after only 25% of the theoretical amount of hydrogen had been absorbed and the products separated by distillation, there was obtained pure hexahydroindole (5.80 g. from 30 g. XX) followed by unchanged ketonitrile (XX) (18.0 g. recovered from 30 g.); the yield of hexahydroindole was 53% based on unrecovered ketonitrile. The purity of the base was ascertained by quantitative hydrogenation over Adams' catalyst whereupon 98% of the theoretical amount of hydrogen was absorbed.

1-Homoveratryl-2,3,4,5,6,7-hexahydroindole

A mixture of 7.30 g. of homoveratryl bromide (b.p. 120–125° at 0.5 mm.) and 3.60 g. of hexahydroindole was heated to 100°. Within a few minutes, the mixture solidified.

The crystals were suspended in dry ether and collected on a filter. However, the product was too hygroscopic for adequate characterization. It was decomposed with excess alkali and the free base isolated in the usual way. It distilled at 165–170° at 0.4 mm. (yield 5.0 g.). It darkened when left standing in the air and failed to give crystalline salts. Calc. for $C_{18}H_{25}O_2N$: C, 75.22; H, 8.42. Found: C, 75.15; H, 8.36. It was also refractory to cyclization conditions in phosphoric or sulphuric acid.

2-(2'-Phenylacetamidoethyl)cyclohexanone (VII)

Hexahydroindole (3.08 g., 0.025 mole) was treated at 0° in 20 ml. of 7.5% aqueous sodium hydroxide with phenylacetyl chloride (4.65 g., 0.03 mole) in the usual fashion. There was isolated 6.20 g. of an oil which crystallized to small colorless needles from hexane, m.p. 53–54° (5.20 g. or 80% yield). This material exhibited peaks in the infrared region at 2.92 μ , 5.85 μ , 6.02 μ , 6.60 μ , and 6.70 μ (chloroform) in complete agreement with expectations. Calc. for $C_{16}H_{21}O_2N$: C, 74.09; H, 8.16. Found: C, 73.96; H, 8.18.

8-Oxoerythrinane (XI)

A solution of 25 g. of phosphorus pentoxide in 25 g. of 85% orthophosphoric acid was prepared, and 5.0 g. of the preceding amide (VII) added; the solution was heated to 100° for 15 to 20 hours, then diluted with water, and the mixture extracted with chloroform. The extract was washed with dilute alkali, dried, and evaporated to yield an oil which crystallized from ethyl acetate in the shape of large prisms, m.p. 130–133° (2.80 g. or 60% yield). The analytical sample had m.p. 132–133° and exhibited a peak in the infrared region at 6.14 μ (chloroform). Calc. for $C_{16}H_{19}ON$: C, 79.62; H, 7.93; N, 5.80. Found: C, 79.71; H, 8.02; N, 5.62. It was recovered unchanged in quantitative yield after protracted heating in 10% alcoholic sodium hydroxide or concentrated hydrochloric acid.

Oxidative Degradation of 8-Oxoerythrinane (XI)

A solution of 500 mg. of XI in 40 ml. of nitric acid ($d = 1.42$) was heated under reflux for 20 hours. The nitric acid was distilled *in vacuo*, the residue extracted with ether, and the extract washed with water, dried, and evaporated to a sirup. A little acetic anhydride was added and distilled from the sirup, which was then carefully heated over a free flame in a sublimation apparatus. The oily sublimate was triturated with ether, whereupon crystallization occurred. The crystals were resublimed *in vacuo* (1 mm.) and twice recrystallized from anhydrous ether to give cream-colored leaflets, m.p. 116–119° (yield 51 mg.). When admixed with an authentic sample of 4-nitrophthalic anhydride of m.p. 117–119°, no depression of the m.p. was observed. About 15 mg. of the anhydride was boiled for a few minutes with 3 drops of aniline in a little toluene. A solid separated which was recrystallized from methanol to give cream-colored leaflets, m.p. 198°. This m.p. was not depressed when the product was admixed with an authentic specimen of 4-nitrophthalanil, itself melting at 197–198°.

Erythrinane (XIII)

A mixture of 2.0 g. of 8-oxoerythrinane and 1 g. of lithium aluminum hydride in 150 ml. of dry ether was heated under reflux for 5 hours, after which time the excess hydride was decomposed with ethyl acetate followed by hydrolysis with water. The ethereal layer was extracted with dilute hydrochloric acid and the acid extract made alkaline and extracted with ether. Evaporation of the ether gave an oil which when treated in

ether with dry hydrogen chloride yielded 1.72 g. of a crystalline hydrochloride. Recrystallization from acetone afforded colorless needles of erythrinane hydrochloride, m.p. 275° (decomp.) (shrinks over 200°). Calc. for $C_{16}H_{22}NCl$: C, 72.84; H, 8.40. Found: C, 72.81; H, 8.45. Erythrinane also formed a picrate separating as yellow blades from methanol, m.p. 184–185°. Calc. for $C_{22}H_{24}O_7N_4$: N, 12.27. Found: N, 12.29. It gave a crystalline methiodide separating as colorless prisms from ethyl acetate–acetone, m.p. 201–203°. Calc. for $C_{17}H_{24}NI$: I, 34.3. Found: I, 34.1.

2-(2'-Homoveratramidoethyl)cyclohexanone (VIII)

Ten grams of 3,4-dimethoxyphenylacetic acid in 50 ml. of benzene was treated with 10 g. of pure thionyl chloride at 50–60° for 1 hour. The benzene was evaporated *in vacuo* and more benzene added and distilled from the residue. The oil was dissolved in 50 ml. of dry benzene and the solution added dropwise to a stirred mixture of 7.3 g. of hexahydroindole, 50 ml. of benzene, and 50 ml. of 12% aqueous sodium hydroxide. Working up in the usual way gave an oil which crystallized from ethyl acetate–ether as fine colorless needles, m.p. 89–90° (crystalline change at 85°). The yield amounted to 15.0 g. (93% yield). Calc. for $C_{18}H_{25}O_4N$: C, 67.68; H, 7.89. Found: C, 67.61; H, 7.92.

2,3-Dimethoxy-8-oxoerythrinane (XII)

To a solution of 50 g. of phosphorus pentoxide in 50 g. of sirupy phosphoric acid was added 9.0 g. of the preceding ketoamide (VIII) and the mixture stirred at 100° for 3 hours. It was cooled and worked up as above in the case of XI. There was obtained 5.40 g. (71% yield) of colorless crystals, m.p. 156–158°. Two recrystallizations from ethyl acetate–ether afforded colorless prisms, m.p. 158–159°. On recrystallization it occasionally gives crystals of m.p. 147–148°. This low-melting form is reconverted to the high-melting one by seeding with crystals of m.p. 159° and vice versa. Calc. for $C_{18}H_{23}O_3N$: C, 71.73; H, 7.35; N, 4.67. Found: C, 71.78; H, 7.30; N, 4.77.

DL-Hexahydroapoerysotrine (XIV)

A solution of 5.10 g. of 2,3-dimethoxy-8-oxoerythrinane (XII) in 30 ml. of dry tetrahydrofuran was added slowly to a solution of 2.5 g. of lithium aluminum hydride in 125 ml. of tetrahydrofuran. After heating under reflux for 4 hours, it was decomposed and worked up as above in the case of erythrinane (XIII). Treatment of the base in ether with dry hydrogen chloride afforded 3.10 g. of crystals, which upon recrystallization from acetone gave colorless needles, m.p. 225–227° (decomp.). Calc. for $C_{18}H_{25}O_2NCl$: N, 4.32; Cl, 10.94. Found: N, 4.38; Cl, 11.03. The base also gave a picrate separating from methanol as yellow prisms, m.p. 186–189°, or small rods, m.p. 170–172°. Both forms are interconvertible by cross-seeding and had an identical infrared spectrum which also proved indistinguishable from the spectrum of an authentic sample of hexahydroapoerysotrine picrate in chloroform solution. Calc. for $C_{24}H_{28}O_9N_4$: C, 55.80; H, 5.46; N, 10.85. Found: C, 55.67; H, 5.24; N, 10.81.

(—)-Hexahydroapoerysotrine

A solution of 0.713 g. of pure dimethoxyerythrinane (regenerated from its purified crystalline hydrochloride) in ethyl acetate was treated with a solution of 0.934 g. of dibenzoyltartaric acid in ethyl acetate. The mixture was chilled overnight and the crystalline precipitate collected. After four recrystallizations from acetone (containing a few drops of methanol) it afforded 492 mg. of large, colorless flat needles with a constant

m.p. of 133–133.5°. Calc. for $C_{36}H_{29}O_{10}N$: C, 66.96; H, 6.08. Found: C, 66.76; H, 6.25. The free base was regenerated from its dibenzoyltartrate and treated with picric acid in methanol to give yellow crystals (325 mg.) which upon recrystallization from methanol afforded yellow prisms, m.p. 205–207° (reported (14): 205–206°). When admixed with the authentic specimen obtained from Professor V. Prelog, no depression of the m.p. was obtained. Calc. for $C_{24}H_{28}O_9N_4$: C, 55.80; H, 5.46. Found: C, 55.88; H, 5.28. The infrared spectra of chloroform solutions of the two picrates were identical. The regenerated base from its pure picrate had $[\alpha]_D^{24} = -43^\circ \pm 3^\circ$, (ethanol); (reported (14): $[\alpha]_D^{21} = -39^\circ \pm 3^\circ$ (ethanol)).

1,1-Pentamethylene-3-oxo-1,2,3,4-tetrahydroisoquinoline (XV)

A mixture of 6 g. of phenylacetamine, 4.5 g. of cyclohexanone, and 140 g. of equal weights of phosphorus pentoxide and phosphoric acid was heated to 100° for 10 hours; it was worked up in the usual way and the crude product extracted with boiling concentrated hydrochloric acid which was decanted while hot from an insoluble gum. The clear extract was diluted, whereupon white crystals separated. Recrystallization from methanol afforded 3.2 g. of colorless blades, m.p. 176–178°. Calc. for $C_{14}H_{17}ON$: C, 78.10; H, 7.96; N, 6.50. Found: C, 78.41; H, 8.11; N, 6.42. The product was recovered unchanged after protracted heating in concentrated hydrochloric acid. It exhibited a maximum at 265 $m\mu$ (log ϵ , 2.6) in the ultraviolet region.

ACKNOWLEDGMENTS

The author is very grateful to Dr. Gilles Papineau-Couture of Ayerst, McKenna, and Harrison (Montreal) for the infrared determinations, to Professor V. Prelog for a sample of hexahydroapoerysotrine picrate, and to the National Research Council of Canada for financial support. Deep gratitude is also expressed to the referee for having kindly suggested a number of key experiments and for his constructive criticism of the manuscript.

SYNTHESIS IN THE FIELD OF THE ERYTHRINA ALKALOIDS

PART II. APPROACHES TO THE RING SYSTEM OF β -ERYTHROIDINE¹

B. BELLEAU

ABSTRACT

The newly developed method for the elaboration of the ring system of the aromatic class of *Erythrina* alkaloids has been successfully extended to the synthesis of 1,2,3,4-tetrahydro-erythrinane (VI), a non-aromatic analogue. The key step in this synthesis involves ring closure of ketoamide (IV) itself, obtained from hexahydroindole and cyclohexenylacetic acid. Attempts to further extend this sequence to the use of 2H-5,6-dihydropyranacetic acid as starting material met with failure at the stage of preparation of the latter. A new and unrelated stepwise approach illustrated on Chart III was investigated but failed at the ultimate step. Other unsuccessful approaches are also briefly described.

The complete structure elucidation of β -erythroidine (I), the most important member of the non-aromatic class of *Erythrina* alkaloids, was reported by Boekelheide and his collaborators (4). The essential features of this brilliant investigation have been reviewed recently by Boekelheide (3) and it may be pertinent to recall that by demethoxylation and hydrogenation it was possible to convert β -erythroidine to demethoxyhexahydro- β -erythroidine (II) in which the ring system of the original alkaloid is retained. Further reduction of II with lithium aluminum hydride afforded demethoxyhexahydro- β -erythroidinol (III), a cleavage product of II. It is the purpose of this communication to describe synthetic approaches to any of those two unrearranged transformation products of β -erythroidine.

In a preceding communication, the successful synthesis of the intact ring system (1) of the aromatic *Erythrina* alkaloids was reported. It was of interest at first to explore the possibility of extending our findings in the field of the aromatic series of alkaloids to the synthesis of hydroaromatic analogues, with the hope that subsequent appropriate variations might lead to a synthesis of either II or III or both. In view of Grewe's success (8) in substituting cyclohexenyl ethylamine for the usual phenethylamines in the classical Pictet-Spengler synthesis, it was logical in a parallel mode of reasoning to expect cyclohexenylacetamide derivatives to be similarly cyclizable, especially because of our previous success with arylacetamide derivatives (1). In a preliminary investigation, this presumption was indeed verified and the successful condensation of N-methyl cyclohexenylacetamide with formaldehyde is included in a separate report (2). By analogy, the ketoamide (IV) obtainable from cyclohexenylacetyl chloride and hexahydroindole would be expected to ring close to the tetracyclic spiroamide (V) under acid conditions. In fact, when the oily ketoamide (IV) was heated in polyphosphoric acid for several hours, there was obtained in good yield an oily amide analyzing correctly for V. Although its structure has not been rigorously established, it can be strongly inferred that V is the correct one on the basis of its refractoriness to alkaline hydrolysis coupled with an infrared absorption band at $6.10\ \mu$ characteristic of a disubstituted amide carbonyl (unconjugated). Mechanistic considerations also point to V as the best possibility. Reduction of V with lithium aluminum hydride readily gave the corresponding base (VI), which formed crystalline salts.

reaction being presumably complicated by the acid sensitivity of the allylic ether bond. This approach was set aside at this point because of other seemingly promising routes.

Another possible approach centered about the tricyclic ketone (XXII) which theoretically appeared accessible by well-established methods and from which it may be possible

CHART II.

to construct an unsaturated lactone of the type present in β -erythroidine. As starting material, hexahydroindole (I) was chosen and the first problem consisted in converting it to the amino acid ester (XVIII) through the aminonitrile (XV) as an intermediate. However, even though hexahydroindole reacted readily with hydrogen cyanide, subsequent acid hydrolysis always led to quantitative recoveries of hexahydroindole. This reversal of aminonitrile synthesis has since been found to be general when the amine is secondary or tertiary with the exception of aromatic amines, and it is hoped to discuss this work separately in a future publication. As an alternative, hexahydroindole was first quaternized with methyl 4-bromobutyrate to give XVI, which also failed to give a stable adduct when reacted with potassium cyanide. In order to circumvent these difficulties, recourse was made to the observations of Cobb and McEwen (5) in connection with their mechanism studies on the hydrolysis of Reissert's compounds. They showed that there exists a strong interaction between the amide carbonyl and nitrile groups of quinaldonitrile benzoate and consequently that the amide carbonyl group participates in the hydrolysis of the nitrile group. Accordingly, if the nitrile benzoate (XVII) could be obtained, a similar participation of the amide carbonyl group might occur and it is conceivable that the first step in the hydrolysis of XVII might be over-all addition of one molecule of water to give the amide (XVIIc) as pictured in formula XVIIa and XVIIb. Reversal to hexahydroindole would obviously be impossible upon subsequent removal of the benzoyl group. Consequently, hexahydroindole was reacted with benzoyl chloride in the presence of sodium cyanide with anhydrous hydrogen cyanide as the solvent to give a single isomer of the desired nitrile benzoate (XVII) in high yield. Acid hydrolysis of the latter followed by esterification of the crude hydrolyzate finally afforded the desired methyl ester (XVIII) in good over-all yield. Alkylation of the latter with methyl 4-bromobutyrate proceeded smoothly to give XIX, which underwent ready Dieckman ring closure to a single isomer of the tricyclic β -ketoester (XX). It was hoped from there that the introduction of an acetic acid residue onto the carbonyl group might be accomplished, in which case subsequent reduction would have led to demethoxy- β -erythroidinol (III). However, all attempts at condensing the ketoester (XX) with

either ethyl cyanoacetate or malononitrile following Cope's directions (6) were fruitless, starting material being recovered unchanged. This failure is undoubtedly ascribable to prohibitive steric hindrance about the carbonyl group.

As an alternative approach, the β -ketoester (XX) was submitted to acid hydrolysis, whereupon the tricyclic ketone (XXII) was formed in excellent yield. This ketone is

CHART III.

also hindered since it failed to react with phenylhydrazine. Nevertheless, it was of interest to attempt the introduction of an acetic acid residue onto this carbonyl group through the use of ethoxyacetylene magnesium bromide (10) in view of the extremely small molecular volume of the acetylene carbanion, a fact that should minimize steric inhibition of approach to the carbonyl carbon. Indeed, this reaction gave an oily adduct (XXIII), which without purification was rearranged with acid followed by saponification in the usual manner (10) to give an amorphous amino acid hydrochloride in about 40% over-all yield. The latter was shown to be homogeneous as judged by paper chromatography and paper electrophoresis even though no reliable elementary analysis could be performed presumably because of its hygroscopic character. Nevertheless, being transparent in the ultraviolet region up to 205 $m\mu$, it was assumed that the unconjugated amino acid (XXIV) was on hand and our newly developed procedure for the synthesis of unsaturated δ -lactones (2) directly applied to the crude product (XXIV). In this manner, treatment of the amino acid with paraformaldehyde in trifluoroacetic acid afforded a homogeneous

CHART IV.

crystalline substance, m.p. 98° , in about 35% yield (based on unrecovered starting material) which from its elementary composition ($C_{15}H_{23}O_3N$) contained one more oxygen atom than required by demethoxyhexahydro- β -erythroidine (II), the expected final product. Quite revealing was the infrared spectrum of this crystalline product, which showed a strong band at 1770 cm^{-1} normally attributable to a saturated γ -lactone grouping. In agreement with a lactone structure, the product dissolves in warm aqueous alkali but, *in conflict with a γ -lactone structure, it cannot be recovered from the acidified solution*. It seems therefore that not only does the lactone grouping suffer opening in the presence of alkali but that some element essential to its existence is actually destroyed by it. These facts taken together with theoretical considerations agree with a structure such as XXV, which provides for the irreversible opening of the lactone ring by virtue of the loss of the elements of formaldehyde. There remains to explain the infrared absorption at 1770 cm^{-1} , which is in conflict with the δ -lactone structure (XXV). It has been shown (11) that in 1,1-diacetoxyp propane, the ester carbonyl band appears at 1761 cm^{-1} instead of 1740 cm^{-1} where it should normally appear. Since structure XXV is in fact a cyclic hemiacetal ester in which the carbonyl group is in a similar situation as in propylidene acetate, a shift to lower frequencies would then be expected. On that basis, structure XXV becomes logical, and in agreement with this formulation, lithium aluminum hydride reduction led in high yield to a crystalline diol analyzing correctly for a $C_{14}H_{25}O_2N$ formula (XXVI).

Since the amorphous amino acid used as starting material in this last step could not be adequately characterized as yet, further comments on the structure and mechanism of formation of lactone (XXV) are deferred. It is conceivable in spite of the chromatographic evidence that the amorphous amino acid actually contained some hydroxyamino acid (XXVII) which would best account for the production in low yield of lactone (XXV).

It is hoped to publish elsewhere the pharmacological properties of several of the intermediates.

EXPERIMENTAL*

2-(2'-Cyclohexenylacetamidoethyl)cyclohexanone (IV)

An ethereal solution of cyclohexenylacetic acid (12 g.) was treated with 12 ml. of thionyl chloride; the solution was heated under reflux for 1 hour and the acid chloride purified by distillation *in vacuo*; yield 10 g., b.p. 75° at 10 mm. Cyclohexenylacetyl chloride (6.90 g.) in a little ether was reacted with hexahydroindole (5.11 g.) under the usual Schotten-Baumann conditions. There was obtained 10.5 g. of an oily amide which proved resistant to crystallization. It was filtered in benzene through activated alumina prior to analysis. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.56. Found: C, 72.60; H, 9.71.

1,2,3,4-Tetrahydro-8-oxoerythrinane (V)

To a solution of 80 g. of phosphorus pentoxide in 80 g. of sirupy phosphoric acid was added 10 g. of the preceding oily ketoamide and the mixture kept at 100° for 20 hours. It was worked up in the usual way to yield a viscous oil which failed to crystallize. It was purified by heating under reflux in excess methanolic potassium hydroxide for 15 hours followed by extraction with ether of the insoluble material. This yielded 5.67 g. of a yellow viscous oil which was further purified by evaporative distillation *in vacuo* at a bath temperature of 180–200° at 0.5 mm. This material gave satisfactory analytical figures. Calc. for $C_{16}H_{23}ON$: C, 78.32; H, 9.44. Found: C, 78.10; H, 9.61.

1,2,3,4-Tetrahydroerythrinane (VI)

A mixture of 5.0 g. of the preceding lactam (V) and 4 g. of lithium aluminum hydride in 250 ml. of dry ether was heated under reflux for 4 hours, the excess hydride was decomposed with ethyl acetate, and the base extracted from the ether with dilute hydrochloric acid. The acid extract was made alkaline and extracted with ether and the extract dried and evaporated. The residual oil was treated with 50 ml. of hot ethanol containing 5.5 g. of picric acid. On cooling, 3.65 g. of golden blades separated and had m.p. 175–180°. Recrystallization from methanol raised the m.p. to 178.5–180.5°. Calc. for $C_{22}H_{28}O_7N_4$: C, 57.38; H, 6.12; N, 12.16. Found: C, 57.47; H, 6.02; N, 11.98. The base was regenerated from its picrate and converted to a crystalline hydrochloride which separated from acetone as fine colorless needles, m.p. 233–235° (crystalline change at 160° and shrinking at 225°). Calc. for $C_{16}H_{26}NCl$: C, 71.74; H, 9.78. Found: C, 71.83; H, 9.65.

2H-5,6-Dihydropyran-3-carboxaldehyde (IX)

This was prepared according to Geyer and Mortimer (7) except that neutralization of the acid at the end of the reaction was accomplished more conveniently with sodium

*All boiling and melting points are uncorrected. Microanalyses by the Schwartzkopf Microanalytical Laboratory and Messrs. B. Mercier and B. Girard of our laboratories.

bicarbonate instead of basic lead carbonate. The yield of twice-distilled aldehyde (b.p. 88–90° at 16 mm.) was 20%. Its 2,4-dinitrophenylhydrazone had m.p. 233–234° (reported (9): 234–235°).

2H-5,6-Dihydropyran-3-methanol

To a solution of 9.0 g. of sodium borohydride in 100 ml. of 80% aqueous ethanol was added in portions 40 g. of the preceding 2H-5,6-dihydropyran-3-carboxaldehyde with intermittent cooling. The mixture was allowed to stand overnight and the alcohol evaporated on the steam bath. The residue was extracted with ether and the solution dried, filtered, and evaporated. Distillation of the residue *in vacuo* afforded 35.0 g. of colorless liquid, b.p. 112–114° at 15 mm. Calc. for $C_6H_{10}O_2$: C, 63.13; H, 8.83. Found: C, 63.06; H, 8.91.

3-Chloromethyl-2H-5,6-dihydropyran

The preceding 35 g. of 2H-5,6-dihydropyran-3-methanol in 60 ml. of chloroform and 24 g. of pyridine at 0° was treated over 1 hour with 37 g. of thionyl chloride. The solution was stirred at 0° an additional 30 minutes after which time it was poured into cold water and extracted with ether. The extract was washed with cold dilute sodium hydroxide, then dried and evaporated. The residue was distilled *in vacuo* to give at 75–80° and 14 mm. 27.3 g. of colorless liquid which is very irritating to the eyes. Calc. for C_6H_9OCl : Cl, 26.77. Found: Cl, 26.82.

2H-5,6-Dihydropyran-3-acetonitrile (X)

Twenty-seven grams of the preceding chloride was mixed with 40 g. of cuprous cyanide and 100 ml. of xylene. The mixture was stirred and heated under reflux for 8 hours, then cooled, and the solvent decanted from a black tar. Evaporation *in vacuo* followed by distillation afforded 10 g. of a colorless liquid, b.p. 120–122° at 18 mm. Calc. for C_7H_9ON : N, 11.37. Found: N, 11.34.

2-Hydroxyl-tetrahydropyran-3-acetic Acid Lactone (XIII)

Nine grams of the preceding nitrile (X) was heated under reflux in ethanolic potassium hydroxide for 20 hours; the alcohol was removed by distillation, the residue diluted with water, and, after one ether wash, it was carefully acidified to litmus and extracted with ether. The ether extract was dried and evaporated and the residue distilled *in vacuo*; at 86–88° and 0.2 mm. there was obtained 5.80 g. of a colorless neutral distillate. Its saponification equivalent was 141 (theory, 142). It decolorized bromine in carbon tetrachloride with copious evolution of hydrogen bromide and gave no color with tetranitromethane. Calc. for $C_7H_{10}O_3$: C, 59.14; H, 7.09. Found: C, 59.22; H, 7.20.

Methyl 2H-5,6-Dihydropyran-3-acetate

The above nitrile (X), 27.5 g., was mixed with a cold solution of 22 g. of concentrated sulphuric acid in 100 ml. of dry methanol. The solution was allowed to stand for 24 hours after which time 4 ml. of water was added followed by heating under reflux for 2 hours. The mixture was concentrated *in vacuo*, diluted with ice water, and extracted with ether. The extract was dried and evaporated and the residue distilled; at 103–105° and 6 mm. there was obtained 20.0 g. of colorless distillate. Calc. for $C_8H_{12}O_3$: C, 61.61; H, 7.74. Found: C, 61.63; H, 7.60.

Methyl 2,3,4,5,6,7-Hexahydroindole-1-butyrate and Its Quaternary Bromide (XVI)

Equimolar amounts of hexahydroindole and methyl 4-bromobutyrate were heated to 100°. A very exothermic reaction took place spontaneously and required cooling. Within a few minutes, the mixture completely solidified. The crystals were suspended in dry ether and collected under dry nitrogen. The yield was quantitative and the product very hygroscopic. On treatment with cold aqueous potassium cyanide in the usual way, an oil separated, which on distillation *in vacuo*, yielded in almost quantitative yield a colorless liquid, b.p. 150–153° at 11 mm. Calc. for $C_{13}H_{21}O_2N$: C, 69.91; H, 9.48. Found: C, 70.05; H, 9.55.

1-Benzoyl-7a-cyano-octahydroindole (XVII)

To a solution of 15.4 g. of hexahydroindole in 40 ml. of anhydrous hydrogen cyanide at –15° was added 6.3 g. of powdered sodium cyanide, and dropwise, while stirring, 18.3 g. of benzoyl chloride in 35 ml. of dry ether was introduced over a period of 45 minutes. Stirring was continued an additional 45 minutes, and the excess hydrogen cyanide swept out with nitrogen. The mixture was quenched with ice water and the crystalline mass that separated was collected. Recrystallization from methanol afforded colorless thick blades, m.p. 148.5–149.5°. The yield of pure material was 29.1 g. Calc. for $C_{16}H_{18}ON_2$: C, 75.55; H, 7.13; N, 11.01. Found: C, 75.58; H, 7.21; N, 11.08.

7a-Methoxycarbonyl-octahydroindole (XVIII)

The preceding nitrile (XVII), 27.9 g., was heated under reflux in 250 ml. of concentrated hydrochloric acid for 18 hours. The solution was cooled, one volume of water added, and the benzoic acid removed by filtration. The filtrate was twice washed with ether and evaporated to dryness *in vacuo*. The solid residue was dissolved in 300 ml. of dry methanol containing 25 ml. of concentrated sulphuric acid and the solution heated under reflux for 15 hours. About half of the solvent was evaporated and the solution poured into water. After one ether wash, the aqueous phase was made alkaline with cold sodium hydroxide solution and extracted with ether. The ether extract was dried and evaporated and the residue distilled *in vacuo*; at 60–80° and 12–13 mm. there was recovered 7.50 g. of crude hexahydroindole followed by 8.40 g. of XVIII as a colorless liquid, b.p. 100–101° at 10 mm. The latter was characterized as its crystalline hydrochloride which separated from methanol–acetone as small colorless needles, m.p. 183–184° (decomp.). Calc. for $C_{10}H_{18}O_2NCl$: N, 6.37; Cl, 16.18. Found: N, 6.41; Cl, 16.11. Its picrate separated from methanol as yellow prisms, m.p. 174–175°. Calc. for $C_{16}H_{20}O_5N_4$: N, 13.58. Found: N, 13.52.

Methyl 7a-Methoxycarbonyl-1-octahydroindolebutyrate (XIX)

The above 7a-methoxycarbonyl-octahydroindole, 6.22 g., was mixed with 6.4 g. of methyl 4-bromobutyrate and 2.4 g. of anhydrous potassium carbonate in 15 ml. of methanol. The mixture was heated under reflux for 18 hours after which time 5.0 g. of methyl 4-bromobutyrate and 2.8 g. of potassium bicarbonate were added and the reflux resumed for 6–8 hours. The solution was diluted with water and extracted with ether. The extract was dried and evaporated and the residue distilled *in vacuo* to give at 170–173° and 8 mm. 5.48 g. of colorless diester (XIX). It gave a crystalline hydrochloride separating from acetone as colorless rods, m.p. 150–151° (decomp.). Calc. for $C_{15}H_{26}O_4NCl$: N, 4.38; Cl, 11.08. Found: N, 4.25; Cl, 11.17. The picrate was obtained from methanol

as yellow parallelograms, m.p. 127–128°. Calc. for $C_{21}H_{28}O_{11}N_4$: N, 10.93. Found: N, 11.04.

1,11-Ethylene-4-methoxycarbonyl-1-azaspiro[5,5]undecane-5-one (XX)

Fresh sodium methoxide was prepared from 1.40 g. of sodium in a little absolute methanol and dried at 100° under 1 mm. To the dried powder was added 4.18 g. of the preceding diester (XIX) in 75 ml. of dry xylene. The mixture was heated under reflux under dry nitrogen for 90 minutes, after which time 30–40 ml. of xylene was allowed to distill over an additional hour. The mixture was cooled and poured into dilute hydrochloric acid, and the acid solution neutralized with aqueous potassium carbonate and extracted with ether. The ether was dried and evaporated to a viscous oil which was treated with dry hydrogen chloride in ether, whereupon 3.65 g. of white crystals, m.p. 170–175°, separated. Recrystallization from acetone afforded colorless prisms, m.p. 174° (decomp.). This material gave a deep purple color with alcoholic ferric chloride. Calc. for $C_{14}H_{22}O_3NCl$: N, 4.86; Cl, 12.32. Found: N, 4.78; Cl, 12.41. All attempts at condensation of the base with malononitrile or cyanoacetic ester using ammonium acetate as the catalyst led only to unchanged starting material.

1,11-Ethylene-1-azaspiro[5,5]undecane-5-one (XXII)

One gram of the preceding ketoester hydrochloride was heated under reflux for 5 hours in 50 ml. of concentrated hydrochloric acid. The solution was taken to dryness *in vacuo*, the residue shaken with excess aqueous alkali and extracted with ether. The ether extract was dried, concentrated, and treated with dry hydrogen chloride, whereupon 640 mg. of crystals, m.p. 184–188°, separated. Recrystallization from acetone afforded colorless cubes, m.p. 186–187° (decomp.). This material gave no coloration with alcoholic ferric chloride. Calc. for $C_{12}H_{20}ONCl$: N, 6.09; Cl, 15.43. Found: N, 6.13; Cl, 15.52. The base was recovered unchanged after protracted heating with excess phenylhydrazine in methanol.

1,11-Ethylene-1-azaspiro[5,5]undec-4-ene-5-acetic Acid (XXIV)

A benzene solution of ethoxyacetylene magnesium bromide was prepared in the usual way from 1.90 g. of ethoxyacetylene (10) and propylmagnesium bromide itself, obtained from 1.13 g. of magnesium and 5.80 g. of propyl bromide. To this was added 5.50 g. of pure oily ketone (XXII) in 25 ml. of benzene and the mixture stirred at room temperature for 5 hours. A viscous brown oil slowly separated. The mixture was treated with saturated ammonium chloride solution followed by extraction with chloroform. The extract was dried and evaporated and the residue treated at reflux temperature for 1 hour with aqueous alcoholic hydrogen chloride (10% solution). After it had been standing for 2 days, the solution was taken to dryness *in vacuo* and the residue treated for 1 hour with excess 10% alcoholic sodium hydroxide at the boiling point. The solution was concentrated *in vacuo*, diluted with water, and washed with several portions of ether which removed some neutral material that was not further investigated. The washed aqueous phase was filtered through a column of Amberlite IRA-400 in basic form and the column washed with water until the eluate was neutral. The product was eluted with 2% hydrochloric acid and the eluate evaporated to dryness *in vacuo* under a carbon dioxide atmosphere. The residue was a yellow sirup weighing 2.13 g. which failed to crystallize or to yield crystalline derivatives. It was freely soluble in water and aqueous alkali. Paper chromatography using 80% aqueous pyridine and dilute permanganate as the developer

revealed it to be homogeneous as judged by the appearance of a single sharp spot with R_F 0.64. Paper electrophoresis at pH 8.5 also gave a single sharp band with a mobility characteristic of monoamino-monocarboxylic acids.

Accurate analytical figures could not be obtained, presumably because of the hygroscopic properties of the product.

Lactone (XXV) from the Amino Acid (XXIV)

A mixture of 1.36 g. of the preceding amorphous amino acid and 160 mg. of trioxymethylene in 6 ml. of trifluoroacetic acid was allowed to stand at room temperature for 6 days. The solution was taken down to dryness *in vacuo* and the residue treated with cold aqueous sodium carbonate and extracted with ether. The ether extract was washed with several portions of aqueous sodium carbonate, dried, and evaporated to yield an oil which crystallized from ether as colorless needles, m.p. 95–97° (yield: 310 mg.). Recrystallization from acetone–ether raised the m.p. to 97.5–98.5°. Calc. for $C_{15}H_{23}O_3N$: C, 67.89; H, 8.73; N, 5.28; mol. wt. 265. Found: C, 68.00; H, 8.34; N, 5.25; mol. wt. 220 (Rast).

From the combined sodium carbonate washings there was recovered 620 mg. of unchanged starting amino acid, the identity of which was ascertained by mixed paper chromatograms.

The crystalline lactone dissolves in warm aqueous alkali but cannot be recovered from its solution. In the infrared region is exhibited a band at 1770 cm^{-1} (CHCl_3). It was transparent in the ultraviolet region.

1,11-Ethylene-1-azaspiro[5,5]undecane-5-(β -hydroxyethyl)-5-ol (XXVI)

To a solution of 100 mg. of lithium aluminum hydride in 2 ml. of tetrahydrofuran was added 50 mg. of the preceding lactone and the mixture was allowed to stand overnight after which time it was decomposed with aqueous sodium hydroxide. The mixture was worked up in the usual way to yield a colorless oil which crystallized from hexane. Two recrystallizations from hexane afforded fine colorless needles, m.p. 78–79°. Calc. for $C_{14}H_{26}O_2N$: C, 70.25; H, 10.52. Found: C, 69.95; H, 10.48. It was insoluble in hot aqueous alkali and showed no absorption in the carbonyl region in the infrared.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Dr. G. Papineau-Couture (Ayerst, McKenna, and Harrison, Montreal) for the infrared determinations and interpretations and to the National Research Council of Canada for financial assistance.

THE PRINS REACTION WITH β,γ -UNSATURATED ACIDS AND AMIDES¹

B. BELLEAU

ABSTRACT

The acid catalyzed condensation of cyclohexenylacetic acid and its corresponding N-methylamide with formaldehyde was investigated. Good yields of the expected δ -lactone (V) or δ -lactam (IX) were obtained when trifluoroacetic acid was used both as catalyst and solvent for the reaction.

In connection with another problem (2), it was of interest to develop a specific method for the synthesis of β,γ -unsaturated- δ -lactones from β,γ -unsaturated acids of the cyclohexane series. On theoretical grounds, the Prins reaction (1) appeared attractive since it can be expected that the carboxyl group of the unsaturated acid would participate in the condensation through the formation of intermediates II and III, thus bringing about favorable proximity of carbonium ion III to the double bond. In this manner, ring closure to the desired lactone should be facilitated. The Prins reaction as applied to a long chain ω -unsaturated acid has been reported recently by Braude and co-workers (4) but there appears to exist no report on the behavior of β,γ -unsaturated acids in this reaction.

In a preliminary experiment, cyclohexeneacetic acid (I) was treated with trioxymethylene in boiling acetic acid as solvent and sulphuric acid as the catalyst to give a 45% yield of a neutral liquid whose properties agreed with structure V. The product was insoluble in cold but soluble in warm aqueous alkali, had the correct saponification equivalent, and exhibited a band in the infrared region at 1750 cm^{-1} which is characteristic of a β,γ -unsaturated- δ -lactone. In an attempt to improve the yield of lactone (V), the reaction was carried out in dioxane as the solvent and again sulphuric acid as the catalyst. Surprisingly, there was obtained also in 45% yield a single crystalline substance which proved to be the isomeric conjugated lactone (VI) on the basis of its typical behavior toward alkali and the following spectral evidence: it exhibited strong absorption in the ultraviolet region at $223\text{ m}\mu$ ($\log \epsilon = 3.95$) and a characteristic band in the infrared region at 1733 cm^{-1} , in agreement with an α,β -unsaturated- δ -lactone structure. It is of practical interest that both lactones can be obtained essentially free from one another by the simple expedient of substituting dioxane for acetic acid or vice versa. The reasons for this are not clear.

In subsequent attempts to improve the yield of lactone (V), it was ultimately found that trifluoroacetic acid can serve both as solvent and catalyst in this reaction and that it appears to be the reagent of choice for our purposes. Indeed, by the simple expedient of mixing equimolar amounts of cyclohexeneacetic acid and trioxymethylene in trifluoroacetic acid at room temperature, the unconjugated lactone (V) was obtained consistently in yields of 75 to 80% of the theoretical. This new technique may prove of value in the general application of the Prins reaction.

In connection with still another problem (2), it was necessary to explore the possibility of applying the Prins reaction to the corresponding β,γ -unsaturated amides with a view to preparing octahydroisoquinolones such as IX. The successful application of the

Contribution from the Department of Biochemistry, School of Medicine, Laval University, Quebec, Que.

Pictet-Spengler synthesis to cyclohexenylethylamine, as reported by Grewe (5), coupled with our recent finding that arylacetamide derivatives can substitute advantageously for phenethylamines in the same reaction (3) raised the question whether cyclohexenylacetamide derivatives can also be of use in the Pictet-Spengler reaction. At this point, with formaldehyde as a reactant, no fundamental mechanistic demarcation can be discerned between the Pictet-Spengler and Prins reactions except perhaps that the former implies participation of a basic nitrogen leading to a Schiff base type of compound

CHART I.

as an intermediate. For this reason, the term Pictet-Spengler reaction may be more appropriate in the case under discussion. The condensation of N-methyl cyclohexenylacetamide with formaldehyde was therefore investigated and, taking advantage of our experience in the Prins reaction as described above, the amide was reacted with trioxymethylene in hot trifluoroacetic acid. In this manner, there was obtained in 65% yield a colorless liquid whose properties agreed with structure IX. Inertness to warm alcoholic alkali, transparency in the ultraviolet region, and strong absorption in the infrared region at 1655 cm^{-1} served to establish that the reaction followed the anticipated course. It is of practical interest that octahydro-3-isoquinolones appear to be easily accessible by this method and further applications of this finding are described in a separate communication.

EXPERIMENTAL*

2-Hydroxymethyl-1-cyclohexeneacetic Acid Lactone (V)

Method A.—A solution of 16 g. of cyclohexeneacetic acid and 4 g. of trioxymethylene in 50 ml. of acetic acid containing 0.5 ml. of concentrated sulphuric acid was heated under reflux for 5 hours, after which time the mixture was cooled and treated with 2 g. of anhydrous sodium acetate. Distillation *in vacuo* gave 8 g. (46% yield) of colorless liquid, b.p. 145–147° at 8 mm. The product is insoluble in cold aqueous sodium hydroxide but dissolves readily upon warming. It gave a band in the infrared at 1750 cm^{-1} (CS_2). Calc. for $\text{C}_9\text{H}_{12}\text{O}_2$: C, 71.02; H, 7.95. Found: C, 71.18; H, 7.82.

Method B.—Cyclohexeneacetic acid (14 g.) was mixed at room temperature with a solution of 3.16 g. of trioxymethylene in 40 ml. of trifluoroacetic acid. After it had been left for 40 hours at room temperature, the solution was distilled *in vacuo* to give at 158–160° and 12 mm. 11.5 g. (75% yield) of colorless liquid which proved identical in the I.R. region with the preceding lactone.

2-Hydroxymethyl-cyclohexylideneacetic Acid Lactone (VI)

A mixture of 8 g. of cyclohexeneacetic acid, 2 g. of trioxymethylene, 35 ml. of dioxane, and 0.25 ml. of concentrated sulphuric acid was heated to 95° for 18 hours. The solution was concentrated *in vacuo*, the residue taken up in ether, and the solution washed several times with dilute aqueous sodium bicarbonate. The ethereal phase was dried and evaporated and the residue distilled *in vacuo*; at 150–152° and 7 mm., there was obtained 4 g. (46% yield) of crystalline distillate. It was recrystallized from ether–hexane to give colorless needles, m.p. 59–60°; $\lambda_{\text{max}}^{\text{EtOH}} = 223 \text{ m}\mu$ ($\epsilon = 9000$); absorption maxima in the I.R. at 1733 cm^{-1} and 1700 cm^{-1} (CS_2). The product is soluble in warm aqueous sodium hydroxide but not in the cold. Calc. for $\text{C}_9\text{H}_{12}\text{O}_2$: C, 71.02; H, 7.95. Found: C, 71.22; H, 8.10.

N-Methyl Cyclohexeneacetamide (VII)

This was prepared in the usual fashion from cyclohexeneacetyl chloride and aqueous methylamine. The product crystallized from hexane as colorless leaflets, m.p. 33–34°. Calc. for $\text{C}_9\text{H}_{15}\text{ON}$: N, 9.14. Found: N, 9.26.

2-Methyl- $\Delta^{9(10)}$ -octahydro-3-isoquinolone (IX)

A mixture of 13 g. of the preceding amide, 2.7 g. of trioxymethylene, and 35 ml. of trifluoroacetic acid was heated on the steam bath for 6 hours, after which time it was distilled *in vacuo*; at 158–160° and 12 mm., there was obtained 10 g. of a colorless liquid. This was further purified by treatment with hot methanolic sodium hydroxide for 3 minutes, followed by extraction with ether and isolation by distillation. If this treatment was omitted, the analytical values for nitrogen were too low. This product gave a band in I.R. at 1655 cm^{-1} (CS_2) as expected for IX and did not consume alcoholic sodium hydroxide after 1 hour at reflux temperature. Calc. for $\text{C}_{10}\text{H}_{15}\text{ON}$: C, 72.68; H, 9.15; N, 8.48. Found: C, 72.51; H, 9.29; N, 8.42.

ACKNOWLEDGMENTS

The author wishes to thank Dr. G. Papineau-Couture for the infrared determinations and interpretations and the National Research Council of Canada for financial assistance.

THE LOCATION AND DISTRIBUTION OF SUBSTITUENTS IN A PURIFIED HYDROXYETHYL CELLULOSE¹

H. H. BROWNELL² AND C. B. PURVES

ABSTRACT

A purified hydroxyethylcellulose of molar substitution 1.33 was completely hydrolyzed in acid, and paper chromatography of the neutral hydrolyzate separated glucose, the three possible hydroxyethyl glucoses, the three di(hydroxyethyl) derivatives, and 2,3,6-tri-*O*-hydroxyethyl glucose. These substances were isolated as sirups possibly contaminated with the corresponding hydroxyethoxyethyl and higher homologues, which had nearly the same R_f values in the system used. The chromatographic behavior of each of the seven hydroxyethyl glucoses was established by synthetical methods from methyl 4,6-*O*-benzylidene glucoside, 1,2;5,6-di-*O*-isopropylidene, and 1,2;3,5-di-*O*-methylene glucofuranose. Methyl 2,3-di-*O*-hydroxyethyl-4,6-*O*-benzylidene- β -glucopyranoside, m.p. 98°–100° and 119–121°, and 1,2-mono-*O*-methylene glucofuranose, m.p. 147°, were new substances.

A quantitative examination of the hydrolyzates showed that the condensation between alkali cellulose and ethylene oxide was nearly homogeneous, that the primary hydroxyl groups in the anhydroglucose units reacted fastest, and those in the third positions slowest. The average substituent had a polyoxyethylene chain length of 1.6 units. Three commercial hydroxyethylcelluloses of apparent M.S. about 1.4 contained non-carbohydrate polyethylene glycols.

INTRODUCTION

It has long been known that the condensation of alkali cellulose with ethylene oxide or ethylene chlorohydrin yields the commercially valuable hydroxyethylcelluloses, the literature of which has been reviewed (26). The problem of locating the position of the substituents in these derivatives is unusually complicated, because any particular hydroxyl group in the cellulose might become substituted by a polyethylene oxide chain instead of by the monomeric hydroxyethyl unit, and in consequence the actual degree of substitution in the glucose residues (D.S.) would be less than the observed molar substitution (M.S.). Division of M.S. by D.S. would give the average length of the polyethylene oxide chains. Even if the maximum chain length were only three units, there are 64 different ways in which a single glucose residue in the cellulose derivative could be substituted. Moreover, the customary methods of locating substituents in cellulose ethers proved to be of limited value for the hydroxyethyl derivatives. The tosylation-iodination method of differentiating primary from secondary alcoholic groups was found by Tasker and Purves (26) and by Fournier (11) to be attended by side-reactions, one of which probably involved the elimination of hydroxyethyl groups. Sonnerskog (24) and Cohen and Haas (3) estimated unsubstituted 2,3-glycol groups by oxidation with lead tetraacetate or with periodate, but the occurrence of overoxidation necessitated an extensive correction. It became obvious that a thorough structural study of the hydroxyethylcelluloses required the development of new methods.

Creamer, Brownell, and Purves (5) then observed that crystalline 3-*O*-hydroxyethyl- α -D-glucose gave a single, well-defined spot of R_f 0.180 when chromatographed on paper with butanol saturated with water as the eluant. Although this spot was easily differentiated from that of R_f 0.09 given by glucose, it was practically coincident with that of 3-*O*-hydroxyethoxyethyl glucose, R_f 0.187. Chromatography had to be prolonged for

²Present address: Dominion Forest Products Laboratory, Ottawa, Ont.

many days to separate the last two spots completely. Since the R_f values of the hydroxyethyl, $\text{HOCH}_2\text{CH}_2-$, and the hydroxyethoxyethyl, $\text{HOCH}_2\text{CH}_2-\text{O}-\text{CH}_2\text{CH}_2-$, derivatives did not differ by more than 3 or 4% in the system used, and the difference was probably no greater for higher homologues, it seemed probable that the chromatography of a completely hydrolyzed hydroxyethylcellulose would yield no more than eight spots corresponding to glucose, and to glucose substituted in the 2-, 3-, 6-, 2,3-, 2,6-, 3,6-, and 2,3,6-positions, by polyethylene oxide chains of variable length. The present article describes the identification and estimation of the material in these spots, and discusses the structure of the original hydroxyethylcellulose in the light of the results.

Although the paper chromatographic behavior of authentic ethylene glycol, diethylene glycol, and triethylene glycol could not be detected by the aniline phthalate spray used for reducing sugars, these compounds were readily distinguished from sugars by the distinct brown spots of R_f 0.55, 0.62, and 0.63, respectively, which they gave when an ammoniacal silver spray was employed. When ethylene oxide was bubbled into water (mole ratio 1:13 or only 1:1.1) containing sodium hydroxide, and the resulting mixtures of glycols were chromatographed on paper, the spot of R_f 0.63 was marked and that of R_f 0.55 was faint. Polyethylene glycols therefore formed in preference to ethylene glycol under conditions similar to those used in the preparation of hydroxyethylcelluloses. Weibull and Nycander (28) similarly found that ethylene oxide condensed more rapidly with ethoxyethanol than with ethanol itself. In a search for physically adsorbed polyethylene glycols, hydrolyzates of six commercial hydroxyethylcellulose ethers were chromatographed on paper simultaneously with reference samples of ethylene glycol. Polyethylene glycols, but not ethylene glycol itself, were present in three hydroxyethylcelluloses of specified M.S. about 1.4, but were absent in three lots of M.S. 0.44 to 0.82.

An aqueous solution of one of these commercial products, Cellosize WS-100 with an observed M.S. 1.56, was then poured into a large volume of acetone and the precipitate was reprecipitated in the same way. This treatment gave a product whose M.S. was decreased to 1.33, but which after hydrolysis was chromatographically free of polyethylene glycols. Evaporation of the mother liquors from the precipitations recovered 4.2% of the original sample as a distillable oil with a combined ethylene oxide content of 83.9%—or a value intermediate between those of di- and tri-ethylene glycol. This non-carbohydrate oil contained 12% of the combined ethylene oxide content of the original hydroxyethylcellulose and accounted for 0.18 units in its apparent M.S. of 1.56.

Although Davis (7) described hydroxyethylcelluloses of M.S. as high as 6, the analytical method he used was unreliable. Morgan (15), however, condensed ethylene oxide and alkali cellulose in a mole ratio of 10:1 to prepare a sample of M.S. 4.1, determined after purification by a series of precipitations and leachings followed by dialysis. In this case the M.S. was found by Morgan's own reliable method, but the efficacy of the purification in removing adsorbed polyethylene glycols had to be assumed. Since the amount of the latter retained by such a highly substituted product might be considerable, a hydroxyethylcellulose was prepared by condensing alkali cellulose with ethylene oxide in a molar ratio of 25:1, and was unequivocally freed of polyethylene glycols by precipitations from aqueous acetone. The fact that the M.S. was 6.9 confirmed earlier claims that values greater than 3.0 could be attained, and that true polyethylene oxide substituents actually existed in hydroxyethylcelluloses.

A sample of the purified hydroxyethylcellulose of M.S. 1.33 was then completely hydrolyzed in acid. The neutral hydrolyzate, when chromatographed on paper for a prolonged period, yielded eight distinct spots shown in Fig. 1 and numbered according to increasing R_f values. Since Dolgoplov, Melnikov, and Nametkin (9) found that 1% of concentrated sulphuric acid promoted an equilibrium between the monoalkyl ethers of ethylene, diethylene, and polyethylene glycols, it was possible that a similar migration or cleavage had occurred during the above hydrolysis. This possibility was discounted, because careful examination of the chromatograms revealed no traces of spots attributable

FIG. 1. Paper chromatogram of hydroxyethyl glucose mixture from hydrolyzed hydroxyethylcellulose, M.S. 1.33, D.S. 0.85. Developer: Butanol-1 saturated with water. Spray: Aniline phthalate.

to the polyethylene glycol series. Since crystalline 3-*O*-hydroxyethyl glucose was still chromatographically pure after subjection to the same conditions of hydrolysis, a migration of hydroxyethyl units within the glucose structure was also improbable.

The sugar, or series of sugars, causing each spot was then identified. Spot 1 was ascribed to glucose, which had the same R_f value. In confirmation, fermentation of the hydrolyzate with yeast removed this spot, and only this spot, from the subsequent chromatogram. Synthetic 3-*O*-hydroxyethyl glucose, when chromatographed simultaneously with the hydroxyethylcellulose hydrolyzate, had an R_f value identical with that of spot 4. Information about the chromatographic behavior of glucose substituted in the 2- and 2,3-positions was obtained by condensing methyl 4,6-*O*-benzylidene- α - or - β -D-glucopyranoside with ethylene oxide. When a suitable excess of the reagent was used, methyl 2,3-di-*O*-hydroxyethyl-4,6-*O*-benzylidene- β -glucoside was isolated as a new, crystalline compound, which when hydrolyzed yielded 2,3-di-*O*-hydroxyethyl glucose as a chromatographically pure sirup. This hydrolyzate, when chromatographed, gave a single spot identical in R_f value to spot 7. When the benzylidene glucoside was condensed with a lesser amount of ethylene oxide, and the uncrystallized product was hydrolyzed, the resulting mixture of hydroxyethyl glucoses gave a chromatogram with only four spots, one for glucose, two for the known 2,3- and 3-derivatives, and a fourth which was ascribed with confidence to 2-*O*-hydroxyethyl glucose. This substance had the same R_f value as spot 3 in Fig. 1.

In order to prepare a known mixture containing 3,6-di-*O*-hydroxyethyl-D-glucose, 3-*O*-hydroxyethyl-1,2;5,6-di-*O*-isopropylidene glucose (I) was partially hydrolyzed to a mixture containing much of the 1,2-mono-*O*-isopropylidene derivative. Condensation of the mixture with ethylene oxide, followed by hydrolysis of the remaining 1,2-*O*-isopropylidene group, gave a mixture containing glucose with hydroxyethyl substituents only in the 3-, 3,6-, 3,5-, and 3,5,6-positions. The corresponding chromatogram had four spots,

I, R = CH₂CH₂OH

II

III, R = CH₂CH₂OH

of which two failed to coincide with any in the chromatogram of the hydrolyzed hydroxyethylcellulose (Fig. 1). These spots were ascribed to the 3,5- and 3,5,6-derivatives. One of the other spots was that of the known 3-derivative, and by elimination the fourth spot was that of 3,6-di-*O*-hydroxyethyl glucose. This spot coincided with spot 6 in Fig. 1.

Five years ago, Hough, Jones, and Magson (13) condensed glucose with formaldehyde and isolated a new, non-reducing dimethylene glucose (II) as a crystalline 6-acetate. After this acetyl group had been saponified and replaced with a hydroxyethyl unit, hydrolysis yielded an uncrystallized sample of 6-*O*-hydroxyethyl glucose. Chromatographic comparison with Fig. 1 then indicated that spot 2 was caused by glucose substituted in the sixth position. A partial hydrolysis of the dimethylene glucose (II) then gave two new monomethylene derivatives, one a reducing sirup and the other a crystalline compound. Since the latter was non-reducing, one point of attachment of the methylene group was at the 1-position of the glucose. This compound and also crystalline 1,2-*O*-isopropylidene glucose were then condensed with ethylene oxide in parallel experiments, and after hydrolysis the two products yielded chromatograms with identical series of spots. The methylene, like the isopropylidene, substituent therefore occupied the 1,2-positions in glucose, which in both cases had a furane or 1,4-ring structure. This ring structure was confirmed by the observation that the monomethylene derivative yielded 1 mole of formaldehyde when oxidized with periodate. The parent substance (II) was therefore 1,2;3,5-di-*O*-methylene glucose, since the sixth position was known to be free, and the uncrystallized, reducing monomethylene glucose was the 3,5-derivative. This simple proof of the structure of the dimethylene glucose (II) supplemented the more rigorous ones given by Schmidt, Distelmaier, and Reinhard (20) and by Shyluk, Honeyman, and Timell (22). Shyluk and Timell (23) also synthesized the 2-, 3-, and 6-*O*-hydroxyethyl glucoses, as well as 3-*O*-hydroxyethoxyethyl glucose, by reducing the corresponding carboxymethyl ethers with lithium aluminum hydride, and noted their chromatographic behavior.

The 6-*O*-hydroxyethyl derivative of II was then partly hydrolyzed to the two analogous monomethylene derivatives, and a sample of the reducing one, 6-*O*-hydroxyethyl-3,5-di-*O*-methylene glucofuranose, was isolated as a sirup from a series of paper chromatograms. In accord with its furanose structure, this sugar was easily converted to a mixture of methyl α - and β -glucosides (III) by methanol and hydrogen chloride. Condensation of this glucoside with ethylene oxide caused the substitution of the hydroxyl group in the second position, and hydrolysis of the methyl and methylene groups yielded 2,6-di-*O*-hydroxyethyl glucose as a sirup whose R_f value was identical to that of the sugar producing spot 5 in Fig. 1. Conversion of this 2,6-derivative to its methyl glucopyranoside, condensation of the latter with ethylene oxide, and subsequent hydrolysis of the methyl group gave a mixture which produced a chromatogram with three spots. One of these spots was that of unchanged 2,6-di-*O*-hydroxyethyl glucose, and another was probably caused by the 2,4,6-derivative, since it did not appear in the chromatogram of hydrolyzed hydroxyethylcellulose (Fig. 1). The third spot coincided exactly to spot 8 in Fig. 1, and was therefore ascribed to 2,3,6-tri-*O*-hydroxyethyl glucose.

All eight spots in Fig. 1 were thus individually identified as one or other of the eight sugars or series of sugars theoretically to be expected from the hydrolysis of a hydroxyethylcellulose. Although the identifications were based almost entirely on paper chromatograms and were therefore not conclusively proved, they were complete and self-consistent. Spots 4 and 6 were difficult to resolve from spots 3 and 5, respectively, and at one time the possibility was considered that the former pair were simply the hydroxyethoxyethyl or higher derivatives of the latter. This possibility was remote because the relative intensities of the spots from the hydrolyzates of hydroxyethylcelluloses of M.S. 1.33 and 0.44 were approximately the same, in spite of the fact that the latter sample should have contained much less hydroxyethoxyethyl substitution than the former. When a sample of crude 6-*O*-hydroxyethyl glucose prepared with a large excess of ethylene oxide was chromatographed on paper for 10 days, the original single spot separated into two spots very close together, one of which could be ascribed to the hydroxyethoxyethyl glucose by analogy with the similar behavior of the 3-*O*-hydroxyethyl derivatives (5, 23). In a few of many attempts made with the hydrolyzed hydroxyethylcellulose of M.S. 1.33, an incomplete resolution of the spot ascribed to 6-*O*-hydroxyethyl glucose (No. 2, Fig. 1) was obtained, and the presence of two or more ethylene oxide units in this position of the hydroxyethylcellulose was considered probable.

The hydrolyzate of the hydroxyethylcellulose was then chromatographed on a larger scale, so that the material in the various spots could be recovered quantitatively. The two weakest spots in Fig. 1, Nos. 4 and 6, which were later estimated to represent less than 4% of the sugars—and which were difficult to resolve—were included with the adjacent spots, Nos. 3 and 5, respectively. Reducing sugars in each extract were then determined by oxidation with alkaline hypoiodite, since this method was found to be very satisfactory for the estimation of pure 3-*O*-hydroxyethyl glucose. Column 4 of Fig. 1 gives the results as mole fractions of the hydroxyethylcellulose substituted in the positions indicated in Column 3.

The degree of substitution (D.S.) of this hydroxyethylcellulose was calculated to be 0.85, and the average number of ethylene oxide units in a substituent group was $1.33/0.85$, or about 1.6. Reese, Siu, and Levinson (18) observed that the low resistance of a hydroxyethylcellulose of M.S. 1.47 to biological degradation suggested a D.S. of only 0.8 to 0.9, and concluded that their sample contained polyoxyethylene substituents averaging

1.6 to 1.8 units in length. The average number of primary alcohol groups in the hydroxyethylcellulose was obviously unity plus the D.S. in the 2-, 3-, 2,6-, 3,6-, and twice the D.S. in the 2,3- and 2,3,6-positions (Fig. 1). This number, 1.43 per anhydroglucose unit, lay between the values of 1.22 and 1.46 found by the tosylation-iodination method for hydroxyethylcelluloses of M.S. 0.44 (26) and 1.50 (3) respectively. The number of unsubstituted 2,3-glycol units in the present sample was 0.67, whereas Cohen and Haas (3) found by the periodate method that only 0.5 mole was present in their sample of M.S. 1.50. In this case the agreement was poor, presumably because overoxidation occurred in the latter estimation. The data of Fig. 1 also showed that the substitution in the sixth or primary alcohol positions of the hydroxyethylcellulose was 0.42 mole per anhydroglucose unit, or was one-half of the total D.S. of 0.85. The condensation of ethylene oxide therefore proceeded most rapidly with the primary alcohol units in the alkali cellulose; condensation with the unit in the second position was substantial, and was least with that in position three.

Spurlin (25) and Timell (27) calculated that if substituents in cellulose were distributed between the second, third, and sixth positions, equations of the form

$$x_2 = S_2 + S_{2,3} + S_{2,6} + S_{2,3,6}$$

were valid. If the distribution was according to the laws of chance, then

$$S_2 = x_2(1-x_3)(1-x_6).$$

There were similar equations for S_3 to $S_{2,3,6}$. In these equations, x_2 , x_3 , and x_6 were the over-all mole fractions of the anhydroglucose units substituted in the positions indicated by the subscript, while S_2 , $S_{2,3}$, etc. gave the fractions substituted *only* as indicated. The failure to estimate S_3 and $S_{3,6}$ independently of S_2 and $S_{2,6}$ (Fig. 1) made it necessary to assume that the former substitutions were zero or had some small value like 0.02 mole. The first equations were then used to calculate x_2 , x_3 , and x_6 , and the second group could then be solved for S_0 to $S_{2,3,6}$. Although none of the assumptions made gave close agreement between the calculated S values and those observed (Fig. 1), the great discrepancies observed by Timell (27) for methylcelluloses prepared in a heterogeneous system were absent. The reaction between alkali cellulose and ethylene oxide therefore appeared to be more homogeneous than the corresponding methylation. Cohen and Haas (3) reached the same conclusion for other reasons.

Four months ago, Croon and Lindberg (6) published an interesting article on the location of the substituents in a hydroxyethylcellulose of M.S. 0.60–0.55. The hydrolyzate was separated into 15 fractions (including hydroxyethoxyethyl and higher homologues) by elution from a carbon–Celite column, and glucose, the 2-, 3-, and 6-*O*-hydroxyethyl glucoses, and six uncrystallized disubstituted ethers were isolated in a pure or nearly pure form. These products were characterized by their relative mobilities in paper chromatography before and after oxidation with periodate according to Lemieux and Bauer (14), and also by their relative mobilities during electrophoresis in a borate buffer (10). These identifications, like those in the present article, depended for the most part on indirect methods, but the agreement in the results of the two independent researches tended to confirm the validity of both. Croon and Lindberg's more detailed statistical analysis of the distribution of substituents also suggested that all the anhydroglucose units in alkali cellulose were equally accessible to ethylene oxide, and that hydroxy groups in C_6 , C_2 , C_3 , and hydroxyethyl positions condensed at rates proportional to 10:3:1:20.

EXPERIMENTAL

Materials and Methods

Unless otherwise mentioned, the alkali used in condensations with ethylene oxide was aqueous 5% sodium hydroxide at 70–75°. Combined ethylene oxide content was estimated by Morgan's modified Zeisel method (15). All chromatograms were prepared on Whatman No. 1 or No. 4 paper by the descending flow technique (1) with *n*-butanol saturated with water. An aniline phthalate spray (17) was used to locate reducing sugars, and ammoniacal silver nitrate (16) for non-reducing substances. With the exceptions noted below, the chromatographic behavior of the various preparations was discussed in the Introduction. Analyses for substituent groups were corrected for ash.

Polyethylene glycol, sample A, was prepared by passing 5.5 g. (0.125 mole) of commercial ethylene oxide gas during 45 minutes through a fritted glass Filterstick into 30 ml. (0.04 mole) of alkali. After being kept for an additional 75 minutes at 70°, the solution was passed through a column of Amberlite IR-120 to remove the base, and evaporation of the neutral effluent yielded 6.31 g. of a colorless oil. To prepare sample B, a 50 ml. flask was loosely packed with glass wool wet with 3.2 ml. (0.18 mole) of water containing 1.8 g. of sodium hydroxide. After being evacuated, 7.1 g. (0.16 mole) of ethylene oxide gas was gradually introduced. The product was extracted from the glass wool with 70 ml. of water and was isolated as in the previous case.

Examination and Preparation of Hydroxyethylcelluloses

One-gram samples of six commercial hydroxyethylcelluloses were separately heated with 25 ml. volumes of 2% hydrochloric acid for 14 hours at 100° in sealed tubes filled with nitrogen. Four samples, of specified M.S. 0.8 or more, dissolved almost completely, but two, of M.S. 0.39 and 0.44, to the extent of only 80%. Each hydrolyzate was centrifuged, deacidified by passage through Amberlite IR-4B resin, and evaporated to 50 ml. Paper chromatograms were then prepared simultaneously from 0.007 ml. aliquots of these solutions, and from 0.0003 ml. reference samples of pure ethylene glycol. When sprayed with ammoniacal silver nitrate, the hydrolyzates from three hydroxyethylcelluloses of apparent M.S. 1.4, —, 1.44 gave spots with the R_f value of polyethylene glycol; one sample of M.S. 0.82, which was swollen in water, and two water-insoluble samples of M.S. 0.44 and 0.39 appeared to contain none of these glycols, even when 0.02 ml. aliquots were chromatographed.

One sample, Cellosize WS-100 of specified M.S. 1.44 and containing 6.2% of moisture, was analyzed. Found (oven-dry basis): ash, 2.88; OCH_2CH_2 , 29.7, 29.8, 29.7%, corresponding to the apparent M.S. 1.56. A solution of 9.6 g. in 86 ml. of water was poured slowly, with stirring, into 860 ml. of acetone and the precipitate was recovered on the centrifuge. Evaporation of the mother liquors gave 0.37 g. (4.2%) of a yellow oil. Found: OCH_2CH_2 , 83.9%. Calc. for $\text{H}(\text{—OCH}_2\text{CH}_2)_2\text{OH}$: 83.05; for $\text{H}(\text{—OCH}_2\text{CH}_2)_3\text{OH}$: 88.0%. The oil distilled at 0.2 mm. pressure from a bath at 200° and a chromatogram prepared from 0.0005 ml. showed only one spot with the R_f value of polyethylene glycols. A second precipitation of the hydroxyethylcellulose yielded only 0.05 g. of these glycols. After this second purification, the air-dry product was dissolved in water and recovered by evaporation to free it from traces of acetone. Found (oven-dry basis): ash, 2.50; $\text{—OCH}_2\text{CH}_2$, 26.6, 26.5%, corresponding to M.S. 1.33. This sample, which was chromatographically free of polyethylene glycols, was used in the later work (Fig. 1).

To prepare a highly substituted hydroxyethylcellulose, 5 g. of linters was steeped in

30% sodium hydroxide and the mass was pressed to a weight of 14.6 g. Ethylene oxide was passed into a partially evacuated flask containing this alkali cellulose and cooled externally in water. After 5 hours, when the gain in weight was 34.2 g., the contents of the flask were dissolved in 700 ml. of water, freed of base, and concentrated to 300 ml. The solution was precipitated into 6 l. of acetone. After two similar precipitations the product was chromatographically free of polyethylene glycols. Found (oven-dry basis): ash, 0.24; $-\text{OCH}_2\text{CH}_2$, 65.6, 64.9%, corresponding to M.S. 6.9. A large part of the ethylene oxide had yielded non-carbohydrate products, of which 28.9 g. was recovered from the mother liquors as a crude oil. The hydroxyethylcellulose could also be purified by dialysis against water for 14 days.

Methyl 2,3-Di-O-hydroxyethyl-4,6-O-benzylidene- β -D-glucopyranoside

Ethylene oxide gas, 71 g. (1.62 mole), was passed into a slurry of pure methyl 4,6-O-benzylidene- β -glucoside, 5 g. (0.018 mole), in 25 ml. of alkali during 3.5 hours, the mixture being maintained at 90–95°. The gain in weight was 31.7 g. The resulting solution was neutralized with hydrochloric acid and extracted with five 65-ml. volumes of ethyl acetate; these extracts were combined, washed with small volumes of water, and evaporated to an oil which crystallized on standing. Yield: 6.85 g. or 104%. Two recrystallizations from 50 ml. of water, or one from water and one from isopropyl ether, left about 25% of the product with a melting point of 98–100°. The substance, however, recrystallized in the melting point tube and remelted at 119–121°. The higher melting form, which had the same composition as the other, separated from an aqueous solution which had been boiled for 10 minutes. Found: C, 58.5, 58.2; H, 7.2, 6.9; alkoxyl as $-\text{OCH}_2\text{CH}_2$, 34.2%. Calc. for $\text{C}_{18}\text{H}_{26}\text{O}_8$: C, 58.4; H, 7.1; alkoxyl as $-\text{OCH}_2\text{CH}_2$, 35.7%.

2,3-Di-O-hydroxyethyl Glucose

A solution of 0.05 g. of the above benzylidene methyl glucoside in 5 ml. of 3% hydrochloric acid was kept at 100° for 3.5 hours. The hydrolyzate was extracted with three 1-ml. volumes of chloroform to remove benzaldehyde, was deionized, and was evaporated to a colorless sirup. A paper chromatogram of this sirup revealed only one spot, which was attributed to 2,3-di-O-hydroxyethyl glucose.

2- and 3-O-Hydroxyethyl-D-glucose

(a) Ethylene oxide gas, 2.2 g. (50 mM.), was bubbled through a glass capillary into a solution of 0.25 g. of pure methyl- α -4,6-O-benzylidene glucoside (0.89 mM.) in 6.3 ml. of alkali. One hour after the addition was complete, the solution was extracted with three 1.5-ml. volumes of chloroform; the combined extracts were washed with a little water, and evaporation of the chloroform left 0.27 g. of sirup. When hydrolyzed as just described for the 2,3-di-O-hydroxyethyl derivative, and chromatographed on paper, this sirup gave the spots for glucose, 3-O-hydroxyethyl glucose, and spot 3 in Fig. 1, which was assigned to 2-O-hydroxyethyl glucose.

(b) Preparation (a) was repeated with five times as much ethylene oxide, the time of addition being 1 hour. When the product, 0.37 g., was hydrolyzed and chromatographed on paper, only the spots for the known 3-O-hydroxyethyl and the 2,3-di-O-hydroxyethyl glucoses appeared, together with the one attributed to the 2-derivative.

6-O-Hydroxyethyl-D-glucose

(a) A solution of 1,2,3,5-di-O-methylene-D-glucofuranose 6-acetate (13), 2.5 g. (0.01 mole), was saponified in 15 ml. of alkali kept for 70° for 15 minutes. Then 4.4 g. (0.1 mole)

of ethylene oxide gas was bubbled into the solution during 1 hour at 70°, and 2 hours later the solution was extracted with six 7-ml. volumes of chloroform. The combined extracts were washed with small volumes of water and were evaporated to an oil, which was dried *in vacuo* over phosphorus pentoxide for 10 days. Yield, 2.59 g. or 103%. This oil was hydrolyzed by boiling for 12 hours with 20 parts of 2% hydrochloric acid, and after the solution had been deionized and evaporated crude 6-*O*-hydroxyethyl glucose remained as an uncrystallized sirup. An aliquot, when chromatographed, gave the spot for glucose and spot 2 of Fig. 1.

(b) Preparation (a) was repeated with three times as much ethylene oxide added during 3 hours. After the product had been hydrolyzed, its chromatogram was developed for 5 days on a 75 cm. length of Whatman No. 1 paper. No spot for glucose appeared, but the spot for the 6-*O*-hydroxyethyl derivative was resolved into two spots differing in R_f value by 8%.

3,6-Di-O-hydroxyethyl Glucose

Six 0.1-g. samples of 3-*O*-hydroxyethyl-1,2;5,6-di-*O*-isopropylidene-D-glucofuranose (I) (5) were boiled in 1 ml. volumes of dry ethyl acetate containing 1% of concentrated nitric acid for 0.5, 2, 8, 12, 20, and 60 minutes. Each solution was neutralized with 0.025 g. of sodium bicarbonate plus 1 drop of water, and was evaporated to dryness. The partly hydrolyzed products were extracted from the residues with acetone, which was later evaporated. Paper chromatograms of the last two products, developed for 12 hours, showed only spots for the original di-isopropylidene derivative (R_f 0.84), faint spots for 3-*O*-hydroxyethyl glucose (R_f 0.18), and a third at R_f 0.71. The inference that the latter spot pertained to 3-*O*-hydroxyethyl-1,2-*O*-isopropylidene glucofuranose was supported by the observation that the R_f value in similar chromatograms of 1,2-*O*-isopropylidene glucofuranose (4) lay between those of glucose and the di-isopropylidene derivative. The chromatograms of the first four partial hydrolyzates revealed increasing amounts of 3-*O*-hydroxyethyl-1,2-isopropylidene glucofuranose, but no hydroxyethyl glucose.

Ethylene oxide gas, 0.1 g., was passed into a solution of half of the neutral product from sample 4 in 0.5 ml. of alkali. After a total time of 1.55 hours, the mixture was extracted with chloroform, and the aqueous residue was saturated with carbon dioxide and evaporated to dryness. The salts were extracted with acetone, which removed the more highly substituted sugars. Evaporation of the acetone solution gave an oil, which was redissolved in 1 ml. of 1% hydrochloric acid and heated at 100° for 3 hours. The resulting hydrolyzate was neutralized with silver carbonate, filtered, saturated with hydrogen sulphide, refiltered, and evaporated to 0.20 ml. Aliquots (0.004 ml., 0.016 ml.) of this solution were chromatographed for 5 days on a 75 cm. strip of Whatman No. 4 paper. One spot was that of 3-*O*-hydroxyethyl glucose; two more, which lay between spots 6 and 7, and 7 and 8 (Fig. 1), were attributed to 3,5-di- and 3,5,6-tri-*O*-hydroxyethyl glucose. The remaining spot was by elimination that of the 3,6-derivative.

The experiment was repeated with the other half of partial hydrolyzate 4 and three times as much ethylene oxide. No additional spots appeared on the chromatogram of the product.

1,2-O-Methylene-D-glucofuranose

A solution of 10 g. of 1,2;3,5-di-*O*-methylene glucofuranose 6-acetate in 300 ml. of dry methanol was quantitatively deacetylated at 6° by addition of 1 ml. of 1 *N* barium

methylate in methanol. After isolation 2 days later as a dry sirup, 13 g. of the dimethylene glucose (II) resulting from two runs was heated in 175 ml. of 2% hydrochloric acid at 100° for 1 hour. The solution was deionized, concentrated to 42 ml., and extracted with eight 70-ml. volumes of ethyl acetate to remove unchanged dimethylene glucose, as shown by the disappearance from chromatograms of the spot of R_f 0.65 pertaining to this substance. Fermentation of the aqueous residue then removed glucose, and the liquor was filtered and evaporated to a sirup, which was taken up in ethanol. Filtration and evaporation of this solution yielded 1.95 g. of a sirup which when chromatographed gave only the two spots of R_f 0.32 and R_f 0.46 for 3,5- and 1,2-mono-*O*-methylene glucose, respectively. After this sirup had partly crystallized, it was diluted with 4 ml. of ethanol and the crystals, 0.24 g., were recovered. One recrystallization from 1.5 ml. of ethanol gave pure 1,2-*O*-methylene-D-glucofuranose melting at 146–146.6°. Found: C, 43.8, 43.7; H, 6.1, 6.3%. Calc. for $C_7H_{12}O_6$: C, 43.8; H, 6.3%.

The substance was not reduced by the Shaffer–Somogyi (21) alkaline copper reagent, and oxidation with sodium metaperiodate according to Bourne, Bruce, and Wiggins (2) gave no detectable amount of formic acid within 2.5 hours. A periodate oxidation by the method of Reeves (19), however, yielded 1.025 moles per mole of formaldehyde. Samples of 1,2-*O*-methylene and 1,2-*O*-isopropylidene glucofuranose were condensed with 10 molar equivalents of ethylene oxide in parallel experiments; the products were hydrolyzed and after deionization the two hydrolyzates gave identical chromatograms containing four spots when developed for 5 days on Whatman No. 4 paper.

2,6-Di-O-hydroxyethyl-D-glucose

A chloroform solution containing 6-*O*-hydroxyethyl-1,2;3,5-di-*O*-methylene glucofuranose, contaminated with unchanged dimethylene glucose, was prepared with a 50-fold molar amount of ethylene oxide in the way already described. This product was distilled *in vacuo* without a column, 0.66 g. of forerun and 0.05 g. of still residue being discarded. Partial hydrolysis of the main fraction, 3.5 g., with 25 ml. of 4% hydrochloric acid at 100° for 75 minutes, was followed by deionization of the hydrolyzate, evaporation to 18 ml., and extraction of the liquor with six 10-ml. volumes of chloroform. These extracts contained the dimethylene glucofuranose and its 6-*O*-hydroxyethyl derivative, both of which appeared to have the same R_f value of 0.65. The chromatogram of the aqueous residue gave the four spots characteristic of partial hydrolyzates of the unsubstituted dimethylene glucose (R_f 0.09, 0.32, 0.46, and 0.65), also the one of R_f 0.12 for 6-*O*-hydroxyethyl glucose, and two new ones of R_f 0.38 and 0.55 which were attributed to the 6-hydroxyethyl analogues of 3,5-*O*-methylene and 1,2-*O*-methylene glucofuranose, respectively.

More of the aqueous residue, 0.65 ml., was spotted in 52 aliquots on sheets of Whatman No. 1 filter paper which had been washed with ethanol, and after development for 30 hours the sections containing the substance of R_f 0.38 were cut out and extracted with ethanol. These extracts yielded 38 mg. of a dry, colorless reducing sirup, which was accepted as 6-*O*-hydroxyethyl-3,5-*O*-methylene glucofuranose. Treatment of this sirup with 1% methanolic hydrogen chloride for 45 minutes at room temperature, neutralization with silver carbonate, and evaporation gave the corresponding methyl glucofuranoside (III) as 38 mg. of a non-reducing oil. A 20-fold molar excess, 0.13 g., of ethylene oxide was passed at 70° into a solution of this oil in alkali, and after 1.6 hours the mixture was deionized and evaporated. Hydrolysis of the residual oil by 5 ml. of

2% hydrochloric acid at 100° for 10 hours was carried out in a sealed tube filled with nitrogen. The hydrolyzate, when deionized and evaporated, yielded 45 mg. of a sirup whose chromatogram contained only a single spot which coincided with spot 5 of Fig. 1 and which was attributed to 2,6-di-*O*-hydroxyethyl glucose and its homologues. Non-carbohydrate polyethylene glycols probably contaminated the product.

2,3,6-Tri-O-hydroxyethyl Glucose

The crude 2,6-dihydroxyethyl derivative, 45 mg., was converted to the methyl glucopyranosides by heating for 7 hours at 65° in a sealed tube with 1% methanolic hydrogen chloride. After neutralization with silver carbonate, the liquor yielded a non-reducing oil, which was dissolved in 0.5 ml. of alkali and treated with 0.09 g. of ethylene oxide gas at 73° for 1.5 hours. After recovery by deionization and evaporation, the oil was hydrolyzed in 2 ml. of boiling 2% hydrochloric acid for 3 hours, and the resulting neutral sirup was isolated. The sugars were separated from relatively large amounts of associated polyethylene glycols by spotting some of the sirup on a series of paper chromatograms. After these chromatograms had been developed, the proper sections of the paper were extracted with water by the method of Dent (8), and the extracts evaporated to 0.07 ml. under a jet of nitrogen. When rechromatographed, the sugars gave three spots, one in the position for 2,6-di-*O*-hydroxyethyl glucose, one of R_f value between spots 7 and 8 of Fig. 1, and presumably the 2,4,6-derivative, and one coinciding with spot 8, which was accepted as that of the 2,3,6-derivative. The material responsible for spot 8 in the hydrolyzate of the hydroxyethylcellulose was recovered and when rechromatographed still had the same R_f value.

Quantitative Determination of Sugars

Exactly 1 g. of the purified hydroxyethylcellulose was hydrolyzed in 50 ml. of 4% hydrochloric acid for 14 hours near 100°, and the hydrolyzate was passed through a column made from 43 ml. of Amberlite IR-4B resin. The neutral effluent, plus 250 ml. of washings from the column, was evaporated under reduced pressure to 5.0 ml., and a series of accurately measured aliquots, each 0.00650 ml., was chromatographed for 2.5 days on Whatman No. 4 paper which had been washed with water. After the sugars were located, they were extracted with water using Dent's technique (8). Spots 3 and 4 (Fig. 1) were extracted together, and so also were spots 5 and 6. In order to obtain consistent blanks, 0.045 ml. of water was used for each square centimeter in the section of paper extracted. The aqueous extracts were not concentrated prior to the determination of their reducing sugar content, because concentration reduced the blank values erratically. The determinations were by stoichiometric oxidation with alkaline hypoiodite as described by Hirst, Hough, and Jones (12) and accounted for 93% of the original purified hydroxyethylcellulose.

ACKNOWLEDGMENT

H. H. B. wishes to express his thanks to the Research Council of Ontario for the scholarship, and to the Pulp and Paper Research Institute of Canada for the two summer stipends, awarded to him during the research.

THE KINETICS OF ADSORPTION OF *n*-HEPTANE ON CARBON BLACK AT LOW PRESSURES¹

J. R. DACEY, D. M. YOUNG,² AND H. J. MCDUGALL³

ABSTRACT

The rates of adsorption at constant pressure of *n*-heptane on 'Spheron 6' carbon black have been measured between 0° and 30° C. in the pressure range 0.005–0.120 mm., using a sensitive quartz spiral technique. From the results the diffusion coefficient has been calculated both as a function of temperature and as a function of surface concentration, and the activation energy for diffusion calculated as a function of surface concentration. The heat of adsorption, calculated as a function of surface concentration from isotherms measured under the above conditions, is the same as the activation energy. Accordingly, a model is proposed in which the heptane molecules diffuse into the powder mass by a series of jumps across the interparticle space. The distribution of heptane within the carbon bed at various times during adsorption has been calculated.

INTRODUCTION

The attainment of adsorption equilibrium with *n*-heptane at room temperature and low pressures has been found to be a slow process on non-porous solids such as graphite (27, 28), molybdenum sulphide (1), and powdered metals (18). Since van der Waals' adsorption per se is invariably instantaneous (7), the delay in reaching equilibrium must be attributed to some slow transport phenomenon. The present study was undertaken in order to determine the mechanism whereby heptane molecules are transferred from the gas phase into the interior of the powder mass.

There exists a comprehensive literature on the diffusion of gases in porous adsorbents (2, 19), but non-porous impermeable powders appear to have received less attention although they offer the considerable advantage that C_0 , the adsorbate concentration on the outer surface of the mass, can readily be evaluated since it is equal to the concentration of adsorbate on the entire adsorbing surface at equilibrium. This parameter is important in the elucidation of the diffusion kinetics. In much of the work reported for porous adsorbents, the value of C_0 could only be estimated (or maintained constant) by approximate methods (14).

The non-porous carbon black designated 'Spheron 6' was deemed the most suitable adsorbent for the present work. It has a specific surface area large enough to permit adsorption measurements to be carried out at constant pressure using a quartz spiral technique, and its crystallographic and adsorptive properties have been extensively examined (6, 5, 17).

EXPERIMENTAL

Materials

A sample of 'devolatilized Spheron 6' was obtained from Godfrey L. Cabot, Inc. through the kindness of Dr. W. D. Schaeffer. Its specific surface area was found to be 131 m.²/g. by the B.E.T. low temperature nitrogen adsorption method (8).

Research grade *n*-heptane (99.9 mole %) was supplied by the National Bureau of Standards.

Apparatus

Approximately 75 mg. of Spheron 6 was accurately weighed into a small aluminum foil bucket which was suspended from a quartz spiral (maximum load 0.1 g., sensitivity 723.7 cm./g.) supplied by the Houston Technical Laboratories. The bed of carbon was cylindrical in shape, 8 mm. in diameter and 5 mm. deep. The whole assembly was housed in a cylindrical glass envelope, 40 mm. in diameter, connected to the heptane reservoir and vacuum pumps.

The pressure of heptane vapor in the system during an experiment could conveniently be kept constant by the use of a two-phase system, as shown diagrammatically in Fig. 1.

FIG. 1. The heptane reservoir.

The 20 cm.³ sample was contained in a massive brass cylinder D, fitted with thick copper fins (not shown) to facilitate heat transfer between the heptane and the surrounding thermostat bath. The cylinder was connected, via a Kovar-Pyrex seal, directly to the apparatus. The surface of the liquid was continuously renewed by means of a magnetic stirrer comprising an iron slug C soldered to a steel spring. A coil surrounding C was connected, through an appropriate timing device, to a d-c. supply. The trap F containing sodium chips was used for storing the heptane sample when not in use and for bulb-to-bulb distillations. The heptane system could be isolated from the rest of the apparatus by closing a metal diaphragm valve B, supplied by Hoke, Inc. The bulb H was equal in volume to the balance case plus the connecting tubing as far as A and B (Fig. 1); its function will be explained later. Dow-Corning silicone grease proved satisfactory as a stopcock lubricant.

The heptane thermostat consisted essentially of a Dewar flask whose annulus enclosed air at atmospheric pressure. It was filled with acetone and supported inside a larger Dewar flask containing liquid air. The inner bath was fitted with a stirrer, an immersion heater, and a pentane thermometer calibrated at 0° and -78° C. Originally the operation of the immersion heater was controlled by a Cenco bimetallic regulator, but it was later found that closer control could be obtained if a nice balance of the heater voltage and the level of the liquid air in the outer bath were achieved. Using the latter method, the maximum variation never exceeded $\pm 0.1^\circ$, which at the low temperatures employed (-80° to -37° C.) corresponds to a variation in pressure of less than 1%. The choice of vapor pressure data used to calculate the heptane pressures is discussed below.

The adsorption thermostat was contained in an 18 in. deep Dewar vessel equipped with a stirrer and an immersion heater controlled by a chloroform-mercury regulator. To maintain a temperature of 15° C., additional cooling was provided by pumping water from the thermostat through a copper spiral immersed in melting ice and returning it to the Dewar vessel. A temperature of 0° was achieved by continuously stirring a mixture of pure ice shavings and distilled water. The maximum variation was always within $\pm 0.01^\circ$, as measured with a mercury-in-glass thermometer calibrated at the National Physical Laboratory. The adsorbent bucket was at all times during measurements at least 12 in. below the surface of the liquid.

Procedure

After the adsorbent had been outgassed at 120° for a minimum period of 8 hours in a vacuum of $\sim 5 \times 10^{-6}$ mm. or better, the balance case was surrounded by the adsorption thermostat. After careful bulb-to-bulb distillations to remove all traces of dissolved gas from the heptane, the reservoir was immersed in its thermostat bath, the magnetic stirrer set in operation, and stopcocks E and G (Fig. 1) opened so that the bulb H became filled with heptane vapor at the pressure of the forthcoming experiment. About 30 minutes later stopcock E was closed, trap F cooled in liquid air until all the heptane in H was condensed, and stopcock G closed. The trap F, which was then allowed to warm to room temperature, thus contained enough heptane vapor to rapidly fill the volume enclosed by stopcock A, valve B, and the balance case to the pressure of the experiment. The two-phase system was, therefore, only required to replace the small amount of heptane vapor 'lost' through adsorption. After the balance case had been isolated from the pumps (stopcock A), the Hoke valve B was cautiously opened and the moment it was fully opened (taken as $t = 0$), the heptane in trap F was allowed to fill the balance case. The movement of the lower hook on the quartz spiral relative to a fixed mark on the outside of the balance case was then followed as a function of time using a cathetometer. At the end of the experiment the valve B was closed and the balance case evacuated through a series of fine capillaries (not shown in Fig. 1) before stopcock A was opened and the outgassing furnace switched on. These precautions were essential to avoid spilling the adsorbent powder by too vigorous pumping.

The Vapor Pressure of Heptane

Mündel in 1913 measured the vapor pressure of heptane between -63° and -40° C. (22). These appear to be the most recent direct pressure measurements available in this temperature range. Rossini and his co-workers have more recently reported precise measurements at temperatures from room temperature upwards (24). The extrapolated pressures from Rossini's data do not agree with Mündel's pressures. The latter used heptane which was separated from a naturally occurring turpentine. He recorded its boiling point to be 97.5° C. while the present accepted value is 98.427° C. (26).

It is possible to calculate the vapor pressure from the relative free energies of the liquid and vapor by means of the equation:

$$RT \ln P = [F^\circ(\text{sat. liq.}) - H_0^\circ] - [F^\circ(\text{gas}) - H_0^\circ] - PB,$$

where $F^\circ - H_0^\circ$ is the relative free energy and B the second virial coefficient. Accurate values of the relative free energy of the liquid from the melting point (182.562° K.) upwards have been published by Douglas *et al.* (15). The same authors have calculated

the relative free energy of the vapor from 25° C. upwards. Using their standard values of enthalpy and entropy at 298.16° K. we have calculated the relative free energy of the vapor at several temperatures below 0° C. by means of the relations:

$$-(F^\circ - E_0^\circ) = TS^\circ - (H^\circ - E_0^\circ),$$

$$H^\circ - E_0^\circ = \int C_p^\circ dT,$$

$$S^\circ = \int (C_p^\circ/T) dT,$$

FIG. 2. The vapor pressure of heptane; $\log_{10} p$ (mm.) is plotted against $1/T$. Mündel's data, - - -; Rossini's data, - · - ·; calculated vapor pressure, ———.

where $H^\circ - E_0^\circ$ is the relative enthalpy. To do this we have assumed that Douglas' equations for the specific heat of the vapor and for the second virial coefficient are valid below 0° C. These equations are:

$$C_p^\circ = 197.28 + 0.4498(T - 370),$$

and

$$B = -776 - 18.71e^{1.400/T}.$$

The results of these calculations are shown in Table I and appear graphically in Fig. 2 together with the vapor pressure curve from Mündel's data and the extrapolated curve from Rossini's data. It is our opinion that the vapor pressures calculated from the thermodynamic data are the most reliable values, and these are used in all the subsequent calculations.

EXPERIMENTAL RESULTS

Equilibrium Measurements

Some of the preliminary rate experiments were continued until equilibrium was established and a number of points on the adsorption isotherms gradually accumulated. However, owing to small ($\sim 1\%$) variations in the surface properties of the adsorbent, the resultant isotherms were not as smooth as was desired. More consistent results were obtained by measuring all five isotherms in a single continuous experiment, starting at 30° , proceeding up the 30° isotherm, changing to 22.5° , descending the 22.5° isotherm,

FIG. 3. Adsorption isotherms of *n*-heptane on Spheron 6.

and so on. The criterion for equilibrium was that at each point no change in the amount adsorbed should be detected over a period of 20 minutes. The results are shown in Fig. 3; the weight of heptane (w), expressed as a percentage of the weight of adsorbent (W), is plotted against the logarithm of equilibrium pressure in mm. Hg. The maximum uncertainty in the cathetometer readings was ± 0.002 cm., so the values of $100w/W$ are accurate to ± 0.004 units.

The heat of adsorption as a function of the amount adsorbed was calculated from the isotherms using the Clausius-Clapeyron equation; a similar calculation was applied to the isotherms measured under similar conditions of temperature and pressure by Smith (27) for the adsorption of heptane on graphite. The monolayer capacity of the present adsorbent ($w/W = 0.038$) was calculated from its specific surface area, taking $64 \text{ \AA}^2$ for the area of an adsorbed heptane molecule (20); that for Smith's graphite was

obtained by applying the 'Point B' method (16) to his four isotherms and taking the mean result. The results for the two surfaces, using these values, are compared in Fig. 4, in which the heat of adsorption is plotted against the estimated fractional surface coverage. The data for Spheron 6 have been calculated using both Mündel's vapor pressures and those derived from the thermodynamic data. The latter are in excellent agreement with Smith's data for graphite. It is interesting to note that Beebe has found for a 5% coverage on Spheron 6 a heat of adsorption of 3 kcal. per mole per $-\text{CH}_2$ group for straight-chain hydrocarbons up to pentane (4). This agrees with our value of 20.50 kcal. per mole for this surface concentration. Polley, Schaeffer, and Smith (23) have also

FIG. 4. The heat of adsorption as a function of surface coverage. ●, Smith's data for graphite; ○, present work using calculated vapor pressure; ◐, present work using Mündel's vapor pressure.

investigated the variation of ΔH with the number of carbon atoms in the adsorbing molecule. The interpolation of C_7 on their graph gives 20.5 kcal. per mole for heptane, in excellent agreement with our results. It is unlikely that the heat of adsorption of heptane on Spheron 6 could be 3 kcal. per mole less than its heat on graphite, which would be so if we accept Mündel's vapor pressure data.

Kinetic Measurements

The solution of the diffusion equation for the conditions prevailing in the present experiments is given by Barrer (3) as

$$[1] \quad Q = C_0 \sqrt{(Dt/\pi)},$$

where Q is the amount of vapor adsorbed in time t , C_0 is the concentration of adsorbed vapor on the outer layer of the powder mass, and D is the diffusion coefficient. Satisfactory and reproducible linear plots of Q versus $t^{1/2}$ were obtained between 0° and 30°C. and over a wide range of pressures; the data for various pressures at 15°C. on sample I are shown in Fig. 5. If the reasonable assumption is made that the outer layer is at all times in equilibrium with the vapor phase, then the value of C_0 may be interpolated from the appropriate adsorption isotherm and D calculated for any particular experimental condition. The equation given above was derived on the assumption that D is independent

of C , but it applies equally well when D is a function of C . In the latter case the D determined is an average value, the exact nature of the average depending on the functional relationship between D and C (9).

Two series of rate measurements were made using two different samples of Spheron 6 of approximately equal weights (0.0745 and 0.0738 g.). Twenty-four rate measurements were made with the first sample at three different temperatures, 30.2°, 15.2°, and 0.0° C., of which the six carried out at 15.2° C. are shown in Fig. 5. In the second series 18 rates

FIG. 5. The rate of adsorption of heptane on Spheron 6 at 15.2° C. and various concentrations; Fick's law is obeyed since the amount adsorbed plotted against $\sqrt{t}$ gives a straight line. The concentrations used were: 0.0155, 0.0135, 0.0111, 0.0093, 0.0073, and 0.0059 grams of heptane per gram of charcoal.

were determined at five different temperatures, 30.0°, 22.5°, 15.0°, 7.5°, and 0.0° C. The two samples differed slightly in weight, shape, and density of packing. Because of this, the adsorption at any given temperature and pressure was slightly different for each sample. On the average, sample II adsorbed the vapor 12% more slowly than sample I.

In Fig. 6 the slopes of the Q vs. $t^{1/2}$ plots for series I are shown as a function of C_0 , the equilibrium surface concentration. If the coefficient of diffusion were independent of the concentration of adsorbed molecules on the surface over which diffusion is taking place, the data in Fig. 6 would give straight lines. The fact that the lines curve rapidly upward as C increases implies that D increases, probably exponentially, with surface coverage. During any given run D varies throughout the bed as the adsorbed concentration varies, and the value of D calculated from equation [1] is an average D which we will designate by $\bar{D}$. In Fig. 7 the logarithms of $\bar{D}$ for each temperature are plotted against C_0 . The straight lines were fitted to the experimental points by the method of least squares.

The Calculation of D as a Function of C

Crank and others have developed a number of methods for calculating the concentration dependence of diffusion coefficients from data of the kind given above (9). All of these methods involve some form of approximation since the differential equation for diffusion where D depends on the concentration cannot be integrated directly (2, 8, 16).

Crank has found that the relationship

$$\bar{D} = \frac{5}{3} \frac{1}{C_0^{5/3}} \int_0^{C_0} C_0^{2/3} D dC$$

holds with an accuracy of 1% for diffusion coefficients that depend on the concentration in many different ways (10). Thus by plotting $\frac{5}{3} \bar{D} C_0^{5/3}$ against C_0 one may determine D

for any concentration by graphical differentiation. The data for series I at 15° C. treated in this way are shown in Fig. 8. The results are given in Table II. This method is known as the 'Method of Weighted Means'.

FIG. 8. The plot at 15° C. of $\frac{3}{5} \bar{D} C_0^{5/3}$ vs. C_0 from which D as a function of C_0 is determined by Crank's method of "Weighted Means."

By assuming an exponential relationship between $\bar{D}$ and C_0 one can extrapolate $\bar{D}$ to zero concentration and obtain a value of $\bar{D}_0$. This can be done from the series I data of Fig. 7. Crank has published a correction curve which gives the difference between $\bar{D}/\bar{D}_0$ and $(1/C_0) \int_0^{C_0} (D/D_0) dC$ for exponential dependence of D on C (10). Making use of this curve and following the procedure given by Crank we have calculated D as a function of C by this method. The data for series I appear in Table III. Values of $\bar{D}$

0.009	9.22×10^{-4}	1.88×10^{-3}	-2.726
0.008	7.51×10^{-4}	1.50×10^{-3}	-2.824
0.007	6.13×10^{-4}	1.10×10^{-3}	-2.959
0.006	5.00×10^{-4}	8.05×10^{-4}	-3.094
0.000	1.46×10^{-4}	1.46×10^{-4}	-3.834

were taken from Fig. 7 in the concentration range 0.005 to 0.01. Higher values of concentration could not be used because the correction curve is only applicable below $\bar{D}/D_0 = 30$.

In Fig. 9 the results for the above methods are combined to show the exponential dependence of D on C for series I data.

The series II data (given in Table IV) were treated only by the "Correction Curve" method. The results are shown graphically in Fig. 10. In this case the measured values of $\bar{D}/D_0$ were generally less than 30 so that the calculated D values correspond to the experimental points.

The Calculation of Activation Energies

By use of the Arrhenius equation one may calculate, from the above data, the activation energy for diffusion as a function of surface coverage. The results of this calculation are shown graphically in Fig. 11. The equations relating activation energy and concentration for each series of data are:

$$E_{\text{I}} = 20,700 - 280,000C,$$

$$E_{\text{II}} = 20,800 - 294,000C.$$

FIG. 11. The activation energy for diffusion plotted as a function of concentration. The heat of adsorption calculated from the isotherms is included for comparison. ●, series I data; ○, series II data.

FIG. 12. The rate of adsorption of heptane on Spheron 6 which had already been equilibrated to various heptane concentrations. Curves I, II, and III were equilibrated to 0.0088, 0.0070, and 0 grams of heptane per gram of charcoal respectively.

Further Rate Measurements

A number of rate measurements were made where the heptane was allowed to adsorb on a surface which had been previously equilibrated to some predetermined value of C_0 . As would be expected the rates of adsorption for equal concentration gradients were very much higher than when adsorption occurred on a completely bare surface. The data

for several conditions of temperature and concentration appear in Table V while Fig. 12 shows the rates for a constant concentration gradient of 0.060 adsorbed on initial concentrations of 0.088, 0.070, and 0.

DISCUSSION

The methods of calculating D as a function of concentration involving the fitting of data to generalized curves, the use of correction curves, and the determination of slopes and intercepts of lines which are not entirely free from ambiguity cause some uncertainty in the final results. However, despite this, the over-all picture is clear, that is, that the activation energy for the movement of the heptane into the bed of Spheron 6 is not significantly different from the heat of adsorption. From this we conclude that the rate-determining step in the adsorption of heptane on Spheron 6 is one which involves desorption of the heptane molecule from the surface.

The particles of Spheron 6 are known to be approximately spherical, each sphere being composed of a number of similar graphite crystallites (6, 17). From the particle size distribution a value of approximately 250 Å is obtained for the arithmetic mean particle diameter (25). If the density of a spheron particle is 2.2 g. per cc., then the average width of the spaces between the particles must be 500 Å to satisfy the density of packing used in these experiments, i.e. 0.075 g. occupying a volume of 0.25 cc. There is, therefore, ample room for the passage of a heptane molecule, the Sutherland collision area of which is given by Melaven and Mack (21) as 26.7 Å (2). The mean free path of *n*-heptane vapor at 15° C. and 0.05 mm. pressure (the average value in the present work) is approximately 0.2 mm., which is 4×10^8 times the average distance between the spheron particles. It is, therefore, concluded that the vapor cannot enter the spheron bed by Poiseuille flow but must move by Knudsen flow.

When the vapor is first admitted to the adsorbent there is nothing to prevent the rapid establishment of adsorption equilibrium on the uppermost particles of the powder mass. However, a heptane molecule is able to penetrate only by pursuing a zig-zag path brought about by collisions with adsorbent particles. Since heptane is quite strongly adsorbed under the present experimental conditions, a heptane molecule striking a vacant adsorbent site will become adsorbed and remain so until it can acquire sufficient energy to re-evaporate. The energy necessary for evaporation is equal to the differential heat of adsorption, the value of which depends on the fractional surface coverage of the particular element of surface from which the molecule evaporates.

When a molecule evaporates it may leave the surface in any direction, the probability of it taking a given direction being given by the Knudsen cosine law. As long as a concentration gradient exists, however, more molecules will move with a forward component than with a backward one, so that a net forward flow results. The rate of attaining equilibrium will depend not only on the concentration gradient but also on the time

the molecules moving into the bed spend 'resting' in the adsorbed state. This latter factor is temperature dependent so that for the same concentration gradient, adsorption takes place quicker at higher temperatures. Since the activation energy necessary to desorb is the greater the more sparsely the surface is covered, the more advanced a molecule is the more slowly it will move into the carbon bed. This will cause a steeper concentration gradient towards the front of the advancing heptane than if D were independent of surface coverage. From the dependence of D on C one can calculate the distribution of heptane in the charcoal bed at any time after exposure to the vapor. This has been done, by the method of Crank and Henry (11), for a heptane pressure of 0.002 mm. and a temperature of 0° C. The results are shown graphically in Fig. 13.

FIG. 13. The concentration distribution of *n*-heptane in a 5 mm. bed of Spheron 6 at various times after exposure to heptane vapor at a pressure of 0.002 mm. at 0° C.

Confirmation of the proposed mechanism comes from the few data obtained when heptane was allowed to move into a bed already partly but uniformly covered with adsorbed vapor. At 15° C. for instance, and a concentration gradient of 0.006, $\bar{D}$ increased from 7.08×10^{-5} for a bare surface to 31.0×10^{-5} for a coverage of 0.007 and 58.3×10^{-5} for a coverage of 0.0088 g./g. From the linear variation of $\log \bar{D}$ with C one can predict that these values should be 35.5×10^{-5} and 59.7×10^{-5} .

It is not difficult to reconcile the model with the theoretical results of Crowell and Young (12, 13), who have shown that there is virtually no barrier to the translation of an argon atom on a uniform basal plane of graphite. It is likely that a considerable potential energy barrier exists across the points of contact of cotangent Spheron 6 particles where, to cross from one particle to its neighbor, a molecule must pass along a narrow crevasse within the potential fields of both surfaces (that of the particle which it is leaving and that of the particle to which it is destined). Thus, even if an appreciable number of adsorbed molecules are able to surmount the potential barrier, which is of the same order of magnitude as the heat of adsorption, the points of contact are so small in area and few in number that a negligible proportion of adsorbed molecules are able to make use of this mode of transport.

These considerations do not, of course, apply to migration across the boundaries separating the graphitic crystallites which compose each Spheron 6 particle, a process which probably requires a somewhat lower activation energy. Thus, while migration

over the surfaces of the individual particles may play an important role in the establishment of adsorption equilibrium, it is not rate-determining.

ACKNOWLEDGMENTS

The authors are grateful to Professor Sir Eric Rideal, F.R.S., for his interest in this work. They wish to thank Dr. R. Nelson Smith for making available his tabulated isotherm data and to acknowledge the assistance of Mr. J. Smelko in the developing of the experimental methods. The Defence Research Board of Canada provided generous financial support, under D.R.B. Grant 8220-12.

A STUDY OF SULPHATE IN NITROCELLULOSE USING $S^{35}O_4^{=}$ AS TRACER¹

A. G. BRICKNELL, L. W. TREVOY, AND J. W. T. SPINKS

ABSTRACT

$S^{35}O_4^{=}$ has been used to show that the residual sulphur in nitrocellulose is not held by adsorption on the surface, as sulphate. Evidence has been obtained to support the view that the sulphur which is not removed by washing after nitration and subsequent stabilization is present within the fibrous structure.

INTRODUCTION

It is well known that commercial nitrocellulose contains a small amount of residual sulphur, representing about 0.05–0.10% of the product, expressed as sulphuric acid, which resists removal by the usual stabilizing procedures and to which the tendency of nitrocellulose to instability in storage may be attributed. Many authorities suggest that the sulphur is chemically bound (7, 10, 11) through an ester linkage, but the alternative suggestion that this residue is adsorbed has also been made (19). More recently Smith (13) has suggested that the residue is not adsorbed in the usual sense, but that there is an inclusion of free sulphuric acid within the fiber. This could result from swelling during the initial stages of nitration, which would permit entry of the acid, and subsequent shrinking during drowning, washing, and stabilization. Reeve and Giddens (16) have also suggested that free sulphuric acid might be held within the fibrous structure and that its retention would not make the assumption of chemical bonding essential but that it might be explained on a basis of selective permeability of the membrane.

Relatively little work has been done to determine whether the adsorption mechanism is the correct one. The object of this investigation was to apply radioactive tracer techniques to the problem.

If the residual sulphuric acid were merely adsorbed, it would be expected that if the material were brought into contact with a further supply of sulphuric acid in which the sulphate ion was tagged with radioactive sulphur, S^{35} , exchange would take place and as a result the nitrocellulose sample would acquire activity while the original active preparation of sulphuric acid would decline in activity.

Since the molecular species involved are identical, there seems no reason to suppose that exchange would not be complete in the case of adsorption of sulphuric acid on the nitrocellulose. If the acid were held by inclusion within the fibers, exchange might be expected to depend on the possibility of swelling of the fibers. The ultimate equilibrium achieved would depend upon the diffusion rate and thus upon the elapsed time, the concentration, and the temperature at which the experiment was performed.

The first and principal portion of the work to be described consisted in the placing of samples of nitrocellulose of known weight and sulphur content into carrier-free solutions of active sulphuric acid of known activity. The system was shaken, continuously at room temperature and at frequent intervals at higher temperatures, and at definite time inter-

¹Manuscript received March 21, 1957.

Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Sask.

vals aliquots of the active solution were withdrawn and their activity determined. The nitrocellulose samples used were both stabilized and unstabilized, damp and dry. The detail of this work will be found in the experimental section of this account.

A second and briefer experimental series was conducted on samples of nitrocellulose recovered after the exchange experiments had been completed, to determine the magnitude of any acquired activity and any variations it might exhibit with varying treatment of the nitrocellulose.

EXPERIMENTAL

Materials

Sulphur-35.—This was obtained as carrier-free $\text{H}_2\text{S}^{35}\text{O}_4$ in dilute hydrochloric acid from Atomic Energy of Canada Limited. The activity was 1 mc. per ml. The acid contained no detectable inactive sulphate or sulphur, and half-life and absorption half-thickness agreed with values given in the literature (1).

Nitrocellulose.—This took the form of nitrated cotton linters. Four samples were employed:

Sample A. Unstabilized—654 mg. H_2SO_4 per 100 g.

Sample B. Stabilized—60 mg. H_2SO_4 per 100 g.

Sample C. Unstabilized—412 mg. H_2SO_4 per 100 g.

Sample D. Stabilized—125 mg. H_2SO_4 per 100 g.

Samples A and B were of the same batch, manufactured February 4, 1954. Sample B was stabilized by refluxing for 30 hours with water. Both sulphate analyses were by Canadian Armament Research and Development Establishment. Samples C and D were not of the same batch. Sample C was manufactured March 28, 1955, and Sample D on April 1, 1955. Sample D was stabilized by boiling with distilled water for 9 hours, the water being changed every 3 hours. Samples C and D were shipped in 2.0 *N* NaCl solution. The above material was supplied by Canadian Armament Research and Development Establishment, Valcartier, Quebec.

Barium chloride.—This material was crystalline $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$ of A.C.S. Reagent Grade. It was used as supplied by Anachemia Chemicals Limited, Montreal.

Counting equipment.—A thin window Geiger tube, with window thickness 1.4 mg. per cm^2 , was employed in conjunction with a Nuclear Instrument and Chemical Corporation scaler.

Storage and Washing of Nitrocellulose

The samples as received were well agitated with distilled water in a 4-liter beaker, using 3 liters of water for each of four to five washings. The material was stored in distilled water and the unstabilized samples were washed every 2 or 3 days. Stabilized samples of nitrocellulose were usually washed at the same time, though frequent washing is not so important in this case.

The samples that were forwarded packed in 2.0 *N* sodium chloride solution gave great difficulty. Continuous washing in distilled water for 48 hours was recommended but could not reasonably be arranged for. These samples were washed four to five times daily, with vigorous stirring, in 3-liter quantities of distilled water, the samples being left in the water to equilibrate between changes. It was found that 30 such washings were required before the wash water, on being tested with silver nitrate, showed no more than a faint opalescence.

When samples were required for experimental purposes the whole supply of a given nitrocellulose was transferred to a large beaker and washed three times with 2 liters of distilled water, vigorous stirring being given. After each wash, the material was poured onto an 8-inch Büchner funnel and pressed well down. After the third washing and pressing, the required sample was taken.

Sampling of Nitrocellulose

When moist samples were required, a bulk of nitrocellulose was squeezed as dry as possible, a moist sample taken from the center of the mass and placed in a weighing bottle, and after weighing a suitable portion removed for the experimental work. The balance of the material was dried to constant weight, either for 10 hours in a vacuum oven at 42° C. or for 14 hours over phosphorus pentoxide in a vacuum desiccator at room temperature (8, 9), and the moisture content calculated. Each of these drying methods had been shown to give reproducible results. Dried nitrocellulose, obtained as described, was employed as dry samples and also in determinations of sulphur content.

Determination of Sulphate in Samples

The modification of Dunncliff's method, as described by Kierstead and Myers, was used (9).

"Infinite Thickness" for Labelled Barium Sulphate Precipitate

"Infinite thickness" was determined to be 30–35 mg. of barium sulphate per sq. cm. The value is in good agreement with the suggestions of Libby (12) and current estimates of the range of S^{35} radiation (20). Weights of precipitate used for counting were made just sufficient to exceed this value (1).

Method

Samples of nitrocellulose were shaken with dilute solutions of $H_2S^{35}O_4$ for successive known periods, and aliquots of the active acid were removed at the end of each period. The aliquots were added to fixed quantities of carrier sulphuric acid and the whole precipitated as barium sulphate, which was filtered in such a way as to give a disk of reproducible dimensions. The activity of each disk was then determined.

Having comparison disks prepared from the active acid prior to addition of nitrocellulose, it was felt that any significant change in activity due to exchange of active sulphate with inactive sulphate residing upon the nitrocellulose could easily be followed. In order to make the method sensitive the active acid was used carrier-free, and the total number of active atoms present in the acid was made about 10^5 times as small as the number of inactive sulphur atoms present in a suitable sample of the most highly stabilized nitrocellulose. At the same time, it was necessary to ensure that sufficient activity was present so that removal of a very small aliquot, insufficient to affect the total concentration of activity too greatly, would still give an adequate count when precipitated as barium sulphate.

Trial experiments showed that a sample of nitrocellulose of convenient size to shake in a stoppered tube of 30 ml. capacity had a dry weight of about 0.15 g., while it required a volume of 10 ml. of liquid to give adequate free liquid for removal of aliquots.

The tubes employed were made from 24/40 standard taper outer joints, suitably sealed off and provided with ground glass stoppers.

Prior to use, the glass tubes were cleaned with acid and alkali, followed by five scrub-

In order to ensure that any change in activity noted during an experiment was due to exchange with inactive sulphate and not to adsorption upon the glass surface, when the active acid had been placed in the tubes they were stoppered and shaken under the conditions of the particular experiment for $\frac{1}{2}$ hour before the initial reference aliquot was removed.

FIG. 1. Variation with time of activities of solutions in contact with nitrocellulose. Series 2-9 as in Table I. The activity of each aliquot is expressed as a percentage of the mean activity of all aliquots taken from a particular sulphate solution (see Table II). Key: unstabilized nitrocellulose —●—●—●—●—●; stabilized nitrocellulose —●—●—●—●—●; blank —○—○—○—○—○.

The nitrocellulose sample was then added, and the tube stoppered and shaken. Since ovens were used for the runs carried out at 42° and 80° C., the temperature was not well controlled during the 2-minute period prior to the removal of the first aliquot. For all other periods of time the ovens were observed to vary only by $\pm 1.0^\circ$ C.

For experiments made at room temperature shaking was continuous, a Burrell wrist-action machine being used. Those experiments carried out at higher temperatures did not permit use of this method, but the tubes were hand shaken at frequent intervals.

In general, aliquots were removed from the active solution after 2 and 30 minutes, and 2, 6, 24, and 48 hours. As previously mentioned, the initial volume of active acid decided upon was 10 ml., and the aliquots were withdrawn with a 100 λ micropipette. In all experimental series other than the first two a blank was run and aliquots withdrawn from it at the same intervals as with the samples being investigated.

The radioactive sulphate was precipitated using 4.0 ml. 0.202 *N* sulphuric acid as carrier and 7.0 ml. 0.2 *N* barium chloride solution plus hydrochloric acid. Precipitates were digested on the steam bath for $\frac{1}{2}$ hour and allowed to stand overnight prior to filtering. The apparatus used for filtering had a filter disk of porous stainless steel (15) and Whatman filter paper No. 40 was used. The surface area of the disk was 2.69 sq. cm. By strict adherence to a standardized procedure, counts on various samples agreed to within the limits to be expected for radioactive samples. Ten thousand counts were usually measured.

The results of the experiments are summarized graphically in Fig. 1, in which the activity relative to the mean is shown against an arbitrary time scale. These diagrams are intended merely to illustrate that the results obtained were random in distribution.

TABLE I

Mean					2.02

The points are joined solely to facilitate following the readings obtained for a given sample. The standard deviations of the activities with respect to the mean are recorded as a percentage in the last column in Table I. It will be noted that the mean of the standard deviations is 2.02%. Also, that the deviations for the blank experiments vary as widely as do those for the experiments involving nitrocellulose, and that we might expect a deviation of 1% on the basis of counting statistics alone. Consequently, we feel that we can say that there was no appreciable exchange under the conditions of the experiments, i.e., using tracer quantities of $S^{35}O_4^{=}$, times up to 48 hours, and temperatures from 24° to 80° C.

The reversibility of adsorption has been experimentally established in numerous cases, and there would seem to be no reason to expect that sulphate adsorption on nitrocellulose would form an exception (3, 4, 5, 6, 18). It thus seems highly probable that had the sulphate of the nitrocellulose merely been adsorbed in the physical sense, it would have undergone a considerable and easily measurable exchange under these conditions. The fact that it did not seems to indicate quite definitely that the residual sulphur is not held by adsorption as sulphate. This does not, of course, rule out the possibility that the sulphuric acid may be held by occlusion, as suggested by Smith.

Δ , 1 register = 64 counts.

The diagrams relating activity and time, though indicating that the number of points lying within the statistical limits is appropriate for a series of values which should all be of the same magnitude, do occasionally tend to suggest a slight increase in activity

with time. Since the trend is followed by the blank determinations in these cases, it would, at first sight, seem reasonable to attribute the effect to evaporation losses.

All activity values appropriate to a given time interval were next averaged, and while these average values still lay between the standard deviation limits they showed a definite increase in activity with time.

The capacity of nitrocellulose to hold water is extreme, and a sample squeezed "dry" may still retain as much as 25% of water by weight. Thus, since the majority of determinations made in this work involved dry samples, water absorption may well account for the tendency to increasing activity, particularly since plotting the mean values of activity against time indicated that the rate of increase was greatest during the early stages of a run. The much reduced rate later observed might be the result of evaporation losses. It would seem that the apparent steady increase in activity shown by the blank in Series 7 was the result of some individual circumstance obtaining in this case, since the experimental temperature was 42° C. and neither of Series 3 or 5, both carried out at 80° C., shows such a definite gain on the part of the blank.

One would expect such an effect due to water absorption to be much less marked when moist samples were examined, and this is indeed the case in Series 8 and 9.

These results are also confirmatory of suggestions which have been made that sulphuric acid is not adsorbed physically by nitrocellulose (14), since, if it were, a fall in activity would have been expected in these experiments, even though no exchange might be taking place.

Extended Hydrolysis of Stabilized Nitrocellulose

Robertson, in reporting his early work on the stabilizing of nitrocellulose (17), pointed out that a satisfactory method must be rapid and produce minimum degradation of the material and fall in nitrogen content. It, therefore, appeared of interest to determine how a stabilized sample behaved on further boiling treatment.

To this end, a fairly large portion of Sample B, containing 60 mg. H_2SO_4 per 100 g., was placed in a 2-liter flask fitted with thermometer, stirrer, and reflux condenser. One liter of distilled water, which had been tested for sulphate, was added and the material digested with continuous stirring for 24 hours. It was not found possible to reproduce the beating action of a commercial stabilizer, but the contents of the flask were stirred in the top by a rotating stirrer and in the bottom by a magnetic stirrer, the two producing considerable turbulence. The temperature was maintained at 90° C. to 95° C.

After 24 hours the water was poured off and retained, and a further liter of distilled water was added to the flask. The operation was continued for a further 24 hours and then the second batch of extract was added to the first, the residual nitrocellulose being well washed and the washings added to the combined extracts. The extract was carefully evaporated down to small volume, treated with concentrated nitric acid and potassium chlorate, and evaporated to dryness to oxidize any organic matter in suspension or solution. Concentrated hydrochloric acid was then added and evaporation to dryness repeated. After the residue was dissolved in distilled water, sulphate was determined (1).

Sample B was employed as being the most highly stabilized available, and though it was old, it had been regularly washed and showed no visible signs of decomposition.

After 24 hours' refluxing, decomposition was pronounced, the material being quite yellow and showing some degradation. After the second period of reflux, the color was

brown-yellow, and degradation was such that the fibrous network of the sample had completely disappeared. The residue was finely divided and soft to the touch.

The barium sulphate recovered corresponded to a sulphuric acid content of 52 mg. per 100 g. of sample, or 87% of the residual H_2SO_4 originally present.

Therefore the residual sulphate can be removed by extending the stabilizing treatment only at the expense of degradation and decomposition of the nitrocellulose. The results are similar to those reported by Chédin and Tribot, who found that when nitrocellulose was boiled with water for an extended period of time, most of the residual sulphuric acid came off in the first 90 hours (2). An approximate value for the removal after 48 hours, taken from their figures, is 85%, which is in good agreement with the figure found above.

Examination of Recovered Samples of Nitrocellulose

Since the work done by measuring activity of the $\text{H}_2\text{S}^{35}\text{O}_4$ solution had indicated no significant exchange with the sulphate present in the nitrocellulose, the samples employed in exchange series 7 and 9, together with a pair of oven-dried samples, were recovered, washed, dried, and counted with the object of determining whether any activity was resident upon them.

The washing method adopted was shaking for 4-5 minutes with 25 ml. of distilled water in a stoppered tube, five such washings being given. The samples were then filtered on a small Hirsch funnel, well pressed, and dried over phosphorus pentoxide in a vacuum desiccator. They were then worked by hand into circular pads, as nearly as possible of the same diameter as the barium sulphate disks previously counted.

It has been suggested that residual sulphate present in cellulose acetate is entirely in the form $\text{R.SO}_4\text{H}$, and that complete drying of cellulose acetate causes splitting off of the sulphate-containing groups (9). For comparison purposes, therefore, some recovered cellulose acetate samples were also examined. These samples, having been counted after recovery as described above, were in each case soaked again in distilled water, washed, collected, and dried, the object of this operation being to determine whether the original drying had freed any of the sulphate groups which should then be washed off by this second process. The results are shown in Table III.

TABLE III
SAMPLES RECOVERED OR SEPARATELY TREATED AT 42° C.

* V.d.—vacuum dried.

had earlier been obtained, but the recovered samples also showed considerable evidence of decomposition, having been stored for some time under rather unfavorable conditions.

It was felt that the change in behavior accompanying decomposition suggested that the activity might be within the cells of the fibers and that therefore cell rupture and subsequent washing might cause a decline in activity.

Some samples were therefore torn apart extensively under 5 ml. of cold water, using steel tweezers. The tearing was carried out for at least 2 hours until each sample had completely lost its reticulate structure and only very finely divided material remained. This treatment must have caused the fracture of a moderate proportion of the cells. These teased samples were washed, separated by centrifuging, dried, worked into pads as before, and counted. The results obtained are shown in Table V.

TABLE V

Ref. No.	Initial appt. sp. act. (c.p.m./mg.)	Wt. recovered after tearing (mg.)	Net count (reg./40 min.)	Appt. sp. act. (c.p.m./mg.)
1	0.210	109.1	10.41	0.153
7	0.475	94.0	22.47	0.383
8 (a)	0.442	74.8	18.33	0.392
(b)	0.392	70.2	14.09	0.321

At all stages the recovered dried material was weighed so that the apparent specific activity could be determined. These activities could then be compared satisfactorily with one another since changes were not simply the result of loss of material during manipulation. Correction for decay was also made. Nevertheless, the results are not considered to be more than indicative, as the likelihood of working the different samples into exactly similar pads was small.

First, it will be noticed that moist cellulose acetate showed a specific activity about 30 times greater than the dried material, and further, that after soaking, drying, and again recovering, the specific activity fell to about one-seventh of the original value. These results are in agreement with the view that the sulphate groups are split out on complete drying.

The first results using nitrocellulose, shown in Table III, indicated much lower specific activities, which were of the same order for both the stabilized and unstabilized samples, though the sulphate content in the latter case was four times that in the former. Soaking and drying also caused a decline in the specific activities, though not so extensive as in the case of cellulose acetate. Further, the ratio of the specific activities of moist cellulose acetate and moist stabilized nitrocellulose was 22:1, while that of the respective sulphur contents was 17:1. Since the cellulose acetate was much more finely divided than the nitrocellulose and its sulphate content therefore more accessible to the active acid, these similarities in behavior are suggestive that the sulphate might be in the same condition in both cases. Even though the sulphuric acid might have penetrated the cellular structure as the result of swelling during immersion in the strong nitrating acid there seems to be no greater likelihood of its remaining uncombined than its reacting with hydroxyl groups directed within the cell. The fact that the activities of stabilized and unstabilized samples were of the same order also suggests that a particular fraction of the residual sulphur was concerned with the activity. Removal of the sulphate present in stabilized nitrocellulose can also be effected only at the expense of degradation.

The figures given in Tables IV and V support these suggestions. The higher specific activities noted in Table IV would be expected if partial decomposition had resulted in some degradation and therefore greater accessibility of sulphate groups. Also it will be observed that the moist samples showed notably higher activities than the dried, in agreement with the suggestion that drying causes splitting off of sulphate groups, and any activity associated with such groups would be washed away during the preparation of the samples for counting.

After tearing, a decline in activity of about 25% was observed in each case, and in the case of a sample torn in two stages, a decline was observed at each stage.

CONCLUSION

From the foregoing, it seems to be definitely established that the residual sulphur in the nitrocellulose is not held, as sulphate, by adsorption. The residual sulphate can be removed by extending the stabilizing treatment but only at the expense of degradation and the decomposition of the nitrocellulose. This fact, supported by the results obtained from investigation of the activity of nitrocellulose which has been in contact with active sulphuric acid, suggests that the residual sulphate is present within the fibrous structure.

A SYNTHESIS OF PORPHOBILINOGEN¹

A. H. JACKSON² AND S. F. MACDONALD

ABSTRACT

The pyrrole Ib has been converted by several routes into 5-carboxy-porphobilinogen (IIe), the lactam of which is easily decarboxylated to porphobilinogen lactam (IVc). Hydrolysis of the latter gives porphobilinogen (V).

Porphobilinogen (V) (1) is an intermediate in the biosynthesis of heme and occurs in the urine of patients with acute porphyria. Its Knorr synthesis from δ -amino-levulinic acid has been carried out both enzymically (7) and by a purely chemical method (16). Also, although porphobilinogen was not isolated, paper chromatography indicated that it was formed by the decarboxylation of 5-carboxy-porphobilinogen (IIe) (15). The latter was synthesized by Prasad and Raper (14) from Ia (11) over I(X = CH₂OH), Ib, Ic, and the free base Ie.

We have reported the conversion of Ia through Ib and IIb into IIc, which took up 2 moles of hydrogen in dilute ammonia over palladium black (9). The reduction product formed stable colorless needles and was presumed to be 5-carboxy-porphobilinogen (IIe). It was not reported because the analyses were low and variable and because it could not at the time be satisfactorily characterized.

The same product (IIe) has now been obtained from Ib (9) using the same reactions in different orders and first converting it into the oxime Ic. This was hydrolyzed to the known IIc (9), which was reduced as above to IIe. Alternatively, either Ic or the nitrile Id obtained from it were reduced in ethanolic hydrochloric acid over palladium to the hydrochloride of Ie. When Ic was reduced in alcoholic ammonia the product was the lactam III, also obtained from the hydrochloride of Ie with alkali. Both the hydrochloride and the lactam also gave IIe on alkaline hydrolysis. The over-all yields of IIe from Ia by these different routes are similar, but Ic and the hydrochloride of Ie are the optional intermediates most readily isolated.

However synthesized, the infrared spectra of the 5-carboxy-porphobilinogen (IIe) in Nujol mull showed inconsistent differences and the carbon analyses remained low and variable. This could not be due to incomplete reduction of the oximino group because the reduced intermediates were well characterized and analyzed well. The nature and purity of the 5-carboxy-porphobilinogen is no longer doubted because all samples give identical X-ray powder photographs if not allowed to dry, behave identically on paper chromatography, and give the same well-characterized lactam (IVb). We assume that unstable hydrates or polymorphic forms were responsible for the difficulties.

As noted in the Experimental section, our results differed from those reported by Prasad and Raper (14) in that our Ib and Ic melted higher, we obtained the lactam III instead of their free base Ie, and our IIe was colorless and stable, like analogous acids when these are not readily decarboxylated. The analogues of Ie with free acetic acid groups, IIe, V, VIIb, are obtained without difficulty.

V

VI

As pyrrole nitriles were assumed to be rather unreactive (4a), we attempted the preparation of II*d*, which could presumably be decarboxylated conveniently. However, not only was the nitrile group of I*d* easily reduced, but alkaline hydrolysis gave either VII*a* or II*f*. Also, the partial hydrolysis of III did not provide a shorter route to IV*b* but gave either IV*a* or VII*b*. The latter formed a hydrochloride which was also obtained by the reduction of VII*a*.

We had assumed that II*e* would be relatively difficult to decarboxylate like 2-(hydroxymethyl)-5-carboxy-pyrroles (17) or 5,5'-dicarboxy-dipyrromethanes (4c), whereas its N-acyl derivatives would decarboxylate with water at 100° like 2,3,4-tri-alkyl-5-carboxy-pyrroles (4b). Repeated unsuccessful attempts were made to prepare such acyl derivatives of II*e*, particularly the carbobenzoxy derivative, in view of the apparent instability of porphobilinogen toward acid and alkali (1). Neither could porphobilinogen be isolated after heating II*e* under various conditions, e.g., in 2 *N* hydrochloric acid, or better, in aqueous pyridine with copper acetate according to Rimington and Krol (15), although paper chromatography indicated its presence. As V gives a much more intense Ehrlich reaction than does II*e*, the quantitative course of this reaction cannot be satisfactorily followed by paper chromatography. Finally, II*e* was converted into its lactam IV*b* under conditions which had converted porphobilinogen into its lactam (1), and boiling water decarboxylated IV*b* to porphobilinogen lactam IV*c*. The identity of the latter with material of natural origin (1) was confirmed by mixed melting point, paper chromatography, infrared spectra, X-ray powder photographs, and the melting points of the derived methyl ester and keto-lactam VI (1). This last was also prepared more directly from IV*b*.

Although porphobilinogen, V, was presumably unstable in alkali (1), it was obtained from its lactam IVc with sodium hydroxide at 100°, incomplete hydrolysis giving the best yield. The removal of about 10% of unchanged lactam by repeated treatment with lead and mercuric acetates and recrystallizations (1) reduced the yield from 80 to 20%. The identity and purity of the synthetic porphobilinogen was established by paper chromatography, and by the infrared spectra and X-ray powder photographs of the natural and synthetic porphobilinogens and of their hydrochlorides. Also, the nature and amounts of the porphyrins formed indicated that the natural and synthetic porphobilinogens behaved identically in an appropriate enzyme system.

There is evidence that the biosynthesis of type III porphyrins from porphobilinogen (PBG) proceeds through uroporphyrinogen III (12, 13). As the yield of porphyrin produced enzymically from porphobilinogen is nearly quantitative (2c), the most direct routes involving analogues of known reactions (5, 6) would be through cycles involving a penta or higher polypyrrane. The simplest possibilities would be expressed by³

The above pyrrole, opsopyrrole-dicarboxylic acid, is known (9), and possible dipyrromethane intermediates are being reported elsewhere.

EXPERIMENTAL

The melting points are uncorrected as taken in capillaries. The infrared spectra in Nujol mull and X-ray powder photographs are by Dr. R. N. Jones and Mr. R. Lauzon, and by Dr. Maria Przybylska. Ascending paper chromatograms were used with the upper layer of *n*-butanol – acetic acid – water (4:1:5); development was with Ehrlich's reagent. We are grateful to Professor D. Shemin for samples of natural porphobilinogen and to Professor C. Rimington, F.R.S., for samples of its hydrochloride and lactam, as well as for the comparison of the natural and synthetic porphobilinogens in an enzyme system.

2-Formyl-5-carboxy-pyrrole-3-acetic acid-4-propionic acid Triethyl Ester Oxime (Ic)

Hydroxylamine hydrochloride (2.4 g.) in 2.5 ml. of water was added to a solution of 0.82 g. of sodium in 50 ml. of ethanol, then sodium chloride was filtered off and washed with ethanol. The filtrate and washings were refluxed for 45 minutes with 10 g. of the aldehyde Ib,⁴ cooled, poured into 400 ml. of ice water, and left at 0°. The oxime separated, and was recrystallized from 750 ml. of 30 vol. % ethanol forming colorless needles (8.3 g., 80%), m.p. 86° (lit. 58° (14)). Ehrlich's reaction was positive after long heating. Found: C, 55.47; H, 6.33; N, 7.26%. Calc. for C₁₇H₂₄N₂O₇: C, 55.43; H, 6.56; N, 7.61%.

2-Cyano-5-carboxy-pyrrole-3-acetic acid-4-propionic acid Triethyl Ester (Id)

The ester oxime (Ic) (10 g.) was heated with 50 ml. of acetic anhydride on the steam bath for 1 hour. After the acetic anhydride was removed *in vacuo*, the residual oil was dissolved in 250 ml. of ether. The solution was extracted twice with dilute aqueous sodium

³Dr. J. J. Scott has independently considered this hypothesis.

⁴We reported this aldehyde with m.p. 81° (9). Dr. Raper has informed us that Prasad and Raper found its melting point to be 78°, not 67° as they reported (14).

carbonate, dried with sodium sulphate, and the ether removed *in vacuo*. The residue, which solidified slowly at 0°, was recrystallized from ether-hexane to give the nitrile (7.2 g.) as colorless needles, m.p. 96–98°. When the mother liquor was evaporated and the residue sublimed (160°, 1×10^{-5} mm.), a further 0.7 g. of the product was obtained (total 83%). For analysis, the nitrile was recrystallized from aqueous ethanol; it then had m.p. 105–106°, Ehrlich's reaction was positive after long heating. Found: C, 58.31; H, 6.21; N, 8.16%. Calc. for $C_{17}H_{22}O_6N_2$: C, 58.27; H, 6.33; N, 8.00%.

2-Formyl-5-carboxy-pyrrole-3-acetic acid-4-propionic acid Oxime (IIc)

A solution of the ester oxime (Ic) (1 g.) and 0.5 g. of sodium hydroxide in 50 ml. of water was heated on the steam bath for 2 hours, cooled, and put through a column of Amberlite IR-120 (hydrogen form, 25 g.), eluting with water which had been boiled and cooled under nitrogen. The eluate (about 200 ml.) was evaporated at 30–35° *in vacuo* under nitrogen, and the residue dried at 20 mm. over sulphuric acid. The resulting crystalline product was extracted into acetone (Soxhlet) from which it separated as cream colored needles when pentane was added (0.68 g., 88%), m.p. 204–205° (decomp.) (lit. 201° (9), mixed m.p. 203–204°). Ehrlich's reaction was negative in the cold and red-violet on heating.

2-Aminomethyl-5-carboxy-pyrrole-3-acetic acid-4-propionic acid Triethyl Ester Hydrochloride (I (R = CH_2NH_3Cl))

(a) The ester oxime (Ic) (5 g.) in 250 ml. of ethanol and 2 ml. of concentrated hydrochloric acid was shaken with 0.5 g. of palladium black under hydrogen (1 atm.) until the latter ceased to be absorbed (about 3 hours). The catalyst was removed by filtration, and the filtrate concentrated at 30° *in vacuo*, the crystalline product being filtered off from time to time and dry ether finally being added to the mother liquors to precipitate the last of it (total 4.7 g., 89%). For analysis, the melting point was raised from 193–194° to 195–196° by recrystallizing the product from ethanol-ether; the tiny colorless needles were dried *in vacuo* at 80°. The product is soluble in warm dilute acid. Ehrlich's reaction was positive on prolonged heating. Found: C, 52.36; H, 6.90; N, 7.41; Cl, 8.97%. Calc. for $C_{17}H_{26}N_2O_6 \cdot HCl$: C, 52.23; H, 6.96; N, 7.17; Cl, 9.07%.

(b) The cyano ester (Id) (0.5 g.) in 50 ml. of ethanol and 0.25 ml. of concentrated hydrochloric acid was shaken overnight under hydrogen (60 lb./in.²) with 100 mg. of Adams' platinum oxide catalyst. After the catalyst was filtered off, the solution was concentrated *in vacuo* at 20° to about 15 ml. when crystallization began. The separation of the product was completed by adding ether to the residue and leaving the mixture at 0°. The hydrochloride (0.35 g., 63%) formed colorless tiny needles, m.p. 190–192°, mixed m.p. 192–194° with the product obtained as in (a) above.

5-Carboxy-porphobilinogen Lactam Diethyl Ester (III)

(a) The hydrochloride of the amine ester (I(R = CH_2NH_3Cl)) (2 g.) was dissolved in 30 ml. of warm ethanol, and a solution of 0.13 g. of sodium in 20 ml. of ethanol added. The solution was filtered hot, cooled, and left at 0°. The lactam (1.3 g., 82%) separated as tiny colorless needles, m.p. 228–230° (decomp.). It is insoluble in warm dilute acid. Ehrlich's reaction is faintly positive on prolonged heating. For analysis the lactam was recrystallized from aqueous ethanol and the product, m.p. 235–236° (decomp.), dried at 80° *in vacuo*. Found: C, 58.76; H, 6.57; N, 9.33; OEt, 28.92%. Calc. for $C_{15}H_{20}N_2O_5$: C, 58.43; H, 6.54; N, 9.09; OEt, 28.58%.

(b) The ester oxime (Ic) (5 g.) in 100 ml. of absolute ethanol and 5 ml. of ammonium hydroxide was shaken with 0.25 g. palladium black under hydrogen (50 lb./in.²) until absorption of the latter ceased (about 6 hours). The catalyst was filtered off and washed with ethanol. The filtrate and washings were concentrated *in vacuo* to about 75 ml., then diluted with 250 ml. of hot water, and left at 0°. The colorless needles (3.4 g., 81%) had the melting point of 228–231° (decomp.) raised to 233–235° (decomp.) by recrystallization from aqueous ethanol, mixed m.p. 233–234° with the product obtained as in (a) above.

5-Carboxy-porphobilinogen (IIe)

(a)⁵ The oxime (IIc) (200 mg. prepared from IIb (9)) in 10 ml. of water and 0.5 ml. of ammonium hydroxide was shaken with 50 mg. of palladium black under hydrogen (1 atm.) for 4 hours; 34 ml. of hydrogen was taken up (theory 34.2 ml.). After the catalyst was filtered off and washed with water, the product (146 mg., 77%) separated at 0° at pH 4–5. After recrystallization from dilute ammonia – acetic acid, the melting point was 233–234° (decomp.). Found in material dried *in vacuo* at room temperature: e.g., C, 48.21, 47.72; H, 5.92, 5.83; N, 10.28%. Calc. for C₁₁H₁₄N₂O₆: C, 48.89; H, 5.22; N, 10.37%; for C₁₁H₁₄N₂O₆·H₂O: C, 45.83; H, 5.60; N, 9.72%.

The result was the same when 4.5 g. was reduced (88%), or when oxime had been obtained from Ic.

(b) The lactam (III) (5 g.) was heated for ½ hour on the steam bath with 30 ml. of 2 N sodium hydroxide and 20 ml. of ethanol. After the solution was cooled and filtered, the product was isolated as under (a) above, giving 3.8 g. (87%), m.p. 225–230°, raised to about 233° (decomp.) by recrystallization. It was dried *in vacuo* at 25° and then exposed to the air. Found: C, 46.35, 46.42; H, 5.70, 5.55; N, 9.88%.

(c) The hydrochloride of the amine ester (I(R = CH₂NH₃Cl)) (3.2 g.) in 20 ml. of 2 N sodium hydroxide was heated in the steam bath for ½ hour beyond the time required for its complete dissolution. The product (2.01 g., 90%) was isolated as under (a) above. Recrystallization raised the melting point from 220–225° to 230–233° (decomp.).

All these products formed stable colorless needles, *R*_f 0.38. Ehrlich's reaction was slowly positive in the cold. Regardless of the method of preparation the infrared spectra and X-ray powder photographs of dried samples showed some identities but usually varied within limits. However, the X-ray powder photographs were identical when the crystals were kept wet. This compound had previously been described as rapidly turning red (14).

5-Carboxy-porphobilinogen Lactam (IVb)

5-Carboxy-porphobilinogen (IIe) (10 g.) in 100 ml. of pyridine and 300 ml. of water was treated dropwise with ammonium hydroxide until solution was complete. The solution was cooled in ice, 50 ml. of acetic acid added, and 50 ml. of acetic anhydride added dropwise to the clear solution, with stirring, at 0–5° over 40 minutes. After a further hour at 0°, the slightly yellowish microcrystalline product was centrifuged off and washed successively with water, acetone, and ether. More was obtained by concentrating the mother liquor *in vacuo* at 25–30° in a Craig-type rotary evaporator, the total being 5.25 g. (56%). It was recrystallized for analysis by dissolving in warm N ammonium hydroxide, adjusting the pH to 4–5 with N acetic acid and allowing the solution to cool slowly, finally to 0°. It formed colorless hexagonal plates, decomposing above 325°,

⁵This was carried out by Dr. D. M. MacDonald (Ref. 9).

slowly turning yellowish in air. Ehrlich's reaction was weak in the cold but strong on heating, R_f 0.58. Found: C, 52.10; H, 4.65; N, 11.00%. Calc. for $C_{11}H_{12}O_5N_2$: C, 52.38; H, 4.80; N, 11.11%.

Porphobilinogen Lactam (IVc)

5-Carboxy-porphobilinogen lactam (IVb) (5 g.) was completely extracted from a Soxhlet thimble into 250 ml. of boiling water under nitrogen. The suspension was cooled to 0° under nitrogen and the product filtered off. More was obtained by concentrating the mother liquors under nitrogen. It then formed colorless rhomboidal plates, becoming yellowish in air (3.32 g., 80%), R_f 0.78. Ehrlich's reaction was strongly positive in the cold, m.p. 280–283° (decomp.). After recrystallization from boiling water under nitrogen (for analysis), the product had m.p. 282–284° (decomp.). It was dried at 80° and 1×10^{-5} mm. Found: C, 57.55; H, 5.80; N, 13.19%. Calc. for $C_{10}H_{12}N_2O_3$: C, 57.68; H, 5.81; N, 13.46%.

The fluorescence appears to be due to a small amount of impurity (perhaps the pyridone) running slightly behind the Ehrlich-positive spot on paper chromatography.

Porphobilinogen Lactam Methyl Ester

In agreement with the results reported by Cookson and Rimington (1), this formed colorless needles, m.p. 248–250°, when prepared from synthetic porphobilinogen lactam (IVc) in 60% yield by their method. Ehrlich's reaction was positive in the cold. Found: C, 59.29; H, 6.17; N, 12.73%. Calc. for $C_{11}H_{14}N_2O_3$: C, 59.44; H, 6.34; N, 12.60%.

Porphobilinogen Keto-lactam (VI)

(a) This was prepared from the synthetic porphobilinogen lactam (IV(R = H)) in 50% yield according to Cookson and Rimington (1). It formed colorless prisms which darkened and decomposed above 325°.

(b) 5-Carboxy-porphobilinogen lactam (IVb) (35 mg.) in 2 g. of polyphosphoric acid was slowly heated to 80–90°. After carbon dioxide ceased to be evolved, the temperature was slowly raised to 110° and held at 110–115° for 10 minutes. The solution was cooled, diluted with 20 ml. of water, and kept 1 hour at 0°. The product was filtered off, washed, and recrystallized from boiling water, giving colorless plates (13 mg., 50%) decomposing above 325°. Ehrlich's reaction was negative hot. The product was dried at 100° *in vacuo*. Found: C, 63.09; H, 5.43; N, 14.81%. Calc. for $C_{10}H_{10}O_2N_2$: C, 63.15; H, 5.30; N, 14.73%.

In Nujol mull, the infrared spectra of the products prepared according to (a) and (b) were identical.

Porphobilinogen (V)

The synthetic porphobilinogen lactam (IVc) (500 mg.) in 3 ml. of 2 *N* sodium hydroxide was heated on the steam bath under nitrogen for 40 minutes.⁶ After the solution was cooled under nitrogen, diluted to 50 ml. with water, and brought to pH 4–5 with acetic acid, excess 10% lead acetate was added and the precipitate filtered off, washing with 1% lead acetate. The colorless filtrate and washings were treated with a slight excess of 15% mercuric acetate, and the yellowish white precipitate centrifuged off and washed with 1% mercuric acetate. The mercury precipitate was diluted to 15 ml. with water and decomposed by hydrogen sulphide. Mercuric sulphide was removed by centrifuging, then filtering, washing it with 2×10 ml. of water. The filtrate and washings were freeze-

⁶Porphobilinogen may be precipitated in about 80% yield at this stage but paper chromatography then shows it to contain about 10% of the lactam.

dried, the slightly pink residue dissolved in a little *N* ammonium hydroxide, the pH adjusted to 4–5 with acetic acid, and the solution cooled in ice and salt. Porphobilinogen crystallized slowly (about 200 mg., 35%) as a slightly pink microcrystalline powder, m.p. 170–174° (decomp.). Ehrlich's reaction was strongly positive in the cold, *R_f* 0.49–0.50. This product usually still contained traces of the lactam, which were removed by a repetition of the lead and mercury treatments, giving a product of melting point 172–175° (decomp.) in a yield reduced to about 20%. For analysis, it was dried at 25° in a high vacuum, then exposed to air. Found: C, 49.15, 49.29; H, 6.56, 6.63; N, 11.23%. Calc. for $C_{10}H_{14}O_4N_2 \cdot H_2O$: C, 49.17; H, 6.60; N, 11.47%.

Like the natural product (1), it is converted to uroporphyrins by hot dilute hydrochloric acid (10). The infrared spectrum of porphobilinogen is not nearly as characteristic as those of its hydrochloride and lactam.

Porphobilinogen Hydrochloride

The synthetic porphobilinogen was converted into its hydrochloride according to Cookson and Rimington (1). Found: C, 43.37; H, 6.52; N, 9.77%. Calc. for $C_{10}H_{14}N_2O_4 \cdot HCl \cdot H_2O$: C, 42.78; H, 6.10; N, 9.98%.

The natural and the synthetic porphobilinogen hydrochlorides (3 mg.) were converted to porphyrins by a blood hemolyzate (2a), the porphyrins separated and estimated (2b) and their type purity established by paper chromatography with lutidine (3). Only the following resulted (the respective amounts in μ g.): uroporphyrin III together with "pseudo-uroporphyrin" (436 and 444), coproporphyrin III (140 and 130), protoporphyrin (13 and 10).

2,5-Dicarboxy-pyrrole-3-acetic acid-4-propionic acid (II_f)

The cyano ester (Id) (2.5 g.) was heated on the steam bath with 25 ml. of 10% sodium hydroxide for 2 hours under nitrogen. The cooled solution was deionized in a column of Amberlite IR-120 (100 g., hydrogen form), eluting with about 400 ml. of water which had been boiled and cooled under nitrogen. The eluate was evaporated at 25–30° *in vacuo* under nitrogen, and the slightly pink crystalline residue was recrystallized from a little hot water. The product (1.30 g., 64%) separated as colorless needles, darkening above 200° and decomposing at about 230°. Ehrlich's reaction was very weak in the cold but stronger on heating. There was no trace of a CN band in its infrared spectrum. Found: C, 46.58, 46.39; H, 3.98, 3.73%. Calc. for $C_{11}H_{11}O_8N$: C, 46.32; H, 3.89%.

2-Cyano-5-carbethoxy-pyrrole-3-acetic acid-4-propionic acid (VIIa)

The cyano ester (Id) (300 mg.) in 5 ml. of ethanol and 2.0 ml. of *N* sodium hydroxide was heated for $\frac{1}{2}$ hour on the steam bath. After the ethanol was removed by passing nitrogen through the heated solution, the slightly yellowish crystalline product (160 mg., 63%) was precipitated with sulphur dioxide at 0°, filtered off, and washed with ice water. For analysis it was recrystallized three times by extracting into ether (Soxhlet) and precipitating with hexane; it was then dried at 80° *in vacuo*. It formed tiny colorless needles, m.p. 172–174° (decomp.). Ehrlich's reaction was slowly positive on prolonged heating. Found: C, 52.38; H, 5.03; N, 8.98%. Calc. for $C_{13}H_{14}O_6N_2$: C, 53.06; H, 4.80; N, 9.52%.

5-Carbethoxy-porphobilinogen Lactam (IVa)

The lactam (III) (600 mg.) was heated for 20 minutes on the steam bath with 10 ml. of ethanol and 2.1 ml. of *N* sodium hydroxide in an open flask. The cooled solution was

diluted to 20 ml. with water, brought to pH 4-5 with acetic acid, and left 1 hour at 0°. The fine precipitate was centrifuged off, dried at 1×10^{-5} mm., and crystallized from dry acetone (Soxhlet). The product (320 mg., 60%) formed tiny colorless needles, m.p. 260-265° (decomp.), raised to 264-267° by two similar recrystallizations. Ehrlich's reaction was slowly positive on heating. It was dried at 80° *in vacuo*. Found: C, 55.76; H, 5.70; N, 10.09%. Calc. for $C_{13}H_{16}O_5N_2$: C, 55.71; H, 5.75; N, 10.00%.

5-Carbethoxy-porphobilinogen (VIIb)
