ORGANIC DEUTERIUM COMPOUNDS

XXI. SYNTHESIS OF DEUTERATED AZOBISMETHANE[1]

A. T. MORSE,[2] T. F. MASSIAH,[2] AND L. C. LEITCH

ABSTRACT

Deuterated azobismethane was synthesized in the conventional way from dimethyl sulphate and hydrazine.

The principal sources of methyl radicals for photochemical investigations are acetone, dimethyl mercury, and azomethane. Deuteromethyl radicals are similarly obtained from the corresponding deuterated compounds, of which only acetone-d_6 and bistrideuteromethyl-mercury have been reported (2). It seemed of interest to prepare deuteroazobismethane, since it is the only convenient way of obtaining methyl-d_3 radicals for certain work.

With the exception of 2,2′-azobispropane-2,2′-d_2, which was reported by us a few years ago (8), deuterated azoalkanes are unknown. The synthesis of azoalkanes from aldehydes or ketones via the azines and 1,2-dialkylhydrazines described in that paper is not applicable to the preparation of azomethane or deuteroazomethane because condensation of formaldehyde and hydrazine hydrate gives rise to polymers rather than the azine. Furthermore, formaldehyde-d_2, which is required in the present instance, is very difficult to prepare (1). Initially, lithium aluminum hydride reduction of 1,2-diacylhydrazines was found to be unsuccessful. This was also experienced by Hinman (6). However, we were led to reinvestigate this reaction by the appearance of a paper by Stewart (10) on the facile preparation of formic-d acid which readily yields 1,2-diformyl-d_2 hydrazine. Eventually, 1,2-dimethylhydrazine was obtained in 50% yield when 1,2-diformylhydrazine was reduced with a large excess of $LiAlH_4$ in dioxane as a solvent. However, the excessive cost of lithium aluminum deuteride precludes the use of the method for preparing more than very small quantities of azomethane-d_6.

As methyl-d_3 iodide is now readily available (9), methylation of 1,2-dibenzoylhydrazine was attempted with methyl iodide instead of dimethyl sulphate, but no methylation took place under a variety of conditions. Consequently, the method of Folpmers (3) and Hatt (5) remained the only practical route to azomethane-d_6:

$$C_6H_5CONHNHCOC_6H_5 + 2(CD_3)_2SO_4 + 2NaOH \rightarrow C_6H_5CON{=}NCOC_6H_5 + 2CD_3NaSO_4 + 2H_2O$$

$$C_6H_5CON(CD_3)N(CD_3)COC_6H_5 \xrightarrow{HCl} CD_3NH\overset{+}{N}H_2CD_3Cl^-$$

$$CD_3NHNHCD_3 \xrightarrow{HgO} CD_3N{=}NCD_3$$

[2]*Present address: Merck and Company, Limited, Montreal, Que.*

In our first experiments with dimethyl-d_6 sulphate the ester was prepared from methyl-d_3 alcohol and chlorosulphonic acid. This method was somewhat inconvenient because methyl-d_3 alcohol had to be prepared from the bromide. Recent work from this laboratory on the preparation of deuterated esters from methyl-d_3 bromide and silver salts of the acids (7) held out the promise that dimethyl-d_3 sulphate might be prepared from methyl-d_3 bromide and silver sulphate. These reactants did in fact give the inorganic ester in 90% yields. From the investigations of Gragorov (4) on the mobility of radicals it would appear that deuterated dimethyl sulphate could also be prepared by exchanging methyl-d_3 iodide with normal dimethyl sulphate or preferably a homologous sulphate ester. This method is probably less convenient than the one described.

The succeeding steps in the synthesis of azomethane-d_6 paralleled those used to prepare the light compound (8) and call for no special comments.

EXPERIMENTAL

Dimethyl-d_6 Sulphate

(*a*) *By direct esterification of methyl-d_3 alcohol.*—To chlorosulphonic acid (665 g; 6.0 moles), cooled to −15° C in a 1-liter flask fitted with a dropping funnel, a reflux condenser, and a magnetic stirrer, methyl-d_3 alcohol (175 g; 5.0 moles) was added dropwise while maintaining the temperature below 0° C. After the addition of alcohol had been completed the reaction mixture was fractionated under reduced pressure in a Vigreux column. The yield of dimethyl-d_6 sulphate, b.p. 69 to 71° C/11 mm, n_D^{25} 1.3858, was 309 g (90%).

(*b*) *From methyl-d_3 bromide and silver sulphate.*—Methyl-d_3 bromide was prepared as described in a previous paper of this series (9). Silver sulphate (31.0 g; 0.1 mole) was ground to a fine powder in a mortar and placed in a heavy-walled glass tube which was then constricted near the top to facilitate sealing later. Methyl-d_3 bromide (21.0 g; 0.22 mole) was condensed into the tube on a vacuum manifold. The sealed tube was then heated for 4 to 5 hours at 100° C. The contents of the cold tube was washed out with ether into a gravity funnel. The silver iodide on the funnel was washed several times with small portions of ether. The combined ether extracts were freed of solvent and the residue was distilled in a Späth bulb from an air bath at 50° C under 0.1 mm on the vacuum line. The yield of product, n_D^{20} 1.3851, was 10.6 g (85%). The index of refraction of normal dimethyl sulphate is 1.3860.

sym-Dimethyl-d_6 Dibenzoylhydrazine

To a stirred suspension of 40 g (0.165 mole) 1,2-dibenzoylhydrazine in 300 ml of 2% sodium hydroxide solution heated to 80° C were added dropwise and simultaneously from two dropping funnels, 65 ml (0.65 mole) of dimethyl-d_6 sulphate and 125 ml of 50% aqueous sodium hydroxide solution. After it was stirred for an additional hour at 80° C the reaction mixture was set aside to crystallize in the refrigerator. The crystalline solid which had separated was collected on a funnel and dissolved in 50 ml of chloroform. The solution was dried over magnesium sulphate and treated with 100 ml of a 50% mixture of ether and pentane. After the mixture had been allowed to stand at 0° C in the refrigerator for several hours the crystals were filtered off and washed with pentane. Yield: 23 g (24.4%), m.p. 85–86° C.

1,2-Dimethyl-d_6-hydrazine

The dibenzoyldimethyl-d_6-hydrazine obtained above (23.0 g; 0.085 mole) was heated under reflux for 3 hours with 95 ml of 35% concentrated hydrochloric acid. The reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

mixture was steam-distilled to remove benzoic acid and then evaporated to dryness in a flash evaporator. The residue of crude 1,2-dimethyl-d_6-hydrazine monohydrochloride was dissolved in 40 ml of water and added slowly with stirring to 100 ml of 50% aqueous sodium hydroxide. The base liberated was purified and freed of water by distillation on the vacuum line through a U-tube filled with potassium hydroxide pellets. Yield: 5.3 g, n_D^{24} 1.4188 (95.5%).

Bisazomethane-d_6

A solution of 1,2-dimethyl-d_6-hydrazine (5.3 g; 0.08 mole) in 50 ml of water was added to a stirred suspension of 22.0 g (0.11 mole) of yellow mercuric oxide in 40 ml of water in a flask with a reflux condenser to which was attached a spiral trap cooled to −78° C in a bath of acetone and solid carbon dioxide. After addition of the base was completed the reaction mixture was slowly heated to reflux. The apparatus was swept with a slow stream of nitrogen. The yield of azomethane-d_6 which analyzed 99.3 atom % deuterium by mass spectrometry was 3.2 g (62.2%).

1,2-Dimethylhydrazine

1,2-Diformylhydrazine (22.0 g; 0.25 mole) was extracted in a Soxhlet by a refluxing solution of 66 g (2.0 mole) of lithium aluminum hydride in 1 liter of dioxane. After 24 hours the hydride was decomposed by careful addition of water. Inorganic hydroxides were removed by centrifugation. The filtrate was acidified and evaporated to dryness in a flash evaporator. The residue was dissolved in the minimum amount of water and the solution added to an excess of 50% alkali. The supernatant layer of insoluble 1,2-dimethylhydrazine was distilled off on a vacuum manifold. Yield: 7.5 g (50%). It was converted into azomethane by oxidation with mercuric oxide as described in ref. (8). The azo compound was identified by mass analysis.

POTATO X VIRUS

PART II. PREPARATION AND PROPERTIES OF PURIFIED, NON-AGGREGATED VIRUS FROM TOBACCO[1]

M. E. REICHMANN

ABSTRACT

When sap from tobacco, infected with potato X virus, was dialyzed against 0.05 *M* and then against 0.005 *M* sodium citrate, no aggregation of the virus was detected after ultracentrifugation. Flow birefringence measurements were made to compare virus preparations obtained by ultracentrifugation of untreated sap and of sap that had been treated with various buffers. Only versene and citrate were found to prevent aggregation. The influence of pH in the range 5.7–7.3 was very slight. Possible explanations of this effect are discussed.

Nitrogen and phosphorus content and the sedimentation constant of the purified, non-aggregated virus are reported.

INTRODUCTION

An investigation of size and size distribution of viruses in solution requires that special precautions be taken, during the process of isolation and purification, not to change these characteristics. Even in the case of the most studied virus, the tobacco mosaic virus, few authors emphasize this point (1) and only recently has the preparation of purified uniform tobacco mosaic virus been described (2).

The irreversible end-to-end aggregation of potato X virus in the process of purification is a well-known phenomenon (3, 4, 5). In a previous publication from this laboratory the size and size distribution of potato X virus in tobacco sap was reported (6). For more accurate studies a purified preparation was needed. This paper describes conditions under which this virus can be isolated without alteration in its state of aggregation. Preliminary conclusions concerning the nature of the aggregation processes are drawn from some of the properties of this preparation.

EXPERIMENTAL

Purification

The potato X virus and the conditions under which it was grown in tobacco have been described previously (6). Freshly frozen tobacco leaves were squeezed with a mortar and pestle. The sap was centrifuged at 4000 r.p.m. for 30 minutes. The brown supernatant was dialyzed overnight against a large volume of 0.05 *M* sodium citrate. The dialysis bags were then transferred to a large volume of 0.005 *M* sodium citrate and the dialysis continued for another 10 hours. The sap was then centrifuged at 4000 r.p.m. for 20 minutes and the supernatant was ultracentrifuged at 75,000$\times g$ for 90 minutes. The pellet was water-clear with a brown core in the center. After decantation the pellet was resuspended in 0.005 *M* sodium citrate. It dissolved readily except for the brown core which was insoluble. The insoluble material was removed by slow centrifugation and the supernatant was submitted to two additional cycles of ultracentrifugation and slow centrifugation in 0.005 *M* sodium citrate. The final pellet obtained was water-clear and dissolved readily with only traces of insoluble material. In contrast, virus material prepared from sap that had not been treated with sodium citrate was slower to dissolve and the amounts of insoluble material in each step were larger.

Flow Birefringence Measurements

The extinction angles χ were measured at different velocity gradients G in a small flow birefringence apparatus manufactured by Rao Instrument Company, Brooklyn, New York (7). Comparisons between different samples were made in a concentration range of 0.08 to 0.02% virus in 0.005 *M* sodium citrate. The extinction angles were found independent of virus concentration in this range. In Fig. 1 typical extinction angles vs. gradient measurements are shown for virus in sap, virus purified as described above, and virus isolated from untreated sap by one ultracentrifugation. The low extinction angles of the latter sample confirm findings reported in the literature that the virus aggregates under these conditions (3, 4, 5). Similar results were obtained whether the virus was resuspended in distilled water or in 0.005 *M* citrate. Moreover, each ultracentrifugation – slow centrifugation cycle increased the amount of aggregated material.

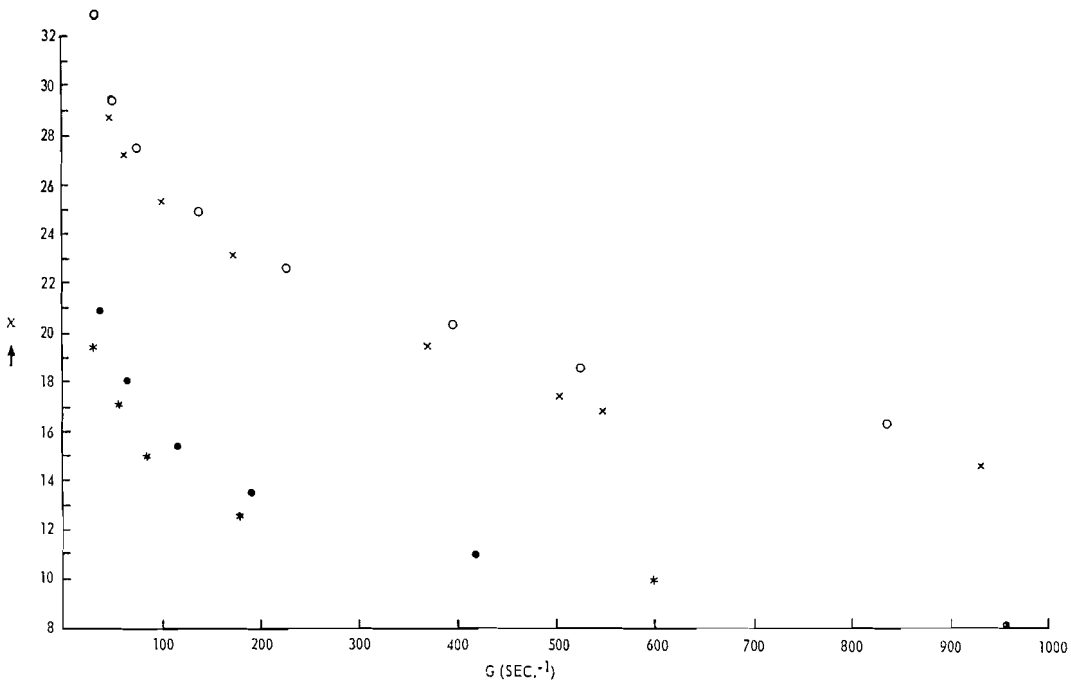

FIG. 1. Extinction angle χ vs. gradient G plot: ×, virus in sap; ●, once ultracentrifuged and dissolved in 0.005 *M* sodium citrate; *, once ultracentrifuged and dissolved in distilled water; ○, ultracentrifuged after citrate treatment.

On the other hand, virus obtained from citrate-treated sap showed virtually no change in the χ vs. G curve. The small shift towards higher extinction angles was probably a result of minor losses of aggregated material in the process of ultracentrifugation.

In Fig. 2, δ, the phase difference in degrees, divided by the concentration c (in per cent virus) is plotted for the purified non-aggregated material. The downward curvature in this plot indicates the rigid nature of the particle. This is in agreement with similar earlier measurements of the virus in tobacco sap (6).

The Effect of pH and Ionic Strength

To speed up the purification procedure several short cuts were attempted. One aliquot of a sap was dialyzed against 0.05 *M* sodium citrate and a second aliquot was dialyzed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

directly against 0.005 *M* sodium citrate. Both samples showed an increase in aggregation after ultracentrifugation. To test the effect of pH, citrate buffer at pH 5.7 was used. Other ions were also tested. The results are summarized in Tables I and II.

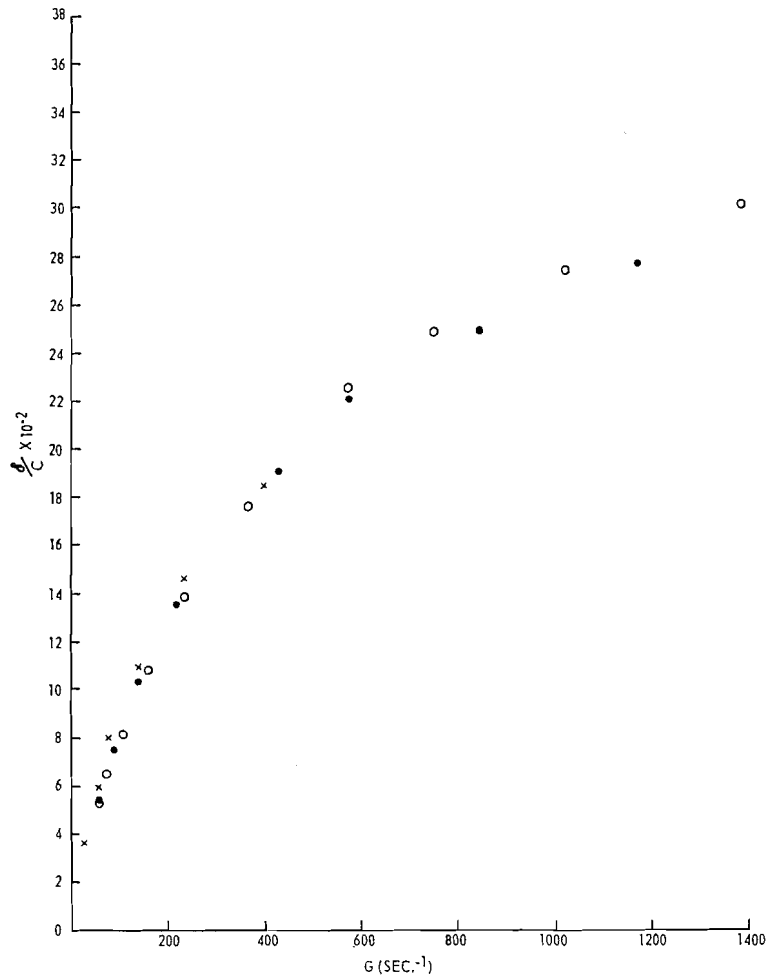

FIG. 2. Amount of birefringence divided by concentration, plotted against velocity gradient. Purified non-aggregated virus in 0.005 *M* sodium citrate.

The purified non-aggregated virus was insoluble in water in the complete absence of electrolytes. When thoroughly dialyzed against distilled water, the virus solution became turbid and upon centrifugation at 4000 r.p.m. for 20 minutes practically all the virus was in the pellet. This pellet could be redissolved in 0.005 *M* sodium citrate. Flow birefringence measurements indicated that no aggregation occurred in this process.

Nitrogen and Phosphorus Content

Kjeldahl nitrogen was determined using essentially the procedure of Miller and Miller (8). The theoretical curves and experimental data were determined on a Beckman DU spectrophotometer at 480 mμ, in a concentration range of 0.06 to 0.12 mg of nitrogen. Phosphorus content was determined by the method of Michelson (9). The virus concentration was obtained from dry weights at 100° C in a vacuum oven by subtracting

+, Lower extinction angles (see points ● in Fig. 1).

the dry weight of the citrate solvent. The nitrogen and phosphorus values were 15.7±0.4% and 0.59±0.02% respectively. These data are in good agreement with the values found by Loring (4).

Serology

Antisera were prepared by injecting the citrate-treated, three times ultracentrifuged preparation into rabbits. These sera were compared by means of the complement fixation serological technique (10, 11) with sera prepared from four times ultracentrifuged – slow centrifuged aggregated material. In addition to antibodies against virus, traces of antibodies against normal plant proteins were detected in all sera. However, the virus, given cyclic centrifugation only, produced considerably more of these antibodies than the citrate-treated virus.

Ultraviolet Absorption

An attempt was made to determine the extinction coefficient at 260 mμ. It was found that in 0.005 *M* sodium citrate Beer's law was not followed in a virus concentration range of 0.01 to 0.045% indicating interactions of the chromophoric groups. The same was true when higher sodium citrate concentrations or 0.05–0.1 *M* phosphate buffer at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

pH 7.2 were used. At pH 5.7 in 0.1 *M* phosphate, however, the extinction coefficient was independent of concentration. An average value of 26.8 g virus/100 ml cm was derived.

The ultraviolet absorption spectrum under these conditions showed a minimum at 245 mμ and a broad maximum at 260 mμ. The ratio of the 260/280 mμ absorptions was 1.20. After correction for scattering from measurements at 320 to 410 mμ (12) this ratio became 1.19. On the other hand, virus prepared by four cycles of ultracentrifugation – slow centrifugation from sap untreated with sodium citrate had a 260/280 mμ ratio of 1.30 when corrected for scattering.

Sedimentation

The sedimentation coefficient of the non-aggregated purified preparation was determined in 0.1 *M* phosphate buffer, pH 5.7, in a virus concentration range 0.25–0.02%. Photographs were taken at 4-minute intervals in a Spinco Model E Analytical Ultracentrifuge at 25,980 r.p.m. The sedimentation coefficients were converted to corresponding values at 20° C in water. The least-squares line derived from the data followed the equation $1/S_{20} \times 10^{10} = 8.49 + 4.58\ c$ giving a sedimentation coefficient S_{20} of 117.7 Svedbergs at zero concentration. Similar studies at pH 7.1 reported in the literature gave the value 123.5 Svedbergs (5). As stated in reference (5) the preparation contained a small amount of material that sedimented very rapidly. With the preparations described in this paper, however, there was no indication of the presence of material other than that contained in the major peak. Figure 3 represents the ultracentrifuge patterns of a 0.25% and 0.02% solution respectively.

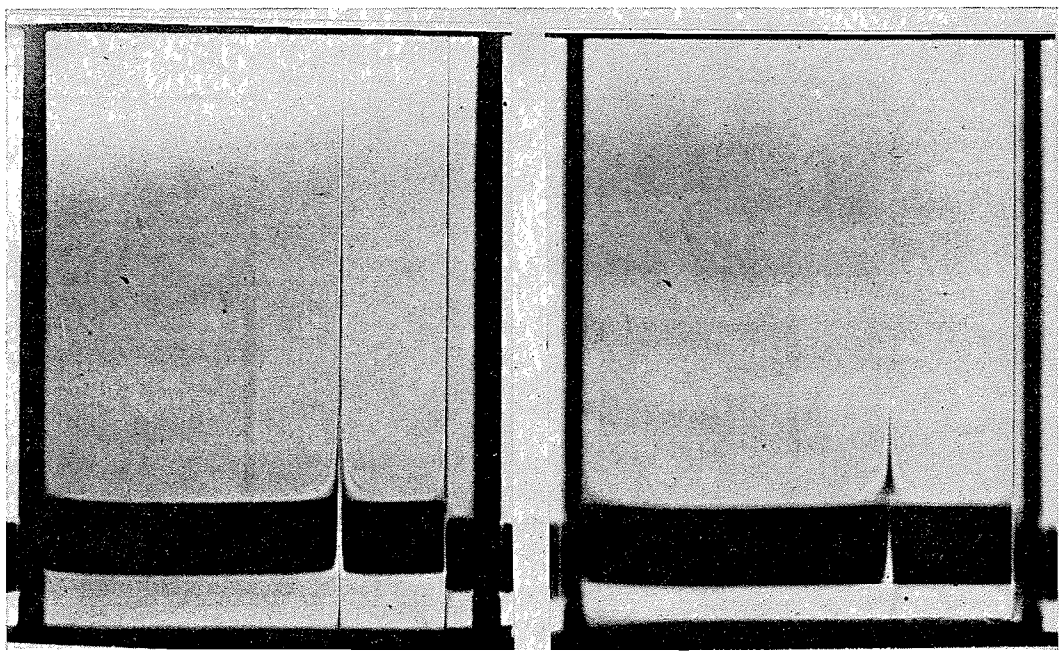

Fig. 3. Sedimentation pattern of purified non-aggregated virus in 0.1 *M* phosphate, pH 5.7. Virus concentrations 0.25% and 0.02% bar angles 70 and 55° respectively. Sedimentation from right to left.

DISCUSSION

The data in Table I indicate that when potato X virus in tobacco sap was exposed to 0.05 *M* sodium citrate, some of its structural features connected with its tendency to aggregate end-to-end irreversibly were altered. Once this change had taken place the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

virus only aggregated when ultracentrifuged at high ionic strength. The influence of pH in the range 5.7–7.4 was very small. Versene buffer at pH 7.2 under the same conditions had a similar effect, while potassium phosphate and sodium chloride were not active. The data in Table II furnished further evidence indicating irreversible changes in the virus structure. In contrast to the untreated virus, the preparation purified with citrate did not aggregate when ultracentrifuged after "exhaustive" dialysis against 0.005 *M* phosphate or sodium chloride at pH 7.2. At higher salt concentrations, however, aggregation occurred.

Recently a more critical attitude to the degree of purity in tobacco mosaic virus preparations has revealed that treatment with citrate and other ions alters the composition of these preparations (13, 14, 15, 16). Thus Ginoza *et al.* (13) were able to prepare colorless pellets of a group of strains of T.M.V. after citrate, versene, and phosphate treatments, while the untreated virus when ultracentrifuged always gave amber-colored pellets. This color was found to be associated with small nucleoprotein molecules that were split off the virus during these procedures. The amount of nucleoprotein removed increased with increasing phosphate concentration and at higher temperatures. Pirie (15) also reported the release of labile phosphorus-containing compounds when T.M.V. was exposed to citrate.

It is possible that the tendency of potato X virus to aggregate is linked with the presence of phosphorus-containing or other compounds that are removed when potato X virus is treated with 0.05 *M* citrate or versene at 5° C. The action of such compounds could be either limited to the facilitation of a close approach of virus particles, similar to the non-specific action of electrolytes, or could be of a more specific nature. The change in the 260/280 mμ absorption ratio cannot be taken as evidence for the splitting of such compounds. It merely indicates that the surrounding of the chromophoric groups has changed under the influence of citrate.

The possibility of heavy metals participating in the aggregation processes cannot be ruled out. The chelating properties of citrate and versene would lead to considerations similar to those made in connection with preparations of colorless T.M.V. pellets (13).*

Finally, the chemical purity of the preparation described in this paper should be considered. The complement fixation experiments indicate that a higher degree of purity has been achieved than in samples prepared by techniques described in the literature. The author is well aware, however, that it may be subject to the same criticism as T.M.V. preparations obtained by ultracentrifugation (15, 17, 18). As stated in the introduction, the main concern of this study was to preserve the size and size distribution intact. Methods offered by critics of the degree of purity of virus preparations unfortunately change these properties in the case of most viruses. Consequently, to the author's knowledge no method is available at the present time which would completely satisfy both the criteria of chemical purity and the requirements for physicochemical studies.

THE N- AND C-TERMINAL END GROUPS OF HAIR KERATIN[1]

M. F. KERR AND C. GODIN

ABSTRACT

The N-terminal and the C-terminal residues of human and horse hair and partially reduced hair have been determined. Aspartic acid, glutamic acid, glycine, serine, threonine, alanine, and valine were identified as N-terminal groups. Aspartic acid, glutamic acid, glycine, serine, threonine, and alanine were identified as C-terminal groups. These are the same N-terminal and C-terminal amino acids as have been found previously for wool and feather keratin.

INTRODUCTION

The purpose of the following work was to establish a procedure which would serve to differentiate among the hair keratins of different species of animals, including man. At present a visual microscopic procedure is used in practically all forensic work involving hair. For most cases this is sufficient, particularly if negative results will suffice. In some cases, however, the microscope is simply inadequate in providing the information required by the examiner.

Recently, the N-terminal and the C-terminal residues of wool keratin were determined (1, 2, 3, 4, 5, 6). Complex mixtures of end groups were found and it was hoped that some qualitative differences could be established between the hair keratins of different species using these methods. This paper reports the identification of N-terminal and C-terminal residues in human and horse hair.

EXPERIMENTAL

Hair.—The human hair was obtained from the "N" Division, R.C.M.P. Barracks, and was exclusively male. The horse hair was obtained from the "N" Division, R.C.M.P. Stables, and was exclusively tail hair. To degrease the hair it was extracted in a Soxhlet for 2 hours each with acetone and ether and then air-dried. Finely ground hair was obtained by grinding the hair in liquid nitrogen in a porcelain mortar.

Dinitrophenylation.—Finely ground hair (0.5 g) was suspended in water (12 ml) containing sodium bicarbonate (0.5 g). Ethanol (25 ml) containing 1-fluoro-2,4-dinitrobenzene (FDNB) (0.86 g) was added and the mixture was shaken for 48 hours at 40° C (2). The hair was then isolated by filtration, washed with water, alcohol, and ether. When partly reduced keratin was dinitrophenylated, the mixture was first extracted with ether, then acidified. The insoluble dinitrophenyl-proteins (DNP-proteins) were centrifuged down and washed with water, alcohol, and ether.

Hydrazinolysis.—The method described by Niu and Fraenkel-Conrat (7) was used.

Hydrolysis.—The DNP-proteins were hydrolyzed in 6 *N* HCl in sealed tubes for 24 hours at 100° C.

Chromatography.—The DNP-amino acids were spotted on Whatman paper No. 3 MM buffered at pH 6. The chromatograms were developed with *tert*-amyl alcohol saturated with pH 6 phthalate buffer (8). Each spot obtained was run again after elution from the paper. The same paper was used for the second run but the phthalate buffer alone was used as solvent. In the buffer alone the R_f values are different from those obtained in *tert*-amyl alcohol.

Reduction.—Hair keratin was partly reduced with sodium thioglycolate (9). Hair (0.5 g) was suspended in water (25 ml) containing sodium hydroxide (4 g). Thioglycolic

[1]*Manuscript received August 15, 1958.*
Contribution from the Department of Chemistry, Faculty of Science, University of Ottawa, Ottawa, Ontario.

acid (2.5 ml) was added. The mixture was shaken at room temperature for a given period of time (3 to 5 hours). The residue was then filtered off and the keratin precipitated by careful acidification with acetic acid or dilute hydrochloric acid. The acidification was followed with a pH meter; a first protein fraction (black solid) came out between pH 8 and pH 7 and a second fraction (white solid) between pH 4 and pH 1.

RESULTS

Hair.—The N-terminal amino acids obtained from human and horse hair by the dinitrophenyl method were aspartic acid, glutamic acid, glycine, serine, threonine, alanine, and valine. Using the hydrazinolysis method for the determination of C-terminal groups in proteins, six C-terminal residues were detected in human and horse hair. They were identified by paper chromatography after transformation into DNP-derivatives. They were shown to be aspartic acid, glutamic acid, glycine, serine, threonine, and alanine.

Partly Reduced Keratin.—Treatment with alkaline thioglycolate for 3 hours transforms keratin into a protein mixture containing 25% of its sulphur as cysteine (9). When the reduction was allowed to proceed for 3 to 5 hours, the protein fractions obtained by acidification to pH 8–7 and pH 4–1 had the same N-terminal and C-terminal groups as intact hair.

DISCUSSION

Human hair and horse hair have the same seven N-terminal groups and the same six C-terminal groups. The same amino acids are also found as N-terminal and C-terminal residues of wool keratin (1–6). The same seven N-terminal groups have also been found recently in feather keratin (10). No attempt was made to do a quantitative estimation of end groups because it was shown recently that the results of quantitative determination in wool are not very reliable (4), at least not reliable enough to establish species differences with certitude. Crude wool keratin was also shown recently to have the same N-terminal groups as intact wool (4). It is therefore not surprising that partly reduced hair keratin has the same N-terminal and C-terminal groups as intact hair.

As no qualitative differences are found between keratin terminal groups in four species —man, horse, sheep, and fowl—this method was not investigated any further as a means of distinguishing between the hair keratins of different species.

A NOTE ON THE ELECTRICAL CONDUCTANCES OF DIELECTRIC FLUIDS IN ULTRASONIC FIELDS[1]

N. BERKOWITZ

ABSTRACT

The electrical conductances of ethyl bromide, *n*-propyl bromide, *n*-butyl bromide, methanol, and ethanol in ultrasonic fields have been measured at frequencies between 250 kc/s and 2 Mc/s and intensities between 0.7 and 24 w/cm^2. Measurements were made at room temperature, using a simple d-c. technique. It is shown that a *simple* transient increase in conductance, such as has previously been observed by Seidl, may be confined to unassociated fluids and that it can occasionally give way to a much more complex—and not as yet fully understood—behavior pattern.

When a dielectric liquid (such as hexane or toluene) is placed in an ultrasonic field, a marked transient change in its electrical conductance K is induced. As soon as irradiation is begun, a sharp (and often virtually instantaneous) rise in K, followed by a relatively slow approach to a new equilibrium conductance, is observed; and when the acoustic field is removed, K will more or less rapidly return to its original value (1, 2). The plot of K vs. time t (at constant frequency f and intensity I) will, in other words, take the form illustrated in Fig. 1. Meyer (1) has interpreted these phenomena by assuming transfer of adsorbed impurities from the electrodes into the liquid, while Seidl (2), working with toluene, hexane, and carbon tetrachloride, rejects Meyer's explanation and postulates, instead, an acoustic splitting of "complex ions" and a consequent increase either in the number or in the mobility of the charge carriers.

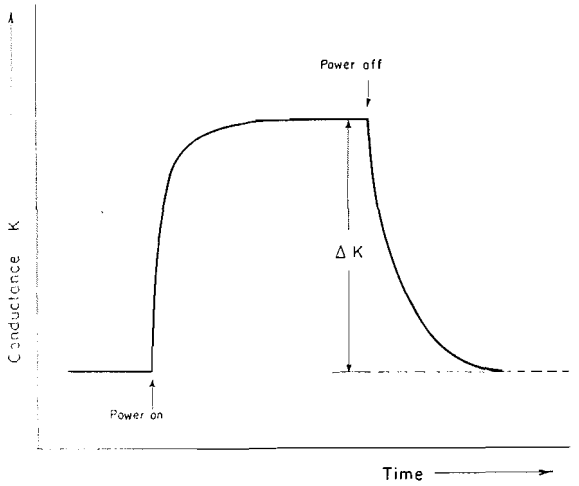

FIG. 1. General variation of conductance with time of irradiation (after Seidl).

Measurements made in this laboratory tend, broadly, to support Seidl's thesis: desorption of impurities—or a simple temperature effect that would accrue from acoustic heating of the liquid under test— appear quite insufficient to account for the experimental observations (and, indeed, to be generally irreconcilable with them). Both processes are, for instance, inconsistent with the very rapid initial rise in K and with its almost equally

[1]*Manuscript received September 4, 1958.*
Contribution No. 74 from the Research Council of Alberta, Edmonton, Alberta.

rapid fall when the ultrasonic field is switched off; and ΔK is always far greater than can be accounted for by the relatively small temperature rise in the test fluid during irradiation (cf. Seidl). On the other hand, the available evidence now suggests that "complex ion" splitting represents only one of several phenomena. If the range of fluids under examination is extended, and if measurements of K are made at several frequencies and intensities, seemingly more complex changes than those exemplified by Fig. 1 are occasionally recorded. Pronounced differences can, in particular, be noted in the responses of associated and unassociated liquids; and under certain conditions, ultrasonic irradiation appears to cause a *fall* rather than an increase in the conductance.* The purpose of this note is to report data illustrating these statements.

In the study here under review, a Mullard E.7562 generator, coupled to an oscillating ($\sim$15 cm^2) quartz crystal mounted in a sealed transducer housing, was used to produce ultrasonic waves in the frequency range 250 kc/s to 2 Mc/s. Maximum intensities of the tuned beams varied from about 2.3 w/cm^2 at 250 kc/s to nearly 35 w/cm^2 at 2 Mc/s. The conductivity cell was blown of thin pyrex glass and fitted with two platinum plate electrodes disposed at 90° to the acoustic wave front; a 1.5-volt potential was applied to these electrodes from a (frequently checked) dry cell. Resistances were measured by connecting cell and battery in series to a Leeds & Northrup d-c. bridge and a Pye "Scalamp" galvanometer. No attempt was made to determine the cell constant and

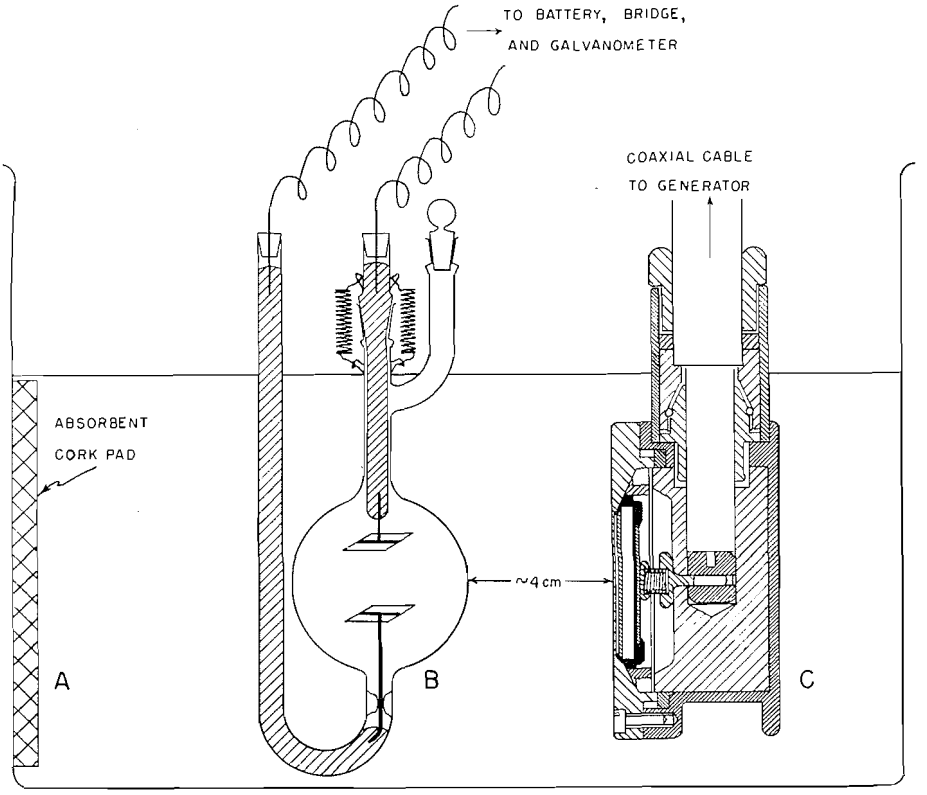

FIG. 2. Diagram of apparatus (not to scale):
A: constant-temperature bath; B: conductivity cell; C: transducer.

**It should be noted that this phenomenon further militates against attributing the observed change in K—or any substantial part of this change—to a temperature rise in the liquid under test.*

to convert the measured resistances to absolute resistivities; and similarly, no attempt was made, at this time, to investigate the variation of the measured response with the cell/crystal distance. Since large changes in K during ultrasonic irradiation did not apparently require a particularly critical adjustment of the assembly (or, for that matter, a critical design of the cell), it was deemed adequate to select an arbitrary cell/crystal distance (*ca.* 4 cm) and to maintain this constant throughout the investigations. Spurious conductance changes (such as might arise from impurities) were minimized by employing pure liquids and by conditioning the cell for several hours with the particular liquid under test. (The conditioning aliquot was removed and the cell freshly filled immediately prior to a measurement.) Further, in order to eliminate back e.m.f.'s, measurements of K in the ultrasonic field were only begun after the external potential had been applied to the test sample for at least 30 minutes and the conductance had attained a constant value. Both cell and transducer were immersed in a constant-temperature bath controlled to within $\pm 0.02°$ C. The assembly is shown diagrammatically in Fig. 2.

Liquids chosen for study were (*a*) a homologous series of unassociated fluids (comprising ethyl, *n*-propyl, and *n*-butyl bromide, all obtained from the Matheson Company Inc. with "reagent grade" purity), and (*b*) two highly associated fluids (methyl and ethyl alcohol).* The latter were purified by careful drying and subsequent double redistillation. In the case of (*a*), K was always measured at $25 \pm 0.02°$ C and in the case of (*b*), at $35 \pm 0.02°$ C. In the diagrams shown below, all experimental data are expressed as conductances (in reciprocal ohms). The degree of reproducibility can be gauged from the duplicates that are shown in several instances.

Plots of K/t for the three unassociated dielectrics (EtBr, *n*-PrBr, *n*-BuBr) are reproduced in Figs. 3 and 4. They follow closely upon the course of Seidl's curves (cf. Fig. 1)—a course here designated as Type A—but they differ from them in some quantitative aspects. Thus, at $f = 250$ kc/s and $I = 2.3$ w/cm², ΔK is in all three instances of the order of 10% (as compared with 31% and 47% reported by Seidl for CCl_4 and hexane respectively); and the return of K to its initial value after the field has been switched off occurs over a rather shorter period (*ca.* 5 minutes as compared with 20 minutes for

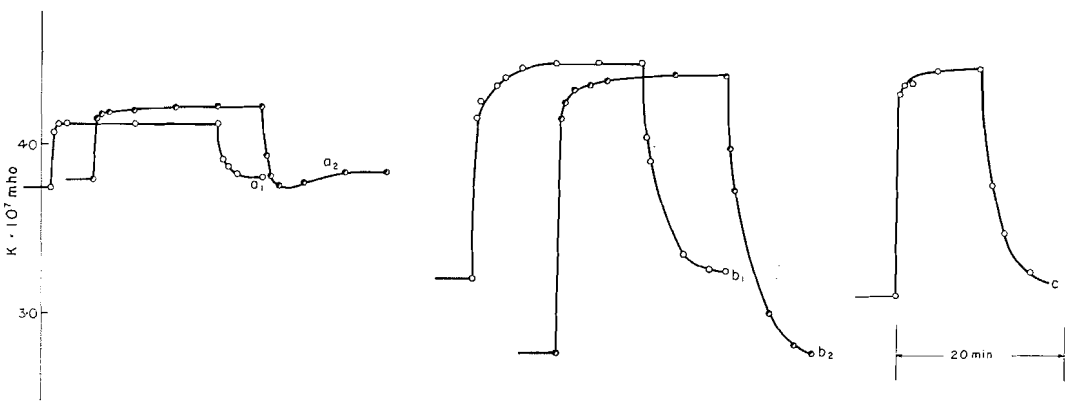

FIG. 3. a_1, a_2: Ethyl bromide; $f = 250$ kc/s, $I \sim 2.3$ w/cm².
b_1, b_2: Ethyl bromide; $f = 1$ Mc/s, $I \sim 12.4$ w/cm².
c: Ethyl bromide; $f = 2$ Mc/s, $I \sim 24$ w/cm².

**Because Seidl concentrated on non-polar or very weakly polar dielectrics, attention in the present study was focused upon relatively strongly polar ones.*

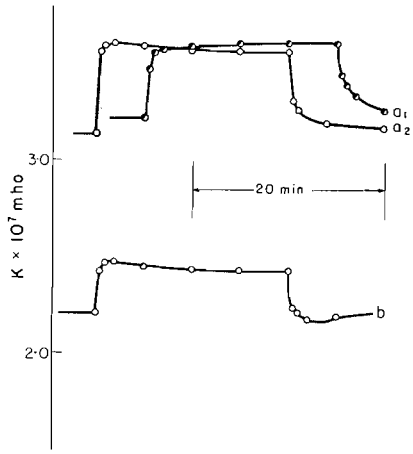

FIG. 4. a_1, a_2: *n*-Propyl bromide; f = 250 kc/s, $I \sim 2.3$ w/cm^2.
b: *n*-Butyl bromide; f = 250 kc/s, $I \sim 2.3$ w/cm^2.

CCl_4). These differences, however, are almost certainly merely a consequence of different experimental conditions. For example, the rate of fall in K after termination of irradiation will depend upon the rate of cooling of the liquid to bath temperature and upon acoustic reverberation within the cell; and ΔK itself may be expected to depend upon the frequency and/or intensity (i.e. upon parameters not mentioned in Seidl's paper). This latter dependence is, in fact, clearly shown in Fig. 3: for ethyl bromide, ΔK increases from roughly 10% at f = 250 kc/s and I = 2.3 w/cm^2 to nearly 50% at f = 1 Mc/s and I = 12.4 w/cm^2. The fact that no further increase in ΔK is observed when irradiating at f = 2 Mc/s and I = 24 w/cm^2 suggests, however, that there is a more or less definite limiting value that cannot be appreciably exceeded. In Seidl's terms, it may correspond to *complete* splitting of complex ions and, hence, to maximum mobility of the resultant simple charge carriers. Significantly, ΔK was unaffected by molecular size or by the extent of cavitation (which could be varied by dissolving variable quantities of pure nitrogen in the outgassed liquid).

In the case of the two alcohols, however, much more profound departures from Seidl's data are noted. With methanol, the general behavior is still reminiscent of that of the bromides; but ΔK at 250 kc/s and I = 2.3 w/cm^2 now amounts to nearly 50% (instead of 10% as recorded with the bromides under the same conditions), and K tends to *fall* slightly after rapid attainment of its maximum value (cf. Fig. 5—a form designated as Type B). It should here be pointed out that this fall cannot be associated with a back e.m.f., since termination of the irradiation is accompanied by a rapid return of the conductance *to its original value, not to a lower one.* This is particularly well exemplified by curve d of Fig. 5; the same curve, incidentally, suggests that ΔK_{max} lies close to 50% reached at f = 250 kc/s, I = 2.3 w/cm^2.

Finally, with ethanol, neither Type A nor Type B K/t curves are found. At f = 250 kc/s and $I < 1$ w/cm^2 as well as at f = 1 Mc/s and I = 12.4 w/cm^2, K *falls* under the influence of ultrasonic irradiation ($-\Delta K$ amounting to about 9 and 15% respectively); at f = 1 Mc/s, recovery of K requires inordinately long periods of time (25–30 minutes); and an upward change of the conductance during irradiation is only observed at f = 250 kc/s and I = 1.4 and 2.3 w/cm^2. Even in this range, the *initial* response to irradiation is a reduction (cf. Figs. 6 and 7).

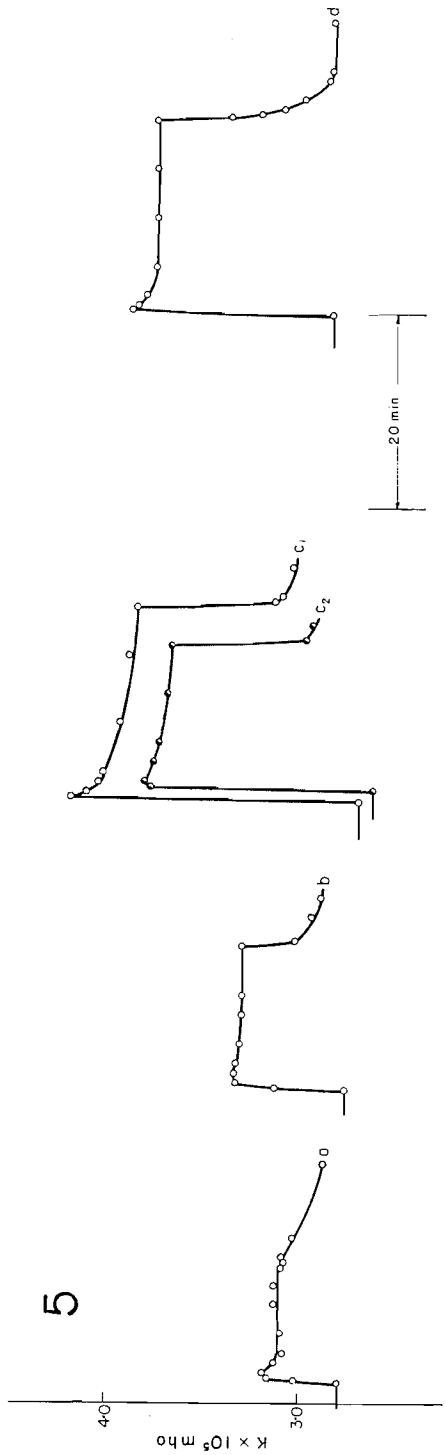

FIG. 5. *a*: Methanol; $f = 250$ kc/s, $I \sim 0.7$ w/cm².
b: Methanol; $f = 250$ kc/s, $I \sim 1.4$ w/cm².
c_1, c_2: Methanol; $f = 250$ kc/s, $I \sim 2.3$ w/cm².
d: Methanol; $f = 1$ Mc/s, $I \sim 12.4$ w/cm².

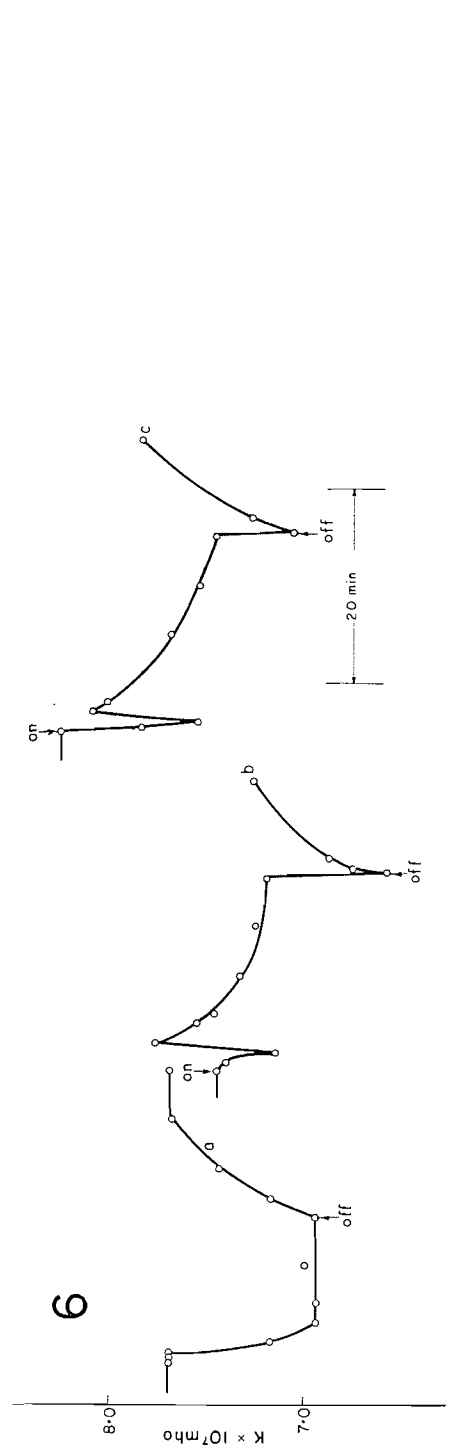

FIG. 6. *a*: Ethanol; $f = 250$ kc/s, $I \sim 0.7$ w/cm².
b: Ethanol; $f = 250$ kc/s, $I \sim 1.4$ w/cm².
c: Ethanol; $f = 250$ kc/s, $I \sim 2.3$ w/cm².

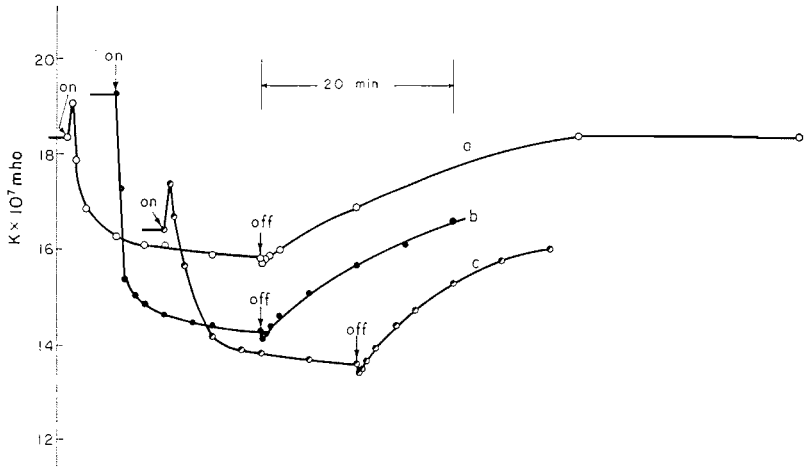

FIG. 7. *a*, *b*, *c*: Ethanol; $f = 1$ Mc/s, $I \sim 12.4$ cm².

To account for the observations made with methanol, only a slight modification of Seidl's hypothesis appears to be necessary: if the initial upward change of K is once again (as in the case of unassociated fluids) ascribed to disruption of complex ions (or better, to disruption of associated complexes), the subsequent slight fall of the conductance can be attributed to the re-establishment of some form of equilibrium between associated and non-associated charge carriers. But in the case of ethyl alcohol, the experimental data indicate a much more complex pattern of events. The nature of these events remains, at this stage, necessarily speculative and it is therefore not proposed to discuss them here. Two notable features of the K/t curves obtained at $f = 250$ kc/s and $I = 1.4$–2.3 w/cm² (Fig. 6, curves *b* and *c*) might, however, usefully be noted. First, the rise in conductance after the 2nd or 3rd minute of irradiation was in all cases accompanied by a sudden onset of cavitation. As long as the liquid was not cavitating, K continued to fall towards an equilibrium value similar to that shown in Fig. 6*a*.* Secondly, the form of curve (excluding the initial portion) is strongly reminiscent of the dielectric relaxation

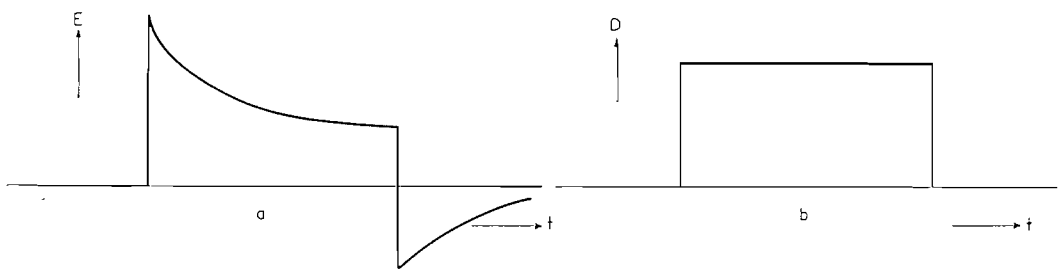

FIG. 8. Dielectric relaxation under prescribed D (after Böttcher).
a: Variation of electrical field with time.
b: Variation of dielectric displacement with time.

**In the case of the bromides and methyl alcohol, there was no apparent connection between an upward change of K and cavitation. For example, at f = 250 kc/s and I = 0.75 w/cm², the conductance of methanol increased despite complete absence of visible cavitation; and with the bromides, ΔK was found to be independent of the extent of cavitation. In the light of these observations, one is tempted to suggest that cavitation (insofar as it can occur at all) and an upward change in the conductance are two events following upon a single cause, e.g. an energy build-up in the liquid to a critical threshold value.*

curves discussed by Böttcher (3); the particular case considered by him involves a polar dielectric between the plates of an ideal condenser to which a uniform static field is applied and in which one is concerned with the time variation of the resultant electrical field E. (This variation, and the corresponding variation of the dielectric displacement D, are shown as curves a and b in Fig. 8.)

DETERMINATION OF URANIUM IN FLOTATION CONCENTRATES AND IN LEACH LIQUORS BY X-RAY FLUORESCENCE[1]

G. L. SMITHSON, R. L. EAGER, AND A. B. VANCLEAVE

ABSTRACT

X-Ray fluorescence has been applied to the analysis of flotation concentrates obtained from pegmatitic uranium ores occurring in Northern Saskatchewan. Approximate uranium analyses can be obtained by direct measurement on flotation concentrates but more accurate results are obtained by using an internal standard such as strontium or yttrium. The time required for an analysis, as compared to that of conventional chemical or fluorimetric methods, is considerably reduced and flotation pilot plant operations can therefore be more effectively controlled. The method has been extended to include the analysis of sulphate leach liquors obtained from the leaching of pegmatitic ores and their flotation concentrates. Organic phases obtained in liquid – liquid extraction studies can also be rapidly analyzed for uranium by X-ray fluorescence.

INTRODUCTION

The application of X-ray fluorescence to quantitative analysis for uranium has been the subject of studies by Cope (1), Pish and Huffman (2), and Kehl and Russell (3). It has generally been found desirable to use internal standards such as strontium, molybdenum, yttrium, or bromine to avoid matrix effects. Claisse (4) has suggested a fusion method by which accurate X-ray fluorescence analysis can be done without an internal standard. The fusion method involves dilution of the sample with the flux, thus decreasing the limit of detection.

The authors have been interested in developing rapid and reasonably accurate methods for the determination of uranium in flotation concentrates collected from the low grade pegmatitic ores of Northern Saskatchewan (5). Uranium analyses on sulphate leach liquors and on aqueous and other liquid phases resulting from liquid – liquid extraction studies are also of interest. The conventional chemical methods and the widely used fluorimetric method (6) of uranium analysis are very time consuming and of little value in the control of a flotation pilot plant. The possibility of applying X-ray fluorescence to this problem has therefore been investigated.

EXPERIMENTAL

Equipment

A General Electric XRD-5D/F X-ray spectrometer equipped with a Machlett AEG 50 tungsten target tube, a lithium fluoride crystal, a 0.010-inch Soller slit, and a No. 2 SPG (Krypton) proportional counter tube was used. The X-ray tube was operated at 50 KVP and 50 ma. In charting spectra the following settings were normally employed: scanning speed 0.2 deg/min; chart speed 6 in./hr; time constant 8; full-scale pen deflections of 200, 1000, or 2000 c.p.s. Bakelite sample holders with $22 \times 22 \times 3$ mm recesses were used for solid samples.

The grinding and mixing of solid samples was done in a motor-driven mullite mortar and pestle.

ANALYSIS OF FLOTATION CONCENTRATES WITHOUT AN INTERNAL STANDARD

Since the matrix minerals and the average particle size in the flotation concentrate from a particular pegmatitic ore were believed to be reasonably uniform, an attempt was made to apply X-ray fluorescence analysis to the concentrates without any pretreatment other than drying. Typical results are shown by the lower line in Fig. 1 in which the intensity of the U L_{α_1} line (as determined from chart recording) is shown plotted against the per cent of U_3O_8 (as determined fluorimetrically (6)) in the sample. The positions of the straight lines in Fig. 1 were determined by the method of least squares. The scatter

For personal use only.

of the experimental points about the lower line is partly due to errors inherent in both the fluorimetric and X-ray fluorescence methods, and partly due to variations in particle size of the samples. Some measure of the effect of particle size variation is shown by the results given in Figs. 1 and 2. The intensity of the U L_{α_1} line was observed to increase as the particle size was reduced,* finally reaching a constant level after about 30 minutes of grinding of the sample in a mortar. The top line in Fig. 1 could be used as a calibration curve to determine the per cent U_3O_8 in flotation concentrates from the particular ore used, provided that the particle size of the samples had been sufficiently reduced either in the grinding circuit of the pilot plant or by subsequent treatment in a mortar. Calibrations lying anywhere between the two lines shown in Fig. 1 could be obtained for the particular ore depending on the degree of comminution of the sample. Standards would have to be set up for each ore for a particular set of grinding conditions. Obviously, this would not be a very satisfactory procedure if a number of ores were being treated under a variety of pilot plant conditions. However, if a large number of analyses were required on flotation concentrates from a given ore, and the grinding circuit remained unchanged, it would be possible to apply X-ray fluorescence methods directly to the concentrate samples without further preparation. The results obtained would not be as reliable as those that can be obtained by employing a suitable internal standard. The main advantage would be in obtaining an approximate result in the minimum of time.

The per cent deviation from the mean intensity of the U L_{α_1} line produced by removing samples from the sample holder and repacking them, varied from 0.2 to 2.4%. Such fluctuations are considered to be within the accuracy of the X-ray technique.

ANALYSIS OF FLOTATION CONCENTRATES USING AN INTERNAL STANDARD

Uranium Determination

If uranium analyses of flotation concentrates collected by a variety of methods or of ores from a variety of sources are required, the addition of a suitable internal standard is desirable. Since no significant amounts of strontium have been detected in the Saskatchewan pegmatites under study, it has been convenient to use it as an internal standard for solid samples.

The procedure adopted for adding the internal standard to solid samples is as follows:

(*a*) A 3-g sample of dry flotation concentrate is poured into a watch glass to form a cone-shaped mass.

(*b*) A crater is formed in the cone by pressing the bottom of a small test tube down on the apex of the cone.

(*c*) One milliliter of absolute ethanol is added to the crater. (The dry flotation concentrates are hydrophobic. The ethanol facilitates the spreading of the aqueous solution of the standard through the sample.)

(*d*) One milliliter of aqueous $Sr(NO_3)_2$ solution containing 10 mg of Sr per milliliter is added to the crater.

(*e*) The sample is dried for 30 minutes under a heat lamp, transferred to the mullite mortar, and ground for 30 minutes.

A portion of the sample prepared as above is packed into a sample holder and the significant part of the X-ray spectrum either recorded or determined by setting the spectrogoniometer at 2θ angles as listed in Table I and counting for 100 seconds. The background count at the position of the peak is interpolated from the background counts on either side of the peak.

**The original flotation concentrates were approximately 90% minus 270 mesh. Grinding for 30 minutes reduces the sample to approximately 90% minus 400 mesh.*

The samples used for calibration (Fig. 3) were obtained from the Department of Mines and Resources, Ottawa, and the New Brunswick Laboratory of A.E.C., New Brunswick, N.J., together with two samples analyzed chemically (7) by the authors. Although these samples contained a variety of uranium minerals in differing matrices, the experimental points, whether determined from chart recordings or by counting at the specified angles, occur within experimental error on the straight line shown in Fig. 3. Although this method of analysis requires more time than would be the case if no internal standard was used, it yields more accurate and reliable results. Using the chart-recording technique, a single operator can analyze about 24 samples in an 8-hour day. Since samples of flotation concentrate can be fairly rapidly dried, analytical results can be transmitted to the pilot plant operator much more rapidly than is the case when the ultraviolet fluorimetric method is used.

The reproducibility of the method of using strontium as an internal standard was tested by repeating the procedure for adding the standard on 10 separate portions of a given sample. The ratio $I(\text{U } L_{\alpha_1})/I(\text{Sr } K_\alpha)$ was determined for each preparation both from the chart recording and by counting at fixed positions. The mean intensity ratios and the standard deviations were 0.649 ± 0.015 and 0.670 ± 0.020 for the direct-count and chart-recording methods respectively. The standard deviations for the two methods indicate an overlap in the ratio values. As expected, the results calculated from chart recordings are less precise than those obtained by direct counting.

Table II shows a comparison of analytical results on three flotation concentrate samples as determined by chemical analysis, fluorimetric analysis, and by X-ray fluorescence analysis using strontium as an internal standard. The agreement between the results for the three methods is well within their estimated limits of accuracy. The approximate relative time required for an analysis by each of these methods was estimated on the assumption that a single operator worked full time on a routine basis.

Iron Determination

There is a tendency for acid-consuming minerals, such as iron oxides and other minerals containing iron, to be collected along with uranium minerals in the flotation of pegmatitic ores (5). A knowledge of the approximate iron content of uranium ore flotation concentrates is therefore useful in assessing the value of various collectors and systems of flotation. A good estimate of the iron content of these flotation concentrates can be made by referring the intensity of the Fe K_α line to that of the internal standard used to determine the uranium content. A calibration curve used for this purpose is shown in Fig. 4.

The samples used for calibration were (*a*) synthetic mixtures prepared by mixing iron ores of known iron content with quartz and (*b*) flotation concentrates which had been chemically analyzed for their iron content by the authors. The failure of the calibration curve to go through the origin is due to the occurrence of a small peak for this element inherent in the X-ray equipment (see also Fig. 6).

ANALYSIS OF SULPHATE LEACH LIQUORS

Uranium Determination

The X-ray fluorescence technique has also been applied to the analysis of pregnant leach solutions resulting from the leaching of uranium ores or their flotation concentrates with sulphuric acid. The design of the sample holder for liquids is similar to that described by Pish and Huffman (2) except that a polyethylene washer is used and the cell is covered with a piece of 0.0005-inch mylar film. It has been found necessary to replace the mylar film each time that the sample is changed to avoid effects due to uranium adsorption. Liquids are transferred to and from the sample holder by means of a hypodermic syringe equipped with a curved-tip stainless steel needle.

Although strontium is a convenient internal standard to use with solid samples, it is not suitable for use with solutions which contain sulphate ions. An alternative standard, yttrium, has been found to be quite satisfactory for use with sulphate leach liquors. The pegmatitic ores under investigation contain only trace amounts of rare earths and there is no evidence for the presence of yttrium in the ore or sulphate leach solutions. In the event that significant amounts of rare earths were present in the ore, another internal standard such as bromine could be selected. The calibration for the determination of uranium in aqueous solution shown in Fig. 5 was set up by diluting a standard solution of uranyl nitrate and using yttrium nitrate as the internal standard. Aqueous solution samples are prepared for analysis by adding 0.50 ml of stock yttrium nitrate solution (10 mg of yttrium per milliliter) to a 10-ml volumetric flask and diluting to volume with the solution containing dissolved uranium. Relative intensities determined from chart recordings and by direct counting (see Table II for spectrometer settings) were found to agree within estimated experimental error.

The greater precision of the direct-counting method, as compared to that of the chart-recording method of determining relative intensities for samples in the same concentration range, is shown in Table III. The data in Table III also indicate the decrease in precision that occurs in the chart-recording method when the concentration of U_3O_8 in the sample drops below 1 mg/ml. The per cent standard deviation of the intensity ratio determined by direct count for samples containing more than 1 mg/ml of U_3O_8 would undoubtedly be less than the $\pm 2.2\%$ shown for the chart-recording method. Concentrations as low as 0.1 mg U_3O_8 per milliliter can readily be determined by this method.

TABLE III

Comparison of percentage standard deviations in $I(\mathrm{U}\ L_{\alpha_1})/I(\mathrm{Y}\ K_\alpha)$ determined by chart-recording and by direct-counting methods

Method	No. determinations	Concn. range U_3O_8 in mg/ml	% Standard deviation
Chart record	30	1.0–10	±2.2
Chart record	15	0.5–1.0	±10.9
Direct count	15	0.5–1.0	±3.8

FIG. 6. Calibration for the approximate determination of dissolved iron in aqueous solutions by reference to yttrium internal standard.

No special precautions were taken to provide for additional heat exchangers to prevent temperature changes in the liquid samples during irradiation.

Since the concentration of dissolved iron in sulphate leach liquors varies considerably, the effect of adding varying amounts of iron on the observed $I(\text{U } L_{\alpha_1})/I(\text{Y } K_\alpha)$ ratio was studied. Experiments were done in which the iron content of the solutions was varied from 2 to 20 mg/ml. Although the intensities of both the U L_{α_1} and Y K_α lines were decreased as the iron concentration in the solution was increased, the ratio of their intensities was found to be constant within experimental error. This analytical method for uranium can therefore be applied to the analysis of pregnant leach liquors with confidence.

Iron Determination

It is often useful to have at least an approximate idea of the dissolved iron content

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in uranium ore leach liquors. Yttrium would not normally be used as an internal standard for iron because of the considerable difference in the wave lengths of their K_α lines. However, since yttrium is already present in the sample for the uranium analysis, a good approximation of the iron content can be made by reference to it. An example of a calibration curve used for such determinations is shown in Fig. 6 (see comment regarding Fig. 4).

Determination of Uranium in an Organic Solvent

In the course of liquid – liquid extraction studies of the recovery of uranium from pregnant leach solutions, many uranium analyses of both aqueous and organic phases are required. Although the ultraviolet fluorimetric method of uranium analysis is usually the most satisfactory one to use in determining the normally small concentrations of uranium remaining in the aqueous phase, it is often cumbersome and inaccurate when applied to the loaded organic phase. If the fluorimetric method is used for the analysis of the organic phase it is generally necessary to back-extract the uranium to an aqueous phase (8), a step which often reduces the accuracy of the determination. An X-ray fluorescence analysis method applied directly to the loaded organic phase does not suffer from this difficulty. Since inorganic substances such as strontium and yttrium are generally not very soluble in the organic liquids that extract uranium, some other internal standard has to be chosen. Bromine in the form of bromobenzene has been suggested for this purpose (2).

Calibrations for the use of bromine as an internal standard are shown in Fig. 7 for both aqueous solutions of uranyl sulphate and for uranium in 0.1 *M* solutions of tri(iso)-octyl amine in kerosene containing 2.5 volume per cent of *n*-decyl alcohol. The calibration for aqueous solutions shown in Fig. 7 was obtained by adding 0.50 ml of sodium bromide solution (10 mg Br per milliliter) to a 10-ml volumetric flask and diluting to volume with standard uranyl sulphate solution. The organic solution calibration was obtained by successively extracting 50 ml of standard uranyl sulphate solution (pH adjusted to 1.5 with sulphuric acid) with five 20-ml portions of a 0.1 *M* solution of tri(iso)octyl amine in kerosene containing 2.5 volume per cent of *n*-decyl alcohol. (A fluorimetric analysis of the raffinate showed that at least 99.4% of the uranium had

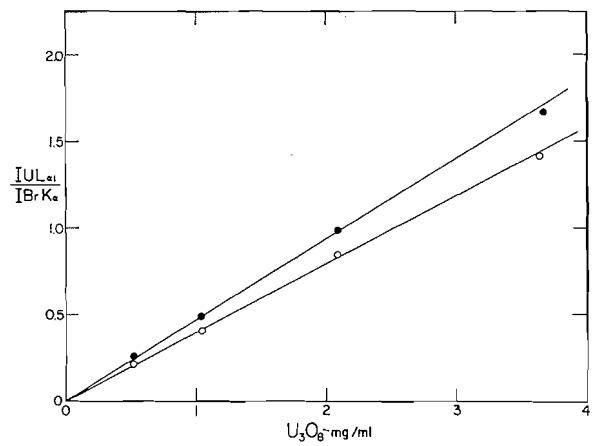

FIG. 7. Calibrations for the determination of U_3O_8 in aqueous and kerosene solutions with bromine as internal standard.

For personal use only.

been extracted to the organic phase.) The organic extracts were combined and a 9.5-ml aliquot taken for analysis along with 0.50 ml of a solution of analyzed bromobenzene in kerosene (10 mg Br per milliliter). As long as the concentration of dissolved uranium (expressed as U_3O_8 equivalent) exceeds 0.1 mg/ml, this method of analyzing aqueous or organic phases is very satisfactory and requires much less time than other standard analytical methods. However, it is necessary to have a calibration for each organic diluent used, as the reflection of X-rays is dependent on the density of the medium (9).

CONCLUSIONS

X-Ray fluorescence analysis greatly reduces the time required for the analysis of flotation concentrates accumulating from pilot plant studies on uranium ores. It is possible to do uranium analyses directly on concentrate samples from a given ore that has been subjected to a standard treatment but, if reliable and more accurate results are required, the addition of an internal standard such as strontium or yttrium and further comminution of the sample is necessary. An approximate analysis for iron in an ore or concentrate can be made by reference to the internal standard used for uranium. The lowest concentration of uranium that can conveniently be determined by X-ray fluorescence analysis of solids is about 0.02% U_3O_8.

Uranium analyses and approximate iron analyses can also very conveniently be done on sulphate leach liquors containing uranium by X-ray fluorescence with reference to a yttrium internal standard. The use of bromine as an internal standard for the determination of uranium in organic solvents is quite satisfactory. The low limit for the accurate determination of uranium in solution is about 0.1 mg of U_3O_8 per milliliter.

X-Ray fluorescence could probably readily be adapted to continuous control analysis in commercial uranium mills.

ACKNOWLEDGMENTS

Financial assistance provided by the Saskatchewan Research Council is gratefully acknowledged. The authors are indebted to Dr. Brad Gunn for the ultraviolet fluorimetric analyses.

URONIC ACIDS FROM WHITE SPRUCE (PICEA GLAUCA (MOENCH) VOSS)[1]

G. A. ADAMS

ABSTRACT

Acid hydrolysis of extractive-free white spruce wood produced a number of neutral and acidic sugars and oligosaccharides. The acidic components were isolated and three of these were shown to be 4-*O*-methyl-D-glucuronic acid, 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylose, and tentatively *O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylopyranose.

Investigations of the hemicelluloses of white spruce (*Picea glauca*) have yielded an arabogalactan (1) and a glucomannan (2). Since neither of these fractions contained more than a trace of uronic acids, it seemed likely that the acid components were associated with the xylan portion of the wood. The present communication is concerned with the composition and identification of three uronic acid components isolated from spruce wood by partial hydrolysis.

The uronic acids were obtained by acid hydrolysis of extractive-free white spruce wood and separated from the neutral sugars by adsorption on an anion exchange resin. Further separation of the recovered uronic acid components yielded several fractions of which three (I, II, and III) were identified.

Chromatographic evidence, methoxyl content, and equivalent weight tentatively identified fraction I as 4-*O*-methyl-D-glucuronic acid. Conversion of the acid to its methyl ester methyl glycoside and reduction with lithium aluminum hydride yielded 4-*O*-methyl-D-glucose, which was characterized as crystalline 4-*O*-methyl-D-glucose phenylosazone.

Hydrolysis of fraction II and chromatographic examination of the hydrolyzate indicated the presence of D-xylose and 4-*O*-methyl-D-glucuronic acid. Reduction of the ester glycoside gave the corresponding disaccharide glycoside which on hydrolysis yielded crystalline D-xylose and 4-*O*-methyl-D-glucose, the latter being identified as its crystalline phenylosazone. The point of attachment of the 4-*O*-methyl-D-glucuronic acid to the D-xylose residue was determined by methylation studies. The aldobiouronic acid methyl ester, methyl glycoside, was converted to methyl-*O*-(4-*O*-methyl-D-glucopyranosyl)-D-xyloside by reduction with lithium aluminum hydride and the product was then fully methylated. On hydrolysis it yielded 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose thus proving that the acid was attached glycosidically to $C_{(2)}$ of the xylose residue. Recent evidence has established that the glycosidic bond in this aldobiouronic acid is in the α configuration (3). These findings showed that the aldobiouronic acid was 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose.

The aldotriouronic acid (fraction III) was composed of 4-*O*-methyl-D-glucuronic acid and D-xylose and had $[\alpha]_D^{25}$ +59°. It could not be obtained in crystalline form. The attachment of the 4-*O*-methyl-D-glucuronic acid and the xylose units to one another was determined by methylation studies. The aldotriouronic acid was converted to its corresponding methyl ester methyl glycoside by treatment with 1% methanolic hydrogen chloride at room temperature. Reduction with lithium aluminum hydride provided the

Issued as N.R.C. No. 4970.

glycoside of the trisaccharide which was methylated with methyl iodide and silver oxide. Hydrolysis of the fully methylated trisaccharide yielded approximately equimolecular quantities of 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,3-di-*O*-methyl-D-xylose, and 3,4-di-*O*-methyl-D-xylose. The lower rotation of the aldotriouronic acid (+59°) as compared to that of the aldobiouronic acid (+97°) indicated that the xylobiose moiety in the former had a negative rotation and its glycosidic linkage was β. The foregoing findings established the aldotriouronic acid tentatively as *O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylopyranose.

The aldobiouronic acid, 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylose, is the most common uronic component of wood. Its presence was first suggested in oak wood (4) and in 1952 it was identified in aspen wood (5). Since that time it has been found in all woods examined for it including both coniferous (6–13) and deciduous species (14–21).

Aldotriouronic acids containing 4-*O*-methyl-D-glucuronic acid and D-xylose have been isolated from aspen wood (17) in crystalline form and from Monterey pine (22), although the structures have not been reported. The aldotriouronic acid, *O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylose, has been obtained in crystalline form from western hemlock (23) and jute (24). The present aldotriouronic acid of white spruce, although not obtained in crystalline form, has a chemical structure identical with the crystalline uronic acids of western hemlock and jute.

It was pointed out in an earlier publication (25) that the presence of a methyl ether substituent on $C_{(4)}$ of the glucuronic acid is associated with glycosidic attachment to $C_{(2)}$ of the xylose unit. Recently Brasch and Wise have isolated 3-*O*-α-(4-*O*-methyl-D-glucuronosyl)-D-xylose from Monterey pine (13) and have suggested that it may be a component of other woods; however, careful examination of the hydrolyzate from white spruce has not revealed the presence of this component.

EXPERIMENTAL

All specific rotations were equilibrium values unless otherwise stated and melting points are corrected.

Paper Chromatography

Chromatographic separations were carried out by the descending method on Whatman No. 1 paper using the following solvents: (A) ethyl acetate: pyridine: water (2:1:2); (B) ethyl acetate: acetic acid: formic acid: water (19: 3: 1: 4); and (C) ethanol: benzene: water (47: 200: 15). A 3% solution of *p*-anisidine hydrochloride in ethanol was used as the spray reagent.

Preparation of Uronic Acids

White spruce wood (*Picea glauca* (Moench) Voss) was reduced to shavings and rendered extractive-free as previously described (26). The wood (500 g) was heated with 0.5 *N* sulphuric acid (7000 ml) at a temperature of 94° C until the reducing power became constant (9 hours). The hot solution of sugars and sugar acids was recovered by filtration through a sintered glass filter (porosity C) and the wood residue was washed free of acid. The hydrolyzate and washings were brought to pH 6.0 by careful addition of barium hydroxide and barium carbonate. The barium sulphate was removed by filtration and the solution and washings were passed through a column of Amberlite IR-120 resin to remove cations. The uronic acid components were then absorbed on a column of Dowex 1-X^4 (acetate form) (30×180 mm). The column was washed with water until the eluate gave a negative anthrone test for sugars. Electrophoretic examination of the

washings on paper in 0.025 *N* sodium bicarbonate solution showed no trace of uronic acids. The uronic acid components were eluted from the column by 0.1 *N* formic acid and were collected by an automatic fraction collector in 200 tubes (13 ml in each tube). Chromatographic examination of the recovered fractions in solvent B showed that only minor separation of four major components had been achieved. The major fraction (tubes 41–80) contained 74% of the material put on the column. Further separation of this fraction was carried out on a cellulose column (30 mm × 450 mm) using solvent B. Four main fractions were obtained having R_x values (movement relative to that of xylose) as follows: 0.49, 0.64, 0.93, 1.16. Paper chromatographic examination (solvent B) showed that one fraction (R_x 0.49) was a mixture of two components. The eluting solvent was partly removed by evaporation at 40° C under reduced pressure and the aqueous solution of the residual uronic acid extracted thoroughly with ether to remove formic acid. Freeze drying of the aqueous solution yielded the uronic acids as white porous solids. Three fractions having the following properties were recovered: fraction I (0.222 g); R_x 1.16 (solvent B); $[\alpha]_D^{25}$ +48.6°; methoxyl 14.9; acid equivalent 205 (calculated for $C_7H_{12}O_7$, methoxyl 14.9%; acid equivalent 208). Fraction II (0.816 g); R_x 0.93 (solvent B); $[\alpha]_D^{25}$ +97°; methoxyl 9.4%; acid equivalent 340 (calculated for $C_{12}H_{20}O_{11}$, methoxyl 9.1%; acid equivalent 340). Fraction III (0.988 g); R_x 0.64 (solvent B); $[\alpha]_D^{25}$ +59°; methoxyl 6.1%; acid equivalent 510 (calculated for $C_{17}H_{28}O_{15}$, methoxyl 6.54%; acid equivalent 472).

Hydrolysis Products of Uronic Acid Fractions

Samples of fractions II and III (approximately 10 mg each) were heated in sealed tubes with 4 ml of methanolic hydrogen chloride (8%) for 10 hours at 80° C. After removal of solvent, hydrolysis was continued with *N* hydrochloric acid for 12 hours at 100° C. Chromatograms of the hydrolyzates in solvent A and B showed the presence of D-xylose and 4-*O*-methyl-D-glucuronic acid. On the basis of chromatographic comparison in solvent B with a known reference, fraction I was identified tentatively as 4-*O*-methyl-D-glucuronic acid.

Examination of the Uronic Acid Fractions

4-O-Methyl-D-glucuronic Acid (Fraction I)

The acid (113 mg) was converted to its methyl ester methyl glycoside by heating in a sealed glass tube with 15 ml of methanolic hydrogen chloride (3%) for 10 hours at 80° C. The product (123 mg) was dissolved in dry tetrahydrofuran (25 ml) and the solution was added dropwise over a period of 1 hour to a stirred suspension of lithium aluminum hydride (500 mg) in tetrahydrofuran (25 ml). The reaction mixture was refluxed gently for 1 hour, cooled, and the unused lithium aluminum hydride was decomposed by addition of ethyl acetate and finally water. After filtration, concentration, and deionization by Amberlite IR-120 and Amberlite IR-4B the glycoside of the monosaccharide was recovered (112 mg). Hydrolysis by 0.5 *N* hydrochloric acid (6 ml) in a sealed glass tube at 100° C for 8 hours yielded 4-*O*-methyl-D-glucose, as shown by chromatographic examination of the neutralized hydrolyzate in solvent A.

The phenylosazone of 4-*O*-methyl-D-glucose was prepared by heating the sugar (88 mg) with water (2.0 ml), acetic acid (0.3 ml), and phenylhydrazine (0.5 ml) for 1 hour at 90° C. The recovered 4-*O*-methyl-D-glucose phenylosazone was recrystallized from benzene and had a m.p. and mixed m.p. of 158–159° C (27).

2-O-(4-O-Methyl-α-D-glucopyranosyluronic Acid)-D-xylose (Fraction II)

Identification of the constituents of the aldobiouronic acid was made as follows: the aldobiouronic acid (370 mg) was converted to the methyl ester methyl glycoside (390

mg) and reduced by lithium aluminum hydride to the glycoside of its corresponding disaccharide (398 mg) by the methods described above. Hydrolysis with 0.5 *N* hydrochloric acid yielded a syrup (383 mg) which on chromatographic examination in solvent A was found to contain D-xylose and 4-*O*-methyl-D-glucose. A portion of the mixture (250 mg) was separated on a Celite column (28) (35 mm × 160 mm) using butanol saturated with water as the eluting solvent. Xylose (89 mg) was obtained in crystalline form and on recrystallization from methanol had a m.p. and mixed m.p. of 142–143° and $[\alpha]_D^{25}$ +19.2° (*c*, 1.7% in water). The syrupy 4-*O*-methyl-D-glucose (115 mg), $[\alpha]_D^{25}$ +60.1 (*c*, 2.3% in water) methoxyl 15.6% (calculated for $C_7H_{14}O_6$, methoxyl 16.0%), was converted to its crystalline phenylosazone. The 4-*O*-methyl-D-glucose phenylosazone on recrystallization from 25% aqueous acetone solution had a m.p. of 158–159° C.

Conversion of Aldobiouronic Acid to Disaccharide

The aldobiouronic acid (896 mg) was converted to its methyl glycoside methyl ester by refluxing with 2% methanolic hydrogen chloride (30 ml) for 8 hours. The methyl ester methyl glycoside (924 mg) in tetrahydrofuran solution (25 ml) was reduced by lithium aluminum hydride (1 g) to the glycoside of the neutral disaccharide (842 mg) $[\alpha]_D^{25}$ +95° (*c*, 1.29% in water).

Methylation of the Glycoside of 4-O-Methyl-D-glucosyl-D-xylose

The disaccharide (842 mg) was dissolved in 20% sodium hydroxide (10 ml) and methylated by the simultaneous dropwise addition of 45% sodium hydroxide and dimethyl sulphate 30 ml; two additional methylations were carried out prior to the recovery of the product. The reaction mixture was heated at 95° for 1 hour, cooled, acidified with sulphuric acid to pH 5.0, and extracted with chloroform. Evaporation of the chloroform yielded a syrup (805 mg). The infrared spectrum of this product indicated that a small amount of free hydroxyl groups was still present. One methylation with Purdie's reagents, methyl iodide (25 ml) and silver oxide (10 g), yielded a syrup (798 mg) having no free hydroxyl groups as shown by its infrared spectrum. Anal. Calc. for $C_{18}H_{34}O_{10}$: OCH_3, 52.9%. Found: OCH_3, 51.9%.

Hydrolysis of Methyl-2-O-(2,3,4,6-tetra-O-methyl-D-glucopyranosyl)-3,4-di-O-methyl-D-xyloside and Recovery of Methylated Sugars

The methylated disaccharide (798 mg) was dissolved in 8% methanolic hydrogen chloride (25 ml) and refluxed gently for 18 hours. Solvent was removed and the hydrolysis was continued in 0.5 *N* hydrochloric acid (20 ml) for 9 hours at 100° C. The hydrolyzate was neutralized with silver carbonate, deionized by Amberlite IR-120 resin and Amberlite IR-4B resin, and concentrated *in vacuo* to a clear syrup (584 mg). Chromatographic examination of the syrup in solvent C revealed two spots similar in mobility and color reaction to 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose. The sugars were separated on a Celite column (30 mm × 350 mm) using butanol saturated with water to give 3,4-di-*O*-methyl-D-xylose (120 mg) and 2,3,4,6-tetra-*O*-methyl-D-glucose (281 mg).

Identification of 3,4-Di-O-methyl-D-xylose

The clear syrup had $[\alpha]_D^{25}$ +21±1° (*c*, 1.0% in water); methoxyl content calculated for $C_7H_{14}O_5$: 34.8%; found: OCH_3, 34.8%. Chromatographic examination in solvent C showed that the syrup had the same R_g value (0.38) as 3,4-di-*O*-methyl-D-xylose and was easily distinguished from the 2,3- and 2,4-isomers (R_g values 0.31 and 0.27 respectively). Electrophoresis (29) in borate buffer using the same reference sugars showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

that the unknown sugar had the same mobility as 3,4-di-*O*-methyl-D-xylose. The sugar (71 mg) in water (1.5 ml) containing barium carbonate (65 mg) was oxidized in the dark with bromine (0.6 ml) for 48 hours. The bromine was removed by aeration, and the solution was extracted continuously with chloroform for 48 hours. The syrup which was recovered from the chloroform extract was distilled, boiling point (bath temp.) 120–150° (0.02–0.018 mm), and on seeding with 3,4-di-*O*-methyl-D-xylono-δ-lactone, crystallization occurred. Recrystallization from ether solution to which a few drops of hexane were added yielded 3,4-di-*O*-methyl-D-xylono-δ-lactone, m.p. and mixed m.p. 66–67° C, $[\alpha]_D^{25}$ $-22°\pm1°$ (*c*, 1.0 in water) (30).

Identification of 2,3,4,6-Tetra-O-methyl-D-glucose

The clear syrup recovered from the Celite column crystallized on seeding with 2,3,4,6-tetra-*O*-methyl-D-glucose. Recrystallization from ether – petroleum ether solution gave needles having m.p. and mixed m.p. 94–96° C and $[\alpha]_D^{25}$ $+84°\pm2°$ (*c*, 1.07 in water). A methanolic solution of the sugar (52 mg) was refluxed with aniline (25.4 mg) for 2 hours to give crystalline 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine which on recrystallization from hexane had m.p. and mixed m.p. 134–136° C, $[\alpha]_D^{25}$ $+239°\pm1°$ (*c*, 1% in chloroform) (31).

Characterization of O-4-O-Methyl-α-D-glucopyranosyluronic Acid-(1 → 2)-O-β-D-xylopyranosyl-(1 → 4)-D-xylose (Fraction III)

Attempts to crystallize the aldotriouronic acid were unsuccessful. The acid (500 mg) was converted to its methyl glycoside methyl ester by reacting with 1% methanolic chloride (10 ml) at room temperature. Within 5 hours the specific rotation had become constant and the solution no longer reduced Fehling's solution. Chromatographic examination in solvent C showed only one component and hence no hydrolysis had occurred. The methyl ester methyl glycoside (481 mg) was reacted with diazomethane in methanol solution to assure esterification of all carboxyl groups. Reduction with lithium aluminum hydride in tetrahydrofuran solution yielded the glycoside of the neutral trisaccharide (493 mg).

Methylation of Methyl[O-4-O-methyl-α-D-glucopyranosyl-(1 → 2)-O-β-D-xylopyranosyl-(1 → 4)]-D-xyloside

The trisaccharide (493 mg) was dissolved in methanol (10 ml) and methylated with methyl iodide (30 ml) and silver oxide (6 g) by refluxing 20 hours. After the third methylation the product was completely soluble in methyl iodide. Five methylations yielded a brownish syrup (315 mg) having no free hydroxyl groups as shown by its infrared spectrum. Anal. Calc. for $C_{25}H_{46}O_{14}$: OCH_3, 48.9. Found: OCH_3, 46.8; $[\alpha]_D^{25}$ $+52.9°$ (*c*, 1% in methanol).

Hydrolysis of Methyl[O-2,3,4,6-tetra-O-methyl-α-D-glucopyranosyl-(1 → 2)-O-β-3,4-di-O-methyl-D-xylosyl-(1 → 4)]-2,3-di-O-methyl-D-xyloside

The methylated trisaccharide (300 mg) was dissolved in 8% methanolic hydrogen chloride and refluxed for 12 hours; after removal of the solvents, the hydrolysis was completed by heating in 0.5 *N* hydrochloric acid for 8 hours. Recovery after neutralization with Amberlite IR-4B yielded a clear syrup (230 mg). Chromatographic examination in solvent C showed the presence of three sugars which corresponded in color reaction and rate of movement to authentic samples of 2,3-di-*O*-methyl-D-xylose, 3,4-di-*O*-methyl-D-xylose, and 2,3,4,6-tetra-*O*-methyl-D-glucose. The methylated sugars were separated on sheets of Whatman No. 1 filter paper using solvent C. Elution of the paper

strips with methanol yielded solutions of the crude syrups which were filtered and then dried to constant weight. Yields: 2,3,4,6-tetra-*O*-methyl-D-glucose, 69.8 mg; 3,4-di-*O*-methyl-D-xylose, 48.3 mg; and 2,3-di-*O*-methyl-D-xylose, 42.6 mg.

Identification of Component Sugars

*3,4-Di-O-methyl-*D*-xylose.*—The colorless syrup had $[\alpha]_D^{25}$ +22.2° (*c*, 1.20% in methanol) and the R_g values in solvent C were identical with those of an authentic sample of 3,4-di-*O*-methyl-D-xylose. Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8. Found: OCH_3, 34.4. Bromine oxidation as described above yielded crystalline 3,4-di-*O*-methyl-D-xylono-δ-lactone, m.p. 66–67° C, $[\alpha]_D^{25}$ −21° (*c*, 1% in water).

*2,3-Di-O-methyl-*D*-xylose.*—This sugar had $[\alpha]_D^{25}$ +20.8° (*c*, 1.06% in methanol). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8. Found: OCH_3, 34.6. The R_g value in solvent C was identical with that of 2,3-di-*O*-methyl-D-xylose. Conversion to the anilide provided crystalline 2,3-di-*O*-methyl-*N*-phenyl-D-xylosylamine, m.p. and mixed m.p. 123–124° C and $[\alpha]_D^{25}$ +188 (*c*, 0.5% in ethyl acetate) (32).

*2,3,4,6-Tetra-O-methyl-*D*-glucose.*—The rate of movement of this sugar on paper strips in solvent C was the same as that of an authentic sample of 2,3,4,6-tetra-*O*-methyl-D-glucose. Refluxing with aniline in methanolic solution provided the characteristic crystalline 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glycosylamine which on recrystallization from hexane had a m.p. and mixed m.p. of 134–136° C, $[\alpha]_D^{25}$ +235±1° (*c*, 1.1% in chloroform).

PHOTOCHEMICAL SEPARATION OF MERCURY ISOTOPES

II. THE REACTION OF $Hg^{202}6(^3P_1)$ ATOMS, PHOTOEXCITED IN NATURAL MERCURY VAPOR, WITH WATER VAPOR AND OTHER HgO-FORMING SUBSTRATES[1]

R. PERTEL[2] AND H. E. GUNNING[3]

ABSTRACT

An investigation has been made of the reaction of $Hg^{202}(^3P_1)$ atoms, photoexcited in natural mercury vapor, with several HgO-forming substrates, including water vapor, nitrous oxide, and oxygen. The reactions were carried out under flow conditions at room temperature. Emphasis has been placed on the Hg^{202} content of the HgO product. Enrichment in Hg^{202} would be evidence of the primary formation of a mercury compound.

In the reactions with nitrous oxide and oxygen, it was found that the HgO product contained the normal abundance of Hg^{202}. With water vapor, a product containing up to 35% Hg^{202} was obtained, compared to the normal abundance of 29.8%. The addition of 1,3-butadiene to the water vapor substrate was found to have a marked effect on the enrichment in Hg^{202} in the HgO product. A product containing 85% Hg^{202} was recovered when the substrate contained 21 mole % of added butadiene. A systematic study of the effect of butadiene concentration on the enrichment reaction showed that the Hg^{202} content remains constant for butadiene concentrations exceeding approximately 10 mole %. The water–butadiene reaction is recommended as a simple method for preparing Hg^{202} from natural mercury.

The factors influencing the enrichment process are discussed, together with the significance of the results with respect to the mechanisms of decomposition of the molecules studied.

INTRODUCTION

In the mercury-$6(^3P_1)$-photosensitized decomposition of certain gaseous oxygen-containing compounds, HgO is formed as a product of the reaction. Important among such substrates are water vapor, oxygen, and nitrous oxide. Through the technique of monoisotopic photosensitization, it is possible to obtain information on the extent to which a mercury compound is formed in the primary process. Thus, in the water reaction, if a single isotope specie, Hg^{i}, is photoexcited in the natural mercury vapor (Hg^{N}) present in the reaction cell, it is possible to distinguish between primary processes of the type:

$$Hg^{i}6(^3P_1) + HOH \rightarrow Hg^{i}OH + H \quad [1]$$

and

$$Hg^{i}6(^3P_1) + HOH \rightarrow H + OH + Hg^{i}6(^1S_0), \quad [2]$$

since reaction [1] could lead to the formation of an HgO enriched in the exciting isotope.

The reaction of $Hg^{198}6(^3P_1)$ atoms, in Hg^{N}, with HOH–N_2 mixtures has been studied previously (1). The HgO was found to contain 15% Hg^{198}, compared to the natural abundance of 10.0%. The photoexcitation of $Hg^{198}6(^3P_1)$ atoms in Hg^{N} is complicated by the juxtaposition of the 201*b* of Hg^{201} in the h.f.s. of Hg^{N}. Some excitation of $Hg^{201}6(^3P_1)$ atoms in Hg^{N} would be expected in irradiation with an Hg^{198} source. The experimental and theoretical aspects of the photoexcitation of single mercury isotopes in Hg^{N} has been discussed in an earlier study (2).

Zellikoff, Aschenbrand, and Wyckoff (3) have made a preliminary study of the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^{N}, with HOH–N_2 mixtures. At low substrate pressures the HgO product was found to contain 35% Hg^{202}, compared to the natural abundance of 29.8%.

In the present investigation, major emphasis has been placed on the reaction of $Hg^{202}6(^3P_1)$ atoms with water vapor. Certain of our preliminary findings have already

been published (4, 5). Experimental conditions have been sought which yield maximum enrichment in Hg^{202} in the HgO product of the reaction. In addition to the information on reaction mechanism which can be obtained from such a study, it was hoped that the reaction could be developed into a simple method for proliferating mercury isotopes.

Preliminary data are also reported on the reaction of $Hg^{202}6(^3P_1)$ atoms with O_2 and N_2O, in order to assess the importance of primary HgO formation in these reactions.

The details of the investigation follow.

EXPERIMENTAL

The reactions were carried out under flow conditions, at room temperature, in a high-vacuum system. The reaction cell consisted of a 5-coil helix, fashioned of 12 mm O.D. optical quartz. The cell was attached to the flow system by standard tapers. For the light source, a quartz electrodeless discharge was used, 8 mm O.D., 150 mm in length, containing a few milligrams of 98.3% Hg^{202}. The discharge was sustained with a Baird Microwave Exciter, operating at a wavelength of 12.2 cm. The lamp was maintained at 25.0° C by being enclosed in a jacket of Vycor 7910 glass, through which thermostatted distilled water was circulated. The lamp-water jacket assembly was axially disposed within the coils of the spiral reaction cell. The microwave reflector was placed a few centimeters from the reaction cell.

Flow rates were measured with calibrated, U-shaped manometers containing dibutyl phthalate. The flow rates were expressed in milliliters per minute at 25° C and 760 mm pressure. Hoke high-vacuum needle valves served to control the flow rate.

Efficient mercury vapor saturation of the substrate gases was achieved by allowing the gases to pass through an operating, umbrella-type, mercury diffusion pump. The partial pressure of mercury vapor in the gas stream was controlled by circulating thermostatted water through the jacket of the mercury diffusion pump.

Small Emil Greiner vernier manometers were used to measure pressures in the reaction zone.

In the water reaction, difficulty was encountered in maintaining a constant pressure of water vapor under flow conditions. This problem was partially solved by installing a water reflux assembly with two 60-cm Graham Coil condensers in series, with a spray trap at the top of the reflux unit, connecting to the flow system. The vapor pressure of water in the stream was controlled by circulating water from a thermostat through the condenser jackets.

The gases used were the highest purity grades obtainable from the Mathieson Company. The nitrous oxide and butadiene were further purified by trap-to-trap distillation. When gas mixtures were used, the mole ratio was controlled by separate flow control units. Samples of the gas mixtures were analyzed by low temperature distillation.

The HgO deposits were removed from the cell by solution in hydrochloric acid. The mercury was recovered from the neutralized solution by deposition on gold wire. The fraction of Hg^{202} in the recovered mercury was determined, by Resonance Radiation Absorbiometry. The method has been described elsewhere (6).

RESULTS

Calibration of Isotope Analysis Unit

The analytical unit was repeatedly calibrated, during the course of the investigation, by determining the absorption of the radiation from the Hg^{202} source by a sample of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Hg^N in the absorption cell. Aminco, style F, calibrated, fused quartz absorption cells with path length of 0.1003 cm were used throughout the study. The temperature of the Hg^N in the absorption cell was varied from 10° C to 40° C in the calibration runs. The mercury vapor pressure data used were those of Busey and Giauque (7), as in the original investigation on the analytical method (6). The natural abundance of Hg^{202} was taken to be 29.80% (8). The validity of the calibration is dependent upon the shape of the emission line from the Hg^{202} source. There must be negligible overlap of the emission line on absorption contours adjacent to that of Hg^{202}. In order to check this point, AEC-enriched samples, containing up to 98.5% Hg^{202}, were analyzed, using the afore-mentioned method of calibration. The deviation from the mass spectrometric values on the samples did not exceed 2%.

Nitrous Oxide

Data obtained over the pressure range 2–102 mm are shown in Table I. For these runs the mean percentage of Hg^{202} in the oxide is 29.8±0.9%. These data would suggest that HgO is not formed in the primary process in the nitrous oxide reaction. It should be emphasized, however, that failure to find enrichment in the exciting isotope in the HgO is not unequivocal proof that primary formation of HgO is absent. This matter will be discussed in a later section of this paper.

TABLE I

Hg^{202} enrichment in the HgO product of the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with nitrous oxide under flow conditions

Pressure, mm	Temp., °C	Flow rate ml/min at 25° and 760 mm	% Hg^{202} in HgO
2.2	29	80	29.0
21.1	34	47.2	30.3
26.0	28	36	29.3
100	30	50	28.8
102	29	—	31.6
		Average	29.8±0.9

At reaction pressures less than one millimeter the apparent percentage of Hg^{202} in the HgO product was found to vary from 21.5% to 27.8%. The most reasonable explanation of these subnormal values is that there was insufficient mercury from the HgO product to achieve equilibrium vapor pressure in the absorption cell. The product yield was observed to be small at low pressures, owing, presumably, to incomplete quenching.

Oxygen

The enrichment data for dry oxygen and oxygen–nitrogen mixtures are shown in Table II. Copious HgO formation was observed at all pressures studied. No problem was therefore encountered in obtaining sufficient material for analysis.

From the data in Table II, it is apparent that there is no evidence for Hg^{202} enrichment in the HgO product of the reaction of $Hg^{202}6(^3P_1)$ with oxygen and oxygen–nitrogen mixtures. The mean value of 30.2±1.2 can be considered, within the experimental error, as normal abundance. There is, therefore, no evidence for primary HgO formation from these data.

Water Vapor

In the initial work on the reaction of water vapor with $Hg^{202}6(^3P_1)$ atoms, a number of exploratory runs were made in order to test various hypotheses, and to confirm the findings of the previous study (3). In all runs, the total pressure was kept low, in order to avoid broadening effects in absorption (2).

In these preliminary runs, the flow rates varied appreciably during the course of a run, and the rates given are averaged values. Both nitrogen and helium were used as carrier gases, in order to ascertain whether the ability of nitrogen to induce $6(^3P_0)$ atom formation in mercury would be significant in the enrichment process.

Several runs were made in which gases were added to suppress the secondary formation of Hg^NO. Thus NO was added to combine with free oxygen atoms, since the latter are capable of forming Hg^NO with the Hg^N in the gas stream.

Isobutane was used as the carrier gas in one series, as a possible method of reducing the concentration of H atoms and OH radicals in the reaction zone, by abstraction reactions of the type:

$$H + C_4H_{10} \rightarrow H_2 + C_4H_9, \quad [3]$$

$$OH + C_4H_{10} \rightarrow HOH + C_4H_9. \quad [4]$$

Unfortunately the addition of isobutane to the stream resulted in a rapid reduction of the HgO product to Hg, and hence insufficient product was recovered for analysis.

Data representative of a large number of runs are given in Table III.

TABLE III

Hg^{202} enrichment in the HgO product of the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with water vapor

For personal use only.

As can be seen from Table III, the percentage of Hg^{202} in the HgO product varied from 30–35%. Carrier gases were not found to play an advantageous role. Later in this paper data will be presented which suggest that the variation in the isotopic abundance of Hg^{202} in the HgO product is intimately associated with the method of recovering mercury from the product. Our findings at this stage of the investigation were in general agreement with those of Zelikoff, Aschenbrand, and Wyckoff (3).

Since it appeared probable that the enrichment in Hg^{202} arose from the formation of $Hg^{202}OH$, from reaction [1] the failure to obtain pure $Hg^{202}O$ could be due to the secondary formation of $Hg^{N}OH$ by interaction of OH radicals formed in [2], with the Hg^{N} always present in the reaction zone:

$$Hg^{N} + OH + M \rightarrow Hg^{N}OH + M. \quad [5]$$

It is conceivable that reaction [1] is the only primary process under which conditions the degradation of the $Hg^{202}OH$ could arise from exchange reactions of the type:

$$Hg^{202}OH + Hg^{N} \rightarrow Hg^{N}OH + Hg^{202}. \quad [6]$$

Butadiene would be expected to react rapidly with OH radicals, and also possibly with $Hg^{202}OH$, since the latter should have free-radical character. Studies were therefore undertaken with water–butadiene mixtures as a possible means for suppressing the isotopically degradative reactions [5] and [6]. The remarkable effect of the addition of butadiene to the reaction stream is shown in Table IV for runs of 90-minute duration.

From Table IV, it can be seen that the addition of butadiene to the gas stream has resulted in a marked increase in the Hg^{202} content of the HgO product. During these runs, it was observed that a thin film of polymer formed on the walls of the spiral cell. The mercury-6($^3P_1$)-sensitized decomposition of 1,3-butadiene was investigated by Gunning and Steacie (9). These authors showed that butadiene does not polymerize under flow conditions, since free radicals are not formed in the primary process. The presence of butadiene polymer would therefore be evidence, in our study, of the formation of free radicals in the water decomposition.

TABLE IV

Hg^{202} enrichment in the HgO product of the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^{N} with water vapor – 1,3-butadiene mixtures

Pressure, mm	Temp., ° C	Comp. mole % HOH	Comp. mole % C_4H_6	Flow rate ml/min at 25° C and 760 mm	% Hg^{202} in HgO

*There may have been a trace of moisture in the butadiene.
†45% Nitrogen added, 45-minute exposure.

In a reaction of this type, there are many variables which require systematic study: i.e. flow rate, pressure, reaction temperature, water-to-butadiene ratio, product-recovery methods, etc. These studies will form the basis of further investigations. In the apparatus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

used in this study, it was difficult to vary flow rate and reaction pressure independently. A series of runs of 120-minute duration were carried out, however, in which the reaction pressure was held constant at 3.7 ± 1.0 mm at low flow rates, while the water-to-butadiene ratio was varied. The results of these runs are summarized in Table V.

From Table V it can be seen that at constant pressure, low flow rate, and butadiene concentrations exceeding 10 mole %, the percentage of Hg^{202} appears to reach a constant value, independent of butadiene concentration, of $75 \pm 3\%$. A major experimental difficulty in this investigation was the maintenance of a constant partial pressure of water vapor over the course of a run. In obtaining the data for Table V, great care was taken to maintain a constant pressure of water vapor during each run. This accounts, in large measure, for the greater consistency in the enrichment values obtained, in comparison with those given in Table IV. Furthermore, in comparing the data of Tables IV and V, it should be borne in mind that the former are values for runs of 90-minute duration, while the latter are for runs of 120-minute duration. In general, it was found that prolonging the exposure time decreased the enrichment.

TABLE V

Hg^{202} enrichment in the HgO product of the reaction of $Hg^{202}6(^3P_1)$ atoms of Hg^N with water vapor – 1,3-butadiene mixtures as a function of the butadiene concentration (Total pressure 3.7 ± 1.0 mm)

Temp.	Comp. mole % HOH	Comp. mole % C_4H_6	Flow rate ml/min at 25° C and 760 mm	% Hg^{202} in HgO
27	96	4	10.6	58
25	93.5	6.5	7.7	72
27	90	10	8.5	77
25	87.5	12.5	8.6	76
32	86	14	16.2	64
24	79	21	12.2	63
27	73	27	11.0	73
25	71.5	28.5	7.5	77
20	48.1	51.9	5.3	76

A variable which was appreciated relatively late in the investigation was the degradative effect of product-recovery techniques on the percentage of Hg^{202} in the recovered mercury. In an earlier paper (5), data were presented which showed that Hg^{202++} ions will be isotopically degraded when the solution is in contact with a globule of Hg^N. The exchange occurs presumably between dissolved Hg^N and Hg^{202++}. The $Hg^{202}O$ deposited in the reaction cell has chemisorbed upon it a layer of Hg^N. This adsorbed layer is extremely difficult to remove. A number of experiments were performed in which the cell, after reaction, was exhaustively evacuated through a trap containing liquid nitrogen, in an attempt to drive off the adsorbed Hg^N. This procedure had little effect upon the percentage of Hg^{202} in the product.

The kinetics of the exchange reaction between dissolved Hg^N and Hg^{202++} ion will require detailed study. It is fairly clear, however, at this stage, that the rate of exchange decreases with decreasing concentration of the hydrochloric acid used to dissolve the HgO from the reaction cell. The effect of acid concentration is illustrated by the following data: three runs were made with a substrate containing $5.5 \pm 1.5\%$ butadiene. Acid concentrations of 12.0 *M*, 6.0 *M*, and 2.5 *M* were used in recovering the HgO product. The analyses of the recovered mercury samples gave, for the percentage of Hg^{202}, 72, 78,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

and 84 respectively. There appeared to be little effect on the Hg^{202} enrichment when acid concentrations less than 2.5 *M* were employed. For the runs reported in Table V, 0.16 *M* hydrochloric acid was used to dissolve the HgO product from the cell.

DISCUSSION

Nitrous Oxide and Oxygen Reactions

The failure to obtain an HgO product, enriched in Hg^{202}, in the nitrous oxide and oxygen reactions, would suggest that a mercury compound is not formed in the primary process. However, even with the pure water vapor reaction, the enrichment is small, butadiene being required to suppress the isotopically degradative processes operative. The oxygen and nitrous oxide reactions will require further study, in the presence of free-radical acceptor addends, before unequivocal statements can be made concerning the primary formation of mercury compounds.

Water Vapor Reaction

As a positive result of this investigation, it has been shown that in the flow reaction between $Hg^{202}6(^3P_1)$ atoms in Hg^N and mixtures of water vapor and 1,3-butadiene, the HgO product of the reaction is highly enriched in Hg^{202}. The reaction recommends itself as a simple method for preparing Hg^{202} from natural mercury.

In the reaction with pure water vapor, the Hg^{202} content of the HgO product was not found to exceed 35%, in agreement with an earlier study (3). From the kinetic standpoint, it can be conservatively stated that some fraction of the primary interaction between $Hg^{202}6(^3P_1)$ atoms and HOH molecules leads to the formation of a mercury compound. The role of butadiene in increasing the Hg^{202} content of the oxide can be explained, at this stage of our knowledge, on two bases:

(*a*) There are two primary processes—reactions [1] and [2]. The butadiene serves to clean up OH radicals, formed in [2], thereby suppressing the formation of Hg^NO by reaction [5].

(*b*) Reaction [1] is the only primary process operative and the failure to obtain pure $Hg^{202}O$, from water substrate alone, is attributable to exchange reactions, similar to [6], occurring in the gas phase or on the wall. Here the butadiene could suppress exchange degradation by combining with the quasi-free radical $Hg^{202}OH$.

It should be pointed out that $Hg^{202}OH$ is not necessarily the initial mercury compound formed. The primary step could be

$$Hg^{202}6(^3P_1) + HOH \rightarrow Hg^{202}H + OH. \qquad [7]$$

The unstable species HgH has been adduced many times to explain the preference of Hg $6(^3P_1)$ atoms for C–H bond scission in hydrocarbon reactions. The problem has been thoroughly discussed by Steacie (10). The low heat of formation of HgH (8.5 kcal) would argue against its surviving sufficiently long to form a stable product in the water reaction.

Investigations are now in progress in the laboratories of one of us (H.E.G.) which should yield further information on the kinetics of the water reaction. In addition to systematic studies of the effects of the various reaction parameters on the Hg^{202} content of the HgO product, the quantum yield of $Hg^{202}O$ formation is being investigated. Quantum yield measurements are difficult in water vapor – butadiene mixtures, owing to the high quenching cross section of butadiene. The situation is further complicated by the fact that water vapor converts Hg $6(^3P_1)$ atoms to the $6(^3P_0)$ state at least as efficiently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

as nitrogen. Finally, information is being obtained on the nature of the polymer formed in the reaction with water–butadiene mixtures. The presence of Hg–C bonds in the polymer would be evidence of interaction of butadiene with mercurial free radicals.

FUSED HETEROCYCLICS

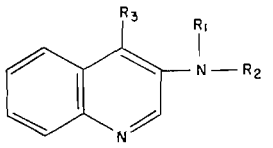
PART III. SYNTHESIS OF QUINOLINO-(2′:3′:3:4)-QUINOLINE[1]

RAGINI ANET[2]

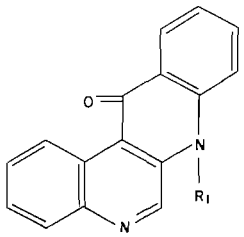
ABSTRACT

Quinolino-(2′:3′:3:4)-quinoline has been synthesized from 3-aminoquinoline-4-carboxylic acid via 4′-hydroxyquinolino-(2′:3′:3:4)-quinoline.

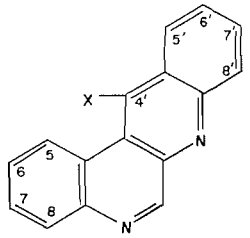
Quinolinoquinolines containing fused pyridine rings were of interest in connection with the structure of calycanine (1). In Part II of this series (2) the synthesis of quinolino-(2:3:3′:2′)-quinoline was reported. The synthesis of an angular isomer, quinolino-(2′:3′:3:4)-quinoline, is now described.



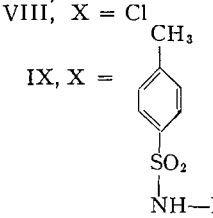
I, $R_1 = R_2 = H$; $R_3 = COOH$
II, $R_1 = Ph$; $R_2 = H$; $R_3 = COOH$
III, $R_1 = R_2 = Ph$; $R_3 = COOH$
IV, $R_1 = Ph$; $R_2 = R_3 = H$
V, $R_1 = R_2 = Ph$; $R_3 = H$



VII, $R_1 = Ph$



VI, X = OH
VIII, X = Cl



IX, X =

X, X = H

Although the base itself (X) has not been synthesized previously, 4′-hydroxy derivatives with substituents in the 2-, 6′-, 7′-, and 8′-positions have been prepared by the cyclization of appropriately substituted 3-arylaminoquinoline-4-carboxylic acids (3, 4, and 5). This method, in its essentials, was followed for the synthesis of 4′-hydroxyquinolino-(2′:3′:3:4)-quinoline.

The preparation of 3-phenylaminoquinoline-4-carboxylic acid (II) was carried out by the extension of the arylation reaction described in Part II (2). When 3-aminoquinoline-4-carboxylic acid (I) (6) was treated with iodobenzene and copper catalyst, a mixture of 3-phenylamino- and 3-(diphenylamino)-quinoline-4-carboxylic acids (II and III respectively) was obtained. As in the case of the corresponding quinaldine acid (2), the monosubstituted acid could not be obtained exclusively. The acids were separated by fractional crystallization and decarboxylated to the corresponding bases 3-phenylamino- and 3-(diphenylamino)-quinolines (IV and V), which were characterized as their picrates.

The mixture of acids obtained in the arylation reaction was cyclized with phosphoryl

chloride, and the intermediate chloro derivatives hydrolyzed to give 4′-hydroxyquinolino-(2′:3′:3:4)-quinoline (VI) and 4′-keto-1′-phenyldihydroquinolino-(2′:3′:3:4)-quinoline (VII). The cyclized products were separated readily as they had markedly different solubilities in organic solvents. The 4′-hydroxy derivative (VI) gave a typical acridone-like fluorescence in presence of alkali (7) and was characterized as its picrate; whereas the 4′-keto compound was non-fluorescent and did not give any crystalline salts.

The reduction of the 4′-hydroxy derivative to the unsubstituted quinolinoquinoline with zinc dust did not prove successful. However, by using the method of Albert and Royer (8) for the conversion of acridone into acridine, the desired compound (X) was obtained. The 4′-hydroxy derivative (VI) was refluxed with phosphoryl chloride to give the 4′-chloro compound (VII) which was sensitive to hydrolysis with acid, but could be stored satisfactorily over potassium hydroxide *in vacuo*. It was characterized as the picrate. On treatment of the chloro derivative with *p*-toluenesulphonylhydrazide (8) in chloroform, the 4′-*p*-tosylhydrazidoquinolino-(2′:3′:3:4)-quinoline (IX) was obtained as the hydrochloride. Attempts to prepare the free base from its hydrochloride were unsuccessful and led to considerable decomposition. It was found that the reaction of the chloro derivative with *p*-tosylhydrazide was slower than in the case of the acridine derivative (8). The 4′-hydrazido hydrochloride was treated with 1 *N* sodium hydroxide in ethylene glycol to give a mixture of the 4′-hydroxy derivative (VI) and the desired quinolino-(2′:3′:3:4)-quinoline (X) which were readily separated by chromatography over alumina. The quinolinoquinoline crystallized from methanol in cream-colored needles m.p. 179°–180° C. Its ultraviolet absorption spectrum is recorded in Fig. 1.

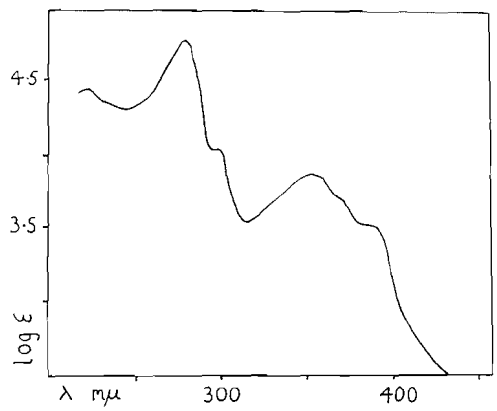

FIG. 1. Ultraviolet absorption spectrum of quinolino-(2′:3′:3:4)-quinoline in methanol.

EXPERIMENTAL

All melting points are uncorrected. Analyses by Drs. Weiler and Strauss, Oxford.

3-Phenylaminoquinoline-4-carboxylic Acid (II)

3-Aminoquinoline-4-carboxylic acid (I, 6.35 g) (6), 10 g (7.35 ml) iodobenzene, 9 g anhydrous potassium carbonate, and 0.8 g copper catalyst (Naturkupfer C) were refluxed in a mixture of 20 ml benzyl alcohol and 40 ml cyclohexanol for 3 hours with strict exclusion of moisture. The reaction mixture was cooled, diluted with 50 ml water, and steam-distilled to remove the alcohols. The solution was filtered hot into dilute acetic acid and allowed to stand at room temperature for 6–8 hours. The orange precipitate (9.2 g, m.p. 224°–232° C, with decomposition) was dried, and crystallized from a 1:1 mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of chloroform–methanol. Lemon-yellow feathery needles of the 3-phenylamino acid (II), m.p. 243°–244° C (decomp.), were obtained after several crystallizations. Found: C, 72.1; H, 4.8; N, 10.9. Calc. for $C_{16}H_{12}N_2O_2$: C, 72.7; H, 4.5; N, 10.6%. The acid was sparingly soluble in water, benzene, ether, and alcohol. Its solutions in alkali were colorless.

3-Phenylaminoquinoline (IV)

The acid (II, 1.2 g) was heated at 250° C for 1 hour. The acid melted with decomposition and after the first few minutes, some of the base started to sublime into the air condenser attached to the flask. After decarboxylation was complete, the contents of the flask were allowed to cool and were extracted with methanolic hydrochloric acid. The acid solution was poured into an excess of aqueous potassium hydroxide, and the aqueous solution extracted with ether. Evaporation of the ether extract after charcoal treatment gave an oil (0.9 g), which solidified on refrigeration. Crystallization from dilute methanol gave the base (IV) as needles, m.p. 121°–123° C. Found: C, 81.9; H, 5.45; N, 12.4. Calc. for $C_{15}H_{12}N_2$: C, 81.8; H, 5.45; N, 12.4%. The base was very soluble in organic solvents and its solutions exhibited a strong blue fluorescence in ultraviolet light.

The *picrate* prepared in methanol gave orange needles, m.p. 189°–190° C with decomposition. Found: N, 15.4. Calc. for $C_{21}H_{15}N_5O_7$: N, 15.6%.

3-(Diphenylamino)-quinoline-4-carboxylic Acid (III)

A suspension of 1.5 g of 3-amino acid (I) in 25 ml benzyl alcohol was refluxed with 2.0 g anhydrous potassium carbonate, 0.2 g. Naturkupfer C and 2.3 g (1.7 ml) iodobenzene for 6 hours. The reaction was worked up as in the case of the 3-phenylamino acid (II) described above when 1.95 g of a bright yellow solid, m.p. 255°–264° C, was obtained. This was washed with acetone and crystallized from chloroform–methanol in stout yellow rods, m.p. 270°–272° C with decomposition. Found: C, 77.5; H, 4.8; N, 8.1. Calc. for $C_{22}H_{16}N_2O_2$: C, 77.6; H, 4.8; N, 8.2%. The acid was sparingly soluble in most organic solvents but was readily soluble in aqueous alkali to give colorless solutions. It was insoluble in dilute mineral acids but dissolved in concentrated hydrochloric acid on prolonged boiling.

3-(Diphenylamino)-quinoline (V)

The acid (III, 1.5 g) was decarboxylated at 270° C for 1 hour. On working up the reaction as in the case of the 3-phenylamino compound (IV), an oil (1.0 g), solidifying on refrigeration was obtained (m.p. 155°–164° C with previous softening). Repeated crystallizations from dilute methanol or other organic solvents failed to raise the melting point and the base was therefore purified by sublimation at 180° C under reduced pressure (20 mm). Crystallization of the sublimate from dilute methanol gave colorless needles, m.p. 162°–164° C. Found: C, 84.7; H, 5.4; N, 9.7. Calc. for $C_{21}H_{16}N_2$: C, 85.1; H, 5.4; N, 9.4%. The base was very soluble in organic solvents to give yellowish solutions with a vivid blue fluorescence.

The *picrate* prepared from equimolecular quantities of the base and picric acid in benzene–methanol formed orange needles, m.p. 205°–206° C with decomposition. Found: C, 61.9; H, 3.7; N, 13.6. Calc. for $C_{27}H_{19}N_5O_7$: C, 61.7; H, 3.7; N, 13.3%.

4′-Hydroxyquinolino-(2′:3′:3:4)-quinoline (VI)

Five grams of the crude 3-phenylamino acid (II) were refluxed with 12.5 ml phosphoryl chloride under anhydrous conditions. A vigorous reaction set in at 60°–65° C and heating was interrupted till it was over. The refluxing was continued for 90 minutes the bath temperature being maintained at 110–120° C. Phosphoryl chloride was removed under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

reduced pressure, care being taken that the bath temperature did not exceed 100° C. The dark residue, after removal of the acid chloride, was heated on the steam bath with 300 ml 1 *N* hydrochloric acid for 2 hours, filtered, and poured into excess ammonium hydroxide. After 16 hours at room temperature the dark solid was filtered, dried, and extracted with hot chloroform to remove the 4′-keto compound (vide infra) formed from the disubstituted acid (III). The residue was extracted with hot ethanol (charcoal) and the 4′-hydroxy derivative obtained by evaporation of the ethanol was crystallized from dilute acetic acid in yellow needles, m.p. 360° C. Found (sample dried at 100° C under 2 mm): C, 72.9; H, 4.6. Calc. for $C_{16}H_{10}N_2.H_2O$: C, 72.7; H, 4.5. Found (sample dried at 250° C under 0.5 mm): C, 74.9; H, 4.6. Calc. for $C_{16}H_{10}N_2O.H_2O$: C, 75.0; H, 4.3%. Attempts to remove the last 0.5 molecule of water of crystallization were unsuccessful even after repeated sublimation and extensive drying. The 4′-hydroxy compound was sparingly soluble in ether, benzene, and chloroform but readily so in ethanol and ethyl acetate. Its alcoholic solutions were non-fluorescent but gave a vivid green fluorescence in presence of a pellet of potassium hydroxide.

The *picrate* formed by refluxing (VI) with picric acid in ethanol for 4 hours gave needles, m.p. 255°–258° C. Found: C, 55.9; H, 3.1; N, 14.8. Calc. for $C_{22}H_{13}N_5O_8$: C, 55.6; H, 2.7; N, 14.8%.

4′-Keto-1′-phenyldihydroquinolino-(2′:3′:3:4)-quinoline (VII)

Diphenylamino acid (III, 0.8 g) was refluxed with 5 ml phosphoryl chloride and the reaction worked up as above. The 4′-keto derivative (VII) was obtained from the chloroform extract as a dark solid (0.6 g). Treatment with charcoal and crystallization from methanol gave pale yellow needles, m.p. 282°–284° C. Found: C, 81.8; H, 4.4; N, 8.7. Calc. for $C_{22}H_{14}N_2O$: C, 82.0; H, 4.4; N, 8.7%.

4′-Chloroquinolino-(2′:3′:3:4)-quinoline (VIII)

4′-Hydroxy compound (VI, 1.5 g) was refluxed with 20 ml phosphoryl chloride under anhydrous conditions for 6 hours. After removal of the acid chloride under reduced pressure, the orange-colored solid was added to a vigorously stirred 5% aqueous ammonium hydroxide containing crushed ice. The solution was kept alkaline to phenolphthalein by adding more ammonia if necessary. After 30 minutes the solution was centrifuged and the cream-colored solid dried in a vacuum desiccator over potassium hydroxide. Extraction of the dry solid with benzene containing a pellet of potassium hydroxide gave the 4′-chloro compound which crystallized from petroleum ether (b.p. 40°–60° C) in colorless prismatic needles, m.p. 191°–192° C. Found: C, 73.0; H, 3.8; Cl, 13.1. Calc. for $C_{16}H_9N_2Cl$: C, 72.6; H, 3.4; Cl, 13.4%.

The *picrate* formed in benzene gave orange needles, m.p. 209°–210° C with decomposition. Found: C, 54.0; H, 2.6. Calc. for $C_{22}H_{12}N_5O_7Cl$: C, 53.5; H, 2.4%.

4′-p-Tosylhydrazidoquinolino-(2′:3′:3:4)-quinoline Hydrochloride (IX)

The 4′-chloro compound (VIII, 0.18 g) was dissolved in the minimum quantity of chloroform and added to a saturated solution of 0.17 g *p*-tosylhydrazide (8) in the same solvent. After 48 hours at room temperature, the solution turned pale yellow but no solid separated. The chloroform was removed on the steam bath and fresh chloroform added to the reaction mixture which was left at room temperature for a further 72 hours. (It was found that a fast stream of hydrogen chloride when passed through the solution after the initial 48 hours gave the hydrochloride of (VIII) in one experiment.) After the completion of the reaction, the red solid was filtered from the chloroform, dried, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

crystallized from methanol containing a drop of hydrochloric acid in red needles which did not melt but decomposed at 320° C. Found: C, 61.5; H, 4.2. Calc. for $C_{23}H_{19}N_4SO_2Cl$: C, 61.3; H, 4.2%.

Quinolino-(2′:3′:3:4)-quinoline (X)

One half gram of (IX) was heated on the steam bath with 10 ml 1 *N* sodium hydroxide in ethylene glycol (4 g sodium hydroxide dissolved in a mixture of 70 ml ethylene glycol and 30 ml water) for 3 hours. The solution turned crimson and lumps of a precipitate were formed which were broken up from time to time with a glass rod. Evolution of gas began after the first few minutes and continued for 2 hours, when the solution became clear. It was then diluted with 20 ml water and refrigerated overnight. The flocculent precipitate that had separated was filtered after 24 hours, taken up in 1 *N* hydrochloric acid, and reprecipitated with ammonia. The base was taken up in ethyl acetate and chromatographed over alumina, when the quinolinoquinoline (X) separated as a strongly fluorescent band in ultraviolet light. Elution with ethyl acetate gave (X) which crystallized from methanol in needles, m.p. 179°–180° C. Found: C, 83.1; H, 4.5. Calc. for $C_{16}H_{10}N_2$: C, 83.5; H, 4.4%. The base was readily soluble in ethyl acetate, alcohol chloroform, and ether. It dissolved in mineral acids to give non-fluorescent solutions

THE INTERACTION OF FRIEDEL–CRAFTS CATALYSTS WITH ORGANIC MOLECULES

I. THE CH_3COCl:$AlCl_3$ SYSTEM[1]

DENYS COOK[2]

ABSTRACT

An infrared study of the liquid complex of aluminum chloride with acetyl chloride has been undertaken. The results indicate that the pure liquid complex is not a simple mixture, but consists of (1) the donor–acceptor complex $CH_3\underset{\displaystyle Cl}{\underset{|}{C}}{=}O \ldots AlCl_3$ and (2) the ions $[CH_3CO]^+$ and $[AlCl_4]^-$. A solution of the liquid complex in a solvent of high dielectric constant like nitrobenzene ($\epsilon = 36.1$) contains both these species, but in a low dielectric constant solvent like chloroform ($\epsilon = 5.05$) only (1) is present. The carbon–chlorine bond in (1) is modified. The mechanism of Friedel–Crafts ketone synthesis is briefly examined in the light of these results.

A variety of metallic halides have been used as catalysts in the Friedel–Crafts ketone synthesis. The most widely used of these is $AlCl_3$, but others, such as BF_3, $AlBr_3$, $SbCl_3$, $SbCl_5$, $FeCl_3$, $TiCl_4$, $SnCl_4$, and $ZnCl_2$ etc., have all been used. All these halides have in common the function of Lewis acids, due either to electron deficiency, or to hybridization changes to give complex ions.

Numerous examples exist in the literature of complexes formed from such Lewis acids and various donors. The characteristics of the donor molecule are usually those of well-directed lone-pair electrons. Thus compounds like R_2O, $R_2C{=}O$, RCN, R_3N, RNO_2 etc. can all form more or less stable complexes with Lewis acids, the electron deficiency of the latter being satisfied by sharing the lone-pair electrons of the donor group. Some of the Lewis acids can function as acceptors in a slightly different way. Thus NaCl and $AlCl_3$ form the compound $NaAlCl_4$, which has been shown to consist of Na^+ and $[AlCl_4]^-$ ions (1, 2).

The presence of two functional groups in an acyl halide, namely a carbonyl donor group and an ionizable chlorine atom, suggests that two types of intermediates may be possible in the Friedel–Crafts ketone synthesis: (*a*) the ions $[CH_3CO]^+$ and $[AlCl_4]^-$, and (*b*) the donor–acceptor complex formed between the carbonyl–oxygen lone-pair electrons and the vacant orbital of the $AlCl_3$, as suggested by Pfeiffer (3). An extension of (*b*) proposed by Dilthey (4) involved loss of a Cl^- from the donor–acceptor complex to give a complex ion.

It is the purpose of this paper, from the spectroscopic evidence presented, to show that the donor–acceptor complex as in (*b*) is present in solution in solvents of low dielectric constant, but that in the pure complex or in its solution in solvents of high dielectric constant ions such as in (*a*) are present as well as the donor–acceptor complex.

After the experimental work described here was completed, two papers by Susz and Wuhrmann (5, 6) appeared on the infrared spectra of the complexes CH_3COF:BF_3 and CH_3COCl:$AlCl_3$. These gave the first clear indication of the presence of the $[CH_3CO]^+$ ion. The present work corroborates their findings but important differences exist which are detailed below.

EXPERIMENTAL

Aluminum chloride was purified by vacuum sublimation of reagent grade $AlCl_3$ in the apparatus shown in Fig. 1*a*. The $AlCl_3$ was sublimed from the bulb to the cold finger and then transferred to the seal-off tube with continuous pumping. A known quantity, 4.729 g, was then transferred to the reaction tube (which had been flamed and then cooled with dry nitrogen) in Fig. 1*b* which was sealed off as quickly as possible. The molar equivalent of CH_3COCl, 2.77 g, was distilled onto the $AlCl_3$ at liquid nitrogen temperatures. On warming to room temperature the $AlCl_3$ gradually went into solution, though slight heat was necessary to make the last traces dissolve, giving a homogeneous light brown solution. Excessive heat which would favor decomposition was avoided. Even so some slight decomposition occurred as HCl was found in the gas phase. Infrared examination of the gas phase showed the evolved gases to be chiefly HCl and CH_3COCl, and mass spectrometry confirmed this but also indicated the presence of further unidentified fragments of mass 45, 60, 73, and 87. The total volume of gas evolved was computed from the pressure and an estimate of the volume of the apparatus. Assuming only the two components mentioned above to be significant, the weight of these products lost from the reaction tube was 0.072 g HCl and 0.157 g CH_3COCl. These represent maximum values, since the unidentified products would lower these figures.

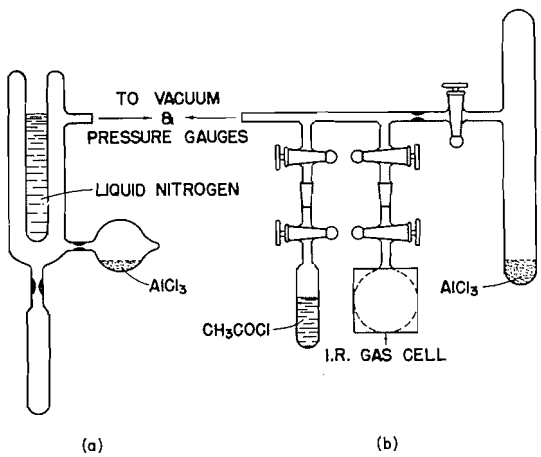

FIG. 1. (*a*) $AlCl_3$ sublimation apparatus. (*b*) Apparatus for preparation of complex.

The reaction tube was transferred to a dry box which contained a bed of silica gel, and which had been well flushed with dry nitrogen for a few hours before. After it had been left standing for at least two hours in the dry box the reaction tube was opened, and the various cells made up for spectroscopic analysis.

A double beam rock salt spectrometer was used to record the spectra in the region of 4000 cm^{-1} to 625 cm^{-1}. From 625 cm^{-1} to 350 cm^{-1} a modified Perkin–Elmer 12C spectrometer with CsBr optics was used. The standard bands in a thin film of polystyrene were used for calibration.

RESULTS

The principal bands of the various spectra are shown in Table I together with those of pure acetyl chloride. Figure 2 shows the spectrum of the pure liquid complex.

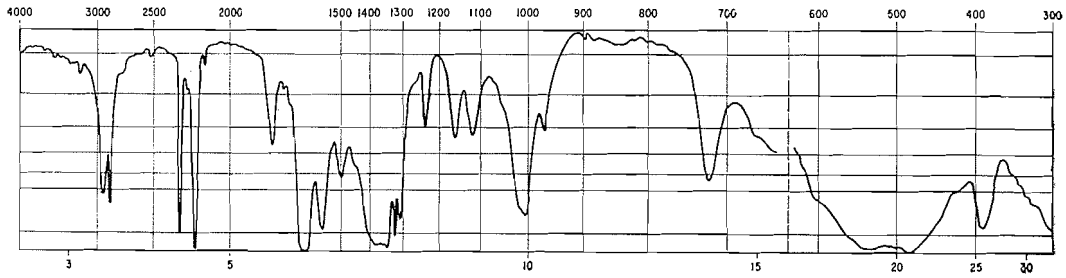

FIG. 2. Spectrum of pure liquid complex. Capillary film between NaCl plates.

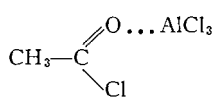
DISCUSSION

The strongest band in the spectrum of the pure liquid complex is at 1637 cm^{-1}. On account of its intensity it is likely that this is a carbonyl group vibration, and it seems logical to assign this band to the C=O vibration in the complex I:



I

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Since $\nu_{C=O}$ for acetyl chloride is 1807 cm^{-1} in the liquid, this band in the complex is lowered by 170 cm^{-1}. Shifts in $\nu_{C=O}$ of comparable magnitude have been observed by Susz and Cooke (7) in the equimolar complex of benzophenone and $AlCl_3$. In the complex $\nu_{C=O}$ was 1525 cm^{-1} and in pure benzophenone it was 1650 cm^{-1}, a shift of 125 cm^{-1}.

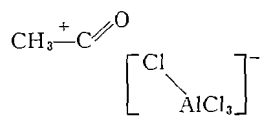
Susz and Wuhrmann tentatively assigned the 1639 cm^{-1} band to the C=C vibration in $CH_2{=}C(Cl){-}O{-}AlCl_2$ which they thought might have been present in small amounts in their complex, and the 1567 cm^{-1} band to the perturbed carbonyl vibration. The high intensity of the 1637 cm^{-1} band would seem to rule out this interpretation, since such a C=C vibration would be expected to be quite weak. It is much more likely that their band at 1639 cm^{-1} was due to a small amount of the complex I which could very well have been present in their complex.

Two strong bands are located at 2307 cm^{-1} and 2203 cm^{-1}. These two bands are in the region of triple bond stretching frequencies and their presence in the spectrum is of unusual interest. They constitute the grounds for suspecting the presence of the ion $[CH_3CO]^+$ in the complex. This ion should be linear (it is isoelectronic with CH_3CN). Variations in carbonyl stretching frequencies are due, in part, to the electronegativity of the group, or groups, attached to the carbonyl group (8). The positive charge on the carbon atom of the carbonyl group should have a very strong electron-withdrawing effect. This would, therefore, raise the carbonyl frequency by a large amount. The band at 2307 cm^{-1} is thought to be compatible with such a structure. Alternatively the structure may be described in terms of resonance, where the actual structure is a hybrid of the forms $CH_3C^+{=}O$ and $CH_3C{\equiv}O^+$. The bond order of the carbonyl group would be between 2 and 3, and the carbonyl frequency much higher than an ordinary ketone.

This is in harmony with the findings of Susz and Wuhrmann (5), who observed a very strong band at 2305 cm^{-1}. In contrast, the band at 2200 cm^{-1}, which they report to be of weak intensity, is very strong. This band could have two possible causes. It may be due to the complex ion II, as proposed by Dilthey, or an ion pair of the form III

$[CH_3CO]^+ \ldots AlCl_3$

II



III

in which there is little interaction between the Cl atom and the central C atom. In support of II the lowering of $\nu_{C=O}$ from 2307 cm^{-1} in $[CH_3CO]^+$ to 2203 cm^{-1} in $[CH_3CO]^+ \ldots AlCl_3$ seems to be in accord with other data on the lowering of $\nu_{C=O}$ of carbonyl compounds in complexes with strong Lewis acids. However, it might be argued that III seems more probable, since the cation $[CH_3CO]^+$, by virtue of its electron deficiency, might not be able to form a donor–acceptor complex with a Lewis acid. Evidence presented later in this paper tends to support III as a better interpretation of the 2203 cm^{-1} band.

The main differences between the spectra of Susz and Wuhrmann and the present work can be ascribed to the different physical state of the respective complexes. Susz and Wuhrmann worked exclusively with the solid complex, whereas the complex reported here was a viscous liquid. The solid would be disposed to allow the maximum contribution from the ionic species, but in the liquid state such long-range order would break down leading to the presence of both the ions $[CH_3CO]^+$ and $[AlCl_4]^-$, and the donor–acceptor complex I, with the latter probably predominating.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The band at 2941 cm^{-1} is assigned to the antisymmetrical CH stretching frequency, the other sharp band at 2874 cm^{-1} being the symmetrical CH stretching vibration. The lowered CH_3 stretching frequencies in the complex, 2941 and 2874 cm^{-1} (compared with 3012 and 2960 cm^{-1} in acetyl chloride), are compatible with the ionic structure $[CH_3CO]^+$, since hyperconjugation ($H^+CH_2{=}C{=}O$ etc.) in the ion should produce such shifts. Two strong bands 1379 cm^{-1} and 1348 cm^{-1} are probably associated with the CH deformation frequencies of the CH_3—C group.

In the low frequency region one significant feature emerges. This is the disappearance of the bands at 436 cm^{-1} and 593 cm^{-1} associated with the C—Cl bond. The formation of the ion $[CH_3CO]^+$ would naturally result in the absence of these bands. However, the formation of the complex I would modify them. Three alternatives can be considered: (1) In the complex I all the group frequencies may be altered so that, even though the C—Cl bond still has the same force constant, its frequency is shifted. (2) The force constant is increased leading to a band at higher frequency. (3) The force constant is lowered leading to a lower frequency. Of these (2) can be ruled out, since there is no band in this region of sufficient intensity to be considered a C—Cl fundamental. Since many of the other bands are found in approximately the proper region this would tend to discount (1), and leave (3) as the probable reason for the disappearance of the two bands. Since the low frequency cutoff of CsBr is about 320 to 350 cm^{-1} it is not possible to observe bands with lower frequencies.

If the cation $[CH_3CO]^+$ is present then there should be signs in the spectrum of $[AlCl_4]^-$. Little is known of the spectroscopic behavior of this anion in the infrared. Gerding and co-workers (2) have investigated some systems containing $AlCl_3$ by Raman spectroscopy. In the system $Na^+ + [AlCl_4]^-$ they found the following frequencies: $\nu_1 = 349$, $\nu_2 = 146$, $\nu_3 = 575$, and $\nu_4 = 180$ cm^{-1}. For liquid $NO^+ + [AlCl_4]^-$ they found $\nu_1 = 349$, $\nu_2 = 136$, $\nu_3 = 450$–539 very broad, $\nu_4 = 182$ cm. However, for solid $NO^+ + [AlCl_4]^-$ ν_3 seemed to be a composite band with peaks at 460, 470, and 549 cm^{-1}. Of these Raman frequencies only ν_3, and ν_4 should be infrared active, and because of wavelength limitations only ν_3 visible.

In the CH_3COCl: $AlCl_3$ complex two broad strong bands at 485 and 540 cm^{-1} are observed. It is not possible to ascribe these to any specific vibration, but their presence suggests the structures $[AlCl_4]^-$ or $Cl_3Al\ldots O$. The spectrum of $AlCl_3$ dissolved in acetone contains these bands and here the complex can only be formed between the O lone-pair electrons and the $AlCl_3$.

Preliminary experiments had indicated the presence of the 2203 cm^{-1} band in mixtures prepared without taking extensive precautions to exclude air. This band at 2203 cm^{-1} was at that time thought to be due to the $[CH_3CO]^+$ ion, but the possibility remained that it could be due to a ketene-like structure, possibly as a result of dehydrohalogenation of the acyl halide. Ketenes have bands considerably higher in frequency than ordinary carbonyl bands. On account of the volatility of such compounds (ketene b.p. −56° C) it would be expected that some of it should be present in the vapor phase. However, no bands in the appropriate region were found in the infrared spectrum of the evolved vapors, nor did analysis by mass spectrometer reveal any ketene. The possibility of any ketene-like compound being present in the liquid complex is therefore very remote.

The behavior of the complex alone should be compared with the results obtained by dissolving the complex in various solvents. Frequently nitrobenzene is used as solvent in Friedel–Crafts ketone synthesis. The bands in the spectrum of the complex in nitrobenzene, in which it dissolves completely to give a yellow solution, are shown in Table I.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Some similarities exist between these bands and those of the complex alone. The band at 2193 cm^{-1} (cf. 2203 cm^{-1} in the pure complex) is present, as is the band at 1642 cm^{-1} (cf. 1637 cm^{-1} in the pure complex). The band at 1805 cm^{-1} is more intense than that (1779 cm^{-1}) in the pure complex. The band at 2307 cm^{-1} has completely disappeared. These changes can be explained by a partial dissociation of the complex I to give essentially free CH_3COCl (the band at 1805 cm^{-1}). The $AlCl_3$ released can interact with the excess nitrobenzene (to form the complex $C_6H_5NO_2.AlCl_3$ which is soluble in excess nitrobenzene), or complex with the $[CH_3CO]^+$. The former seems more likely, since it is probable that nitrobenzene is a better donor than the $[CH_3CO]^+$ ion. The absence of the 2307 cm^{-1} band and the strong 2193 cm^{-1} band suggests that the $[CH_3CO]^+$ is present as the ion pair III.

The liquid complex is only slightly soluble in $CHCl_3$. Most of it remains as an oily layer at the bottom of the tube, but the $CHCl_3$ layer turns a pink color which gradually fades with time. Table I lists the bands observed in the latter layer. Apart from the chloroform bands the strongest band is at 1660 cm^{-1}. It is assumed that this is the same band as that at 1637 cm^{-1} in the complex and in $C_6H_5NO_2$ solution. This band is apparently doubled with another subsidiary peak at 1613 cm^{-1}. The weaker band at 1793 cm^{-1} is undoubtedly due to CH_3COCl interacting with $CHCl_3$. It is significant that no bands are observed in the 4.5 μ region. The two bands at 436 cm^{-1} and 493 cm^{-1} associated with the C—Cl bond in CH_3COCl are either weak or absent, while those at 500 and 540 cm^{-1} are due to the complex I, as observed earlier.

In solution in CS_2 the only bands present are reasonably well accounted for by CH_3COCl.

The foregoing provides strong evidence that the pure complex contains the $[CH_3CO]^+$ ion, which is currently accepted as being an intermediate in the Friedel–Crafts ketone synthesis. In solvents of high dielectric constant like nitrobenzene ($\epsilon = 36.1$) the same conclusion holds. In solvents of low dielectric constant like chloroform ($\epsilon = 5.05$) no ions have been detected *in solution*, and the CH_3COCl and $AlCl_3$ exist in the form of the donor–acceptor complex I. In this complex the C—Cl bond is thought to be weakened. This would have the effect of lowering the activation energy of the reaction between the complex and an aromatic hydrocarbon to form a ketone, and facilitate reaction. Two important experimental conditions would be fulfilled on this view. Firstly, the yield of ketone would be proportional to the amount of $AlCl_3$ used, and secondly, the $AlCl_3$ would be complexed with the carbonyl group throughout the reaction. It should be reiterated, however, that the pure liquid complex is not completely soluble in $CHCl_3$, but forms a lower insoluble layer. Reaction at the surface of this layer could still take place via an ionic intermediate.

THE ADSORPTION OF KRYPTON ON GRAPHITE ABOVE AND BELOW THE TRIPLE POINT[1]

H. L. McDermot and B. E. Lawton

ABSTRACT

The adsorption of krypton on graphite has been measured above and below its Triple Point. Above the Triple Point, a smooth isotherm was found which showed two types of hysteresis. In contrast, the isotherm measured below the Triple Point displayed two discontinuities. The surface area of this graphite measured by means of the krypton isotherm was found to be in agreement with that previously measured by nitrogen adsorption.

INTRODUCTION

The adsorption of krypton by artificial graphite has been studied as part of a program directed toward a study of these graphites. The adsorption of krypton by a substance closely related to graphite (P33 carbon black graphitized at 2700° C) has been studied by Singleton and Halsey (10); Amberg, Spencer, and Beebe (1); Clark (4); and Ross and Winkler (9). In every instance stepwise isotherms were obtained at 77° K. The reversibility of the isotherm was demonstrated by Clark. Heats of adsorption measured by Amberg, Spencer, and Beebe were found to show a maximum at a coverage close to the monolayer. A second smaller maximum coincided with the completion of the second layer. The stepwise isotherms, coupled with the heat curve, are strong evidence that the surface of this graphitized black was homogeneous. Ross and Winkler conducted measurements down to low pressures and presented isotherms which displayed discontinuities characteristic of two-dimensional phase changes. They made measurements at 77° and 90° K and showed that the vertical discontinuity signifying two-dimensional liquefactions occurred at 77° but not at 90° K. The two-dimensional critical temperature was estimated to be 82° K. The measurements reported here were undertaken to investigate further the rather unusual hysteresis effects reported previously for artificial graphites manufactured by Acheson Co. Previous papers in this series (6, 7) have presented evidence of two types of hysteresis occurring on the adsorption of oxygen, nitrogen, and argon (6, 7) by artificial graphites at liquid air temperatures. These measurements have now been extended to krypton and sulphur dioxide (8). Those with krypton were done above and below the Triple Point. Two types of hysteresis have been reported with the artificial graphites: the normal type of hysteresis due to pores occurring at high relative pressures and a second type extending down to low relative pressures which has been termed "swelling hysteresis". This type of hysteresis has also been demonstrated for the adsorption of nitrogen by the carbon black "Spheron 6" at 77° K and for the adsorption of diethyl ether by charcoal (2, 7).

EXPERIMENTAL AND RESULTS

The graphite used in these experiments was a purified Acheson graphite designated by us as GF-3. Its properties have been given before (7, 11).

The krypton was obtained from the Matheson Co. and used without further purification.

Isotherms were measured at 119° K and 78° K. Before each isotherm was measured, the sample was evacuated for at least 12 hours at 200° C. The isotherm at 119° K was

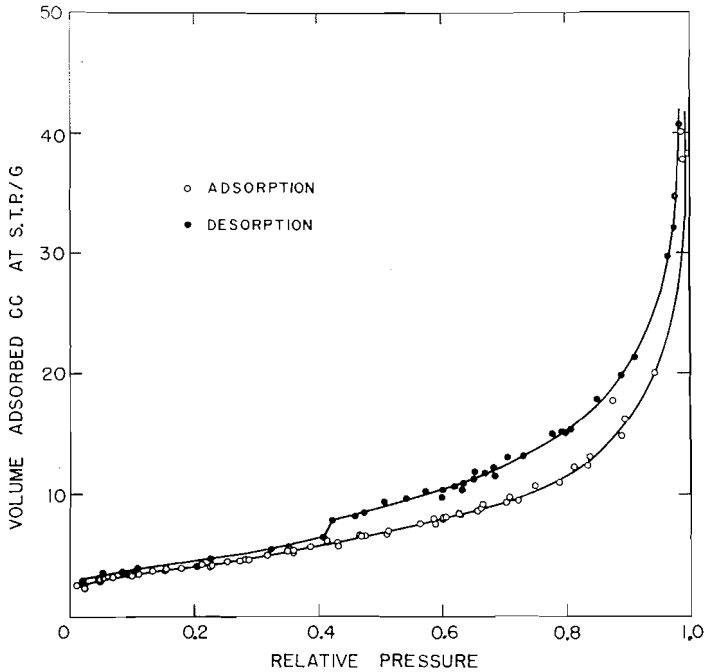

FIG. 1. The adsorption of krypton by graphite at 119° K.

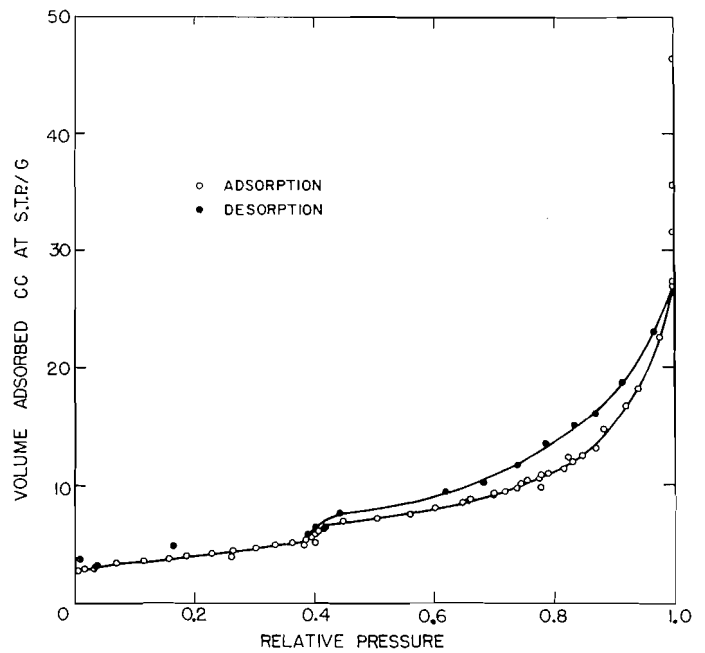

FIG. 2. The adsorption of krypton by graphite at 78° K.

measured with a standard volumetric adsorption apparatus. The constant-temperature bath consisted of Dewar flask containing Freon 12, which was cooled externally by a liquid nitrogen bath and heated internally by means of a nichrome heater. Control was effected by means of a krypton vapor pressure thermometer. The temperature was maintained at 119.4° K to better than a tenth of a degree. The isotherm at 78° K was measured using an open bath of liquid nitrogen. Pressures were measured by means of a McLeod gauge. Low pressures were corrected for thermal transpiration by the formula of Liang (5).

The isotherms at 119° and 78° K are presented in Figs. 1 and 2 respectively. It is clear that the isotherm at 119° K is smooth and displays pore hysteresis and swelling hysteresis. Although swelling hysteresis was observed above the Triple Point of krypton, it was found impossible to demonstrate it at 78° K, below the Triple Point, owing to difficulties in desorption at low pressures. The few points obtained by warming the sample were not conclusive. The 78° K isotherm is presented because it gives evidence of two discontinuities for adsorption on a heterogeneous surface in contrast to those discussed in the Introduction which were observed with a homogeneous carbon surface. One discontinuity observed at a relative pressure of 0.4 is shown in Fig. 2, while the second found at a pressure of 1.7 μ is shown in Fig. 3.

DISCUSSION

The hysteresis loop shown in Fig. 1 is similar in shape to those previously reported for argon, oxygen, and nitrogen (6). It is interesting that the isotherm resembles closely the argon isotherm (6) on another artificial graphite despite the fact that the diameter of the krypton is about 17% greater than that of the argon. Figure 2 gives the isotherm

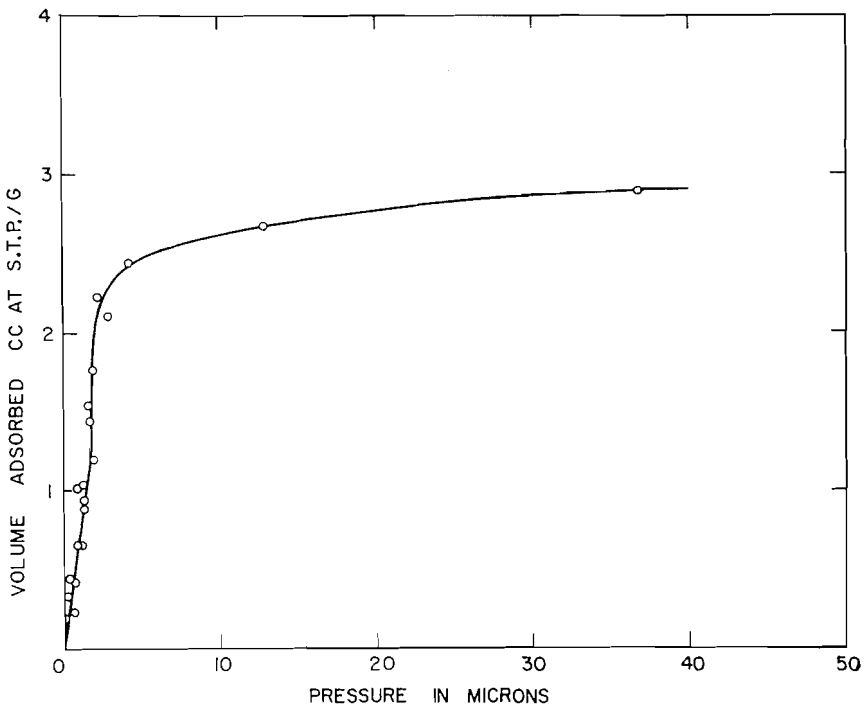

FIG. 3. The adsorption of krypton by graphite at 78° K (low pressure region).

at 78° K below the Triple Point of krypton. The isotherm is quite different from that measured above the Triple Point. The hysteresis loop is differently shaped and it shows a marked discontinuity at a relative pressure of 0.4. A second discontinuity shown in Fig. 3 was found at a pressure of 1.7 μ. This type of discontinuity, which is generally interpreted as a two-dimensional condensation, is usually seen only with homogeneous surfaces. The surface of this graphite is known to be heterogeneous (11), hence this phenomenon can be explained in these terms only if one postulates that the surface contains homogeneous regions of widely different surface energies. Thus it might be imagined that two-dimensional condensation occurs on a homogeneous region of high surface energy, while little adsorption occurs at other sites. The second discontinuity occurs at the completion of two monolayers. It may conceivably signal the point at which a solid lattice starts to form in the pores.

The surface area of the graphite was estimated from the isotherm at 78° K using the B.E.T. equation and the value of 19.5 Å^2 (3) for the area of the krypton molecule. The area was found to be 17.4 m^2/g, in good agreement with the area of 18.4 m^2/g previously reported (6) using nitrogen as the adsorbate.

FORMATION OF AN ORGANOCHROMIUM COMPOUND IN THE REDUCTION OF CHLOROFORM BY CHROMOUS PERCHLORATE[1]

F. A. L. ANET

ABSTRACT

The reduction of chloroform by chromous perchlorate in aqueous solution gave chloropentaaquochromium(III) perchlorate and dichloromethylpentaaquochromium(III) perchlorate in equimolecular amounts.

Anet and Leblanc (1) reported that the reduction of benzyl chloride by chromous perchlorate gave an organochromium ion of the structure $Cr(H_2O)_5CH_2Ph^{++}$(I). This method of preparing organochromium compounds could not be extended to simple alkyl halides for these were resistant to reduction under the conditions used. Other halides, e.g. phenacyl chloride, were reduced (1), but did not give organometallic compounds. The present communication deals with the formation of an organochromium compound in the reduction of chloroform by chromous perchlorate.

Whereas methyl chloride and methylene chloride were not reduced by chromous perchlorate at room temperature, chloroform was reduced in a few minutes, and carbon tetrachloride in a few seconds. In both cases where reduction took place, as observed by a change in color from blue (Cr^{++}) to red, it was immediately apparent that the chromous ion was not being oxidized solely to either $Cr(H_2O)_6^{+++}$ (pale blue-violet) or $Cr(H_2O)_5Cl^{++}$ (green), or to a mixture of the two ions. The red solution obtained from carbon tetrachloride decomposed to a green solution in a few seconds, and was not examined further. However, the red solution obtained in the reduction of (excess) chloroform appeared to be unchanged after a few hours, even in the presence of air. The products in this solution were therefore investigated.

The solution, which was actually grayish-red in color, contained no free chloride ion, for addition of silver nitrate did not give a precipitate. Since it was suspected that there was more than one chromium species present, separation of the components from the red solution by extraction with butanol was tried. This failed, although the procedure had been successful (1) in separating the products from the reduction of benzyl chloride. A separation into two components was achieved by ion-exchange chromatography of the solution on Dowex 50-X4 resin and elution with *M* perchloric acid. The first fraction eluted was green in color and its visible absorption spectrum and reactions showed that it contained the ion $Cr(H_2O)_5Cl^{++}$. The second fraction was pinkish-red and appeared to contain only a single colored ion, as shown by the constancy of its absorption spectrum (λ_{max} 395 mμ and 510 mμ) as it was being eluted. Analysis of this fraction (*vide infra*) showed that the color was due to an organochromium ion of the structure $Cr(H_2O)_5CHCl_2^{++}$.

The method of analysis previously (1) used with I was not applicable, as no reaction took place on addition of mercuric chloride to the red fraction. When the red fraction was heated, chloride ions were liberated and a reducing solution was produced. Accordingly, it was heated with silver perchlorate and potassium permanganate. Silver chloride was precipitated along with manganese dioxide, but addition of hydrogen peroxide left only the former, which was collected and weighed. The carbon dioxide which was evolved during the oxidation was swept out by nitrogen and determined as barium

For personal use only.

carbonate. Finally, chromium was determined spectrophotometrically in the solution left after filtration of the silver chloride. These results gave a ratio of Cr: C: Cl very close to 1: 1: 2. The amount of potassium permanganate consumed was determined in separate experiments and corresponded to the oxidation of $Cr(H_2O)_5CHCl_2^{++}$ to Cr^{+++}, Cl^-, H_2O, and CO_2.

The position of elution of the red fraction strongly suggested that the colored ion had two positive charges, for King and Dismukes (2) have found that the minimum concentrations of perchloric acid required to easily elute chromium species of charges +1, +2, and +3 from Dowex 50 resin are 0.1 *M*, 1 *M*, and 5 *M* respectively.

The amounts of chromium present in the green and red fractions above were equal, and accounted for all the chromous perchlorate used in the reduction.

These results can be explained most simply if the red fraction contains the ion $Cr(H_2O)_5CHCl_2^{++}$(II), analogous in structure to $Cr(H_2O)_5CH_2Ph^{++}$ obtained from benzyl chloride (1), and formed as follows:

$$CHCl_3 + 2Cr^{++} + 10H_2O \rightarrow Cr(H_2O)_5Cl^{++} + Cr(H_2O)_5CHCl_2^{++}.$$

The ion II may be described as an octahedral complex of chromium(III) with five water molecules and the dichloromethyl anion as ligands. The stability of this organochromium ion, like that of I, is due to the substitution-inertness of chromium(III) complexes (3). Thus the chromium–carbon bond behaves like a covalent bond with little polar character.

The reactions of II were rather different from those of I previously studied (1). Whereas I underwent decomposition on heating to give bibenzyl, presumably via benzyl radicals, II did not give tetrachloroethane, or its reduction product, dichloroethylene (since chromous ions would be formed as well). Instead, chloride ions were liberated but no volatile organic compound was formed. This reaction is at present under investigation. Unlike I, II did not react with oxygen, sulphur dioxide, or mercuric chloride, nor was it reduced by hydrogen in the presence of a palladium catalyst. Attempts to obtain sparingly soluble salts of II were not successful.

Taube and Myers (4) have found that chromous perchlorate reduced $Co(NH_3)_5Cl^{++}$ as follows:

$$Co(NH_3)_5Cl^{++} + Cr^{++} + 5H_2O \rightarrow Cr(H_2O)_5Cl^{++} + Co^{++} + 5NH_3.$$

In this one-electron reduction, no free chloride ion was liberated, and it was shown that the reduction took place by direct transfer of a chlorine atom from cobalt to chromium. If it is assumed that the first step in the reduction of chloroform proceeds in a similar fashion, with transfer of a chlorine atom from carbon to chromium, then dichloromethyl radicals will be formed,

$$CHCl_3 + Cr^{++} + 5H_2O \rightarrow Cr(H_2O)_5Cl^{++} + \cdot CHCl_2.$$

These radicals can either dimerize or react with chromous ion to give an organochromium ion as follows:

$$\cdot CHCl_2 + Cr^{++} + 5H_2O \rightarrow Cr(H_2O)_5CHCl_2^{++}.$$

If this reaction is fast, no dimerization will take place.

Thus the mechanism is consistent with the observed facts that no chloride ion was produced and that an equal amount of II and $Cr(H_2O)_5Cl^{++}$ were formed.* It is also

**It was stated in our communication (1) on the reduction of benzyl chloride with chromous perchlorate that the inorganic chromium species formed were* $Cr(H_2O)_5^{+++}$ *(mainly) and* $Cr(H_2O)_5Cl^{++}$. *It seems, however, that the* $Cr(H_2O)_6^{+++}$ *was formed as a result of the decomposition of* $Cr(H_2O)_5CH_2Ph^{++}$, *for under suitable conditions we have now found that no chloride ion is liberated during the reduction.*

in agreement with the fact that carbon tetrachloride was reduced most easily and methyl chloride least easily, for it is known (5) that chlorine substitution stabilizes the methyl free radical. Further work on the mechanism of these reductions is in progress.

EXPERIMENTAL

Preparation of Chromous Perchlorate Solution

Chromous perchlorate was prepared by the electrolytic reduction of chromic perchlorate containing perchloric acid at a mercury cathode. A carbon anode separated from the cathode by a porous porcelain pot was used. The chromic perchlorate was prepared (6) by reduction of reagent grade chromium trioxide with formic acid in dilute perchloric acid and was recrystallized from a small amount of dilute perchloric acid. The reagent was prepared, stored, and used under an atmosphere of nitrogen, purified by bubbling through two solutions of chromous chloride containing amalgamated zinc followed by a water wash. As found recently by Schug and King (6), this reagent is stable for some months, unlike that prepared by zinc–amalgam reduction. Various strengths of the reagent from 0.2 *M* to 0.5 *M* Cr^{++} in perchloric acid of concentration 0.2 *M* to 1 *M* were prepared.

Reduction of Chloroform with Chromous Perchlorate

Water (1 l) was freed of oxygen and then shaken with chloroform (10 ml). Chromous perchlorate (500 ml, 0.2 *M*) solution was added in an atmosphere of nitrogen and the solution allowed to stand 2 to 3 hours at room temperature. The grayish-red solution gave no precipitate with silver nitrate solution at room temperature. A portion (100 ml) of this solution was placed on a column (15 cm × 2 cm) of Dowex 50-X4 (200–400 mesh) in the hydrogen form and the column eluted with *M* perchloric acid at the rate of 1–2 drops per second. A green fraction (100 ml) was soon eluted, followed by a colorless solution (150 ml), and then by a red fraction (110 ml). The green fraction had the same visible absorption as described for $Cr(H_2O)_5Cl^{++}$ by Elving and Zemel (7). It gave no precipitate with silver nitrate in the cold, but on heating, silver chloride was gradually precipitated leaving a bluish-violet solution of $Cr(H_2O)_6^{+++}$. The chromium content of the green fraction was determined by direct spectrophotometric measurement in a 1-cm cell, taking $\epsilon = 17.8$ for $Cr(H_2O)_5Cl^{++}$ at λ_{max} 605 mμ (7).

Analysis of Dichloromethylpentaaquochromium(III) Perchlorate Solution

For analysis a quantity of the red fraction above was heated to boiling for 5 minutes with excess (about twofold) of silver perchlorate and potassium permanganate solutions. The cooled solution was treated with hydrogen peroxide to dissolve the manganese dioxide, and the silver chloride filtered off on a sintered glass crucible. The filtrate was made up to a definite volume and its absorbance at 575 mμ measured in a 5-cm cell. For $Cr(H_2O)_6^{+++}$ ϵ was taken as 13.9 at λ_{max} 575 mμ (7). The consumption of potassium permanganate was determined in separate experiments carried out as above except that instead of adding hydrogen peroxide a known quantity of ferrous ammonium sulphate was added, sufficient to react with the excess potassium permanganate and manganese dioxide. The excess ferrous salt was then back-titrated with 0.1 *N* $KMnO_4$.

A number of analyses were carried out on samples from the same reduction and from different reductions; a typical value obtained for the Cr: C: Cl ratio was 1.00: 1.02: 2.06.

Reactions of Dichloromethylpentaaquochromium(III) Perchlorate Solutions

Solutions in dilute perchloric acid were stable for several hours at room temperature,

For personal use only.

and many days at 0°. When the solutions were heated the red color gradually disappeared and the solution became greenish-blue and contained large amounts of chloride ion.

THE KINETICS OF THE DECAY OF NITROGEN ATOMS AS DETERMINED FROM CHEMICAL MEASUREMENTS OF ATOM CONCENTRATIONS AS A FUNCTION OF PRESSURE[1]

ROGER KELLY[2] AND C. A. WINKLER

ABSTRACT

A method is described for studying both the surface and homogeneous decay of N atoms in which the atom concentration reaching a reaction vessel after a period of decay is measured as a function of pressure by HCN production from ethylene or ethane under conditions of complete consumption of the atoms and complete initial dissociation of the nitrogen. The results indicated that the surface decay proceeded by a first-order mechanism between 55° C and 400° C, with the collision efficiency for an Na_2HPO_4 surface essentially constant at 2.75×10^{-4}. The activation energy of surface decay was 1.0 kcal mole^{-1} and the concentration of surface species 1.9×10^{14} cm^{-2}. It was concluded that the surface decay probably leads directly to molecules in the ground state.

Depending on the temperature and whether or not N_2 and N were considered equivalent as third bodies, the rate constant of the homogeneous decay varied from 1.09×10^{-33} to 13.2×10^{-33} cc^2 molecule^{-2} sec^{-1}. The homogeneous decay therefore appears to have a positive temperature coefficient and to be of only secondary importance below about 2 mm pressure under the prevailing conditions. The similarity of *one-half* the rate constant of homogeneous decay at 25° C (0.55×10^{-33} to 0.97×10^{-33}) to the rate constant of afterglow emission obtained by Berkowitz *et al.* (2×10^{-33}) suggests that *all* homogeneous decay gives rise to afterglow via the $^5\Sigma$ state.

Of the numerous studies on atom decay that have been published, perhaps the most conclusive have been those of Smith (1) and Linnett and Marsden (2, 3) on the surface decay of H and O atoms respectively. In both cases, atom concentrations in a side arm attached to a discharge tube were measured with a thermocouple probe. Since complications due to flow were eliminated, the mathematical analysis of the results was fairly simple, and it was possible to show that first-order surface decay with a collision efficiency in the range 10^{-3} to 10^{-5} was the dominant mode of decay at the pressures and temperatures used. The homogeneous decay of H atoms has also received considerable attention (e.g. 4).

Studies on the decay of active nitrogen and therefore on the recombination of the N(^4S) atoms which are its major constituent (5, 6) have, on the other hand, generally been qualitative. In fact, the only rate constant for N atom decay that has apparently been published is that for the emission of afterglow in homogeneous decay (6), while, in the case of the surface decay, even the order itself has not been settled beyond question. The main facts known about N atoms are thus the following. They decay in part on surfaces and in part homogeneously (7). The surface decay is nonluminous, i.e. the afterglow does not intensify in the neighborhood of surfaces (7), and probably first-order (7, 8, 9). Part or all of the homogeneous decay is accompanied by the emission of yellow-orange afterglow (7), the intensity of which is proportional to [active nitrogen]^2 [inert gas] (10, 6). (The work cited did *not* determine whether the inert gas could include the active nitrogen itself.) The rate constant of afterglow emission is 2×10^{-33} cc^2 molecule^{-2} sec^{-1} (6) and the mechanism probably involves an $N_2(^5\Sigma)$ intermediary (6, 11).

The present work was undertaken to confirm the order of the surface decay of N atoms, and to obtain rate constants for both the surface and homogeneous decay.

EXPERIMENTAL

Choice of Method

The measurement of N atom concentrations is complicated by the fact that, though active nitrogen contains the ^4S atom as a major constituent, there is still a possibility that excited molecules are present (12, 13, 14, 15, 16), if only in low vibrational levels of the ground state. Virtually any excited form would, of course, be deactivated on a metal surface (14), so that measurements of the activity using a thermocouple probe (cf. 1, 2, 3) would be of uncertain significance. On the other hand, the production of HCN from ethylene under conditions of complete consumption ("cleanup") of active nitrogen (high ethylene flowrates and elevated temperatures), a mode of measurement frequently used in past work (e.g. 17, 18), would likely reflect the *atom* concentration alone owing to the high activation energy to be expected in most reactions involving excited nitrogen molecules (13).[3] HCN production also has the advantages that it is not subject to mechanical failure and, since negligibly small quantities of other nitrogen-containing compounds are formed (20, 21), it provides an absolute value of the atom concentration. Production of HCN from ethylene was therefore chosen to measure the N atom concentration and the results were checked using ethane.

Apparatus

The use of chemical measurement of the atom concentrations meant that a fast-flow system of the type employed by Winkler and co-workers (see, in particular, 21, 22, 23) rather than the much simpler diffusion system of Smith (1) or static system of Rayleigh (7) had to be used (Fig. 1).

Dry, oxygen-free nitrogen[4] at atmospheric pressure was introduced at A and passed through a needle reduction valve B and a capillary flowmeter C. In the discharge tube D the nitrogen was subjected to a rapid condensed discharge. (Internal electrodes which had been machined from solid aluminum were used. They were about 60 cm apart, and were each 7.0 cm long, 1.8 cm O.D., and 7/16 inch I.D.; two setscrews were used to affix them to lengths of 0.060-inch diameter tungsten wire.) The resulting atom-containing mixture was then passed through a tube E, which will be called the "decay tube". In most of the work the decay tube had a volume of 281 cc, a length of 31.7 cm, and an I.D. of 3.36 cm (see, however, series 2). The large volume served to increase the time of decay and therefore (i) to lower the N atom concentration sufficiently, even under conditions of complete initial dissociation, for cleanup to be readily achieved, and (ii) to make the effect of dissociation on the decay time less marked (Appendix C). The large diameter served (i) to reduce the pressure gradient in the decay tube (Appendix A), and (ii) to reduce the rate constant of surface decay. A cylindrical, electrically heated furnace was built around the decay tube to determine the effects of temperature on the rate constants. At the lower end of the decay tube was a constriction 2.0 cm long and 0.60 cm I.D. which served (i) to terminate the region of decay sharply and independently of pressure (i.e. the reaction flame was invariably located just below the constriction), (ii) to enable independent heating and poisoning of the decay tube and reaction vessel, and (iii) to prevent back-diffusion of the reactant from the reaction vessel. The decay tube was followed by a 300-cc spherical reaction vessel F into which the reactant could be injected

[3]*Direct evidence to this effect appears to have been obtained in a study of the reaction of active nitrogen with nitric oxide (19). However, even if the excited molecules could react to give* HCN, *such* HCN *production would be automatically eliminated by the use of limiting slopes as described in a following section, provided the excited molecules were formed only by homogeneous atom decay.*

[4]*The method of purification is that described in references (21) and (23) rather than (22), i.e. passing the nitrogen over heated copper and through a liquid-air trap.*

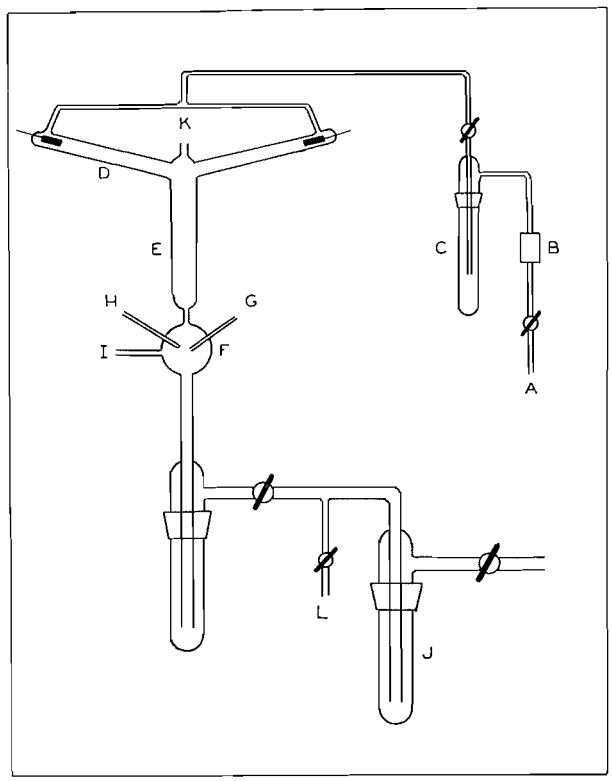

FIG. 1. Apparatus.

through jet G. (The arrangement for metering in the reactants has been described elsewhere (21).) The reaction vessel was surrounded by a second furnace, the temperature of which was measured by a thermocouple in the well H; a McLeod gauge was attached at I. From the reaction vessel the gas mixture was led through a trap J surrounded by liquid air, and thence to a pump. The Wrede gauge outlet K was present only during the experiments of series 4.

In the majority of the experiments the discharge tube, decay tube, and reaction vessel were poisoned by drawing up a 20% aqueous solution of Na_2HPO_4. This poison was used, rather than the more efficient HPO_3, since it did not react with ammonia and was unusually stable and reproducible. In a few experiments of series 6 the poison on the reaction vessel alone was changed to KCl; however, KCl could not be used in the discharge tube nor on any heated surface, since the active nitrogen then reacted with it, creating an intense reddish-orange glow.

Power was supplied from a 220-v a-c. source, transformed first with a 2400-w, 220-v variac and then with an 1897-w, 110 → 4820-v transformer, and finally rectified with two Raytheon 866A tubes in parallel. The weakest element in the circuit was the variac, which burned out several times. For most of the work the secondary circuit had a resistance of 1250 ohms and a capacitance of either 4 μf (for pressures <1.7 mm) or 2 μf (for pressures >1.7 mm, <4 mm). If the variac were adjusted to give a flashrate of 60 per second (except in the pressure range 1.2 to 1.7 mm, when 30 to 40 per second was adequate), complete dissociation of the nitrogen could be brought about. (This is treated in detail in a following section.)

HCN production was determined by titrating the recovered HCN with $AgNO_3$ (24) after it had been distilled at $-23°$ C from the trap (previously coated with solid CCl_4) into a removable unit attached at L and containing about 15 cc of frozen water (cf. 25). A sufficient amount of product to enable convenient analysis was generally obtained with reaction times of 100 seconds.

THEORY

To derive decay equations, i.e. equations which will relate the atom concentrations measured in the reaction vessel to the rate constants for decay, it is necessary to know the rate-controlling step in each mode of decay. These steps may be summarized as follows:

radiative decay $\quad N + N \rightarrow N_2 + h\nu,$

homogeneous decay $\quad N + N + M \xrightarrow{k_2} N_2^* + M,$

where M is a third body and N_2^* an unspecified excited molecule;

first-order surface decay $\quad N + N \cdot \text{surface} \xrightarrow{k_1} N_2 + \text{surface},$

and *second-order surface decay* $\quad N + N + \text{surface} \xrightarrow{k_3} N_2 + \text{surface}.$

The constants k_1, k_2, and k_3 will be defined to give the rate of atom destruction directly, without a factor of two.

Before proceeding further it will be necessary to introduce certain simplifications. Radiative decay will be neglected altogether, in general because stabilizing radiation is seldom observed in the recombination of atoms and free radicals, in particular because the nitrogen afterglow, which might be identified with such radiation, is neither continuous (26, p. 400) nor diffuse (26, p. 414), and obeys termolecular kinetics. For homogeneous decay only extreme cases of third-body efficiency will be treated. In the one case, which in the present work turns out to correspond to a lower limit of k_2, N_2 and N will be considered to be equivalent as third bodies for N atom recombination, so that [M] becomes simply the total observed pressure P. In the other, which corresponds to an upper limit of k_2, the efficiency of N as a third body will be considered to be much less than that of N_2, so that [M] becomes $(P-[N])$.[5] The two orders of surface decay will be assumed to be mutually exclusive. In terms of the mechanisms of surface decay to be discussed later this situation should prevail at temperatures or atom concentrations where the number per cm^2 of surface species (C_s in equation [10]) either approaches its maximum (i.e. monolayer) value to yield first-order surface decay, or becomes proportional to the atom concentration, corresponding to second-order surface decay.

Depending on the order of the surface decay and the relative efficiencies of N_2 and N as third bodies, four differential equations of decay are thus possible:

$$[1] \qquad d[N]/dt = -k_1[N] - k_2[N]^2 P,$$

$$[2] \qquad = -k_1[N] - k_2[N]^2 (P - [N]),$$

$$[3] \qquad = -k_3[N]^2 - k_2[N]^2 P,$$

$$[4] \qquad = -k_3[N]^2 - k_2[N]^2 (P - [N]).$$

[5] *In the event that evidence was obtained that the efficiency of* N *was greater than that of* N_2, *the case where* [M] = [N] *would have to be considered instead. This case cannot, of course, be eliminated a priori, since according to the mechanism of homogeneous decay proposed by Berkowitz et al. (6) the main function of the third body is to induce an electronic transition.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The significance of each is obvious. If $[N]_0$ is the value of [N] at $t = 0$, the solutions of equations [1] and [3] are, respectively,

$$P/[N] = e^{k_1 t}P/[N]_0 + (e^{k_1 t}-1)k_2P^2/k_1 \quad [5]$$

and

$$1/[N]-1/[N]_0 = (k_3+k_2P)t. \quad [6]$$

Though an exact solution to equation [2] can also be obtained, it is not readily used for interpreting experimental data unless $[N]_0 = P$ and $[N] \ll P$. Then

$$\ln P/[N]-k_1t \approx (k_2P/\sqrt{q})\ln\frac{1+k_2P/\sqrt{q}}{1-k_2P/\sqrt{q}},$$

where $q = k_2^2P^2+4k_1k_2$. If, in addition, $k_2P \ll 2\sqrt{k_1k_2}$, an even simpler form arises,

$$1/(\ln P/[N]-k_1t) \approx \tfrac{1}{2}+2k_1/k_2P^2. \quad [7]$$

Equation [7] is obviously valid only at low pressures and also requires a prior knowledge of k_1t obtained from equation [5]. Since the surface decay will be shown to be first order, equation [4] will not be further considered except to note that at not too low pressures its solution reduces to equation [6].

In interpreting experimental data in terms of equations [5] to [7], the data obtained at low pressures must be weighted more heavily than those at high pressures. For example, in plots of $P/[N]$ versus P^2, the limiting slopes as $P \rightarrow 0$ would be derived rather than slopes of best fit. The reasons are the following: (i) Equations [1] to [7] actually presume a number of conditions respecting diffusion, the time of decay, etc., such that the equations are more valid at low pressures (see Appendix A). (ii) Equation [7] is *inherently* valid only at low pressures. (iii) If excited molecules are present, there is a possibility that their reactivity will be superimposed upon that of the atoms; however, if they are formed only by the homogeneous decay of the atoms, their concentration necessarily falls off rapidly as the pressure is decreased.

Though equations [5] to [7] can in general be applied to studies in which any one of $[N]_0$, time, or pressure is varied, pressure variation alone is used in the present work. However, it is then necessary that the initial dissociation be complete, i.e. $[N]_0 = P$, since otherwise $[N]_0$ becomes an unknown function of P. Additional reasons why complete dissociation is desirable are that a precise control of the flashrate is then not necessary, equation [7] is inherently valid only under such conditions, and it becomes possible to distinguish unambiguously the different orders of surface decay simply by comparing the low-pressure asymptote of a graph of [N] versus P with the line corresponding to the maximum possible atom flowrate, i.e. $2[N_2]$ versus P. The asymptote would coincide with this line if the surface decay were second order, but would have a much reduced slope (Pe^{-k_1t}) if it were first order. These relations hold irrespective of the relative efficiencies of N_2 and N as third bodies. (While the striking feature of Smith's method was a similar clear-cut distinction of reaction order, it should be pointed out that the present method, in contrast to that of Smith, enables the evaluation of rate constants for homogeneous decay. It is not sufficiently sensitive, however, to determine the relative efficiencies of N_2 and N as third bodies.)

An additional relation that will be required is that for obtaining the collision efficiency or "recombination coefficient" from a rate constant for first-order surface decay. For a cylindrical decay tube of radius r_0 it is given by (27)

$$\gamma = (2r_0/\bar{c})(k_1/2), \quad [8]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

where $\bar{c}$ is the mean kinetic velocity. If γ is known, the activation energy of surface decay (E_1) and the number per cm^2 of surface species (C_s) can also be obtained using absolute rate theory (28, 27):

[9] $$E_1 = -Rd(\ln \gamma T)/d(1/T)$$

and

[10] $$C_s = 2\pi mkT\gamma/h^2 e^{-E_1/RT},$$

where T is the absolute temperature and k the Boltzmann constant. Equations [9] and [10] should be valid for any mechanism of surface decay which assumes an *immobile* surface layer.

The use of $k_1/2$ rather than k_1 in equation [8] represents a departure from the original treatment (27), but is likely more correct. Thus, considering a given surface site, each instance of decay will be followed by an instance of surface-layer formation. Since dissociation or bond stretching are not involved in the formation of a surface layer of atoms, the activation energy should be zero (28) and the process correspondingly rapid. The result is that the observed rate of decay will be double that due to the activated process described by equations [8] to [10]. Conversely, the use of an uncorrected rate constant in equation [8] as in previous publications (e.g. 1, 2, 3, 27) would make γ *high* by a factor of two.

RESULTS

Conditions of Cleanup

A cleanup of N atoms is achieved only at high reactant flowrates and above a certain temperature. For the reactants used in the present work the minimum temperatures (about 300° C) were readily obtained from published data (21). Since minimum flowrates, on the other hand, depend on the atom concentration, on the reaction temperature, and on factors peculiar to each apparatus, the results of past work could not be used. It was therefore necessary to determine, at a series of atom concentrations, the minimum flowrate applicable with each reactant and reaction temperature. The data obtained in these preliminary experiments will not be given, though it will be understood that in all experiments to be described plateau flowrates of reactant were used.

Extent of Initial Dissociation

The first four series of experiments were designed to determine if complete initial dissociation, i.e. $[N]_0 = P$, could be brought about without overtaxing the electronic components. In all cases the decay tube and reaction vessel were unheated. In *series 1* the amount of HCN formed from ethylene at 0.80 mm pressure and a capacitance of 4 μf was determined as a function of primary voltage (variac setting) and thence flashrate. Discharge was observed to start at 35 v, while the HCN production remained constant from 45 to 70 v.

The apparatus used in *series 2* differed in having a much smaller decay tube: 14.0 by 1.55 cm, volume = 26 cc. Accordingly, the time of decay was much shortened and the data should have indicated more directly the variation of $[N]_0$. However, a cleanup of N atoms was difficult to achieve, so that the destruction of ammonia, which is apparently due to excited molecules present in the active nitrogen in small amounts (12, 13, 16), was measured instead. (The amount of ammonia destroyed was determined as the difference between pressure–volume measurements of the amount drawn from the storage vessel and the amount recovered.) The results, obtained as a function of pressure, primary voltage,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

and capacitance are given in Fig. 2A. It is seen that, as the pressure was increased, the ammonia destruction at each primary voltage and capacitance at first followed a common curve, but finally dropped below as the flashrate decreased to zero. No energy expenditure would bring the reactivity above this common curve.

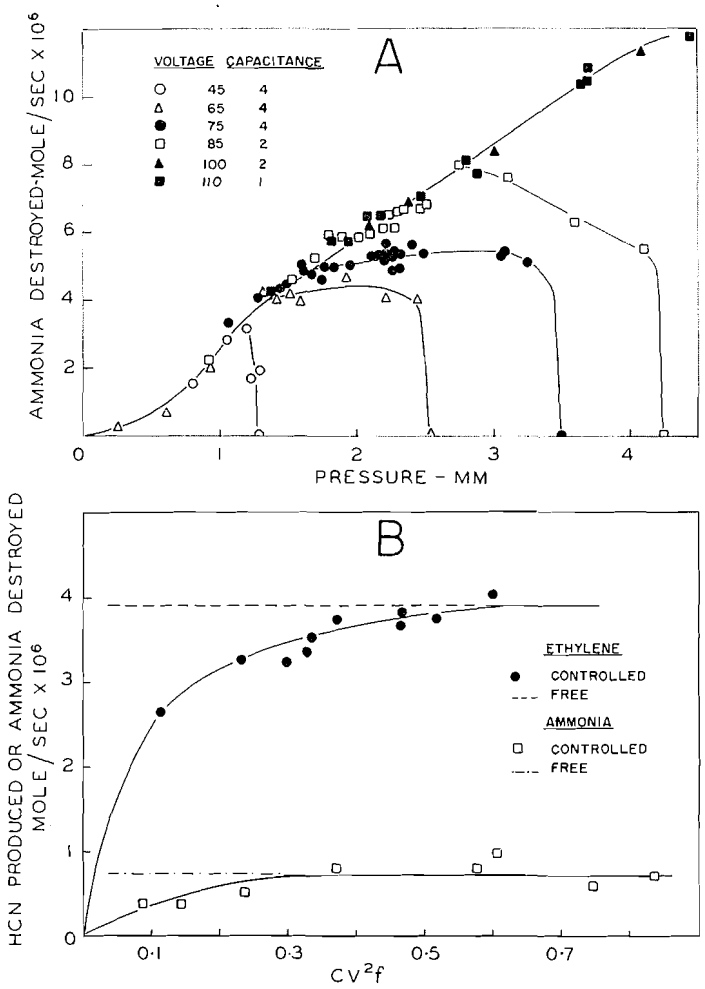

FIG. 2A. Series 2. Ammonia destruction as a function of pressure, primary voltage, and capacitance (μf).
FIG. 2B. Series 3. HCN production from ethylene and ammonia destruction as functions of CV^2f and the nature of the discharge.

In *series 3* a more precise energy variation study was conducted at 1.4 mm pressure with the flashrate electronically controlled.[6] The exact amount of energy expended in terms of CV^2f, where C is the capacitance, V the primary voltage, and f the flashrate, could thus be determined. As in series 1 and 2, the reactivities of ethylene and ammonia were readily made independent of energy expenditure (Fig. 2B), and it will be noted that the values then corresponded to those obtained at a similar pressure but under the conditions of series 5 and 6, viz. free discharge and with the circuit described earlier.

[6]*A General Electric FG105 thyratron was incorporated into the high-voltage circuit, a 90-v dry cell being sufficient to keep it non-conducting. The flashrate could then be controlled by shorting out the dry cell with a variable speed, motor-driven, rotary spark gap.*

The observation in the preceding series that reactivities could be made independent of energy expenditure indicates, of course, either that the desired condition of complete initial dissociation was achieved, or else that an equilibrium condition of partial dissociation occurred. Accordingly, in *series 4* a Wrede gauge made of sintered glass (Fisher filter stick of fine porosity) was attached to the discharge tube as indicated in Fig. 1 (K), and then connected to a differential manometer consisting of a nearly horizontal U-tube filled with diffusion-pump oil. The manometer was calibrated against a McLeod gauge. However, some difficulty was encountered using the Wrede gauge, since each reading required at least 20 minutes before the manometer was steady, so that, by the time several readings had been made at the high energy expenditures used, the discharge tube became contaminated with material from the electrodes (cf. 2, p. 496) and $[N]_0/P$ values in the range 0.15 to 0.20 were the highest that could be obtained. In an attempt to counteract this contamination, ethane was injected into the nitrogen stream at a point prior to the discharge tube for a few seconds at the beginning of each experiment. The polymeric material which would be laid down on the walls was expected to restore the apparatus to a condition more nearly like that during normal experiments, and greatly increased $[N]_0/P$ values (in the range 0.55 to 0.60) were in fact observed.

In interpreting the gauge measurements, it must be borne in mind that they represent the *average* atom concentrations in the discharge tube, not those at the instant of discharge. The observed $[N]_0/P$ values should therefore be compared with the maximum average values obtainable at the flashrates used, i.e. with

$$\overline{[N]_0/P} = 1/t \int_0^t ([N]/P)\, dt.$$

Expressing $[N]/P$ in terms of equation [5], and substituting $P = 1.4$ mm (the pressure at which most of the gauge measurements were made), $k_1 = 17.2$, $k_2 = 1.77$ (rate constants applicable at 400° C, from Table II), it is possible to show that the values of $\overline{[N]_0/P}$ corresponding to flashrates of 60 and 30 per second are 0.85 and 0.73. If k_1 is doubled, the values for the same flashrates are 0.70 and 0.58. It is therefore evident that, while the $\overline{[N]_0/P}$ values calculated for high flashrates and for normal values of k_1 are slightly in excess of the gauge measurements, the effect of a moderate increase in the rate constant of surface decay k_1, such as would result if the discharge tube were contaminated from the electrodes, is sufficient to make the values agree quite closely. Complete initial dissociation therefore appears to have been achieved (cf. Armstrong and Winkler (29)). (The $\overline{[N]_0/P}$ values given above are of incidental interest in that they indicate the upper limits of active nitrogen concentration that can be obtained at a given flashrate by shortening the decay tube or increasing the flowrate.)

With the information available in series 1 to 4, the minimum energy expenditures which bring about complete initial dissociation at a given pressure can, in principle, be determined. However, a general statement of conditions which give adequate, but otherwise unspecified, energy expenditures is sufficient for the present purposes: see description of circuit. All subsequent experiments will be understood to be conducted under these conditions.

HCN *Production as a Function of Pressure*

The actual study of the decay of N atoms was now undertaken. With the furnace on the reaction vessel set for about 350° C and the decay tube either unheated (average temperature = 55° C; *series 5*) or at 400° C[7] (*series 6*), the HCN production from ethylene

[7]*When the decay tube was at 400° C it was not necessary to heat the reaction vessel to achieve maximum reactivity with ethylene. This was not true, however, with ethane.*

and ethane was determined as a function of pressure (Fig. 3). The maximum possible N atom flowrates, obtained from the observed relation between nitrogen flowrate and pressure by doubling the flowrate values to take dissociation into account, are also indicated in Fig. 3. The experimental values for the two series were obtained in random order so that any differences would be real and not due to permanent changes in the glass or poison. In some of the experiments of series 6 the poison on the reaction vessel alone was changed to KCl. The fact that the low-pressure asymptotes of the curves for HCN production lead to a pressure slightly greater than zero (0.15 mm) probably has no great significance, since a similar property is evident in the relation between nitrogen flowrate and pressure.

The main conclusions to be drawn from Fig. 3 are the following:

(i) Since the amounts of HCN formed from ethylene and ethane coincide at all pressures investigated, a complete cleanup of N atoms rather than fortuitously similar reactivities *without cleanup* is proved.

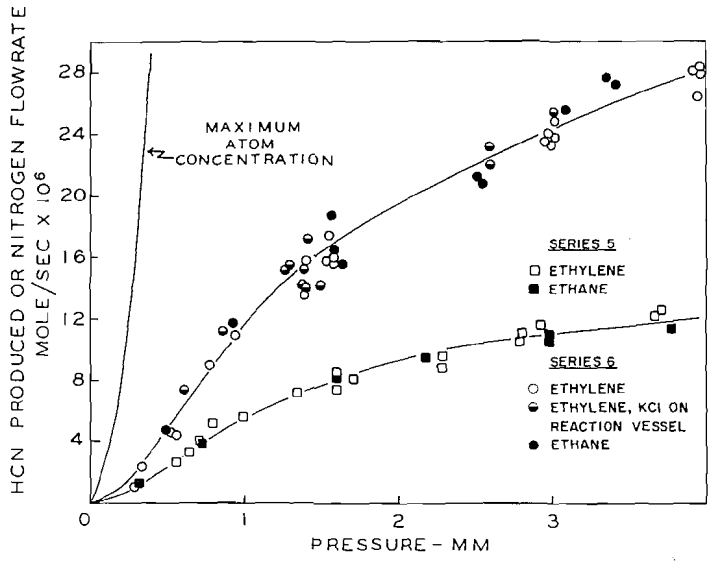

FIG. 3. Series 5 and 6. HCN production from ethylene and ethane as a function of pressure at elevated temperatures.

(ii) Since the use of KCl on the reaction vessel has no effect on the results, surface effects may be assumed absent unless, as is unlikely, KCl and Na_2HPO_4 happen to have equivalent poisoning qualities. The absence of surface effects further confirms that cleanup was achieved.

(iii) Heating the decay tube greatly increases the number of N atoms which reach the reaction vessel, though, since the rate constants for decay will be shown to *increase* with temperature, this effect must be due solely to a decreased time of decay (cf. equation [15]).

(iv) Since the low-pressure asymptotes of the curves for HCN production do not coincide with the line giving the maximum possible atom flowrate, the surface decay is shown to be first order and the relevant decay equations are therefore [5] and [7].

(v) The curves for HCN production diverge only slightly from their low-pressure asymptotes up to 2 mm pressure. Surface decay is therefore more important than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

homogeneous decay in this pressure region, at least with the poison used and for the given diameter of decay tube.

It was also shown in experiments which will not be described here (*series 7*) that the effect of temperature on decay varies continuously without maxima between the temperatures used in series 5 and 6. All conclusions on N atom decay may therefore be generalized over this range. Such a generalization would not otherwise follow, since, as seen in the H atom study of Smith (1) and in several instances cited by Shuler and Laidler (27, p. 1215), the surface collision efficiency may maximize under certain conditions.

Calculations

As a first step in fitting the data of series 5 and 6 to the relevant decay equations [5] and [7], it was necessary to convert the observed HCN flowrates into partial pressures. This was done by means of the empirical relation between nitrogen flowrate and pressure (part of which is shown in Fig. 3, though with a factor of two), with a suitable correction for dissociation. These relations are discussed in Appendix B and lead to equation [14]. Values of $P/[N]$ calculated from the data of series 5 and 6 by means of this equation are included in Table I.

TABLE I

Data used for the calculation of the rate constants for N atom decay

Pressure, mm	[N] = HCN μm/sec$\times 10^6$ (from Fig. 3)	Conversion factor μm/sec $\leftrightarrow$ mm (from eq. [14])	$P/[N]$	$1/(\ln P/[N]-k_1t)$
		Temperature of decay tube: 55° C		
0.5	2.3	.0233	9.32	24.
1.0	5.4	.0190	9.74	11.6
1.5	7.7	.0180	10.8	5.26
2.0	9.3	.0176	12.2	3.22
2.5	10.3	.0174	13.95	2.25
3.0	11.0	.0173	15.75	1.76
3.5	11.6	.0172	17.55	1.48
4.0	12.2	.0172	19.1	1.32
		Temperature of decay tube: 400° C		
0.5	4.6	.0223	4.87	23.
1.0	11.6	.0180	4.79	37.
1.5	16.0	.0171	5.48	6.21
2.0	19.4	.0168	6.14	3.64
2.5	22.2	.0167	6.73	2.72
3.0	24.4	.0166	7.40	2.17
3.5	26.4	.0166	7.97	1.87
4.0	28.0	.0166	8.59	1.64

To obtain k_1, the lower limits of k_2, and certain related quantities, plots of $P/[N]$ versus P^2 in accordance with equation [5] were now made (Figs. 4A and 4B). From the intercepts of the limiting slopes as $P \rightarrow 0$, i.e. e^{k_1t} (note that the factor $P/[N]_0$ drops out under conditions of complete initial dissociation), the quantity k_1t was obtained, with k_1 following from equation [17] as derived in Appendix C. The lower limits of k_2 could then be obtained from the limiting slopes themselves, i.e.

$$d(P/[N])/dP^2 = (e^{k_1t}-1)k_2/k_1,$$

and values for the collision efficiency (γ), activation energy of surface decay (E_1), and number per cm^2 of surface species (C_s) from equations [8], [9], and [10] respectively.

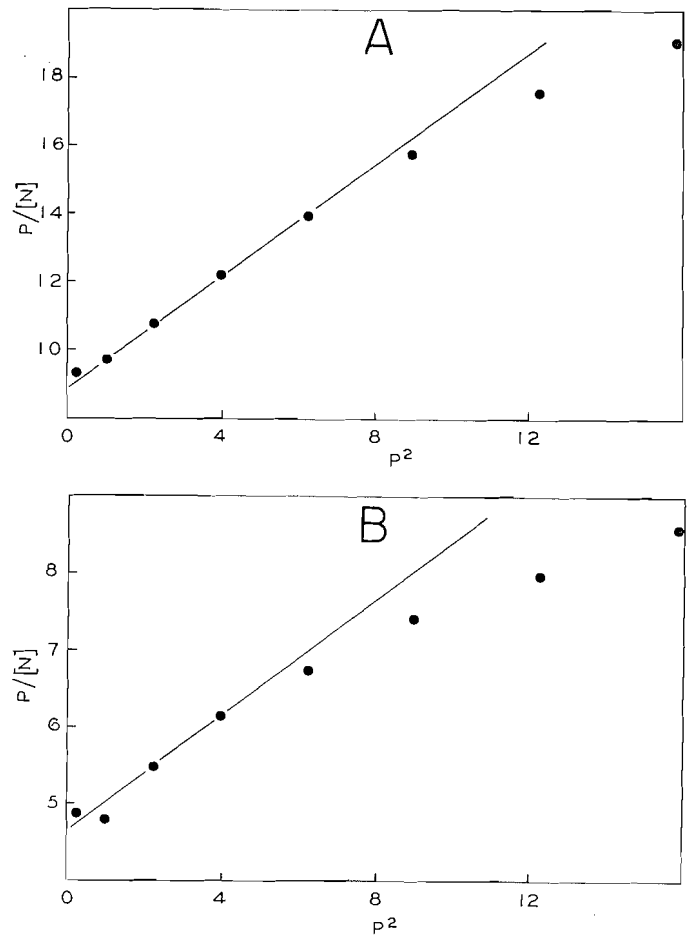

FIG. 4A. Analysis of the data of series 5 in accordance with equation [5]. (Intercept = 8.9, limiting slope = 0.82 mm^{-2}.)
FIG. 4B. Analysis of the data of series 6 in accordance with equation [5]. (Intercept = 4.65, limiting slope = 0.375 mm^{-2}.)

Finally, to obtain the upper limits of k_2, plots of $1/(\ln P/[\mathrm{N}]-k_1t)$ versus $1/P^2$ in accordance with equation [7] were made (Fig. 4C). (Values of $1/(\ln P/[\mathrm{N}]-k_1t)$ were included in Table I.) The upper limits of k_2 followed from the slopes of the lines joining the point $(0, \frac{1}{2})$ with *high* values of $1/P^2$, i.e.

$$\frac{d(1/(\ln P/[\mathrm{N}]-k_1t))}{d(1/P^2)} = 2k_1/k_2.$$

The values for the various quantities that were derived are given in Table II.

To evaluate exactly the relative importance of homogeneous and surface decay *under the prevailing conditions*, the following relation was used: mean ratio of homogeneous to surface decay =

$$1/P\int_0^P (k_2/k_1)P[\mathrm{N}]d[\mathrm{N}] = k_2P^2/2k_1.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

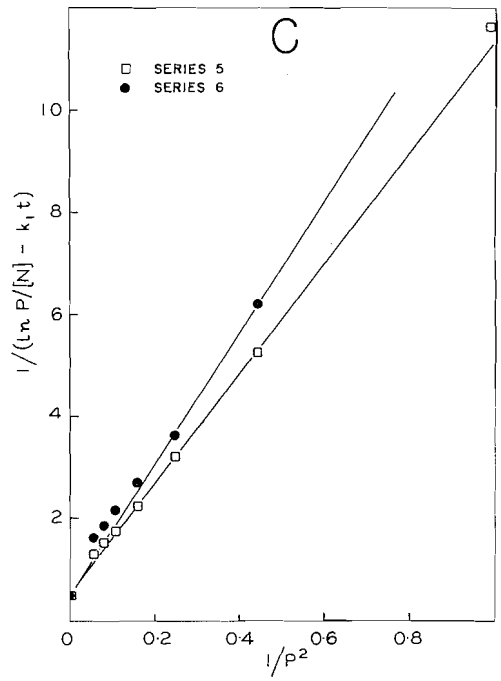

FIG. 4C. Analysis of the data of series 5 and 6 in accordance with equation [7]. (Limiting slopes = 10.90 mm² [series 5], 12.60 mm² [series 6].)

Using $k_1 = 11.1$ and $k_2 = 1.15$ this expression yields 0.052 at 1 mm and 0.83 at 4 mm. The previous conclusion is therefore confirmed that homogeneous decay is of secondary importance below about 2 mm pressure *under the prevailing conditions.*

TABLE II

The rate constants for N atom decay and related quantities

Quantity*	Value at 55° C	Value at 400° C
$k_1 t$	2.19	1.54
k_1	11.1 sec^{-1}	17.2 sec^{-1}
γ	2.65×10^{-4}	2.86×10^{-4}
k_2 (lower limit)	1.15 A	1.77 A
	1.32×10^{-33} B	8.6×10^{-33} B
k_2 (upper limit)	2.04 A	2.73 A
	2.35×10^{-33} B	13.2×10^{-33} B
E_1	1.0 kcal $mole^{-1}$	
C_s	1.9×10^{14} cm^{-2}	

*k_1, γ, E_1, and C_s apply only to surfaces coated with Na_2HPO_4. The units of k_2 are abbreviated as follows: A $\equiv$ $mm^{-2}\,sec^{-1}$, B $\equiv$ cc^2 $molecule^{-2}\,sec^{-1}$. Values for k_2, obtained from those at 55° C by usiug 298° K in the factor to convert mm^{-2} to cc^2 $molecule^{-2}$, are as follows: $>1.09\times10^{-33}$ B, $<1.94\times10^{-33}$ B.

DISCUSSION

The Decay of N, H, *and* O *Atoms*

The present work has confirmed that the surface decay of N atoms follows first-order kinetics. While this result was anticipated, it is perhaps significant that close similarities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

exist in the behavior of N, H, and O atoms. All exhibit first- rather than second-order surface decay with collision efficiencies (γ) in the range 10^{-3} to 10^{-5}, activation energies (E_1) in the range 1 to 2 kcal mole^{-1}, and values of 10^{14} to 10^{15} cm^{-2} for the concentration of surface species (C_s).[8] It would therefore be expected that the mechanism of the surface decay of N atoms would be the adsorption mechanism which has been so successful in explaining the behavior of H atoms (27). This mechanism proposes that the gas-phase atoms recombine with a layer of atoms adsorbed on the surface (8, 9, 27, 28), the order of the process depending on whether the surface layer is complete or concentration dependent. However, Linnett and Marsden (2, 3) have pointed out that at room temperature O atoms are only weakly adsorbed on glass. To explain the first-order decay they therefore suggested a slightly different mechanism according to which the gas-phase O atoms combine directly with the structural oxygen of the glass or poison, with water of hydration, or with a surface layer of oxide. This mechanism would give second-order kinetics only at temperatures sufficiently high to decompose the surface compound, i.e. at temperatures well in excess of the "desorption" temperature.

Since there seems to be no information available on the adsorption of N atoms on Na_2HPO_4 or related solids, it is not possible to decide with certainty whether the surface layer responsible for the surface decay consisted of adsorbed atoms or a true surface compound (a nitride or nitrate). However, whatever the origin of the layer, it evidently remains intact even at 400° C so that it was valid to assume, in deriving equations [1] to [7], that the two orders of surface decay were not competitive. Furthermore, as stated before, the decision does affect the validity of equations [8] to [10].

The homogeneous decay of N and H atoms is perhaps less comparable than the surface decay, since the rate constants for N atoms (Table II) appear to be an order of magnitude smaller than those for H atoms (Amdur's values of 30×10^{-33} to 61×10^{-33} (4) are typical of a number of H atom studies), in spite of the greater diameter of nitrogen. However, the difference is probably adequately explained by the steric factor shown by Berkowitz *et al.* (6) to be associated with the transition $N_2(^5\Sigma) + M \rightarrow N_2(B^3\Pi) + M$.

A positive temperature coefficient was observed for the rate constant of N atom homogeneous decay. This was unexpected in view of Rayleigh's (10) observation of a negative temperature coefficient in measurements of afterglow intensity between the temperature of liquid air and 100° C, and it is therefore possible that the results of the present work were subject to a large, systematic error. Perhaps the most likely source of such an error lies in the assumption of complete initial dissociation, since, had $[N]_0/P$ steadily decreased as pressure was increased, the effect would have been easily mistakable for a pressure-dependent mode of decay; however, no pressure dependence in $[N]_0/P$ was observed in the Wrede gauge measurements of series 4. The positive temperature coefficient therefore appears to be real. If the positive temperature coefficient observed by Robinson and Amdur (30) in the decay of H atoms could be attributed not only to the surface decay, but also to the homogeneous decay, the present results for N atoms could be considered to have good precedent.

Details of the Decay Mechanisms

To good approximation, a ^4S atom can combine only into $^1\Sigma_g^+$, $^3\Sigma_u^+$, $^5\Sigma_g^+$, and $^7\Sigma_u^+$ molecular states (6). For nitrogen, the $^7\Sigma$ state is probably higher than the ^4S dissociation

[8]*For* H *atoms the values of* E_1 *and* C_s *are:* $E_1 = 0.9$ *(30),* $C_s = 1.35\times10^{15}$ *(31, 32, 27), where* E_1 *applies only to dry surfaces (27). The corresponding values for* O *atoms can be calculated from the data of Linnett and Marsden as given in Table I of ref. (2) (Fig. 8 of this reference could not be used as it appears to have an error in the ordinate):* $\gamma = (1.2/2)\times10^{-4}$ *at 17° C,* $\gamma = (3.56/2)\times10^{-4}$ *at 400° C. Hence* $E_1 = 2.0$, $C_s = 2.7\times10^{14}$. *The introduction of a factor of two was justified in an earlier section.*

energy, while the $^5\Sigma$ state is believed to be the precursor of the afterglow (6, 11). Therefore, since it has been observed both by Rayleigh (7) and in the present work[9] that the afterglow intensity remains unchanged in the neighborhood of various surfaces, the *final* molecules formed in surface decay must be in the $A^3\Sigma$ or ground states. A further decision between these two states could perhaps best be made if the long-lived $A^3\Sigma$ molecules (14) could be shown absent from active nitrogen, or, if present, formed only from homogeneous atom decay. Such information is not available, but it is significant that the surface layer responsible for the surface decay remained intact at 400° C. That is, the *transition* molecules formed in surface decay probably exist briefly in close association with the wall, so that complete deactivation to low vibrational levels of the ground state should occur before the molecules separate. It is therefore suggested that the following mechanism accounts for *all* the surface decay (cf. 27):

$$\begin{aligned} N(^4S) + \text{surface} &\rightarrow N(^xS)\cdot\text{surface}, \\ N(^4S) + N(^xS)\cdot\text{surface} &\xrightarrow{k_1} N_2(^y\Sigma)\cdot\text{surface}, \\ &\rightarrow N_2(^1\Sigma)\cdot\text{surface}, \\ &\rightarrow N_2(^1\Sigma) + \text{surface}, \end{aligned}$$

where x and y cannot be specified with certainty due to the proximity of a surface, and $N_2(^y\Sigma)\cdot$ and $N_2(^1\Sigma)\cdot$ are transition molecules.

With homogeneous decay there exists a similar choice of paths and it was, in fact, considered by Berkowitz *et al.* (6) that recombination into the $^5\Sigma$ state with subsequent afterglow emission accounted for only part of the decay. This conclusion was based on a comparison of the rate constant of afterglow emission (2×10^{-33}) with the rate constant for a three-body collision process ($\sim10^{-32}$). However, comparing the former with *one-half*[10] the rate constant of homogeneous decay at 25° C as obtained in the present work (0.55×10^{-33} to 0.97×10^{-33}), it appears that *all* homogeneous decay must give rise to afterglow via the $^5\Sigma$ state, since the constants are essentially equal. This conclusion would be unaltered even if the afterglow constant were *high* by a factor of two or three, so that the following mechanism, which is identical with that proposed by Berkowitz *et al.* (6), may be tentatively assumed to account for *all* the homogeneous decay:[11]

$$\left.\begin{aligned} 2N(^4S) + M &\rightleftharpoons N_2(^5\Sigma) + M \\ N_2(^5\Sigma) + M &\longrightarrow N_2(B^3\Pi) + M \end{aligned}\right\} k_2$$

$$N_2(B^3\Pi) \rightarrow N_2(A^3\Sigma) + h\nu$$

$$N_2(A^3\Sigma) \rightarrow ?.$$

The last step will be considered further in a subsequent paper.

APPENDIX A

Assumptions in the Decay Equations

The decay equations assume a number of simplifying conditions beyond the basic ones already discussed. The use of a time-independent pressure, P, requires that there be no significant pressure gradient in the decay tube whether due to flow, heating, or dissociation (valid at all pressures). The use of plots extending over a range of pressure requires that the molar flowrate of nitrogen vary directly with pressure, for only then will the linear velocity of the gas and thence the time of decay (at least in the absence of dissociation) be pressure independent (see Fig. 3; the validity increases with pressure). The effect of dissociation on the time of decay must also be pressure independent (see Appendix C; valid only at low pressures or large decay times). The use of an average temperature for the decay tube in calculating the time of decay (Appendix C) assumes that the temperature of the decay tube is uniform (valid, in particular at higher temperatures). The decay tube must be of uniform diameter so that k_1 and k_3 will be constant.

Axial diffusion, i.e. diffusion in the direction of flow, must transport an insignificant amount of mass compared with the flow. This is borne out by the following calculation: the maximum contribution by diffusion to the flow occurs initially when, at 55° C and a pressure of 2 mm, and with $[N]_0 = P$, it amounts to

$$-D\partial[N]/\partial t \cdot \partial t/\partial x \cdot \pi r_0^2 = 6.6\ \mu m/sec,$$

where $D = \bar{c}\lambda/3$, λ is the mean free path, $-\partial[N]/\partial t = (k_1P + k_2P^3)(n\mu/P)$, $n\mu$ is the number of micromoles per cubic centimeter at a pressure P, $\partial t/\partial x = t_0/2 \times 31.7$, t_0 is given by equation [15], 2 is a factor to take dissociation into account, and 31.7 is the length of the decay tube. Since the flow under the same conditions is 218 μm/sec (from equation [11]), diffusion can be neglected.[12] This would not necessarily be true at very

[12]*Steiner (33) has made a similar calculation to determine if diffusion could be neglected.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

high pressures owing to the greater value of $\partial[N]/\partial t$. Radial diffusion, on the other hand, must eliminate any radial concentration gradient (see Appendix D; valid at low pressures and high temperatures).

APPENDIX B

Conversion of Flowrates to Partial Pressures

It was found that above about 0.30 mm the relation between nitrogen flowrate and pressure (cf. Fig. 3) was approximately linear and could therefore be represented simply by

$$[N_2]_{\mu m/sec} = 59.0(P-0.15), \quad [11]$$

where μm/sec is the abbreviation for micromoles per second and P is in millimeters. The temperature at which the measurements were made was 25 to 30° C. Neglecting the effect of dissociation, a relation applicable to N atoms formed in the nitrogen stream follows as

$$[N]_{\mu m/sec} = 59.0([N]_{mm}/P)(P-0.15). \quad [12]$$

However, equation [12] must be corrected for the fact that with the apparatus used, dissociation brought about an increased flowrate rather than an increased pressure such that (cf. 33)

$$\text{flowrate} \propto \frac{P}{P-[N]_{mm}/2}. \quad [13]$$

Substituting for $[N]_{mm}$ in equation [13] the approximate value $[N]_{\mu m/sec}/59.0$ obtained from equation [12], and then using the result as a correction factor for equation [12], one obtains the desired relation:

$$[N]_{mm} \approx \frac{[N]_{\mu m/sec}(P-[N]_{\mu m/sec}/118)}{59.0(P-0.15)}. \quad [14]$$

APPENDIX C

The Time of Decay

The volume flowrate can be derived directly from equation [11] and has an average value of 1006 cc sec^{-1} at 25° C and in the region 1 to 3 mm pressure. It therefore follows that the average time of flow through the 281 cc decay tube, provided the nitrogen is undissociated, is

$$t_0 = 0.279\times 298/T \text{ sec}, \quad [15]$$

where T is the average temperature of the decay tube in ° K. The increased flowrates arising from dissociation will reduce the time, so that it is necessary to find a relation between t_0 and the true time of decay t. Let x be distance measured along the decay tube, x_0 the length of the decay tube, and v_0 the linear flowrate in the absence of dissociation. Then, if there is no dissociation, $x_0/v_0 = t_0$, while if there *is* dissociation (cf. equation [13]),

$$dx/dt = v_0/(1-[N]/2P). \quad [16]$$

Neglecting homogeneous decay, the substitution $[N] \approx Pe^{-k_1 t}$ can now be made and equation [16] integrated, so that, on equating the two expressions for x_0/v_0, one obtains

$$k_1 \approx \frac{k_1 t+\ln 2-\frac{1}{2}e^{-k_1 t}}{t_0}. \quad [17]$$

Equation [17] is necessarily valid only at low pressures (when homogeneous decay is of secondary importance) or at large decay times (when the entire effect of dissociation becomes less marked).

APPENDIX D

Radial Diffusion

As a result of surface decay it is inevitable that a radial concentration gradient, however slight, will exist, and that the surface decay will therefore be self-inhibiting. However, such an effect has in the past generally been treated with such a rigid application of Fick's laws that a simple method of correcting for radial diffusion has apparently not been obtained (cf. 34). Since the formal approach involves assigning variability to the "shape" of the gradient, it was natural to try an approach in which a constant "shape" was used, in particular a *linear* gradient such that, as seen along a diameter of the system, it appears as an inverted "V".[13] A simple expression for the effect of radial diffusion when the surface decay is first order is then readily obtained.

Equating the rate of decay to the rate of diffusion towards the walls in the manner indicated by Steiner (34), one obtains

$$2\times\bar{c}[\mathrm{N}]'\gamma/4 = -D\partial[\mathrm{N}]/\partial r = (\bar{c}\lambda/3r_0)([\mathrm{N}]''-[\mathrm{N}]'), \qquad [18]$$

where [N]′ is the atom concentration at the surface of the decay tube, [N]″ is the concentration at the center of the decay tube, and r is the variable corresponding to r_0. The necessity of the factor of two on the left side was indicated in an earlier section. It is readily shown that the average atom concentration in a *cylindrical* system, $\overline{[\mathrm{N}]}$, is related to [N]′ and [N]″ by

$$\overline{[\mathrm{N}]} = \tfrac{1}{3}[\mathrm{N}]''+\tfrac{2}{3}[\mathrm{N}]'. \qquad [19]$$

Combining equations [18] and [19],

$$[\mathrm{N}]' = \overline{[\mathrm{N}]}/(1+\gamma r_0/2\lambda),$$

where the term $(1+\gamma r_0/2\lambda)$ is the desired correction for radial diffusion. The rate constant for surface decay is therefore more correctly given by

$$k_1' = k_1/(1+\gamma r_0/2\lambda) = k_1/(1+\alpha P),$$

where k_1 is given by equation [8] and (assuming $\sigma = 3.84\times10^{-8}$ cm) $\alpha = 3.16\times10^4\gamma r_0/T$ mm^{-1}.

If similar arguments are applied to a *spherical* system, where

$$\overline{[\mathrm{N}]} = \tfrac{1}{4}[\mathrm{N}]''+\tfrac{3}{4}[\mathrm{N}]',$$

then $\alpha = 3\gamma r_0/8\lambda = 2.37\times10^4\gamma r_0/T$ mm^{-1}. It can be proved that, provided $\alpha P \ll 1$, no correction is necessary to k_2 in either a cylindrical or spherical system.

The treatment given is general and can be applied to experimental situations other than the present, e.g. static systems. However, it may not be valid for a short-lived species formed in the *interior* of a system, since a very marked pressure effect would be expected if the time for diffusion to the walls were comparable to the life of the species. As far as the present work is concerned, since α would amount to only 0.043 mm^{-1} (for $r_0 = 1.68$ cm, $\gamma = 2.65\times10^{-4}$, $T = 328°$ K), the correction for radial diffusion can be neglected, at least at the lower pressures.

[13] *A gradient of this sort appears to have theoretical justification, since it represents the limiting case as Dt gets large, i.e. it applies at high temperatures, low pressures, or when decay is slow. (That a decreasing rate of decay is very approximately equivalent to an increasing value of Dt is evident from the fact that there is no gradient in the absence of decay.) Compare the exact expression for radial diffusion in a cylinder (35, p. 272).*

RADIOLYSIS OF TETRACHLOROETHYLENE[1]

J. W. SUTHERLAND AND J. W. T. SPINKS

ABSTRACT

When tetrachloroethylene is irradiated with Co^{60} gamma rays in the presence of oxygen or air, the main products are trichloroacetyl chloride, phosgene, and oxalyl chloride. The reaction is a chain reaction. Possible reaction mechanisms are discussed.

INTRODUCTION

Tetrachloroethylene, when irradiated in a two-phase aqueous system or when irradiated with a soluble pH indicator dye, liberates acidic products. The acid yields are high (G_{H^+} values up to 6000), suggesting that a chain mechanism is operative (1, 2). Chain reactions, although highly sensitive, are often greatly influenced by dose rate, temperature, and the presence of trace impurities. In addition, this particular reaction proceeds to some degree under the influence of light (3, 4). These complicating factors, undesirable in chemical dosimetry, can be effectively removed and in some cases totally suppressed by the addition of stabilizing reagents such as ethyl alcohol, resorcinol, and thymol. Although the sensitivity of the system to radiation is thereby markedly reduced (G value about 30), the use of stabilizers has made it possible to use tetrachloroethylene dosimeters which can register doses in the range, 1.0 to 10^6 r and which show excellent reproducibility (1).

The purpose of this study is to arrive at a more fundamental understanding of the chain mechanism in this sytem and to see whether further study of it would be useful in interpreting some of the processes occurring when ionizing radiation interacts with matter, e.g., in providing evidence of track effects (5).

EXPERIMENTAL

Reagent grade Kodak Eastman tetrachloroethylene, stabilized by the addition of 0.5% ethyl alcohol, was used as starting material. The alcohol can be removed by repeated water extractions or by fractional distillation. Pure tetrachloroethylene is prone to decompose under the influence of light and oxygen (3, 4), and thus a large sample of pure material cannot be prepared and stored for any length of time. Since this necessitates preparation of alcohol-free reagent immediately prior to each irradiation run, the following procedure was adopted.

Approximately 50 ml of reagent grade tetrachloroethylene (ethyl alcohol stabilized) was shaken with $CaCl_2$, filtered, and fractionally distilled. The middle fraction, b.p. 120–121° C, was used. Samples which had been treated for 24 hours and 3 days, respectively, were equally sensitive to radiation. Samples which had been extracted for periods of 2 and 12 hours were found less radiation sensitive.

The system irradiated, unless stated otherwise, was a 3-ml sample of pure tetrachloroethylene overlayered with 2 ml of water which had been distilled from alkaline permanganate and then redistilled from an alkaline suspension of manganous hydroxide. Samples were irradiated in glass-stoppered Pyrex tubes (12×100 mm), with gamma radiation from either a 1-curie or a 1000-curie Co^{60} source (6). After irradiation the solution was transferred to a 10-ml Erlenmeyer flask, and two 1-ml portions of wash water added. The acids liberated were titrated against standard base (NaOH) using a

[1]*Manuscript received June 20, 1958.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.

microburette and a 0.1% solution of chlorophenol red as indicator. Samples were titrated to the same color as a blank (pH about 6), which had received identical treatment except for irradiation.

Irradiations were carried out at room temperature.

Dose rates were measured with a ferrous sulphate dosimeter ($G_{Fe^{+++}} = 15.5$) (7).

Infrared spectra were recorded with a Perkin–Elmer double beam infrared spectrophotometer.

RESULTS

In general, titration of the acids formed on irradiation was difficult owing to a pronounced postradiation effect which, however, apparently decreased in magnitude the less acid there was liberated. For example, there was no measurable postradiation effect with a 0.3% hexylresorcinol stabilized, air-equilibrated system (Table I).

TABLE I

*G values are calculated on the basis that only the energy absorbed by the tetrachloroethylene phase is responsible for the chemical reactions. The factor for converting column 4 to column 5 is 703.

However, with a more sensitive system, e.g., using tetrachloroethylene which had been freed from alcohol and saturated with oxygen prior to irradiation, complete extraction of acid products was more difficult (Table II).

Preliminary experiments were also done in air-equilibrated tetrachloroethylene–water systems. In such systems, reproducibility was apparently achieved by periodic shaking

TABLE II

Irradiation of purified tetrachloroethylene saturated with oxygen

(Samples, 3 ml purified tetrachloroethylene ($CaCl_2$ extracted for 24 hours, redistilled) saturated with O_2 prior to irradiation. Acidic products extracted with H_2O after irradiation. Temp., 25° C; mean dose rate, 10 r/minute.)

of samples during a 24-hour period before titration. It was also noted that if the samples were titrated immediately following irradiation, a sharp end-point color was reached which rapidly changed to the acidic color on standing. When the sample was left to stand without stirring, an acid aqueous layer formed at the interface of the water and tetrachloroethylene phase. This behavior occurred whether the system was left in the dark or not. Identical treatment of the blank showed no such behavior, even on exposure to sunlight. When bromocresol purple indicator was used, some of the indicator (chlorophenol red is insoluble in the tetrachloroethylene layer) dissolved in the tetrachloroethylene phase and showed a persistently acid reaction. The addition of hexylresorcinol, subsequent to irradiation (even in large amounts), had no inhibiting effect on this behavior, although it would presumably prevent decomposition under the influence of light and temperature. The more acid liberated, the more difficult it was to reach a stable end point. Shaking the solution or stirring it more vigorously produced more acid in the aqueous layer. Samples overlayered with different amounts of water gave similar acid yields.

When water saturated with tetrachloroethylene was irradiated, no detectable acid was liberated in the dose range being studied (0–2000 r).

These observations suggest that the continued acid production after irradiation is a result of gradual extraction of acidic products from the tetrachloroethylene phase, rather than a continuation of a chemical decomposition of the tetrachloroethylene.

Variation of Acid Yield with Absorbed Dose

Experimental data are summarized in Figs. 1, 2, and 3. Data for Fig. 1 were obtained for tetrachloroethylene which had been extracted for about 24 hours with $CaCl_2$ and redistilled before irradiation.

A series of runs at different dose rates was made with a sample of air-equilibrated tetrachloroethylene which had been left for a month overlayered with water. The water was separated, the tetrachloroethylene dried with $CaCl_2$ and redistilled. The results are shown in Figs. 2 and 3.

It is evident that we are now dealing with a more sensitive system. In samples where the tetrachloroethylene was overlayered with water the same limiting value of acid liberated was obtained, viz., about 4 meq $\times 10^{-3}$/ml, but this value was reached at

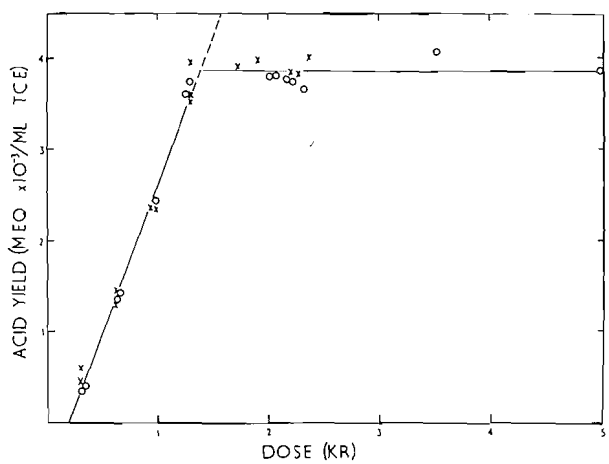

FIG. 1. Acid yield as a function of absorbed dose. Tetrachloroethylene extracted 24 hours with calcium chloride and redistilled. Samples consisted of 3 ml of tetrachloroethylene overlayered with 2 ml of water and air equilibrated. Temperature, 25° C; dose rate, 10 r per minute.

○ Samples were 3 ml of air-equilibrated tetrachloroethylene overlayered with 2 ml of water.

lower doses of the order of 200 r (cf. Fig. 1, 1.4 kr). The probable explanation for the increased rate is that traces of alcohol left by the $CaCl_2$ method of purification were removed from the system by the water, thus making it more radiation sensitive. The G values are extremely high, e.g., at 41.3 r/minute G_{H^+} is of the order 12,600, over the initial range of absorbed dose.

Figure 3 shows a comparison of the acid yields obtained when tetrachloroethylene alone and tetrachloroethylene overlayered with water, both systems being air equilibrated, are irradiated. When tetrachloroethylene alone is irradiated, there is no limiting value to acid production though the rate of reaction changes after a time. The change in slope

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

is attributed to progressive exhaustion of the original oxygen present in the solution followed by diffusion of the oxygen from the gas phase into the tetrachloroethylene. This is extremely slow when the tetrachloroethylene is overlayered with water but is fast enough to support an appreciable rate of reaction when the tetrachloroethylene is in direct contact with air.

The induction period is reduced to about 50 r for the more highly purified tetrachloroethylene system.

Studies on the Effect of Oxygen

It is seen that the same limiting value of acid produced is reached in all systems overlayered with water despite their differing sensitivities. These observations suggest that an oxidation reaction is occurring in the tetrachloroethylene phase, the extent of the reaction being determined by the oxygen content of the tetrachloroethylene phase layer. This view was supported by the results of experiments in which the system was flushed, (*a*) with N_2, and (*b*) with oxygen, prior to irradiation. (See Table III.)

TABLE III

Effect on acid yield of flushing system with oxygen or nitrogen prior to irradiation

(Samples, 3 ml of tetrachloroethylene overlayered with 2 ml H_2O; dose rate, 10 r/minute; temp., 25° C.)

Pretreatment	Dose, kr	Acid yield, meq $\times 10^{-6}$ per r per ml	G_{H^+} values
(*a*) Tetrachloroethylene purified by $CaCl_2$ extraction (24 hours), followed by distillation			
Air-saturated	2.17	1.80	1270
	2.16	1.85	1300
N_2-flushed	2.18	0.0038	2.7
	2.12	0.0036	2.7
O_2-flushed	2.15	8.75	6150
	2.10	8.90	6250
(*b*) Ethyl alcohol stabilized tetrachloroethylene (0.5% EtOH)			
Air-saturated	16.8	0.190	133
	21.0	0.160	112
N_2-flushed	6.9	0.0049	3.4
	7.1	0.0057	4.0

From Fig. 3, the limiting amount of acid produced in an air-saturated sample is 3.94 meq $\times 10^{-3}$ per ml, i.e., 23.7×10^{17} hydrogen ions per milliliter of TCE.

In a subsequent section, the analysis of the radiation products is described. From this, it appears that 2 molecules of acid are formed from each molecule of acid chloride formed, and that the percentages of $(COCl)_2$, $COCl_2$, and CCl_3—COCl are 3–4%, 37–38%, and 59%, respectively.

Hence, 11.85×10^{17} molecules of acid chloride are formed per milliliter of TCE, and using the percentage analysis figures, the total number of acid chloride molecules liberated per milliliter of tetrachloroethylene is 0.35×10^{17} molecules $(COCl)_2 + 4.5 \times 10^{17}$ molecules of $COCl_2$ and 7.0×10^{17} molecules CCl_3COCl.

Therefore, the total number of oxygen molecules required to produce the products is 6.1×10^{17}.

No value for the oxygen content of an air-saturated solution of tetrachloroethylene is available in the literature. However, values for various related compounds, given in International Critical Tables (8), are tabulated below:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Compound	No. oxygen molecules per milliliter of air-saturated compound
CCl_4	1.2×10^{18}
$CHCl_3$	1.1×10^{18}
$C_2H_2Cl_4$	5.5×10^{17}
C_2Cl_4	4.8×10^{17}

together with a value for C_2Cl_4 obtained in a preliminary experiment done in these laboratories. It is in line with the values reported for similar compounds.

The above evidence suggests that the observed break in Figs. 1, 2, and 3 is due to oxygen depletion and that the radiolysis of tetrachloroethylene is essentially an oxidation reaction.

Identification of Reaction Products

Fifty milliliters of purified tetrachloroethylene was irradiated with gamma rays, a slow stream of oxygen being bubbled through to promote the yield of product. The solution was given a dose of about 10^3 r.

The irradiated solution had a pungent odor. On distillation the first 0.5–1 ml distilled at about 118° C (fraction 1). The bulk (fraction 2) distilled at 120–121° C, the boiling point of TCE, and retained to some extent the pungent odor. A residue of about 0.2 ml of a higher boiling fraction (fraction 3) remained. An attempt to find its boiling point resulted in some decomposition.

Infrared spectra were measured of pure tetrachloroethylene, irradiated tetrachloroethylene, and fractions 1, 2, and 3.

Irradiated tetrachloroethylene showed an additional band of low intensity at 1800 cm^{-1}, characteristic of the C=O of an acid chloride (9). Fraction 1 gave a sharper, much enhanced, band at 1810 cm^{-1} and also a strong band at 830 cm^{-1}, the C–Cl region of an acid chloride. In addition, a weak band appeared at 1650 cm^{-1}, which was tentatively ascribed to a C=C linkage. The spectrum of fraction 3 was identified as that of a trichloroacetic acid – tetrachloroethylene mixture.

It was concluded that the main chemical reaction taking place on irradiation of an oxygen–tetrachloroethylene solution was an oxidation to acid chlorides. Part of the acid chloride has been hydrolyzed to trichloroacetic acid, presumably by traces of H_2O which may have been present in the O_2 supply. One of the acid chlorides is trichloroacetyl chloride.

In order to identify any other acid chlorides which may have been present, 50 ml of irradiated tetrachloroethylene was reacted with excess primary amine and the reaction products isolated and identified as far as possible by comparing their melting points and infrared spectra with those of specimens of pure compounds. The method used for the working up of the products of reaction with aniline is shown in Table IV.

The compounds isolated from the reaction in this manner of aniline and *p*-toluidine respectively were aniline hydrochloride, trichloroacetanilide, N,N′-diphenylurea, oxanilide, and the corresponding *p*-toluidine derivatives. Unidentified derivatives of aniline and *p*-toluidine having m.p.'s of 137 and 179° C, respectively, were also obtained. The data available suggest that they were derived from the same compound. For the aniline derivative, empirical formula $C_{16}H_{14-16}N_2O$, infrared spectra indicates N—H, C—H aromatic, C=N, a monosubstituted phenyl —X, a carbonyl linkage  ·Cl is absent.

TABLE IV

One possible formula* is: and it is probable that the precursor is a 4-carbon molecule formed in the radiation reaction.

Identification of Acids Formed on Hydrolysis

The irradiated solution was extracted with water and the water phase separated and evaporated to dryness at room temperature. Crystals were obtained, m.p. 54° C (trichloroacetic acid, m.p. 57–58° C). Evaporation must be at a low temperature, since in hot water or basic solution (10) trichloroacetic acid decomposes in the manner, $CCl_3COOH \rightarrow CO_2 + CHCl_3$.

The crystals, on being shaken with concentrated aqueous ammonia containing Cu_2Cl_2, gave a dark blue color instantly. This is characteristic of trichloroacetic acid (10), though similar behavior is exhibited by dichloroacetic acid. Aqueous hydrolysis of $COCl_2$ and $(COCl)_2$ yields only hydrochloric acid (10). No oxalic acid is formed, although vapor-phase hydrolysis of $(COCl)_2$ is said to yield some.

$$COCl_2 + H_2O \rightarrow CO_2 + 2HCl,$$
$$(COCl)_2 + H_2O \rightarrow CO + 2HCl + CO_2.$$

Quantitative Determination of Products

The three main reactions which yield acidic products in the irradiation of TCE are:

**Suggested by Dr. R. A. Abramovitch.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$CCl_3C(=O)Cl + H_2O \rightarrow CCl_3COOH + HCl, \quad [1]$$

$$COCl_2 + H_2O \rightarrow CO_2 + 2HCl, \quad [2]$$

$$(COCl)_2 + H_2O \rightarrow CO + CO_2 + 2HCl. \quad [3]$$

About 30 ml of TCE + 5 ml H_2O (to trap the phosgene) were irradiated for 3 days. A stream of oxygen was bubbled through during the irradiation. The irradiated mixture was extracted three times with water (about 30-ml portions each time) over a period of 24 hours. The water layer was separated and its acid content determined by titrating 5-ml samples with standard alkali to pH 4 using screened methyl orange as indicator. The chloride content of the sample was estimated by titration of 5-ml samples, which had been neutralized by NaOH (phenolphthalein as indicator), with standard $AgNO_3$ solution using dichlorofluorescein as an indicator. The amount of HCl expressed as a percentage of the total acid was 70.5. Hence:

acidity due to $CCl_3COOH = 29.5\%$,
acidity due to $CCl_3COCl = 59\%$,
acidity due to $COCl_2 + (COCl)_2 = 41\%$.

Since CCl_3COCl, $COCl_2$, and $(COCl)_2$ all yield 2 molecules of acid per molecule of acid chloride, the percentages of the acid chloride formed in the irradiation of TCE are 59% CCl_3COCl and 41% ($COCl_2$ + $(COCl)_2$).

Determination of $COCl_2$ *and* $(COCl)_2$ *Content*

Since these two compounds behave very similarly chemically, it is difficult to estimate the composition of a mixture of them by chemical means. However, under experimental conditions phosgene ($COCl_2$) is a gas, b.p. 8° C, and oxalyl chloride a liquid, b.p. 62° C, and therefore the mixture should be readily separable by refluxing. Approximately 30 ml of TCE was irradiated, with O_2 bubbling through, for 5 days. Ten milliliters of solution was refluxed for 2 hours to distill off the phosgene, the remaining acid chlorides hydrolyzed, and the percentage chloride of the total acid content determined. The value obtained was 51.4%. A second sample, which was refluxed for 45 minutes, gave 52.0%. Taking the HCl content of the solution as 52%, then 96% of the acidity is due to hydrolysis of CCl_3COCl and 4% due to oxalyl chloride. Hence, since originally a sample of irradiated TCE contained 59% trichloroacetyl chloride, the true percentage of oxalyl chloride in a sample of irradiated TCE is $59/96 \times 4 = 3\%$. While no great accuracy is claimed for this figure it does indicate that oxalyl chloride is found in relatively small amounts and that the main reaction products are: CCl_3COCl (59%), $COCl_2$ (37–38%), and $(COCl)_2$ (3–4%). An implicit assumption in these calculations has been that the same fraction of each acid chloride is formed irrespective of dose received.

DISCUSSION

G Values

G_{H^+} values were calculated, assuming that acidic products are formed only as the result of energy absorbed by the tetrachloroethylene phase.

At the water–tetrachloroethylene interface there may be some reaction by H and OH radicals from the radiolysis of water. These reactions may lead to acidic products, but such reactions will probably not produce long chains, and in these circumstances their effect will be negligible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Because of the influence of oxygen depletion in the solution, and the presence of an apparent induction period, G values are taken from the slopes of the straight lines in Fig. 2. From the analysis figures found for the relative amounts of CCl_3COCl (59%), $COCl_2$ (39%), and $(COCl)_2$ (3%), the following G values can be calculated (Table V).

TABLE V

Tetrachloroethylene extracted with $CaCl_2$ and H_2O

(Samples, 3 ml air-equilibrated tetrachloroethylene overlayered with 2 ml water)

(*a*) Tetrachloroethylene extracted with $CaCl_2$ (24 hours) redistilled	(*b*) Tetrachloroethylene extracted with H_2O (about one month), dried over $CaCl_2$, and redistilled
$G_{(H^+)} = 2250$	$G_{(H^+)} = 12{,}600$
G (acid chloride) = 1125	G (acid chloride) = 6300
G (CCl_3COCl) = 660	G (CCl_3COCl) = 3700
G ($COCl_2$) = 430	G ($COCl_2$) = 2400
G ($(COCl)_2$) = 34	G ($(COCl)_2$) = 190
G (C_2Cl_4) = 910	G (C_2Cl_4) = 5000
G (O_2) = 570	G (O_2) = 3240

One question arises which the present experimental data cannot settle, viz., is the production of oxalyl chloride a primary oxidation product or is it a secondary product resulting from radiolysis of CCl_3COCl or $COCl_2$?

The large G $(COCl)_2$ value, 190, suggests that $(COCl)_2$ is a primary oxidation product. (N.B. In these calculations of G values we have assumed that we can extrapolate analysis data from a sample which had been given a dose of 1000 kr with O_2 bubbling to the dose range being studied, viz., about 1 kr.) The final concentration of acid chloride reached in the 1000-kr run was 0.16 molar $\equiv$ 4.3% conversion on a mole basis.

Radical Yields

Radical yields G_R for several organic liquids have been measured. Chapiro *et al.* (11) find values of G_R for CCl_4 and $CHCl_3$ of about 70 and 60, respectively, using the D.P.P.H. method. Schulte (12), using tagged Cl_2 in CCl_4, finds a value for G_R as $\lesssim 3.5$.

If we assume that G_R for C_2Cl_4 is between 60 and 3.5, and assume each radical initiates a chain reaction leading to acidic products (see later this section) approximate values for kinetic chain lengths can be derived, e.g., for systems (*a*) and (*b*) Table V. We have: $G_{H^+} = 2250$, kinetic chain length between 34 and 650; $G_{H^+} = 12600$, kinetic chain length between 210 and 3600.

Tetrachloroethylene Dosimeters

The radiation reaction in a tetrachloroethylene air-equilibrated solution has been shown to be an oxidation reaction, and there will be a limiting value to the dose which can be measured by a dosimeter consisting of tetrachloroethylene overlayered with water. From our results this limiting value will correspond to a maximum value of 3.94 meq $\times 10^{-3}$ per ml TCE of acid liberated. A typical value for the rate of acid production in a stabilized two-phase tetrachloroethylene dosimeter is 0.05 meq $\times 10^{-6}$ per ml per r (1). Hence, for a system of this particular sensitivity, one would expect that for doses greater than 80 kr, this system would lose its sensitivity (provided no oxygen has diffused into the tetrachloroethylene phase during irradiation).

Our work emphasizes the observation by Taplin (1) that, after exposure of the dosimeter, vigorous shaking over a period of time is required to bring about complete extraction of acidic products.

Effect of Stabilizers

Certain reagents, notably alcohols and phenols, retard the radiation-induced reaction (1). Bailey (3, 4) has found that the photochemical oxidation of perchloroethylene is accelerated by I_2, slightly retarded by quinol, fairly well retarded by butyl-α-isobutyl alcohols, turpentine, benzaldehyde, resorcinol, naphthols, napthylamine, and sulphur, and well retarded by alcohol, ether, thymol, *o*-toluidine, sodium thiosulphate, and thiourea. He observes that in certain cases, e.g., quinol, benzaldehyde, resorcinol, diphenylamine, napthylamine, and the naphthols, the retarding agent caused development of color. This is interesting, since such reactions might be easily followed spectrophotometrically and might help in elucidating the chain propagating reactions or in development of a method of finding the radical yield in tetrachloroethylene.

Oxidation Reaction

The main reactions occurring in the radiolysis of tetrachloroethylene can be summarized thus:

$$C_2Cl_4 + \tfrac{1}{2}O_2 \rightarrow CCl_3COCl, \qquad [a]$$

$$C_2Cl_4 + O_2 \rightarrow 2COCl_2, \qquad [b]$$

$$C_2Cl_4 + O_2 \rightarrow (COCl)_2 + 2Cl. \qquad [c]$$

Reaction [*c*] is non-stoichiometric, there being a loss of 2 atoms of chlorine. This may appear in the system as molecular Cl_2 or C_2Cl_6. Such compounds have not been looked for, but other workers (13) have detected molecular Cl_2.

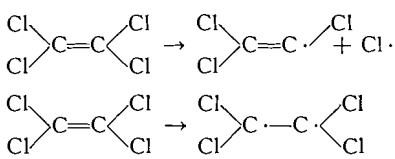
Reaction Mechanism

In the present system the oxygen concentration is about 0.002 molal and if it is assumed that the ease of ionization of O_2 and C_2Cl_4 is about the same, and that there is no preferential transfer of ionization or excitation energy to the O_2 molecules, then ionization and excitation will be mainly confined to the C_2Cl_4 molecules.

Both ionic and molecular species will be in a variety of excited states. The nature of the secondary processes ultimately leading to chemical reaction is still obscure, although theoretical evidence has been advanced showing that in a liquid charge neutralization occurs before the ions can react chemically (14, 15, 16). Ion molecule type reactions have also been proposed. Iodine scavenger studies (17) have shown that molecular decomposition processes occur in organic systems.

However, the chain characteristics of the oxidation reactions are such that initiation and propagation must be by free radicals. Molecular products can be assumed to be of negligible importance. These radicals probably arise from dissociation of excited molecules.

Because of its simplicity, changes in the excited tetrachloroethylene molecule are limited to rather few possibilities, e.g.



The formation of a diradical will be energetically more improbable, and hence as a result of the primary act we would anticipate the production of Cl· and C_2Cl_3· radicals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Important in any radiation scheme is the spatial distribution of such radicals. Chapiro (5) has recently discussed the distribution of free radicals and is of the opinion that the over-all spatial distribution of free radicals is similar but not identical with the distribution of the ions.

In the radiolysis of C_2Cl_4, Cl and C_2Cl_3 radicals will be produced. Some of these radicals will recombine and react with each other yielding molecular products, possibly Cl_2 and C_4Cl_6 (hexachlorobutadiene). The yield of these products will be influenced by the rate of diffusion of radicals, the velocity constants of their reactions, and the presence and efficacy of any scavenger molecules present.

It is interesting to note that in a N_2-saturated system a value of G_{H^+} of $\backsim 4$ was obtained (Table III), whether pure tetrachloroethylene or stabilized tetrachloroethylene was used.

Thus we would anticipate that, in a tetrachloroethylene solution overlayered with water, acids will continue to be produced after exhaustion of the dissolved oxygen. However, the rate will be so low that it is not measurable under our conditions up to an absorbed dose of 20 kr.

With gamma radiation, where the clusters are widely separated, there will be little chance of radical–radical reactions from different tracks, and hence there will be a finite number of radicals escaping into the solvent from the clusters for a fixed amount of radiation absorbed.

These radicals can then interact with solvent molecules, C_2Cl_4, and solute molecules, O_2. The ensuing reactions will again be governed by: (*a*) rate of diffusion of radicals, (*b*) velocity constants of the reaction, and (*c*) concentration of solute and solvent molecules.

Pertinent to this work are the studies by Schumacher (18, 19) and co-workers, and Dickinson and co-workers (20, 21, 22) on the photochemical chlorine sensitized oxidation of tetrachloroethylene. The products of the oxidation reaction, isolated by them, were CCl_3COCl and $COCl_2$. The reaction was studied in the gas phase and in CCl_4 as solvent (21). Dickinson and Leermakers (20, 21) show that the products of oxidation, CCl_3COCl and $COCl_2$, undergo little or no further oxidation on prolonged exposure to light. In CCl_4 solution the rate of oxidation of C_2Cl_4 is independent of $[O_2]$ (provided the latter is not too low), proportional to the first power of the light intensity, and dependent on the chlorine concentration but only to the extent that the amount of chlorine affects the rate of energy absorption. The reaction rate varies to some extent with the tetrachloroethylene concentration and the temperature. A quantum yield of 1–2.5 moles of C_2Cl_4 oxidized per einstein is found.

In the gas phase (22), the rate of reaction has no strong dependence on the partial pressures of Cl_2, O_2, and C_2Cl_4. However, the reaction is much faster and quantum yields of 200–500 were found.

Schumacher (19) has also studied this reaction in the vapor phase and finds that approximately 80% of tetrachloroethylene is converted to CCl_3COCl and 20% to $COCl_2$, in agreement with Dickinson's figures. The phosgene content of the reaction product slowly increases with temperature. The over-all temperature coefficient is unity and the total pressure has little effect on the rate of reaction. The addition of alcohol strongly retards the reaction. With pure tetrachloroethylene he finds a quantum efficiency of 230 molecules of tetrachloroethylene per quantum at a temperature of 60° C and at 100 mm Cl_2, 200 mm O_2, and an absorbed intensity of 1.6×10^{12} hv/sec cc.

Possible Reaction Mechanisms in the Radiolysis of Air-equilibrated Tetrachloroethylene

From the foregoing one can postulate that the following chain mechanism is occurring in our system:

Initiation	$C_2Cl_4 \rightsquigarrow Cl + C_2Cl_3\cdot$	[1]
Propagation (I)	$Cl + C_2Cl_4 \rightarrow C_2Cl_5\cdot$	[2]
	$C_2Cl_5\cdot + O_2 \rightarrow C_2Cl_4O_2\cdot$	[3]
	$C_2Cl_5O_2\cdot \rightarrow CCl_3COCl + ClO$	[4*a*]
	or $\rightarrow 2COCl_2 + Cl$	[4*b*]
	$ClO + C_2Cl_4 \rightarrow CCl_2COCl + Cl$	[5*a*]
	or $\rightarrow COCl_2 + CCl_3\cdot$	[5*b*]
	$CCl_3\cdot + O_2 \rightarrow CCl_3O_2\cdot$	[6]
	$CCl_3O_2\cdot \rightarrow COCl_2 + Cl$	[7]
Propagation (II)	$C_2Cl_3\cdot + O_2 \rightarrow C_2Cl_3O_2\cdot$	[8]
	$C_2Cl_3O_2\cdot \rightarrow COCl_2 + COCl\cdot$	[9*a*]
	or $\rightarrow (COCl)_2 + Cl$	[9*b*]
	$COCl\cdot + C_2Cl_4 \rightarrow COCl_2 + C_2Cl_3\cdot$	[10]

Chain termination is probably by mutual destruction of radicals. Propagation step [2] can account for increased phosgene to trichloroacetyl chloride ratio found in the radiolysis reaction.

Other equally plausible mechanisms can be advanced based on the formation of epoxides (23, 24) or of the ClOO radical (cf. (25)). Further work in the absence of oxygen and using E.P.R. techniques might help to establish the mechanism.

THE HEAT AND ENTROPY OF ASSOCIATION OF THE COMPLEX IONS FORMED BY EDTA WITH THE LANTHANIDE ELEMENTS IN AQUEOUS SOLUTION[1]

R. H. Betts and Olive F. Dahlinger

ABSTRACT

A radio tracer method has been used to measure the heat and entropy of association of all the lanthanide ions (except promethium) with the chelating agent EDTA. Entropy terms are largely responsible for the remarkable stability of these complex ions. The results suggest, but do not prove, that a change in configuration of the complex occurs after gadolinium (element 64).

INTRODUCTION

All of the trivalent lanthanide ions in aqueous solution form very robust 1:1 complexes with the chelating agent ethylenediamine tetraacetic acid (EDTA). Wheelwright *et al.* (1) found the association constant K for the complex in 0.1 M potassium chloride to increase with atomic number, rising from 5×10^{14} for lanthanum (element 57) to 1.2×10^{19} for lutetium (element 71). The *average* difference between association constants for successive members of this group is 2.4. However a "plateau" occurs in the region Eu–Gd, for which $K_{Eu} = 4.9\times10^{16}$ and $K_{Gd} = 5\times10^{16}$. Beyond gadolinium, the interval between the association constants opens out again.

These authors suggest, as an explanation for this plateau, that the progressively smaller radii of the lanthanide ions in the series from La to Lu imposes increasing steric hindrance on the interaction between EDTA and the ion; they also suggest that for the series La to Gd, EDTA exerts its maximum chelating effect, all six groups (four carboxyls and two amino nitrogens) being co-ordinated to the metal ion. After Gd, only five of the chelating groups can fit around the central ion, leaving 1 molecule of water still attached. The evidence of Moeller *et al.* (2), however, suggests that Nd^{3+} is probably penta-co-ordinated by EDTA rather than 6 co-ordinated. A change in co-ordination after Gd would then be from penta-co-ordination to tetra-co-ordination, rather than from 6- to 5- as proposed by Wheelwright.

If such changes in co-ordination occurred, then on the basis of Cobble's discussion of the entropy of complex ions (3), one might expect significant differences in the entropy of formation of the complex ions of the two groups. The only experimental information available relating to the heat and entropy changes in these systems is given in an earlier paper from this laboratory (4). It was shown there that the difference in the heats of reaction for the systems

$$La^{3+} + X^{-4} \leftrightharpoons LaX^{-} \qquad [1]$$

and

$$Nd^{3+} + X^{-4} \leftrightharpoons NdX^{-} \qquad [2]$$

was zero (X^{-4} represents the fully ionized form of EDTA). Moreover, the differences in the entropies of formation of LaX^{-} and NdX^{-} appeared to be satisfactorily related to the differences in the partial molal entropies of the hydrated cations.

[1]*Manuscript received September 18, 1958.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 720.

The present paper records the application of a radiochemical technique, described in ref. 4, to measurements of the relative stability, as a function of temperature, of the complex ions of EDTA with all the lanthanide elements except element 61. The object of the measurements was to provide further quantitative data on those factors which determine differences in stability among the members of this group of elements. In particular, heat and entropy changes which occur on formation of the complexes have been evaluated. The results also provide an independent confirmation of earlier isothermal measurements of the stability of these complex ions (1).

The method used depends on measurement of the position of equilibrium in the system:

$$R_1X^- + R_2^{3+} \leftrightharpoons R_2X^- + R_1^{3+} \qquad [3]$$

where R_1 and R_2 represent different lanthanides. The equilibrium constant $K_{1,2}$ for reaction [3] is

$$K_{1,2} = (R_2X^-)(R_1^{3+})/(R_1X^-)(R_2^{3+}).$$

The association constant K_1 for formation of the complex ion R_1X^- may be written as:

$$K_1 = (R_1X^-)/(R_1^{3+})(X^{-4})$$

corresponding to the equilibrium:

$$R_1^{3+} + X^{-4} \leftrightharpoons R_1X^-.$$

A similar relation can be written for the association constant K_2 for the formation of R_2X^-. Clearly, $K_{1,2} = K_2/K_1$; measurement of the position of equilibrium in reaction [3] gives therefore the *ratio* of the stability constants for the formation of the two complex ions concerned. Similarly, the thermodynamic quantities $\Delta F^\circ_{1,2}$, $\Delta H^\circ_{1,2}$, and $\Delta S^\circ_{1,2}$ of reaction [3] are simply related to the corresponding quantities for the formation of the complex ions. Thus, for element 1:

$$\Delta F^\circ_1 = -RT \ln K_1 = \Delta H^\circ_1 - T\Delta S^\circ_1;$$

for the element 2:

$$\Delta F^\circ_2 = -RT \ln K_2 = \Delta H^\circ_2 - T\Delta S^\circ_2,$$

$$\Delta F^\circ_{1,2} = -RT \ln K_{1,2} = -RT \ln K_2/K_1 = (\Delta H^\circ_2 - \Delta H^\circ_1) - T(\Delta S^\circ_2 - \Delta S^\circ_1),$$

whence

$$\Delta F^\circ_{1,2} = \Delta F^\circ_2 - \Delta F^\circ_1,$$
$$\Delta H^\circ_{1,2} = \Delta H^\circ_2 - \Delta H^\circ_1,$$

and

$$\Delta S^\circ_{1,2} = \Delta S^\circ_2 - \Delta S^\circ_1.$$

Evidently the enthalpy and free energy of formation for a single lanthanide–EDTA system can be calculated from the equilibria including two lanthanides, provided these quantities are available for one of them. The results in this paper have been normalized using the value of $-21{,}890$ calories, for ΔF_{Nd}, from the results of Wheelwright *et al.* (1). Their value was measured at 20° C, but has been adjusted to 25° using $\Delta H_{Nd} = -800$ cal/mole, a value obtained in this present work. For our single normalizing value of ΔH, we are indebted to Dr. R. W. Attree of these laboratories. Using a Tian–Calvet calorimeter recently described (5) reaction [1] above was found to be exothermic, $\Delta H_{La} = -800 \pm 20$ cal per mole. As will be seen below the discussion of the results depends primarily on the *differences* among the lanthanides, so that errors associated with the normalizing values ΔF_{Nd} and ΔH_{La} will have no serious consequences.

EXPERIMENTAL

Materials

The lanthanide chlorides, with the exception of cerium, were prepared by dissolving a weighed amount of oven-dried (110° C) oxide in a slight excess of hydrochloric acid. The excess acid was removed by several evaporations to near dryness, after which the material was made up to a known volume in water. The oxide formula was taken to be R_2O_3 for all of the lanthanides except for praeseodymium (Pr_6O_{11}) and terbium (Tb_4O_7). Cerium chloride was prepared by dissolving CeO_2 in a mixture of sulphuric acid and hydrogen peroxide. The trivalent hydroxide was then precipitated with ammonia, washed several times, and then redissolved in hydrochloric acid. The resulting solution was taken to near dryness several times, and finally dissolved in a known volume of water.

The oxides of La, Pr, Nd, Sm, Eu, Gd, Tb, Ho, Er, and Tm were purchased from Lindsay Chemical; the analyses supplied indicated a chemical purity of 99.8% or better. The cerium was Johnson–Matthey "spec-pure" CeO_2. Dy, Yb, and Lu were provided as 99.8% pure oxides by courtesy of the Ames Laboratory of the U.S.A.E.C.

The solutions prepared in this way were used, except for Nd, without further standardization. The Nd stock solution was standardized by titrating aliquots with versene (the disodium salt of EDTA) in the presence of calcium, using eriochrome black T as an indicator for the end point. This method, which is adopted from a procedure described by Cheng *et al.* (6), uses calcium carbonate as a primary standard.

EDTA was purified by recrystallization of the acid H_4X from a water solution of the disodium salt. The insoluble acid was washed, dried at 105° C, and samples assayed in the presence of excess calcium chloride by titration with standard sodium hydroxide. The pH was monitored with a Beckman model G glass electrode assembly. An aqueous stock solution of EDTA, fully neutralized with potassium hydroxide, was prepared from this purified and standardized material.

The radio tracers used in the analytical scheme (see below) were 11.6-day Nd^{147}, $Yb^{169,175}$ (30-day and 4.2-day), and 72-day Tb^{160}. These were prepared by neutron irradiation in the NRX reactor of the corresponding pure oxides. The steps taken to establish the radiochemical purity of the neodymium and ytterbium activities have been described previously (4, 7). The radioactive decay of Tb^{160} was followed for 7 months (three half-lives) and showed no indication of extraneous radio nuclides. A half-life of 72.8±0.1 days was observed. Values of 72.3-day (8) and 73.0-day (9) have been recorded in the literature.

Procedure

Solutions for which equilibrium measurements were made were 0.10 *M* in potassium chloride and 0.01 *M* in ammonium acetate. The KCl was added to maintain the solutions at constant ionic strength, and also to make the results directly comparable with those of Wheelwright *et al.* (1). Ammonium acetate was added to ensure that all comparable experiments were made at the same pH (5.3±0.1). Doubly distilled water was used throughout this investigation.

Solutions were prepared containing known amounts of two lanthanides, together with a known concentration of K_4X. Conditions were so chosen that the concentration of the chelating agent (2×10^{-4} *M*) was never more than 50% of the sum of the concentrations of the two lanthanides present ($4-12\times10^{-4}$ *M*). Under these conditions, all of the EDTA was present at equilibrium either as R_1X^- or R_2X^-; the concentrations of the species H_4X, H_3X^-, .../X^{-4} etc. being negligible in comparison.

TABLE I
Summary of equilibrium constants at various temperatures

Lanthanide pair	0°	25.7°	35.2°	ΔH, cal/mole	$K_{25°}$

Values of the equilibrium constants enclosed in parentheses were not used in the calculations. The probable errors in the ΔH values in column five are indicated by parentheses.
*Data for the La–Nd system from ref. 4.

The appropriate tracer was prepared as an aqueous solution of RCl_3, and added to each equilibrium solution concurrently with the other components of the systems.

Three aliquots were taken from each solution, one of which was allowed to reach equilibrium at 0° C, the second at 25.7° C, and the third at 35.2° C. After equilibrium had been reached (as judged by analysis on successive days*), three samples for each

**In some cases, particularly those involving the heavier lanthanides at 0° C, equilibrium was attained only after several weeks. This is not unexpected, since earlier work (4) has shown that the rate of dissociation of* RX^{-} *ions in aqueous solution at pH 5.3 is very slow.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

temperature were taken for determination of the position of equilibrium (see below). Each lanthanide pair was studied at three different values of the ratio R_1Cl_3/R_2Cl_3 (1:1, 2.5:1, and 5:1), so that in all nine measurements of the position of equilibrium (three sets in triplicate) were obtained at each temperature for each pair of elements examined. Altogether about 300 such measurements were made in the present study.

The pH of the equilibrium systems was measured in every case, and was found to be 5.3 ± 0.1.

The position of equilibrium in each system was calculated from the distribution of a radioactive tracer for one of the lanthanide ions between the forms R^{3+}_{aq} and RX^{-}. The cationic form is held quantitatively on a short Dowex 50 cation resin column, while the form RX^{-}, being anionic, passes through to the effluent. The relative amounts of the element R in the anionic or cationic form were calculated from the radioactivity in the effluent relative to that in the original solution. Further details of this technique, and of the methods of radioassay used are given in ref. 4.

Tb^{160} was used in the first series of experiments, in which the lanthanides Sm, Eu, Gd, Dy, Ho, and Er were compared with Tb. Nd^{147} was used in the second series, in which Nd was compared with La, Ce, Pr, and Sm. $Yb^{169,175}$ was used as the tracer in the last series, involving comparisons of Ho, Er, Tm, and Lu with Yb.

Gd	65.7	50	Lu	13800	12000

RESULTS

The experimental results are summarized in Table I. The first column in the table identifies the lanthanide pair, and defines the form of the equilibrium constant. The second, third, and fourth columns list the experimental values at 0° C, 25.7° C, and 35.2° C, respectively, of the equilibrium constant defined in column one. Three values for each temperature are recorded, and represent the results of separate experiments for different concentration ratios of the lanthanide pair. The fifth column gives the value of the enthalpy change (ΔH) for the equilibrium. These values of ΔH are calculated in each case by a least squares fit of the data to the relation:

$$\log K = -(\Delta H/2.303\,RT) + \text{constant}. \qquad [4]$$

Least squares analyses were also used to calculate the probable errors in the ΔH terms; the appropriate uncertainties are given in parentheses in column 5. The final column gives the value of K at 25.0° C, calculated from the appropriate form of equation [4] above. The probable errors indicated for K in this column were also calculated by least squares analyses.

Thermodynamic Quantities for Each Lanthanide–EDTA System

The results of Table I have been normalized to yield values for changes in the free energy ($\Delta F°$), entropy ($\Delta S°$), and enthalpy ($\Delta H°$) involved for each lanthanide–EDTA system.

(*a*) *Normalization of the $\Delta F°$ Terms*

The value of 1.12×10^{16} for the equilibrium constant for the NdX–Nd system at 25° C has been taken from the work of Wheelwright *et al.* (1). Thus the value of K_{La}, from the results in Table I, is therefore

$$1.12\times10^{16}/7.2 = 1.56\times10^{15},$$

while that for K_{Sm} is

$$1.12\times10^{16}/0.333 = 3.36\times10^{16}.$$

The result for Tb is then calculated from that for Sm, and the values for Eu, Gd, Dy, Ho, and Er are then calculated relative to Tb. The value for K_{Yb} is calculated by comparison with both K_{Ho} and K_{Er} and finally the values of K_{Tm} and K_{Lu} are calculated relative to that of K_{Yb}. The results of these comparisons are shown in Table II. Column two of Table III gives the same results expressed in calories per mole at 25.0° C. The free energy change $\Delta F°$ has been calculated from the relation $\Delta F° = -RT \ln K$.

(*b*) *Normalization of the $\Delta H°$ Terms*

The reaction: $La^{3+} + X^{-4} \leftrightharpoons LaX^{-}$ is found to be exothermic (see Introduction) and $\Delta H_{La} = -800$ cal per mole. The equilibrium constant for the La–Nd system is independent of temperature and therefore ΔH_{Nd} is also -800 cal per mole. Equilibria in the systems Nd–Pr and Nd–Sm are also temperature independent, and this implies that $\Delta H_{La} = \Delta H_{Pr} = \Delta H_{Nd} = \Delta H_{Sm} = -800$ cal per mole.

The value of ΔH for the Tb–Sm system is $+2300$ cal per mole, which leads to a value of $+1500$ cal per mole for the Tb system. (See the appropriate equations in the Introduction, where $\Delta H°_2 = -800$ cal, $\Delta H°_{1,2} = +2300$ cal, and $\Delta H°_1 = (2300-800) = +1500$ cal per mole.)

Proceeding in this way, the value of ΔH for each lanthanide–EDTA system was calculated; the results are listed in column three of Table III.

TABLE III

Thermodynamic quantities for the formation of lanthanide–EDTA complex ions at 25° C

Lanthanide	$\Delta F°$, cal/mole	$\Delta H°$, cal/mole	$\Delta S°$, cal/mole/° C
La	−20,720	− 800*	66.8
Ce	−21,070	− 470	69.1
Pr	−21,490	− 800	69.4
Nd	−21,890*	− 800	70.7
Sm	−22,540	− 800	72.9

The entropy change accompanying complex formation was calculated directly from the relation

$$\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ, \text{ for } T = 298.1^\circ \text{ K.}$$

These values are given in column four of Table III.

Precision of the Derived Results

Table I shows that the probable error in the enthalpy change for each lanthanide pair lies between 60 and 330 calories, the average uncertainty in this quantity being ±150 calories. The equilibrium constants listed in Table I appear to be precise to ±2%. However, the method of intercomparison used to deduce the thermodynamic quantities for each lanthanide–EDTA system inevitably causes a carry-over and multiplication of these errors. Assuming a coefficient of variation of ±2% in every ratio given in Table I, then (relative to K_{Nd}, for which no error need be assigned) K_{Sm} is in doubt by ±3%, as are the values for K_{La}, K_{Ce}, and K_{Pr}. The Tb value relative to K_{Sm} is precise to ±2%, but relative to K_{Nd}, it is precise to $\sqrt{(3^2+2^2)} \cong \pm 4\%$. The further stages of intercomparison give rise to a maximum uncertainty in the values of K_{Lu} and K_{Tm}, *relative to* K_{Nd}, of ±6%.

The uncertainty in ΔF°, relative to ΔF° for Nd, then varies from ±10 cal per mole for La, to ±35 cal per mole for Lu and Tm.

The uncertainty of ±150 cal per mole for each value of ΔH listed in Table I leads in a similar way to a maximum uncertainty of ±370 cal for ΔH°_{Lu}, again relative to the value of −800 cal per mole for the normalizing value of ΔH°_{La}. The relative uncertainty between ΔH values for adjacent lanthanides is about ±210 cal per mole.

These errors in both ΔF° and ΔH° are reflected in the precision of the ΔS° terms; the values for this quantity listed in the last column of Table III are thought to be precise to ±2.0 e.u.

DISCUSSION

A comparison of the present results at 25° C with those of Wheelwright *et al.* (1) is shown in Table II. The two sets of data have been normalized to give agreement at K_{Nd}. In addition, the earlier results have been adjusted to 25° C from 20° C, using the appropriate ΔH values listed in Table III. The largest adjustments required (5.7%) are in the K values for Tb to Yb, inclusive.

The errors quoted for the K values in ref. 1 vary from a minimum of ±15%, in the region from La to Sm, and gradually increase to reach ±250% at Lu. Generally speaking, with the possible exception of the values for K_{La}, the two sets of data are in reasonable agreement. However, the present results are thought to be considerably more precise than the previously published measurements.

The results in Table III show very clearly that the remarkable stability of these complex ions is due almost entirely to the large increase in the entropy of the system when the complex is formed. The differences in stability among the complex ions are also in large measure due to the entropy terms, although in some cases, both ΔH and ΔS terms contribute appreciably in this respect.

The results in Table III may be used, with reservations, to calculate the *relative* partial molal entropies of the complex ions themselves. For this purpose it is convenient to consider the relation between the observed entropy change, ΔS°, and the conventional partial molal entropies, $\bar{S}^\circ$, of the species concerned. Thus for the reaction:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$R^{3+}_{aq} + X^{-4} \rightleftharpoons RX^{-}$$

$$\Delta S^\circ = \bar{S}^\circ_{RX^-} - \bar{S}^\circ_{R^{3+}} - \bar{S}^\circ_{X^{-4}},$$

and

[5] $$(\Delta S^\circ + \bar{S}^\circ_{R^{3+}}) = \bar{S}^\circ_{RX^-} - \bar{S}^\circ_{X^{-4}}.$$

For a series of lanthanide–EDTA systems, the left hand side of equation [5] provides a *relative* measure of $\bar{S}^\circ_{RX^-}$, since the term $\bar{S}^\circ_{X^{-4}}$ is common. To make such comparisons, it is necessary to know the appropriate value of $\bar{S}^\circ_{R^{3+}}$, in addition to the experimental quantity ΔS°. Unfortunately, no experimentally based values of $\bar{S}^\circ_{R^{3+}}$ are available, and it is necessary to calculate these quantities for semiempirical formulae.

The two most generally accepted equations for calculation of $\bar{S}^\circ$ terms for aqueous ions are due to Powell and Latimer (10) and, more recently, to Laidler (11). Both equations provide a good fit to a large assembly of experimental information. In the following, both formulae are used to calculate the partial molal entropies of the lanthanide cations. The fundamental parameter required by both equations is the radius of the ion. The recent measurements of Dauben and Templeton (12) are particularly suitable in this connection, since as these authors observe, the radii have been estimated with sufficient precision to permit meaningful comparison of the properties of the lanthanides which depend on this parameter.

Table IV summarizes the results of these calculations. The data in columns 2 and 3 depend on the Powell–Latimer equation, while the last two columns are derived from the Laidler equation. The latter treatment gives results for $\bar{S}^\circ$ which are slightly more

negative than the corresponding values calculated from ref. (10). However, the results for either equation, when combined with the experimental entropy change ΔS° shown in Table III, gives results which are qualitatively compatible.

The relative entropy of the complex ion RX^- (as expressed by the quantity $(\Delta S^\circ + \bar{S}^\circ_{R^{3+}})$ in Table IV) is essentially constant for the lanthanides La to Gd; after Gd, a second group of constant values is apparent, which differ significantly from the first group. A quantitative statement of this result is shown in Table V.

TABLE V

Average values for the relative entropies of the complex ions RX^-

	$(\Delta S^\circ + \bar{S}^\circ_{R^{3+}})$ cal/mole/° C	
Elements	Ref. 10	Ref. 11
La to Gd	33.3±1.4	27.1±0.9
Tb to Lu	43.1±1.1	33.3±0.7
Difference	9.8±1.8	6.2±1.1

The difference between the entropies of the complex ions of the two groups is from 6 to 10 e.u., depending on which equation is used to evaluate the terms in $\bar{S}^\circ_{R^{3+}}$. The constancy of the values in each group is particularly striking; in only two cases (Lu and Gd) does an individual value of $(\Delta S^\circ + \bar{S}^\circ_{R^{3+}})$ differ from the average value of the subgroup by more than the estimated uncertainty attached to the quantity ΔS°.

Clearly, the results shown in Table V depend very critically on the validity of the calculations of the terms in $\bar{S}^\circ_{R^{3+}}$. In this connection, no allowance has been made for possible contributions to the entropy of the lanthanide ions arising from the term $R \ln p$, when p is the multiplicity of the ground state of the ion (10). These reservations must be borne in mind during the discussion which follows.

The entropy of a simple hydrated ion is determined primarily by its charge and radius, while the entropies of complex ions have additional contributions arising from structural factors (3). The constancy of the entropies within each of the two groups of complex ions (La to Gd, and Tb to Lu) would therefore appear to indicate the close similarity in structure and radius of the individual ions comprising each subgroup. Moreover, the trend with atomic number that is evident in the terms $\bar{S}_{R^{3+}}$ has largely disappeared when the corresponding ions RX^- are compared. This is thought to be a consequence of the reduction of charge (from +3 to −1); in addition the ionic charge is spread over a relatively large structure. The radius of the individual ions RX^- in each subgroup appears to be determined mainly by the EDTA part of the ion and the slight differences in the radii of the central ion are evidently smoothed out. As a result, the lanthanide contraction, the effect of which is evident in the entropies of the hydrated ions, is no longer reflected in the individual members of each subgroup of the complex ions.

On the other hand, the entropies of the two groups of complex ions differ by 6 to 10 e.u. An unreasonably large change in the radius would have to be postulated to account for a change of this magnitude in the entropy of a singly charged ion in solution. It appears likely therefore that a change in configuration occurs after Gd, as suggested by Wheelwright *et al.* (1). However, it is not possible from entropy considerations alone to state with precision the exact nature of the structural changes that may be involved. The following comments must therefore be considered as speculative, and are put forward to indicate that reasonable changes in structure will account for the observed entropy differences.

If the central ion is co-ordinated to five chelating groups in the EDTA molecule (2), then one of the nitrogen atoms participates in two 5-membered rings in the chelate structure. One ring involves the sequence N–C–C–N–R, and the other N–C–C–O–R. The opening of this N–R bond gives rise to a tetra-co-ordinate structure, and would lead to an entropy gain of ∽28 e.u. (14 e.u. for each ring involved (3)). The co-ordination

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

position freed on the central ion would then be occupied by a water molecule, leading to an entropy decrease of ∽17 e.u. (3). The net result is that the entropy of the less highly organized complex would be approximately $28-17=11$ e.u. more positive than that of the fully co-ordinated species, in reasonable agreement with the experimental result.

SUMMARY AND CONCLUSION

The complex ions formed by the lanthanide ions with EDTA owe their exceptional stability to the large positive increase in entropy which occurs when the complex ion is formed. Two subgroups (La to Gd, and Tb to Lu) can be distinguished on the basis of the entropy changes involved. The differences between the two subgroups can be accounted for by plausible changes in the structure of the complex ions of the two groups. Within each subgroup, the differences in the partial molal entropy of the hydrated ions account very largely for the successive gradation in the association constants. The partial molal entropies of the individual complex ions is constant within experimental error in each of the two groups.

ACKNOWLEDGMENTS

We are indebted to Dr. R. W. Attree of A.E.C.L. for calorimetric measurements of the heat of association of lanthanum ion with EDTA. Samples of pure Dy_2O_3 and Yb_2O_3 were provided by courtesy of the Ames Laboratory of the U.S.A.E.C.

ISOMERIC 5-(SUBSTITUTED)AMINOTHIATRIAZOLE AND 1-SUBSTITUTED-TETRAZOLINETHIONES[1]

EUGENE LIEBER[2] AND J. RAMACHANDRAN

ABSTRACT

The reaction of organic isothiocyanates with sodium azide in ethanol and water has been investigated. Water is shown to be the more advantageous solvent for this reaction giving higher yields and initially purer 1-substituted-tetrazoline-5-thiones. A series of these latter compounds was made by this procedure. The yield of product appears to be dependent on the electrical properties of the substituent of the isothiocyanate, the yields decreasing as the electron-donating properties increase. A series of new 4-substituted-thiosemicarbazides has been prepared and converted by diazotization to the corresponding 5-(substituted)amino-thiatriazoles. A theory to account for the differences in the mode of reaction of hydrazoic acid and azide ion is presented and discussed. The basic conversion of 5-(substituted)amino-thiatriazoles to 1-substituted-tetrazolinethiones may involve a simple dearrangement–rearrangement mechanism complicated by side reactions. A summary of known isomeric 5-(substituted)aminothiatriazoles and 1-substituted-tetrazolinethiones is presented.

INTRODUCTION

Recently, Lieber, Pillai, and Hites (1) have shown that the reaction of 4-substituted-thiosemicarbazides (I) as well as the reaction of alkyl- or aryl-isothiocyanates (II), with hydrazoic acid, leads to identical 5-(substituted)amino-1,2,3,4-thiatriazoles (III). Oliveri-Mandala (2) had previously assigned a thiocarbamyl azide structure (V) to the reaction product of compound II with hydrazoic acid. The resolution of this problem is similar to that discussed by Lieber and co-workers (3, 4) for the reaction of azide ion with carbon disulphide, which was shown to be thiatriazolinethione (VI), rather than the

acyclic azidodithiocarbonic acid (VII) (5). On the other hand, Stolle (6) had previously shown that the reaction of azide ion (sodium azide) with II leads to the formation of 1-substituted-tetrazole-5-thiols (IV, R = alkyl or aryl), the end products of the reaction (B) (isomerization of III with base for R = aryl substituents only (1)). More recently, Lieber and co-workers (7) have shown, by infrared absorption spectroscopy, that IV exists in the *thione form*, VIII, and, hence, is more properly termed 1-substituted-tetrazolinethiones. The interesting divergence in the mode of reaction of hydrazoic acid and azide ion, as illustrated by (B) and (C), prompted an investigation of the effect of solvent on the behavior of azide ion with organic isothiocyanates, since it was considered that the type of product produced, III or IV, would be dependent on the reactive intermediates involved, which in turn would be influenced by the solvent used. The influence of solvent should be particularly noted for azide ion owing to its initially charged character, in contrast to hydrazoic acid. Stolle (6) carried out the reaction with azide ion in boiling ethanol, whereas Oliveri-Mandala (2) used an ethereal solution of hydrazoic acid. Lieber and co-workers (1) showed that the reaction with hydrazoic acid can be carried out equally well in either ethanol or water, reaction (B), the 5-(substituted) amino-1,2,3,4-thiatriazole (III) being obtained in each case, and identical with the initial product of reaction (A).

The present communication relates to a study of reaction (C), particularly with the effect of solvents on the yields and purity of the reaction product,[3] IV, and extends the number of isomeric 5-(substituted)aminothiatriazoles, III, reported previously (1).

EXPERIMENTAL[4, 5]

Organic isothiocyanates, RNCS.—The organic isothiocyanates described previously (1) were used in the present study. Additional isothiocyanates prepared were R = *p*-nitrophenyl-; 2,4-dichlorophenyl-; *p*-dimethylaminophenyl-; and *p*-fluorophenyl-; by the reaction of the corresponding amine hydrochloride with thiophosgene.[6] The *p*-fluorophenylamine was made by the sequence: *p*-nitraniline; *p*-nitrophenyl diazonium fluoborate (8) (yield 90%, m.p. 156° (decomp.)); *p*-nitrofluorobenzene (8) (yield 33%, m.p. 27°); *p*-fluoroaniline (9) (yield 45%, b.p. 182–187° at 748 mm). The following data gives in sequence R, % yield, m.p. or b.p., and references: *p*-nitrophenyl, 90, m.p. 113° (10); 2,4-dichlorophenyl, 94, m.p. 39–40° (11); *p*-dimethylaminophenyl, 90, m.p. 70° (12); *p*-fluorophenyl, 63, b.p. 222–226° at 740 mm (10).

4-Substituted-thiosemicarbazides (Table I).—These were prepared as previously described (1). With the exception of the *p*-fluorophenyl-derivative, all of the 4-substituted-thiosemicarbazides described in Table I are new compounds. The melting point of the *p*-fluorophenyl-derivative obtained in this research does not agree with that previously reported. While a well-defined white crystalline product was obtained for the *p*-dimethylaminophenyl-derivative, an acceptable analysis could not be obtained, although its diazotization (see below, Table II) gave a correctly defined thiatriazole.

Syntheses of thiatriazoles (Table II).—These were prepared by suspending the 4-substituted-thiosemicarbazide in 10% hydrochloric acid and diazotizing according to the method described by Lieber and co-workers (1). The resulting precipitates were purified by recrystallization from aqueous acetone.

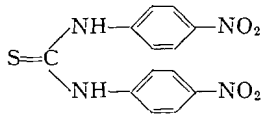
*New compound. [a]Refluxed for 6 hours. [b]Calculated for $C_7H_4Cl_2N_4S$: Cl, 28.75%. Found: Cl, 28.80%. [c]Refluxed for 8 hours. [d]Stirred at room temperature for 3 hours. [e]Worked up by alternate procedure.

1-Substituted-tetrazoline-5-thiones (*Table III*).—The following general procedure was adopted. A mixture of 0.05 mole of the isothiocyanate and 0.075 mole of sodium azide dissolved in 100 cc of water was refluxed for a period ranging from 4 to 8 hours. The mixture was then cooled and filtered from any insoluble material present. The filtrate was then extracted twice with ether to remove any unreacted isothiocyanate present. The aqueous layer was cooled and acidified with concentrated hydrochloric acid to pH 3 (Congo red paper end point). If the product precipitated out at this stage (as was usually the case), it was filtered and washed with water. An alternative procedure (designated in Table III by the superscript [e]) was employed if the product did not precipitate subsequent to acidifying to Congo red paper. The acidified solution was extracted with ether and the ether extract washed with a little ice-cold water. The ether extract was then dried, filtered from the drying agent, and the ether carefully removed on a steam bath. The product which remains as a residue was purified. The purification was effected in the case of the 1-aryl tetrazoline-5-thiones by recrystallization from ethanol and a mixture of chloroform and petroleum ether was employed in the case of the 1-alkyl derivatives.

The reaction of n-heptyl isothiocyanate and n-butyl isothiocyanate with sodium azide.—The products obtained were oils which decomposed on distillation and consequently could not be purified. In the case of the *n*-heptyl isothiocyanate, 70% of the isothiocyanate was recovered unchanged after refluxing for 10 hours. In the reaction of *n*-butyl isothiocyanate with sodium azide, 50% of the isothiocyanate was recovered after refluxing for 10 hours.

The reaction of sodium azide with p-nitrophenyl isothiocyanate.—An insoluble orange-red precipitate was obtained. This was found to melt at 172–174°. The melting point identified the substance to be 1,3-di-(*p*-nitrophenyl)-thiourea:



as the reported (15) m.p. is 175°.

The reaction of phenyl isothiocyanate with sodium azide.—This reaction was studied under different conditions. The results are summarized in Table IV, where the experimental conditions are also given.

Reaction of 5-methylamino-1,2,3,4-thiatriazole with sodium azide.—Sodium azide, 2.6 g (0.04 mole), dissolved in 100 cc of water was refluxed with 2 g (0.02 mole) of 5-methylamino-1,2,3,4-thiatriazole for 4 hours. The reaction mixture was cooled and the yellow

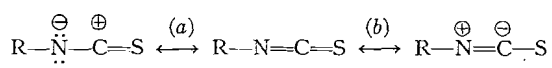
material that had precipitated was filtered. The filtrate was acidified, extracted with ether, washed, and dried. The ether was then removed by distillation and the white crystalline residue washed with petroleum ether and filtered. Yield, 0.3 g (15%), m.p. 124–126°; no depression of mixed melting point with an authentic (1) sample of 1-methyltetrazoline-5-thione.

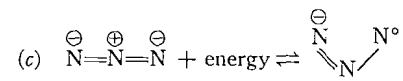
DISCUSSION

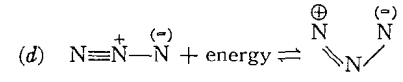
Water was used as the solvent for the synthesis of the 1-substituted-tetrazoline-5-thiones summarized in Table III. It will be noted that the yield of product is approximately doubled as one proceeds from the 1-alkyl- to the 1-aryl-derivatives. This trend in yield suggests that resonance interaction is important for the activation of the organic isothiocyanate. This is reasonable, since competitive conjugation is possible in the isothiocyanates as indicated below:



When R is an aryl group resonance interaction by process (*a*) is predominant, facilitating the creation of an electron-deficient carbon atom; whereas if R is an alkyl group resonance interaction by process (*a*) is inhibited and activation is then probably achieved by process (*b*). It is evident that this latter activation will be considerably less than in process (*a*), primarily as a result of the smaller difference in electronegativities of carbon and sulphur and, secondly, because of the electron-releasing properties of alkyl groups. The reaction may be considered as a nucleophilic attack of the azide ion on the electron-deficient carbon atom of the isothiocyano-group, followed by ring closure to the tetrazole by donating of electrons to an electron-deficient nitrogen atom of the azido-moiety. This suggests two conceivable pathways by which the reaction may proceed on this basis, the driving force being the considerable resonance stabilization of the tetrazolinethione anion, (1). While thus far only the activation of the isothiocyanate has been discussed, it must be considered that the activation of the azide ion is also an important step in the process. The observation that the yields and purity of 1-substituted-tetrazoline-5-thiones are improved considerably when the solvent is changed from alcohol to water suggests that the activation of the azide ion is of importance. While the solvent thus appears to be of considerable importance, the interpretation of the data is made difficult by the occurrence of side reactions.

The propensity of hydrazoic acid or azide ion to react with reagents leading to the formation of tetrazoles or 1,2,3-triazoles (16) necessitates the concept of a reactive intermediate for the azido-moiety which departs from the rigid linearity of this group in order that ring closure be effected. This concept suggests the necessity for the activation of the azide ion by the following processes:





Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The advantage of this theory is that the activated structures produced by either (*c*) or (*d*) (or both) is not restricted by any criterion of linearity. The departure from linearity can be assumed to take place after the initial attack of the azide ion. On the other hand there is a great deal of attraction to the alternative assumption that *both the isothiocyano- and azido-moieties are activated prior to condensation.* This latter assumption then leads to the process in which the tetrazole ring is the result of a simple neutralization of charges, illustrated for one case as follows:

X

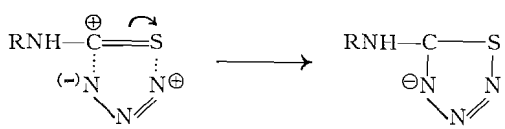
Similar reactive intermediates to that of X can be considered for the other resonance forms of the isothiocyano- and azido-groups.

The trend in the yields of the 1-aryl tetrazoline-5-thiones also lends support to the idea that resonance interaction of the isothiocyano group with the aromatic ring influences the activation of the isothiocyanate. Thus, the dimethylamino-, fluoro-, and methyl-groups in the para position of the aryl ring lower the yields (Table III) to a small extent, since the resonance interaction, in these cases, tends to suppress activation of the isothiocyano group by process (*a*), with probably increase of process (*b*). On the other hand, ortho substituents in the aromatic ring of the isothiocyanate increases the yields to a small extent probably because of steric inhibition of resonance. The above considerations lead to the expectation that the maximum yield of 1-substituted-tetrazoline-5-thione would be obtained by reaction of *p*-nitrophenyl isothiocyanate owing to the relatively greater electron-withdrawing ability of the nitro group. The apparent fall in yield is due to a side reaction involving the hydrolysis of the isothiocyanate to *p*-nitraniline, which is subsequently converted to 1,3-di(*p*-nitrophenyl)-thiourea. Dyson and Browne (10) have demonstrated that the solvolytic (in ethanol) attack on substituted-aryl-isothiocyanates increases as the electron-withdrawing ability of the substituent increases. This factor readily explains the lower yields of 1-substituted-tetrazoline-5-thiones when ethanol is used as solvent (Table IV), where as in water the solvolytic attack is reduced *owing to a higher degree of activation of the azide ion in water as contrasted with ethanol.*

The difference in the types of products formed when hydrazoic acid is used remains to be explained. It is suggested that the tetrazole ring closure is blocked as a result of the protonation of the organic isothiocyanate due to an initial acid–base reaction:

$$RNCS + HN_3 \rightarrow (R{-}NH{-}\overset{+}{C}{=}S)N_3^-.$$

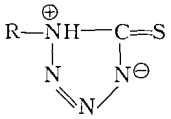
The subsequent step involving a neutralization of charges which may be indicated as follows:



XI

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

the protonation of the nitrogen preventing ring closure at that point, since such a ring closure would produce a *high energy* form of the isomeric structure:



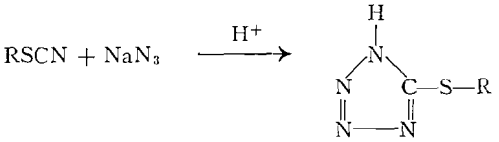
The process thus proceeds by a path producing the product of minimum energy, the anion XI.

In the previous investigation (1) on the chemistry of 5-(substituted)amino-1,2,3,4-thiatriazoles, it was noted that their isomerization with base to give the 1-substituted-tetrazoline-5-thione could be effected only with the 5-arylaminothiatriazoles (III, R = aryl). The yields in this reaction ranged from 22 to 37% and 1,3-diaryl thioureas were formed as by-products. Azide ion was identified among the degradation products. Organic isothiocyanates were also identified (either *per se* or as the 1,3-diaryl thiourea). The present investigation accordingly suggests that the mechanism of the base isomerization of III to IV may simply involve a dearrangement–rearrangement:

$$\text{III} \rightarrow \text{RNCS} + N_3^- \rightarrow \text{IV}.$$

However, the speculations are complicated by the observations (1) that III simultaneously undergoes an internal oxidation–reduction to form elemental sulphur, nitrogen, and cyanamid derivatives. The observation that a 15% yield of 1-methyltetrazoline-5-thione (IV, R = CH_3) was obtained by refluxing 5-methylamino-1,2,3,4-thiatriazole with sodium azide is of considerable interest in that it suggests that the yields obtained in the base isomerization of III to IV is dependent upon the base strength. The latter factor will determine the rate at which the isothiocyanate *undergoes hydrolysis rather than recombination* to IV.[7] It is also interesting to note that when *n*-heptyl isothiocyanate was refluxed with sodium azide in water, 75% of the isothiocyanate was recovered unchanged after 10 hours. The apparent inertness of *n*-heptyl isothiocyanate to react with azide ion[8] may be accounted for by a too high electron density on the carbon of the isothiocyano group due to the electron-donating character of the heptyl radical. Under the same conditions, 50% of *n*-butyl isothiocyanate was recovered unchanged.

A summary of the known isomeric 5-(substituted)amino-1,2,3,4-thiatriazoles and 1-substituted-tetrazoline-5-thiones are presented in Table V together with their uncorrected melting points. It is unlikely that a correlation can be found, since both types of structures are thermally unstable. It is interesting to note that a third structural isomer can be readily made by the reaction of organic thiocyanates with azide ion, in which 5-mercaptotetrazoles are formed (17):



[7]*In unpublished data from the authors' laboratory, III (R = C_6H_5) (1 mole) was refluxed for 30 minutes in aqueous media with 2 mole proportion of the respective bases: (a) sodium carbonate; (b) sodium bicarbonate; (c) ammonium hydroxide; and (d) sodium acetate. The data following represents the percentage yields of IV (R = C_6H_5) and 1,3-diphenyl thiourea isolated: (a) (44) (20); (b) (58) (4); (c) (25) (62); (d) (7) (none). In only the latter case, 80% of unchanged III (R = C_6H_5) was recovered. This phase of the investigation is being continued.*

[8]*Further unpublished work from the authors' laboratory has found that attempts to base isomerize III (R = n-(C_7H_{15}) yields only n-heptyl isothiocyanate, azide ion, and n-heptyl urea; the latter product offering evidence for the internal oxidation–reduction disruption of the molecule.*

THE CONDENSATION OF 3-AMINO-5-PYRAZOLONES WITH ALDEHYDES SYNTHESES OF 5-PYRAZOLONOGUANIDINES[1]

PAUL E. GAGNON, JEAN L. BOIVIN,[2] AND JOSEPH ZAUHAR[3]

ABSTRACT

3-Amino-5-pyrazolones did not react with guanidine in aqueous solution, but with aldehydes in the presence of piperidine, the amino group was removed in some cases. 5-Pyrazolonoguanidines were synthesized by the direct fusion of 3-amino-5-pyrazolones and dicyandiamide. The infrared spectra of the pyrazolone derivatives prepared are briefly discussed.

INTRODUCTION

Previous investigations by Nencki and Sieber (1) have shown that the amino function of α-amino acids could interreact with guanidine carbonate to yield guanidoaliphatic acids. It was expected that 3-amino-5-pyrazolones (2, 3, 4, 5, 6, 7) and 3-amino-1-phenyl-5-pyrazolone (8) would behave similarly towards guanidine or guanidine carbonate when heated in aqueous solution. However, in all the experiments made, the starting materials were recovered, no evidence of condensation being detected. This was attributed to the prototropic shift occurring in 3-amino-5-pyrazolones and its 4-substituted derivatives which can exhibit 10 possible tautomeric structures (5) of which configurations I, II, and III contribute to their stability towards guanidine.

Since the amino group of 3-amino-5-pyrazolones did not react with guanidine, the behavior of pyrazolones towards aldehydes was studied in order to determine the stability of the amino groups.

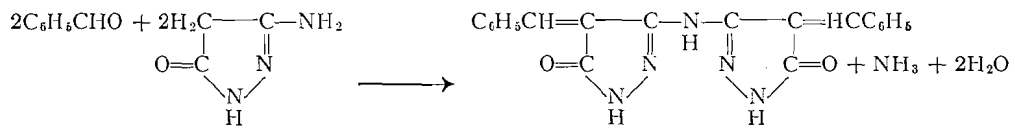
Theoretically, condensation between 3-amino-5-pyrazolones and aldehydes in a basic medium would be expected to yield pyrazolones IV, IV*a*, V, VI, VII, and VII*a*.

In formula IV the amino group is stabilized by the tautomeric form IV*a* and consequently, no reaction would be expected. Configuration V would result from the condensation of 1 mole of pyrazolone and 2 moles of aldehydes. The formation of a Schiff base in position 3 would give evidence of the existence of a free amino group. If 3-amino-5-pyrazolones reacted with 1 mole of aldehyde, 1 mole of ammonia being liberated in the process, pyrazolone VI would be formed. This type of condensation would justify the existence of a free amino group in position 3, the condensation occurring in a similar manner with α-amino acids and guanidine. Graham, Reckhow, and Weissberger (9) have shown that such a condensation was possible between 3-amino-1-phenyl-5-pyrazolone and ethylamine. A mixture of 3-ethylamino-1-phenyl-5-pyrazolone and 3,3-imino-bis(1-phenyl-5-pyrazolone) was obtained, the latter being the principal product of the reaction. Condensation of type VII would indicate that the stability of the amino group is probably due to the prototropic shift giving the tautomeric form VII*a*.

RESULTS AND DISCUSSION

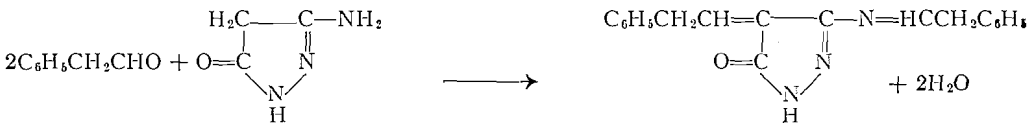
3-Amino-5-pyrazolone, Benzaldehyde, and Phenylacetaldehyde

When a mixture of benzaldehyde and 3-amino-5-pyrazolone, in a molar ratio of 3 : 1 respectively, was refluxed in the presence of piperidine, the reaction proceeded according to the following equation:



The compound isolated was slightly soluble in bases, insoluble in acids, and gave a negative test with ferric chloride, indicating no actual or potential enolic group.

With phenylacetaldehyde under similar conditions, the reaction was quite different. The amino group was not eliminated but reacted with the aldehyde.



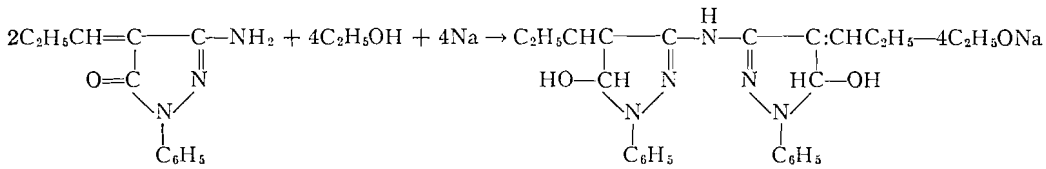
The compound which was isolated indicated that an active amino group, similar to those of primary amines, was present in position 3.

3-Amino-1-phenyl-5-pyrazolone and Aldehydes

3-Amino-1-phenyl-5-pyrazolone was also condensed with five aldehydes under similar conditions as in the foregoing experiments. The results obtained are recorded in Table I. Acetaldehyde condensed with only the methylene group of the pyrazolone and similar results were obtained with propionaldehyde indicating that under the above conditions,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

the amino group was not reactive. Previous investigations by Knorr (10) have shown that 3-methyl-1-phenyl-5-pyrazolone, when treated with sodium ethylate, was not transformed into the corresponding hydroxy compound. However, in the present work, when the propylidene derivative was treated with sodium and ethyl alcohol, not only the corresponding hydroxy compound was formed but also ammonia was evolved to yield 3,3′-imino-bis(4-propylidene-1-phenyl-5-pyrazalin-5-ol).



The equation indicates that the amino and not the imino structure of the pyrazolone was the predominant tautomeric form, the amino group being susceptible to elimination, *n*-valeraldehyde, on the other hand, condensed with both the methylene and the amino group. According to the elemental analyses and molecular weight determinations, both a monomer and a dimer having the same empirical formula $C_{19}H_{25}ON_3$ were isolated.

When benzaldehyde and the pyrazolone were condensed in a solution of benzene without piperidine, reaction occurred only with the methylene group. No ammonia was eliminated and the compound formed could be reduced to the corresponding pyrazalin-5-ol. On the other hand, in the presence of piperidine, benzaldehyde condensed with the methylene group and 1 mole of ammonia was eliminated from 2 moles of the intermediate product to yield 3,3′-imino-bis(4-benzylidene-1-phenyl-5-pyrazolone). A dimer with the same empirical formula, $C_{32}H_{23}O_2N_5$, was also isolated. With *p*-methoxybenzaldehyde in the presence of piperidine, condensation occurred with the methylene group, and 1 mole of ammonia was eliminated from 2 moles of the intermediate to give 3,3′-imino-bis(4-*p*-methoxybenzylidene-1-phenyl-5-pyrazolone). The corresponding pyrazalin-5-ol was easily obtained by reduction with sodium and ethyl alcohol. All the above compounds gave negative tests with ferric chloride, indicating the absence of an enolic group. No evidence for compounds having the structure VII could be found in the present work.

The condensation products of 3-amino-5-pyrazolones with aldehydes clearly indicate that the amino group in position 3 does not always exhibit the same stability and can be removed in some cases under appropriate conditions.

5-Pyrazolonoguanidines

4-Butyl-, 4-amyl-, and 4-benzyl-3-amino-5-pyrazolones, when heated with dicyandiamide, yielded the corresponding 5-pyrazolonoguanidines. For instance, 4-butyl-3-amino-5-pyrazolone and dicyandiamide heated at 150° C yielded 4-butyl-5-pyrazolonoguanidine. The biguanide intermediate probably formed at 150° C decomposed to the 5-pyrazolonoguanidine.

The guanidine derivative isolated was soluble in acids and bases and gave a positive test with ferric chloride for an enolic structure.

With 4-amyl-3-amino-5-pyrazolone, the reaction was carried at 180° C, since fusion was complete at a much higher temperature than in the case of 4-butyl-3-amino-5-pyrazolone. The reaction took place through the formation of a biguanide intermediate which decomposed at 180° C to give N,N′-bis(4-amyl-5-pyrazolono)-guanidine and ammonia. With 4-benzyl-3-amino-5-pyrazolone, the result was similar to that obtained with 4-amyl-3-amino-5-pyrazolone. The above compounds were soluble in bases and insoluble in acids and gave a positive test with ferric chloride.

Infrared Absorption Spectra

The infrared absorption spectra were obtained with a Perkin–Elmer Model 21, double beam self-recording spectrophotometer and the bands corresponding to the 16 compounds studied are recorded in Table II. With most of the pyrazolones investigated, three absorption bands at 3400, 3300, and 3100 wave numbers were obtained and are attributed to the NH stretching vibrations of these compounds. However, these absorption bands are absent in the spectra of 4-phenylethylidene-3-iminophenyl-ethylidene-5-pyrazolone and 4-pentylidene-3-iminopentylidene-1-phenyl-5-pyrazolone where the

hydrogen has been substituted by a benzyl and butyl group respectively. The ketonic function was exhibited in the range of 1620 to 1690 wave numbers by all the compounds but the spectra of 3,3′-imino-bis(4-propylidene-1-phenyl-5-pyrazalin-5-ol) and 3,3′-imino-bis(4-*p*-methoxybenzylidene-1-phenyl-5-pyrazalin-5-ol) failed to show their hydroxyl function.

An analogy found in these spectra and attributed to the over-all molecule is the three absorption bands in the range of 750 to 720 and 690 wave numbers.

EXPERIMENTAL*

3-Amino-5-pyrazolone and Benzaldehyde

3,3′-Imino-bis(4-benzylidene-5-pyrazolone).—Benzaldehyde (0.56 mole) was introduced into a flask containing cooled ethanol (200 ml), piperidine (4 ml), and 3-amino-5-pyrazolone (0.20 mole) and the resulting mixture refluxed. 3-Amino-5-pyrazolone slowly passed into solution, during which time ammonia was liberated, and after refluxing for 24 hours, the reaction was complete. The resulting reddish-brown solution was then filtered, the filtrate was evaporated to one-half of its original volume, and left to stand in a cool place. The white product which separated from the solution after it had been left standing for 24 hours was filtered, washed with ethanol, and dried. The compound 3,3′-imino-bis(4-benzylidene-5-pyrazolone) was recrystallized from ethanol. It was insoluble in acids and slightly soluble in bases and gave a negative test with ferric chloride, m.p. 252–253° C. Yield, 17%. Calc. for $C_{20}H_{15}O_2N_5$: C, 67.20; H, 4.23; N, 19.60%. Found: C, 67.6; H, 4.1; N, 19.3%.

3-Amino-5-pyrazolone and Phenylacetaldehyde

4-Phenylethylidene-3-iminophenylethylidene-5-pyrazolone.—To a cooled mixture of 3-amino-5-pyrazolone (0.20 mole) in ethanol (715 ml) and piperidine (4 ml), phenylacetaldehyde (50%, 134.4 g, 0.56 mole) was slowly added, and the mixture refluxed for 24 hours and treated as in the preceding experiment. A white solid separated from the concentrated solution when it was left standing. The crude product was filtered, washed with ethanol, and dried. 4-Phenylethylidene-3-iminophenylethylidene-5-pyrazolone, which crystallized from methanol in plate-like crystals, was insoluble in acids and slightly soluble in bases. It gave a negative test with ferric chloride and could not be reduced with sodium in ethanol, m.p. 264–266° C. Yield, 30%. Calc. for $C_{19}H_{17}ON_3$: C, 75.21; H, 5.65; N, 13.85%. Found: C, 75.7; H, 5.4; N, 13.9%.

3-Amino-1-phenyl-5-pyrazolone and Aldehydes

3-Amino-1-phenyl-5-pyrazolone.—To a cooled mixture of aldehyde (0.14 mole), ethanol (50 ml), and piperidine (2 ml) was added 3-amino-1-phenyl-5-pyrazolone (0.06 mole). The mixture was refluxed for 24 hours and the alcoholic solution was then evaporated under reduced pressure to one-half of its original volume, and upon cooling, the crude material separated from the solution. The products isolated together with their recrystallizing solvents, melting points, yields, molecular weights, analyses, and solubility tests are given in Table I. All the compounds isolated gave negative tests with ferric chloride.

Benzaldehyde

4-Benzylidene-3-amino-1-phenyl-5-pyrazolone. To a cooled solution of benzaldehyde (0.34 mole) in benzene (800 ml) was added 3-amino-1-phenyl-5-pyrazolone (0.11 mole).

**All melting points are uncorrected.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The reaction mixture was refluxed for 24 hours, after which time a white solid precipitated from the solution. The product was cooled, filtered, and washed with ethanol. The crude product was extracted with methanol (375 ml), the extract was filtered and evaporated to one-half of its original volume, and then left to crystallize overnight in the refrigerator. 4-Benzylidene-3-amino-1-phenyl-5-pyrazolone crystallized out in clustered colorless needles. The compound was soluble in hot ethanol, soluble in acids, and insoluble in bases. No coloration was obtained with ferric chloride, m.p. 231–233° C. Yield, 85%. Calc. for $C_{16}H_{13}ON_3$: C, 72.98; H, 4.98%. Found: C, 72.8; H, 5.1; N, 16.0%.

Reduction of 5-Pyrazolones with Sodium and Absolute Ethanol

3,3′-Imino-bis(4-propylidene-1-phenyl-5-hydroxypyrazolone).—A suspension of 4-propylidene-3-amino-1-phenyl-5-pyrazolone (0.01 mole) in absolute ethanol was prepared in a 3-necked flask fitted with a condenser. To the mixture were added clean pieces of sodium (0.07 mole) at such a rate that vigorous refluxing was continuous. The mixture was then refluxed for 1½ hours to assure that all the sodium had reacted, and during this time, ammonia was evolved. The ethanol was then removed by evaporation under reduced pressure. The resulting yellow sludge was dissolved in water (40 ml) and the solution filtered. The filtrate was neutralized with acetic acid (50%), whereupon a red amorphous product precipitated immediately. The reduced compound, 3,3′-imino-bis(4-propylidene-1-phenyl-5-pyrazalin-5-ol), was separated by filtration, washed with water, and dried. The crude product crystallized from methanol in red cubical crystals. 3,3′-Imino-bis(4-propylidene-1-phenyl-5-pyrazolone) was found insoluble in water, acids, and ether, and slightly soluble in bases. A negative test was obtained with ferric chloride, m.p. 215–217° C. Yield, 82%. Calc. for $C_{24}H_{27}O_2N_5$: C, 69.0; H, 6.52; N, 16.78%. Found: C, 70.0; H, 6.4; N, 16.6%.

4-Benzylidene-3-amino-1-phenyl-5-pyrazalin-5-ol. — 4-Benzylidene-3-amino-1-phenyl-5-pyrazolone (0.01 mole) in absolute ethanol (125 ml) was reduced with sodium (0.17 mole) as in the foregoing experiment. The reduced compound, 4-benzylidene-3-amino-1-phenyl-5-pyrazalin-5-ol, was recrystallized from methanol and isolated as colorless needles; it was soluble in acids and bases and insoluble in ether. A negative test was obtained with ferric chloride; the compound had a tendency to decompose in air, m.p. 197–199° C. Yield, 58%. Calc. for $C_{16}H_{15}ON_3$: C, 72.43; H, 5.70; N, 15.84%. Found: C, 72.0; H, 5.2; N, 15.2%.

3,3′-Imino-bis(4-p-methoxybenzylidene-1-phenyl-5-pyrazalin-5-ol.—A suspension of 3,3′-imino-bis(4-*p*-methoxybenzylidene-1-phenyl-5-pyrazolone (0.02 mole) and ethanol (300 ml) was treated with sodium (0.38 mole) so that refluxing was continuous and the reaction mixture was then treated as in the preceding experiments. The crude product obtained recrystallized from benzene gave a colorless compound, m.p. 170–172° C. Yield, 38%. Calc. for $C_{34}H_{31}O_4N_5$: C, 71.19; H, 5.45; N, 12.21%. Found: C, 70.5; H, 5.6; N, 11.8%.

5-Pyrazolonoguanidines

N,N′-bis(4-substituted-5-pyrazolono)-guanidines. — 4-Substituted-3-amino-5-pyrazolone (0.03 mole) was fused with dicyandiamide (0.02 mole), with stirring. The mixture began to melt at 90° C, during which time a slight exothermic reaction occurred and ammonia was liberated. The temperature of the melt was then raised to 180° C and kept there for 3 hours. The molten mass was then cooled, extracted with ethanol, and precipitated with a large quantity of water. The guanidine derivative was then recrystallized several times from an ethanol–water mixture. The compound was soluble in acetone and bases,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

and insoluble in acids. A positive test for an enolic group was obtained with ferric chloride. The guanidine derivatives isolated were: N,N′-bis(4-amyl-5-pyrazolono)-guanidine, m.p. 197–199° C. Yield, 86%. Calc. for $C_{17}H_{29}O_2N_7$: C, 56.20; H, 7.99; N, 27.0%. Found: C, 55.9; H, 7.8; N, 27.4%. Molecular weight: Calc. 363. Found (Rast method): 382 and 395. N,N′-bis(4-benzyl-5-pyrazolono)-guanidine, m.p. 258–261° C. Yield, 75%. Calc. for $C_{21}H_{21}O_2N_7$: C, 62.53; H, 5.21; N, 24.30%. Found: C, 62.3; H, 5.0; N, 23.6%. Molecular weight: Calc. 403. Found (Rast method): 419 and 427.

4-Butyl-5-pyrazolonoguanidine.—4-Butyl-3-amino-5-pyrazolone (0.03 mole) was fused with dicyandiamide (0.02 mole), with stirring. The mixture began to melt at 85° C, and the temperature was slowly raised to 150° C and held at that temperature for 3 hours. The melt was then treated as in the preceding experiments. The crude 4-butyl-5-pyrazolonoguanidine was then recrystallized from an ethanol–water mixture. The compound was soluble in acetone, acids, and bases and gave a positive test with ferric chloride, m.p. 239–241° C. Yield, 57%. Calc. for $C_8H_{15}ON_5$: C, 48.73; H, 7.61; N, 35.53%. Found: C, 48.4; H, 7.6; N, 35.5%. Molecular weight: Calc. 197. Found (Rast method): 210 and 221.

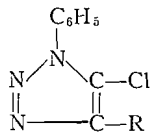
NOTES

SYNTHESIS OF ALKYL 1-PHENYL-5-CHLORO-1,2,3-TRIAZOLE-4-CARBOXYLATE

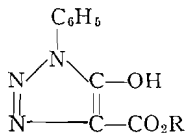
EUGENE LIEBER,* T. S. CHAO, AND C. N. R. RAO

INTRODUCTION

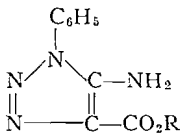
The ability to exchange the chlorine in position 5 of the *vic*-triazoles by nucleophilic substitution makes it a desirable intermediate in synthetic work in this field. Dimroth (1), and later Dutt (2), reported on the preparation of I and II by the reaction of the esters of 1-phenyl-5-hydroxy-1,2,3-triazole-4-carboxylate (3), III, with phosphorus pentachloride and by the diazotization of the hydrochloride of the ester of 1-phenyl-5-amino-1,2,3-triazole-4-carboxylate (1), IV; in the latter synthesis Dimroth (1) gave no details of procedure nor yield of product. The phosphorus method is also sketchily described, the literature (1, 2) implying that it



I (R = $CO_2C_2H_5$)
II (R = CO_2CH_3)



III (R = CH_3; or, C_2H_5)



IV (R = CH_3; or, C_2H_5)

merely involves heating IV and phosphorus pentachloride together. In our hands the yields obtained with the phosphorus pentachloride method were found to be dependent on the care taken to maintain anhydrous conditions and the rates of phosphorus pentachloride addition. As triazoles of the general structure I and II were required for previous studies (4, 5, 6), detailed experimental procedures were worked out starting from the intermediates III and IV and are reported upon in the present communication. The diazotization procedure offers an advantage in that the required intermediate IV can be made more easily and in higher yields than III (4) and in turn gives comparable conversions to the required 5-chloro-compounds (I, II). The experimental section presents typical preparations involving both the phosphorus pentachloride and diazotization methods, respectively.

EXPERIMENTAL†,‡

Methyl 1-Phenyl-5-chloro-1,2,3-triazole-4-carboxylate (II)

Phosphorus pentachloride procedure.—A 500-ml, 3-necked flask was equipped with a stirrer and a reflux condenser. To the third neck was connected a 125-ml Erlenmeyer flask connected by a short piece of $\frac{1}{2}$-in.-diameter Tygon tubing through 16 mm glass tubing from the necks of the Erlenmeyer flask and reaction flask respectively. The Tygon connector was of sufficient length to permit the Erlenmeyer flask to rest on its bottom when not in use as described below. The complete setup was flame-dried and cooled to room temperature under a nitrogen atmosphere. The reaction flask was then charged with 65.7 g (0.3 mole) of *methyl 1-phenyl-5-hydroxy-1,2,3-triazole-4-carboxylate* (II, R = CH_3) (3), which had been dried in a vacuum desiccator over Drierite for 2 days.

*To whom all inquiries for additional information should be addressed.
†Melting points were taken on a Fisher–Johns heating block and are corrected.
‡Microanalyses by Dr. C. Weiler and Dr. F. B. Strauss, Oxford, England.

Seventy-four grams (0.33 mole) of PCl_5 was placed in the Erlenmeyer flask. The reaction flask was heated in a water bath to 70° and kept at 65–70° during the reaction. By raising the Erlenmeyer flask containing the PCl_5 to a slightly inverted position and gently tapping its wall, PCl_5 was caused to flow slowly and intermittently into the reaction flask. The progress of the reaction was indicated by the HCl evolution and was controlled accordingly, completing the addition of PCl_5 in about 90 minutes, after which time the reaction mixture was heated in a gently boiling water bath for 4 hours in order to complete the reaction. After being cooled to room temperature the system was connected to a water pump through a $CaCl_2$ tower and a dry-ice trap. The dissolved HCl was first removed, after which the $POCl_3$ was distilled off at 31–32° at 47 mm. The last traces of $POCl_3$ were removed by distilling at 1–2 mm, using a well-protected oil pump. The residue solidified into a brown mass while being stirred with a glass rod. The suspension was poured into 500 ml of water and filtered. The solid was suction dried and weighed 44 g, m.p. 80–82°. The filtrate was separated into two layers. The ether layer was washed with water, dried, and evaporated under vacuum recovering 4 g additional product. Purification was effected by recrystallization from methanol; yield, 41 g (57.4%), white needles, m.p. 87° (1). Anal. Calc. for $C_{10}H_8ClN_3O_2$: C, 50.52; H, 3.40; N, 17.70; Cl, 14.92. Found: C, 50.57; H, 3.48; N, 17.60; Cl, 14.82. The mother liquor was in the form of a dark red thick oil which failed to crystallize.

Ethyl 1-Phenyl-5-chloro-1,2,3-triazole-4-carboxylate (I)

Diazotization procedure.—A mixture of 250 ml of absolute ethanol and 23.2 g (0.1 mole) of *ethyl 1-phenyl-5-amino-1,2,3-triazole-4-carboxylate* (1, 4) was placed in a 1-l. 3-necked flask equipped with a stirrer, dropping funnel, and a gas inlet tube, all exits were protected with drying tubes. The mixture was cooled to 0–5° with stirring, whereupon a slow stream of *dry* HCl gas was slowly bubbled through the mixture until the suspended solid went into solution. Seventeen grams (0.1 mole) of freshly prepared isoamyl nitrite (7) was then added rapidly and the reactants stirred at 0–5° for 48 hours. It was then poured into 500 ml of ice water with vigorous stirring. A fine orange-colored precipitate was obtained. It was filtered, suction dried, and dissolved in 50 ml of boiling methanol. After evaporation *in vacuo*, 12 g (47%) of deeply yellow-colored needle-like crystals was obtained. Recrystallization from methanol containing a small amount of water gave pale yellow needles, m.p. 79°. Dutt (2) reported a m.p. 80–81°. Anal. Calc. for $C_{11}H_{10}ClN_3O_2$: C, 52.50; H, 4.01; Cl, 14.09; N, 16.70. Found: C, 52.24; H, 4.10; Cl, 13.90; N, 17.00. The mother liquor, after evaporation of all of the solvent, gave about five grams of a red viscous oil which could not be crystallized.

Symposium on Charge Transfer Processes

A REPORT ON A SYMPOSIUM HELD BY THE PHYSICAL CHEMISTRY DIVISION OF THE CHEMICAL INSTITUTE OF CANADA[1]

B. E. Conway

INTRODUCTION

A symposium on Charge Transfer Processes both in the homogeneous solution phase and at electrode interfaces was held at the Chemistry Department of the University of Toronto on 4th and 5th September, 1958. The meeting was sponsored by the Chemical Institute of Canada, supported by the National Research Council, and organized under the chairmanship of B. E. Conway (University of Ottawa). Twenty-seven invited papers were presented, the majority of which had been preprinted and circulated to participants prior to the meeting. The sessions were devoted to ten-minute presentations of these papers together with periods of discussion on related groups of papers. A number of the invited papers are being published in the present issue of the Canadian Journal of Chemistry. In this paper a general account of the meeting is given together with reports on the main matters which arose in discussion and the conclusions arising therefrom.

Although individual papers on some aspects of Charge Transfer Processes have been presented at various meetings in North America and Europe, it is some time since a meeting specifically on this topic has been held. The last general meetings held specifically on electrochemical charge transfer processes were the Faraday Society Discussion in 1947 and the Bunsengesellschaft meeting at Goslar in 1951. Since these meetings, there have been considerable advances made in the field both in homogeneous and heterogeneous processes. In the present symposium an attempt was made to bring together contributions from those interested in homogeneous and also heterogeneous processes, since similar problems are encountered in both of these types of charge transfer processes; thus, the degree of solvent reorganization which occurs in the charge transfer step, the nature of the electron transfer process, specific effects of aquo- and non-aquo-ligand interaction with the ions involved are problems common to both the fields of homogeneous and heterogeneous processes. For the latter type of reactions, adsorption of reactants and solvent, the effect of electrode field on the reaction kinetics and adsorption of reactants and the electronic character of the metal (e.g. *s*, *p*, or *d*-band character) must also be considered. Papers were therefore also invited on adsorption at electrodes and the nature of the double layer at electrode interfaces. The somewhat specialized fields of so-called "charge-transfer spectra" and "charge-transfer complexes" were considered to be outside the scope of the present meeting.

HOMOGENEOUS PROCESSES

Despite their familiarity in classical inorganic solution chemistry, the detailed mechanism of a number of apparently simple redox reactions involving simple and complex inorganic ions has not until relatively recently been examined or understood. The first four papers of the symposium dealt with theoretical and experimental results obtained with such systems.

Electron Transfer Reactions between Ions in Solution

H. Taube (University of Chicago), in giving the opening paper on "Bridging and Simple Ligand Effects in Electron Transfer Reactions", stressed the role of changes which must occur in the co-ordination sphere of the ions when the transfer of the electron(s) occurs. Two types of transition states are to be distinguished: (i) the outer sphere activated complex in which both of the ions concerned in the redox reaction are relatively inert to ligand substitution (e.g. as determined by isotopic exchange experiments) and in which the inner co-ordination spheres hence cannot suffer appreciable interpenetration; (ii) the bridged activated complex in which a ligand, often anionic, is shared between the metal ions, so that a change in the first co-ordination sphere of at least one of the partners of the redox pair must occur. Examples of redox pairs involved in the first type of reaction are $Fe(CN)_6^{-3,-4}$, $IrCl_6^{-2,-3}$, $Mo(CN)_8^{-3,-4}$, $Fe(dipy)_3^{+3,+2}$, $Os(o\text{-phen})_3^{+3,+2}$, $MnO_4^{-1,-2}$; in the second type of case the redox reaction between $(NH_3)_5CoCl^{++}$ with Cr^{++} was discussed. $CrCl^{++}$ is formed as a product and not $Cr(H_2O)_6^{+++}$ in this reaction, thus suggesting that a Cr—Cl bond is involved in the activated state. A variety of other anions which may take part in the formation of bridged transition states were listed, and kinetic data were presented in cases involving reactions between Cr^{++} and Cr(III) complexes. The role of conjugation when organic ligands are involved in the reaction between Cr^{++} and Co(III) complexes was examined. It was pointed out that, although the reaction mechanisms are known in a number of selected cases, the subject of inorganic redox reactions must be regarded as still being in an unsatisfactory state of development so long as relatively common reactions such as those between Fe^{++}–Fe^{+++} and Fe^{++} and Ce(IV) are not understood with regard to their detailed mechanism.

In regard to the Fe^{++}–Fe^{+++} case, K. J. Laidler (University of Ottawa) presented some interesting theoretical considerations concerning the mechanism and free energy of activation of this reaction. The reaction between Fe^{++} and Fe^{+++} was considered to be diffusion controlled, the approach of the ions being hindered by their electrostatic repulsion, which was estimated taking into account the dielectric saturation in the solvent near to the ions. As the ions are brought together the electrostatic repulsion rapidly increases but the probability of electron tunneling between the ions increases at the same time. An optimum separation of the ions exists for which the redox reaction has a maximum rate or minimum free energy of activation $\Delta G^{\ddagger}$. The value of $\Delta G^{\ddagger}$ calculated is in good agreement with that derived from experimental data.

The applicability of the Franck–Condon principle to the electron transfer and solvent redistribution which occurs in electron transfer reactions such as that between Fe^{++}–Fe^{+++} ions, was vigorously discussed by R. A. Marcus (Brooklyn Polytechnic Institute) and K. J. Laidler. It was felt that since the electron transfer must occur by a relatively rapid tunneling step, the solvent distribution about the ions could be regarded as essentially remaining static during the electron transfer. This is what had been assumed in the calculations.

The principle of equivalence change in redox systems was dealt with in a paper by J. Halpern (University of British Columbia). A number of oxidizing and reducing reagents are known where stable oxidation states differ by two electron equivalents, e.g. Tl(I)–Tl(III); Sn(II)–Sn(IV). The mechanism of the reactions in which such redox pairs react with 1-equivalent reductants or oxidants, e.g. Fe(II)–Fe(III) or Ce(III)–Ce(IV), is of interest. The principle of equivalence change (Schaffer (1)) states that such reactions are generally slow compared with analogous reactions between 1-equivalent reductants

and 1-equivalent oxidants or between 2:2 equivalent systems. The equivalence principle was examined by Halpern with reference to the kinetics of three types of reaction: (i) electron transfer reactions between two metal ions; (ii) oxidation of metal ions by molecular oxygen; and (iii) reduction of metal ions by molecular hydrogen. It was concluded that the principle has only limited applicability to the reactions studied and that other factors are involved in determining the kinetics, viz. formation of intermediate complexes between the oxidant and reductant, participation of chain reactions. Some reactions are complicated in that they proceed by simultaneous bimolecular and termolecular paths, the latter being favored by lower activation energies.

A general theoretical paper by R. A. Marcus (Brooklyn Polytechnic Institute) "On the Theory of Electrochemical and Chemical Electron Transfer Processes" brought together some of the problems common to the fields of homogeneous and heterogeneous charge transfer reactions. The solvent configuration about the reacting ions was considered gradually to change during the reaction to a configuration characteristic of the final state of the reaction; at the same time the electronic configuration was regarded as undergoing a corresponding change, following the molecular redistribution adiabatically. This view was disputed by K. J. Laidler, who regarded the electron tunneling as fast and preceding the molecular rearrangement of the solvent. The role of image forces in heterogeneous reactions was given some qualitative examination in the light of recent calculations of Sachs and Dexter (2). It must be pointed out, however, that a problem of some magnitude still exists. Thus in electrode processes and in ionic adsorption, it appears that the effect of the image potential is surprisingly small; thus the absence of any significant specific adsorption of NaF and of simple cations at the electrocapillary maximum of Hg is unexpected. In the double layer the water molecules in the first coordination sphere about the ions will have a low dielectric constant (cf. (6); see (3), and K. J. Laidler, this symposium), so that the image potential might be expected to be not less than three or four kilocalories. It was pointed out by R. A. Marcus that the attraction of the ions to the interface may lower the entropy of solvation of the ions. However, this would not be in the direction which would cancel the effect of the electrostatic image interaction. It appears that this matter requires some further examination.

Proton Transfer Reactions

In recent years, considerable interest has been shown in the mechanism of proton transport in solutions and in hydrogen bonded solids. Two papers concerning this topic were presented: one on the "Limiting Conductance of Lyonium and Lyate Ions" by M. Kilpatrick (Illinois Institute of Technology) and the second on "Some Considerations on the Role of Proton Tunneling in Certain Charge Transfer Processes" by B. E. Conway (University of Ottawa). M. Kilpatrick presented data for the ratio of equivalent conductances of HCl–DCl mixtures to that of KCl in H_2O–D_2O solutions and also for the ratio of conductance of $HClO_4$–$KClO_4$ and HCl–KCl in H_2O–H_2O_2 and H_2O–CH_3OH mixtures, respectively. In H_2O–H_2O_2 solutions the anomalous proton conductance is partially eliminated; in H_2O–D_2O mixtures it is diminished at intermediate concentrations of D_2O. Preferential solvation effects are important in determining the anomalous proton conductance in solutions of acids in mixed solvents. The conductance behavior of a number of interesting non-aqueous systems was discussed.

The conductance of solid D_2O had been measured under conditions of rigorous purification by B. E. Conway in order to obtain an estimate of the isotopic ratio of equivalent conductance of H^+/D^+ in their respective pure ices. A value of about 1.6 was obtained for this ratio. The proton tunneling theory previously given (4) was re-examined using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

a quantal energy distribution and it was shown that an isotopic ratio of conductance of H^+ to that of D^+ in H_2O and D_2O ices, respectively, of 1.1 could be derived and a better value of the absolute mobility of H^+ in H_2O ice obtained. Classically, an isotopic ratio of conductance in the ices should be about nine.

The electrochemical behavior which would arise if proton tunneling occurred at electrodes was also examined and criteria were proposed for recognition of the effect. At intermediate overpotentials the Tafel equation is still obeyed but has an anomalously high slope which is dependent upon the isotopic mass. High separation factors do not necessarily arise in H^+/D^+ tunneling. Values comparable with those deduced classically (*ca.* 3 to 10) should arise at moderate cathodic overpotentials. It was pointed out that except in ice, the proton tunneling mechanism is not unambiguously demonstrable experimentally yet is theoretically indicated in a number of reactions. R. A. Marcus suggested that this could be because energy levels in initial and final states of the reaction were not available at comparable energies except in the case of proton transfer in ice where the initial and final states of the reaction are identical. J. E. B. Randles (University of Birmingham) pointed out that in the case examined by B. E. Conway for electrodes, some suitable levels should become available as the electrode potential was varied. Similarly, B. E. Conway referred to the *o*, *p*-hydrogen conversion case as one where the necessary levels should be available yet proton tunneling was not clearly indicated as the mechanism (5) of this reaction.

HETEROGENEOUS PROCESSES

Electrolytic Metal Deposition

Three papers on metal deposition were presented. The first by J. O'M. Bockris and W. Mehl (University of Pennsylvania) was concerned with the determination of the rate-determining step(s) in the electrolytic deposition of silver. A galvanostatic method had been employed in which the overpotential build-up lines at constant current density were interpreted with the aid of kinetic equations deduced for various limiting conditions corresponding to (i) slow ionic transfer of Ag^+ to the metal surface; (ii) comparably slow transfer and surface diffusion of adsorbed ions or atoms; and (iii) slow surface diffusion alone. The results indicated that path (iii) was rate-determining at low current densities whilst (i) was rate determining at high current densities. A useful comparison of expressions used in crystal growth from the vapor phase, with corresponding ones arising in electrolytic metal deposition was presented.

The kind of information which can be deduced from a study of radioisotope exchange reactions between ions and their corresponding metals was examined by C. V. King (New York University). The roles of the exchange current, adsorption of ions, local cell electrolysis and corrosion, and self-diffusion in the metal were discussed. It was shown that, in general, the exchange current cannot unambiguously be measured by the radiotracer method unless conditions are unusually favorable. Some results were presented which demonstrated the importance of internal self-diffusion as a factor to which too little attention had been paid in previous work.

The mechanism of growth of electrolytic metal whiskers was described by D. A. Vermilyea (General Electric Company) in terms of the theory of crystal growth. Incorporation of organic additives into the growing whiskers was likely and poisoning of the non-growing crystal faces was indicated below a certain critical current density, i_c. An estimate of i_c made theoretically was in quite good agreement with that found experimentally for silver whisker formation from $AgNO_3$ solutions.

Some discussion of these papers centered around the question of the nature of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

adsorbed entity resulting from the first ionic transfer stage in metal deposition and the mechanism by which a whisker begins its growth from a non-dendritic surface. It is probable that the adsorbed species which undergo surface diffusion across planar crystal faces to growing edges are not completely neutral atoms. Some appreciable ionic character in the bond between the adsorbed species and the bulk metal is probably preserved, e.g. as with H atoms adsorbed at metals where the surface dipole moment is considerable. Ionic transfer directly from the double layer to growing edges or kinks is unlikely as is indicated theoretically (6) on general energetic grounds.

The Hydrogen Evolution Reaction

Three papers were read on various aspects of the cathodic hydrogen evolution reaction. D. J. G. Ives (Birkbeck College, University of London) described some anomalies in the behavior of gold electrodes with respect to rest potentials and kinetics of the hydrogen evolution reaction, when the electrodes had been thermally deactivated at 800° C. The rest potentials were positive and overpotentials increased during polarization. The behavior was similar to that observed with poisoned platinum electrodes. The desorption of adsorbed H as molecule ions through the mechanisms

$$H_{ads} + H^+_{aq} \rightarrow H_2{}^+_{aq} \text{ (acid solutions)}$$

and

$$H_{ads} + H_2O_{aq} \rightarrow H_2{}^+_{aq} + OH^- \text{ (alkaline solution)}$$

was considered. It was shown that such processes are energetically not unlikely if it can be assumed that $H_2{}^+$ has a heat of hydration of at least -221 kcal mole^{-1}. The molecular dimensions and electron distribution in $H_2{}^+$ are not inconsistent with such a solvation energy. The desorption mechanism involving $H_2{}^+$ was suggested as a possible explanation for "reduction at a distance" claimed by Kobosew and Nekrassov (7) and again demonstrated by Poltorak (8). It was suggested that H_2 molecule production could occur in the solution by dissociation and recombination of the H atoms with liberation of the protons. Protons from the solution would thus only be involved as "carriers" in this desorption and H_2 production mechanism.

Electrolytic hydrogen production at single and polycrystalline silver electrodes was considered by A. Antoniou and F. E. W. Wetmore (University of Toronto), who reported new experimental data over a range of temperatures for polarization of silver in 1 M H_2SO_{4aq}. Tafel lines having an inflection were observed thus confirming qualitatively the previous work on silver (9); the Tafel slopes were approximately 0.059 (i.e., $2.3RT/F$) and 0.112 (i.e., 2.3 $(2RT/F)$). The apparent heat of activation was 18.8 kcal for low current densities and 14.3 kcal mole^{-1} for higher current densities. The lower slope of 0.059 could be explained in terms of slow surface migration of H atoms to recombination sites or on the basis of a first order H atom recombination step (10). At high current densities $\nu/\beta = 1$ (where ν is the stoichiometric number and β the symmetry factor taken as 0.5) so that a slow H^+ ion discharge reaction is indicated as the rate-determining step. It was pointed out by R. Parsons (University of Bristol) in discussion that a previous explanation (11) of the change of slope in terms of the change of the ψ_1* potential, as the electrode potential passes through the potential of zero charge of the metal, could not explain the magnitude of the change of Tafel slope observed. B. E. Conway emphasized that a similar effect would also be expected at other metals, e.g. Pb, Cu, Ni, where the potential of zero charge is within the range of potentials accessible in cathodic overpotential studies. The fact that inflections in Tafel lines are not observed for these

*ψ_1 *is the potential of the outer Helmholtz plane.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

metals lends support to Parson's comment. Moreover, it is only for silver that the potential of zero charge is positive to the hydrogen reversible potential, i.e. outside the range of cathodic overpotentials examined. The somewhat unique polarization behavior of silver therefore appears to reflect a genuine change of rate-determining mechanism with change of electrode potential (see also (12)).

The nature of the Pd–H system and the mechanism of hydrogen transport through the metal have been problems of interest for some years. Technological interest in these phenomena has arisen on account of the effect of dissolved H on the mechanical properties of certain metals, e.g. iron. S. Schuldiner and J. P. Hoare (U.S. Naval Research Laboratory) reported some interesting experiments on the transport of hydrogen through Pd and Pt bielectrodes and through Pd-clad electrodes in the form of sandwiches with the Pd as the outside metal. Studies were made by measuring the current–potential or potential behavior on both sides of diaphragm electrodes. Transport of hydrogen in an *atom* concentration gradient (i.e. using the β-phase of the Pd–H system) occurs with Pd and Pd-clad Fe only. Under a proton concentration gradient, hydrogen transfer occurs readily through Pd but not through Pt unless this is sandwiched between Pd. Transfer also occurs through sandwiched Fe. No transport of hydrogen either as protons or atoms occurs through Au or Ni. The latter result is surprising and occasioned some discussion, since under other conditions Ni dissolves hydrogen and the time variation of overpotential at Ni in ultrapurified solutions is believed to be due to uptake of H into the metal with consequent change in the electronic properties of the metal.

Other Electrochemical Reduction Processes

Three papers were devoted to heterogeneous reduction reactions other than those involved in the deposition of metals or hydrogen. J. E. B. Randles (University of Birmingham) described methods of calculating kinetic parameters of fairly fast redox reactions, from current potential curves obtained with rotating electrodes or stationary electrodes in stirred solutions or with dropping mercury electrodes. A comparison between the results obtained by means of the steady state current–potential relationship and by a-c. impedance measurements for the V^{2+}/V^{3+} reaction at the dropping mercury electrode was made. Satisfactory agreement between the kinetic parameters obtained by means of the two methods is found if in the interpretation of the current–potential curves due allowance is made for concentration polarization effects. This was achieved in the case of the expanding mercury drop at which the slow V^{++}/V^{+++} electrochemical reaction was occurring, by using Koutecky's analysis of the diffusion problem for this case. A mathematical and numerical analysis was given.

In the case of the reduction of chloraquo–Cr(III) ions at the dropping mercury electrode, P. J. Elving (University of Michigan) and B. Zemel (Shell Development) showed that the polarographic waves for Cr(III) species in various concentrations of perchloric acid, hydrochloric acid, and neutral salts were best interpreted by assuming two concurrent mechanisms for the electron transfer process: (i) the direct transfer of an electron to the Cr(III) ion from the electrode at the interface of the drop and (ii) the transfer of an electron to the Cr(III) ion from a Cr(II) ion produced at the interface. Only in the case of $[CrCl_2(H_2O)_4]^+$ ions in 12 *M* HCl is the direct electron transfer mechanism dominant.

Some problems in electrochemical reduction and cathodic preparation of certain organic compounds of pharmacological and biochemical interest were discussed by M. J. Allen (C.I.B.A. Pharmaceutical Products) and apparatus used in controlled potential electrolysis was described.

Anodic Electrode Processes

The development of the field of anodic processes has in general lagged behind that of cathodic processes mainly on account of the greater complexity of problems involved. This is due, for example, to the variety of surface oxide species which can be formed anodically on certain metals, the resistance of the surface films, and the time variation of electrode potential during formation of the films and during oxygen evolution on them. Two papers were given on the anodic passivation of iron; in the first paper by Snavely and Hackerman (University of Texas) a study of passivation at iron was made by determining the charge corresponding to the amount of iron dissolved in solution compared with the charge required to reach passivation in an anodic polarization of the iron. The number of coulombs found to be involved in the formation of the passive layer corresponding to a film of Fe_2O_3 15 Å thick if the electrode surface were planar was 0.002 cm^{-2}. A Flade arrest is not observed in anodic decay traces unless a potential of at least 1.2 v (E_H) is reached during the anodic charging. The passive layer is thus probably incomplete below this potential. The charge corresponding to the Flade arrest is equivalent to only about 10% of the passive layer.

The mechanism of formation and the properties of passive films on iron were discussed by M. Cohen (National Research Council). The reactions of water with iron under the following conditions were described: in the absence of oxygen and additives; in the absence of oxygen but in the presence of additives (oxidizing anions, e.g. nitrite, chromate, tungstate, molybdate); in the presence of oxygen; in the presence of oxygen plus oxidizing ions; and in the presence of oxygen and non-oxidizing buffering ions. Film-stripping techniques have shown that the films are mainly anhydrous ferric oxides. The thickness and chemical nature of the films formed under various conditions were reported.

L. Young (British Columbia Research Council) considered the growth of anodic oxide films, mainly from a theoretical standpoint; a number of models were considered for the formation and growth of oxide films. The roles of movement by metal ions, by oxygen, by lattice vacancies or interstitial ions, and the creation of defects by the applied field were examined.

Electrochemical processes at the nickel – nickel oxide electrode were examined by B. E. Conway and P. Bourgault (University of Ottawa) particularly with respect to the mechanism of the self-discharge and oxygen evolution which occurs on open circuit after charging the electrode. The open-circuit decay occurs by mixed anodic and cathodic processes, the rates of which are limited by the rate of evolution of oxygen at anodic sites. The potential on open circuit is determined by the quasi-equilibrium between the reduced and oxidized forms of the nickel oxide present at a given potential, the rate constants of the redox reactions between these species being large compared with that of the oxygen evolution process. Rates of self-discharge were determined as a function of KOH and H_2O activity and it was shown that two consecutive processes were involved in the decay, one having a Tafel slope of 2.3 $\frac{2}{3}(RT/F)$ and the other 2.3 $\frac{2}{5}(RT/F)$ (or 2.3 $\frac{1}{3}(RT/F)$). The rate of the process which was more dependent upon potential was also more dependent on KOH activity. The rates of both processes were increased by increasing KOH activity but decreased by increasing H_2O activity thus confirming the rate-controlling process as the oxygen evolution reaction. Mechanisms of anodic oxygen evolution which could explain the experimental results were proposed. In discussion of these papers, R. Parsons pointed out that under the limiting conditions for which rate laws for complex anodic processes have been previously calculated by the Christiansen method (13), this method was not in fact always necessary, since the same results could be obtained by

use of a simpler direct procedure using "quasi-equilibrium" steady-state concentrations of reacting intermediates for steps prior to the rate-determining step in a series of consecutive reactions.

Adsorption at Electrode Interfaces and the Double Layer

The last six papers of the symposium were concerned with the properties of the double layer and with adsorption in relation to electrode processes. In a paper by A. Frumkin *et al.* (Academy of Sciences, Moscow) some interesting effects of specifically adsorbed anions on the rate of electroreduction of $S_2O_8^{-2}$ ions at the negatively charged mercury electrode were reported. At a given potential and for a given cation the rate of reduction is increased in the order $Cl^- < Br^- < I^-$. The acceleration of the electroreduction, e.g. by I^-, depends on the nature of the cation, increasing in the sequence $Na^+ < K^+ < Cs^+$. It is concluded that the ψ_1 potential which determines, in part, the kinetics of the reaction is a fluctuating one influenced locally by the proximity of cations and anions, and is not the usually considered average ψ_1 potential in the double layer. In this way the specific effect of cations can be explained. The adsorption of anions at the negatively charged mercury electrode depends to a considerable extent on the formation of cationic "bridges".

Some general considerations on the correlation between the double-layer structure and electrode kinetics were presented by M. Breiter and P. Delahay (Louisiana State University). Experimental results on the reduction of IO_3^-, CH_3NO_2, and discharge of $[Cd(CN)_4]^{2-}$ were considered in terms of the double-layer structure and specific adsorption at the electrode. R. S. Hansen (Iowa State College) described some results on the frequency dependence of the double-layer capacity at mercury and deduced relaxation times, τ, for the water in the double layer as low as 10^{-2} seconds. Since this was very much higher than τ values for H_2O bound in ice (10^{-6} seconds) it was felt that the results and their interpretation might require further examination. R. Parsons presented a rigorous thermodynamic analysis for calculation of heats and entropies of adsorption of ionic species from electrocapillary data obtained at various temperatures, and showed results for adsorption of KI at mercury. E. Blomgren and J. O'M. Bockris (University of Pennsylvania) described electrocapillary data obtained for adsorption of HCl and aromatic amine hydrochlorides at mercury and deduced the components of charge in the double layer as a function of electrode potential. J. M. Los and C. K. Tompkins (University of New Brunswick) reported results obtained for the adsorption of methylene blue on mercury, determined by allowing many drops of mercury to come into equilibrium with the solution, and then to fall off into a common pool in a separate vessel, the solution in which was subsequently analyzed. The adsorption followed a Langmuir type of isotherm. B. E. Conway and R. G. Barradas in discussion reported some determinations of adsorption of organic ions and molecules at *solid* metal electrodes of Cu, Ni, and Ag using a direct spectrophotometric method. Isosteric heats of adsorption had been derived for acridine in aqueous solution at copper.

ACKNOWLEDGMENTS

The author would like to take this opportunity of acknowledging the assistance he has received from Professor F. E. W. Wetmore of the University of Toronto and Dr. R. J. Cvetanović, National Research Council, in the organization of the meeting and in the technical production of the preprints of the papers. The author and the Chemical Institute of Canada are much indebted to the National Research Council for providing technical facilities for the preprinting of the papers presented at the meeting.

BRIDGING AND NON-BRIDGING LIGAND EFFECTS IN REDOX REACTIONS OF METAL IONS[1]

HENRY TAUBE

In this paper we shall be concerned with a description of the processes which are involved in the transfer of an electron from one metal ion center to another in solution, emphasizing in the description the changes in the first co-ordination spheres. Two distinct types of activated complexes have been characterized for these reactions, which throughout this article will be called the "outer sphere" activated complex and the "bridged" activated complex. In the outer sphere activated complex, the number and identity of the groups comprising the first co-ordination sphere remains unaltered on electron transfer; in the bridged activated complex, a common group is shared by the metal ions, so that a change in the first co-ordination sphere of at least one of the partners accompanies the formation of the activated complex. Other types of activated complexes have been suggested for redox reactions of metal ions, but for none of the others has as direct a demonstration of the characteristic features been possible as for the two which have been described above. This remark applies also to the hydrogen atom transfer formulation (1, 2, 3) (or its variations) according to which it is proposed that the redox process is brought about by the transfer of a hydrogen atom from the first co-ordination sphere of a hydrated reducing cation to that of the oxidizing cation. Although such a mechanism may apply in some cases, there is no proof that it operates in the systems for which it has been proposed.

A property of the ions in the system undergoing reaction which is significant in determining the reaction mechanism, and in permitting classification of the reaction type, is the ease with which they undergo substitution. Only when certain conditions are fulfilled with respect to the substitution lability of the redox partners has it been possible to draw fairly definite conclusions as to the nature of the activated complexes. The majority of the systems do not meet the rather special requirements which the substitution labilities compared to rates of electron transfer must fulfill, and for them the evidence as to mechanism type thus far advanced remains indirect.

The differences in the activated complexes recognized by the classification which has been made are not trivial. It is obvious that for the outer sphere types, the readjustments which accompany electron transfer may take place largely in the solvent and in the ion atmospheres. Such effects exist outside the first co-ordination sphere also for bridged activated complexes, although in certain cases they may be much reduced in intensity, but in addition, important chemistry in the first co-ordination spheres must be recognized as taking place. For reactions involving activated complexes which differ so markedly in structure as the two outlined, it is difficult at the present stage of development to propose a single simple theory of reaction rates which embraces both. Rather, it appears essential first to delineate experimentally each type of mechanism, and to try to assess the importance of the factors that affect the rate by each kind of reaction path. In this area as in others concerned with reaction mechanisms, it is in general not a question of either/or, and contributions to the over-all rate by rival paths must in general be acknowledged.

[1]*Manuscript received July 18, 1958.*
Contribution from the Department of Chemistry, University of Chicago, Chicago 37, Illinois. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

The emphasis which is placed on the bridged activated complex in this paper in no sense implies that this kind of mechanism is considered more important—in fact, the development of the subject will show that definite proof of the operation of the mechanism involving bridged activated complexes is restricted thus far to only a small number of different central cations. However, the mechanisms involving the bridged activated complex have associated with them interesting chemistry in large variety, and are worthy of consideration for their own sake, so that no apology for the present lack of generality is due. Further, it is likely that the most fruitful way to attack the systems which do not readily lend themselves to direct tests of mechanism will be from ground thoroughly prepared by understanding systems of known mechanisms.

A brief outline of observations and problems in the field of mechanisms involving outer sphere activated complexes is offered, and following this, a more detailed discussion of the bridged activated complex.

THE OUTER SPHERE ACTIVATED COMPLEX

In many redox reactions, reactant and product complex ions are substitution inert, or at least submit to substitution much less rapidly than to electron transfer. If in addition the species concerned are co-ordinatively saturated, it can reasonably be supposed that there is no interpenetration of the co-ordination spheres on electron transfer. The conclusion that an outer sphere activated complex operates for such systems is for the most part based on evidence no more direct than that outlined, yet some of the systems in question are so extremely inert to substitution that there is little doubt that an outer sphere activated complex is all that is accessible to the systems. Thus redox reactions or exchange reactions involving only species drawn from among the following and their like: $Fe(CN)_6^{-3,-4}$, $IrCl_6^{-2,-3}$, $Mo(CN)_8^{-3,-4}$, $Fe(dip)_3^{+3,+2}$, $Os(o\text{-phen})_3^{+3,+2}$, $MnO_4^{-1,-2}$ almost certainly take place without interpenetration of, or dislocations in, the first co-ordination spheres of the reactant ions. Substitution in the first co-ordination spheres of these ions is slow (for the manganese oxy-ions, this is true only in alkaline solution), and it is doubtful that any useful labilization of the ligands takes place on close approach of the reactants (this is particularly true when the products resulting on electron transfer are also substitution inert). For the MnO_4^-–$MnO_4^=$ electron exchange reaction, which is the one which has been most thoroughly studied (4), it is known that the co-ordination spheres are not disrupted on electron transfer. This follows from Symons' observation (5) that the reduction of MnO_4^- to $MnO_4^=$ in alkaline solution takes place preserving the oxygen-isotopic composition of the complex ions.

It is a feature of all the systems mentioned above that not only is the co-ordination sphere not reorganized on electron transfer, but in fact there is little change in the dimensions of the molecules when the indicated change in electronic charge takes place. For these systems, electron exchange takes place rapidly (specific rates at 25° of the order of 10^{-3} $mole^{-1}$ sec^{-1} and higher) (6). Whether the conditions that the geometry remains unchanged when electron transfer takes place is sufficient to ensure that the process be rapid is not at all certain, however. The ions referred to are also of such nature that the *d* electrons are probably not localized on the central metal ions, and for them, Marcus's (7) assumption that they be considered conducting spheres may well be justified. However, for a pair of fully ammonated ions, which then present a shell of protons on their exterior and which satisfy the geometric requirements, the rates may well be slower by several powers of 10. Such a system may be hard to find, for the property of the ligands which brings *d* electrons to the exterior of the complex ion is also the property that ensures that little change in dimensions takes place on electron transfer.

It is by no means a necessary condition for the operation of the outer sphere mechanism that there be little change in dimensions of the ions, for if the ligands are chosen to be unfavorable to the formation of the bridged activated complex, electron transfer through the intact co-ordination spheres may still be the easier route to products. Thus the electron exchange between $Co(en)_3^{++}$ and $Co(en)_3^{+++}$ (8) presumably must occur by the outer sphere mechanism, for although $Co(en)_3^{++}$ is substitution labile, $Co(en)_3^{+++}$ is not, and the groups on the co-ordinated nitrogens prevent the formation of a bridged activated complex. The $Co(en)_3^{++}$–$Co(en)_3^{+++}$ reaction is much slower ($k \sim 10^{-3}$ $mole^{-1}$ sec^{-1} at 25°) than the others of this class mentioned above. This is a result in part at least of the cost in energy for making the substantial change in the dimensions of the ions prior to electron transfer, which is necessary to bring about the matching of the energy of the electron at the two sites. As already mentioned, the difference in specific properties of en as compared to *o*-phen, for example, may also be a factor but it is impossible at the present time to evaluate its importance.

Some of the features of interest in the reactions which proceed by outer sphere activated complexes have been referred to already, as for example, the influence on the rates of the geometrical requirements and the properties of the ligands. Of interest also are the dielectric properties of the reaction medium, which are dealt with in Marcus's theory (9), and salt effects, which are delineated partially in the experiments by Sheppard and Wahl (4). An important problem which remains to be settled is the average separation of the ions in the activated complexes for electron transfer: the experimental solution of this problem is by no means obvious.

THE BRIDGED ACTIVATED COMPLEX

Introduction

For a system in which the oxidizing agent is substitution inert, the reducing agent is labile to substitution, but the product formed on its oxidation is inert to substitution, a direct demonstration of a bridged structure for the activated complex can be made by simple analysis of reaction products. The significance of the conditions imposed on the substitution properties is most easily developed by using a specific example. The reaction of $(NH_3)_5CoCl^{++}$ with Cr^{++} has been found to take place forming as product not $Cr(H_2O)_6^{+++}$ but $CrCl^{++}$ (9) (in addition to Co^{++} and NH_4^+ as other products). Cr^{+++} is very slow to undergo substitution, thus $CrCl^{++}$ can not have been formed from Cr^{+++} and Cl^-. This conclusion is reinforced by repeating the experiment in the presence of radioactive Cl^-; it is found that substantially no radioactivity gets into the $CrCl^{++}$ (10). The formation of $CrCl^{++}$ proves a Cr–Cl bond in the activated complex; the property of the oxidizing agent $Co(NH_3)_5Cl^{++}$ as being substitution inert ensures that a Co–Cl bond is maintained, and the property of $Cr^{++}{}_{aq}$ as being substitution labile provides for the formation of the bridged structure.

Most of the work in this field has been done with Co(III) complexes as oxidizing agents and $Cr^{++}{}_{aq}$ as reducing agent. $Cr^{++}{}_{aq}$ appears to be unique among the pure aquo-ions under ordinary conditions in having the combination of properties required to establish the operation of the bridged activated complex. If interest is not restricted to pure aquo-ions, Co(II) can also be mentioned as a reducing agent which can be similarly exploited. In the presence of NH_3 and numerous other ligands, Co(II), although itself labile to substitution, becomes substitution inert on oxidation. As oxidizing agents that lend themselves to the type of experiment outlined, we have a wider choice, including most Co(III) complexes, Cr(III) complexes, Pt(IV) complexes (though here a complication enters because the stable product is 2 e^- removed), Ir(IV) complexes, Ru(IV)

complexes, and some complexes of Fe(III). It is possible that at lower temperatures, such as become accessible when CH_3OH is solvent, many more oxidizing agents and reducing agents will show the necessary relation of rates of substitution to rate of electron transfer to make a direct test of mechanism possible for them. Before these general remarks are concluded, attention should be drawn explicitly to the remarkable feature of inorganic cations that a change in oxidation number by one unit can cause enormous changes in substitution lability. Thus, the replacement of water in $Cr(H_2O)_6^{+++}$ by solvent water takes place at 25° with a half time of the order of 30 hours. The similar exchange for $Cr^{++}{}_{aq}$ is so rapid that it has not been measured and $t_{\frac{1}{2}}$ is likely of the order of 10^{-5} seconds. To add interest to the situation, Cr(IV) is again probably very labile to substitution (12, 13).

For the remainder of this section, experimental results on features of the bridged activated complex will be presented, and any discussion of the implications of these observations for other systems will be deferred.

Variety of Bridging Groups

Complexes of the type $(NH_3)_5Co^{III}L$ can be prepared with a great variety of ligands L. Experiments using oxidizing agents of this class and Cr^{++} as reducing agent have demonstrated group transfer from Co to Cr for L = F^-, Cl^-, Br^-, I^-, CNS^-, N_3^-, $SO_4^=$, $PO_4^{\equiv}$, $P_2O_7^{\equiv}$, and a variety of carboxylic acids, results for which will be discussed in some detail in the next subsection. Of special interest are experiments on the transfer of H_2O and OH^-, as relating to redox reactions of aquo-cations. A definitive result has been obtained for L = OH^-, showing that transfer is complete for this ion; the experiments with L = H_2O are inconclusive but some transfer at least by this path is indicated (14). With L = NO_3^-, net transfer to chromium is not observed. Many of the ligands mentioned have also been shown to transfer when Cr(III) complexes act as oxidizing agents (15).

Relative Rates for Various Bridging Groups

A rate comparison which has an obvious qualitative interpretation is that for the reactions of Cr^{++} with $Co(NH_3)_6^{+++}$ and with $Co(NH_3)_5OH_2^{+++}$, the reaction with the aquo-ion is more rapid by a factor of at least one hundred. The significant difference between the two oxidizing agents is that only with the aquo-ion is a pair of electrons exposed to make a bridged complex readily accessible. The totally ammonated complex may in fact react by making use of an outer sphere activated complex.

Other rate comparisons which will be offered are somewhat more subtle. Thus it is not obvious what progression in rates should be observed for the series of halo complexes. Kinetic experiments on reactions of the two types

$$(NH_3)_5Cr\ X^{++} + Cr^{++} + 5H^+ = Cr^{++} + 5NH_4 + Cr^{++}$$

and

$$(H_2O)_5Cr^*\ X^{++} + Cr^{++} = Cr^{*++} + (H_2O)_5Cr\ X^{++}$$

agree that rates increase progressively from X = F^- to X = I^-. It should be noted that in each class of reaction, the rates are first order in chromic complex, first order in chromic ion, and independent of (H^+). The data for these reactions and other similar ones are summarized in Table I.

A comparison of special interest displayed in this table is that of the rate of reaction of Cr^{++} with CrN_3^{++} and $CrNCS^{++}$. Ball and King (15) make the point that attack by Cr^{++} at the atom bearing the Cr^{+++} is impossible for steric reasons, and that attack

TABLE I

The rates of reaction of Cr^{++} with various Cr(III) complexes

Oxidant	k, mole^{-1} sec^{-1}	Temp.	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	Ref.
CrF^{++}	2.6×10^{-2}	27	13.7	−20	15

$CrNCS^{++}$	1.8×10^{-4}	27	—	—	15
CrN_3^{++}	>1.2	0	—	—	15
$(NH_3)_5CrF^{++}$	2.7×10^{-4}	25	13.4	−30	17
$(NH_3)_5CrCl^{++}$	5.1×10^{-2}	25	11.1	−23	17
$(NH_3)_5CrBr^{++}$	3.2×10^{-1}	25	8.5	−33	17
$(NH_3)_5CrI^{++}$	5.5 ± 1.5	25	—	—	17
t-$CrCl_2^+$	$\sim2\times10^3$	25	—	—	10

takes place at the remote end of the ligand. The slower rate for NCS^- compared to N_3^- can be attributed to this, that remote attack by Cr^{++} on NCS^- forms products different from the reactants, and in a less stable form, so that the energy requirements of the over-all process must be added to the pure kinetic requirements in determining the rate.

The results of experiments done by Sebera and Taube (18) on carboxylic acids as electron mediators are summarized in Table II. These experiments are still in progress, and a large number of experiments of obvious interest still remain to be done.

Oxalate	>200			19

One comparison of interest is that of the rate for fumaric acid as ligand with that for succinic acid. The latter reacts at a specific rate much like those at which monocarboxylic acids react. Thus for all of this group including succinic acid attack by Cr^{++} at the carboxyl adjacent to the Co(III) is indicated. To explain the higher rate for fumaric acid it is suggested that when it is the bridging group, attack by Cr^{++} takes place at the end remote from the Co(III). This mechanism is possible because fumarate can offer a conjugated system of double bonds for electron transfer. The higher rates come about because the Cr^{++} is not required to approach as closely to the Co(III) center as is the case when succinate is bridging group. An extraordinary result, not included in the table, and consistent with this interpretation is that the rate of electron transfer when fumaric acid is bridging group, is strongly accelerated by acid. The function of the additional proton may be to improve the conjugation between the Co(III) and Cr(II) centers.

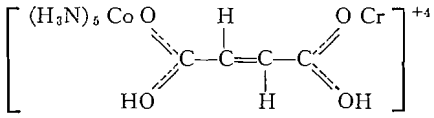
By associating with the carbonyl oxygen adjacent to Co(III), it brings about the necessary redistribution of the electrons, as indicated in the formulation below of the activated complex.



These general conclusions are supported by the observations made with the isomers of phthalic acid. Conjugation is not possible for the ortho or meta acid (but for different reasons) and the rates are slow. For the para isomer conjugation is possible and the rates are very high; furthermore, with this isomer but not the others, acceleration by acid is observed.

The high rate for the maleate complex is not understood by the considerations outlined thus far. The maleate complex reacts more rapidly than does the fumarate complex, although the geometry prevents effective conjugation, and it reacts much more rapidly than the *o*-phthalic complex which has similar geometry. An hypothesis which is reasonable in the light of these comparisons and which furthermore accommodates the observations that of all the ligands mentioned maleate is the most easily reduced by Cr^{++} is that when maleate is the ligand we are dealing not with electron transfer *through* the ligand, but *to* the ligand. A similar mechanism may operate for oxalate, which is also easily reduced by Cr^{++}. Isotopic fractionation experiments can differentiate the mechanisms proposed on the one hand for fumarate and on the other for maleate, but these have not been done, and they will in fact be rather difficult to do.

The Reaction of $(NH_3)_5CoOH_2^{+++}$ *with* Cr^{++}

This reaction is especially featured because of its relation to the important class of redox reactions between aquo-ions. It differs from most other reactions of its class in admitting much more incisive tests of mechanism than are usually possible. One of these which provided proof that reaction takes place by transfer of oxygen has already been mentioned.

In common with other redox reactions of aquo-cations which have been studied, the reaction in acidic medium proceeds by two parallel paths differing in the dependence on (H^+). The rate law for this reaction may be represented by the equation:

$$-d(Cr^{++})/dt = k_1(Cr^{++})[(NH_3)_5CoH_2O^{+++}]+k_2'(Cr^{++})[(NH_3)_5CrOH_2^{+++}]/(H^+)$$

The kinetic data on this system, including experiments with D_2O as solvent are shown in Table III (20). It should be noted that the second term on the right of the equation above can be cast in the equivalent form:

$$k_2(Cr^{++})[(NH_3)_5CoOH^{++}],$$

where $k_2 = k_2'/K_D$ and K_D is a dissociation constant of $(NH_3)_5CoOH_2^{+++}$ under the specific experimental conditions (21).

TABLE III

Kinetics of the reaction of Cr^{++} with $(NH_3)_5CoOH_2^{+++}$ (at $\mu = 1.0$, temp. 20° second as unit of time)

Solvent	k_1	k_2'	k_2	E_1	E_2	$\Delta S_1^{\ddagger}$	$\Delta S_2^{\ddagger}$
H_2O	0.50	1.58	1.5×10^6	3.3	4.8	−48	−15

Of interest in the kinetic data is the large change in specific rate caused by the loss of the proton from the aquo-ion, and the low values of the activation energies. These points will not be developed further here, but should not be dismissed without mentioning that a case for the existence, not merely of a binuclear activated complex, but of a binuclear intermediate can be based on the low values of E observed here and in other cases as well. Of significance equal to that of the oxygen-tracer experiments are experiments on oxygen-isotope fractionation in the reaction (14). These experiments have shown that $(NH_3)_5CoO^{16}H^{++}$ reacts more rapidly than the ion having O^{18} in the OH group by a factor of 1.03_5. This is a relatively large kinetic oxygen isotope effect, and it shows that the Co–O bond is greatly weakened in the activated complex. Thus the OH^- is not to be regarded merely as a means of binding Co(III) and Cr(II) together, but in fact an important event in the transfer of the electron is the stretching of the Co–OH bond, and presumably the simultaneous shortening of the Cr–OH bond. The question of other bond dislocations in the activated complex will be dealt with in the next subsection.

The measurement of the effect on the rate of electron transfer caused by the change from H_2O to D_2O as solvent has been suggested as a means of distinguishing the "hydrogen atom transfer" mechanism from other mechanisms. The significance of the H_2O–D_2O experiments in the present system is that they test the magnitude of the effect for a reaction which does not involve hydrogen atom transfer, but which by one path at least proceeds by transfer of OH. The remarkable result is that a large H–D isotope effect is found, a decrease in k_1 and k_2' of almost a factor of 4 in changing from H_2O to D_2O as solvent. The effect on k_2' must be factored into the effect on k_2 and K_D. The H_2O–D_2O effect on K_D has been measured as 1.5 (21) (K_D in H_2O compared to K_D in D_2O), thus a healthy kinetic isotope effect in k_2 of 2.6 is still left. The origin of this large isotope effect is in the hydrogen-containing bridging group (the specific rate for the reaction $(NH_3)_5CrCl^{++} + Cr^{++}$ decreases by only a factor of 1.3 in changing to D_2O as solvent). It means presumably that the H–O bond is substantially stretched in the activated complex. Possibly the complex adopts a linear arrangement of Co–O–Cr centers, and the p-electrons of oxygen are used to contribute to the bonding. The two paths for the reaction may be quite similar except that when the aquo-ion reacts, both hydrogens in water are removed in the activated complex, but when the hydroxy complex reacts, one is removed by an equilibrium process preceding the rate-controlling step and one in the activated complex. Rather similar H–D isotope effects are to be expected on this basis, as is observed.

Effects of Non-bridging Ligands

This important subject will be dealt with only briefly, because little in the way of systematic work on this feature of these reactions has been done. The existence of important ligand effects, short of bridging ligand effects is, of course, to be expected and is easily demonstrated. Thus, when the reaction of $(NH_3)_5CoOH_2^{+++}$ with Cr^{++} proceeds in the presence of pyrophosphate ion, it takes place much more rapidly than when pyrophosphate is omitted, and pyrophosphate is incorporated into the chromic product (19). The inertia of the Co(III) complex to substitution ensures that the pyrophosphate does not act as a bridging group, yet it does get into the activated complex, presumably by replacing water molecules on Cr^{++}. That a bridging group is involved is proved by the experiment using $(NH_3)_6CoCl^{++}$ as oxidizing agent. When this is done, both Cl and pyrophosphate are incorporated into the chromic complex.

Groups differ widely also in their capacity to influence rates in non-bridging positions.

Pyrophosphate, $SO_4^=$, and Cl^- decrease in effect in this order; the effect of Cl^- is so small that in 0.1 *M* solution, its influence on the rate of the reaction of $(NH_3)_5$ to OH_2^{+++} with Cr^{++} is not detected.

The non-bridging ligand effects can conveniently be studied by working with a series of Co(III) complexes containing a common bridging group. Such studies have not been carried far, and only a single problem in this field has been given some attention. Orgel (22) has discussed the reaction of Cr^{++} with Co(III) complexes, and has suggested that the electron gained by Co(III) is accommodated in the d_{z^2} orbital. This orbital is made available by removing not only the bridging ligand from the cobalt, but also the group *trans* to it. This interesting suggestion finds support in the observation that *trans* $Co(en)_2Cl_2^+$ is reduced *more* rapidly by $V^{++}{}_{aq}$ or $Fe^{++}{}_{aq}$ than is the *cis* form (23). It has been tested by observing the fractionation of nitrogen in NH_3 when *cis-* and *trans-* $NH_3(en)_2CoCl^{++}$ react with Cr^{++}. These experiments have shown (24) that there is no significant N-isotope fractionation either when NH_3 is *cis* or when it is *trans* to the Cl bridging group. This experimental result, if sustained, would show that the principal bond dislocations of the Co(III) center take place at the bridging group and would suggest that the primary product of the reaction is a penta-co-ordinated Co(III) complex which retains the configuration of the parent complex, but which has in place of the bridging group a single electron. The result cannot be considered general even for all Co(III) complexes and the ion $NH_3(dip)_2CoCl^{++}$ might in fact show a strong *trans* effect on electron transfer.

CONCLUSION

Not all aspects of interest in the field of reactions proceeding by the bridged activated complex have been discussed nor even referred to, but perhaps a sufficient number of results were reviewed to indicate the nature of the problems and the nature of the experiments which can be done to elucidate mechanisms. Most of the techniques used unfortunately do not apply to the redox reactions of ions when both partners are substitution labile. However much is written concerning the outer sphere and bridged activated complexes the subject of redox reactions of metal ions remains in an unsatisfactory state when a reaction as much studied as the Fe^{++}–Fe^{+++} electron exchange is not understood nor a reaction as much applied as the Fe^{++}–Ce(IV) reaction. It is to be hoped that experimental techniques will be introduced which will yield conclusions for these systems as direct as some of those possible for specially selected systems. Failing to discover such techniques an indirect attack must be used, to develop thoroughly an understanding of the field in which mechanisms can be established, to develop the experimental observations in the field of the labile systems, and to bring to bear on these observations the principles which have been established for systems of known mechanisms.

An illustration of this kind of approach which will serve better perhaps to expose its limitations than to reveal its capacities is the following: from the fact that Cl^- does not markedly accelerate the reaction of $(NH_3)_5CoOH_2^{+++}$ with Cr^{++}, that $CrCl^{++}$ is not formed in this reaction, and that Cl^- does markedly accelerate the reaction of Fe^{+++} with Cr^{++} forming $CrCl^{++}$, we argue that in the activated complex for the latter process both Fe^{+++} and Cr^{++} make a bond to Cl^- (i.e., the difference in the kinetic behavior of the two systems is understood by invoking the difference in substitution lability of the two oxidizing agents). Thus the reaction of Fe^{+++} with Cr^{++} accelerated by a variety of ligands can be brought into the field of the bridged activated complexes. There is a close similarity (9) of the rates at which Fe^{++} reacts with Fe(III) complexes to the rates at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

which Cr^{++} reacts with the same complexes and therefore similar mechanisms are indicated. These considerations thus lead to the conclusion that the Fe^{++}–Fe(III) exchange reactions also proceed by bridged activated complexes. Considerations of this kind are hardly satisfactory however, because they do not expose the contributions of minor, but nevertheless interesting, rival paths, nor is a sufficiently convincing case for the mechanism by the major paths made.

A field for experiment which may improve our understanding of the redox process under discussion is in the reactions of reducing agents having differing electronic structures with a series of substitution-inert complexes. Thus, some interesting conclusions are indicated by results recently obtained (23) using V^{++} as reducing agent when these results are considered in the context of those already obtained with Cr^{++}. A large number of Co(III) complexes show the same order of reactivity with V^{++} as they do with Cr^{++}, but the contrast in rates is much less. The reaction of $(NH_3)_5CoOH_2^{+++}$ is abnormally rapid, however, and shows some unusual salt effects. We believe at present that V^{++} reacts by both kinds of mechanism. When a suitable bridging group is present, the bridged activated complex is still formed. But when the aquo-ion or the hexammino-ion is used the outer sphere activated complex predominates as providing the reaction path. The differences in V^{++} and Cr^{++} are to be understood as resulting from the differences in electronic structure, V^{++} having only the three lower lying *d*-orbitals populated but Cr^{++} having one electron more. Eu^{++} will also be of interest in these studies as will Fe^{++} (its reactivity can be enormously increased by suitable complexing).

Another area which promises to be fruitful is the reduction of Co(III) and, if possible, Cr(III) complexes by reaction through outer sphere activated complexes. This can be done by using $Cr(dip)_3^{++}$ or $V(dip)_3^{++}$ as reducing agent. The reaction of $Co(NH_3)_6^{+++}$ with $Cr(dip)_3^{++}$ in fact proceeds so rapidly that we (23) have not succeeded in measuring its rate, in marked contrast to the slow rate when $Cr^{++}{}_{aq}$ is used. Rate comparison for the same series of Co(III) complex being reduced by both mechanisms should prove to be very instructive, and instructive also in comparison with rates of reduction of the same complexes at electrodes.

SOME THEORETICAL ASPECTS OF ELECTRON-TRANSFER PROCESSES IN AQUEOUS SOLUTION[1]

KEITH J. LAIDLER

ABSTRACT

A theoretical treatment has been developed for the rates of electron-transfer reactions in aqueous solution, with particular reference to the ferric–ferrous system. The reactions are considered to be diffusion-controlled processes, the approach of the ions being hindered by the electrostatic repulsion between them. Calculations have been made of the free energy of the diffusion process and for the repulsion, account being taken of the variation in dielectric constant with the electric field. The form of the potential-energy barrier between the ions is calculated for various separations, and the transmission coefficient calculated using the quantum-mechanical expression corresponding to a rectangular barrier. The total free energy of activation for the reaction, which is the sum of the contributions due to diffusion, repulsion, and tunnelling, is found to pass through a minimum at a separation of about 4 Å. The calculated free energy of activation for the reaction is 15.4 kcal, in good agreement with the experimental value of 16.8 kcal. The energy and entropy of activation for the reaction are also briefly discussed.

INTRODUCTION

During the past few years a considerable number of kinetic studies have been concerned with electron-transfer processes between ions in different valency states. A well-known process of this type is that between ferric and ferrous ions in aqueous solution,

$$Fe^{++} + Fe^{+++} \rightarrow Fe^{+++} + Fe^{++}.$$

Although many complexities exist, the evidence indicates that in some cases these reactions occur by a simple transfer of an electron from one ion to another. This is possibly true of the ferric–ferrous reaction, and Silverman and Dodson (1) have determined values of 9.9 kcal and -25 e.u. for the energy and entropy of activation of the process.

This paper is concerned with the theory of simple electron-transfer reactions, and for the most part deals quantitatively with the factors influencing the rate of the Fe^{++}–Fe^{+++} reaction. Several previous theoretical discussions of these reactions have been presented, notably by Libby (2), Weiss (3), Eyring and co-workers (4, 5), and by Marcus (6*e*). In the case of the latter two treatments, an attempt was made to calculate the free energies of activation (ΔF^*) of a number of reactions, including the Fe^{++}–Fe^{+++} one. The quantitative agreement with experiment was not, however, completely satisfactory. The experimental ΔF^* for the Fe^{++}–Fe^{+++} system is 16.8 kcal at 25° C: Eyring *et al.* obtain agreement only by arbitrarily adding a term of 8.1 kcal, while Marcus (6*a*) calculated a value of 9.8 kcal.* It has appeared to the present writer that this lack of good agreement could be attributed to failure to take into consideration certain important factors which must influence the rate. In particular it would seem that neither Eyring nor Marcus treated in sufficient detail the collisions (or, more correctly, *encounters*) between the reacting ions.

In the present work an attempt has been made to bring about some improvement, particularly with respect to the two points noted above. If in the present paper a somewhat critical view appears to have been taken of the preceding theoretical treatments

[1]*Manuscript received May 23, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

**In a later paper (6b) Marcus quotes a calculated value of 18 kcal, but details are not given.*

this has been done entirely to clarify the main points, and not to deprecate the earlier work which contains many valuable features and upon which the present work relies very heavily.

THE FREQUENCY OF IONIC ENCOUNTERS

In what follows it will be concluded, on the basis of the experimental evidence, that there does occur a direct transfer of an electron from the ferric to the ferrous ion. The electron-transfer process will be seen later to occur by quantum-mechanical tunnelling, and is much more probable when the ions are close together. The very close approach of the ions is obviously rendered unlikely by the electrostatic repulsions. A compromise is therefore struck, the most likely transfers occurring (as will be seen) when the ions are about 4 Å apart.

In the treatment of Eyring *et al.* (4) the rate of encounter has been taken as equal to the term $\mathbf{k}T/h$ multiplied by the factor $\exp(-\Delta F^*_{rep}/RT)$, where ΔF^*_{rep} is the free energy of repulsion between the two ions. This, however, cannot be correct, since it does not take proper account of the variation in the frequency of encounter with the separation of the ions, σ, in the activated state. The distance σ does appear in the ΔF^*_{rep} term, but it should also appear in the pre-exponential term; quite apart from electrostatic effects an encounter with a large σ is intrinsically more probable than one with a small σ, and intuitively one would expect the pre-exponential term to be proportional to σ.

A more satisfactory treatment of the frequency with which the ions come within a distance of σ of one another is provided by the theory of diffusion-controlled reactions, a theory that has been developed to explain the coagulation of colloids (7, 8), the rates of quenching of fluorescence in solution (9), and more recently the rates of certain enzyme-catalyzed reactions (10). The theory is briefly as follows. According to Smoluchowski (7), in the absence of electrostatic interactions the frequency of approach of two molecules to within a distance of σ cm is given by

$$Z = 2\pi(D_1+D_2)n_1n_2\sigma, \qquad [1]$$

where n_1 and n_2 are the numbers of the two types of molecules in unit volume and D_1 and D_2 are the diffusion constants. Bradley (11), however, argues that Smoluchowski's equation is too large by a factor of 12, and instead proposes

$$Z = \tfrac{1}{6}\pi(D_1+D_2)n_1n_2\sigma. \qquad [2]$$

This expression is equivalent to the following expression for the rate constant:

$$k = \tfrac{1}{6}(\pi N/1000)D_{12}\sigma \text{ liter mole}^{-1} \text{ sec}^{-1}, \qquad [3]$$

where $D_{12} = D_1+D_2$. The above equations are arrived at by integration of the appropriate differential equations for diffusion.

When the reacting species are ions the electrostatic interactions have to be taken into account in the setting up of the differential equations. This has been done by Debye (9), who found that the reaction rate in the case of a free energy of repulsion equal to ΔF^{**}_{rep} must now be divided by the integral

$$1/f = \sigma \int_\sigma^\infty \Delta F^{**}_{rep}/kT \, \frac{dr}{r^2}. \qquad [4]$$

The repulsive free energy is given for the case of constant dielectric constant ϵ by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$\Delta F^{**}_{rep} = z_1 z_2 e^2/\epsilon k T r, \quad [5]$$

where e is the electronic charge and z_1 and z_2 the valencies of the ions. When ϵ is independent of σ the reciprocal of the integral becomes

$$f = (z_1 z_2 e^2/\epsilon k T \sigma)(e^{z_1 z_2 e^2/\epsilon k T \sigma} - 1)^{-1}. \quad [6]$$

When z_1 and z_2 are of the same sign, as for the reactions under consideration, the exponential term is always much larger than unity, so that

$$f = (z_1 z_2 e^2/\epsilon k T \sigma)\ e^{-z_1 z_2 e^2/\epsilon k T \sigma} \quad [7]$$

$$= (\Delta F^{**}_{rep}/kT)\ e^{-\Delta F^{**}_{rep}/kT}. \quad [8]$$

The expression for the rate constant for the encounter is therefore

$$k_{enc} = \tfrac{1}{6}(\pi N/1000)\ D_{12}\sigma\ (\Delta F^{**}_{rep}/kT)\ e^{-\Delta F^{**}_{rep}/kT} \quad [9]$$

with ΔF^{**}_{rep} given by eq. [5].

Since the experimental results are usually quoted in terms of a conventional free energy of activation, defined by

$$k = (\mathbf{k}T/h)\ e^{-\Delta F^{*}_{exp}/RT}, \quad [10]$$

it is convenient to express k_{enc} in the same form, namely as

$$k_{enc} = (\mathbf{k}T/h)\ e^{-\Delta F^{*}_{diff}/RT}\ e^{-\Delta F^{*}_{rep}/RT}, \quad [11]$$

where ΔF^{*}_{diff} relates to the diffusion process only and ΔF^{*}_{rep} to the repulsive term f. The term ΔF^{*}_{diff} depends slightly upon the value taken for D_{12}. There is not a large variation in the diffusion constants for ions, and a value of 1.2×10^5 cm^2 sec^{-1} has been taken as typical of the diffusion constant of ions such as Fe^{++} and Fe^{+++}. With $D = 2.4 \times 10^5$ it is then readily calculated that at a temperature of 25.0° C,

$$\Delta F^{*}_{diff} = 1.358 \log_{10} 8.203\times10^4/\sigma. \quad [12]$$

In the same way it is found that since

$$e^{-\Delta F^{*}_{rep}/RT} = (\Delta F^{**}_{rep}/RT)\ e^{-\Delta F^{**}_{rep}/RT}, \quad [13]$$

$$\Delta F^{*}_{rep} = \Delta F^{**}_{rep} - 2.303RT \log_{10} \Delta F^{**}_{rep}/RT. \quad [14]$$

THE FREE ENERGY OF ACTIVATION DUE TO ELECTROSTATIC REPULSION

The exact treatment of electrostatic repulsion presents a problem of very considerable difficulty. If the solvent were a continuous dielectric having a dielectric constant ϵ that is independent of the field strength, the free energy ΔF^{**}_{rep} corresponding to a separation of σ would be given by eq. [5] with r equal to σ; ΔF^{*}_{rep} could then be readily calculated using eq. [14]. The true ΔF^{*}_{rep} values are, however, at all distances somewhat greater than calculated in this way, since the dielectric constant in the neighborhood of the ions is actually less than the macroscopic value. This effect has a significant effect on the calculated free energies of activation, as will be seen later.

The dielectric behavior of water in the near neighborhood of ions has recently been treated by Laidler and Pegis (12), whose work will now be extended to give an approximate treatment of electrostatic repulsive energies. According to Kirkwood (13), Booth (14), and Grahame (15) the variation of the differential dielectric constant ϵ_d with the field strength E is given extremely closely by the expression

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[15] $$\epsilon_d = dD/dE = [(\epsilon_0 - n^2)/(1+bE^2)] + n^2,$$

where D is the electric displacement, ϵ_0 the dielectric constant at zero field strength (taken as 78.5 for water at 25.0° C), n is the optical refractive index ($n^2 = 1.78$), and b is a quantity the value of which is given by Booth's theory. In the present calculations a value of 1.08×10^{-8} e.s.u.$^{-2}$ has been taken for b, since this value agrees closely with Booth's theory and with the experimental results obtained by Malsch (16).

Equation [15] integrates to

[16] $$D = n^2E + [(\epsilon_0 - n^2)/b^{\frac{1}{2}}] \tan^{-1} b^{\frac{1}{2}}E$$

and since the electric displacement D at a distance r from an ion of valency z is ze/r^2 we have

[17] $$n^2E + [(\epsilon_0 - n^2)/b^{\frac{1}{2}}] \tan^{-1} b^{\frac{1}{2}}E = ze/r^2.$$

Although E cannot be expressed explicitly as a function of r, eq. [17] can be used to prepare curves showing the variation; such curves are shown in Fig. 1 for $z = 1$, 2, 3, and 4. By interpolation, values of E can therefore be obtained corresponding to various values of r, and eq. [15] can then be used to calculate the differential dielectric constant at various distances from the ion. Such plots are shown in Fig. 2, from which it is seen that for a ferric ion, for example, the dielectric constant has the low value of 1.78 up to a distance of about 3 Å, after which the value rises fairly steeply. Even at a distance of 10 Å, however, the value is significantly below the limiting value of 78.5.

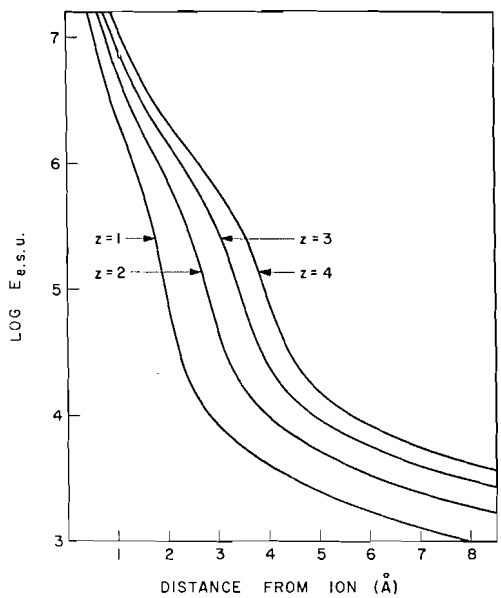

FIG. 1. Plots of the logarithm of the field strength, in electrostatic units (dynes), against the distance from the ion, for ions of valencies equal to 1, 2, 3, and 4.

The difficulty of calculating the repulsive free energy between two ions such as the ferric and ferrous ions arises from the fact that each ion produces a field, so that there is a considerable superposition of fields when the ions are close together. This superposition affects the dielectric constant, which in turn affects the individual fields. There appears

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

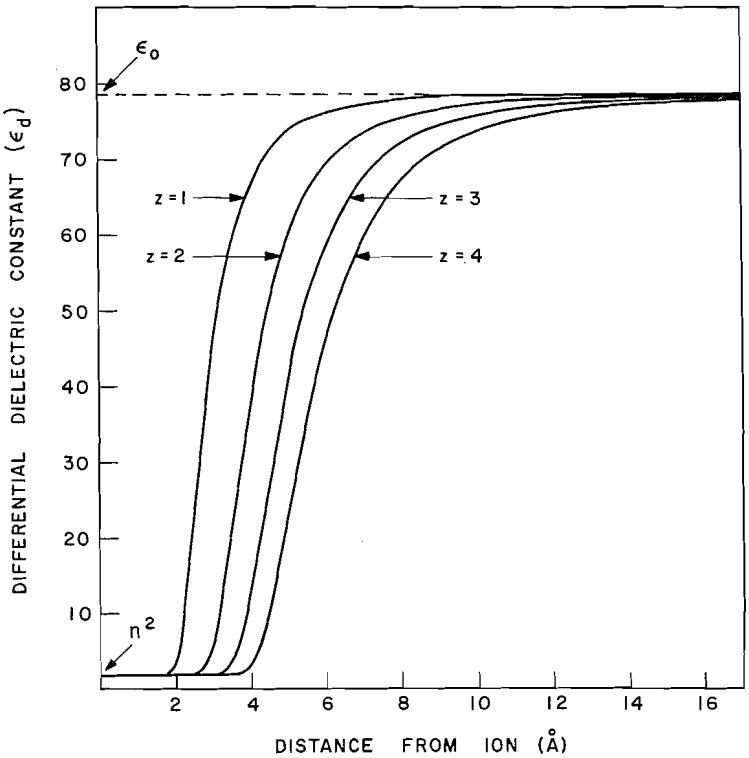

FIG. 2. Plots of the differential dielectric constant against the distance from the ion, for ions of valencies equal to 1, 2, 3, and 4.

to be no simple way of treating this problem, and the only exact procedure seems to be to bring the ions together in a vacuum and then to calculate the energy residing in the dielectric. Mathematically this problem has so far proved intractable and a simpler procedure has therefore been employed.

The method adopted was to calculate the field at a distance r from the ferric ion, and to assume that the force acting on the ferrous ion is equal to this field multiplied by the charge on the ferrous ion. This procedure would, of course, be strictly correct if instead of the ferrous ion one were considering a test charge sufficiently small as not to affect the field of the ferric ion. Owing to the mutual interference of fields there will, however, be some error in the case of a large charge such as the ferrous ion. The procedure employed will, however, undoubtedly give a repulsive energy that is a significantly better approximation than that given by assuming the dielectric constant to be 78.5, and will probably not be far from the truth.

The procedure used is as follows. From the $z = 3$ curve in Fig. 1 it is possible to evaluate numerically the area under the curve from $r = \infty$ to r equal to any desired value σ. This area is a measure of the work required to bring a unit charge from infinity to σ. Multiplication by the charge on the ferrous ion then gives a value for the work, i.e. of ΔF^{**}_{rep}, required to bring the ferrous ion from infinity to a distance of σ. Figure 3 shows another plot of E against σ, and also gives ΔF^{**}_{rep} plotted against σ. Included on the figure are the curves that are calculated on the assumption that there is no dielectric saturation, i.e. that ϵ remains 78.5 at all distances. The difference between the two cases is seen to be negligible at distances greater than about 5 Å, but to be extremely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

great at smaller distances. Neglect of the saturation effect would therefore lead to considerable error, in that the ions would be permitted to approach much more closely than they are actually able to do.

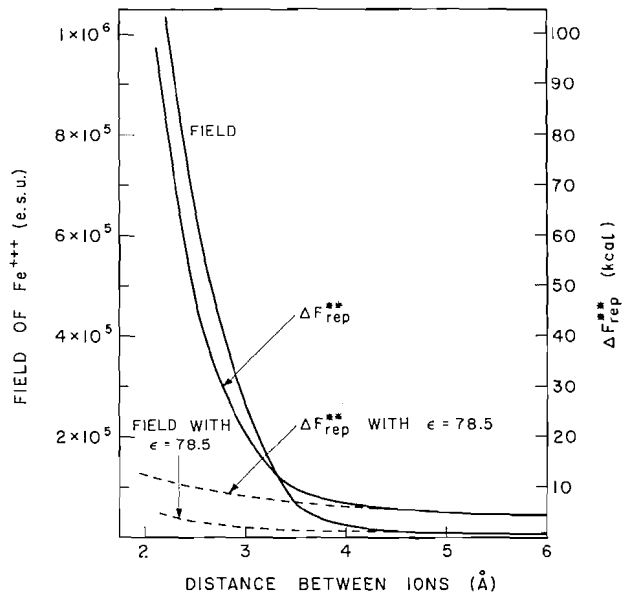

FIG. 3. Plots of the field due to a ferric ion (left-hand scale), and of the free energy of repulsion between a ferric ion and a ferrous ion (right-hand scale) against the distance. The dotted curves are calculated on the assumption of a dielectric constant of 78.5, the full curves for a dielectric constant that varies with field strength according to equation [15].

QUANTUM-MECHANICAL TUNNELLING

Inspection of Fig. 3 shows that the two ions cannot approach to within a distance of 3 Å without a considerable expenditure of free energy. Calculations of the work of electron transfer show that except at distances shorter than 3 Å the energy barrier for the transfer of an electron is more than 200 kcal in height. It therefore follows that the transfer must occur by quantum-mechanical tunnelling, and it is readily found that for the types of energy barriers involved the tunnelling rates are sufficiently large to permit reaction to proceed by this mechanism.

The first problem is the calculation of the potential-energy barrier. Here the main point that must be taken into consideration is that the rates of electron tunnelling are so large that there is insufficient time for the reorganization of neighboring solvent molecules. In other words, after the electron has left the ferrous ion the surrounding solvent molecules remain oriented in the same manner even though the ion has now become a ferric ion. The field around the newly formed ferric ion must therefore be calculated on the basis of a charge of $3e$ on the ion, but with a ferrous-type ionic atmosphere. This can simply be done by calculating the field due to a ferrous ion in its ferrous-type atmosphere and multiplying the result by 3/2.

The calculations of the barriers have therefore been carried out in this way, and the assumption of superposition of fields has again been made. The procedure has been to calculate, using the methods of the preceding section, the field round the newly formed ferric ion, with its ferrous-like atmosphere, and also that round the ferric ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

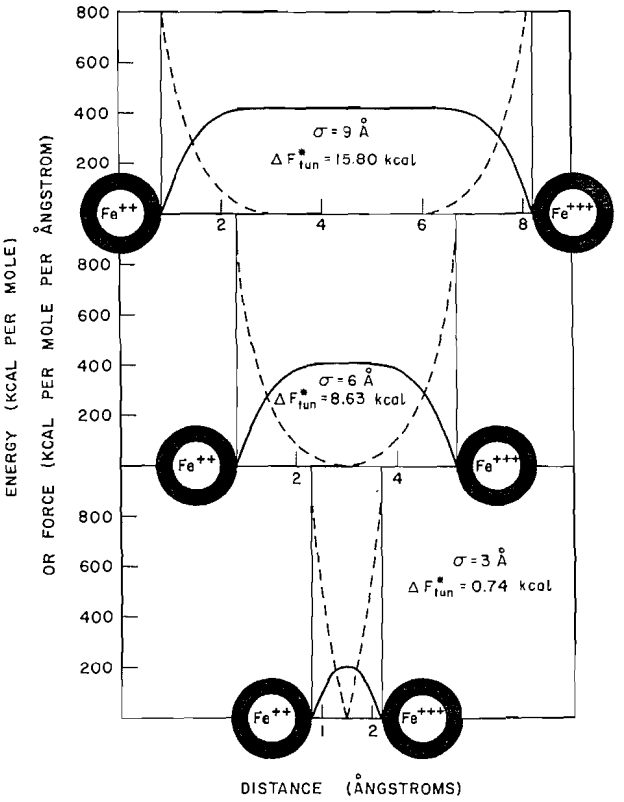

FIG. 4. Plots of force between ferric and ferrous ions against their separation (dotted curves) and of the potential-energy barrier (full curves). The ferric ion produced when the electron leaves the ferrous ion is in a ferrous-like atmosphere; this causes a slight asymmetry in the potential-energy barriers.

which the electron is approaching; this has a normal ferric-type atmosphere. For a given value of σ the two fields can be superimposed, and a curve can therefore be plotted for the force on the electron at various positions. By graphical integration the energy can then be calculated, and the barrier plotted. Figure 4 shows, for separations of 3, 6, and 9 Å, the plots of force and energy. In making these calculations the radius of the ferric ion was taken as 0.8375 Å, which is the crystal radius of 0.67 Å multiplied by the factor 1.25, as suggested by Couture and Laidler (17) and by Laidler and Pegis (12). It is to be noted that the energy curves in Fig. 4 rise and fall fairly steeply; this is because, during the first and last parts of its progress, the electron is moving through a region where the dielectric constant is small and where the forces are therefore strong.

The expression for the probability of tunnelling takes simple forms for barriers that are triangular or rectangular. The barriers for the present system are closer to rectangles than to triangles, and the approximation will be made of treating them as rectangular; the transmission coefficient is then (18)

[18] $$\kappa = 4e^{-2\gamma a}[2\alpha\gamma/(\alpha^2+\gamma^2)]^2,$$

where

[19] $$\alpha = 2\pi\sqrt{(2mW)/h}$$

and

[20] $$\gamma = 2\pi\sqrt{[2m(V_0-W)]/h},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

m is the mass of the electron, V_0 the height of the barrier, and W is the kinetic energy of the electron prior to tunnelling. Following Marcus, Zwolinski, and Eyring (4) a value of 77.18 kcal per mole has been taken for W.

The values of κ calculated for the three separations of 3 Å, 6 Å, and 9 Å are shown in Fig. 4. The transmission coefficient can formally be expressed as

$$\kappa = e^{-\Delta F^*_{tun} F/RT}, \quad [21]$$

and the ΔF^*_{tun} values calculated in this way are shown in Fig. 4; additional values are included in Table I.

TABLE I

Free energies of activation for the Fe^{++}–Fe^{+++} exchange at various ionic separations

Separation (Å)	ΔF^{**}_{rep}	ΔF^*_{rep}	ΔF^*_{diff}	ΔF^*_{tun}	ΔF^*_{calc}
2.5	48.34	45.73	6.20	0.11	52.04
3.0	20.70	18.60	6.02	0.74	25.36
3.5	9.65	8.00	6.00	2.40	16.40
4.0	6.88	5.43	5.80	3.60	14.83
4.5	5.64	4.30	5.75	4.85	14.90
5.0	5.07	3.80	5.71	6.10	15.60
6.0	4.23	3.07	5.61	8.63	17.31
7.0	3.62	2.55	5.50	11.00	19.05
8.0	3.17	2.18	5.40	13.40	20.98
9.0	2.81	1.89	5.38	15.80	23.07

Weighed average of ΔF^*_{calc} = 15.4 kcal.

THE OVER-ALL FREE ENERGY OF ACTIVATION

The results of the various calculations are summarized in Table I for a range of values of σ. Included in this table are the ΔF^*_{diff} values calculated using eq. [12], the ΔF^*_{rep} values calculated using eq. [14] from the ΔF^{**}_{rep} values shown in Fig. 3, and the ΔF^*_{tun} values calculated in the manner described in the preceding section. Since according to the definitions of the three quantities the over-all rate of reaction corresponding to a given σ is given by

$$k = (\mathbf{k}T/h)\, e^{-\Delta F^*_{diff}/RT}\, e^{-\Delta F^*_{rep}/RT}\, e^{-\Delta F^*_{tun}/RT}, \quad [22]$$

the calculated ΔF^*_{calc} is the sum of ΔF^*_{diff}, ΔF^*_{rep}, and ΔF^*_{tun}, and is shown in the last column of the table. The values are shown plotted against σ in Fig. 5.

It is seen from the plot of ΔF^*_{calc} that the value passes through a minimum of about 14.8 kcal at a separation of about 4 Å. This value does not, however, quite represent the over-all free energy of activation, which will actually be a value averaged over all values of σ. The average ΔF^*_{calc} is given by

$$\Delta F^*_{calc} = \frac{\int_{14.8}^{\infty} \Delta F^*_{calc}\, e^{-\Delta F^*_{calc}/RT}\, d\Delta F^*_{calc}}{\int_{14.8}^{\infty} e^{-\Delta F^*_{calc}/RT}\, d\Delta F^*_{calc}}, \quad [23]$$

the value of which is found to be 15.4 kcal.

In view of the approximation involved, particularly in the treatment of the superposition of fields, the agreement between this calculated value and the experimental value of 16.8 kcal is quite satisfactory. The agreement is much better than that given by earlier treatments, a fact that is to be attributed to the following factors:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

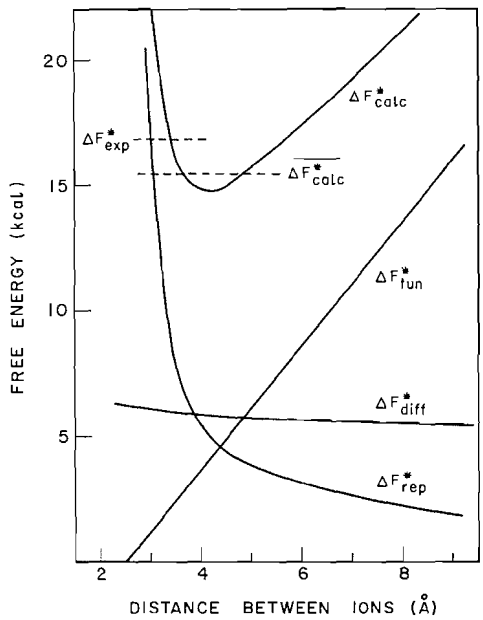

FIG. 5. Plots of the various free-energy terms against the distance between the ions. The upper curve represents the sum of the three contributions, and the lower horizontal line shows the calculated weighted-average free energy of activation, to be compared with the observed value shown by the upper horizontal line.

(1) The present treatment of the reaction as a diffusion-controlled one. The value of ΔF^*_{diff} at 4 Å is seen to have a value of nearly 6 kcal; no corresponding term appears in the earlier treatments.

(2) The more careful consideration devoted, in the present work, to the effects of dielectric saturation. Neglect of these effects allows the ions to approach much more closely than 4 Å, and the resulting ΔF^*_{calc} is less by more than a kilocalorie.

The reason that the present treatment gives a value of ΔF^*_{calc} that is too low is probably due to the fact that the treatment of repulsive effects somewhat underestimates the value of ΔF^*_{rep}. It does not seem likely that the calculated values of ΔF^*_{diff} and ΔF^*_{tun} can be much in error. It is to be noted that the present way of looking at the problem, particularly of treating the energy barriers, leaves no place for the "rearrangement" free energy considered by Eyring *et al.*, this factor having been included in the present treatment of the repulsive energy and the potential-energy barrier.

ENERGIES AND ENTROPIES OF ACTIVATION

The calculation of energies and entropies of activation is always more difficult than that of free energies of activation, since the energies and entropies depend in a more intimate way on the various structural factors. It is, however, of interest to see to what extent the present treatment offers an interpretation of the experimental values of $E = 9.9$ kcal and $\Delta S^* = -25$ e.u. We will consider separately the three terms involved, namely diffusion, tunnelling, and repulsion. Since the average ΔF^* corresponds approximately to a value of σ equal to 5.0 Å, the figures to be quoted below will be related to this separation.

Activation energies for the viscous flow of water (19) and for diffusion processes in water (20) are usually close to 4.0 kcal at 25° C. Since at $\sigma = 5.0$ Å, $\Delta F^*_{\text{diff}} = 5.7$ kcal, it follows that $\Delta S^*_{\text{diff}} = -5.7$ e.u.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The transmission coefficient is proportional to $\exp[k(V_0-W)^{\frac{1}{2}}]$ and V_0 and W are practically temperature independent (since most of the work of transferring the electron is done through the dielectrically saturated layer). The free energy of activation for tunnelling, equal to 6.1 kcal, therefore corresponds entirely to an apparent entropy of activation, so that

$$E_{tun} = 0 \text{ and } \Delta S^*_{tun} = -20.3 \text{ e.u.}$$

Since the heats and entropies for repulsion are very difficult to estimate in a reliable manner they have been obtained by difference, and are shown as starred values in the table below:

	ΔF^*	E	ΔS^*
Diffusion	5.7	4.0	−5.7
Tunnelling	6.1	0	−20.3
Repulsion	5.0*	5.9*	3.0*,†
Experimental values	16.8	9.9	−25

†The apparent discrepancy in the ΔS^* values is due to the fact that in the calculation of ΔS^*_{exp} the pre-exponential factor is taken as $e\mathrm{k}T/h$ rather than $\mathrm{k}T/h$.

The very elementary theory of the entropy of activation for repulsion, with $\epsilon = 78.5$ and $\partial \ln \epsilon/\partial T = -0.0046$, gives,

$$\Delta S^*_{rep} = -18.8(z_1z_2/\sigma) = -22.6 \text{ e.u.},$$

which is very far from the derived value of 3.0 e.u. The entropy of activation will, however, be very markedly increased when there is initially almost complete saturation in the vicinity of both of the reacting ions. It is found, for example, that entropies of activation for reactions between ions of the same sign are frequently larger than predicted by the elementary theory. The reason for these effects may well be that, in order for the ions to approach closely, water molecules must be "unfrozen"; such a process will require energy and will result in an increase in entropy.

THE PRINCIPLE OF EQUIVALENCE CHANGE IN OXIDATION–REDUCTION REACTIONS[1]

J. HALPERN

ABSTRACT

The principle of equivalence change predicts that oxidation–reduction reactions between 1-equivalent oxidants and 2-equivalent reductants (or vice versa) will, in general, be slow, since they must proceed either through termolecular paths or through the formation of unstable intermediates. In this paper, the kinetics and mechanisms of a number of reactions of this type are examined and an attempt is made to assess the validity of the considerations on which this principle is based. Among the reactions considered are (1) electron transfer between metal ions; (2) oxidation of metal ions by oxygen; and (3) reduction of metal ions by hydrogen. In each of these cases it is found that the principle of equivalence change has only limited validity and that a number of other factors are important in determining the relative rates and mechanisms of reactions of different equivalence type. Among these are the formation of stabilized intermediate complexes between oxidant and reductant and the possibility of unstable intermediates acting as carriers in chain reactions. In reactions of thallium(I) or thallium(III) with 1-equivalent metal ions, thallium(II) is formed as an intermediate. Some of these reactions are not as slow as expected, apparently because of favorable entropies of activation. Several of the reactions examined proceed simultaneously through bimolecular and termolecular paths, the latter being favored because of lower activation energies.

INTRODUCTION

A large number of oxidizing and reducing agents are known whose stable oxidation states differ by two electron equivalents (e.g., Tl(I)–Tl(III), Sn(II)–Sn(IV), H_2–$2H^+$, O_2–H_2O_2) and the question arises of how these react with 1-equivalent reductants or oxidants (e.g., Fe(II)–Fe(III), Ce(III)–Ce(IV), etc.). The principle of equivalence change, due to Shaffer (1, 2, 3), states that such reactions are, in general, slow compared to reactions between 1-equivalent oxidants and 1-equivalent reductants or between 2-equivalent oxidants and 2-equivalent reductants. This principle can be interpreted in the following way: Two general types of mechanisms can be conceived for a reaction between a 1-equivalent reductant, A, with stable oxidation states N and N+1, and a 2-equivalent oxidant, B, with stable oxidation states N and N+2.

$$\text{I} \quad \left\{ \begin{array}{l} \xrightarrow{\text{slow}} \\ 2A^N + B^{N+2} \longrightarrow 2A^{N+1} + B^N \end{array} \right.$$

$$\text{II} \quad \left\{ \begin{array}{l} \left. \begin{array}{l} \xrightarrow{\text{slow}} \\ A^N + B^{N+2} \longrightarrow A^{N+1} + B^{N+1} \\ \xrightarrow{\text{fast}} \\ A^N + B^{N+1} \longrightarrow A^{N+1} + B^N \end{array} \right\} (a) \\ \text{or} \\ \left. \begin{array}{l} \xrightarrow{\text{slow}} \\ A^N + B^{N+2} \longrightarrow A^{N+2} + B^N \\ \xrightarrow{\text{fast}} \\ A^N + A^{N+2} \longrightarrow 2A^{N+1} \end{array} \right\} (b) \end{array} \right.$$

[1]*Manuscipt received July 5, 1958.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

It is anticipated that reactions proceeding by the first type of mechanism will be slow because they involve a termolecular step, while reactions of the second type will be slow because of the high activation energy associated with the formation of the unstable intermediate, B^{N+1} or A^{N+2}. It also follows that such reactions should be susceptible to catalysis by species, X, which have three oxidation states, N, N+1, and N+2, with suitably disposed potentials through a mechanism of the type:

III
$$\begin{cases} A^N + X^{N+2} \longrightarrow A^{N+1} + X^{N+1} \\ A^N + X^{N+1} \longrightarrow A^{N+1} + X^N \\ X^N + B^{N+2} \longrightarrow X^{N+2} + B^N \end{cases}$$

Recent studies on the kinetics and mechanisms of a variety of inorganic oxidation–reduction reactions make possible for the first time a detailed assessment of the validity of these considerations. This is attempted in the present paper with particular reference to three relatively simple types of reactions, (1) electron transfer between metal ions; (2) oxidation of metal ions by molecular oxygen; and (3) reduction of metal ions by molecular hydrogen. The principles which emerge from a consideration of these systems appear capable of extension to reactions of more complex species.

1-EQUIVALENT AND 2-EQUIVALENT OXIDANTS AND REDUCTANTS

The inherent tendencies of different oxidizing agents to undergo 1-equivalent or 2-equivalent reduction are revealed by differences in the products that are obtained when they react with certain reducing agents, notably hydrazine (4, 5) and sulphurous acid (6). In the case of sulphurous acid, 1-equivalent oxidation favors the formation of dithionate, while 2-equivalent oxidation results exclusively in the formation of sulphate, according to the mechanisms:

$$SO_3^{2-} \xrightarrow{-e} SO_3^- \longrightarrow \tfrac{1}{2}S_2O_6^{2-},$$

$$SO_3^{2-} \xrightarrow{-2e} SO_3(SO_4^{2-}).$$

The following classification of oxidants, due to Higginson and Marshall (6), is based on this criterion:

1-Equivalent	2-Equivalent	1,2-Equivalent
Ce(IV)	Tl(III)	$Cr_2O_7^{2-}$
Co(III)	H_2O_2	MnO_4^-
Fe(III)	I_2, Br_2, Cl_2	$PtCl_6^{4-}$
Mn(III)	IO_3^-, BrO_3^-	VO_2^+
OH	BrO^-, ClO^-	

Many oxidants can be unambiguously classified as being of the 1- or 2-equivalent type; a few which give intermediate stoichiometry are denoted as 1,2-equivalent.

The occurrence of 2-equivalent steps in oxidation–reduction reactions is now well recognized and Michaelis's hypothesis that all such reactions proceed by successive univalent steps (7) must be considered as without general validity. This conclusion is relevant to the present discussion, since this hypothesis, if valid, would remove the most obvious basis for the principle of equivalence change.

ELECTRON-TRANSFER REACTIONS BETWEEN METAL IONS

A significant test of the principle of equivalence change should be provided by comparing the kinetics of an oxidation–reduction reaction between a 1-equivalent and a 2-equivalent metal ion, with the kinetics of the isotopic exchange reactions between the two valence states of each ion. The data summarized in Table I permit three such comparisons, i.e., for the Fe^{2+}–Tl^{3+}, Tl^{+}–Co^{3+}, and Tl^{+}–Ce^{4+} reactions.

TABLE I

Electron-transfer reactions between metal ions

Reaction	Equivalence type	k (25°), 1 mole^{-1} sec^{-1}	E, kcal	$\Delta S^{\ddagger}$ e.u.	Reference
Fe^{2+}–Fe^{3+}	1–1	4	9.9	−25	8
Co^{2+}–Co^{3+}	1–1	0.75(0°)	—	—	9
Ce^{3+}–Ce^{4+}	1–1	2×10^{-2}	7.7	−40	10
Tl^{+}–Tl^{3+}	2–2	4×10^{-6}	17.6	−21	11
Fe^{2+}–Tl^{3+}	1–2	2×10^{-2}	18	−7	12
Tl^{+}–Co^{3+}	2–1	3×10^{-3}	26.4	+22	13
Tl^{+}–Ce^{4+}	2–1	Very slow	—	—	14

Both the Fe^{2+}–Tl^{3+} and Tl^{+}–Co^{3+} reactions have been shown to proceed through type II mechanisms, involving one-electron transfer steps with the formation of Tl(II) as an intermediate (13, 15). In line with the principle of equivalence change, the activation energy of each of these reactions appears to be higher than the activation energies of both the corresponding isotopic electron-exchange reactions; presumably this reflects the formation of the unstable Tl(II) species. However, the rates of these reactions are not lower than, but in both cases intermediate between, those of the corresponding exchange reactions, i.e., $k_{Tl^{+}-Tl^{3+}} < k_{Fe^{2+}-Tl^{3+}} < k_{Fe^{2+}-Fe^{3+}}$. This is because in each case the mixed reaction is favored by a more positive entropy of activation.

Until data are obtained for more systems, it is not possible to conclude whether this is a general feature of such reactions, but there are grounds for anticipating that this may prove to be the case. These are provided by the recognition that one of the principal contributing factors to the instability of intermediate valence states of metal ions in solution is a low hydration energy; usually this is because the ion is "abnormally" large having, as in the case of Tl^{2+}, only a single electron in its outer shell. However, for the same reason the entropy of hydration of the ion will tend to be more positive than those of stable ions of similar charge (e.g., Tl^{2+} vs. Hg^{2+}). A reaction involving the formation of such an ion would therefore be expected to require considerable energy but to be favored by an abnormally positive entropy. If, as often tends to be the case, the charge distribution of the activated complex approaches that of the products, a similar trend would be reflected in the energies and entropies of activation.

The increase in entropy of activation (relative to the exchange reactions) is more pronounced for the Tl^{+}–Co^{3+}, than for the Fe^{2+}–Tl^{3+} reaction, and this may be due to the influence of an additional factor. The rate-determining step of this reaction,

$$Tl^{+} + Co^{3+} \longrightarrow Tl^{2+} + Co^{2+}$$

involves a change in the ionic charges in the direction of charge equalization (more uniform spreading out of the charge). This is generally accompanied by a decrease in the electrostriction of the surrounding solvent and hence by an increase in entropy. The entropy of activation should also be shifted toward more positive values. This effect should not be apparent in the Fe^{2+}–Tl^{3+} reaction, whose rate-determining step,

$$Fe^{2+} + Tl^{3+} \longrightarrow Fe^{3+} + Tl^{2+}$$

involves no change in charge type, nor in the isotopic exchange reactions which are, of course, symmetrical.

In contrast to the other two systems and more clearly in line with the principle of equivalence change, the Tl^{+}–Ce^{4+} reaction appears to be much slower than either the Tl^{+}–Tl^{3+} or Ce^{3+}–Ce^{4+} exchange reaction. It is not possible to draw any detailed conclusions from this, since there is some uncertainty about the mechanism of oxidation of Tl^{+} by Ce^{4+}. Preliminary kinetic measurements (14) suggest that this proceeds not by direct reaction between the ions but by a mechanism, such as

$$CeOH^{3+} \rightleftharpoons Ce^{3+} + OH,$$
$$Tl^{+} + OH \rightarrow Tl^{2+} + OH^{-},$$
$$Tl^{2+} + Ce^{4+} \rightarrow Tl^{2+} + Ce^{3+}.$$

The possibility that the first step of this mechanism also constitutes a path of Ce^{3+}–Ce^{4+} exchange cannot be dismissed.

Catalysis of the Tl^{+}–Ce^{4+} reaction by Mn^{2+} (1) and by halide ions (16) has been reported and attributed to a type III mechanism.

The above reactions have been discussed without reference to the question of whether they occur by actual electron transfer between the metal ions or by some other mechanism, e.g., H-atom transfer between the hydration shells of the ions. There is still some uncertainty about this question (17), but the considerations which have been invoked here would be applicable in either case.

OXIDATION OF METAL IONS BY MOLECULAR OXYGEN

The first stable reduction product of oxygen is hydrogen peroxide, and it can therefore be considered as a 2-equivalent oxidizing agent. Kinetic data for the oxidation of several metal ions by oxygen are summarized in Table II.

TABLE II
Oxidation of metal ions by oxygen

Reaction	Kinetics	E (kcal)	$\Delta S^{\ddagger}$ (e.u.)	Reference
Fe(II) → Fe(III)	$k[O_2][Fe(II)]^2$	17.4	−15	18
Pu(III) → Pu(IV)	$k[O_2][Pu(III)]^2$	19	+11.2*	19
V(III) → V(IV)	$k[O_2][V(III)]$	20.1	+6†	20
U(IV) → U(VI)	$k[O_2][U(IV)]$	22	—	21

*The high apparent entropy of activation may be due to considerable charge neutralization in the activated complex, since the kinetics suggest that 2–3 sulphate ions participate in the rate-determining step.

†Calculated on the assumption that the reacting species is VOH^{2+}; this is suggested by the pH dependence of the rate.

Fe(II) is a 1-equivalent reductant and its oxidation by oxygen, as evidenced by the third-order kinetics, appears to proceed by a type I mechanism. This is also the case for the oxidation of Pu(III) to Pu(IV), despite the fact that the +5 state of Pu is relatively stable and hence a 2-equivalent oxidation of Pu(III) is feasible. On the other hand, the oxidation of V(III) to V(IV) is a second-order reaction and probably proceeds by a type II mechanism; possible intermediates are V(V) and HO_2. This reaction is very susceptible to catalysis by cupric salts, probably through a mechanism of the type

$$V(III) + Cu(II) \xrightarrow{\text{slow}} V(IV) + Cu(I),$$
$$Cu(I) + O_2 \xrightarrow{\text{fast}} Cu(II).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

It is of interest that the activation energies for the oxidation of these three metal ions are similar.

Despite the fact that U(IV) is a 2-equivalent reductant, its oxidation to U(VI) by O_2 is not accomplished in a single 2-equivalent step. It has been shown (21) that this reaction occurs by a chain mechanism involving the 1-equivalent steps

$$U(V) + O_2 \rightarrow U(VI) + HO_2,$$

$$U(IV) + HO_2 \rightarrow U(V) + H_2O_2.$$

This mechanism involves the formation of the unstable intermediates HO_2 and U(V), but is favored over the direct 2-equivalent oxidation, because of the "amplification factor" introduced by the chain reaction. While this also applies to a number of other reactions between 2-equivalent oxidants and reductants (e.g., the oxidation of $SO_3^=$ by O_2) these do not include any examples of reaction between two metal ions. Thus, the Tl(I)–Tl(III) exchange and the oxidation of U(IV) by Tl(III) (22), which could, in principle, occur by analogous mechanisms, appear to be simple bimolecular reactions.

REDUCTION OF METAL IONS BY MOLECULAR HYDROGEN

Molecular hydrogen reacts homogeneously with a number of metal ions in aqueous solution, reducing them to metallic form or to compounds of lower valence (23). The kinetics of the primary steps in these reactions are summarized in Table III.

TABLE III

Reduction of metal ions by hydrogen

Ion	Kinetics	E (kcal)	$\Delta S^{\ddagger}$ (e.u.)	Reference
Cu^{2+}	$k[H_2][Cu^{2+}]$	26.6	−10	24
Hg^{2+}	$k[H_2][Hg^{2+}]$	18.1	−12	25
Hg_2^{2+}	$k[H_2][Hg_2^{2+}]$	20.4	−10	25
Ag^+ (I)	$k[H_2][Ag^+]$	24.0	−6	26
Ag^+ (II)	$k[H_2][Ag^+]^2$	14.7	−25	26
MnO_4^-	$k[H_2][MnO_4^-]$	14.7	−17	27
$Ag^+ + MnO_4^-$*	$k[H_2][Ag^+][MnO_4^-]$	9.3	−26	27

*Ag^+—Catalyzed reaction between MnO_4^- and H_2.

Since the formation of H atoms (or H_2^+ ions) in aqueous solution is energetically very unfavorable, hydrogen might be expected to behave as a 2-equivalent reductant in these reactions.

The reactions of hydrogen with Hg^{++}, Hg_2^{++}, and MnO_4^- are consistent with this. For example, the mechanism of the reduction of Hg^{2+} to Hg_2^{2+} is probably

$$Hg^{2+} + H_2 \xrightarrow{\text{slow}} Hg + 2H^+,$$

$$Hg + Hg^{2+} \xrightarrow{\text{fast}} Hg_2^{2+}.$$

This mechanism is plausible on energetic as well as kinetic grounds, since the proposed rate-determining step, in which a Hg atom is formed, is exothermic by 27 kcal (23). Similar considerations apply to the reduction of Hg_2^{2+} and of MnO_4^-. In each of these cases the rate-determining step appears to be a 2-equivalent reduction, leading to the formation of Hg_2 and Mn(V), respectively, as intermediates.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

From the standpoint of the principle of equivalence change, the homogeneous bimolecular reactions of H_2 with Cu^{2+} and with Ag^+ are, however, surprising. Cu^{2+} is a 1-equivalent oxidant and either type II mechanism would involve a rate-determining step

$$Cu^{2+} + H_2 \rightarrow Cu^+ + H^+ + H \qquad (\Delta H^\circ \sim 54 \text{ kcal})$$

or

$$Cu^{2+} + H_2 \rightarrow Cu + 2H^+ \qquad (\Delta H^\circ \sim 66 \text{ kcal}),$$

which is energetically inconsistent with the observed activation energy of 26 kcal. The mechanism of the reduction of Cu^{2+} to Cu^+ by H_2 has actually been shown (28) to be

$$Cu^{2+} + H_2 \overset{k}{\rightleftharpoons} CuH^+ + H^+,$$

$$CuH^+ + Cu^{2+} \rightarrow 2Cu^+ + H^+.$$

It is thus apparent that in reactions such as this, where the oxidant and reductant form an intermediate complex which is stabilized by covalent bonding, the principle of equivalence change offers little guidance as to the probable kinetics and mechanism.

The reduction of Ag^+ by H_2 also appears to proceed through the formation of covalently bonded hydride intermediates. It is of interest that two paths are observed for this reaction, in which the rate-determining steps involve the heterolytic and homolytic splitting of hydrogen, respectively,

$$Ag^+ + H_2 \rightarrow AgH + H^+,$$

$$2Ag^+ + H_2 \rightarrow 2AgH^+.$$

Despite the fact that the latter reaction is termolecular, it is favored relative to the alternative bimolecular path, by its lower activation energy (14.7 vs. 24 kcal) and predominates at lower temperatures. Similarly the marked susceptibility of the reduction of MnO_4^- by H_2, to catalysis by Ag^+, is due to a termolecular rate-determining step,

$$Ag^+ + MnO_4^- + H_2 \rightarrow AgH + MnO_4^{2-} + H^+,$$

which competes with the bimolecular uncatalyzed reaction because of its lower activation energy (9.3 vs. 14.7 kcal).

These observations prompt some comment on the question of the relative probabilities of bimolecular and termolecular reactions in general. Some measure of this is provided by the difference in entropy of activation for the two types of processes. In solution, this difference is normally only about 10 e.u., corresponding to a factor of about 100 in the rate constant. This is the equivalent of a difference in activation energy of only about 3000 cal at 25°. Even at reactant concentrations as low as 0.001 M an activation energy difference of about 7000 cal will equalize the rates. Since variations of activation energy of this order, even among closely related reactions in solution, are fairly common the widespread emphasis which is encountered in the literature on kinetics on the improbability of termolecular reactions is somewhat misleading. This is particularly relevant to reactions of the type considered here, in which the presence of alternative bimolecular and termolecular paths (the latter having a lower activation energy) is an intrinsic feature.

ON THE THEORY OF ELECTROCHEMICAL AND CHEMICAL ELECTRON TRANSFER PROCESSES[1]

R. A. MARCUS

ABSTRACT

Kinetic studies of simple electron transfer systems in solution and at electrodes have revealed a number of interesting and simplifying features. The chemical reactions also represent one of the very few cases in kinetics where it has been possible to make reasonable calculations of the absolute rate constant without introducing adjustable parameters or arbitrary assumptions. Because of their comparative simplicity, these processes also serve as a useful kinetic tool for investigating ion–solvent–electrode interactions.

In the present paper the writer's recent theoretical investigations are summarized and used to interpret data obtained from both solution and electrode studies. Various phenomena are discussed in the light of this theory and several predictions of behavior are made. The topics considered include effects of changing the overpotential or the standard free energy of reaction, the ionic structure, temperature, salt concentration, solvent, and electrode material. Both the parallelism between chemical and electrochemical transfers and the role played by the electrostatic image in the latter case are discussed. A classification of reactants is employed throughout, based in part on differences in the theoretical treatment.

INTRODUCTION

In 1952 Libby (19) interpreted the behavior of some isotopic exchange electron transfer reactions in terms of the Franck–Condon principle, a suggestion which served to stimulate much further experimental and theoretical work. About the same time, Randles (31) discussed the rates of simple electron transfer electrode processes in terms of related concepts. This work was followed several years later by Rudolph J. Marcus, Zwolinski, and Eyring's investigation of an electron tunnelling mechanism for electron transfer (28) and by Taube's evidence that a bridge-activated complex may serve as an intermediate in some cases (38). Each of these stimulating contributions was qualitative (19, 31, 38) or semiempirical in nature (28).

More recently the writer has formulated a quantitative theory of electron transfers in solution (20) and at electrodes (26). It is free from arbitrary assumptions and adjustable parameters. In its present form it was devised for *simple* electron transfer reactions in which no rupture or formation of chemical bonds occurs in the transfer step.

THEORY

The basic assumption of the theory is that only a weak electronic interaction of the two reacting species is required for a simple electron transfer process to occur. The reactants may be ions or molecules and, in the electrode system, the electrode and an ion or molecule. Several deductions may be made quantum mechanically from this basic assumption:

(1) The electronic configuration and therefore the charge distribution of the activated complex are inordinately sensitive to the atomic configuration of the medium (as well as to that of the reactants). In this respect and in its consequent mode of treatment it is apparently unique among activated complexes, but it has much in common with the "polaron" (30), the *F*-center (30), and the "solvated electron".

(2) During the course of a reactive encounter, the atomic configuration of the entire

[1]*Manuscript received July 6, 1958.*
Contribution from the Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn 1, N.Y. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

system gradually changes from one characteristic of the reactants to one characteristic of the products. At the same time the electronic configuration undergoes a corresponding change, following this atomic configurational change adiabatically (27).

(3) As in any reaction, the activated complex can possess one of many possible atomic configurations of positions and momenta, but in the present case the configuration must satisfy a severe energy restriction (20). In *this* atomic configuration, a hypothetical system possessing the electronic wave function (and therefore the ionic charges) of the reactants must have the same energy as that of a hypothetical system possessing the electronic wave function of the products in the same configuration.

An infinite number of atomic configurations can satisfy this energy condition, but only a group of these contribute to the macroscopic or "thermodynamic" properties of the activated complex, namely those which minimize its free energy of formation from the reactants.

In setting up an expression for the reaction rate, the atomic configuration of the system outside the co-ordination shell of each reactant was treated as forming a continuous dielectric medium (20, 26). The configuration of the co-ordination shells themselves was expressed in terms of structural properties such as bond force constants and lengths, using statistical mechanics (22). Special methods involving "nonequilibrium" electrostatic considerations were developed for solving the minimization of free-energy problem subject to the energy restriction (21, 25). The group of atomic configurations constituting the activated complex could not be in electrostatic equilibrium with both hypothetical charge distributions at the same time.

On the basis of theoretical considerations it seems appropriate to classify the reactants somewhat loosely into three groups. Class I consists of those species for which the co-ordination shell of the oxidized form has essentially the same interatomic distances as does that of the reduced form. Class II consists of those in which the bonds of one form have become slightly stretched or compressed compared with the other form. Class III consists of those in which large stretching or compression has occurred.

Examples of Class I include (35) MnO_4^-–MnO_4^{-2} and probably $Fe(CN)_6^{-3}$–$Fe(CN)_6^{-4}$. Examples of Class II include many hydrated metal cations such as $Fe(H_2O)_6^{+3}$–$Fe(H_2O)_6^{+2}$, and those of Class III include (3, 6) $Co(NH_3)_6^{+3}$–$Co(NH_3)_6^{+2}$ and $Cr(H_2O)_6^{+3}$–$Cr(H_2O)_6^{+2}$.

The equations given below were derived for reactants of Class I. Some modifications appropriate to the other classes are noted.

THEORETICAL EQUATIONS

Using as a reaction co-ordinate either a solvent polarization co-ordinate or a movement of either reacting ion relative to the solvent, the following relation can be deduced for both solution and electrode–electron transfer rate constants (20, 26):

$$k = A' e^{-\Delta F^*/RT} \qquad [1]$$

where ΔF^* is defined below and where A' is of the order of 10^{15} cc mole^{-1} sec^{-1} and 5×10^4 cm sec^{-1} for solution and electrode processes, respectively.* Defining the activation energy, E_a, in the usual way as $-\partial \ln k/\partial(1/RT)$ and neglecting the minor temperature dependence of A' we find:

**The exact value of A' is under current study. It depends both on the detailed nature of the reaction co-ordinate and on the value of the collision frequency of two uncharged species. Derivations of a high value (10, 20) for the bimolecular collision frequency in solution can be shown to be overestimates for the system under consideration.*

For personal use only.

[2] $$k = A\, e^{-E_a/RT}$$

where

[3] $$E_a = \Delta F^* + T\Delta S^*$$

[4] $$A = A'\, e^{\Delta S^*/RT}$$

[5] $$\Delta S^* = -\partial \Delta F^*/\partial T.$$

ΔF^* represents the change in free energy of ion–ion and ion–solvent interactions accompanying the formation of the activated complex from the reactants:

solution

[6] $$\Delta F^* = w^* + m^2\lambda$$

[7] $$-(2m+1)\lambda = \Delta F^0 + w - w^*$$

electrode

[8] $$\Delta F^* = w^* + m^2\lambda/2$$

[9] $$-(2m+1)\lambda/2 = -ne\eta_a + w - w^*$$

[10] $$\lambda = n^2e^2(1/a - 1/r)\,(1/D_{op} - 1/D_s).$$

The following symbols are employed in these equations:

w^*, w = Work required to bring the two reactants together and the two products together, respectively, from infinity to the positions they would occupy in the activated complex. For the electrode system, w^* and w denote the work required to transport the reactant and the product to the electrode, respectively.

m, λ = Defined by equations [7], [9], and [10].

n = Number of electrons transferred from one reactant to the other (i.e., from a reactant to the electrode, for the electrode case).

e = Unit of electronic charge.

a = Ionic radius (including region occupied by co-ordination shell). If the radii of the two ionic reactants differ, and have values a_1 and a_2, then $2/a = (1/a_1)+(1/a_2)$.

r = Interionic distance in the activated complex or, for the electrode case, twice the distance from the electrode to the center of the ion.

D_{op} = Square of the refractive index.

D_s = Static dielectric constant.

$\Delta F^\circ = -RT \ln K$, K being the equilibrium constant for the reaction at the given salt concentration. ΔF° will be called the "standard" free energy of reaction.

η_a = Activation overpotential (zero for equilibrium at the given salt concentration).

INTERPRETATION OF THE EQUATIONS

Experimentally, various properties of the electron transfer rate constants of both processes can be measured: their dependence on standard free energy or activation overpotential; their dependence on ionic structure; the extent of parallelism between both rate constants for a series of reactants; the frequency factor and activation energy; the dependence of rate constants on added salts, on the solvent medium, and on the electrode material and surface contamination. The equations will be examined with these features in mind.

The theoretical equations of the two processes are closely related. Typically in each

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

case, ΔF^* decreases with increasing a, decreasing ne, decreasing r, increasing D_{op}, decreasing D_s (except for the latter's effect, more important perhaps, on w^* and w), and increasingly negative ΔF° or $-ne\,\eta_a$. This behavior has a simple physical interpretation related to the ease with which the energy restriction discussed earlier can be satisfied (23, 24).

For example, ion–solvent interactions decrease with increasing ionic radius a, so that there would be a smaller energy difference between the two hypothetical charge distributions in the original atomic configuration of the reactants and therefore a smaller reorganization would be needed to equalize the two energies. Similarly, the smaller the charge transferred, ne, or the smaller the distance between the reactants (or between the ion and its electrostatic image in the electrode), the less the medium can discriminate energywise between the two hypothetical charge distributions and therefore the less the reorganization needed for energy equalization. A larger optical dielectric constant, D_{op}, serves to partially neutralize the electrostatic fields of the charges and therefore to reduce their energy difference for a given atomic configuration. The more D_s approaches D_{op}, the smaller the dipolar contribution to the electrical polarization of the medium and the less the necessary rearrangement of the atoms (at least for zero ΔF° or zero η_a).

The RHS of equations [7] and [9] has an interesting interpretation. The effective driving force of the reaction is not really the free energy difference (ΔF° or $-ne\,\eta_a$) between reactants and products when the reacting species are far apart but rather when they are in the positions they occupy in the activated complex. These quantities are simply the $\Delta F^\circ+w-w^*$ and $-ne\,\eta_a+w-w^*$ of equations [7] and [9]. By lowering the free energy of the final state of the system relative to that of the initial state, these terms reduce the amount of necessary reorganization of atomic configuration of the initial state in order to satisfy the energy restriction (24).

One difference between the two sets of equations is that λ in equations [6] and [7] for the homogeneous system has become $\lambda/2$ for the electrode system. This difference can be attributed to the absence of one half of the dielectric medium in the electrode case. (Effectively, the charge is transferred from the ion to its electrostatic image, and the metal surface bisects the line drawn between the two.)

The theoretical expressions for ΔF^* and ΔS^* of Classes II and III naturally would contain additional terms. Interesting suggestions concerning these classes have been made by several groups (e.g., 1, 3, 6, 9, 14, 29).

INTERPRETATION OF THE DATA

The data will be discussed from the point of view of the various factors influencing the reaction rate.

"Standard" Free Energy Change or Activation Overpotential

The influence of this factor alone on the rate constant, holding the other factors essentially constant, is more easily investigated for the electrode process. When w and w^* are sufficiently small, it can be deduced from equations [1], [8], and [9] that the transfer coefficient—$\partial \ln k/\partial (ne\,\eta_a)$—is 0.5, a value found in a number of simple electron transfer processes (11, 14, 33). Complexation of the reacting species with added salt can change this coefficient (11) but equation [8] does not apply to such systems.

The quantitative effect of ΔF° on the homogeneous bimolecular rate constants has been measured experimentally for some nonspherical reactants (4, 5). While ion–solvent interactions in these systems (oxidation of hydroquinone-like compounds) were not as simple as assumed in equation [6] and an atom transfer mechanism could not be ruled out, reasonable agreement with the experimental rate constants was found (24).

Ionic Structure

The effect of ion size on the rates of homogeneous reactions is most conveniently studied using isotopic exchange reactions whose reactants merely exchange their charges, for then ΔF° and w^*-w are both zero, and m of equation [6] is simply $\frac{1}{2}$. The factor of ion size has been extensively investigated by Wahl and co-workers (8, 35, 39, 40). The rates of large ions, probably of Class I, were found to be much larger than those of the smaller ions, $MnO_4^{-1,-2}$ and $Fe(CN)_6^{-3,-4}$. Again, the latter two systems had comparable rates in spite of the greater Coulombic repulsion in the second case, perhaps because of the larger size of the iron cyanide ion (4.5 vs. 2.9 Å). Rather good agreement was obtained between experimental and calculated rate constants using the theoretical equations, taking into consideration the absence of adjustable parameters (16).

The cobalt–nitrogen bonded complexes probably are members of Class III (3, 6) and the rates are therefore extremely slow. The marked increase in rate (3, 18) in the sequence $Co(NH_3)_6^{+3,+2}$, $Co(en)_3^{+3,+2}$, and $Co(phen)_3^{+3,+2}$ may be partly a reflection of increasing ionic size, and partly a reflection of ligand field (29) effects.

The ferrous–ferric system is probably of Class II, and its rate (36) is correspondingly much less than that of the MnO_4^- or $Fe(CN)_6^{-3}$ systems. Nevertheless, its rate greatly exceeds that (1) of $Cr(H_2O)_6^{+3,+2}$, a probable member of Class III (3). Reasonable agreement between calculated and experimental results for the $Fe(H_2O)_6^{+3,+2}$ was found by adapting the theory to Class II reactants (22). Thus far, there is no experimental evidence which definitely establishes either an electron or an atom transfer mechanism for these homogeneous isotopic exchange reactions of hydrated cations. The general parallelism of various rates in the two processes discussed below suggests, however, a common electron transfer mechanism.

Parallelism Between Rates in Solution and at Electrodes

When similar mechanisms are operative, the theoretical equations suggest a close parallelism between the rates of the two processes, particularly when ΔF° and η_a are zero and the work terms are small. The parallelism becomes very close, therefore, when the rates of isotopic exchange reactions are compared with the corresponding electrochemical exchange currents.

The distance of closest approach for the electrode case will depend on the surface contamination and on the strength of metal–solvent binding. Let us write, therefore, $r = 2a+2b$ for this system and $r = 2a$ for the homogeneous system. When the work terms are negligible, we obtain

$$\Delta F^*_{\text{solution}} = \lambda_s^2/4,\ \Delta F^*_{\text{electrode}} = \lambda_e^2/8 \qquad [11]$$

where

$$\lambda_e/\lambda_s = (1+2b/a)/(1+b/a). \qquad [12]$$

The chemical and electrochemical electron transfer rates of the systems (3, 32, 36, 39) $Cr(H_2O)_6^{+3,+2}$, $Fe(H_2O)_6^{+3,+2}$, and $Fe(CN)_6^{-3,-4}$ both increase in the order given as do those of the systems (15, 16, 18) $Co(NH_3)_6^{+3,+2}$ and $Co(en)_3^{+3,+2}$. The absolute rates of various electrochemical processes (32) are in the general range expected from the values of the chemical rate constants, but further work is desirable, both theoretically on Class II and Class III systems as well as experimentally on salt effects and hydrolysis effects.

Frequency Factor and Activation Energy

While some application (24) of the theory has been made to the hydroquinone oxidations referred to earlier, the frequency factors, A, of the simpler isotopic exchange

reactions have been much more revealing. For the latter systems, ΔF^* equals $w^*+\lambda/4$. Correspondingly, ΔS^* is the sum of two terms. The first, $-\partial w^*/\partial T$, is the usual entropy change which results when two ions are brought together. The second, $-(d\lambda/dT)/4$, is the entropy of formation of the "nonequilibrium" atomic configurations from the equilibrium ones at the same r in order to satisfy the energy restriction. Its value may be computed from equation [10]. It proves to be very small for reactants of Class I.

Application of the theoretical equations to Class I reactants by the writer led to good agreement between experimental and calculated frequency factors for the $MnO_4^{-1,-2}$ system and (within a factor of 50) for the $Fe(CN)_6^{-3,-4}$ system, the latter system having an extremely small frequency factor (40).† These results suggest that the probability of adiabatic reaction may be of the order of unity, at least for these systems. The frequency factors of Class I reactants provide the most direct measure of this probability factor.

Many of the hydrated metal cations, which are mainly of Class II, tend to hydrolyze and form other complexes easily. In a careful investigation Silverman and Dodson (36) unravelled the rate constant of the $Fe^{+3,+2}$ system from those involving $FeOH^{+2}$ and others. The frequency factor was very small. If $-\partial w^*/\partial T$ is fairly small at the high ionic strengths (high acidity) needed to minimize hydrolysis, this low A-value indicates an additional negative contribution to ΔS^*.

Recently, Baker, Basolo, and Neumann (3) have reported a most interesting result of a very high frequency factor, 5×10^{16} cc mole^{-1} sec^{-1}, for a Class III system, $Co(phen)_3^{+3,+2}$. One simple extension of the present theory for Class I systems to those of Class III can provide an explanation of this possible behavior if the following reaction has an appreciably positive entropy change:

$$Co(phen)_3^{+3}+M(phen)_3^{+2} = Co(phen)_3^{+2}+M(phen)_3^{+3},$$

where $M(phen)_3^{+2}$ is some reactant of Class I or II, such as $Fe(phen)_3^{+2}$. No entropy data appear to have been reported for this process. A similarly high frequency factor has been reported for another Class III system (2*a*), $Cr(H_2O)_6^{+3,+2}$, but this reaction may be complicated by hydrolysis effects.

The frequency factors of the electrochemical systems have not been measured in the same detail. However, in a recent study, Randles and Somerton (32) found them to be typically in the range 3×10^2 to 3×10^4 cm sec^{-1}. The reactants were primarily hydrated metal cations and so were mostly of Class II. In one system, $Cr(CN)_6^{-3,-4}$, a rather low frequency factor (10 cm sec^{-1}) was found. The electrostatic repulsion between ion and electrode was estimated to be large for this system, and the low A-value was attributed to a small transition probability factor because of the increased r. However, we see from equation [10] that there is also an image term present. This term would tend to favor small r's. An alternative explanation for the A-value could be given on the basis of the usual sign of $-\partial w^*/\partial T$. When two reactants of like sign approach each other, the enhanced electrostatic field polarizes the solvent more strongly and causes a negative ΔS^*. A different region for testing the appropriateness of assuming simple Coulombic interactions and their consequent effects on ΔS^* is suggested in the concluding section.

Activation energies for several electrochemical electron transfers have been measured (32). While these results cannot be precisely compared with those of the isotopic exchange reactions (36, 40), partly because there was no detailed examination of hydrolysis and

†*The data were extrapolated to infinite dilution, taking cognizance of the comparative insensitivity of the theoretical activation energy to salt effects.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

salt effects, the results tentatively indicate the activation energies of the electrode reactions to be more than one-half those of the corresponding exchange processes. Should this result prove to be generally true (at least for Class I and Class II reactants) one possible interpretation would be that the distance between the ion in the activated complex and its electrical image exceeds twice the ionic radius (cf. equations [10] and [11]). An independent, approximate estimate of this distance may be obtainable from an experiment suggested in the concluding section.

Salt Effects

Using a rough model for ionic interactions the w and w^* terms were calculated by the writer for several Class I reactions and compared with the data of Wahl and co-workers (35, 40). Fair agreement was obtained using no adjustable parameters.

No detailed study of salt effects for simple electron transfers at electrodes appears to have been reported. Therefore it is not yet possible to adequately test the usual assumption (one not made here) that the work required to transport an ion from the body of the solution to the electrode, w^* or w, equals the ionic charge multiplied by the difference of potential at the initial and final positions of the ion, these potentials being computed in the absence of the ion. This assumption is clearly valid when the ionic charge is so small that it does not perturb the configuration of the remaining ions. It is also clearly invalid at the point of zero electrode charge. At this point, the work term estimated on the basis of the above assumption is zero, whereas it actually equals the free energy of interaction of the ion with the image. For infinite dilution, the latter term is $-q^2/2D_s r$, q being the ionic charge, while for dilute salt solutions, an approximate (unpublished) estimate of it is $(-q^2/2D_s r)\exp(-\kappa r)$, κ being the usual Debye κ.

Solvent Effects

Solvent effects for simple electron transfers will occur, according to the theory, whenever there is a change in dielectric constant, refractive index, ionic radius, or standard free energy of reaction. Changes in composition of the co-ordination shell, which may include the solvent, naturally alter a, $\Delta F°$, and the ease of intramolecular compression or stretching. In addition, there are effects which were not incorporated in the theory, effects such as changes in ion-pairing, selective solvation of solvent mixtures, and a change of the mechanism itself. A possible example of selective solvation (7) has been described (2).

Heavy water has been used as a solvent in several studies (e.g., 13, 37). Hudis and Dodson (13) have demonstrated the importance, when hydrolyzed species and other complexes are present, of determining the various equilibrium constants so that meaningful electron transfer rate constants for the different species can be obtained and solvent effects evaluated. The rate constant for $Fe^{+3,+2}$ was smaller by a factor of 2 in D_2O (13), while that of $NpO_2^{+2,+1}$ was smaller by a somewhat smaller factor (37). A qualitative interpretation of the solvent effects can be given in terms of atom transfer (13, 37) or electron transfer (23) theories. Thus far, however, comparative studies in the two solvents do not permit either mechanism to be distinguished from the other. This situation results from the fact that ions have different solvation energies in the two media (17), so that water does not behave as an inert solvent.

The rate of the $Co(NH_3)_6^{+3,+2}$ reaction appears to be faster in liquid ammonia (12) than in water, where it was immeasurably slow (18). The activation energy was high, being in the range found for two other Class III compounds (2*a*, 3). Possible explanations

for the solvent effect include a change of mechanism, such as a dissociation (12) or possibly a hydrolyzed intermediate, $Co(NH_3)_5NH_2^{+2}$. However, the effect of pH on the reaction rate is not known.

Effects of Electrode Material

A dependence of rate constant on electrode material will occur if there is any change in surface contamination (32) and possible metal–solvent binding, or if electrode charge density at a given η_a changes sufficiently to alter w^* or w. The rate constants measured for one system with several solid electrodes underwent no great variation (within a factor of 10) but were much smaller than that found for a mercury electrode (32).

The Image Force Law and Its Implications

The role of the electrostatic image has been generally ignored in electrochemical theories. A recent investigation (34) of the quantum limitations of the image force law for a vacuum is reassuring. It has been applied by the writer to dielectric media and to electrochemical theory.

The effect of this image is to partially neutralize the field of the ion and to reduce, thereby, the configurational rearrangement free energy needed to satisfy the energy restriction. It is noteworthy that its calculated effect remains, even at salt concentrations sufficiently large as to make w^* and w negligible. This is because it is impossible for the ionic atmosphere in the activated complex to neutralize the ion–image interactions of the two different hypothetical charge distributions at the same time. A compromise configuration results. A similar behavior exists in the homogeneous case, where the $1/r$ term remains even if w^* and w are zero.

At the point of zero electrode charge there is a net, shielded Coulombic attraction between the ion and its image, which is quite large for very dilute solutions. According to the theory a positive ΔS^* would result, since the attraction lowers the entropy of the solvation. A measurement of the frequency factor in this region would permit a determination of this ΔS^*.

If this prediction is verified for Class I reactants, it will be interesting to compare ΔS^* with the theoretical estimates.

ON THE EQUIVALENT REDOX POTENTIAL OF AQUEOUS SOLUTIONS UNDER IONIZING RADIATION[1]

I. H. S. Henderson, E. G. Lovering, R. L. Haines, and E. J. Casey

ABSTRACT

A study of the electrochemical behavior of aqueous solutions irradiated by Co^{60} γ- and 50–300-kv X-rays is being carried out. Results are presented which show that aqueous solutions of various electrolytes over a pH range of 0.0 to 14.0 attain a steady-state potential under irradiation.

This steady-state potential, whose existence was postulated by Dainton and Collinson (who called it the equivalent redox potential), has been determined to be −0.85 v with respect to a hydrogen electrode in the same solution. This value is a property of water and is independent of pH, solute, temperature and radiation energy, and intensity within the ranges investigated.

Electrodes under irradiation sometimes show potentials different from the potential of the bulk electrolyte. This is considered to be a result of selective adsorption of one or more primary or secondary radiation products. These transient phenomena depend upon source intensity and solute concentration and disappear when irradiation is stopped.

INTRODUCTION

There is much indirect evidence that among the primary products formed during gamma- or X-irradiation of water and aqueous solutions are hydrogen atoms and hydroxyl radicals. These species undergo further reaction to produce hydrogen molecules and hydrogen peroxide as well as oxidation or reduction products which are characteristic of the solute. Ions such as ceric, iodate, nitrate, and permanganate are reduced; while others, such as ferrous, iodide, nitrite, sulphite, and oxalate are oxidized. Allen (1) suggested that prolonged irradiation should lead ultimately to an equilibrium concentration ratio of a redox system. This idea was further developed by Dainton and Collinson (2), who proposed in 1950 that a solution under irradiation attained an equivalent redox potential (ERP) when the rate of oxidation equalled the rate of reduction in the solution. This ERP was assumed to be a characteristic of the solvent and hence independent of the nature and, within limits, the amount of solute. From a consideration of the normal electrode potentials of a number of systems whose behavior under irradiation had been investigated, Dainton and Collinson estimated the ERP for X-, γ-, and α-irradiation to be in the neighborhood of −0.95 v, and that increasing acidity displaced the ERP to even more negative values and that there was an increasing tendency toward oxidation in acid media. These authors argued further that, since on thermodynamic grounds the potential expected from an equimolar solution of H and OH would be somewhat positive, there was a possibility that the highly oxidizing species OH^+ was also present. Its fate was suggested to be $OH^+ + OH^- = H_2O_2$. (Hydrogen molecule ions may also be present as secondary intermediate products.) The effect of oxygen on the ERP was not considered in detail, but from work of Amphlett (3) on ferrous *o*-phenothroline they suggested (2) that the effect of oxygen, and hence HO_2, on the ERP was small.

A survey of the literature reveals that there have been few attempts to follow the course of radiation-induced chemical reactions by measurement of the potential changes in solution during and after irradiation. Veselovsky (4) has reviewed some of his own and other Russian work in this field, and has concluded that the concept of the equivalent

[1]*Manuscript received September 19, 1958.*
Contribution from Defence Research Chemical Laboratories, Ottawa, Canada. Issued as D.R.C.L. Report No. 292. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

redox potential was invalid because it ignored the kinetic behavior of electrochemical processes determining the steady-state potentials of the solution. His argument was based essentially on the observations that (*a*) platinum electrodes in γ-irradiated aqueous solutions of sulphuric acid, particularly in the presence of oxalate, showed a potential corresponding to that of the hydrogen electrode and (*b*) that electrodes such as a silver electrode in oxygen-saturated solution showed potentials approaching that of the oxygen electrode and in oxygen-free solutions showed a potential from 0.5 to 0.6 v more noble than a hydrogen electrode in the same solution. Under his conditions, the steady-state potentials measured were those due to individual radical species in the presence of excess oxidizing or reducing agent, and hence these observations have no direct bearing on the Dainton–Collinson ERP concept, which referred to the steady state obtained when the rates of oxidation and reduction processes in the bulk solution were equal.

Mendvedovsky *et al.* (5) used platinum electrodes in irradiated solutions of 0.8 *N* sulphuric acid containing ferrous and ferric sulphates to follow potential changes in the solution. Ferrous sulphate was oxidized during irradiation until the ratio of ferrous sulphate to ferric sulphate was steady at approximately 0.02. Similar results were obtained in perchloric acid solution and it was concluded that the potential measured was a property only of the final ratio of ferric ion to ferrous ion, and not a direct effect of radiation on the electrodes.

In a recent technical note, Clark (6) has reported the effect of Co^{60} γ-irradiation on the potential behavior of platinum and stainless steel electrodes in 0.1 *N* sulphuric acid under atmospheres of hydrogen, nitrogen, and air. Measurements were made at 85° C using Ag/Ag_2SO_4 reference electrodes. Under irradiation, the Pt electrode potential rapidly approached the hydrogen potential. When irradiation was interrupted, the potential decreased to -0.85 v with respect to the hydrogen electrode. In an experiment carried out under hydrogen, a trace of potassium bromide was added to the electrolyte. The electrode continued to show the hydrogen potential until the hydrogen flow was interrupted, after which the potential of the solution decreased to approximately -0.78 v with respect to the hydrogen electrode in the same solution. When irradiation was discontinued, the potential decreased further to at least -0.82 v.

Because of the apparent uncertainty (3) concerning the existence and the properties of the ERP, it was decided that part of our study of the electrochemical properties of aqueous solutions under irradiation should include an investigation of this concept.

EXPERIMENTAL METHOD

Glass cells containing test solutions were irradiated using a 300-curie Co^{60} source at a distance of approximately 20 cm, or using a 50- to 300-kv, 3-kw X-ray machine. The maximum energies absorbed were approximately 6×10^{13} ev cm^{-3} sec^{-1} and 6×10^{14} ev cm^{-3} sec^{-1} respectively. Each cell had appropriate electrode assemblies so that the potential of the solution could be followed during irradiation.

Potentials were measured using a General Radio type 1230A Electrometer-Amplifier with input resistance settings of 10^{10} ohms or higher.

The solutions were made up using conductivity water and reagent grade chemicals. The acid used was redistilled reagent grade sulphuric acid. Supporting electrolyte solutions for certain experiments were pre-electrolyzed under an argon atmosphere after being placed in the cells. A small weighed amount of "redox indicator" reagent was added directly to the electrolyte in the test flasks. The materials used for this purpose were potassium iodide, potassium iodate, iron, thallium, and cerous sulphate at concentrations of 10^{-4} to 10^{-3} molar.

Argon was deoxygenated by passage over Cu at 700° C and Ti at 800–900° C in a purification train. Stirring was achieved either by magnetic stirrers rotated at about 300 r.p.m., or by vibrating stirrers operated by 60 cycle a-c. Irradiations were carried out at room temperature.

Figure 1 is the photograph of a 100-ml cell which was a round bottom flask having a number of ground glass outlets through which were inserted reference electrodes, polarizing electrodes, and gas inlet tubes. The internal indicator electrode was a piece of Pt gauze, and the external reference was Hg/Hg_2SO_4 for cells containing sulphuric acid as supporting electrolyte, $Pb/PbSO_4$ for cells containing sodium sulphate with $pH < 10$, and Hg/HgO for solutions with $pH > 10$. The reference electrodes were connected to the cell solutions by salt bridges filled with supporting electrolyte of the same concentration as in the reference electrode and cell. The data of Hamer (7) and Harned and Hamer (8) were used to determine the potentials of the Hg/Hg_2SO_4 and $Pb/PbSO_4$

electrodes, and that of Akerlof and Bender (10) for the Hg/HgO electrode in alkaline solutions. The potential of each electrode was checked periodically against a hydrogen electrode in the same solution.

RESULTS AND DISCUSSION

The Steady State ERP

Under the experimental conditions of the present work, radiation had no effect on the reference electrodes, probably because (*a*) the concentration changes brought about by irradiation were small by comparison with the amount of redox material in the reference electrodes, and (*b*) the reference electrodes were exposed to radiation of much lower intensity than that experienced by the test cells.

The iodine redox indicator system in sulphuric acid, sodium sulphate, and potassium hydroxide was found to be the most convenient in the present work over the pH range investigated because of the absence of insoluble products at high pH.

In general, each electrolyte when irradiated showed a definite and reproducible potential, whose value (referred to the normal hydrogen electrode) was to a first approximation a function only of the hydrogen ion activity of the electrolyte, and was independent of the supporting electrolyte and indicator redox system. However, in several cases to be discussed later, transient potential behavior occurred during the first few minutes of the irradiation or after irradiation was stopped. In the iodine-containing electrolytes these transients were found to be the smallest. They were absent at high pH, but were present at low pH in sufficient degree to introduce an uncertainty of ± 0.03 v in the values of the ERP.

Table I gives the final steady-state values obtained during irradiation of several

†Hydrogen electrode in the same solution.

electrolytes. The values for solutions containing iodine and iron are listed as measured; thallium, cerium, and pure acid values listed have been corrected for transient potential behavior. The mean values at each pH are plotted in Fig. 2 as ERP (referred to the normal hydrogen electrode, NHE) vs. pH with a line of calculated slope 0.059 drawn through the points. Hence, the value of the ERP was consistently 0.85 v more noble than the hydrogen electrode in the same solution or 0.38 v less noble than the oxygen electrode.

The steady-state values were found to be independent of the intensity and maximum energy of the radiation within the limits of the available equipment.

The Approach to the ERP

The steady-state potentials obtained in these experiments were attained after a period of irradiation which varied with (*a*) redox indicator concentration, (*b*) source intensity, and (*c*) the number of coulombs by which the system had been oxidized or reduced away from the ERP prior to irradiation.

Figure 3, a plot of potential vs. time for iodine in 1.0 *M* sulphuric acid, shows the typical behavior of solutions in approaching the steady-state value. In the example shown, the solution was reduced with respect to the ERP before irradiation began. The effect of the radiation was to oxidize the solution to a potential of −0.84 v. The value remained constant when the irradiation was stopped, as shown by the regions labelled "open-circuit". After the solution had been oxidized with respect to the ERP by passage of current, irradiation reduced the solution until it again showed a potential of −0.84 v.

The redox reactions taking place as the system approached the ERP were followed by continuous measurement of potential during the irradiation, but the experimental conditions reported here were not conducive to a straightforward analysis of the reaction kinetics. The type of curve obtained for *E* vs. time was a function of redox indicator concentration, the standard electrode potential of the redox system, and the intensity

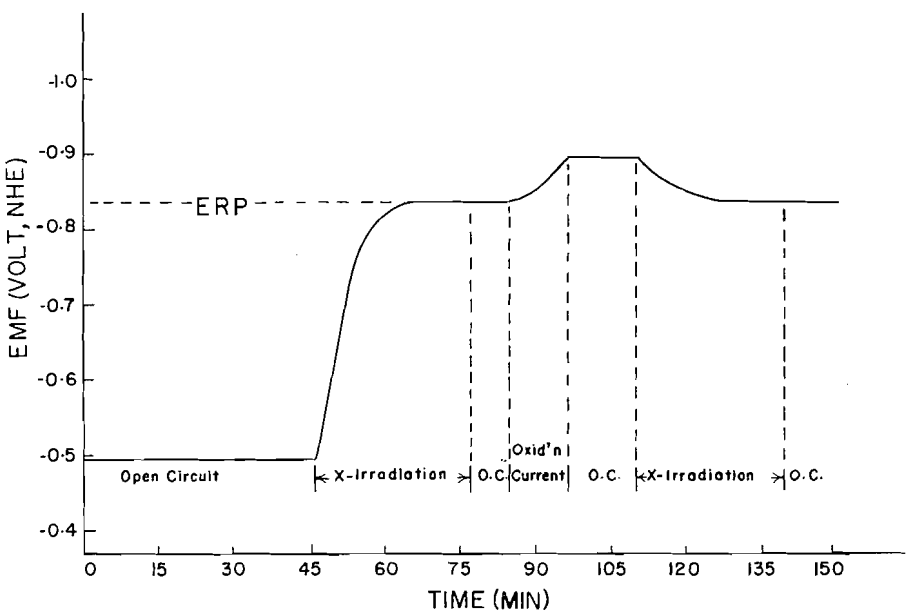

FIG. 3. Potential vs. time curve showing approach to steady state during irradiation for solution (i) reduced and (ii) oxidized with respect to the steady-state value.

and energy of the radiation. The presence of trace impurities such as oxygen had a marked effect on the shape of the potential–time curves. The same steady-state value (within ± 0.005 v for a given solution) was reached whether the solution had been previously oxidized or reduced with respect to the steady-state value, and the potential remained constant for a period of minutes to hours after irradiation ceased. In this respect the results differed from those of Clark (6). However, ERP's estimated from his results at 85° are in good agreement with the present results at 25° C. This indicates that there is no marked temperature coefficient for the ERP, a result consistent with the behavior of free radical reactions.

The potentials listed in Table I as ERP values were not characteristic of the electrode metal under irradiation. In general, the potentials shown by the electrode when a steady state had been attained during irradiation did not change on interruption of the irradiation, and fresh Pt or Au electrodes inserted into the cell after irradiation showed the same potentials as the irradiated electrodes. In one experiment, carried out in potassium hydroxide solution, in which cerium oxides were deposited on a nickel electrode, both the nickel electrode and a platinum electrode in the same solution attained the same steady-state potential. It appeared that prolonged irradiation of platinum electrodes in sulphuric acid solution made the electrode more noble by as much as 0.03 v with respect to a fresh platinum electrode. This effect was not reproducible. Whenever it was observed, the ERP value was taken as the potential shown by fresh electrodes, since the irradiated electrodes after a cleaning in hot concentrated nitric acid solution and flaming to yellow heat showed the same potential as did the fresh electrodes. (This could not be attributed to an overvoltage effect on the electrodes because for all measurements the input resistance of the electrometer was at least 10^{10} ohms, whereas polarization was not observed unless the electrometer input resistance was less than 10^7 ohms.)

Transient Phenomena

With carefully pre-electrolyzed and deoxygenated strong acids containing iodide, a change in the potential of the indicator electrode to a value different from that of the bulk electrolyte was observed when irradiation began. Upon cessation of irradiation the potential quickly (within 3 minutes) assumed the potential of the electrolyte. This phenomenon could be attributed to the preferential adsorption of hydrogen atoms on the platinum electrode which made the electrode show a potential more "hydrogen-like" than the potential of the solution during irradiation. This effect, which was reproducible, was more pronounced with greater source intensities and in the absence of solutes with which hydrogen atoms could react before becoming adsorbed on the electrode. It is interesting to note that, since oxygen is an effective trap for hydrogen atoms via the formation of HO_2, the effect was not observed unless great care was taken to exclude oxygen, or at least until sufficient energy had been absorbed by the solutions to remove oxygen as HO_2. The transient potential behavior observed by Clark (6), obtained with much higher γ-intensities than used in the present work, could also be interpreted as due to hydrogen atom or hydrogen molecule adsorption, even in experiments carried out in cells exposed to the air, since it is probable that the radiation intensity was high enough for hydrogen atoms to remove oxygen from the system as HO_2 more rapidly than oxygen could redissolve in the solution. When there was sufficient oxygen present to react with all the hydrogen atoms during irradiation, platinum electrodes showed a transient potential a few millivolts more noble than that of the solution. This effect was attributable in part to the action of HO_2 radicals on the electrode, and confirms an observation made by Veselovsky.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In the present work, the indicator ions were usually present in sufficient concentration to be potential determining at and near the ERP; that is, the hydrogen or hydrogen atom concentration was not great enough to produce a direct effect on the potential of the platinum electrode. Attempts to measure the ERP of ultrapure water or sulphuric acid would be expected to show transient potentials during irradiation, even though irradiation leads to a steady-state hydrogen peroxide concentration (9), because of the relatively large adsorbability of hydrogen atoms on the platinum surface. Thus Zalkind *et al.* (11), during irradiation of oxygen-free solutions of acid and alkali, have observed potentials as high as 0.95 v between platinum and gold electrodes in the same solution. The effect was attributed to the selective adsorption of hydrogen on platinum and hydroxyl radicals on gold.

General Considerations

The relationship between ERP and the hydrogen and oxygen electrodes indicates that this potential is a characteristic of water and its hydrogen ion concentration only, and is not affected by source intensity or energy. Thus the results of the present investigation are in general agreement with the theory proposed by Dainton and Collinson, and demonstrate its essential correctness, although their estimated value for the ERP (−0.95 v) is more noble by about 0.1 v than the experimental value reported here. In agreement with Dainton and Collinson, it is not anticipated that the ERP of solutions exposed to α- or β-radiation would be very different from the value observed for γ- and X-radiation. However, if α- and β-emitters were present in the solution during measurement, it is expected that the very high local radical density produced would give rise to even larger transient effects than those observed with γ- and X-rays.

The ERP may be expected to change from the value of −0.85 v reported here when the activity of the water is appreciably decreased. In this case the ERP would be a function of the solute and its concentration. The ERP may also be expected to be a function of the ratio of the volume of solution to the area of catalytic surface for combination of radicals, since this would interfere with the steady-state radical concentrations (cf. ref. 4 concerning production of hydrogen peroxide during irradiation of suspensions of zinc oxide).

Veselovsky has pointed out that the application of electrochemical techniques can be a useful tool in the study of a number of problems in radiation chemistry. As an example of this, he has estimated the influence of oxalate on the rate of production of hydrogen atoms (the "G" value) during irradiation of aqueous sulphuric acid. The results which have been obtained in the present work indicate that solvent and solute effects on both the "G" values for primary and secondary products and on the ERP, as well as the influence of radiation on solids (electrodes) in contact with aqueous solution, may also be investigated electrochemically. The major advantage of these techniques over other kinetic methods employed in radiation chemistry is that they permit the investigator to follow and to monitor continuously the chemical changes taking place during irradiation.

LIMITING CONDUCTANCE OF LYONIUM AND LYATE IONS[1]

MARTIN KILPATRICK

ABSTRACT

The problem of proton mobility has been considered in H_2O–CH_3OH, H_2O–D_2O, and H_2O–H_2O_2 solvents from the current viewpoint of the mechanism of proton mobility for aqueous solutions. Mixed solvents are more complicated in that one must consider the relative basicity and acidity of the species competing for the protons. It is concluded that for dilute solutions of $HClO_4$, where water is replaced by hydrogen peroxide, the decrease in equivalent conductance relative to that of KCl in the same solvent mixture is due to the partial elimination of the proton transfer process.

For highly acidic non-aqueous solvents of high dielectric constants such as HF, HCN, and HCOOH, the problem of the weakness of the usual "strong" acids of aqueous solution makes a direct determination of the limiting equivalent conductances difficult. In the case of anhydrous hydrogen fluoride the available experimental evidence indicates that the limiting conductance of the lyonium ion is approximately the same as that of the potassium ion but the lyate ion has a higher limiting conductance than other stable anions.

The higher proton mobility in ice leads one to expect that hydrogen-bonded systems may be found where the conductivity may approach that of electronic semiconductors.

In a paper presented before the 111th meeting of the Electrochemical Society in May, 1957, and to be published elsewhere (1), the author showed that the limiting equivalent conductance of perchloric acid relative to that of potassium perchlorate decreased as the water was replaced by hydrogen peroxide. The experimental results (2) are presented in Fig. 1 together with some more recent results (3) for 0.01 *M* HCl relative to 0.01 *M* KCl when water is replaced by methyl alcohol and some earlier work on the replacement of H_2O by D_2O (4). The conclusion was drawn that the change in structure of the solvent decreased the conductance by proton transfer.

Thomas and Maass (5) offer an alternative explanation on the basis of the reduction of the number of ions in the solution owing to a decrease in the degree of dissociation of the acid. They confirm the experimental results of Shanley *et al.* (2) for sulphuric acid and report additional data for HNO_3 and HF in H_2O–H_2O_2 mixtures at higher concentrations of acid.

The generally accepted view for water is that in addition to 1 water molecule associated with the proton there are 3 molecules of water hydrogen bonded to the hydroxonium ion (6). This cluster forms the inner hydration shell with an outer shell held more loosely by hydrogen bonding. The inner-shell hydrogen bonds are strengthened by dipole interaction and will be less subject to disorder from thermal motion. Within the inner sphere, proton jumps take place readily while transfer of protons beyond this depends on reorientation of the water molecules. From the fact that the number of hydrogen bonds decreases with increasing temperature while the extra mobility increases, Krogh-Moe (7) concludes that the rate cannot be proportional to the mean number of hydrogen bonds. That the model is only a qualitative one has been pointed by Samoilov (8), who points out that the tetrahedral arrangement in ice is partially washed out by the thermal motion. The X-ray diffraction studies show the number of nearest neighbors to be 4.6 at 30° (9).

A mixed solvent will be more complex than a solvent composed of one species and one must deal with strong electrolytes and consider at least three effects. The two solvent

[1]*Manuscript received July 5, 1958.*
Contribution from the Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

species will compete for the proton to form the lyonium ion; there will also be competition for the inner hydration sphere and orientation of both species at the periphery of the inner hydration shell. For low mole fractions of alcohol, the lyonium ions will be hydronium ions and we might conclude that the interference with the proton transfer process occurs first in the outer hydration zone. As the mole fraction of alcohol increases, some water is replaced by alcohol in the inner zone and the lyonium ions are partially alcohol-solvated protons. The increase beyond 90% alcohol is due to proton transfers via alcohol molecules. In this case HCl does show indications of being a weak acid in alcohol but this is not true of perchloric acid.

In the case of the replacement of water by hydrogen peroxide, while it is true that acids become weaker due to the more acidic nature of hydrogen peroxide, perchloric acid at low concentration is a strong electrolyte (10) and at the high dielectric constant of the solvent there should not be ion pairs. The first effect should be in the outer shell and at very high mole fractions of H_2O_2 the lyonium ion will become protons solvated with H_2O_2. It is not impossible that in pure anhydrous H_2O_2 we might have chain transfer via proton jumps between H_2O_2 molecules but these will have to be practically in the absence of water. In other words the curve in Fig. 1 may rise steeply beyond 99%.

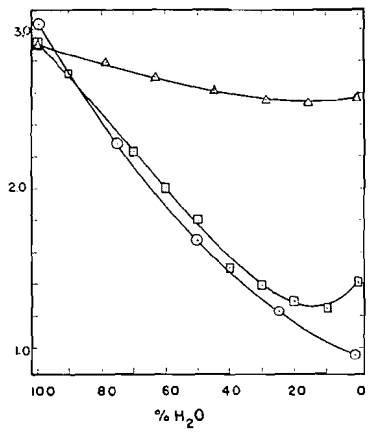

FIG. 1. Ratio of equivalent conductances:
△ H_2O-D_2O; $\Lambda^{\cdot 01}_{HCl+DCl}/\Lambda^{\cdot 01}_{KCl}$

□ H_2O-CH_3OH; $\Lambda^{\cdot 01}_{HCl}/\Lambda^{\cdot 01}_{KCl}$

In the case of the H_2O–D_2O mixtures the D_2O will have a good fraction of the protons at equal mole fractions but even here the non-linearity above the viscosity effect shows that there is some interference in the proton and deuteron transfers. The fraction of protons on H_2O and D_2O could be determined by nuclear magnetic resonance measurements.

Figure 2 shows the ratio of $\Lambda^{\circ}_{KOH}/\Lambda^{\circ}_{KCl}$ for water peroxide solvents and $\Lambda_{KOH}/\Lambda_{KCl}$ at 0.01 molar concentration for water – methyl alcohol. Here the curves are quite different, the addition of methyl alcohol decreasing the proton transfer via the water molecule and showing no appreciable minimum, although there are methoxide ions present at the high alcohol side (11). In the case of hydrogen peroxide – water solvents the hydroxyl ions react with the hydrogen peroxide to form hydroperoxide ions and the lyate ions, hydroxyl and hydroperoxide have both water and hydrogen peroxide in the inner solvation shell.

○ H_2O—H_2O_2; $\Lambda^\circ_{KOH}/\Lambda^\circ_{KClO_4}$
□ H_2O-CH_3OH; $\Lambda^{\cdot 01}_{KOH}/\Lambda^{\cdot 01}_{KCl}$

The ratio $\Lambda^\circ_{HCl}/\Lambda^\circ_{KCl}$ from the data of Barak and Hartley (12) at 25° C gives 0.98 instead of 1.03 (Fig. 2); so we conclude there is no minimum in the curve and there is no increase in the limiting conductance of the methoxide ion in methyl alcohol. Gurney (13) explains this fact by pointing out that although proton jumps do take place, that owing to the removal of the dipole moment on addition of a proton, such proton jumps take place equally well in the direction of the field as against the field.

LIMITING EQUIVALENT CONDUCTANCES IN NON-AQUEOUS SOLUTIONS

In ammonia the lyonium and lyate ions are the ammonium and amide ions.

$$NH_3 + NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$

The ions show no abnormal electrical mobility and Gurney (13) accepts the Hückel explanation on the basis that the ammonium ion has no dipole moment. There is no experimental evidence for abnormal limiting conductance in the solvents hydrazine, pyridine, hydroxylamine, and other amines.

In the highly acidic solvents both the sulphuric acid cation and anion show abnormal conductance (13). In anhydrous hydrogen fluoride the fluoride ion has been shown to have a higher mobility than the borofluoride and antimony hexafluoride ions but there is no evidence that the solvated proton shows abnormal electrical conductance (14). The problem in determining the limiting conductance in this solvent is that the strong acids of aqueous solution are weak electrolytes in anhydrous hydrogen fluoride.

The measurements were based on the fluoride ion accepting property of antimony pentafluoride to form the stable SbF_6^- anion. Conductance measurements showed Na^+ SbF_6^- to be a strong electrolyte and the equivalent conductance of $H_2{}^+F$ SbF_6^- was shown to be less than that of the sodium salt, leading to the conclusion that $l^\circ_{H_2{}^+F} < l^\circ_{Na^+}$. The success of these experiments depended on the exclusion of water, as H_2O would compete with HF for the protons and SbF_6^- would be converted to an hydroxy acid (15). If these experiments are reliable we have a case where the anion of the solvent may be chain conducting but the cation has no abnormal conductance.

Liquid hydrogen cyanide is another high dielectric solvent where the "strong" acids of aqueous solution are weak. Other cations and anions show equivalent conductances

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

which are three or four times higher than the corresponding ions in water (16). The problem of the limiting conductance of the lyonium ion could probably be attacked in analogous fashion to that used for HF. The ion product is 2×10^{-19} (17), and reasoning by analogy from aqueous solution (18) the $[Cu(CN)_2]^-$ anion is quite stable.

$$\begin{array}{l} HCN + HCN \rightleftharpoons H^+\cdot HCN + CN^- \\ \qquad\qquad\qquad\qquad\quad + \\ \qquad\qquad\qquad\qquad\quad CuCN \\ \qquad\qquad\qquad\qquad\quad \downarrow \\ \qquad\qquad\qquad\qquad\quad [Cu(CN)_2]^- \end{array}$$

A comparison of $\Lambda°$ for $NaCu(CN)_2$ and $\Lambda°$ for a solution of CuCN in anhydrous hydrocyanic acid should decide the ratio $l°_{H^+}/l°_{Na^+}$. Mercuric cyanide might be more suitable than cuprous cyanide provided it was sufficiently soluble. The solubilities of non-ionic cyanides in anhydrous hydrocyanic acid are not accurately known. There is no evidence of abnormal conductance of lyonium or lyate ions in acetonitrile.

The carboxylic acids with the exception of formic acids are solvents of low dielectric constant. Potentiometric studies in formic acid (dielectric constant 58 at 16° C) (19) indicate the "strong" acids of water are weak electrolytes. Like sulphuric acid, the autoprotolysis of formic acid is so high that the solvent conductance makes conductivity studies of acids difficult to interpret (20). Formamide (21) and dimethyl formamide (22) are high dielectric solvents but show no abnormal conductance.

PROTON CONDUCTANCE IN SOLIDS

Bjerrum (23) reviews the dielectric properties and conductance of ice and calculates the energy of activation for proton jumps to be 2.5 kcal for $H_3{}^+O$ and 4.7 kcal for HO^-, which corresponds to an over-all E for the equivalent conductance of 3.1 at 0° which is lower than the experimental value. More recent measurements (24) for polycrystalline ice yield a value of 3.9 kcal at $-15°$ C compared to Bjerrum's calculated value of 2.5. These calculations are based on equivalent conductances $\Lambda° = 298$ with $l°_{H^+} = 215$ and $l°_{HO^-} = 83$ at 0° C. Very recently Conway and Bockris (25) emphasized that the conclusions of Bradley (26) and Owston (27) based on specific conductance are on an unsound basis and they recomputed the absolute mobilities and concluded the rate-determining step in ice is proton tunneling but in water the rate-determining step is controlled by the rotation of the water molecules. This conclusion brings their findings into qualitative agreement with the earlier results of Eigen (28), who determined experimentally both the ion product and the proton mobility. Eigen finds that the protonic mobility is appreciably higher in ice than in water but that a small amount of fluoride markedly reduces the conductivity. Ice crystallized from a solution of caesium fluoride has been found to have H–F incorporated in the lattice (29). Certain polyhydric alcohols show a marked change in conductivity with temperature below their melting points and a proton transfer, and molecular rotation mechanism has been proposed (30).

The structures of HF and HCN (31, 32) in the solid state are both known to be linear chains but no conductance measurements have been reported on the solids. The high proton mobility in ice indicates that H—O···H bonds are involved but this phenomenon should also apply to H—N···H bonds.

Polyvalent metal ions form polynuclear complexes in aqueous solution, and the structures are often held together by oxygen or hydrogen bridges (33). In the corrosion of metals the nature of the solid films is similar to the species found in solution, and proton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

mobility along the hydrogen bonds may be the rate-determining step. There have also been some studies of the conductance of hydrocarbon films (34) which indicate that some organic compounds are semiconducting.

SOME CONSIDERATIONS ON THE ROLE OF PROTON TUNNELING IN CERTAIN CHARGE TRANSFER PROCESSES[1]

B. E. CONWAY

ABSTRACT

Quantum mechanical tunneling of H atoms in certain reactions can have a rate comparable with that of the corresponding classical reaction. Proton tunneling appears to be the mechanism of proton transport in ice. Further studies of this mechanism have been made by determination of the a-c. and d-c. conductance of D_2O (and H_2O) ice under rigorous conditions of purification. Pre-electrolysis techniques have been applied to the ultrapurification of the D_2O and H_2O used for the conductance determinations. Isotopic ratios of conductance in solid H_2O and D_2O are obtained and discussed in terms of the mechanism of H^+ or D^+ transport in the solid and liquid substances. The theory of proton tunneling previously given is improved by using a quantal distribution function in the calculation of tunneling rates and better agreement with experiment is then obtained. The theoretical isotopic ratio of conductances by the tunneling mechanism in the ices is similar to that found experimentally and smaller than that predicted classically.

Since the proton tunneling theory is quantitatively successful in the case of conductance of ice, its examination for other electrochemical processes involving H is necessary. A favorable case for investigation is the electrochemical hydrogen evolution reaction for which the barrier height for tunneling can be varied. Tunneling probabilities are calculated for proton and deuteron discharge at mercury from acid solutions using the theory of Eckart. At intermediate overpotentials the Tafel equation is still obeyed; at low overpotentials a linear current–potential relation is found as in the classical theory. H/D separation factors are calculated for the tunneling mechanism and it is shown that at intermediate and high overpotentials, tunneling leads to values of the separation factor comparable with those deduced classically. Only at low electrochemical rates of H or D production are high separation factors predicted. The tunneling mechanism, however, is distinguishable from the classical mechanism by a new criterion: the Tafel slopes for the tunneling process would be considerably larger (0.2–0.3) than those arising classically (0.12) for a simple discharge mechanism assuming a symmetry factor of 0.5. It is concluded that in certain cases proton tunneling may occur simultaneously with the classical reaction in electrochemical proton discharge and lead to anomalous Tafel '*b*' values which are sometimes observed experimentally.

INTRODUCTION

The possibility of quantum mechanical effects arising from tunneling was recognized by Wigner (1) and Bell (2) as a factor to be considered in the kinetics of chemical reactions involving H or D. Several attempts to find experimental support for this effect have been made and some evidence has been given for quantum mechanical tunneling of H ions or atoms in the following reactions: (i) the ortho-para hydrogen conversion (2, 3); (ii) the rate-determining proton transfer step in the bromination of 2-carbethoxy-cyclopentanone (4); and (iii) in the proton conductance of water and ice (5, 6). In the latter case, the tunneling process is the only one which can account for the high mobility of protons in ice. In the first two cases it appears that only participation of the quantum mechanical process in the net reaction occurs, i.e., quantum and classical processes can occur at comparable rates. However, in proton mobility in ice and water, the quantum mechanical process appears to be considerably faster and hence preferred, although in *liquid* water the over-all rate is limited by water dipole rotation (5).

Further tests of the quantum mechanical mechanism should be possible in the case of conductance of ice by determination of the specific conductance, and hence mobility, of deuterons in heavy ice. Measurements of the specific conductance of ice prepared from 99.8% D_2O have been carried out and estimates of the ionic mobility of D^+ in D_2O ice are made.

[1]*Manuscript received June 29, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

Tunneling effects in heterogeneous proton transfer reactions, e.g., in the electrolytic hydrogen evolution reaction may be expected, since in the case of the proton transfer conductance of water and ice such effects occur. The electrochemical kinetic behavior, which would arise if quantum mechanical penetration of the potential barrier at an electrode took place, is deduced and criteria for recognition of the effect are presented.

EXPERIMENTAL

Conductance determinations have been made on D_2O ice (and H_2O ice) and the corresponding liquids by the a-c. and d-c. methods. Alternating-current measurements were made by means of a shielded Wheatstone bridge with capacitative and ohmic components; the a-c. source was a Hewlett–Packard precision oscillator. Direct-current measurements were made on the same bridge but with only ohmic components using a Leeds and Northrup galvanometer of sensitivity 4.5×10^{-9} amp/mm. The cell is shown in Fig. 1 and was mounted in a heavy brass cylinder in order to provide electromagnetic shielding and a region of thermal inertia around the cell. Palladium electrodes were used (cf. 7). The apparatus was maintained at various temperatures constant to 0.05° C in a refrigerated thermostat.

Water was distilled five times: (i) from a Barnstead still; (ii) from alkaline permanganate; (iii) through a column of glass beads heated to 450° C, through which hydrogen

(free from CO_2 and purified by passage through two liquid air traps) was passed; (iv) again in H_2 in another vessel; and (v) in a fused silica still *in vacuo* under conditions of smooth evaporation from a still water surface. Fifteen milliliters of water was then passed over into the silica conductance vessel in order to wash it and then removed through a capillary tube. Further distillation was then carried out *in vacuo* and another 15 ml of water passed into the cell. This water was then frozen by dipping the lower end of the cell into a bath at $-20°$ C (cf. 7). After several freezing and melting cycles *in vacuo*, ice as clear as liquid water was obtained and no flaws, cracks, or bubbles were visible. After clear ice was obtained, the cell was placed in the thermostat and allowed to stand for some days in order to anneal the ice. Melting, evacuation, and freezing cycles were continued until no further change in conductance occurred.

In previous determinations (7, 8) of the conductance of ice, the conductance of the water used for the preparation of the ice was about fifty times that (9) corresponding to the equilibrium concentrations of H_3O^+ and OH^- ions. The significance of the conductance values thus determined may hence be somewhat limited, since the impurities present in the water may, particularly if acidic, contribute to the conductance in the ice. At the same time, the impurities, if slightly soluble in the ice, create defects in the crystal which could change the behavior of the ice. Such impurities have, for example, a marked effect on the dielectric properties of ice (10).

In the present work, electrolytic purification of the water using a mercury cathode has been carried out, in addition to multiple distillation. Electrolytic purification of "pure solvents" was first used in conductance studies by Jaffé (11) and Schroeder (12), who found that considerable diminution of conductance of ordinarily purified solvents could be achieved by this procedure. Water from stage (iii) (see above) was distilled from stage (iv) into the vessel A in Fig. 1, containing mercury which had been anodically purified, dried, and redistilled in a Hewlett still. After 48 hours' electrolysis at 500 v with the mercury cathodic, the liquid was run out into the silica vessel B. Stage (v) distillation was then carried out. A further electrolysis could be carried out at the mercury drop in the cell C (Fig. 1), but this made no significant difference to the specific conductance of the water prior to freezing, which was between 3 and 5 $\times 10^{-7}$ mho cm^{-1}.

Deuterium oxide (99.8%) was purified by distillation, as above, using steps (iv) with N_2 to (v) and subjected to electrolytic purification as described; measurements were made as in the case of water.

Determinations of the cell constant were made at $25.00 \pm 0.02°$ C by means of the Jones and Bradshaw (13) standard solutions of KCl. The resistance of the empty cell under vacuum, and that of the leads in the circuit, was about 100 times greater than that of the cell containing ice, and could only be measured with difficulty.

RESULTS

After several cycles of freezing and melting *in vacuo* the resistance of the D_2O ice reached an approximately constant value. The value was checked by melting the ice and returning the liquid to the silica still and repeating the operation. The a-c. resistance (1000 c.p.s.) measured at $-2.0°$ C varied between 2.30×10^6 and 2.74×10^6, whilst the corresponding d-c. values varied from 16.4×10^6 to 19.6×10^6 ohms. The cell constant was 24.8 so that the specific conductances (κ) were $1.6 \pm 0.5 \times 10^{-8}$ mho cm^{-1} for 1000 c.p.s. a-c. and $2.2 \pm 0.6 \times 10^{-9}$ mho cm^{-1} for d-c. The corresponding values for H_2O ice were $3.5 \pm 0.5 \times 10^{-8}$ and $5.2 \pm 0.7 \times 10^{-9}$ mho cm^{-1}. The latter value falls near to that given by Bradley (7) for H_2O ice at $-2.0°$ C viz. $10^{-8.24}$ mho cm^{-1}. There is some spread in the

present results but it is comparable with that (0.14 in $\log_{10} \kappa$) found in previous determinations (7). The determinations reported here lead to an isotopic ratio of specific conductance of $\kappa_{H_2O\ ice}/\kappa_{D_2O\ ice} = 2.2$ for a-c. measurements (1000 c.p.s.) and 2.4 for for d-c. measurements.

The a-c. values of conductance are frequency dependent as shown in Fig. 2. The d-c. measurements are time dependent as found previously with H_2O ice (7, 14). The values at "zero time" are recorded above and a typical time dependence is shown in Fig. 3; the effect probably arises from build-up of a space charge near the electrodes when the field is applied. This is probably the cause of the frequency dependence of the a-c. conductance and with this in mind we have plotted in Fig. 2 the a-c. conductance as a function of the square root of the reciprocal frequency; the relationship is not, however, linear, as might be expected if there were a concentration polarization of charge carriers when the field was applied. More complex effects are probably involved. Consideration of the significance of the results will therefore be limited to the "zero time" d-c. values.

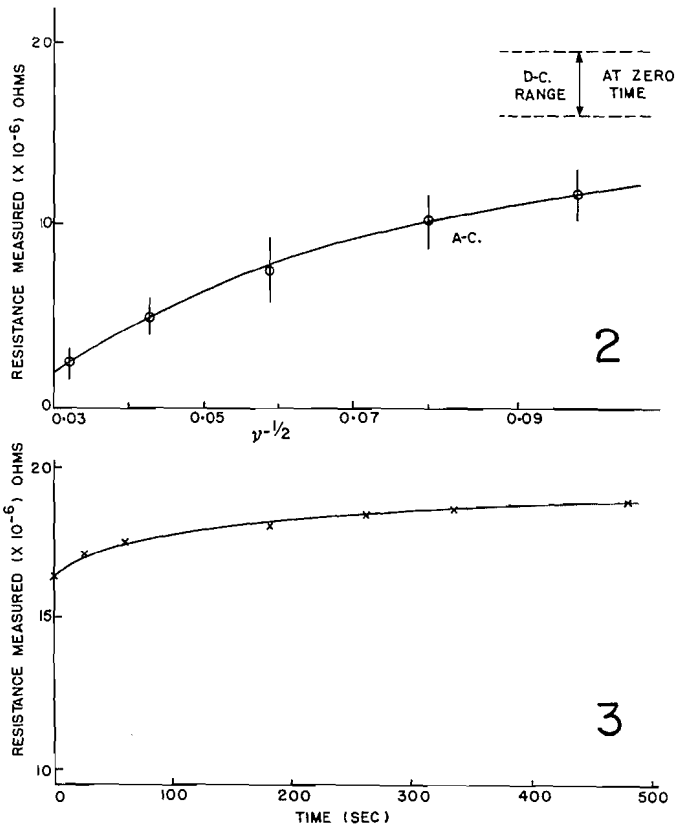

FIG. 2. Comparison of a-c. and d-c. resistance of D_2O ice.
FIG. 3. Typical time variation of d-c. resistance of D_2O ice.

DISCUSSION

1. Proton and Deuteron Mobility and Tunneling in Ice

The above measurements on specific conductance cannot be directly interpreted in terms of ionic mobility and hence of ionic transport mechanisms until values (cf. 15) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

the concentration of D_3O^+ and OD^- ions in the ice are available. In H_2O ice the concentration of the corresponding protium species is known (15) and leads to a proton mobility of 1.9×10^{-1} cm^2 sec^{-1} v^{-1}. The theoretical rate of quantum mechanical tunneling of protons in an unperturbed ice structure (i.e., with all H bonds linear and no librational motion) has been calculated (5, 6) using the theory of Eckart (16) for the permeability and a value of 7×10^{-1} cm^2 sec^{-1} v^{-1} for the tunneling rate has been obtained. In the theory previously given (5) we have used, following Bell (2), the expression

$$N = \frac{N_0}{kT}\int_0^\infty P_w\, e^{-w/kT}dw \qquad [1]$$

in order to calculate the integral tunneling probability, where N is the number of penetrations of the barrier out of N_0 presentations of the particle at the barrier per second, w is the total energy of the particle, and P_w is the quantum mechanical tunneling probability for the particle of energy w, calculated from the theory of Eckart (16). For the OH bond, the vibrational half quantum is about 5 kcal mole^{-1}, so that it would be more correct to use a quantal distribution rather than the classical distribution function in equation [1]. Quantally, the total tunneling rate should then be written

$$N = N_0\,\frac{\sum_0^\infty (P_w.p\, e^{-(n+\frac{1}{2})h\nu_0/kT})}{\sum_0^\infty p.\, e^{-(n+\frac{1}{2})h\nu_0/kT}}, \qquad [2]$$

where n is the vibrational quantum number, ν_0 the ground state vibrational frequency of the OH or OD bond in H_3O^+ or D_3O^+, and p is the quantum weight assumed equal to unity. Since for the OH or OD vibration, $h\nu_0 \gg kT$, the value of N is closely approximated by the value of the *r.h.s* of equation [1] for $n = 0$, other terms contributing negligibly. If we identify N_0 with the frequency of presentations of the particle H or D at the barrier (cf. 2), the rate of tunneling between an H_3O^+ ion and a favorably oriented H_2O molecule follows from the theory previously given as

$$v = \nu\delta\,\frac{\phi_z}{kT}\,\frac{\sum_0^\infty (P_w.p.\, e^{-(n+\frac{1}{2})h\nu_0/kT})}{\sum_0^\infty p.\, e^{-(n+\frac{1}{2})h\nu_0/kT}}. \qquad [3]$$

When $n = 0$ and the particles predominantly approach the barrier with an energy $\frac{1}{2}h\nu_0$, P_w has the values 0.87 for H and 0.60 for D. In equation [3], ν is stretching frequency of the OH or OD bond in H_3O^+ or D_3O^+ undergoing dissociation, δ is the distance (2.8 Å) the proton is transferred per jump, and ϕ_z is the mean change of electrical energy of the particle per jump when unit field is applied; it has the value 1.53×10^{-20} erg (5). In an unperturbed structure with all OH$\cdots$O hydrogen bonds stationary and colinear, v would give the proton mobility. However, the ice is thermally perturbed in so far as each molecule executes librational oscillations in the lattice. Following the argument of Bernal and Fowler (17), the proton transfer rate will be modified from that given by v on account of the necessity that each OH bond be in a suitable orientation to that of the $2p_z$ partially hybridized lone pair orbitals on the oxygen atom of a neighboring water molecule, before transfer can occur. We have previously shown (5) that orientations*

**The orientation requirement discussed here is not the same as the reorientation involved when a proton migrates through liquid water. The molecules in ice are already the "correct way round" for proton transfer to occur, but their librative oscillations restrict proton tunneling since favorable mutual orientations of neighbors in their librational excursions only occur part of the time (17).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of H_3O^+ and neighboring H_2O molecules, mutually favorable for proton transfer by tunneling, occur with a probability of about $\frac{1}{9}$. Owing to the lower zero point librational energy of D_2O in D_2O ice, the librational excursions in the deuterium case will be smaller and the molecule will spend more of its time in orientations favorable to D^+ transfer. This is equivalent to the situation in liquid D_2O, which has a more ordered structure on account of the lower librational zero point energy than in liquid water. Calculations show that in the case of deuteron transfer in D_2O ice the probability factor for mutually favorable orientations is about $\frac{1}{7}$. Using these factors, the mobilities of H^+ and D^+ in their respective ices may now be calculated from equation [3], taking $\nu_{OH} = 1.12\times10^{14}$ sec^{-1} and $\nu_{OD} = (1.12/\sqrt{2})\times10^{14}$ sec^{-1}. The mobilities, u, are then

$$u_{H^+} = 0.11 \text{ and } u_{D^+} = 0.07 \text{ cm}^2 \text{ sec}^{-1} \text{ v}^{-1}.$$

From considerations based on the experimental value of the over-all specific conductance, u_{H^+} in H_2O–ice has been deduced as 0.19 cm^2 sec^{-1} v^{-1} (6). Use of the quantal distribution in equation [2] thus gives better agreement with experiment than that given by the semiclassical equation [1].

The mobility ratio for the H^+ and D^+ isotopic ions calculated from equation [1] is 6.1. That from equation [3] is only 1.6, i.e., near to that (1.4) for rate-determining rotation of H_2O or D_2O dipoles (5). However, although the isotopic ratios of conductance are now similar for the two mechanisms, the large increase of mobility on going from aqueous acid solutions to pure ice can only be explained in terms of a *transition* from rate-determining dipole rotation (in water) to rate-determining proton tunneling in ice. The dependence of anomalous mobility in alcoholic solutions on the length of the hydrocarbon function (5) has in any case confirmed the dipole rotational mechanism in the case of acid solutions.

It is now of interest to examine if the theory is consistent with the experimental data on the conductance of the heavy ice. We can only make mechanistic interpretations of the results if we can obtain the *mobility* from the experimental conductance. At the present time, we can only proceed further by making the not unreasonable assumption that the *ratio* of ionic products in H_2O ice and D_2O ice is the same as the corresponding ratio for liquid H_2O and D_2O, viz. (at 25° C) $1\times10^{-14} : 0.2\times10^{-14}$ (18). Some indication that this assumption is not unjustifiable is given by the following considerations: the difference of the heat of ionization of D_2O and H_2O is 0.94 kcal $mole^{-1}$ (19), and it is readily seen that this figure can account for the difference of the ionization constant to within 10%, so that isotopic entropy differences are not significant in determining the *ratio* of ionization constants of D_2O and H_2O. The difference of heat of ionization arises from the different zero-point energies of the species involved. In ice the same situation should hold and the ratio of ionization constants in H_2O and D_2O ices should be approximately equal to the corresponding ratio for the liquid phases if only heat terms are involved.

In ice at $-10°$ C, the concentration of protons is 5×10^{-11} g ion $l.^{-1}$ (15, 6). If we take the ratio of ionization constants as $1\times10^{-14}/0.2\times10^{-14}$ for H_2O and D_2O, the ratio of proton to deuteron concentrations in H_2O ice and D_2O ice, respectively, will be $(1/0.2)^{\frac{1}{2}}$ i.e., 2.23 : 1. The experimental isotopic d-c. conductance ratio is 5.2/2.2 i.e., 2.35. Hence the ratio of *mobilities** of H^+ and D^+ in their respective ices is about 1.1. The theoretical calculations predict a ratio of 1.6. This must be considered a satisfactory agreement in

**The transport numbers of* H^+ *in* H_2O *and* D^+ *in* D_2O *are approximately equal (viz. 0.64 and 0.66 respectively; see (6) and (34)).*

view of the several assumptions made. The measurements clearly support the tunneling mechanism both for protons and deuterons in ice. The classical mechanism predicts much lower mobilities (5) and an isotopic ratio of mobilities having the approximate value exp. $(\Delta_{D-H}\frac{1}{2}h\nu_0)/kT$ i.e., about 9, which is not observed experimentally. In the case of mobilities of H^+ and D^+ in ice, the isotopic ratio of tunneling rates is hence actually less than that predicted classically. This is contrary to what has usually been supposed for tunneling mechanisms.

2. Proton Tunneling at Electrodes

The quantitative success of the proton tunneling theory (5, 6) in the case of proton conductance in ice suggests that proton tunneling can participate in certain reactions as is also indicated in other cases (2, 4, 20). It is therefore of interest to examine the theory in relation to other electrochemical processes involving proton transfer.

Quantum mechanical effects in electrode processes were first considered by Gurney in 1932 (21) with respect to electrons. Bawn and Ogden (22) suggested that tunneling of protons and deuterons might explain the H/D electrolytic separation factors (s) at various metals and they deduced a value of s for tunneling of about 100. Such a value was experimentally observed by Appelby and Ogden (23) but has never been confirmed (24). On the basis of the theoretical calculations and the more usually observed values of s (from 3 to 10), it has generally been regarded that tunneling could not participate to any important extent in the cathodic hydrogen evolution reaction. However, the calculations of Bawn and Ogden were made on a basis which was not relevant to the case under consideration; thus the barrier widths which were assumed (1.5, 2.0, and 3.0 Å) are too large and no consideration of the effect of applied potential, which modifies the height of the potential energy barrier and hence the probability of tunneling, was made. For the proton transfer reaction

$$H_3O^+ + M + e \rightarrow H_2O + MH_{ads},$$

e.g., at a mercury electrode, the barrier height at the potential of zero charge is about 18 kcal mole^{-1} (25). The barrier width is calculated (cf. 25, 26) from the OH bond length in the hydroxonium ion, the radius of the hydroxonium ion (assumed approximately equal to that of water), and the HgH bond length (27). The width is found (25) to be between 0.55 and 0.50 Å. Such a width is consistent with the probable thickness of the double layer at mercury in acid solutions. For the calculation of the above figures, the "width" is taken to be the distance of the proton about to be discharged in the H_3O^+ ion from the position of the H atom adsorbed on the electrode surface. A barrier of width of 0.50–0.55 Å leads to a theoretical (25) classical heat of activation similar to that observed experimentally (28). The barrier width assumed by Bawn and Ogden is thus about four times too large and, since the tunneling probability is very sensitive to dimensional parameters of the barrier, the value of s calculated is likely to be in error. It is therefore desirable to calculate the tunneling probabilities for protons and deuterons for the more realistic barrier dimensions given above and as a function of electrode potential.

A barrier having a form similar to that arising from the intersection of two Morse curves may be expressed by the function

$$[4] \qquad V_{(x)} = Ae^{2\pi x/l}/(1+e^{2\pi x/l}) + Be^{2\pi x/l}/(1+e^{2\pi x/l})^2,$$

where $V_{(x)}$ is the potential energy at a distance x along the reaction co-ordinate for a barrier having a width of $2l$, A is the difference of potential energy between the final and initial states, and B is $4E^{\ddagger}$, where $E^{\ddagger}$ is the energy of activation, i.e., the value of V at the maximum of the curve, referred to $V = 0$ at $x = -l$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The solution of the Schroedinger equation when $V_{(x)}$ is given by equation [4] leads (16) to the permeability or probability of tunneling, P_w, as

$$[5] \qquad P_w = \frac{\cosh 2\pi(\alpha+\beta)-\cosh 2\pi(\alpha-\beta)}{\cosh 2\pi(\alpha+\beta)+\cosh \pi\frac{(B-c)^{\frac{1}{2}}}{c}},$$

where $c = h^2/2ml^2$, $\alpha = l/h(2mw)^{\frac{1}{2}}$, $\beta = l/h[2m(w-A)]^{\frac{1}{2}}$, m is the mass of the particle undergoing tunneling, and h is Planck's constant. w is the total energy of the particle approaching the barrier. The total number of particles penetrating the barrier per second is then given (2) by equations [1] or [2].

For tunneling at the mercury electrode interface we place $E^{\ddagger}$ equal to $E_0{}^{\ddagger}+\beta\Delta\phi F$, where β is the symmetry factor taken equal to 0.5, $\Delta\phi$ the rational electrode potential, and $E_0{}^{\ddagger}$ is the heat of activation at the potential of zero charge (i.e., about 18 kcal mole^{-1}); $2l$ is taken as 0.5 Å and m values are those for H and D ions. The probable value of A for proton transfer at the potential of zero charge is -2.5 kcal mole^{-1} (25). The value of A for deuteron transfer from H_2DO^+ ions differs from that for proton transfer by 1.1 kcal mole^{-1}, on account of isotopic differences of (i) OH and OD bond dissociation energies, (ii) heats of hydration, (iii) H and D ionization potentials, and (iv) heats of adsorption at mercury, as discussed by Conway (29) in calculations of the classical values of s for various reaction mechanisms. $E_0{}^{\ddagger}$ for deuteron transfer is 1.8 kcal larger than that for proton transfer (29). For various values of $\Delta\phi$, A becomes $A_0+\Delta\phi F$, where A_0 is the change of potential energy in the reaction at the potential of zero charge. The values of w in P_w and in the exponential in equation [1] are also changed to $w' = (w+\Delta\phi.F)$ for various values of w and $\Delta\phi$. P_w is then evaluated for a range of values of w' from 0.2×10^{-14} to 100×10^{-14} erg molecule^{-1} and the integral tunneling probability is obtained from equation [1]. The tunneling functions $P_{w'}\,e^{-w'/kT}$, from which N is evaluated, are shown in Figs. 4, 5, and 6 for five electrode potentials, three temperatures, and for the isotopes ${}_1^1H$ and ${}_1^2D$. In distinction to tunneling through a nuclear potential energy barrier, proton and deuteron tunneling rates are temperature dependent, since the distribution of energies of particles approaching the barrier is temperature dependent and the permeability for a given impact is a function of the total energy of the particle. The apparent energy of activation for a given barrier height is, however, lower than the corresponding classical value (2).

For the electrochemical reaction considered, the main points of interest are the dependence of the tunneling rate upon electrode potential and upon isotopic mass. It is seen from Fig. 7 that the dependence of tunneling probability upon isotopic mass is potential dependent. The values of the separation factor defined by

$$s = (C_D/C_H)_{soln}\cdot v_H/v_D,$$

where C refers to isotopic concentrations in the solution and v_H/v_D is the ratio of rates of discharge of the isotopic ions, may be calculated from the tunneling probabilities together with the ratio of concentrations of H_3O^+ and H_2DO^+ (e.g., in 0.1 N aqueous acid solutions) and the isotopic abundance ratio (30). $a_{H_3O^+}/a_{H_2DO^+}$ has been calculated previously (29) for this case and has a value of 2.6×10^2 in 0.1 N acid solution. Values of s, as a function of electrode potential, are given in Table I.

The separation factor calculated classically is almost independent of potential and has a value of 2.9 (29) for proton discharge at mercury (the experimental value is 3.1 ± 0.2). In isotopic separation work involving the usual analysis of evolved gases, current densities of at least 10^{-3} amp cm^{-2} are required in order to obtain workable rates of gas evolution.

$\Delta\phi$ v	0	0.25	0.50	0.75
s	12.40	5.0	1.6	0.7

The electrode potential at mercury is hence about -1 v (with respect to a hydrogen electrode in the same solution) for such a rate of evolution of gases. The value of s arising from the tunneling mechanism (Table I) is then comparable in magnitude with that calculated for classical transfer. The high values previously predicted (22) are misleading, since the relevant barrier dimensions were not used. Tunneling cannot therefore be excluded as a possible process in electrolytic proton transfer by reference to values of the separation factor, previously indicated as very high if tunneling occurred.

It is possible, however, to propose a new criterion for occurrence of tunneling in electrochemical proton transfer. Fig. 7 shows the logarithm of the integral tunneling probability (to which the electrochemical proton transfer rate is proportional) as a function of electrode potential for proton and deuteron transfer at mercury.

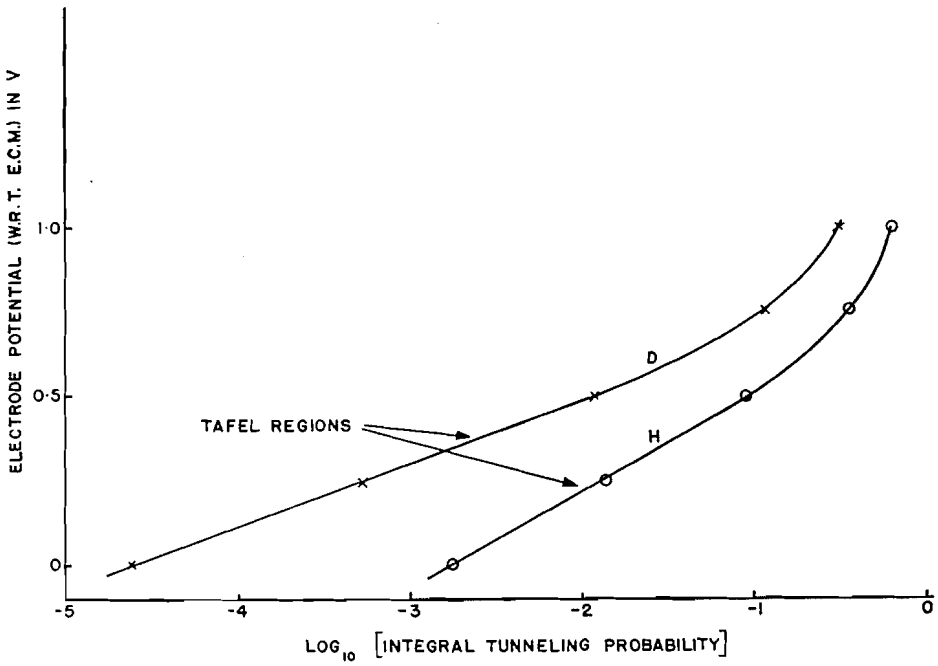

FIG. 7. Tunneling probability and electrode potential.

At intermediate electrode potentials, a linear $\Delta\phi$ – log (rate) law is obeyed, i.e., the Tafel equation holds as in classical proton transfer at an electrode. At very low overpotentials Ohm's law is obeyed (5) and hence a linear $\Delta\phi$ – (rate) law is followed, again as in the classical theory. At high electrode potentials there is some tendency for the tunneling rate to approach a limiting value. In the potential range where the behavior is approximated by the Tafel equation, the slope of the $\Delta\phi$ – log (rate) relationship (Fig. 7) has, however, a value of about 0.25 for proton discharge and 0.17 for deuteron discharge. The

values of these slopes would hence be diagnostic for tunneling transfer, since slopes as high as this do not follow from any mechanism yet proposed for the hydrogen evolution reaction assuming the symmetry factor to be about 0.5. In impure solutions, e.g., at Pb or Hg electrodes, Tafel slopes as high as 0.3 have been observed (33), which are difficult to explain on any of the previously discussed mechanisms (32) of the hydrogen evolution reaction unless unusual values of the symmetry factor are assumed. In impure solutions, the normal barrier height is probably raised as a result of poisoning of adsorption sites for H. Under these conditions the relative participation of proton tunneling compared with classical proton transfer may be enhanced, and hence higher Tafel slopes could arise; some participation of tunneling in the hydrogen evolution reaction at rhodium may account for the anomalous continuously increasing Tafel slope, with increasing overpotential observed for this metal (33). As in the generalized calculations of Bell (2), the tunneling probability calculated here for electrochemical proton transfer is actually larger than the corresponding classical probability, particularly at high cathodic potentials. Use of a quantal distribution in equation [1] instead of the classical one does not materially change the anomaly. In all proton transfer reactions hitherto considered with respect to quantum mechanical effects, only for the case of proton transfer in ice where the potential energy barrier is much lower than in the present case, is the expected tunneling rate actually observed. In the present, and in other cases examined by Bell (2, 4, 20), the experimental kinetic behavior indicates that participation of the classical process in relation to the quantal one is unexpectedly high and constitutes an anomaly of some theoretical interest. Participation of the tunneling process should be more easily observed in relation to the classical process at low temperatures, e.g., in cathodic hydrogen evolution from alcoholic HCl at $-110°$ C. Experiments are in progress to examine this possibility.

ON THE MECHANISM OF ELECTROLYTIC DEPOSITION AND DISSOLUTION OF SILVER[1]

WOLFGANG MEHL AND JOHN O'M. BOCKRIS

INTRODUCTION

The mechanism of crystal growth has been an object of study for many years. Beginning with Gibbs (1), major contributions have been made by Volmer (2), Kossel (3), Stranski (4), Becker and Döring (5), Frenkel (6), and Frank (7). From this work it was concluded that the first step in crystal growth is "adsorption" on the surface, whereafter "adatoms" (2) diffuse to steps and along steps to kinks, where they are incorporated into the lattice, after which repetition of these steps ("repeatable step") brings about the incorporation of a kink atom into the lattice (cf. Fig. 1 and Conway and Bockris (21)).

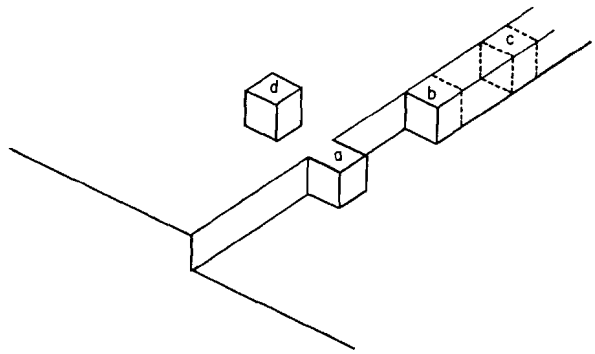

FIG. 1. Schematic view of metal–solution interface depicting (*a*) atom at edge, (*b*) kink, (*c*) atom in edge, (*d*) adion.

After all the stepped surfaces have been used up, two-dimensional nucleation was expected in the earlier theory (1, 2, 3, 4, 5, 6) to occur on surfaces of low index, which implied that some degree of supersaturation was necessary for the continuation of the growth process. Experiments show, however, that usually crystals can grow indefinitely without a large degree of supersaturation of the surface. This discrepancy arises because the model for crystal growth, sketched above, applies to the growth of a perfect crystal, but most real crystals contain imperfections which provide the steps necessary for growth.

Frank *et al.* (7) have studied the influence of imperfections, mainly screw dislocations, on the growth mechanism. Screw dislocations were found to provide a practically inexhaustible source of steps which turn at higher supersaturations into spirals, forming growth pyramids on the surface.

The equations deduced by Frank (7, 8) can also be used for a discussion of electrolytic crystal growth if the parameters are appropriately changed, but it is necessary to keep in mind that the energetic properties of a metal surface in contact with an electrolytic solution differ essentially from those of a surface in contact with its vapor. Thus, in a solution there exists at the metal surface an electrical double layer, with a field strength of about 10^7 v cm^{-1}; ions from the solution phase are adsorbed on the surface, etc. (13).

[1]*Manuscript received July 23, 1958.*
Contribution from the John Harrison Laboratories, University of Pennsylvania, Philadelphia, U.S.A. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

For electrolytic crystal growth an important difference to growth of crystals from the gas phase is also that an activation energy has to be overcome to make it possible for the metal ions to cross the electrical double layer and to strip off the solvation sheath (21).

It is the electric field at the metal–solution interface which gives rise to two possible extreme idealizations for models of electrolytic crystal growth (9).

In model A nearly all the electrode surface is active for the process of transferring ions from the solution to the electrode (transfer reaction). The particles on the surface carry probably a partial charge and are therefore best termed adions (21). The consecutive process to that of transfer is surface diffusion of adions to the growth positions on the surface, the final step being incorporation of adions into the lattice. In addition, at higher concentration of adions, nucleation on the surface may occur.

In model B the ions from the solution transfer directly to growing points on the surface (active centers).

Little informative work has been hitherto possible on electrolytic crystal growth, mainly because of experimental difficulties. Metal surfaces readily adsorb impurities, possibly at the active centers important for the crystal growth process. Because of this sensitivity to impurities, one of the main experimental difficulties in such work is keeping a small metal area (of the order of 0.01–1 sq. cm in area) in contact with solution but free of adsorbed impurities. A further intrinsic difficulty is that of carrying out significant measurements whilst the electrode surface remains essentially constant, i.e., observations of the rate of the reaction of a given potential must be made rapidly.

Because of these experimental difficulties only qualitative discussions of electrolytic crystal growth have been possible until now (9, 10). But experiences gained in the preparation of electrodes for studies of the hydrogen evolution reaction (11) and in the development of improved electronic measuring techniques (12) seemed to make worth while an experimental study of the kinetics of electrolytic metal deposition and dissolution.

At silver electrodes, Gerischer *et al.* (14) observed a deviation from the current–potential relationship to be expected if a rate-determining transfer reaction occurs (a similar observation was recorded by Mattson (15) for copper deposition on copper). These workers found that the exchange current for the system Ag/Ag^+ is independent of the concentration of silver ions in the solutions which appeared to indicate a rate-determining crystallization process for the over-all metal deposition.* Kaischew and co-workers (16) showed by microscopic studies that growth spirals are formed on the silver surface during deposition, thus supporting the applicability of Frank's theory of crystal growth by means of dislocation to electrolytic crystal growth.

It is the aim of the present work to find out: (1) which is the general path (i.e. that of model A or η model B) by which the ions pass from their initial state of hydration in the solution to their final state in the lattice and vice versa, and (2) which step in this path is rate-determining under given sets of conditions.

METHOD OF INVESTIGATION: THE GALVANOSTATIC METHOD

1. Introduction

In the study of the mechanism of crystal growth from the gas phase, the rate of crystal growth is studied as a function of the degree of supersaturation of the vapor. The corresponding measurement here is that of the rate of growth as a function of potential.

**Gerischer has also recently carried out, independently of the present workers, potentiostatic (24) and galvanostatic (25) measurements on silver dissolution, and comes to conclusions similar to those described here (cf. Mehl and Bockris (28)). Different i_0 values recorded in the work of this author, compared with those recorded here, depend upon the quite different methods of preparation of the electrode surfaces used.*

If one tries to obtain this i–η relationship under conditions of long-time (minutes) polarization, changes of the electrode surface with time due to the deposition or dissolution process itself, or adsorption of residual impurities, even from highly purified solutions, may make interpretation difficult. Consequently, short-time (milliseconds) polarization is preferable, and the galvanostatic (constant current) method (17) was chosen for the present investigation. Another advantage of this method compared with long-time measurements is that it enables additional evidence concerning the deposition mechanism to be obtained from the potential–time function.

The electrodes are in contact with the solution for minutes (between the time the protecting bulb around the electrodes is broken and that at which the sweep is taken). Therefore, extreme purification of solutions was carried out.

2. Double Layer Charging and Transfer

If a constant current density, i, is switched onto an electrode, this current divides itself into two components. The first one, i_C, is used for charging the electrical double layer at the electrode–solution interface; the second part, i_F, brings about transfer of ions across the double layer from the solution to the electrode surface. The current density, i_C, rapidly decreases with time, during the galvanostatic charging process, which means that i_F increases with time, because

$$i = i_C + i_F \qquad [1]$$

is constant. If i_F is controlled exclusively by the transfer reaction, then:*

$$i = Cd\eta/dt + i_0(e^{-\beta\eta\, zF/RT} - e^{(1-\beta)\eta\, zF/RT}), \qquad [2]$$

where C = the double layer capacity; i_0 = the exchange current density for the transfer controlled reaction; $0 < \beta < 1$; R, T, and F have their usual significance; and z is the valency of the cation in solution.

A general solution of this equation with the assumption that the double layer capacity is independent of potential was given by Rojter, Juza, and Polujan (17). The η–t relationship thus obtained is complicated and therefore difficult to verify by experiment. For small overpotentials, $\alpha\eta\ zF/RT < 1$, and the solution of equation [2] is, again assuming C independent of potential,

$$\eta_t = \eta_\infty(1 - e^{-t/\tau_1}) \qquad [3]$$

with η_∞ = steady state overpotential,

$$\tau = (RT/zFi_0)C. \qquad [4]$$

Equation [3] is only an approximation as the double layer capacity changes during the charging process with time so that an exact separation of i_F and i_C is not possible (18). This means that for the analysis of electrode reactions with help of the $\eta(t)$ functions, only such reactions are detectable which have a relaxation time of $\tau > \tau_1$.

3. Electrolytic Resistance of Solution

The ohmic potential drop between reference electrode and measurement electrode can easily be determined because it appears in the $\eta(t)$ function as a jump parallel to the potential axis (see Fig. 5).

**It is assumed that the maximum supply of ions from the bulk of the solution to the double layer (by diffusion and electrolytic transport) far exceeds that required for deposition.*

For personal use only.

4. Transfer and Surface Diffusion of Ions

In the following considerations, constant Faradaic current ($t \gg \tau_1$) is assumed. If the surface diffusion coefficient for adions on the metal surface is sufficiently small, so that this process is important for the rate of the over-all process, the surface concentration of adions increases during polarization to a value above that of the surface concentration corresponding to equilibrium, and becomes less than this value during dissolution. In this section the discussion will be limited to the consideration of low overpotential, i.e., a small degree of supersaturation.

Assuming that the adions cause only a small reduction of the free surface area for the transfer reaction and neglecting concentration polarization in the solution, the potential–time function is:

$$[5] \qquad (i_F)_t = i_0[e^{-\beta\eta_t\, zF/RT} - (c_{\eta(t)}/c_0)\, e^{(1-\beta)\eta_t\, zF/RT}]$$

where c_0 is the concentration of adions at equilibrium and $c_{\eta(t)}$ is the concentration of adions at a time t when the overpotential has reached a value of η. For $\eta < RT/\alpha\, zF$ and neglecting second-order terms, one obtains, by expansion of [5] and rearrangement,

$$[6] \qquad -\eta_t = (RT/zF)\ (i/i_0) + (RT/zF)\ (\Delta c_{\eta(t)}/c_0),$$

where

$$\Delta c_{\eta(t)} = c_{\eta(t)} - c_0.$$

Hence, η depends in this case both on i_0 for the transfer reaction and the "concentration overpotential due to surface diffusion".

It is necessary to express $c_{\eta(t)}$ as a function of i and t. Now:

$$[7] \qquad dc/dt = (i_F/zF) - v,$$

where v is the average of the surface diffusion flux of the adions during their passage from the point at which they are transferred to the metal surface and that at which they meet a crystal building point.

Surface diffusion on metal crystals has been dealt with thoroughly by Frank *et al.* (7) and applied to electrolytic deposition by Vermilyea (10). The present results are consistent with the simple assumption (for $|\eta| \leqslant 5$ mv) that the surface diffusion flux is proportional to the surface supersaturation, $[(c_{\eta(t)}/c_0) - 1]$. Hence:

$$[8] \qquad v = v_0[(c_{\eta(t)}/c_0) - 1]$$

assuming that, near to kinks, the adion concentration remains at equilibrium value, c_0, whilst on crystal planes, where the metal ions are regarded as first being transferred from the solution to the metal surface, the mean surface concentration of adions is $c_{\eta(t)}$. Substituting [8] into [7] and integrating yields

$$[9] \qquad \frac{c_{\eta(t)} - c_0}{c_0} = \frac{\Delta c}{c_0} = \frac{i_F}{zFv_0}(1 - e^{-t/\tau_2})$$

$$[10] \qquad \tau_2 = c_0/v_0.$$

Thus, the steady state value of the increased concentration of adions over that expected for pure transfer control is given ($t = \infty$) by:

$$[11] \qquad \Delta c/c_0 = i_F/zFv_0.$$

With [9] and [6] the $\eta(t)$ function at small overpotentials, with both surface diffusion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

and transfer of ions across the double layer as influencing the value of η_t, and for time $t > \tau_1$, becomes:

$$[12] \qquad -\eta_{(t)} = \frac{RT}{zF}\left[\frac{i_F}{i_0}+\frac{i_F}{v_0 zF}\left(1-e^{-(v_0/c_0)\,t}\right)\right].$$

For times t, for which $\tau_1 < t < \tau_2$ and with $\tau_2 = c_0/v_0$, from [12]

$$[13a] \qquad -\eta_{(t)} = \frac{RT}{zF}\left(\frac{i_F}{i_0}+\frac{i_F}{c_0 zF}\,t\right)$$

and

$$[13b] \qquad \frac{d\eta_t}{dt} = \frac{RT}{z^2F^2}\,\frac{i_F}{c_0}$$

5. Current–Potential Relations in the Steady State

(*a*) *Transfer is rate-determining.*—The i–η function will then be controlled by:

$$[14] \qquad i_F = i_0(e^{-\beta\eta\, zF/RT} - e^{(1-\beta)\eta\, Fz/RT}).$$

The adion concentration is at its equilibrium value and therefore surface coverage can be neglected (6).

(*b*) *Transfer and surface diffusion control the role of the over-all reaction.*—With [12] and [11] we get

$$[15]^* \qquad i_F = \frac{e^{-zF\eta/RT}-1}{(1/i_0)\,e^{-(1-\beta)\eta\, zF/RT} + 1/zFv_0}.$$

(*c*) *Surface diffusion is rate-determining.*—For

$$zFv_0 < i_0\, e^{(1-\beta)\eta\, zF/RT}$$

there follows,

$$[16] \qquad i_F = zFv_0(e^{-\eta\, zF/RT}-1).$$

Equations [15] and [16] have been derived under the assumption that v_0 is overpotential-independent. Theoretical work by Frank *et al.* (7) shows, however, that this assumption is incorrect; v_0 increases with increasingly negative overpotential (cf. Discussion).

EXPERIMENTAL

1. Galvanostatic Arrangement (Fig. 2)

The potential source consisted of dry batteries, e.m.f. 90–200 v. Precision resistors (I.R.C.) are represented by R and were arranged in 10 steps, from 1 kilohm to 6.2 meg. The letter O represents a Tektronix oscilloscope, type 531, with type 53/54D plug-in preamplifier. The potential–time curves were photographed with an Exakta camera having a 50-mm lens. Projection of the 35-mm film was made with an enlargement of about ten times to obtain numerical η–t curves. The switch S contained a Western Electric relay, type 175, having a rise time of about 10^{-7} sec[22].

2. Treatment of Solution and Electrodes

The solution was made from A.R. $HClO_4$, which was distilled three times *in vacuo*, the last distillation being into a burette leading directly to the cell. The water was distilled

**Equation [15] is valid only under conditions such that the surface coverage with adions is sufficiently low to yield negligible hindrance to the transfer of ions from the solution. In fact, if v_0 is sufficiently low a surface coverage could build up and the first term in [5] should be preceded by a term of the type $1-\theta_\eta/1-\theta_0$, where θ_η is the surface coverage at overpotential η. A limiting current could then ensue at sufficiently high overpotentials. But this case is unlikely because of nucleation and a possible increase of v_0 with increasing overpotential.*

several times and had a final conductance of about 10^{-7} mho cm^{-1}. The $AgClO_4$ ("pure" grade) was recrystallized twice outside the system and twice inside and then introduced into a special cell in which it was subjected to pre-electrolysis for about twenty-four hours with alternating current density of about 3×10^{-1} amp cm^{-2}. The solution was vigorously stirred with carefully purified nitrogen gas, the cathode was of silver, the anode of platinum (vigorous stirring prevented silver needles from growing through the closed tap between cathode and anode compartments).*

The electrodes were prepared by heating a thin (spectroscopically pure) silver wire (0.5 mm diameter) in an atmosphere of purified hydrogen in a quartz tube. A spherical shape was attained by partial melting. Finally, the electrode was sealed in a glass bulb containing only hydrogen, or helium, and the bulb was broken in the solution shortly before measurement. A detailed description of this procedure has been published (19). This method of preparing electrodes is similar in nature to "thermal etching", which has been studied experimentally and theoretically by several authors (20). During the heating process a rearrangement of surface atoms of the polycrystalline surface occurs, to produce facets with simple crystallographic indices; grain boundaries occur as grooves. As the electrodes are being cooled down in a hydrogen stream (high heat conductivity), a relatively high thermal stress would appear in the metal, producing a high concentration of dislocations.

Electron micrographs were taken of the electrodes prepared in this way. They show etch pits with a density of about 10^7 per sq. cm (Fig. 3). According to Hirth and Pound (26, 27), these may be interpreted as due to dislocations with a screw component normal to the surface. Occasionally electrodes indicate surface films of unknown origin (possibly connected with accidental contact between the hot metal and the glass tube during electrode preparation) and results from such electrodes were not further examined.

Other experimental conditions, particularly with regard to purification of gases, etc., were as already described (29).

**The exterior of the pre-electrolysis cell was coated black to exclude light effects. The measurements were carried out under conditions of minimum illumination.*

3. Procedure

After one of the four electrodes in the cell had been lowered by means of a sliding fit joint into the solution, the glass bulb surrounding it was broken and the electrode adjusted until it was inside a platinum gauze basket which acted as counterelectrode. The outside resistance R (Fig. 2) was set at a value appropriate for the given current density, and a current impulse given to the electrode. By means of the switch S (22) (Fig. 2) the impulse was restricted to an amount of electricity not more than 10^{-4} coulombs cm^{-2} (i.e., the amount to cover about 1 geometric cm^2). The resulting potential–time curve was photographed.

Such photographs were made at some ten current densities (over the range 3×10^{-4} to 8×10^{-1} amp/cm^2) for each electrode and in each run a maximum of four electrodes were examined. Measurements were made at a variety of concentrations between 10^{-2} and 10^{-1} moles $l.^{-1}$ so that concentration polarization could be avoided. At the end of a series of measurements with increasing current density, some sweeps at lowest current densities were repeated and results, closely similar to those taken earlier, found.

4. Results

Figure 4 shows a typical potential–time curve for the current density 2 ma cm^{-2} at a concentration of 0.2 *N* $AgClO_4$ in 1 *N* $HClO_4$ for cathodic polarization. Similar results were obtained for anodic polarization. In Fig. 5, a typical η–t relationship for short times is shown. Figure 6 shows a typical η–t curve measured in unpurified solution, which exhibits the phenomenon of superpolarization.

Figure 7 shows a typical plot of the log i–η_∞ relation for cathodic and anodic polarization, and Fig. 8 a typical linear relation of i to η_∞ at low current densities.

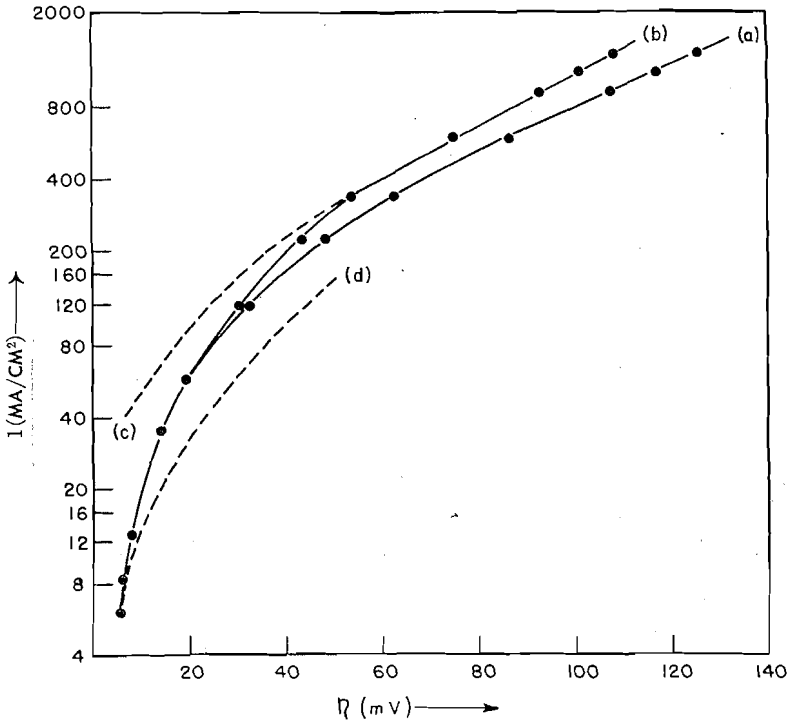

FIG. 7. Log i–η plot for deposition (*a*), dissolution (*b*).
$c_{AgClO_4} = 2\times10^{-1}$ mole/l.
(*c*) Represents (- - - -) slow transfer reaction.

DISCUSSION

1. Potential–Time Curves

At very short times the current flowing during build-up of potential is used almost exclusively for the charging of the double layer, the capacity of which is therefore given (in the linear $\eta_{(t)}$–t region) by:

$$C = it/\eta_{(t)}. \qquad [17]$$

This linear η–t relationship can be expected for times limiting low value of t. With a double-layer capacity of about 20 μ *F* cm^{-2}, RT/zFi_0) = 2 ohm cm^2 and allowing a roughness factor 2, the linear relationship can be expected for times of about $t < 10^{-4}$ second, when $\eta < RT/zF$. In fact, a linear relationship was observed for more than 10^{-3} second with a slope which according to [17] would give an impossible value of 500

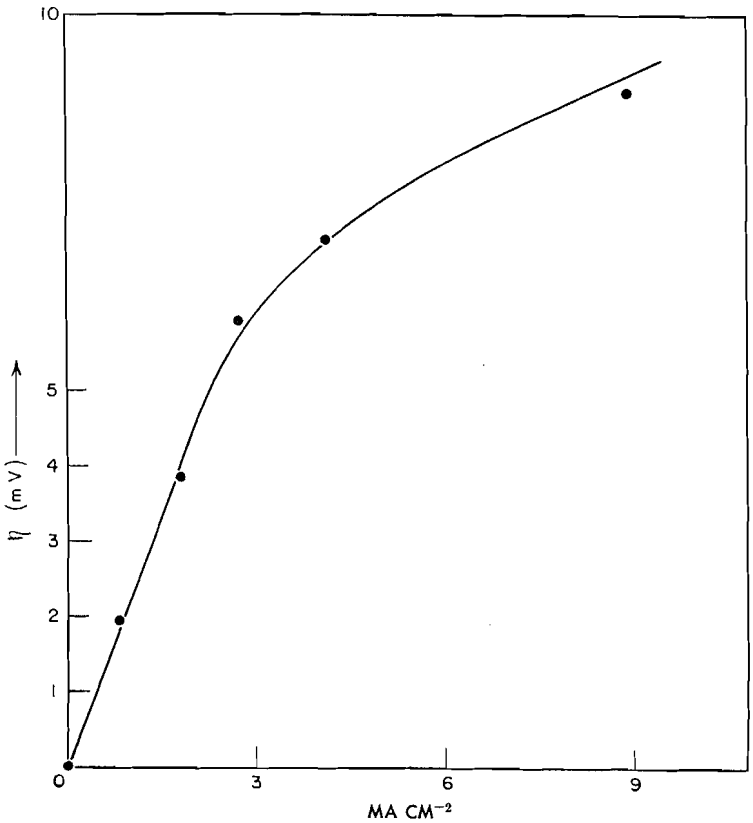

FIG. 8. i–η plot for low current densities. $(AgClO_4) = 2.10^{-1}$ mole $l.^{-1}$.

μ F/cm^2 for the double-layer capacity. Similarly, if the transfer step alone were rate-determining, equation [3] shows that the steady state overpotential should be reached at a time of about

$$t = 4\,(RT/zFi_0)C \qquad [18]$$

for $\eta < RT/zF$. The actually observed values for this time are more than ten times larger than those predicted.

This slow rise time may be interpreted in terms of the build-up of an adsorption layer of adions, as shown in the next section.*

2. Potential–Time Relation and the Role of Surface Diffusion

From [13]:

$$\eta_{(t)} - \eta_\infty = \frac{RT}{zF}\frac{i_F}{zFv_0}\,e^{-(v_0/c_0)t}. \qquad [19]$$

Also, from [12]:

$$\eta_{t=0} = \frac{RT}{zF}\frac{i_F}{i_0} \qquad [20]$$

and

**A slow reaction in the solution cannot be responsible for this behavior because during deposition of metals upon amalgams, behavior may be satisfactorily interpreted in terms of rate-controlling transfer (23).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[21] $$\eta_{t=0} - \eta_\infty = \frac{RT}{zF}\frac{i_F}{zFv_0}.$$

Further, from [12]:

[22] $$\eta_\infty = \frac{RT}{zF}\left(\frac{i_F}{i_0} + \frac{i_F}{zFv_0}\right).$$

Note that in the above equations the double-layer charging has been neglected; they are therefore valid only for times much greater than the rise time of the transfer reaction, i.e., in the systems reported on here, about 10^{-4} seconds (also, it has been assumed that $|\eta| < 5$ mv).

According to [19] $\eta_{t=0}$ can be got by extrapolating a plot of log $(\eta_t - \eta_{st})$ against t to $t = 0$ (Fig. 9).* The value for i_0 obtained this way [22] can be compared with values obtained by the independent method of extrapolating the linear part of η–log i relation to $\eta = 0$. The values agree to about $\pm 30\%$. If one takes into consideration that the accuracy with which the potential can be determined is $\pm 5\%$ and the overpotential due to transfer (at $|\eta| \leqslant 5$ mv) is about 10% of the total overvoltage, the agreement between the i_0 values obtained in these two independent ways is satisfactory. This agreement confirms the interpretation of the slow rise time of the η–t curve on the basis of slow surface diffusion of adions.

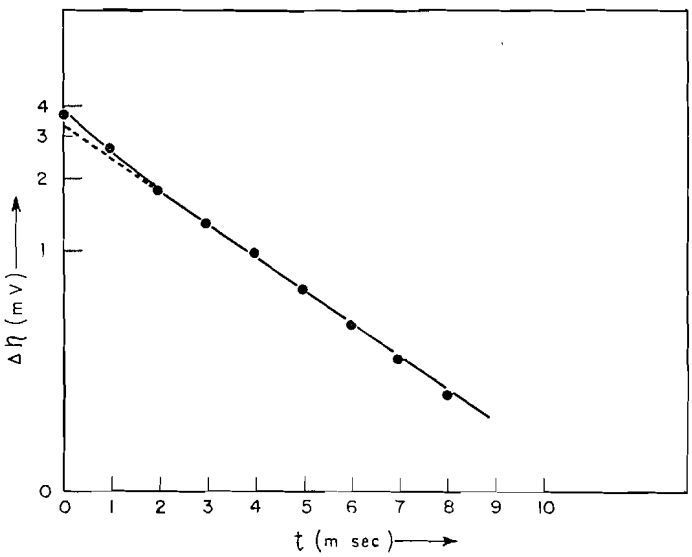

FIG. 9. Separation of total polarization into diffusion and transfer polarization by extrapolation of galvanostatic $\eta(t)$ curves (for parameters, see Fig. 4).

Table I gives values of i_0 obtained by the extrapolation of the Tafel line.† With the known values of i_0, [22] allows the calculation of v_0, values of which are shown in Table I.

3. Concentration of Adions at the Reversible Potential

From [19] we get:

**The* $\eta_{t=0}$ *referred to is a quantity susceptible only to calculation upon a model such as that suggested. It signifies the potential of the electrode during charging with respect to the corresponding electrode, under conditions such that the double-layer charging is terminated, but before the surface diffusion has had time to affect the concentration of adions over that corresponding to the reversible potential. Correspondingly,* $\eta_{t=0}$ *depends only upon* i_0*, and not upon* v_0*.*

†*The* i_0 *values for deposition and dissolution agree well; values of* β *are almost the same* ($\simeq 0.50$) *for each process.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[23] $$(d/dt)\ln(\eta_t-\eta_\infty) = -v_0/c_0.$$

From [23] (with v_0 from [21]) and from [13*a*] directly, the concentration of adions at the reversible potential may be calculated. Both methods lead to the same results. The values obtained this way are presented in Table I.

TABLE I

$AgClO_4$ mole/liter	i_0 amp cm^2	zFv_0 amp/cm^2	c_0 mole/apparent cm^2
2.0×10^{-1}	0.10	1.2×10^{-2}	8×10^{-10}
1.3×10^{-1}	0.08	1.0×10^{-2}	2×10^{-9}
1.0×10^{-1}	0.07	1.4×10^{-2}	4×10^{-10}
0.8×10^{-1}	0.07	1.2×10^{-2}	3×10^{-9}
0.8×10^{-1}	0.07	1.6×10^{-2}	6×10^{-10}
0.6×10^{-1}	0.06	1.2×10^{-2}	1×10^{-9}
0.6×10^{-1}	0.06	1.1×10^{-2}	8×10^{-10}
0.4×10^{-1}	0.05	1.2×10^{-2}	1×10^{-9}
0.2×10^{-1}	0.04	1.5×10^{-2}	6×10^{-10}
0.1×10^{-1}	0.03	1.1×10^{-2}	5×10^{-10}

4. Current–Potential Relation

With the aid of values of v_0 and i_0 calculated as described above, it is possible to evaluate the theoretical η–i and η – log i relations for the steady state. These are compared with experiment in Fig. 7.

5. Mechanism of Deposition and Dissolution

As Fig. 7 shows, for silver deposition and dissolution for electrodes prepared by thermal etching, surface diffusion of adions is the principal rate-determining step at low overpotentials, and at high overpotentials the transfer of ions from the solution to the electrode is the rate-determining step. As v_0 does not depend upon the concentration of silver ions in solution (see Table I), the concentration dependence of i_0 is given by:

$$\partial \ln i_0/\partial \ln \alpha_{Ag} = \beta.$$

It can be predicted from the values for i_0 and v_0 (Table I) that the above statement concerning rate control will be valid down to Ag^+ concentrations of about 10^{-4} to 10^{-5} mole $l.^{-1}$. At lower concentrations than these, the transfer step will be rate-controlling at all current densities (for the type of silver surfaces used in the present study).

The path determined for this fundamental example of simple metal deposition corresponds therefore more closely to model A rather than model B (see above).

The transition from rate-determining surface diffusion to rate-determining transfer is due to the decrease of the average distance between growing lines (and hence increase of v_0) with increasing overpotential. The dependence of v_0 upon potential has not yet been subject to a satisfactory theoretical treatment. Provisionally, the following empirical equation may be suggested: $v_0(\eta) = v_0\, e^{-\eta\, zF/RT}$, whereupon the complete course of the i–η relation can thus be described by the equation:

[24] $$i = \frac{e^{-\eta\, zF/RT}-1}{(1/i_0)\, e^{-(1-\beta)\eta\, zF/RT} + (1/v_0zF)\, e^{zF\eta/RT}}.$$

For higher overpotentials (24) gives:

[25] $$i = \frac{e^{-\eta\, zF/RT}-1}{(1/i_0)\, e^{-(1-\beta)\eta\, zF/RT}},$$

and for low cathodic overvoltages:

[26] $$i = zFv_0\, e^{-\eta\, zF/RT}(e^{-zF\,\eta/RT}-1).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Correspondingly, for crystal growth from the vapor phase, a linear dependence of the rate of growth upon the degree of supersaturation has been found at higher supersaturations (linear law), and a parabolic dependence upon supersaturation at low supersaturations (cf. Frank *et al.* (7)).

The "critical overpotential", which separates the linear and the parabolic law, depends on the ratio i_0/zFv_0 and thus upon the concentration of Ag^+ ions in solution (upon which i_0 depends).

It should be noted here that a perfect parabolic law, viz.,

$$i = k(e^{-zF\,\eta/RT}-1)^2$$

(where k is a constant) can only be expected for a single dislocation and a function such as that reported here for distribution of dislocations on the crystal surface.

6. Equilibrium Concentration of Adions

The equilibrium concentration of adatoms c_{ad} for the system metal–vapor can easily be calculated. With an energy of vaporization for silver of about 65 kcal, it is found that the equilibrium concentration of adions during electrochemical deposition is very much higher than the equilibrium concentration of adatoms during deposition from the vapor phase.

7. Superpolarization

This phenomenon (Fig. 6) occurs at higher overvoltages, 100 mv, and is difficult to study experimentally because of its poor reproducibility. Superpolarization was observed almost exclusively for solutions which had not been well purified so that the phenomenon might well be one of "over-shoot" (24) due to supersaturation of the surface with adions. Vermilyea (10) has discussed this type of phenomenon in terms of dislocation theory (7).

APPENDIX

Certain Terms Used in Electrochemical Crystal Growth Compared with Those Used in Crystal Growth from the Vapor Phase

Burton, Cabrera, and Frank (7) define supersaturation in the vapor by

[1*] $$\sigma = \alpha-1; \quad \alpha = p/p_0,$$

where p is the actual vapor pressure and p_0 the saturation value. The supersaturation of adsorbed molecules on the surface is defined by,

[2*] $$\sigma_s = \alpha_s-1; \quad \alpha_s = c_s/c_0$$

where c_s and c_0 are the actual and equilibrium concentration of adsorbed molecules respectively.

The "current" from the vapor to the surface is written as

[3*] $$j = (\alpha-\alpha_s)c_0/\tau_s,$$

where τ_s is the mean life of an adsorbed atom on the surface defined by

[4*] $$\tau_s = \frac{1}{\nu}\exp(W'_s/RT)$$

where W' = evaporation energy from the surface to the vapor, and ν = frequency factor. In the present theory, the current from the solution to the surface is written (cf. 5) as:

[5*] $$i = (e^{-zF\,\eta/RT}-c_s/c_0)i_0\,e^{(1-\beta)\eta\,zF/RT}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Comparison of [3*] and [5*] yields the following analogies:

Comparison of expressions used in crystal growth from vapor phase and by electrolytic means

	Burton, Cabrera, and Frank (7) (vapor phase)	This paper (electrolytic)
Supersaturation in the vapor (solution)	p/p_0-1	$e^{-zF\eta/RT}-1$
Supersaturation on the surface	c_s/c_0-1	c_s/c_0^0-1
Mean lifetime of adsorbed molecules	τ_s	$(c_0/i_0)\,e^{-(1-\alpha)z\eta F/RT}$

EXCHANGE BETWEEN METALS AND THEIR IONS IN SOLUTION[1]

CECIL V. KING AND NANCY E. MCKINNEY

ABSTRACT

The mechanisms by which a metal specimen can acquire radioactivity when immersed in a tracer solution of its own ions are discussed. Consideration is given to the roles of exchange current, adsorption, local cell electrolysis, corrosion, and self-diffusion within the metal. It is shown that exchange current cannot be measured by the tracer method unless conditions are unusually favorable, and that too little attention has been paid to the role of internal diffusion. Some experimental results with silver are presented and the importance of internal diffusion is shown.

INTRODUCTION

A great many articles dealing with metal – metal ion exchange have been published, but the interpretation of experimental results is not entirely satisfactory. The role of diffusion within the metal has been especially puzzling. It is the purpose of this paper to discuss some of the pertinent factors in exchange and to indicate their relative importance. New experimental work with silver is used for illustration.

Exchange Current

A kinetic interpretation of the Nernst equation for "electrode potential"

$$E = RT \ln P/p$$

or its modern equivalent, implies a continual exchange between ions in solution and ions or atoms within the metal phase. The equilibrium exchange rate, when expressed in electrical units, is known as the exchange current i_0. Direct proof of exchange is possible through the use of radioisotopes as tracers, but the tracer method can measure i_0 only under conditions probably never attainable in practice.

1. Assume one face of a metal single crystal to be immersed in a solution of its own ions (with tracer), and that there is no corrosion, no adsorption or electrical double layer formation involving the salt, no local cell electrolysis, no internal diffusion, and no temporary depletion of tracer in the solution next the interface. Exchange can then take place with only one atomic layer on the metal surface, and the rate of activity pickup, extrapolated to zero time, will give the exchange current. Or, an expression could be found for the rate of attainment of radioactive equilibrium, from which the specific exchange rate could be calculated. A value of $i_0 = 5 \times 10^{-8}$ amp/cm^2 corresponds to exchange of about one atomic layer per hour, but since much re-exchange would occur, radioactive pickup would continue for several hours. For silver, i_0 is reported to be about 10^{-3} amp/cm^2 (1), and radioactive equilibrium with the surface layer should require only a second or two. This has been found to be the case (2), but the actual rate has not been measured.

2. Exchange current could be measured with the same conditions as above except that self-diffusion in the metal should be much faster than exchange. Nearly all the active atoms entering the surface would diffuse inward rather than re-exchange, and the rate of pickup would give i_0 directly.

The fact is that conditions are never as simple as those discussed above.

[1]*Manuscript received July 3, 1958.*
Contribution from the Department of Chemistry, New York University, New York, N.Y. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

Adsorption

Assuming no internal diffusion, but that salt can be firmly adsorbed (through primary attachment of either cation or anion), the rate of attainment of equilibrium could depend on both i_0 and the kinetics of adsorption. In the case of silver–silver salts it is known that adsorption–desorption is a slow process, both from classical and from tracer studies (3, 4). Little is known about adsorption of their own salts on active metals.

If internal diffusion plays a role, then adsorption changes the surface concentration and the activity gradient in the surface layers.

Corrosion

If corrosion products are soluble, the rate and amount of activity pickup by the metal will depend on the exchange current, and whether internal penetration is faster than the metal dissolution. The extreme case has been investigated by dissolving the metal anodically. Matsuura (5) found that the activity acquired by a zinc anode corresponded to about three apparent atomic layers of complete exchange, independent of current density. Gerischer and Tischer found similar results with silver (2). This indicates only that surface exchange is rapid compared to internal diffusion.

If corrosion products are insoluble, activity may be acquired by exchange with the metal and the corrosion products, or by precipitation and adsorption from solution. An extreme case has been found with iron (unpublished results in this laboratory); internal diffusion is inappreciable, i_0 is very small, and there is little activity pickup unless corrosion is quite evident.

Local Cell Electrolysis

There is reason to believe that potential differences, which can cause metal to dissolve at one spot while deposition occurs at another, become negligible after a few hours of immersion. Certain faces of copper single crystals, immersed in $CuSO_4$ solution, undergo recrystallization and the potentials approach an equilibrium value (6). Silver specimens used in exchange experiments have been pre-equilibrated in non-radioactive solutions for periods up to several months (2, 7). Gerischer and Vielstich found no further effect after 24 hours.

Local cell electrolysis which results in solid corrosion products is another matter. The solution becomes alkaline at local cathodes, and radioactive metal can be precipitated as hydrous oxide without any actual exchange. Zinc acquires far more active zinc ion in the presence of air than from deaerated solution, even before an oxide film is visible.

Internal Diffusion

Assuming that corrosion and local cell electrolysis can be eliminated or minimized, then continuing activity pickup, which corresponds to more than adsorption or double layer formation plus complete exchange in one atomic layer, must be due to internal diffusion. Internal diffusion was considered by Gerischer, Vielstich, and Tischer (2) in their work with silver, but was discounted because the calculated diffusion coefficient was several powers of 10 higher than expected. Matsuura (5) found the same difficulty in the case of zinc. We believe that the discrepancies are due to lack of knowledge of the true surface concentration of the diffusing species. The solutions used generally have a concentration of 10^{-4}–10^{-5} moles/cm^3, while the metal contains about 0.1 g-atom/cm^3. Adsorption of a fraction of a monolayer results in a surface concentration much greater than in solution. Adsorption on silver depends on the anion, and can amount to several tenths of a monolayer (8).

In polycrystalline metals grain-boundary diffusion is generally much greater at lower temperatures than lattice diffusion, even though the area of exposed grain boundaries is only a small fraction of the total. Self-diffusion in metals is usually measured by milling thin layers from the surface, after diffusion has taken place from an electrodeposited layer; the activity in each layer is then determined. In diffusion experiments at room temperature much thinner layers must be removed by dissolution in a suitable etching solution.

DIFFUSION EQUATIONS

In the experiments discussed below, it is assumed that the tracer has a constant concentration at the metal surface, which is not strictly true until adsorption equilibrium is reached. This is not the same as in dry diffusion from an electrodeposited layer, where the surface concentration decreases with time. There are two methods of relating the activity pickup and the diffusion coefficient: (1) the total pickup is a function of time, and (2) the activity per unit volume at a given penetration depth after a given time is a function of depth. The equations are analogous to those for heat conduction and are discussed in books on that subject and on diffusion in solids (9); the solutions for *homogeneous* diffusion with the boundary conditions assumed here are described in detail by Darken and Gurry (10).

Total Activity as Function of Time

The activity flux per unit area at the surface (a measure of the number of atoms entering and leaving the metal) is given by:

$$da/dt = a_0 D^{\frac{1}{2}} (\Pi\, t)^{-\frac{1}{2}}, \quad [1]$$

where D is the diffusion coefficient (assumed constant). Integration gives

$$a_t = 2a_0 \Pi^{-\frac{1}{2}}\, (Dt)^{\frac{1}{2}}, \quad [2]$$

where a_t is the total activity acquired at time t. This equation is given by Gerischer and Vielstich (2) with the addition of a constant term for the initial rapidly acquired surface activity. If adsorption is slow as it is with silver, or if the surface changes in any way, the surface concentration represented by a_0 will not be constant.

Distribution of Activity in Depth

For homogeneous diffusion with constant a_0, the activity a_x at a given penetration distance x, after a fixed time t, is given, per unit area, by

$$a_x = a_0[1 - \mathrm{erf}\; x/(4Dt)^{\frac{1}{2}}], \quad [3]$$

where erf refers to the error function. If x can be made small enough and t large enough compared to D, it is convenient to use the expansion

$$\mathrm{erf(y)} = \frac{2}{\Pi^{\frac{1}{2}}}\left(\mathrm{y} - \frac{\mathrm{y}^3}{3} + \frac{\mathrm{y}^5}{5\times 2!} - \cdots\right) \quad [4]$$

and to neglect the higher terms. This gives

$$a_x = a_0 - a_0 x(\Pi\, Dt)^{-\frac{1}{2}}. \quad [5]$$

If thin layers can be etched from a specimen, the activity per milligram (for example) should be linear with x, or if self-absorption of radiation is negligible, the activity remaining on the specimen should be linear with x. This equation has never been tested so far as we know. Diffusion from a thin deposited layer requires that ln a_x be linear with x^2.

Grain-boundary Diffusion

Most of the work on exchange from solution has been done with polycrystalline metal specimens. There is no independent theory of grain-boundary diffusion, which is presumably most important at room temperature. Probably equation [2] should apply with an area term depending on grain size inserted. In diffusion from electrodeposited layers, $\ln a_x$ is linear with x rather than x^2.

An analysis of the relation between the grain-boundary diffusion coefficient D_b and the volume or lattice diffusion coefficient D_v has been made by Fisher (11), through the analogy with heat flow into thin metal sheets imbedded in a semi-insulating medium. His expression may be put in the following form:

$$[6] \qquad D_b = 2D_v^{\frac{1}{2}}(\log e)^2/\delta(d \log a_x/dx)^2 \, (\Pi t)^{\frac{1}{2}},$$

where e is the logarithm base, δ is the grain-boundary thickness. The equation requires that $\log a_x$ be linear with x, as is found in practice.

EXPERIMENTS WITH SILVER

Disks of 99.8% silver, of 5.56 cm² area (both sides), were prepared from commercial rolled sheet. Half of the disks were washed in alcohol–ether, immersed for 1 minute in 0.5 *M* KCN to remove surface compounds, washed, and stored in 0.5 *M* $AgNO_3$ (inactive) for 1 year. The other disks were annealed at about 700° C for several hours, cooled slowly, etched for 1 minute in dilute $KCN–H_2O_2$, washed, and stored in 0.5 *M* $AgNO_3$ for 8 months. The annealed disks were visibly crystalline and noticeably roughened.

All exchange experiments were carried out in 0.5 *M* $AgNO_3$ containing Ag^{110} as tracer. Measurement of activity pickup and conversion of counts per minute to gram atoms per cm² or apparent atomic layers (of complete exchange) were done in the usual manner.

Disturbing the Specimens

In previous work it has been found that frequent removal of silver coupons for washing and counting results in much more activity pickup than if they are undisturbed for an equal immersion time. This has been ascribed to removal of adsorbed salt from the surface (4, 7) or possibly to slight cold-working of the surface by handling (12). It is now certain that hot-water washing increases the internal diffusion which is obviously responsible for most of the pickup.

Several disks were immersed in the active 0.5 *M* $AgNO_3$ for periods up to 98 days. Some were removed frequently, washed in cold water, and counted, and these were found to acquire more activity than others which were counted only near the end of the period. The effect of washing in hot water is shown below.

Activity vs. Time

Twelve cold-rolled disks were taken from the storage solution, six were blotted, and six were washed in boiling water. All were immersed in active 0.5 *M* $AgNO_3$ and kept at room temperature (near 25° C). One of each group was removed each 10 days, washed, and counted. A group of 12 annealed disks was treated in the same way. The activity acquired was plotted vs. the square root of time, as shown in Figs. 1 and 2, as a test of equation [2]. The initial blotting or washing made no apparent difference.

While the points are quite scattered, especially in Fig. 2, it is not inappropriate to draw the straight lines shown, with intercepts of about one day. Gerischer and Tischer have shown that a similar plot, examined over a period of 9 days at 25° C, shows curvature upward during this time, with an intercept at zero time of about three apparent atomic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

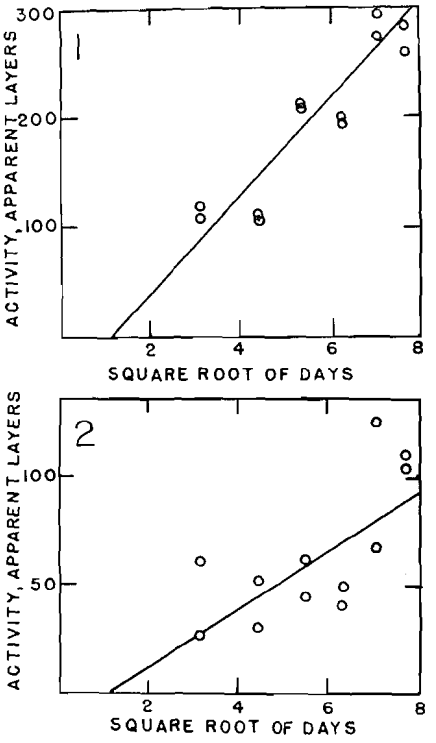

FIG. 1. Cold-rolled disks.
FIG. 2. Annealed disks.

layers (the activity acquired in a few seconds). The upward curvature could be due to two factors: (*a*) the slow establishment of adsorption equilibrium, and (*b*) diffusion along grain boundaries offers a continually expanding area from which lattice diffusion can take place.

Slopes of the straight lines of Figs. 1 and 2 may be inserted in equation [2] to calculate D. Apparent atomic layers are converted to gram atoms/cm^2 by multiplying by 19.9 $\times 10^{-10}$, and $a_0 = 5 \times 10^{-4}$ moles/cm^3, the solution concentration. This gives

$$\text{cold-rolled coupons:} \quad D = 2.0 \times 10^{-13} \text{ cm}^2/\text{sec};$$
$$\text{annealed coupons:} \quad D = 1.8 \times 10^{-14} \text{ cm}^2/\text{sec}.$$

It is probable that the cold-rolled silver has a larger grain-boundary area and volume than the annealed silver (or its equivalent in broken grains and imperfections) so that this "apparent" diffusion coefficient is larger.

Hoffman and Turnbull (13) have measured both lattice and grain-boundary diffusion in silver in the range 375–500° C by the dry method. For the latter they give the equation

$$D_b = 0.03 \exp(-20200/RT) \text{ cm}^2/\text{sec}.$$

Extrapolation to 25° C gives $D_b = 4 \times 10^{-17}$ cm^2/sec. If a_0 were taken as concentrations corresponding to 0.3 and 0.1 atomic layers of adsorbed ion respectively, this value for D would be obtained in the above calculations. Since the roughness factors of the coupons are unknown, and grain size is certainly a factor, further consideration is unwarranted.

Activity vs. Penetration Depth

Although exchange has been reported in most of the literature, in terms of apparent atomic layers of complete exchange, it is evident that exchange occurs to much greater depths. On etching silver coupons which had been immersed for a long time, activity was found to have penetrated as far as 2×10^{-4} cm (about 9000 atomic layers). A solution was prepared which is believed to dissolve silver uniformly: equal parts of (*a*) 0.5 g KCN in 150 ml water, and (*b*) 0.9 ml 30% H_2O_2 in 150 ml water.* A 2-minute etch in this mixture dissolved about 0.8 mg from one of the silver disks (840 layers). The disks were weighed after each etch and comparison was made with the total weight loss after a series of etches.

Four cold-rolled and four annealed coupons were immersed in active 0.5 *M* $AgNO_3$ and used in testing equation [6]. The results of the etching process are shown in Figs. 3 and 4, where log of activity remaining after each etch is plotted vs. weight lost. The history of

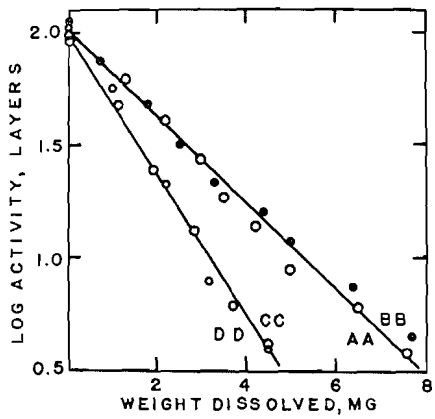

FIG. 3. Cold-rolled disks.

the disks follows: AA and BB were removed from solution three times, washed in boiling water, counted, and reimmersed; they were washed in boiling water at the end of the period (19 and 23 days); CC and DD were immersed for 20 days, washed in cold water, and stored in a desiccator for 18 days before etching; EE and FF were immersed for 50 days and etched immediately; GG was immersed for 20 days and stored for 30 days; HH was immersed 40 days and stored 10 days before etching. Evidently storage makes little difference, although the surface activity must decrease somewhat by diffusion inward; but washing in hot water is equivalent to using a higher temperature throughout.

The difference between the cold-rolled and the annealed specimens is striking. In the latter case 50–60% of the activity was removed in the first 0.8-mg etch. The grain area exposed to the solution is large, the grain-boundary area small, so that a larger part of the diffusion follows a different law. In any case the slopes of the lines drawn in Fig. 4 were used to calculate D_b.

The value of D_v used was taken from the work of Slifkin, Lazarus, and Tomizuka (14), who made measurements over a wider temperature range than Hoffman and Turnbull. Their equation for the temperature coefficient is:

$$D_v = 0.724 \exp(-45500/RT) \text{ cm}^2/\text{sec}$$

**The best evidence we have that this solution does etch the silver uniformly is the linearity of the plots in Fig. 3.*

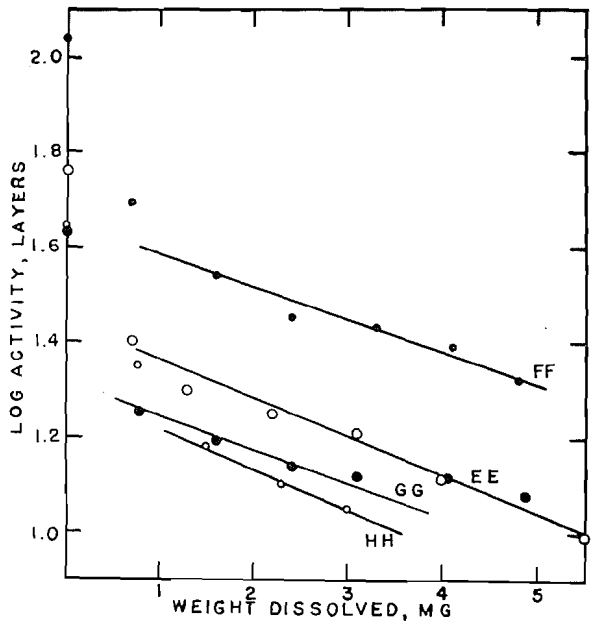

FIG. 4. Annealed disks.

from which $D_v = 4.4\times10^{-34}$ cm²/sec at 25° C. Fisher (11) suggested that δ, the grain-boundary thickness, be taken as 5×10^{-8} cm, and all other workers have used this figure. Inserting numerical values in equation [6], we obtain

$$D_b = 9\times10^{-11}/(\text{slope})^2 t^{\frac{1}{2}} \text{ cm}^2/\text{sec}.$$

In calculating the slope ($= d \log a_x/dx$), mg silver is multiplied by 1.7×10^{-5} to convert to centimeters for the disks used. The results are given in Table I.

TABLE I

Grain-boundary diffusion coefficients from the Fisher equation

Cold-rolled disks	(Diff. time, sec)$^{\frac{1}{2}}$	Slope $\times10^{-4}$ cm^{-1}	$D_b \times10^{21}$ cm²/sec
AA	1280	1.13	0.55
BB	1420	1.13	0.49
CC	1810	1.84	0.15
DD	1810	1.84	0.15
Annealed disks			
EE	2080	0.48	1.9
FF	2080	0.40	2.7
GG	2080	0.42	2.4
HH	2080	0.48	1.9

DISCUSSION

The fact that the values of D_b in Table I are 4 to 5 orders of magnitude smaller than that calculated from the high-temperature experiments, viz. 4×10^{-17} cm²/sec, is not surprising in view of the uncertain extrapolations and other factors. If D_v at 25° C is taken from the temperature-coefficient equation of Hoffman and Turnbull, our values of D_b become about 10^{-24} cm²/sec. The important thing is that continuing exchange *does*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

depend on internal diffusion and that measurements *can* be made at room temperature. Gerischer and Tischer commented that the distribution of activity in depth would be useful to know, but that penetration was too shallow for successful measurements. We believe that the etching technique overcomes the difficulty.

Experiments with silver have the advantage that corrosion can be neglected. Similar experiments have been carried out in this laboratory with zinc and cadmium, in solutions which minimize corrosion; they will be described elsewhere. Plots of a_t vs. $t^{\frac{1}{2}}$ curve upward in the initial immersion period as with silver, and D is larger than D_b calculated from dry-diffusion work in the literature. The Fisher method again gives values which are smaller.

Work with single crystals is indicated, and is under way. Since the amount of adsorption on silver is known, equation [2] should apply directly if the surface area can be controlled. With the etching technique it should be possible to apply equation [3] in some form.

SOME ABNORMAL HYDROGEN ELECTRODE REACTIONS

D. J. G. IVES

ABSTRACT

A brief account is given of experiments in which gold electrodes, as a result of thermal deactivation in hydrogen, change from a state in which their behavior in relation to the hydrogen evolution reaction is normal to a state characterized by high positive rest potentials, greatly enhanced overpotentials which increase progressively during current flow, and which decay slowly on open circuit, generating potential–time curves which resemble desorption isotherms.

Conclusions based on these phenomena are supported by the results of experiments with poisoned platinum electrodes, which not only behave similarly but are also shown to retain reducing power for a limited time on open circuit.

It is suggested that electrodeposited hydrogen atoms may sometimes evaporate from an electrode into solution by a mechanism involving the participation of molecule-ions. A recent theoretical treatment of hydrogen overpotential can be extended to allow for the occurrence of such a final reaction step.

Hydrogen overpotential measurements have been made (1) using gold electrodes in the apparatus illustrated in Fig. 1, into which pre-electrolyzed, decinormal hydrochloric acid was delivered by pressure of hydrogen. Further pre-electrolysis of the solution was conducted by means of the ancillary gold electrode in compartment B. The gold test electrode in compartment A, arranged for even distribution of current over the whole of its surface, was supplied by a rapid flow of solution normal to each face by the powerful

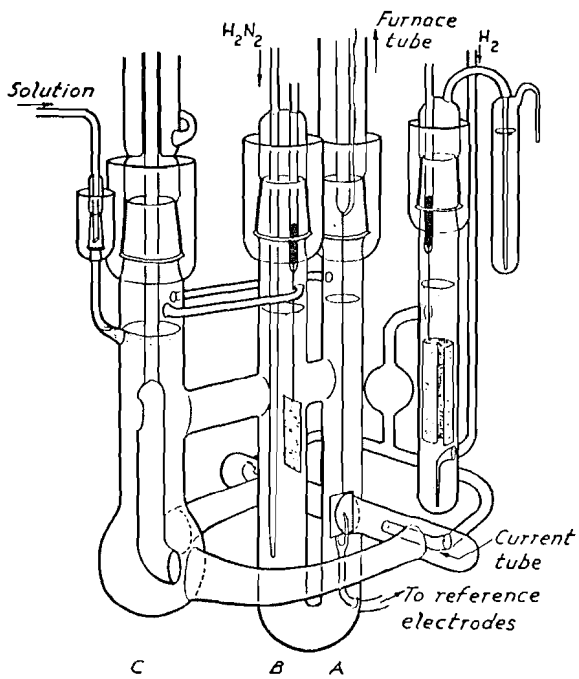

FIG. 1.

centrifugal stirrer C. Except at the highest current densities, all hydrogen produced in the electrode reaction was removed in the dissolved state. Other features of the apparatus are self-explanatory and permit the stringent precautions known to be essential in hydrogen overpotential work to be observed.

Gold electrodes, cleaned by normal chemical methods, showed zero rest potentials with respect to a reversible hydrogen electrode in the same solution. On cathodic polarization, they gave rise to Tafel plots typified by Fig. 2. These plots show slopes consistent with rate-limitation by slow discharge, except where decreasing cathodic polarization allows the back-reaction to assume increasing significance; that the occurrence of a back-reaction must be entertained is shown by, *inter alia*, the effect of sweeping out the cell solution with nitrogen instead of hydrogen.

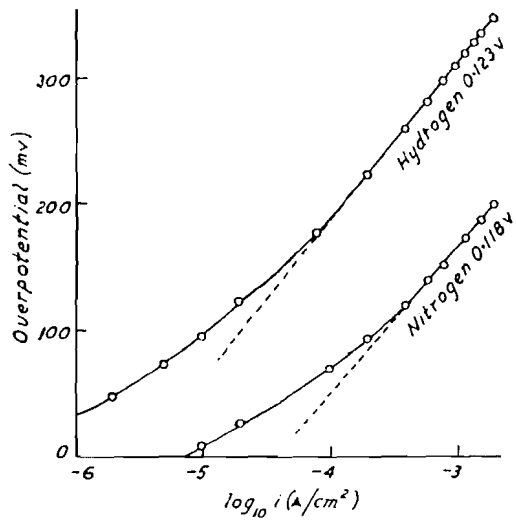

FIG. 2.

This behavior is reasonably normal. The main interest of these experiments arises from the results of withdrawing such a normal electrode from the solution into a silica furnace tube, forming an integral part of the apparatus, and subjecting it to prolonged annealing in hydrogen at temperatures falling from 800° C. On restoration of the cooled electrode to the same solution, its properties were found to be radically changed. It showed a rest potential of about +400 mv, complete insensitivity under all conditions to substitution of nitrogen for hydrogen passing through the cell solution, and greatly enhanced cathodic overpotentials which increased steadily with time and generated curved Tafel plots of varying, but excessively high, gradients. The behavior of the electrode on open circuit after cathodization was even more remarkable. On breaking the polarizing circuit, the negative potential of the electrode fell rapidly and linearly with log time to a value between −150 and −200 mv. From this point, the potential decayed more slowly, passing through zero in its progress to the original resting value of +400 mv. These changes were slow enough to allow some study to be made of the state of the electrode both before and after its potential passed through zero. Thus, connection via a microammeter to a reversible hydrogen electrode in the same solution caused anodic current to flow at the gold electrode whilst its potential was still negative, but cathodic current passed spontaneously under these same conditions when the gold electrode had attained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

positive potentials. In both cases stirring enhanced the current flow, and in both cases the potentials recovered from their displacements towards zero after disconnection. It is thus clearly shown that the potentials through which the electrode passes after cathodic treatment are very well defined, decisively determined by the physical or chemical state of the electrode at each instant. In turn, each state of the electrode must be a function of the stage reached in a slow reaction leading to the final resting state.

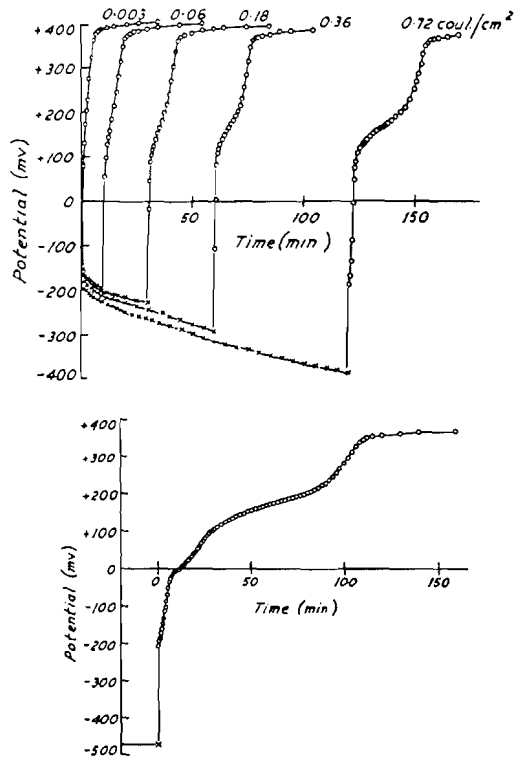

FIG. 3.

Two further facts assist in identifying this reaction. For a given constant current density of cathodization, the course of the open-circuit potential decay which follows depends systematically upon the duration of cathodization. This is illustrated in Fig. 3, where the results of six polarizations at 100 μa cm^{-2} are shown (in the last of these the growth of overpotential, during the cathodization period of 6 hours, is omitted). The form of the open-circuit potential–time curve depends strongly upon the current density in the preceding cathodization *up to a certain current density*, above which there is no such dependence. This is illustrated in Fig. 4, which shows the potential changes following 6-hour cathodizations at three current densities. Attention is drawn to the substantial identity of the curve relating to 20 μa cm^{-2} with that for 100 μa cm^{-2} in Fig. 3. It is believed that this effect is really due to the attainment during polarization of an electrode potential exceeding about -300 mv, when the subsequent potential decay curve assumes the same inflected form, which, for a given electrode, is remarkably reproducible.

There can be little doubt that the main effects of the heat treatment of the gold in hydrogen are the promotion of crystal growth (confirmed by microscopical examination)

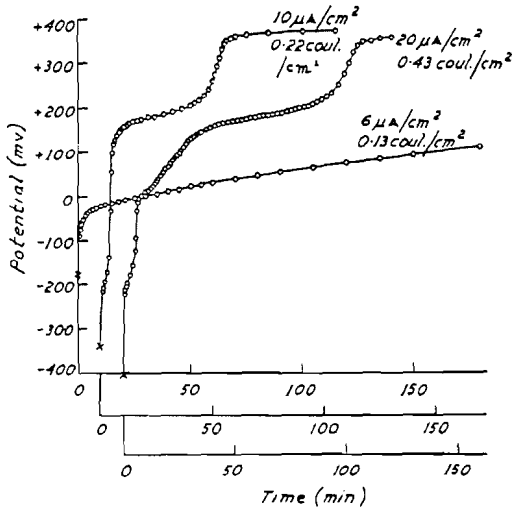

FIG. 4.

and the "burning-out" of catalytically active centers. Certainly, the gold becomes quite indifferent to its gaseous surroundings and is no longer capable of atomizing molecular hydrogen. It follows that it can no longer catalyze the recombination of hydrogen atoms.

The behavior of this thermally deactivated gold as a substrate for the hydrogen evolution reaction is only intelligible in terms of the progressive accumulation of electromotive material during cathodization, and the only material which presents itself is atomic hydrogen. The conclusion is reached that annealed gold forms a "non-equilibrium hydrogen electrode" at which cathodically generated hydrogen atoms pile up and are unable to escape by any *facile* mechanism: combination, evaporation, electrochemical desorption, or ionization. All of the partial processes which are mobile at the reversible hydrogen electrode have become strongly hindered, so that the electrode potential cannot at any stage be determined by a Nernst relation.

In terms of this hypothesis, the sequence of events during cathodization and afterwards is pictured as follows. Hydrogen atoms accumulate at the surface of the electrode at a rate determined by the current density and, normally, the processes by which they leave the surface increase in rate until a steady kinetic state is established. But when these processes are very slow, then at all but the lowest current densities, the accumulation of atoms may become extensive and lead to progressive changes in the properties of the electrode surface, perhaps by the burning-out or saturation of the few remaining active centers. If there is an upper limit to rate of dissipation of hydrogen atoms, not dependent upon potential, *and not kinetically linked with the discharge process*, there will clearly be a critical rate of discharge. For rates of discharge less than this, a kinetic steady state may be established; for higher rates, the accumulation of atoms may proceed unchecked and lead to progressive saturation. Since rate of discharge is a function of electrode potential, this is consistent with the observation that the attainment of a critical potential has a profound effect upon subsequent electrode behavior. The slow and prolonged growth of overpotential, and the dependence of open-circuit potential decay upon the time for which cathodization is continued, coupled with its independence of the current density of cathodization above a certain minimum, strongly suggest that hydrogen atoms penetrate the gold lattice. Gold does not dissolve hydrogen from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

molecular gas phase, but it has recently been shown (2) that an evaporated film of gold takes up gaseous hydrogen atoms quite rapidly; it is believed that a gold cathode which is incapable of catalyzing atom recombination will do the same. If this bulk penetration of the gold can be accepted, then the inflected potential decay curves have a more than superficial relationship to the desorption isotherms (as of hydrogen from palladium) which they so strikingly resemble.

These conclusions have been supported in more detail elsewhere (1), and further discussion must give way to an attempt to meet the obvious demand to demonstrate the alleged heavy, slowly dispersing accumulations of hydrogen atoms at such inactive electrodes.

This has been done with the aid of poisoned platinum electrodes (3) in an apparatus illustrated in Fig. 5, which is largely self-explanatory. The hemispherical platinum "microelectrode" C, cathodized in 0.001 *N* hydrochloric acid by means of the very large hydrogen electrode A, could be depressed at will against a sintered glass "target" F, which carried a deposit of tungsten trioxide, and through which the cell solution was

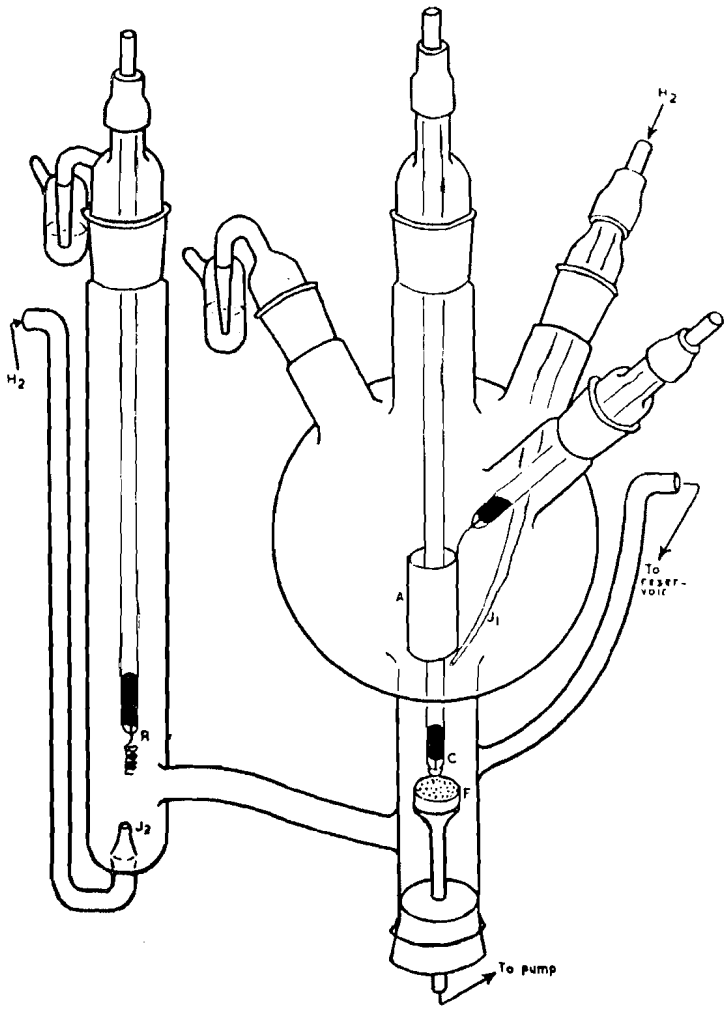

FIG. 5.

For personal use only.

continuously drawn. Since poisoned systems were to be studied, rigorous techniques were not employed and the electrodes were studied in three states: (1) ostensibly unpoisoned, (2) poisoned by an electrodeposition of mercury, and (3) additionally poisoned by 10^{-5} mole l^{-1} of mercuric chloride in the cell solution.

The electrodes showed positive rest potentials increasing from 350 to 625 mv with increasing degrees of poisoning (adventitious and deliberate), and very high and erratic overpotentials during cathodic polarization, rising to tens of volts at the maximum current density of about 125 ma cm^{-2}. Even under these extreme conditions, involving blackening and disruption of the electrode surface, the overpotentials remained strongly influenced by poisoning. After cathodization, the negative electrode potentials decayed in a slow and inflected way on open circuit. Provided that a limiting current density had been exceeded in the preceding cathodization, the potential–time curves showed arrests, of length roughly proportional to current density and duration of cathodization; some examples of these curves are shown in Fig. 6.

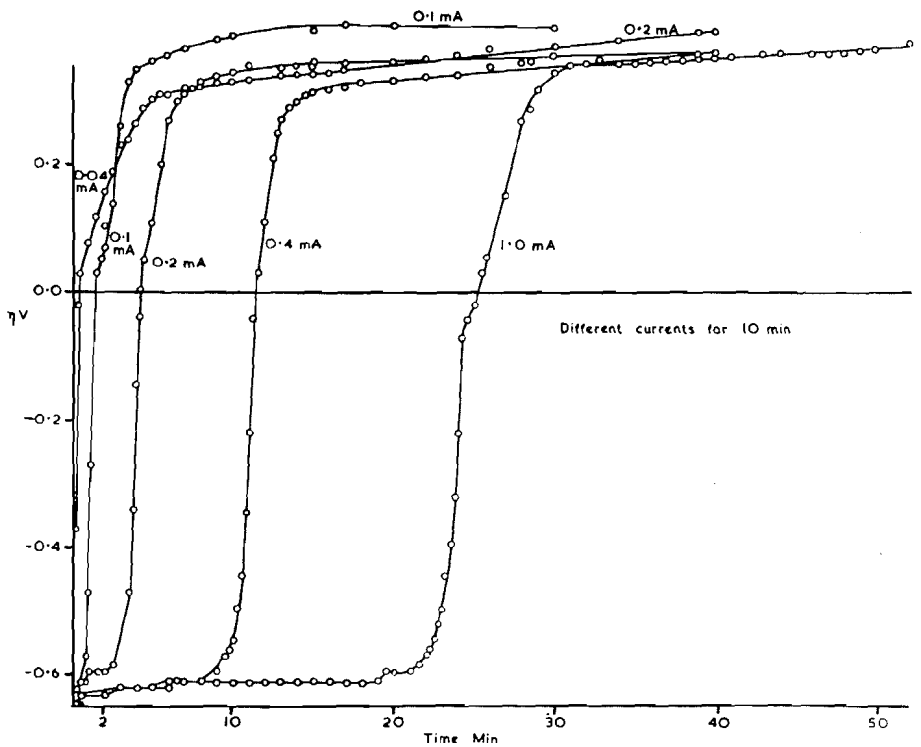

FIG. 6.

A closer correspondence to the behavior of the annealed gold electrodes could hardly be expected, and there can be little doubt that very similar phenomena are involved in the two cases. It was now possible, however, to carry out a chemical test for the presence of a cathodic product with reducing properties, by bringing the cathode into contact with the tungsten trioxide target. Contact established during current flow produced an immediate imprint of tungsten blue, no doubt owing to electronic conduction. For the unpoisoned electrodes, this property vanished instantly the circuit was broken, but it was retained on open circuit by the poisoned electrodes to an extent systematically

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

related to the duration and current density of cathodization and the degree of poisoning. It was possible to follow the decay of reducing power with time in an approximate way by producing imprints in a standardized manner, and by assessing their depth of color in terms of an arbitrary scale of "color numbers" having a maximum of 10 set by an imprint produced during current flow. It is hoped in due course to improve upon the *ad hoc* device used in this preliminary work. For a standard time of cathodization of 30 minutes at a uniform current density of 25 ma cm^{-2}, the results shown in the following table were obtained.

TABLE I

	Electrode state (2)		Electrode state (3)	
Decay interval	Potential on making contact, mv	Color No.	Potential on making contact, mv.	Color No.
3 seconds	−646	8	−646	10
10 seconds	−646	7	−646	10
30 seconds	−596	4	—	—
1 minute	−546	3	−621	9
5 minutes	−509	2	−621	5
10 minutes	+79	1	−496	3
30 minutes	+159	0	−483	1

It is evident that the residual reducing power was not directly linked with electrode potential, and was in fact often retained when this potential had become positive. It is suggested that these experiments support the conclusion previously drawn.

It may be that this work has some importance as a basis for the view that consideration of the hydrogen evolution reaction has perhaps been too closely confined within the narrow framework of but three reaction steps succinctly denoted by the names Volmer, Tafel, Horiuti (VTH), one or other of which, it is almost universally assumed, must be rate-limiting. One is still invited to accept the gullet-sticking conclusion that at platinum electrodes atom recombination is very fast but is rate-limiting, whilst at mercury it is very slow but is not rate-limiting. The work of the Knorr school (4) has shown the weakness of much of the evidence relating to low overpotential metals and has strongly reinforced the inverse relation established by Bonhöffer (5) between overpotential and catalytic power. This relation has been discounted (6) on the basis of work by Schechter (7) which does not, in the author's view, have any relevance. The fact remains that for eight common metals the sequence of increasing overpotential is the same as the sequence of decreasing catalytic activity, and the chance that these two sequences should occur *un*related to each other is about 1 in 1.6×10^9. But it was the assumption that this obvious relationship required the rate-limiting step in the hydrogen evolution reaction to be atom recombination that was false.

The evidence that slow discharge is rate-controlling at mercury electrodes is strong, but there is no satisfactory evidence at all about the subsequent stages of the reaction at this metal (8, 9). The elegant potentiostatic experiments of Gerischer and Mehl (9) suggest that the mercury surface is bare of hydrogen atoms. What then happens to the atoms that are deposited? It must be admitted that the present position is not altogether satisfactory.

Reconsideration of the work of Kobosew and Nekrassow (10) appears to be desirable for two reasons. A relation was established between hydrogen overpotential at horizontally disposed electrodes of various metals and the degree of reduction of tungsten

For personal use only.

trioxide suspended in the electrolyte above the electrodes. The interpretation of this in terms of atomic hydrogen was attacked by the Frumkin school (11), but the resulting polemical exchanges have, in the author's view, been resolved by Poltorak (12), who has convincingly demonstrated "reduction at a distance" (of about 0.5 μ) from a high overpotential cathode, as well as retention of reducing power after cathodization. The present work confirms the latter result, and invites more serious attention to the views of Kobosew. In the earlier paper with Nekrassow (10), he considered both penetration into the metal phase and free evaporation into solution as possible fates for electrodeposited hydrogen atoms, and first introduced, in a rather generalized form, what is now known as electrochemical desorption and generally associated with the name of Horiuti. He has maintained his views for over twenty years, and his quite recent "adsorption theory of hydrogen overpotential" (13), in spite of certain weaknesses, very adequately explains the opposite effects of poisons on the catalytic and "electrocatalytic" activities of metals.

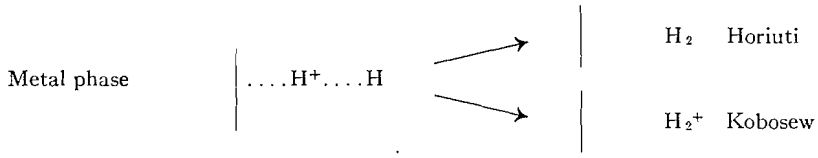
It appears that more attention is now being given to the role of adsorbed hydrogen atoms in relation to hydrogen overpotential, and one of the most satisfactory discussions is due to Gerischer (14), although still largely confined within the VTH framework. The suggestion is made that his treatment could be extended along the following lines.

There is no lack of evidence that hydrogen atoms can exist in solution for a finite time and no reason to suppose that, generated at an electrode, they need be in equilibrium with the gas phase, need be potential-determining according to a Nernst relation, or are unable ever to leave the electrode by evaporating into the solution. Developments in radiation chemistry have established the molecule-ion, H_2^+, as an intermediate of frequent occurrence, and it is suggested that it may well be concerned in an evaporative process. Coulson has recently emphasized (15) that this entity, one sixth of the size of the hydrogen atom, has its single electron almost exclusively located in regions between the nuclei. The protons are therefore substantially unscreened from the outside, so that the molecule-ion may be expected to behave as if it were two halves of a proton separated by about 1 Å. In this case, its considerable bond energy of 61 kcal mole^{-1} might be expected to be supplemented in aqueous solution by a hydration energy of the same order of magnitude as that of the proton itself (282 kcal g-atom^{-1}). An upper limit to this hydration energy of 255 kcal mole^{-1} has in fact been calculated (16), and it can be shown that a lower limit of 221 kcal mole^{-1} is needed to make the reaction $H + H^+_{hydr.} = H_2^+{}_{hydr.}$ exothermic. It is considered to be very likely that the hydration energy lies between these limits, or is at least large enough to make the hydrogen molecule-ion an entity very frequently to be reckoned with in aqueous solution in any reaction ostensibly involving hydrogen atoms.

If this can be accepted, a ready means can be seen for the desorption of hydrogen atoms from an electrode at which the absorption energy is not too great. What happens to these atoms when they have diffused, as molecule-ions, some few Angstroms from the electrode surface ceases to be a part of the electrochemical problem! In alkaline solutions, the alternative reaction $H + H_2O = H_2^+{}_{hydr.} + OH^-_{hydr.}$ may well operate, for it does not seem to be unduly disfavored energetically. Gerischer's calculations may be adapted to this suggestion and, assuming that the standard free energy of hydration of the molecule ion is 50 kcal mole^{-1} less negative than that of the proton, they indicate that for an adsorption energy of hydrogen atoms less than about 30 kcal g-atom^{-1}, an evaporative process involving molecule-ions might well follow a rate-limiting discharge step. It seems appropriate to suggest the name "Kobosew step" for this final stage, which is thought to be operative for high overpotential metals such as mercury.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

It is undeniable that the molecule-ion must be a participant, however transitory, in the Horiuti (electrochemical desorption) step. It is therefore tempting to envisage a transition state which could break down in two ways, according to whether desorption or electron transfer were the easier.



It is clear that the distinction between various proposed mechanisms for the hydrogen evolution reaction depends upon the sequence of acts of discharge, combination, and desorption. The suggestion is now made, in a provocative rather than a didactic spirit, that the usual assumption that desorption must be preceded by, or coupled with, completion of discharge of all the ions involved is not necessarily true.

CATHODIC POLARIZATION OF SILVER IN SULPHURIC ACID[1]

A. A. Antoniou and F. E. W. Wetmore

ABSTRACT

The hydrogen overpotential on fine silver cathodes has been determined from 2 to 35° and over a current density range from 0.03 to 2000 μa cm^{-2}. Two Tafel slopes were observed, RT/F at low currents, $2RT/F$ at high currents. The stoichiometric number was found to be one and the symmetry factor one-half at low currents. The heat of activation changed from 18.8 kcal at low currents to 14.3 at high currents.

EXPERIMENTAL METHODS

The silver cathodes were of high purity (less than 0.001% impurity) and in the form of single crystal and polycrystalline slabs. After being electropolished the metal was held in a hot hydrogen atmosphere for a few days; a small amount of silver was removed by gentle anodizing. Electrodes so treated were more consistent in their behavior than those not strongly hydrogenated; the latter gave high Tafel slopes, as mentioned by Frumkin (3). Teflon containers exposed only one surface of the slab (110 or 111 plane of the single crystals), of area about 3.5 cm^2.

The anode and the Luggin probe were both hydrogen electrodes. A platinum electrode used for pre-electrolysis could be swung out of the solution when not required. In all the experiments the electrolyte was molar H_2SO_4, made up from triply-distilled reagents. All parts of the cell were maintained under a slightly positive pressure of purified hydrogen.

The cells were mounted in an air bath kept within 0.1° of the desired temperature. A danger in lesser control lies in the variation of the temperature of the probe electrode, which usually has a small heat capacity.

Polarizing currents were kept constant by an electronic regulator. Potential difference between probe and cathode was imposed on a direct-coupled amplifier having an input resistance of 10^{10} ohms; the output could be coupled to either a potentiometer or one of three recording devices. For slow changes an Esterline-Angus recorder (0.5 sec) was convenient; for more rapid changes a Kipp galvanometer (0.01 sec) and drum camera were used; a direct-coupled oscilloscope and fixed camera were used for fast changes. In order that transient fluctuations associated with mechanical contacts could be avoided, rapid build-ups and decays were initiated by a thyratron switch.

RESULTS

Rest-potential

The potential E_r to which the electrode decays after removal of the polarizing current can give information about the purity of the system. The most likely contaminant is oxygen. Experiment has shown that oxygen promotes the corrosion of silver and thus the rest-potential can be viewed as an indicator of the silver ion activity or the equivalent effective concentration of oxygen. For the conditions used here, and at 25°, the partial pressure of oxygen above the electrolyte would correspond to

$$\log p_{O_2}(\text{atm}) = 68E_r - 84.$$

[1]*Manuscript received July 12, 1958.*
Contribution from the Department of Chemistry, University of Toronto, Toronto 5, Ontario. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

In most of the experiments E_r lay in the range 0.35 to 0.45 volt positive, but in several was substantially less positive. For example, in a particular series the decays occurred within minutes to zero potential and after 8 hours to only 17 mv positive.

Overpotential–Current Relationships

The Tafel plot was found to consist of two distinct linear portions, as exemplified in Fig. 1. Table I gives the slopes, the exchange current densities, and the potential of intersection of the pairs of lines.

The low current slope corresponded closely to RT/F until the electrode had been polarized and allowed to decay many times. The slope then increased, as the time sequences show. It was evident from examination of electrodes used over long periods that some silver had dissolved and been redeposited; a change in the surface was apparent.

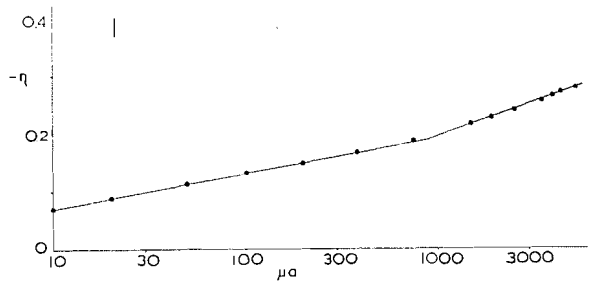
The high current slope remained at approximately $2RT/F$ throughout the experiments.

The change from one slope to the other occurred over a small range of current and potential in any particular run. The average potential of intersection was 196 ± 20 mv. The current density of intersection, like the exchange current densities associated with the two linear portions of the Tafel curve, showed considerable scatter, but for each electrode showed a systematic change with temperature. It is clear that these current parameters depend not only on the temperature, but also on the effective surface area, as evidenced by variation of the capacitance of the electrode in the same sense as the variation in i_0.



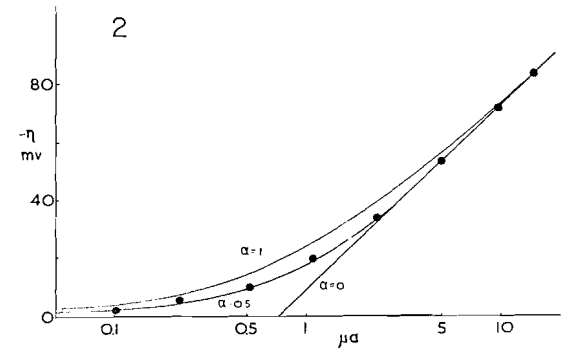


FIG. 1. Typical overpotential–current relationship.
FIG. 2. Low current overpotential–current plot.

Symmetry Factor and Stoichiometric Number

The dots of Fig. 2 show the relationship of the overpotential and the current found when decay occurred to zero potential (oxygen practically absent). The bend from linearity indicates clearly that omission of a term for reverse current makes Tafel's equation (shown by the line marked $\alpha = 0$) unsuitable for the range of current below about $10i_0$. Figure 3 shows the plot of the expression

$$i = 2i_0 . \sinh(-\eta/b)$$

proposed earlier (4) as an improvement over Tafel's expression, but premised on symmetry of energy division ($\alpha = 0.5$).

The curves of Fig. 2 express the equations

$$\begin{aligned}
&\text{(asymmetric, } \alpha = 1) \quad i = i_0[\exp(-36.6\eta) - 1] \\
&\text{(symmetric, } \alpha = 0.5) \quad i = i_0[\exp(-36.6\eta) - \exp(36.6\eta)] \\
&\qquad\qquad\qquad\qquad = 2i_0 . \sinh(-36.6\eta) \\
&\text{(asymmetric, } \alpha = 0) \quad i = i_0 \exp(-36.6\eta)
\end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in which the factor 36.6 is the value of $1/b$ found from consideration of the whole range of current below the change of slope of the Tafel plot. The curve indicating symmetry is in close agreement with experiment.

The stoichiometric number has been defined (5) at high overpotentials by

$$\nu = \alpha nFb/RT$$

and at low overpotentials by

$$\nu = -(nFi_0/RT)(\partial\eta/\partial i)_{\eta\to 0}.$$

As $$\eta \to 0, \sinh(-\eta/b) \to -\eta/b$$

and $$-\partial(\eta/b)/\partial i \to \partial \sinh(-\eta/b)/\partial i = 1/2i_0.$$

Hence $\nu = nFb/2RT$, which is simply the first definition with $\alpha = 0.5$.

Since at low currents b was found to be RT/F and α to be 0.5, the corresponding value of ν is $n/2 = 1$. Owing to the change in slope of the Tafel plot, it is not possible to determine the values of α and ν separately at high currents; all that can be said is that $\nu/\alpha = 4$, to agree with $b = 2RT/F$.

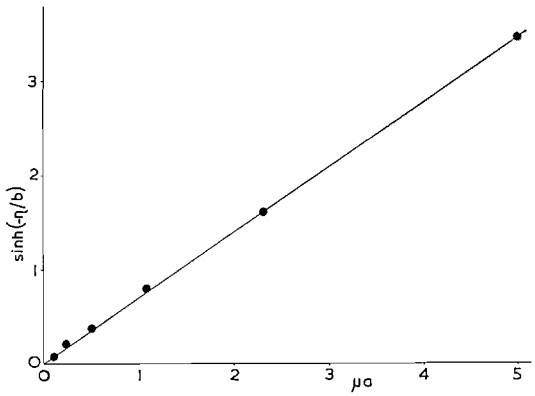

FIG. 3. Linear function plot.

Temperature Dependence of Overpotential

On varying the temperature at constant current and confirming that the overpotential did return to its original value when the original temperature was re-established, the data of Table II were found.

Diffusion of Hydrogen in Silver

In order to determine whether hydrogen diffuses appreciably through silver, an experiment was carried out with a thin silver foil separating two portions of electrolyte. While one face was polarized at 3 ma cm^{-2}, a probe on the other face showed no change of potential.

Build-up and Decay Curves

The change of potential during polarization and in decay was examined, but not as intensively as the steady state overpotential. There are a few points which may merit mention.

At constant charging current the potential build-up was linear with time and then bent off smoothly to the constant value of overpotential, usually taking longer to reach a steady state than would be expected from the simple expression for build-up (4), and sometimes showing a slight drop after the rapid part of the build-up. In some runs, in

which oxygen was known to be present, the initial part of the curve was sigmoid, as would be expected. The apparent capacitance was usually high at very low polarizing currents; capacitances determined through analysis of decay curves did not generally show this same behavior.

Most decays showed linearity of potential in $\log(t+\theta)$ when θ was chosen appropriately (4), but this was not always so for the highest currents. Decay curves taken with the oscilloscope did not show linearity of the potential with time, even initially.

DISCUSSION

Bockris and Conway (2) and Bockris, Ammar, and Huq (1) studied the overpotential on silver in various concentrations of HCl at room temperature. Their results are compared with those found in this work:

	B–C			B–A–H		A–W
	0.1	1.0	5.0	0.1	0.4 *N* HCl	2 *N* H_2SO_4
B, low i	0.09	0.06	0.07	0.057	0.058	0.059
B, high i	0.12	0.13	0.12	0.097	0.101	0.116
Potential of intersection	0.27	0.19	0.28	0.07	0.15	0.20

The present work supports the existence of two distinct Tafel slopes, agrees with the low current slope of B–A–H and the low current stoichiometric number unity, adds that the value of α at low currents is 0.5, and shows a high current slope of $2RT/F$, which lies between the earlier sets. The present work shows that there is a rise in the low current slope as the electrode is worked and that this change may be related to the surface condition; there is no evidence that the change is caused by surface contamination.

Bockris and Conway attributed the existence of two slopes to a phenomenon related to the adsorption of H_3O^+ on the electrode and suggested that the mechanism is probably slow discharge followed by combination.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Bockris, Ammar, and Huq pointed out that the low current slope, RT/F, cannot be explained in terms of simple interpretation of mechanisms already proposed, except by assumption of unrealistic values of α. In order to account for the slope they proposed two explanations. The first of these involves migration of H on the metal surface; they considered it unsatisfactory for silver. Their second and preferred explanation is based on the nearness of the overpotential to the electrocapillary maximum potential and leads to the conclusion that the slope of the Tafel plot can depend on the electrode potential and have the value $2RT/F$ as a maximum. They concluded that electrochemical desorption is the slow step throughout, but did not offer proof that $\nu = 1$ at high currents.

These earlier reports were not in agreement on the low current slope, the high current slope, the variation of the low current slope with concentration, or the potential of intersection. From the second study (B–A–H) there is no indication that the low current slope varies with concentration and it is striking that the present work, at higher acid concentration, shows practically the same value. The considerable variation in the potential of intersection, even in the same solution (0.1 N HCl), raises doubt about the validity of the second explanation (B–A–H) for the change in slope.

Both the sharpness of the break in the Tafel curve and the discontinuity of the heat of activation in going from low to high current point to a change in the nature of the rate-determining step as the current is increased. At high current a slow discharge step with $\alpha = 0.5$ would lead appropriately to $\nu = 2$ and $b = 2RT/F$. At low current $\nu = 1$, which rules out the discharge process as the rate-determining step. The slope, $b = RT/F$, could be attributed to slow surface migration or to another process which is first order with respect to H.

The authors gratefully acknowledge financial support from the National Research Council through Grant A 412.

TRANSPORT OF HYDROGEN THROUGH PALLADIUM-CLAD ELECTRODES

SIGMUND SCHULDINER AND JAMES P. HOARE[2]

ABSTRACT

Electrochemical polarization studies of the transport of hydrogen through Pd, Pt, Pd-clad Pt, Au, Ni, and Fe were conducted under conditions of a concentration gradient of either atoms or protons. Transport of hydrogen through an atom concentration gradient was found for Pd and Pd-clad Fe only. Under a proton concentration gradient, protons migrated readily through Pd, but their transfer through Pt was immeasurable unless the Pt was sandwiched between Pd. Transfer of protons through Fe sandwiched between Pd was also found. Hydrogen atoms evidently did not dissolve to a significant extent in Pt, but if protons are introduced from Pd-clad to Pt they can, under the proper conditions, migrate through Pt. The solution and diffusion of hydrogen atoms and also the migration of protons occurred in Fe. Transport of hydrogen, in any form, through Au and Ni was not detected. Considering the electronic configuration of these metals, it was reasonable that proton migration through Au was negligible; however, it was surprising that protons did not migrate through Ni. Reasons for this anomaly are suggested.

INTRODUCTION

Investigations of the diffusion of atomic hydrogen and deuterium through a β–Pd diaphragm (1, 2, 3) and the migration of protons and deuterons through an α–Pd bielectrode (3, 4) have been reported from the laboratory. For the β–Pd diaphragm a concentration gradient of atomic hydrogen in the palladium cathode arises, whereas for the α–Pd bielectrode there is a migration of protons through the metal under a proton concentration gradient caused by the difference in the electrochemical affinities of the reactions on the cathode and anode sides of the bielectrode.

It was felt that an investigation of the solution and transfer of hydrogen through such metals as Pt, Au, Ni, and Fe could be accomplished by a series of experiments in which these metals would be clad with palladium. The reasons for cladding these metals were twofold. Firstly, by controlling the phase of the palladium–hydrogen alloy (α or β), investigations of the transfer of hydrogen through metals clad with the palladium under conditions of a concentration gradient of either atoms or protons were possible. Secondly, by sandwiching such metals as iron and nickel with palladium, their solution in acid media was prevented. Since the rate of transport of hydrogen through the metals studied was presumably in all cases much slower than for the palladium, the rate would be controlled by these metals. The species of hydrogen which came into contact with these metals at the Pd–metal interface could be controlled also, since the palladium was their only source of hydrogen.

It was also the purpose of this work to try to relate the electronic configuration of the metals studied with the solubility and transfer of hydrogen through them.

EXPERIMENTAL

The experimental techniques and the cell used were the same as reported in references (1, 2, 3, 4). The solution was in all cases highly purified 2 N sulphuric acid. The metal membranes were prepared by cladding the metals on one and/or both sides with palladium. This was done by covering layers of clean metals with sheet titanium, heating red hot with an acetylene torch, and running through a steel roll press with cold rolls. The titanium sheets were then stripped off and the surfaces of the bimetallic sheets were

[1]*Manuscript received June 12, 1958.*
Contribution from the U.S. Naval Research Laboratory, Washington 25, D.C. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.
[2]*Present address: Ford Scientific Laboratory, Ford Motor Company, Dearborn, Michigan.*

polished with metallographic paper, followed by cleaning in concentrated nitric acid.

The metal foils used in preparation of the bimetallic specimens were 99.7% palladium, 0.004 inch; 99.99% nickel, 0.002 inch; mild steel, 0.004 inch; 99.97% gold, 0.010 inch; and 99.99% platinum, 0.005 inch thick. The following bimetallic specimens were prepared: Pd: Au, 0.006 inch; Pd: Pt, 0.006 inch; Pd: Pt: Pd, 0.010 inch; Pd: Au: Pd, 0.009 inch; Pd:Ni:Pd, 0.006 inch; and Pd: Fe: Pd, 0.006 inch thick.

For the experiments in which the bimetallic foils were used as cathode diaphragms, purified hydrogen was bubbled through the solutions in both compartments on each side of the diaphragm. The reference electrodes used in each compartment were Pt/H_2 electrodes. The potential drop due to solution resistance on the cathode side was determined simultaneously with the pseudocapacitance test for electrode cleanliness on each side of the membrane by the current interrupter technique (5, 6).

For the experiments in which the bimetallic foils were used as bielectrodes, after the pre-electrolysis and surface activation procedure was finished, solution resistance and cleanliness of electrodes were determined. Then purified hydrogen was bubbled only through the solution in the compartment on the cathode side of the bielectrode, and purified helium was bubbled through the solution in the compartment on the anode side of the bielectrode. When the anode side of the bielectrode consisted of palladium, hydrogen dissolved in this part of the foil was removed by anodic polarization. The removal of hydrogen was indicated by following the anodic charging curve and observing when the anodic potential was several hundred millivolts positive to the potential plateau which resulted from the dissolved hydrogen. This anodic charging was repeated several times at successively reduced applied current densities to assure the removal of most of the hydrogen from the anode side of the bielectrode. The overvoltages on the hydrogen-saturated cathode side were determined against a Pt/H_2 electrode in the same solution. The overvoltages on the helium-stirred anode side were determined against a $(Pd–H)_\alpha/H^+$ electrode (7) in the same solution.

In addition to the experiments with the above materials, pure palladium and pure platinum bielectrodes were compared. These experiments were conducted with hydrogen bubbling through both compartments.

The ambient temperature was $30 \pm 2°$ C. The apparent exposed area of all the electrodes was 0.14 cm^2.

COMPARISON OF A PLATINUM WITH A PALLADIUM BIELECTRODE

A comparison of the overvoltage on a platinum bielectrode with that on a palladium bielectrode of the same dimensions is shown in Fig. 1. Since the catalytic activity of α-palladium is not far removed from that of platinum (4, 8), these curves show the strong influence of the rate of proton migration through the palladium bielectrode. It was previously shown (2) that atomic hydrogen does not diffuse through a platinum diaphragm with a clean surface. Also, a comparison of the anodic polarization curve of the platinum bielectrode, shown in Fig. 1, with the anodic polarization curve for a simple platinum anode indicates that there is not a significant amount of proton migration through the platinum bielectrode. It should be noted that in Fig. 1 the ordinate is given in terms of η', where η' is defined as the difference in potential between the open circuit, reversible electrode potential compared to the polarized electrode potential of the same metal/solution system. This means that the overvoltages on the platinum bielectrode were against a Pt/H_2 electrode in the same solution, and that the overvoltages on the palladium bielectrode were against a $(Pd–H)_\alpha/H^+$ electrode in the same solution.

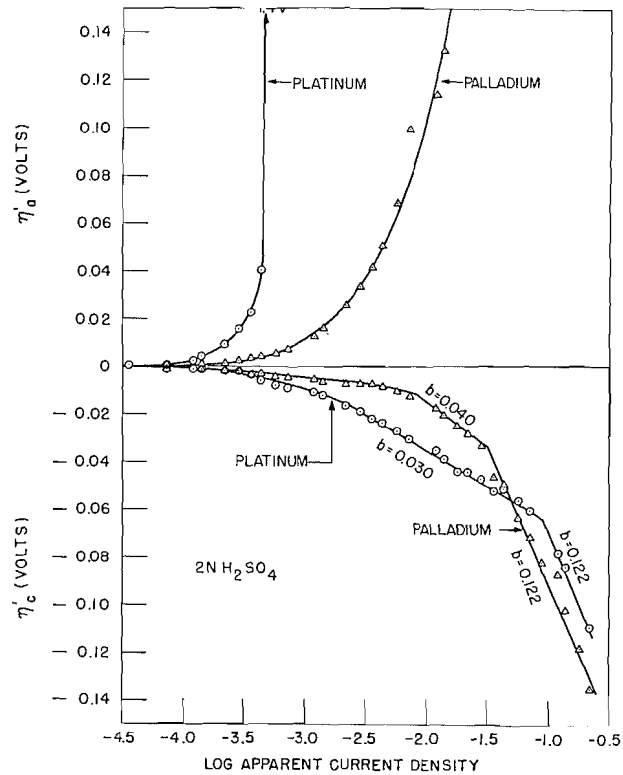

FIG. 1. Comparison of the hydrogen overvoltage on Pd and Pt bielectrodes. Pd and Pt overvoltage values are vs. $(Pd–H)_\alpha/H^+$ and Pt/H_2 reference electrodes, respectively.

In the low current density range the atomic hydrogen concentration on both sides of the palladium bielectrode changes little, while that on the platinum is rapidly changing. This largely accounts for the difference in overvoltage between the two metals. As the current density is increased on both the platinum and palladium cathode sides, there is a change to a Tafel b-slope of 0.12. In the current density range in which the b-slope on the cathode side is 0.12, most of the anodic reaction on the anode sides of these metal bielectrodes goes into the production of oxygen. As was indicated in previous work (4), it is believed that this change in Tafel slope is caused by the poisoning of the cathode surfaces by oxygen which migrates from the anode side. Kalish and Burshtein (9) have shown that oxygen can diffuse from the interior to the surface of platinum at room temperature. Previous work done at this laboratory (5, 10) has indicated that cathodically polarized platinum in strong sulphuric acid solutions will maintain a Tafel slope of 0.03 to current densities well beyond the value at which the change in slope from 0.03 to 0.12 takes place for the Pt curve in Fig. 1.* Thus for both the platinum and the palladium

**The limiting diffusion current density, i_L, for hydrogen ions in 2 N sulphuric acid solution can be approximated by the equation:*

$$\eta_c = 0.059 \log [(i_L - i)/i_L].$$

Using the data for the platinum cathode shown in Fig. 1, at an overvoltage of −0.06 v, the current density is equal to 0.100 amp/cm². Applying these values of η_c and i to the above equation, i_L is equal to about 2.8 amp/cm². Thus the limiting diffusion current density is well beyond the value at which the change in slope from 0.03 to 0.12 takes place for the Pt *curve in Fig. 1.*

cathode sides of their respective bielectrodes there is a change in the rate-controlling step from the catalytic combination or electrochemical desorption to a slow hydronium ion discharge. This change takes place at current densities well below the limiting current densities for hydronium ion depletion in the concentration layer on the solution side of the electrodes.

It should be noted that the previous work of the authors on the mechanism of the hydrogen-producing reactions on platinum (5, 10) and palladium (11) have also indicated a change in Tafel slope from 0.03 or 0.04 to 0.12. For these systems it was shown that at the current density at which the change in slope took place there was a depletion of hydronium ions at the interface, and the change in slope was interpreted to mean a change to a slow discharge of water to atomic hydrogen as the rate-controlling step. In other words, in the case of a simple platinum or palladium cathode, the change in slope to 0.12 occurs at a concentration limiting current density because there are not enough hydronium ions at the interface to support the applied current flow. In the case of the cathode side of a platinum or palladium bielectrode, the change in slope appears to be caused by the poisoning of the catalytic surface with oxygen.

Figure 1 further shows that the change in Tafel slope to 0.12 occurs at a significantly lower current density for palladium than for platinum. This is either because the solubility of oxygen in palladium is higher than in platinum or the effects of poisoning by oxygen is much greater for palladium. This is confirmed by the results shown in Fig. 2. Here both electrodes were anodized at 10 ma for a period of 45 minutes. The circuit was broken and both electrodes were allowed to come to their reversible potentials in hydrogen-saturated sulphuric acid solution. As the curves show, the time required for the palladium to reach its open-circuit, steady-state potential was about three times longer than that for the platinum electrode. This was either because the palladium dissolved more oxygen, which took a longer time to remove because of a slow rate of diffusion of the oxygen from the interior to the surface or, if only an equivalent surface layer of oxygen or oxide was formed by both metals, the rate of reduction of the oxygen by hydrogen was slower on the palladium surface. There is also the possibility that these effects are operating simultaneously.

NOBLE METAL ELECTRODES CLAD WITH PALLADIUM ON ONE SIDE

Cathode overvoltage curves for Pd: Pt, Pt: Pd, Pd: Au, and Au: Pd* diaphragms shown in Fig. 3 indicate that in each case the metal exposed to the solution on the polarization, η_p, side of the cell determined the hydrogen-producing mechanism. The absence of overvoltage effects on the diffusion, η_d, sides indicated that hydrogen did not diffuse through any of these combinations.

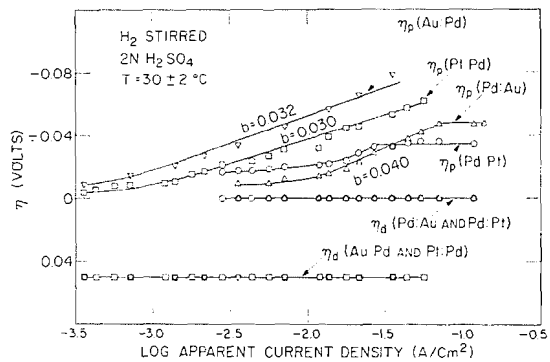

FIG. 3. Hydrogen overvoltage on polarization and diffusion surfaces of Au and Pt cathode-diaphragms clad on only one side with Pd. Pt/H_2 reference electrode.

In order to determine if protons could migrate through the same palladium-clad noble metal combinations, the electrodes were treated as bielectrodes. On the cathode side of these bielectrodes, the solution was stirred with hydrogen, whereas on the anode side the solution was stirred with helium. By this technique the possibility of the oxidation of molecular hydrogen on the anode side was eliminated and, if hydrogen did migrate through the bielectrode, a depolarization effect should be evident on the anode side. Figure 4 shows the results of these experiments. Because of the complete polarization of the anode curves it can be concluded that proton migration through these metal combinations does not occur significantly. The change from the lower to the 0.12 slope on the cathode overvoltage curves can be interpreted, as above, as due to the migration of oxygen from the anode to the cathode sides with the consequent poisoning of the cathode surface.

METALS SANDWICHED BETWEEN PALLADIUM

Hydrogen overvoltage, η_p, curves for Pd: Fe: Pd, Pd: Ni: Pd, Pd: Au: Pd, and Pd: Pt: Pd cathode diaphragms are shown in Fig. 5. The curves for the polarization sides of the diaphragms are similar to those for palladium (11). As expected, the metal in

**Throughout this paper the order of metal foils clad together will be signified by their arrangement from left to right. For the cathode diffusion diaphragms this order will represent the following arrangement in the two-compartment cell:*

polarization side: diffusion side.

For example, Pd: Pt means that the palladium was on the polarization side and the platinum was on the diffusion side of the diaphragm. Pd: Pt: Pd means that palladium was on both the polarization and diffusion sides and that platinum was sandwiched in-between. For the bielectrodes, the order from left to right will represent the following arrangement in the two-compartment cell:

cathode: anode.

For example, Pd: Pt means that the palladium was on the cathode side of the bielectrode and the platinum was on the anode side. Pd: Pt: Pd means that palladium was on both the cathode and anode sides and that platinum was sandwiched in-between.

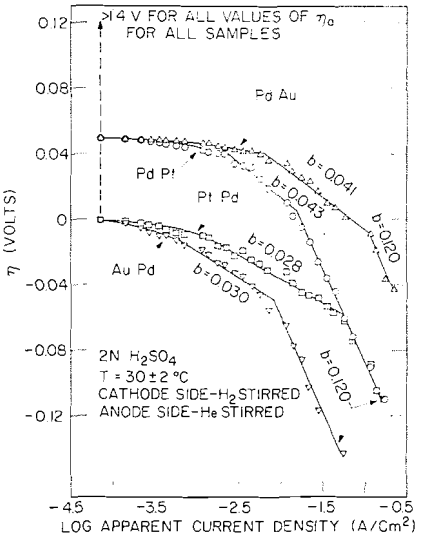

FIG. 4. Hydrogen overvoltage on Au and Pt bielectrodes clad on only one side with Pd. Pt/H_2 reference electrode on cathode side; $(Pd\text{-}H)_\alpha/H^+$ reference electrode on anode side.

the interior does not appear to influence the shape of the overvoltage curves. The differences in the i_0 values and the potentials for the plateaus for these curves are undoubtedly due primarily to the variation in the amount of cold working of each of these sandwiches (2).

Figure 5 shows the diffusion overvoltage, η_d, for the various metal sandwiches. Only for the case of the iron sandwich was there evidence of a significant amount of hydrogen diffusion through the diaphragm. In all cases the potential on the diffusion side at open circuit was equal to 0.05 v. This showed that during the cathodic charging of the palladium with hydrogen on the polarization side not enough hydrogen diffused through the metal in the center to charge the diffusion side to the β-phase. Hence on the polarization sides of these sandwiches the palladium was charged with hydrogen to the β-phase, and on the diffusion side the palladium was in the α-phase. Previous work by the authors (1, 2) has indicated that atomic hydrogen does diffuse through β-palladium. The results shown in Fig. 5 indicate that atomic hydrogen can diffuse through iron also, but not through nickel, platinum, or gold.

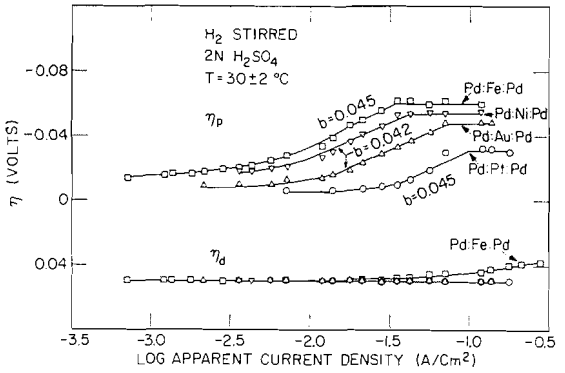

FIG. 5. Hydrogen overvoltage on polarization and diffusion surfaces of cathode-diaphragms consisting of Au, Pt, Ni, and Fe clad on both sides with Pd. Pt/H_2 reference electrode.

The metal sandwiches treated as bielectrodes gave the cathodic overvoltage, η_c, curves shown in Fig. 6. These curves are similar to those found for α-palladium bielectrodes (4). The separation of these curves arises from a complicated combination of conditions which include the migration of protons through the membrane, differences in cold working of the sandwiches, area differences, and the rate of oxygen diffusion from the anodic side. Since the primary purpose of this work was to determine the migration of protons through metals other than palladium, a determination of the effects of each of these factors was not made.

The anodic overvoltage, η_a, curves for this series of sandwiches is shown in Fig. 7. In

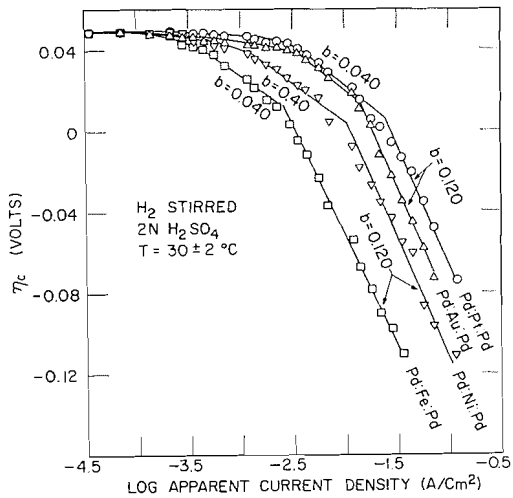

FIG. 6. Hydrogen overvoltage on the cathode surfaces of bielectrodes consisting of Au, Pt, Ni, and Fe clad on both sides with Pd. Pt/H_2 reference electrode.

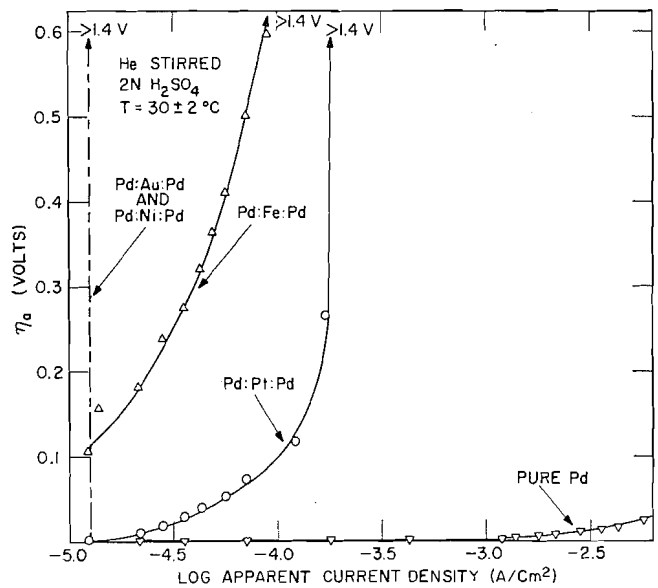

FIG. 7. Hydrogen overvoltage on the anode surfaces of bielectrodes consisting of Au, Pt, Ni, and Fe clad on both sides with Pd. $(Pd\text{-}H)_\alpha/H^+$ reference electrode.

order to determine the magnitude of the migration of protons through the membranes, the anode was stirred with helium. Hence any depolarization effects on this side would be due to the hydrogen which had migrated from the cathode side. As can be seen in Fig. 7, the platinum sandwich showed the most marked depolarization effect. The iron sandwich showed a depolarization effect also; however, neither gold nor nickel showed any evidence of proton migration through the bielectrode. In Fig. 7 is shown also part of the anodic polarization curve for a pure palladium bielectrode in the same solution (a more complete curve under these conditions is shown in ref. (3)). The comparison of the pure palladium with the platinum and iron sandwiches emphasizes the great differences in rate of proton migration through these specimens.

DISCUSSION

Previous work (1, 2) has shown that when a palladium diaphragm which separates two bodies of solution is made a cathode, hydrogen will be generated on the polarization side. Part of this hydrogen will dissolve in the palladium to form the β-phase. Further solution of hydrogen will set up a concentration gradient of atomic hydrogen* across the diaphragm and the atoms diffusing through the metal will cause an overvoltage effect, η_d, on the diffusion side. When palladium on the cathode side of a bimetallic diaphragm is charged with hydrogen in excess of the β-phase (H/Pd > 0.6), atomic hydrogen will exist in its interior. If this atomic hydrogen can diffuse through Pt, Au, Fe, or Ni clad to palladium, then its effect should be evident as an atomic concentration overvoltage. Such an effect was only found for the Pd : Fe : Pd sandwich and this indicated that atomic hydrogen did diffuse through steel.

If a pure palladium membrane is arranged as a bielectrode, the palladium will be maintained in the α-phase because hydrogen will be removed from the anode side as fast as it will dissolve in the metal on the cathode side (4). It has been shown that this hydrogen migrates through the palladium as protons. Low current density experiments in which the bimetallic membranes were used as bielectrodes would give evidence of the transfer of protons through the metals. If hydrogen, owing to the difference in the electrochemical affinities of the reaction on the cathode and anode sides, migrates through the bielectrode the palladium on the cathode side is maintained in the α-phase and atomic hydrogen virtually does not exist in its interior. Evidence of proton migration through the non-palladium metal would be shown by lowered anodic overvoltages, η_a.

The experimental results with platinum and gold clad on only one side with palladium showed that when the palladium was on the cathode side of the bielectrode there was no evidence of proton diffusion through the membrane. Similarly when the platinum or gold was on the cathode side, proton migration did not occur. However, for the steel and platinum sandwiches there was definite evidence of proton migration through these metals. In the case of platinum there apparently was no proton migration through the Pd: Pt combination because at low current densities the hydrogen would merely dissolve in the palladium until it was charged to the β-phase. The solution or removal of the hydrogen atoms on the Pd–cathode side was evidently much more rapid than the oxidation of hydrogen atoms on the Pt–anode side. The small effect of current density on cathodic overvoltage in the low current density range shown in Fig. 4 is indicative of the charging of the palladium with hydrogen. For the case of the sandwich Pd: Pt: Pd, proton migration through the bielectrode occurred, since, in the low density range, the

**Electrons from these atoms can be considered to occupy the* H *1s-band rather than the* Pd *4d-band. These electrons in excess of the amount required to fill the d-band of* Pd *move in a band which is characteristic of the proton lattice.*

rate of removal of hydrogen atoms from the palladium cathode side would evidently be the same as the rate of oxidation of hydrogen atoms on the palladium anode side.

Proton migration through palladium, iron, and platinum bielectrodes can be explained on the basis of the holes in the *d*-bands of these metals. When the hydrogen atom formed on the surface of α–Pd enters the interior of the metal, it donates its electron to the *d*-band of the palladium and the proton exists in an interstitial position in the Pd lattice. In order for the proton to exist in the platinum or steel lattice, an electron must accompany it, so that electrical neutrality may be maintained. Both platinum and iron have holes in their *d*-bands so that the addition of electrons will not increase the total energy significantly, since the density of levels in the *d*-bands of these metals is very large. Hence protons can exist in and migrate through the interior of these metals. On the other hand, gold has a filled *d*-band and electrons would have to enter the 6*s*-band. Since the density of levels in the *s*-band is very low this would require a large increase in energy. As a result, under the experimental conditions used, protons do not migrate through gold.

From this viewpoint it is expected that protons should migrate through nickel. The experimental evidence does not support this, even at current densities as low as 10^{-7} amp/cm^2. A partial explanation may lie in the fact that the holes in the *d*-band of Ni are completely polarized in one spin direction (12), which is not the case for Pd, Pt, or Fe. Since electrons can enter only one half of the *d*-band in Ni but can enter both halves in Pd, Pt, or Fe, the energy for the solution of the same amount of hydrogen will be increased much more in the case of Ni than in the other metals. This, of course, assumes that for these metals the density of levels is nearly the same for the 3*d*-, 4*d*-, and 5*d*-band. This extra energy appears to be prohibitive to the solution of hydrogen as protons in nickel to an appreciable extent. However, other effects such as differences in solvation energy of the proton may be more important.

CONCLUSIONS

For the β–Pd cathode of a Pd : Pt or Pd : Pt : Pd diaphragm where there is an atomic hydrogen gradient and hydrogen can diffuse through the palladium, diffusion through the platinum was not detected. This indicates that under an atomic hydrogen concentration gradient alone hydrogen atoms will not dissolve in platinum. In the case where a concentration gradient of protons exists across a bielectrode of platinum sandwiched between palladium, protons will migrate through. In this case the protons already exist in the palladium in contact with the platinum. Hence, as is also shown in the case of the Pt : Pd bielectrode, the *s*-electron of a hydrogen atom does not enter the *d*-band of platinum spontaneously.

A similar argument can be used for the Pd : Fe : Pd bielectrode. However, for this combination there is some atomic hydrogen diffusion through the steel if a concentration gradient and the *s*-electrons of hydrogen atoms can enter the *d*-band of iron spontaneously.

It can be concluded that, under the experimental conditions used, hydrogen can dissolve and migrate only as protons through platinum, whereas it can either migrate as protons or diffuse as atoms through iron or palladium. Neither protons nor hydrogen atoms can be transported through gold or nickel.

THE DETERMINATION OF KINETIC PARAMETERS OF REDOX REACTIONS FROM CURRENT–POTENTIAL CURVES[1]

J. E. B. Randles

ABSTRACT

Methods are suggested for calculating kinetic parameters of moderately rapid redox reactions from current–potential curves obtained with (*a*) rotating electrodes or stationary electrodes in stirred solutions, (*b*) dropping mercury electrodes. Experimental results for the V^{2+}/V^{3+} reaction at a dropping mercury electrode are presented and compared with a-c. impedance measurements on the same system. It is found that there is a good agreement between the kinetic parameters obtained by the two methods when the current–potential curves are interpreted with the aid of Koutecký's theory of diffusion to a dropping mercury electrode.

INTRODUCTION

In the investigation of the kinetics of moderately rapid electrode reactions by means of the steady-state current–potential relationship, the necessity of taking account of concentration polarization has been recognized for a long time and a number of theoretical treatments have appeared (1). However, no very satisfactory method of deriving the kinetic parameters for such reactions from the current–potential data has emerged. Simple plots of η (overpotential) against log i are still commonly used (2), although this is of little value in the region of the reversible potential or when concentration polarization becomes predominant. Frequently very little of the graph approximates to a straight line. Similar remarks apply to the utilization of current–potential curves obtained with a dropping mercury electrode (D.M.E.) when the deviation from the ideal reversible curve is not large.

For reactions too rapid to be satisfactorily investigated by d-c. polarization in the steady state, or quasi steady state (D.M.E.), relaxation methods are employed.* Of these, measurements of the a-c. impedance of an electrode is probably the most useful. The range of application (in terms of rate of electrode reaction) of this method overlaps with that of the d-c. polarization methods and it is of interest to compare the kinetic parameters obtained by the two types of method for the same electrode reaction. This comparison promises to be of most interest when the D.M.E. is used, for two reasons: (*a*) the reproducibility of the electrode makes an accurate comparison possible, (*b*) there remains some uncertainty in the theory of the current–potential relationship for this electrode which such a comparison may resolve.

The present paper has two purposes: first to present what the author regards as the most convenient method of calculating kinetic parameters of moderately rapid electrode reactions from current–potential curves, and secondly to compare results so obtained with a D.M.E. with the results of a-c. impedance measurements. The reaction selected for this purpose is the V^{2+}/V^{3+} reaction.

Calculation of Kinetic Parameters From Current–Potential Curves

We shall consider a simple electrode reaction of first order in both the cathodic and anodic directions which may be written

[1]*Manuscript received July 5, 1958.*

For reviews of these, and other, methods with their ranges of application, see Gerischer, H. Z. Elektrochem.* **59, *604 (1955), Grahame, D. C. Ann. Rev. Phys. Chem.* **6**, *337 (1955), and Delahay, P. Ann. Rev. Phys. Chem.* **8**, *229 (1957).*

[1] $$(1)+ne^- \rightleftharpoons (2).$$

Substances (1) and (2) are both present in the electrolyte solution or, if the electrode is mercury, (2) may be a metal dissolved in the mercury. Any other molecules such as H_2O or complexing ions which may take part in the reaction are assumed to be present in such large excess that the reaction remains pseudounimolecular in both directions. The modification of the treatment given below to the case when (2) is the metal of the electrode can easily be made.

In practice, free diffusion of ions unaccompanied by migration is ensured by the presence of an excess of an indifferent electrolyte, and this also results in the substances (1) and (2) having activity coefficients independent of their own concentrations. Hence the Nernst equation for the potential E^r, of a reversible electrode becomes

[2] $$E^r = E_f^\circ + (RT/nF) \ln(C_1^\circ/C_2^\circ)$$

where C_1° and C_2° are the bulk concentration of (1) and (2) and E_f° is the 'formal' potential (for $C_1^\circ = C_2^\circ$). Further, if k_1^r and k_2^r are the rate constants of the forward (left to right) and reverse directions of reaction [1] at the equilibrium potential E^r, then

[3] $$k_1^r C_1^\circ = k_2^r C_2^\circ.$$

Hence it is easily seen that for two potentials of the electrode E^r and $E^{r\prime}$ (corresponding to different ratios of C_1° to C_2°),

[4] $$E^r - E^{r\prime} = (RT/nF) \ln(k_2^r/k_1^r)\ (k_1^{r\prime}/k_2^{r\prime}).$$

For a particular system, having given bulk concentrations C_1° and C_2°, we shall denote by k_1^r and k_2^r the rate constants at the equilibrium potential and by k_1 and k_2 the rate constants at any other potential E, thus

[5] $$E - E_r = \eta = (RT/nF)\ \ln(k_2/k_1)\ (k_1^r/k_2^r)$$

or,

[6] $$k_2/k_1 = (k_2^r/k_1^r) \exp nf\eta$$

where F/RT is abbreviated to f, and η is the overpotential of the electrode.

Steady-state Diffusion

For steady-state diffusion, using a rotating electrode or stationary electrode in a stirred solution, the Nernst layer treatment of diffusion leads to

[7] $$i = nFD_1(C_1^\circ - C_1)/\delta = nFD_2(C_2 - C_2^\circ)/\delta$$

where i is the cathodic current density, C_1 and C_2 are the concentrations of (1) and (2) at the electrode surface, D_1 and D_2 are diffusion coefficients, and δ is the thickness of the Nernst layer. Thus, if i_1 and i_2 respectively are the limiting cathodic and anodic diffusion currents (both given positive sign),

[8] $$i_1 = nFD_1C_1^\circ/\delta, \qquad i_2 = nFD_2C_2^\circ/\delta.$$

From [7] and [8]

[9] $$C_1/C_1^\circ = (i_1 - i)/i_1, \qquad C_2/C_2^\circ = (i_2 + i)/i_2.$$

The net current density is also given by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[10] $$i = nF(k_1C_1 - k_2C_2)$$

which, using [9], [3], and [6] becomes

[11] $$i = nFk_1\,C_1^\circ\left[\frac{i_1-i}{i_1} - \left(\frac{i_2+i}{i_2}\right)\exp nf\eta\right].$$

By rearrangement we have

[12] $$-\log_{10} nFk_1\,C_1^\circ = \log_{10}\left[\left(\frac{1}{i}-\frac{1}{i_1}\right) - \left(\frac{1}{i}+\frac{1}{i_2}\right)\exp nf\eta\right].$$

Thus, by plotting the right hand side of [12] against $nf\eta$ a nearly straight line should be obtained.

The slope at any point

[13] $$d(\log_{10} k_1)/d(nf\eta) = -\alpha/2.303$$

gives the cathodic transfer coefficient, α, and the intercept at $nf\eta = 0$ is $\log_{10}(nFC_1^\circ k_1^r)$.

It is advantageous to use $[nf\eta + \ln(C_1^\circ/C_2^\circ)]$ instead of $nf\eta$ as abscissa, since, from equation [2],

$$nf\eta + \ln(C_1^\circ/C_2^\circ) = nf(E-E^r) + nf(E^r-E_f^\circ) = nf(E-E_f^\circ)$$

and this quantity depends only on the potential of the electrode relative to the solution. If also $\log_{10} nFC_1^\circ$ is added to the right hand side of equation [12] before plotting as ordinate, the graphs obtained for any value of C_1° and C_2° should coincide, and the intercept on the axis $nf\eta + \ln(C_1^\circ/C_2^\circ) = 0$ is now $\log_{10} k_s$ where k_s is the standard rate constant of the reaction.*

Dropping Mercury Electrode

The theory of diffusion to a dropping mercury electrode is complicated both by the growth of the drop surface and by the fact that the surface is not planar but spherical. The mathematical difficulties are such that all attempts at an exact solution of the diffusion equations have assumed the electrode reaction to be first order in both directions, as we have already done. A solution of the diffusion equation for an expanding mercury drop electrode and an electrode process involving a slow chemical step was first obtained by Koutecký and Brdička (3). More detailed solutions, specifically for the case of a slow electrochemical step have been given by Smutek (4), Kambara and Tachi (5), and Delahay (6). These workers solved the diffusion equation first for a stationary plane electrode, obtaining expressions for the current density equivalent to

[14] $$i = nF(k_1C_1^\circ - k_2C_2^\circ)\exp Q^2t\ \mathrm{erfc}\ Qt^{\frac{1}{2}},$$

where

[15] $$Q = (k_1D_1^{-\frac{1}{2}} + k_2D_2^{-\frac{1}{2}}),$$

t is the time from the start of the electrolysis, and erfc denotes the complementary error function. This result, for a plane electrode, has to be modified in order to give the current at a dropping mercury electrode. Smutek, and Kambara and Tachi, simply multiplied the whole expression [14] by the area of the drop, while Delahay multiplied also by the Ilkovič (7) factor $(7/3)^{\frac{1}{2}}$. The use of the Ilkovič factor for an expanding drop is certainly

*$k_s = k_1^r = k_2^r$ *when* $C_1^\circ = C_2^\circ$, *see Randles, J. E. B. Discussions Faraday Soc.* **1**, *11 (1947) and Delahay, P. New instrumental methods in electrochemistry. Interscience Publishers, Inc., New York. 1954. Chap. 7.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

necessary but a consideration of the origin of this factor* shows that the continuous lateral expansion of the diffusion layer, by reducing its thickness, has the same effect as multiplying the diffusion coefficients by 7/3. Thus the correct way of introducing the Ilkovič factor appears to be to redefine Q thus

$$Q = (3/7)^{\frac{1}{2}}(k_1 D_1^{-\frac{1}{2}} + k_2 D_2^{-\frac{1}{2}}). \quad [16]$$

This procedure is supported by the fact that it leads to the correct result for the extreme cases, i.e. very slow or very fast electrode reactions, while multiplication of the whole expression [14] by $(7/3)^{\frac{1}{2}}$ leads to an incorrect result for very slow reactions.

An approach distinct from the above was made by Koutecký (18), who solved a diffusion equation appropriate to an expanding electrode but still neglected the curvature of the surface. His results are expressed in terms of a variable χ which is equivalent to $2Qt^{\frac{1}{2}}$ where Q is given by [16]. In later work (9) Koutecký and Cížek have included the effect of the curvature of the surface. Expression [14] and Koutecký's results can be applied with equal ease to the interpretation of polarographic current–potential curves.

It is probably more accurate experimentally, when using a dropping electrode, to measure the instantaneous current at maximum drop size than to measure the average current. Therefore the method of interpreting current–potential curves will be developed for currents measured at maximum drop size. Only minor changes are needed in order to apply it to average currents.

From equation [14] the current at time τ from the start of a new drop (τ = drop life) is given by

$$i_\tau = nFA(k_1 C_1^\circ - k_2 C_2^\circ) \exp Q^2\tau \operatorname{erfc} Q\tau^{\frac{1}{2}}, \quad [17]$$

where A is the surface area of the drop at maximum drop size. Using expressions [3] and [6] which are still valid, [17] becomes

$$i_\tau = nFA\ k_1 C_1^\circ(1 - \exp nf\eta) \exp Q^2\tau \operatorname{erfc} Q\tau^{\frac{1}{2}}. \quad [18]$$

Now if we denote by i_{τ_1} and i_{τ_2} the limiting cathodic and anodic diffusion currents at maximum drop size, then provided that τ is the same for both

$$i_{\tau_1}/i_{\tau_2} = C_1^\circ D_1^{\frac{1}{2}}/C_2^\circ D_2^{\frac{1}{2}}. \quad [19]$$

Also, with the aid of equations [3], [6], and [19] and using the abbreviation

$$i_{\tau_1}/i_{\tau_2} = r \quad [20]$$

expression [16] becomes

$$Q = (3/7)^{\frac{1}{2}}\ k_1 D_1^{-\frac{1}{2}}(1 + r \exp nf\eta). \quad [21]$$

Finally, by using [21] to substitute for k_1 in [18] we reach the equation

$$i_\tau = nFA\ C_1^\circ \left(\frac{7D_1}{3\pi\tau}\right)^{\frac{1}{2}} \left[\frac{1 - \exp nf\eta}{1 + r \exp nf\eta}\right] \theta(Q\tau^{\frac{1}{2}}) \quad [22]$$

where

$$\theta(Q\tau^{\frac{1}{2}}) = \pi^{\frac{1}{2}} Q\tau^{\frac{1}{2}} \exp Q^2\tau \operatorname{erfc} Q\tau^{\frac{1}{2}}. \quad [23]$$

The function $\theta(Q\tau^{\frac{1}{2}})$ has the property of approaching unity as $Q\tau^{\frac{1}{2}} \to \infty$, i.e. for very rapid electrode reactions. Expression [22] may therefore be written

$$i_\tau = i_{\tau\infty}\, \theta(Q\tau^{\frac{1}{2}}) \quad [24]$$

*See Stackelberg, M.v. *Z. Elektrochem.* **45**, 466 (1939).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

where $i_{\tau\infty}$ is the value of i_τ for an infinitely rapid electrode reaction at the same value of η (i.e. k_1/k_2 unchanged but k_1 and $k_2 \rightarrow \infty$). Values of the function $\theta(\chi)$ for a series of values of χ are tabulated in Milner's Polarography (Longmans, Green & Co., Inc., New York and Toronto. 1957. Table 4.1). Koutecký expressed his results in a similar form

$$i_\tau = i_{\tau\infty}F(\chi) \qquad [25]$$

where $\chi = 2Q\tau^{\frac{1}{2}}$, and he tabulates (10) $F(\chi)$. This table is reproduced by Delahay, P' New instrumental methods in electrochemistry. Interscience Publishers Inc., New York. 1954. Table 4.1.

In order to use equation [24] or [25] it is necessary to find $i_{\tau\infty}$. It is given by [22] with $\theta(Q_\tau^{\frac{1}{2}}) = 1$, and may be expressed in terms of either limiting diffusion current. In terms of the cathodic current, i_{τ_1},

$$i_{\tau\infty} = i_{\tau_1}\left(\frac{1-\exp nf\eta}{1+r\exp nf\eta}\right).$$

The calculation of $i_{\tau\infty}$ from this expression for each case is laborious and a sufficiently accurate and much simpler method is as follows. The current i_τ measured at a series of overpotentials is expressed as a fraction of $\frac{1}{2}(i_{\tau_1}+i_{\tau_2})$ (both limiting currents being given positive sign) and plotted against $nf\eta$. Figure 1 shows a typical curve. On this scale the $i_{\tau\infty}$ curve is that of $\tanh -nf\eta/2$ drawn between the limiting current lines and cutting the experimental curve at the point of zero current (see Fig. 1). A template may be used to draw this curve on standard squared graph paper. The results described below were obtained by using a 'Perspex' template on which the full extent of the current axis (i.e. from $\tanh -\infty = -1$ to $\tanh +\infty = +1$) = 20 cm, and one unit on the $nf\eta$ axis = 2.5 cm. The accuracy of the experimental current measurement would justify a somewhat larger scale.

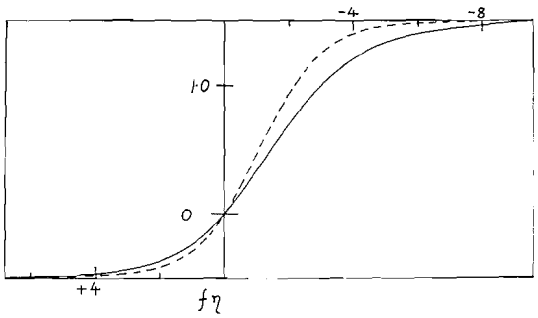

FIG. 1. Full curve: experimental $2i_\tau/(i_{\tau_1}+i_{\tau_2})$.
Broken curve: $i_{\tau\infty}$.
Cathodic current plotted above the zero current axis.

The ratio $i_\tau/i_{\tau\infty}$ is calculated from the two curves at a series of values of $nf\eta$ corresponding (for reasons which will be apparent later) to selected values of $(nf\eta + \ln r)$. These selected values ranged from -5.2 to $+5.2$ in steps of 0.4, in the calculations to be described below. The fraction $i_\tau/i_{\tau\infty}$ is equal to $F(\chi)$ or $\theta(\chi/2)$ and the next step is therefore to read off the corresponding value of $\log(\chi/2)$ from a graph of $F(\chi)$ or $\theta(\chi/2)$ against $\log(\chi/2)$. From equation [22],

$$\log \chi/2 = \log Q\tau^{\frac{1}{2}} = \log(3/7)^{\frac{1}{2}}k_1D_1^{-\frac{1}{2}}\tau^{\frac{1}{2}}[1+\exp(nf\eta + \ln r)]$$

or

$$\log \chi/2 - \log[1+\exp(nf\eta + \ln r)] = \log_{10}(3\tau/7D_1)^{\frac{1}{2}}k_1. \qquad [26]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The left hand side of [26] is calculated with the aid of a previously prepared table of values of $\log[1+\exp(nf\eta + \ln r)]$ for the selected values of $(nf\eta + \ln r)$, and is plotted against $(nf\eta + \ln r)$. Since

$$r = i_{r_1}/i_{r_2} = C_1^\circ D_1^{\frac{1}{2}}/C_2^\circ D_2^{\frac{1}{2}}.$$

Therefore

[27] $$(nf\eta + \ln r) = nf(E - E_f^\circ) + \tfrac{1}{2} \ln D_1/D_2.$$

Equation [27] shows that the abscissa $(nf\eta + \ln r)$ depends on the potential of the electrode relative to the solution but is independent of C_1°/C_2°. Thus the graphs obtained for any values of C_1° and C_2° should coincide. The slope at any point is

[28] $$d \log_{10} k_1/d(nf\eta) = -\alpha/2.303$$

and the intercept with the line $(nf\eta + \ln r) = \frac{1}{2} \ln D_1/D_2$ has the value $\log_{10}(3\tau/7D_1)^{\frac{1}{2}} k_s$.

As will be shown later, these graphs can be compared directly with the results of a-c. measurements.

EXPERIMENTAL

Materials

Solutions were made up in water redistilled in an all-glass still. Perchloric and sulphuric acids were distilled under reduced pressure. A stock solution of VO^{++} in perchloric acid solution was prepared from Analar ammonium vanadate by reduction with SO_2 and boiling out the excess. The solution therefore contained a little $SO_4^=$ and NH_4^+. The final reduction to a mixture of V^{2+} and V^{3+} was carried out in the electrolysis cell.

Apparatus

The dropping electrode consisted of a short length of capillary tube of 0.045 mm bore, sealed at one end to a length of 1-mm bore tubing which was connected to a mercury reservoir by silicone tubing. The lower end of the capillary was blown out to a small bulb which was drawn to a fine thin-walled tube and cut to a square end (i.d. $\sim$ 0.05 mm, o.d. $\sim$ 0.15 mm, at the tip). This ensures the minimum possible shielding of the mercury drop by the end of the capillary. The dropping electrode was inserted through a ground joint in the cap of the electrolysis cell which also carried an inlet for purified hydrogen, a tube closed by a sintered-glass plug and containing an auxilliary platinum electrode, and a J tube containing mercury which served as a reversible reference electrode. Mercury was introduced into the electrolysis cell from a connection at the lower end. The final reduction of the VO^{++} to a mixture of V^{2+} and V^{3+} was carried out cathodically at the large mercury pool stirred by a stream of hydrogen and with the platinum electrode as anode. The mercury pool also served as second electrode in the d-c. polarization measurements and in the a-c. impedance measurements. The whole electrolysis vessel was surrounded by a thermostatic water jacket.

In the d-c. polarization measurements the current at maximum drop size was measured directly by means of calibrated Cambridge 'spot' galvanometer, internal resistance 50 ohms, of period 2 seconds, slightly under damped. The drop time of the capillary was mechanically controlled at 6.0 seconds (natural drop time $\sim$9 seconds). The overpotential was measured between the dropping electrode and the stationary mercury electrode in the J tube. The ohmic potential drop due to the resistance of the capillary and the electrolyte (about 50 ohms) was never greater than 0.3 mv, and was neglected. The capacity current at maximum drop size was also negligible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The a-c. impedance measurements were carried out by means of an improved version of an apparatus already described (11), details of which will appear in a later publication.

RESULTS AND DISCUSSION

Figure 1 shows an experimental current–potential curve for V^{2+}/V^{3+} in 1 M H_2SO together with the i_∞ curve. The temperature was 15.3° C, the total vanadium concentration 0.003 M, and the ratio of the cathodic to anodic limiting currents ($= i_{\tau_1}/i_{\tau_2} = r$) was 3.05. Corresponding curves were obtained for the same solution but with $r = 1.06$ and 0.187 respectively. The left hand side of equation [26] calculated for each of the three curves is plotted against ($nf\eta + \ln r$) in the lower part of Fig. 2 using Koutecký's values (10) of $F(\chi)$ modified by his correction for spherical diffusion (see below). The good agreement between the three sets of points is typical of what is obtained if the difference between i_τ and $i_{\tau\infty}$ is as great as, or greater than, that shown in Fig. 1. In the upper part of Fig. 2 are three sets of points calculated from the current–potential curve for $r = 1.06$. The lowest set (⊙) was obtained by equating $i_\tau/i_{\tau\infty}$ to $\theta(\chi/2)$ (equation [23]). The next set (×) was obtained using Koutecký's tabulated values of $F(\chi)$ and the uppermost set (+) by using $F(\chi)$ corrected for spherical diffusion. This correction has been calculated by Koutecký and Cížek (9) and takes the form $\xi.H_c(\chi)$ where ξ depends on the drop time, rate of flow of mercury, and diffusion coefficients of the reactants, and $H_c(\chi)$ is a function

of χ which they tabulate. The correction is easily applied by drawing a curve of $F(\chi)-\xi.H_c(\chi)$ against $\log(\chi/2)$, ξ being constant for a given system if τ is constant, and in the present case $\xi = 0.191$. The fourth set of points (⊡) in the upper part of Fig. 2 was obtained from the a-c. impedance of the same electrode in the same solution but with the total vanadium concentration raised to 0.009 M to improve the accuracy of the measurements. Impedance measurements were made for a range of values of r. The activation resistance,* R_a, of the electrode is related to the exchange current i_0 by

$$(nFR_a)^{-1} = i_0 = nFA' k_1{}^r C_1{}^\circ = nFA' k_2{}^r C_2{}^\circ$$

where A' is the area of the drop at the time of the impedance measurement. In practice this measurement was made when the age of the drop was 0.9τ so that the ratio of A' to the maximum area is $(0.9)^{\frac{2}{3}}$. It is thence easily deduced that

[29] $$-\log[nF(0.9)^{\frac{2}{3}}\pi^{\frac{1}{2}}R_a i_{\tau_1}] = \log(3\tau/7D_1)^{\frac{1}{2}}k_1{}^r.$$

The right hand side (R.H.S.) of [29] is identical with the R.H.S. of [26], and hence the L.H.S. of [29] is plotted as the fourth set of points (⊡) in the upper part of Fig. 2. The other points which agree best with this set are those calculated with the use of Koutecký's $F(\chi)$ corrected for spherical diffusion; the improved agreement resulting from the inclusion of this correction is often more marked than in this example. It is evident that the use of $\theta(\chi/2)$ would give an erroneously low value of the rate constant. None of the lines from the current–potential curves are very straight but those calculated by means of $F(\chi)$ are straighter than those calculated by means of $\theta(\chi/2)$.

In Fig. 3 points calculated from current–potential curves using $F(\chi)$ corrected for spherical diffusion are compared with those calculated from a-c. impedance measurements, for V^{2+}/V^{3+} in 1 M $HClO_4$ at 14.2° C and 25.0° C respectively. There is again good agreement. In both cases the ratio i_{τ_1}/i_{τ_2} was near unity so that the points from the current–potential curves are absent or very uncertain at small values of $(nf\eta + \ln r)$. In Fig. 4 the data from a-c. impedance measurements are plotted on a larger scale. The

For personal use only.

points for the sulphuric acid base solution at 15.3° C give a straight line corresponding to $\alpha = 0.455$ and $k_s = 1.39 \times 10^{-3}$ cm sec^{-1}. Those for the perchloric acid base solution give slightly curved lines corresponding to α decreasing from 0.57 to 0.50 (25° C) and from 0.57 to 0.49 (14.2° C) with increasing cathodic potential. However, the evidence is as yet insufficient to confirm that this represents a genuine change in α. The values of k_s are 2.20×10^{-3} and 3.64×10^{-3} cm sec^{-1} respectively corresponding to $\Delta H^{\neq} = 7.6$ kcal.

It is concluded from the above results that reliable values of the rate constants and transfer coefficients of redox reactions may be calculated from the current–potential curves obtained with a dropping mercury electrode by means of the Koutecký function $F(\chi)$ corrected for spherical diffusion. With the author's present equipment the method can give an accuracy in the rate constant of $\pm 5\%$ when $k_s \sim 1 \times 10^{-3}$ cm sec^{-1} decreasing to $\pm 30\%$ when $k_s \backsim 5 \times 10^{-3}$ cm sec^{-1}. As k_s decreases, the accuracy improves to about $\pm 3\%$, and for $k_s < 2 \times 10^{-4}$ cm sec^{-1} the d-c. polarization method is preferred to the a-c. impedance method, since the accuracy of the latter falls off as k_s decreases below 1×10^{-3} cm sec^{-1}. A disadvantage of the dropping mercury electrode is the occurrence in some circumstances of the interfacial stirring which causes polarographic 'maxima'. This becomes more marked with an increased rate of mercury flow and shorter drop time, which otherwise would be advantageous for measurements on the more rapid reactions.

MECHANISMS OF REDUCTION OF CHLOROAQUOCHROMIUM(III) IONS IN ACID MEDIA[1]

PHILIP J. ELVING AND BERNARD ZEMEL

ABSTRACT

The polarographic behavior of the hexaaquochromium(III) and dichlorotetraaquochromium(III) ions was observed in the absence of maxima suppressors, and in the presence of various concentrations of perchloric acid, hydrochloric acid, and neutral salt. The polarographic waves obtained for each Cr(III) species in the different media were analyzed by plotting the function $\log[i/(i_d-i)]$ vs. E; the plots generally consist of two straight lines intersecting at about the half-wave potential and can best be explained by assuming two different concurrent mechanisms for the electron transfer process: the direct transfer of an electron to the Cr(III) ion from the electrode at the mercury–solution interface, and the transfer of an electron to Cr(III) from a Cr(II) ion produced at that interface. Only for the dichlorotetraaquochromium(III) ion in 12 M HCl does the direct transfer process appear to be dominant. Polarography of Cr(III) in the latter medium before and after reaction with the medium shows no change in $E_{\frac{1}{2}}$ corresponding to the shift observed in the ultraviolet spectra; this is accounted for by the "catalytic" degradation, i.e., the loss of chloride of the higher chloro complexes due to the rapid anion transfer mechanism for the electron transfer process between halo Cr(III) and Cr(II) ions.

The literature (1) on the polarographic reduction of Cr(III) to Cr(II) indicates the variability of the half-wave potential, $E_{\frac{1}{2}}$, with the natures of the Cr(III) species and of the background electrolyte.

In 0.1 M potassium chloride $E_{\frac{1}{2}}$ of -0.91 v has been reported for the "aged" solution (1*a*, *f*). Two waves ($E_{\frac{1}{2}} \simeq -0.61$, -0.88 v) were found for the "fresh" green chromic chloride in 0.4 M KCl; the height of the first wave decreased with time and the second increased equivalently (1*b*). In saturated calcium chloride solution, $E_{\frac{1}{2}}$ was reported at -0.55 v (1*e*); however, other workers (1*g*) described two waves of $E_{\frac{1}{2}}$ equal to -0.57 and -0.87 v. With time, the wave at -0.57 v increased in height and that at -0.87 showed an equivalent decrease; on heating to 100° C, the second wave disappeared and reappeared only on dilution. An $E_{\frac{1}{2}}$ of -1.04 v was reported for the violet chromic sulphate and $E_{\frac{1}{2}}$ of -1.25 v for the "green" form in 1.0 M K_2SO_4 (1*h*).

All results reported in the previous paragraph involved the addition of varying amounts of gelatin as a maximum suppressor. Unfortunately, gelatin tends to shift $E_{\frac{1}{2}}$ and to change the wave shape. The extent of these effects is a function of the gelatin concentration and of the type and concentration of background electrolyte (1*e*). The mechanism of maximum suppression is not well understood and, while use of a maximum suppressor may make measurement of a wave easier, its presence generally introduces unknown complications into the electrode process.

In the present study, the polarographic behavior of the two commonly occurring forms of Cr(III), the violet hexaaquo and the dark green dichlorotetraaquo ions, has been investigated in various media in the absence of any maxima suppressor; the Cr(III) concentrations used were low enough that maxima did not interfere. The experimental conditions were such as to permit definite knowledge of the Cr(III) species present, e.g., the supporting electrolytes were usually sufficiently high in acid concentration so as to inhibit formation of hydroxo and condensed species.

DISCUSSION OF OBSERVED POLAROGRAPHIC BEHAVIOR

Selected data to illustrate the discussion are given in Table I.

TABLE I

Half-wave potential and wave slope data for reduction of Cr(III) to Cr(II)

Original species added	Background electrolyte	$-E_{\frac{1}{2}}$ v	Slope of log plot* Before $E_{\frac{1}{2}}$ mv†	Slope of log plot* After $E_{\frac{1}{2}}$ mv†
$[Cr(H_2O)_6]^{+3}$	0.1 *M* $HClO_4$	0.80	73 (0.81)	66 (0.89)
	0.5 *M* $HClO_4$	0.85	76 (0.78)	79 (0.75)

*Slope for the plot of $\log[i/(i_d-i)]$ vs. E.
†Value in parentheses corresponds to the slope in millivolts divided into 59.1 mv, i.e., equals the alpha term of equation [2].
‡Data obtained 5 minutes after dissolution of dichlorotetraaquochromium(III) chloride.
§Data obtained after equilibrium was reached.

Hexaaquochromium(III) Ion

The polarography of $[Cr(H_2O)_6]^{+3}$ was investigated using 0.1 to 1.5 *M* perchloric acid as background electrolyte; in 0.1 *M* acid the ionic strength was varied by the addition of $NaClO_4$ to an ionic strength of two.

$E_{\frac{1}{2}}$ shifts considerably with the nature and concentration of the background electrolyte. At higher $HClO_4$ concentrations, the hydrogen discharge is superposed on the first (III $\rightarrow$ II) wave, making it somewhat difficult to evaluate. The waves become increasingly more drawn out with increasing $HClO_4$ concentration and ionic strength; $E_{\frac{1}{2}}$ decreases from -0.80 v in 0.1 *M* $HClO_4$ to -0.91 in 1.0 *M* $HClO_4$; this may be due at least in part to an ionic strength effect, since increasing ionic strength at 0.1 *M* $HClO_4$ shifts $E_{\frac{1}{2}}$ from -0.80 to -0.89 v. Maxima appear when the Cr(III) concentration exceeds 0.8 m*M* in 0.10 *M* $HClO_4$. Polarograms for 0.1 to 5.0 m*M* Cr(III) solutions indicate that above 0.5 m*M* $E_{\frac{1}{2}}$ becomes slightly more negative with increase in chromium concentration; there is little change below 0.5 m*M*.

The polarograms were analyzed by plotting $\log[i/(i_d-i)]$ vs. E; $E_{\frac{1}{2}}$, given by intersection of the plot with the zero log axis, was generally identical with that obtained from the polarographic curve by geometrical plotting to within a few millivolts. The plots are unsymmetrical and may best be represented as two straight lines intersecting at or near $E_{\frac{1}{2}}$. The asymmetry increases with both ionic strength and acidity as the slope of the section above the zero log axis decreases more, relatively, than the section preceding $E_{\frac{1}{2}}$. At higher $HClO_4$ concentrations, presence of the hydrogen wave causes a small uncertainty in the i_d value; the value of $E_{\frac{1}{2}}$ is, however, relatively insensitive to this error, the principal effect being a small curvature at high i values.

Dichlorotetraaquochromium(III) Ion

$[Cr(H_2O)_4Cl_2]^+$ was studied in potassium chloride, hydrochloric acid, and perchloric acid solutions. These were prepared immediately before use by dissolving the anhydrous

salt, $[Cr(H_2O)_4Cl_2]Cl$, in a solution containing the proper amount of background electrolyte, and then diluting to the desired concentration. Delay in using the solutions, particularly in perchlorate media, results in a long, ill-defined wave extending to the hydrogen discharge.

As in the case of the hexaaquo ion, the polarographic waves show relatively large shifts in $E_{\frac{1}{2}}$ with changes in concentration and type of supporting electrolyte. The wave shapes are particularly sensitive to the medium used and are considerably more drawn out than in the case for the corresponding $[Cr(H_2O)_6]^{+3}$ waves. Log plots show these waves to be unsymmetrical about $E_{\frac{1}{2}}$ and representable by two intersecting lines.

Chromium(III) in 12 M Hydrochloric Acid

When either the hexaaquo or dichlorotetraaquochromium(III) ions are dissolved in concentrated hydrochloric acid, a slow reaction occurs, as evidenced by a change in the color of the solution. The absorption spectrum, when equilibrium has been established, is independent of the starting material (2). It is, therefore, of considerable interest to observe the effect of this "leveling" process on the polarographic reduction of the species present in solution.

The reaction between the Cr(III) species and 12 *M* hydrochloric acid, which results in the formation of $[Cr(H_2O)_3Cl_3]^0$, proceeds sufficiently slowly that the polarographic wave obtained within the first 10 minutes after dissolution is merely that for the Cr(III) species added (the wave for the hexaaquo species before appreciable reaction has taken place is cloaked by the hydrogen wave and cannot be deciphered). The wave obtained after equilibrium has been established is then that due to the equilibrium species of Cr(III) in 12 *M* hydrochloric acid. The waves obtained for either case had an $E_{\frac{1}{2}}$ of -0.60 v, although the wave for the former case appears better formed; the difference in the two waves is best illustrated by the log plot. The Cr(III) to Cr(II) reduction wave for the species present before appreciable reaction has occurred is more symmetrical and its slope is nearer that predicted for a reversible reduction where n equals 1. After reaction with the medium, the wave becomes more asymmetric about $E_{\frac{1}{2}}$; the slope of the section positive to $E_{\frac{1}{2}}$ remains unchanged and that at potentials more negative than $E_{\frac{1}{2}}$ changes.

MECHANISMS OF THE CHROMIUM(III) REDUCTION

In general, ions of the so-called transition groups of the Periodic Table yield irreversible polarographic waves; consequently, their polarography cannot always be straightforwardly interpreted.

For a reversible polarographic wave for reduction of a soluble species to a soluble product, the relationship between current and potential is given by

$$E_{d.e.} = E_{\frac{1}{2}} - [RT/nF] \ln[i/(i_d - i)]. \quad [1]$$

For irreversible waves, the same thermodynamic considerations as apply to a reversible wave still hold, but the potential depends also on the rates of the various processes occurring at the mercury drop. By definition, $E_{\frac{1}{2}}$ still is given by the value of $E_{d.e.}$ at the point where $i = i_d/2$, but the simple Heyrovsky–Ilkovic expression of equation [1] no longer holds. Theoretical treatments of the irreversible polarographic wave have been developed (3). The complexity of the process, however, is such that simplifying assumptions must be made and the problem is still far from solved. In the classic treatment developed by Eyring and co-workers (3*b*), the following equation was obtained by assuming that the properties of an irreversible wave are determined by the rates of diffusion and of electrochemical reduction,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$E = E_{\frac{1}{2}} - [RT/\alpha nF] \ln[i/(i_d - i)], \quad [2]$$

where α is the transfer coefficient such that the fraction α of the electrode potential favors the reduction at the cathode, and the fraction $(1-\alpha)$ of the potential applies to the reverse process.

If the plot of the log term of equation [2] vs. E is composed of two or more straight-line segments instead of just one straight line, a number of interpretations concerning the electrode processes involved is possible, e.g., the segments are due to successive electrode processes which, although they merge into one wave, have sufficiently different αn product values to produce slope changes in the log i plot (4). Another possibility is that the slope change is due to different, perhaps even concurrent, mechanisms for the electron transfer process with one mechanism predominating in the early part of the wave and the other predominating in the later development of the wave. Other explanations of such multisegmented slopes are possible (5).

Hexaaquo Ion

For the Cr(III)–(II) reduction, $n = 1$, and the slope of the log plot then gives the value for $2.303RT/\alpha F$, i.e., $0.0591/\alpha$ at 25°. The fact that two values for α are obtained from a single polarographic wave for the hexaaquo ion in perchloric acid media may then be interpreted as indicating two different electron transfer processes. The known reactions of the Cr(III)–Cr(II) system lend considerable support to the notions that these consist of the direct transfer of an electron to the Cr(III) species from the electrode at the solution–electrode interface and a second process involving an electron transfer reaction between Cr(III) and Cr(II).

There is evidence for the occurrence of the latter process; an electron exchange

$$Cr^*(III) + Cr(II) = Cr^*(II) + Cr(III) \quad [3]$$

occurs in 1 M perchloric acid with a rate constant of 0.0073 liter mole^{-1} min^{-1} at 25° C (6*a*). The specific rate of the Cr(III)–Cr(II) electron exchange is likely 0.028 liter mole^{-1} min^{-1} with a water molecule probably being the bridging group in the activated complex (6*b*). Equation [3], which omits ligands, is therefore a simplified statement of the reaction, since water and hydrogen ions are also involved.

When the polarographic reduction of Cr(III) begins, the Cr(II) concentration in the diffusion layer is negligible, and the Cr(III) is presumably reduced at the electrode interface. As reduction proceeds, the Cr(II) concentration at the interface increases and, at $E_{\frac{1}{2}}$, is essentially equal to that of Cr(III). At potentials more negative than $E_{\frac{1}{2}}$, the [Cr(II)]/[Cr(III)] ratio becomes increasingly greater and there is an increased probability that, instead of the entering Cr(III) being reduced directly at the electrode interface, it may be reduced by a Cr(II) ion at the interface or diffusing from the interface into the diffusion layer. A Cr(II) ion at the mercury–solution interface may thus serve as the electron transfer agent between the incoming Cr(III) ion and the electrode, acquiring another electron from the electrode after it has become a Cr(III) species. The latter electron transfer process may occur before the newly formed Cr(II) ion diffuses away from the original Cr(II) ion, which is fixed at the interface, or possibly even during the electron transfer process between fixed Cr(II) and incoming Cr(III).

In extending the reaction summarized in equation [3] to a reaction which may occur at an electrode interface, the difficulty must be recognized of defining the activated complex concerned, which may or may not involve a water molecule as a bridging group and unknown hydrogen ion dependence.

If the electrolysis of an ion at an electrode is assumed to involve at least two stages

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

i.e., transfer of the solvated ion from the bulk of the solution to the electrode surface (with more or less loss of the hydration sheath) and subsequent combination of the adsorbed ion with an electron provided by the electrode (7), it is possible that the secondary process outlined in the previous paragraphs, in which the Cr(III) species is already oriented at the interface for the electron transfer process, would have a lower transfer coefficient than the normal direct reduction, so that qualitatively one may account for the two slopes found in the log slope.

If the transfer coefficient is defined as that fraction of the potential "required" to transform an ion from a solution environment to that of the electrode interface, then it is true that the closer an ion is to the interface environment, the lower is the transfer coefficient. It therefore follows that, if a Cr*(II) formed at this surface is oxidized to Cr*(III) by an incoming Cr(III) ion, we have in effect transformed a Cr(III) ion from a position Cr to Cr*, i.e., closer to the interface, so that part of the transformation occurs under this "exchange potential", and only part is facilitated by an applied potential. Consequently the *total* process must have a lower transfer coefficient than one in which there are no exchanges between Cr(III) and Cr*(II).

In order not to have a lower transfer coefficient for the case of Cr(III)–Cr*(II) position exchange, one would have to assume a completely quantum-like jump from solution environment to surface environment without an intermediate state, which seems highly unlikely. To have a higher transfer coefficient would require a new mechanism, e.g., introduction of other ions.

Dichlorotetraaquo Ion

The polarography of the dichlorotetraaquochromium(III) species follows the same general pattern as that observed for the hexaaquo ion. The waves are considerably more drawn out and occur at more positive $E_{\frac{1}{2}}$ values; the log plots show the same asymmetry. However, the situation is complicated by the fact that the Cr(III)–Cr(II) exchange in the chloro complexes is accomplished by an anion transfer mechanism (8), which, omitting complexed water, may be written as

$$Cr^*Cl_2^+ + Cr(II) = Cr^*(II) + CrCl^{++} + Cl^- \quad [4]$$

Consequently, one must deal with an alteration in the complex ions as well as with multiple electron transfer processes and space charge effects. Under these circumstances, it is difficult to arrive at any consistent picture without knowing considerably more than is now known about these processes.

One point which should be noted concerning the anion transfer mechanism of equation [4] is the "catalytic" degradation of the higher chloro complexes by the Cr(II) formed in the reduction. The specific rate constant (8) for the reaction of equation [4] at 2° C is 10^4 liters mole^{-1} min^{-1}. It is reasonable to suppose that, in view of the greater lability of the chloride ligands in the higher Cr(III) complexes, the rate for the comparable process for these complexes would be considerably higher. It is then not surprising that $E_{\frac{1}{2}}$ for $[Cr(H_2O)_4Cl_2]^+$ in 12 *M* hydrochloric acid solution is the same before and after the reaction with the hydrochloric acid, since this catalytic degradation would tend to "level" the complexity of the species involved. Ultraviolet absorption indicates the Cr(III) species finally formed in 12 *M* HCl to be the trichlorotriaquochromium(III).

EXPERIMENTAL

Preparation, purification, and analysis of the various chromium(III) salts have been described (2). Sodium perchlorate was obtained as a solution of known molarity by titration of sodium hydroxide with a perchloric acid solution.

A Sargent Model XXI Polarograph and a Leeds & Northrup Model E Electro-Chemograph were used in conjunction with a jacketed H-cell (9), maintained at 25±0.1° C, which contained a saturated calomel electrode (S.C.E.) in one arm, separated by a sintered glass disk and KCl–agar plug from the working arm. After runs in perchlorate media, the cell was thoroughly flushed with warm distilled water to remove any precipitated potassium perchlorate from the region near the glass disk.

All $E_{\frac{1}{2}}$ data are referred to the S.C.E.; the iR drop in the cell system was negligible. Some runs were made against a mercury pool electrode in order to ascertain the effect of the agar–KCl bridge; the results were similar to those obtained against the S.C.E.

Oxygen was removed from the test solutions by purging with water-pumped nitrogen which was first deoxygenated by passage through an acid Cr(II) sulphate solution and then equilibrated by passage through some of the test solution; suitable traps were included to prevent contamination. In solutions of high acidity, it was necessary to deoxygenate for extended periods of time before introducing mercury; otherwise, oxygen waves interfered with the polarograms. No maximum suppressors were added.

In order to observe the polarographic wave of the Cr(III) species in 12 M hydrochloric acid before appreciable reaction has taken place, the following procedure was adopted: concentrated hydrochloric acid was placed in the polarographic cell; nitrogen was bubbled through the solution for about 30 minutes; dry $[Cr(H_2O)_4Cl_2]Cl$ or $[Cr(H_2O)_6]Cl_3$, which had been flushed with nitrogen, was then introduced into the solution under a nitrogen cover; the resulting solution was deoxygenated for another 5 to 7 minutes; the polarogram was then taken.

The polarogram of the Cr(III) species existing in 12 M HCl when equilibrium is attained was observed by first dissolving the chromic chloride in the 12 M acid (the form of the complex is immaterial), warming to 90° C to hasten equilibrium, then cooling to room temperature, transferring to the polarographic cell, sweeping with nitrogen for about an hour (from spectrophotometric evidence, reaction is complete within this time), and then taking the polarogram.

ACKNOWLEDGMENT

The authors wish to thank the Atomic Energy Commission, which helped support the work described.

THE INFLUENCE OF SURFACE ACTIVE ANIONS ON THE ELECTROREDUCTION OF THE PERSULPHATE ANION AT NEGATIVE POTENTIALS[1]

A. Frumkin, N. Nikolajeva-Fedorovich, and R. Ivanova

The dependence of the kinetics of electrode processes on the surface layer structure has recently been the subject of a series of investigations. This dependence is especially pronounced if the electrode surface and the reacting particle have charges of the same sign, as in the case of anion electroreduction on a negatively charged surface (1, 2, 3, 4, 5). The phenomena observed under these conditions might be understood if we assume that the rate of the electrode reaction depends not only on the electrode potential, ϕ, but on the potential in that point of the double layer where the center of the particle in the transition state of the reaction is situated too. This local ψ_1-potential value is influenced by the cation which is the nearest neighbor of the reacting anion (5, 6, 7, 8, 9), and might be markedly different from the average potential, $\bar{\psi}_1$, at a distance from the electrode equal to the radius of the reacting particle. The rate of the electrode process depends therefore not only on the interaction between the charge of the anion with the charges on the metal surface, but on its interaction with the charge of the neighboring cation, which facilitates its approach to the negatively charged surface as well. In this sense we can use the concept of the formation of cationic bridges between the negatively charged surface and the reacting anion (Fig. 1). We shall not discuss here the question of the role played by the adjacent cation in the elementary act of the electron transfer itself.

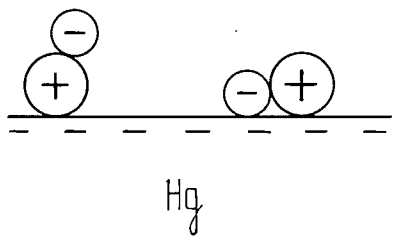

Fig. 1. Schematic representation of the adsorption of anions on a negatively charged metallic surface. The decrease of the absolute value of the negative charge of the mercury surface on anion adsorption shows that the configuration represented to the right is the preponderant one.

The object of this communication is to describe some characteristic features of the electroreduction of the $S_2O_8^{2-}$ anion, which might be considered as an example of the dependence of the kinetics of this reaction upon the details of the double layer structure.

Kalish and Frumkin found that the rate of the persulphate electroreduction on positively charged mercury strongly decreases in the presence of surface active anions (10). Thus, the half-wave potential of this reaction is *ca.* 0.6 v more negative in *N* KBr than in *N* Na_2SO_4. Qualitatively, this can be easily accounted for by the building up of a negative ψ_1-potential, when Br^- anions are adsorbed on mercury, which decreases the surface concentration of the $S_2O_8^{2-}$ ions (and shifts the effective potential difference

[1]*Manuscript received July 24, 1958.*
Contribution from the Institute of Electrochemistry, Academy of Sciences, Moscow, U.S.S.R. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

ϕ–ψ_1 between the electrode surface and the center of the reacting particle in an unfavorable direction too). However, a quantitative comparison of the rates of the process at different potentials shows that the decrease of the reaction velocity caused by the negative ψ_1-potential at equal $\bar{\psi}_1$-values is smaller when the ψ_1-potential arises from a specific anion adsorption than in the case of a negative ψ_1-potential build-up in the neighborhood of a negatively charged metal surface, which attracts cations by coulombic forces only, that is in a double layer with a "normal" structure. Although a quantitative explanation of this discrepancy cannot be given at the present moment, it is probable that the discrepancy is connected with the difference between the average and the local (effective) ψ_1-potential values. In an electric field with localized negative charges, which arise from the specific adsorption of anions, the distribution of the potential parallel to the electrode surface must be much more inhomogeneous than in a "normal" double layer with negative electrical charges smeared on the equipotential metal surface.

Kalish and Frumkin came to another, somewhat unexpected, conclusion. They found that with a negatively charged surface at potentials at which the repulsion between the electrode and the reacting anion manifests itself and a minimum on the current–voltage curve is observed, the sequence of the action of halogen anions is reversed. Thus, when 10^{-4} N $K_2S_2O_8$ is reduced in the presence of potassium halogenides at a concentration of 10^{-2} N, the current strength increases in the sequence $Cl^- < Br^- < I^-$. The small adsorption of anions which occurs on a negatively charged surface therefore exerts on the kinetics of the process an influence opposite to that observed in the case of their strong adsorption on a positively charged surface. The cause of this inversion has not been completely elucidated until now and we shall not consider it here in detail.*

Differential capacity measurements as well as determinations of the zero-charge potential in solutions of fluorides, chlorides, and iodides of sodium, potassium, and cesium showed that the adsorption of surface active anions on a negatively charged surface is strongly influenced by the nature of the cations (8, 11). Thus, the increase of the differential capacity at negative potentials and the shift of the zero charge potential to more negative values is much more pronounced in the case of a transition from a CsCl solution to a CsI solution of equal concentration than in the case of a transition from a NaCl solution to a NaI solution. Apparently, the adsorption of anions on a negatively charged mercury depends to a large extent on the formation of cationic bridges, although, as follows from other considerations, the $\bar{\psi}_1$-potential in the cationic Helmholtz layer is also more positive in the presence of Cs^+ cations than in the presence of Na^+ cations.

On comparing these results with those obtained earlier by Kalish and Frumkin, the conclusion could be drawn that the acceleration of the $S_2O_8^{2-}$ electroreduction by iodide ions described in (10) must depend on the nature of the cation, increasing in the sequence $Na^+ < K^+ < Cs^+$. To check this conclusion some measurements with a dropping electrode were carried out. Current–voltage curves obtained with 2.10^{-4} N solutions of $K_2S_2O_8$ in the presence of fluorides, chlorides, bromides, and iodides of sodium, potassium,

**At any rate, an effect of that kind would be impossible, if the average ψ-potential would determine the rate, as the specific adsorption of anions will always cause a shift of ψ_1 to more negative values, and must therefore decrease the reaction rate. It appears that by taking into account the inhomogeneity of the potential distribution in the double layer in the case of specific anion adsorption and the decrease of the absolute value of the negative charge of the metal surface, caused by the appearance of this double layer, it can be understood that local ψ_1-potential values (in points lying sufficiently far from adsorbed anions) at a given Φ might be, in fact, more positive in this case than in a "normal" double layer. In the paper of Kalish and Frumkin a schematic picture of the double layer was given with the purpose of explaining the kinetic effects observed, but a more detailed consideration showed that this scheme is incorrect and must be abandoned.*

and cesium in a 10^{-2} N concentration are given on Figs. 2, 3, 4, and 5. The potentials are referred to a N.C.E. The parts of the current–voltage curves corresponding to potentials more positive than the zero-charge potential, which are deformed by a polarographic maximum of the first kind, have been omitted throughout. No difference between the current strength $\bar{J}$ in the presence of F^- and Cl^- can be observed within the limits of experimental error in sodium salts solutions (Fig. 2); the transition to a sodium iodide solution causes an increase of the reaction rate amounting to some 20%. On substituting K^+ for Na^+ we observe a marked increase of the velocity of the reaction (Fig. 3), which was already discussed in earlier papers (3, 8, 12) (primary cationic effect); at the same time the difference between the rates in the presence of different anions strongly increases. Thus on transition from 10^{-2} N KCl to 10^{-2} N KI the quantity $\bar{J}/(\bar{J}_d-\bar{J})$ increases *ca.* 1.6 times. In the presence of 10^{-2} N CsI (Fig. 4) the rate of the $S_2O_8^{2-}$ electroreduction on negatively charged mercury becomes so large that the minimum on the current–voltage curve disappears altogether. In order to obtain a quantitative estimate of the I^- anion efficiency in the presence of Cs^+, we have carried out measurements with 5.10^{-3} N solutions of CsCl and CsI. The quantity $\bar{J}/(\bar{J}_d-\bar{J})$ increases in this case on transition from Cl^- to I^- approximately twice* (Fig. 5). The experiments thus confirm the expected dependence of the influence of surface active anions on the rate of the $S_2O_8^{2-}$ electroreduction at negatively charged mercury on the nature of the cation.

**At a potential $\phi = 0.75$ v the current strength is always somewhat smaller in the presence of I^- as in the presence of Cl^-. This effect is caused by the superposition of the current of the anodic dissolution of mercury on the current of the $S_2O_8^{2-}$ electroreduction. The former becomes noticeable in iodide solutions at the given potential on account of complex formation with mercury.*

CATHODIC ORGANIC PROCESSES[1]

M. J. ALLEN

The investigation of cathodic organic processes has been handicapped by two factors: the physical chemist who is qualified to indulge in this work but who feels organic systems too complex to ever be decipherable, and the organic chemist who being aware of the complexity of his medium is generally fearful of a pair of wires, a voltmeter, ammeter, and the other physical accessories, both real and mathematical, required to accomplish an electrochemical investigation. Thus investigations of this type have been left to those too few physical–organic chemists who understand the underlying physical principles and who are not overcome by the thought of working with an organic system.

As the organic electrochemist deals mainly with irreversible systems he must be content with a more empirical approach than his colleagues the inorganic electrochemists, who can readily obtain the potential of their system by application of the thermodynamic expression for a reversible electrochemical reaction:

$$E = E - RT/nF \ln(\mathrm{Ox})/(\mathrm{Red}).$$

The organic electrochemist is at a further disadvantage in that his reactions usually cannot be studied in purely aqueous systems and he must be concerned with the possible side reactions associated with the medium and/or the temperature used in the experiment. However, despite these difficulties, many problems involving cathodic processes have been more readily solved by use of a methodical approach which I admit is somewhat empirical, but still superior to a grossly haphazard attack on the problem which generally results in discouraging negative results. I should like to illustrate my point by a brief discussion followed by a few examples.

The first concern in the performance of a cathodic process is the choice of a medium which will serve as a suitable solvent for the organic compound, and still when mixed with an electrolyte offer as low a resistance as possible to the passage of an electric current. These conditions are far superior to the use of an excellent electrolyte medium but a poor solvent medium. The consequence of the latter is that one has essentially a suspension of the organic compound in the catholyte which leads to low process efficiency. Within this category also lies the choice of electrode material, and the current density or reference potential required to achieve the desired end result. Constant current density electrolysis is suitable so long as it is used in conjunction with an electrode whose potential is such that it will give the desired reduction product and will not further reduce this product. Under these circumstances it must be remembered that maximum efficiency is impossible, for as the depolarizer (the organic compound being reduced) diminishes in concentration as a result of the cathodic process, the limiting reaction current should also diminish. Generally a polarographic or voltammetric investigation prior to a mass electrolysis study will give the desired information as to the optimum reference potential to use when controlled potential electrolysis is being considered, or the ideal electrode material to consider for the process. When controlled potential conditions are to be used the electrode material is generally not a problem as one chooses a high overpotential electrode such as mercury or lead and adjusts its reductive ability by the potential at the electrode

[1]*Manuscript received July 3, 1958.*
Contribution from the Research Department, CIBA Pharmaceutical Products Inc., Summit, New Jersey, U.S.A. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

surface vs. a standard reference electrode. When using constant current density conditions, one can obtain an arbitrary focal point for initial experimentation by application of the limiting current equation, i.e. $L_i = 0.0223DCn$ in which D is the diffusion coefficient, C the concentration of the organic species in g-moles per liter, and n the number of electrons exchanged in the process. By performing experiments at multiples or fractions of this arbitrary calculated limiting reaction current, and by examination of the reaction products, one can then choose those constant current density conditions which will yield maximum results.

Having decided on the aforementioned conditions the next item is the choice of a cell to be used for the actual experiment. Beyond the fact that the electrolysis cell consists of a cathode, anode, a low porosity membrane to separate the catholyte from the anolyte, a stirrer, a thermometer, and a reference electrode if controlled potential conditions are to be employed, the investigator may permit free reign to his imagination in the design of these cells. Two such cells are illustrated in Figs. 1 and 2.

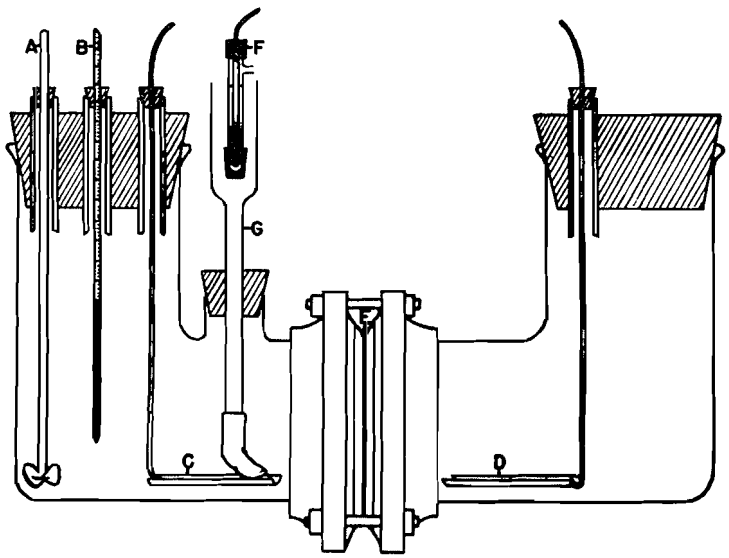

FIG. 1. Electrolysis cell for solid type electrode. A, stirrer; B, thermometer; C, lead cathode; D, platinum, lead, nickel, or stainless steel anode; E, gasketed ion-exchange or cellophane membrane; F, reference electrode; G, salt bridge.

Last but by no means the least important item in performing the electrolysis is the electrical equipment required for this operation. A simple circuit will consist of a variable d-c. voltage supply, a voltmeter, ammeter, and if one desires to investigate the possibilities of controlled potential conditions a reference electrode, and a vacuum tube voltmeter. Such a simple circuit is described in Fig. 3.

The literature, of course, abounds with descriptions of devices for automatic controlled potential electrolysis (1). Each of these devices has its respective advantages and disadvantages. The prime prerequisite for an instrument which is to be used for organic electrochemical investigations is that it have an output of approximately 10 amp and 60 v. The circuit of an apparatus of this type recently designed in our laboratories is illustrated in Figs. 4 and 5.

Essentially this instrument consists of a d-c. power rectifier, the magnitude of whose output is controlled by a motor-driven rheostat on the a-c. side of the power supply. The rheostat receives its activating signal from the amplifier, which in turn receives its signal from the cathode in conjunction with the reference electrode. In Fig. 6 will be seen the front and rear views of the instrument mentioned.

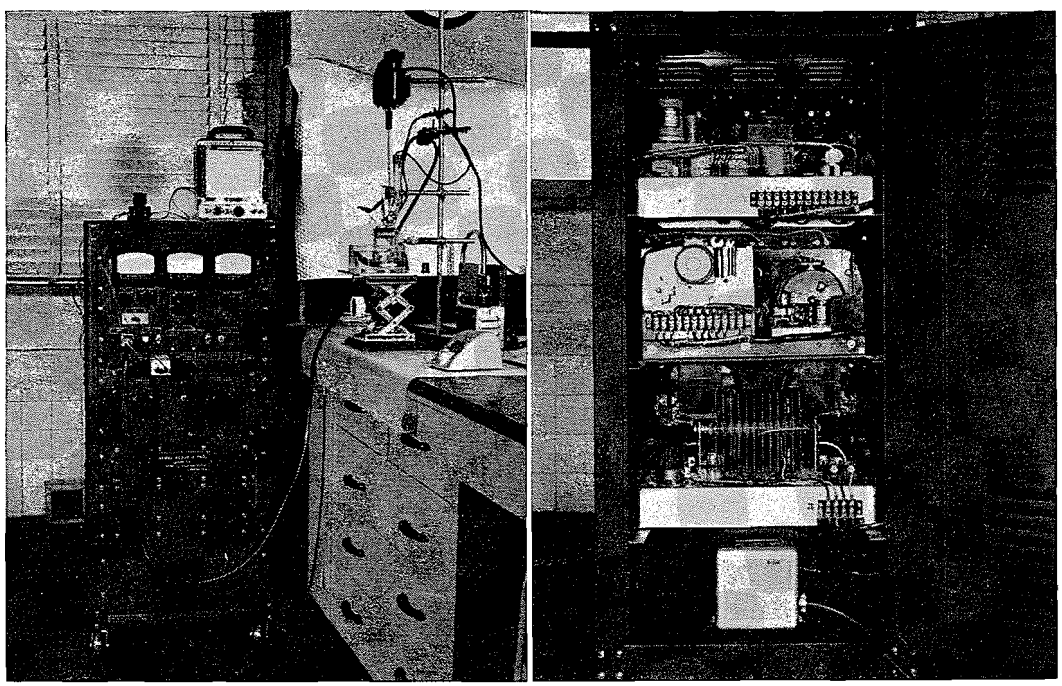

FIG. 6. Redox-o-trol Mark IV: left, front view; right, rear view.

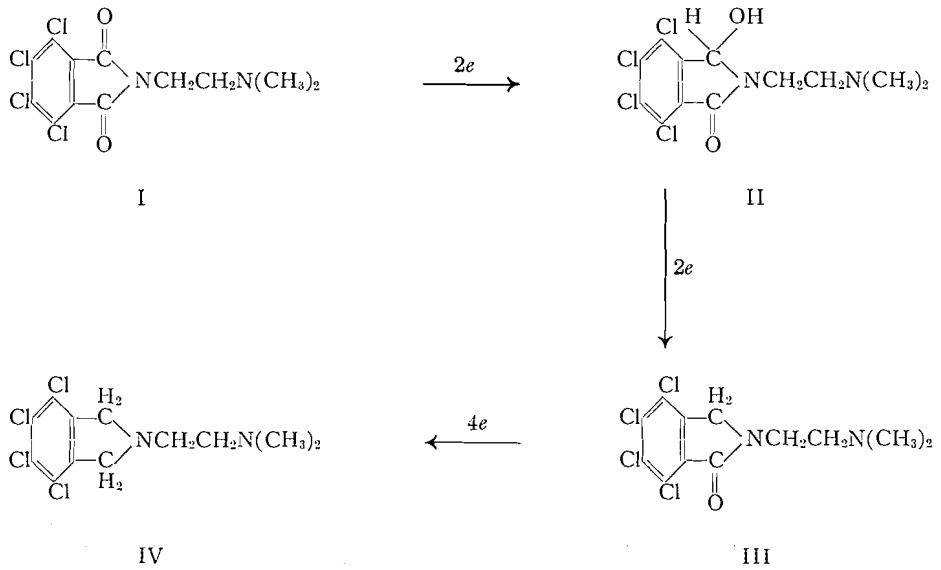
The ammeter of this instrument has seven ranges of 100 divisions each, so that one can obtain a minimum of 0.01 amp to a maximum of 10 amp full scale. The voltmeter indicating total applied voltage has a range of 1 volt to 100 volts full scale. Reference potentials as high as 3 volts can be imposed from a separate voltage supply. In addition the instrument is also suitable for oxidations under controlled potential conditions as well as constant current density electrolysis by the use of a suitable resistor built into the instrument.

I shall now briefly illustrate by a few examples the approach generally taken in the solution of a problem. The first example involves the cathodic reduction of 3,4,5,6-tetrachloro-N-(2-dimethylaminoethyl)phthalimide (I) to the fully reduced isoindoline (IV), an intermediate in the preparation of a potent ganglionic blocking agent used in the treatment of hypertension.



Previous investigators in their studies on phthalimides found that in an aqueous sulphuric acid medium at a copper cathode the phthalimide underwent a 2-electron change to yield the hydroxyphthalimidine. The use of a lead electrode yielded the fully reduced isoindoline via an 8-electron change (a). This indicated that in our case a lead electrode would be the most desirable one to use. It was obvious that the media used in the past which gave a suspension of the starting material accounted, together with the reported excessive current densities, for the low current efficiencies obtained. Therefore, as we in the solution of our particular problem desired improved efficiency, we firstly had to choose a medium which would enable us to perform our reactions on a solution, and secondly determine the optimum current density for the reactions. The former was solved by using an aqueous acetic sulphuric acid medium. By application of the limiting current equation in which D was 0.6 cm^2 day^{-1} and C, 0.2435 g-moles/liter we found our arbitrary current density to be 0.0493 amp/cm^2 when corrected for an electrolysis temperature of 50°. As the process at best was not too efficient we found it necessary to run the reaction twice the theoretical time in order to obtain suitable yields.

The results obtained using multiples and fractions thereof are illustrated in Table I.

TABLE I

Effect of current density on yield of isoindoline

Current density (amp/cm²)	% yield isoindoline	% current efficiency
0.1950	39.6	19.8
↑ 0.1540	52.0	26.0
0.1190	53.9	27.0
H_2 0.0770	56.4	28.2
0.0493	91.1	45.6
0.0243	90.5	45.2

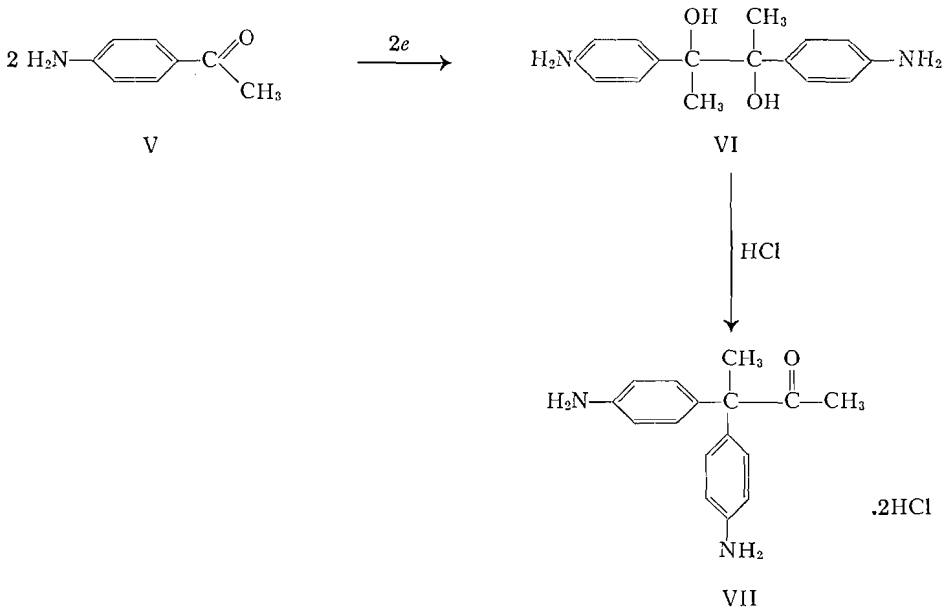
At current densities of 0.0770 amp/cm² and higher, considerable gas evolution was observed initially and throughout the course of the electrolysis which accounted to a great extent for the low current efficiency. Also in these experiments a considerable amount of partially reduced tetrachlorophthalimidine (III) was isolated from the reaction mixture. Use of the two lower current densities resulted in practically no gas evolution until approximately 1.25 times the theoretical current had been passed. In these cases, if there was any partially reduced tetrachlorophthalimidine (III), its quantity was too small to be detected. Thus we see that even the empirical use of an exact physical equation can be useful as an arbitrary focal point for a beginning.

In order to demonstrate the value of controlled potential electrolysis in obtaining maximum current efficiency an experiment was performed using a lead cathode previously treated by Tafel's method and a catholyte, the same as used in previous experiments, consisting of 6.5 g of the tetrachlorophthalimide (I) dissolved in a solution of 30 ml glacial acetic acid, 36 ml distilled water, and 90 ml concentrated sulphuric acid. The anolyte consisted of a solution of 9 ml concentrated sulphuric acid in 66 ml distilled water. At a reference potential of −1.10 v vs. S.C.E. previously determined from a voltammetric curve, the initial current density was 0.0589 amp/cm². After 80 minutes the current plateaued at a current density of 0.0143 amp/cm². From the area under the current vs. time curve the total number of coulombs passed was 15,280. The desired tetrachloroisoindoline (IV) was isolated from the catholyte in a 84.3% yield with a 77.7% current efficiency. Thus we see in this instance the advantage of the use of controlled potential in obtaining greater current efficiency than obtained under constant current density conditions.

Of interest is an experiment performed at a potential of −0.68 v vs. S.C.E. The initial current density was 0.0189 amp/cm². After 70 minutes the current plateaued at 0.0107 amp/cm². From the catholyte was isolated 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-3-hydroxyphthalimidine (II) in 86% yield. Thus we also see here another advantage of controlled potential electrolysis, i.e. the selective reduction of a particular group in a molecule containing more than one reducible center.

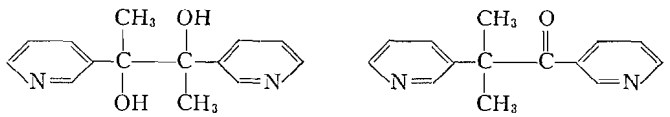
I shall now illustrate another type approach to the solution of an electrochemical problem. Perhaps a brief history of the general problem might be of interest at this point. Some years ago in the course of studying the electrochemical mechanism of bimolecular reductions, one of the compounds studied was *p*-aminoacetophenone (V). The pinacol, 2,3-bis-(*p*-aminophenyl)-2,3-butanediol (VI), obtained from this ketone by cathodic bimolecular reduction was found to be an active anti-estrogen. Further pursuit of the biological aspects of the problem indicated that the animals under test with this compound tended toward demonstration of other biological responses. However, perhaps

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.



V VI VII

because of the lack of proper bodily reagents the animal could not quite accomplish the necessary transformation. Therefore it was decided to perform a pinacol–pinacone type reaction which resulted in the compound 3,3-di(*p*-aminophenyl)-butanone-2-dihydrochloride (VII), commonly referred to as Amphenone and which was found to have interesting adrenal inhibiting effects (3). Unfortunately, however, despite the widespread use of this compound its undesirable side effect precluded general usefulness for this drug. This naturally led us to search for more specific adrenal inhibitory compounds in the Amphenone series. One of the compounds which seemed interesting, but only moderately active, was the pinacol of 3-acetylpyridine (4). This pinacol (VIII) upon being subjected to a pinacol–pinacone type rearrangement gave, as the major product, 2-methyl-1,2-bis-(3-pyridyl)-1-propanone (IX) (5), which has been found to be a potent adrenocortical inhibitor (6).



VIII IX

To return to the electrochemical aspects of this problem I should mention that the acidic medium used in the previously reported preparation of the pinacol of 3-acetylpyridine (4) made isolation of the desired pinacol extremely difficult. Therefore it became necessary for us to find a practical medium for this preparation. As a result of our previous experience it was decided that a basic medium of some type was probably desirable. Preliminary investigations in this direction indicated a solution of potassium acetate in aqueous ethanol at reflux temperature (82.5° C) to be a suitable medium. Analysis of the voltammetric curve indicated two processes occurring, the first at a potential of −1.5 to −1.64 v vs. S.C.E. and the other at a potential of −2.0 to −2.2 v vs. S.C.E.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

As it has been demonstrated by other investigators (7) that pyridine can be fully reduced to piperidine under high potential conditions, it was decided that probably the lower potentials represented the bimolecular reduction to the pinacol. This was confirmed by controlled potential electrolysis at −1.6 v vs. S.C.E. It was further decided to determine the effect of constant current density on yield and efficiency using the calculated current density of 0.378 amp/cm². This electrolysis was run for approximately 1.75 times theory and a plot made of reference potential vs. time. The results are shown in Fig. 7.

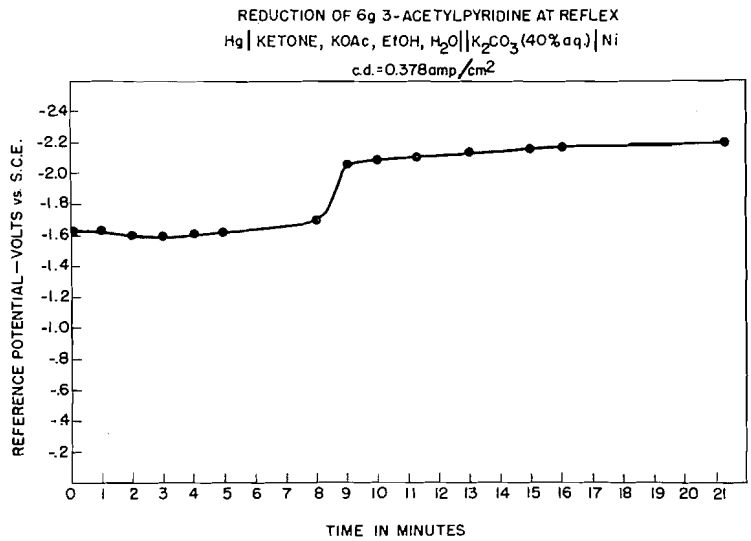


FIG. 7. Reference potential vs. time curve for reduction of 3-acetylpyridine at constant current density.

From this curve it can be seen that at 6 minutes (65.3% of theoretical time) the potential begins to rapidly increase from −1.6 v to −2.05 v vs. S.C.E. At 12.25 minutes (theoretical time) the potential is already at the point known to give a secondary product. It was difficult to isolate more than a small quantity of the desired pinacol from this experiment. Experiments performed for the theoretical time (12.25 minutes) gave satisfactory yields and current efficiencies. In order to try to approach results obtained at controlled potential, experiments were performed using a higher current density for approximately 49% of the theoretical time and then lowering the current density to another fixed value with the object of maintaining the reference potential throughout the course of the electrolysis at −1.5 to −1.64 v vs. S.C.E. This gave yields and current efficiencies approaching that obtained under controlled potential conditions. Finally, as it was observed that the pinacol began to precipitate during the reaction using the original aqueous ethanolic potassium acetate medium, and as it was thought that in so doing the precipitate might occlude the electrode surface and thus prevent maximum efficiency, the alcohol content of the medium was increased with the net result being an increase in yield and efficiency. The results of the various mentioned experiments are tabulated in Table II.

It has been the objective in this presentation to illustrate that it is possible without strict mathematical treatment to arrive at information which can give the organic chemist the desired results. If we few investigators in the field of electroorganic chemistry can reduce the subject from an art to a science as we are rapidly doing it may be in time

TABLE II

Catholyte	Mode of operation	% yield	% current efficiency
Ketone, 6 g EtOH, 25 ml KOAc, 15 g H_2O, 17 ml	Reference potential −1.6 v vs. S.C.E. 0.408 to 0.051 amp/cm²	58.3	61.4
	0.378 amp/cm² 6 minutes 0.2034 amp/cm² 11.6 minutes 1 × theory	52.0	52.0
	0.378 amp/cm² 1 × theory	43.1	43.1
Ketone, 6 g EtOH, 35 ml KOAc, 15 g H_2O, 17 ml	Reference potential −1.6 v vs. S.C.E. 0.403 to 0.029 amp/cm²	68.3	80.3
	0.378 amp/cm² 6 minutes 0.2034 amp/cm² 11.6 minutes 1 × theory	60.2	60.2

NOTE: The anolyte in the above experiments consisted of 40% K_2CO_3.

that organic chemists will begin to look upon the electrochemical technique as a vital tool in his armentarium of reagents. The future lies in the hands of those physical and organic chemists who choose to collaborate to achieve this common goal.

THE ANODIC PASSIVATION OF IRON[1]

EARL S. SNAVELY, JR. AND NORMAN HACKERMAN

ABSTRACT

A study was made of the anodic passivation of iron in solutions of 0.1 *M* sodium sulphate at a pH of 3.0. A mass balance of iron equivalent to coulombs required for passivation and iron found in solution after passivation showed that approximately 0.002 coulomb/cm² is involved in the passive layer. A Flade arrest does not appear in decay traces of anodic potential unless a potential of at least 1.2 v (E_H) is achieved on charging the electrode, indicating incomplete coverage by the passive layer below 1.2 v. Partial cathodic reduction followed by anodic reformation of the passive layer at the Flade arrest showed that the first charging current involved in reformation is highly efficient even when as much as 70% of the Flade arrest is reduced. These results support the view that only a fraction of the passive layer is represented by coulombs involved in the Flade arrest and that after partial reduction the remainder of the passive layer disintegrates spontaneously. Addition of chelating agents to the electrolyte has an adverse effect on passivation by chelation of ferrous ion.

INTRODUCTION

Experimental conditions necessary to achieve passivity of iron are well known; however, the nature of the passive layer is less familiar and has been the subject of many recent investigations. The theories which have been advanced can, in general, be divided into categories of oxide film theories and adsorption theories. The former are concerned with an iron oxide, rich in oxygen and hydrated, which requires specific conditions to form in such a manner as to give a high degree of protection to the base metal. The adsorption theories maintain that passivity is the result of adsorption of chemical species such as hydroxyl ions or molecular and atomic oxygen. Films of either type, oxide or adsorbed, can be similar once formed because of migration of iron atoms or ions through the passive film, and their chief difference lies in their means of formation. An oxide film formed by anodic polarization requires nucleation and lateral growth with a necessary consumption of coulombs, while an adsorbed film forms rapidly and completely on a properly prepared surface.

This paper presents the results of experiments to determine the quantity of electricity involved in the formation of a passive layer by anodic treatment. Other results concerning the phenomena observed on cathodic reduction of the passive layer are presented.

EXPERIMENTS

The iron electrodes used in all experiments were made from stock supplied by the Armco Steel Corporation and were reported to be 99.9% Fe containing 0.04% copper, 0.01% carbon, and traces of manganese, phosphorus, and silicon.

Circular coupons about 3.5 cm in diameter were vacuum-annealed and mounted in bakelite so that one face of the iron disk was exposed. This face was ground flush with the bakelite by means of a surface grinder and polished with 4/0 emery paper. The bakelite–iron junction at the periphery of the electrode, as well as all exposed bakelite, was covered with clean Ucilon or Glyptal to prevent imbibition of solution.

Electrical connection to the iron was accomplished by a tapped hole in the bakelite through which a metal rod could be screwed against the iron. The metal rod was protected with Myva wax.

Contribution from the Department of Chemistry, University of Texas, Austin, Texas. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

All solutions were 0.1 M in Na_2SO_4. They were made from recrystallized salt and triple-distilled water and adjusted to a pH of 3.0 with c.p. H_2SO_4.

The polarization cell was a Pyrex vessel equipped with a large platinum electrode and a fritted gas-dispersion tube through which helium was bubbled to rid the cell and its contents of oxygen. The helium was purified by passage through a tube filled with hot copper followed by a drying tube containing $Mg(ClO_4)_2$. The cell and the electrical circuit are shown in Fig. 1.

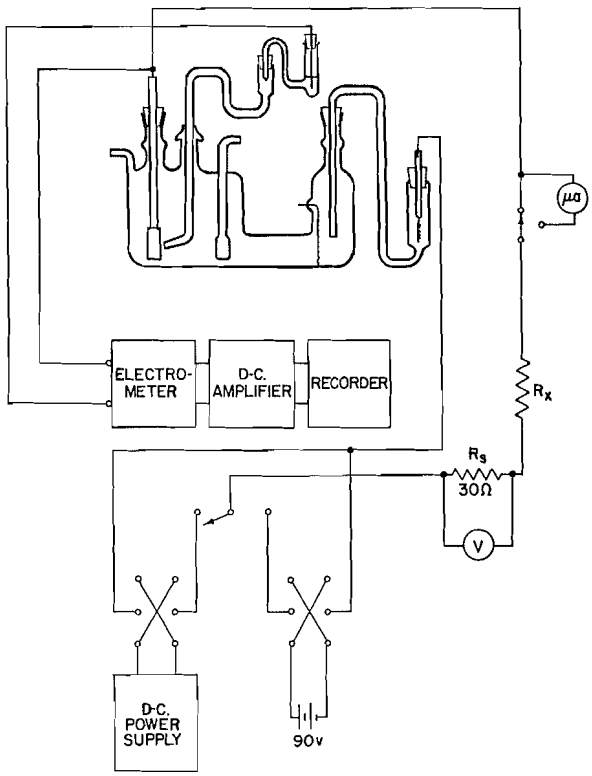

FIG. 1. Passivation cell and circuit.

Potential measurements were made with reference to a Hg, Hg_2SO_4 electrode. All potentials reported here are given with respect to the standard hydrogen electrode. The surface of the electrode is treated as a projected area and results are presented on that basis.

As shown in Fig. 1, the potential measuring circuit consisted of a Keithley Model 210 electrometer having an input impedance of 10^{14} ohms. The output of the electrometer supplied a d-c. amplifier which drove a Brush Recorder equipped for chart speeds of 25, 10, and 5 cm/second.

Analytical Experiments

To determine the amount of electricity required to passivate iron, a material balance was made on the amount of iron actually present in the cell solution after passivation was achieved and the amount of iron equivalent to the coulombs passed during the passivating process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In these experiments the cleaned electrode was placed in the cell about 3 inches above the solution, while the latter was degassed by bubbling He. The iron was then lowered into the solution under an applied cathodic current of 12.5 ma/cm² to prevent corrosion. The recorder was then set on high speed and when the electrode had been in the cell solution 15 seconds an anodic current of 50 to 70 ma/cm² was applied. This passivated the iron and the electrode was then withdrawn from the cell while still passive and while oxygen was being evolved. The exact volume of solution was determined by weighing the cell, and the concentration of iron was then measured by the *o*-phenanthroline method. Cell solution in which iron had been only cathodically treated was used as a blank.

In these experiments the potential changes during passivation were recorded as shown in Fig. 2. The number of coulombs required for passivation was calculated from the constant current applied and the time interval from point A to the reversible oxygen potential or point B. This interval was used for reasons which are pointed out later.

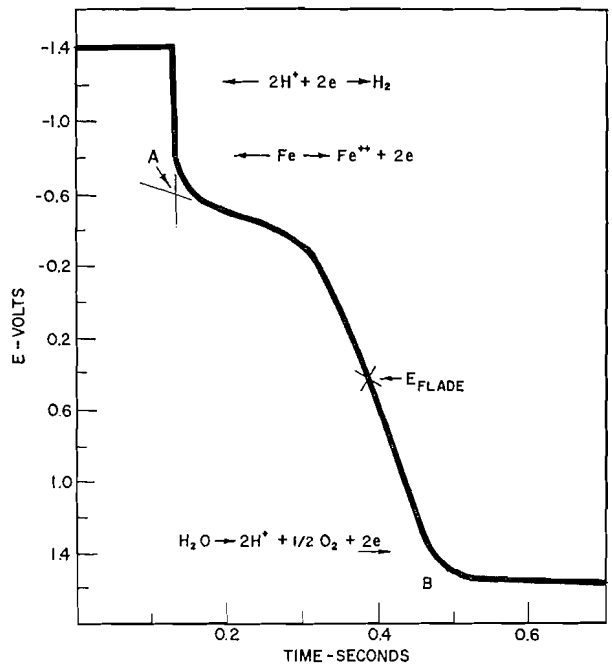

FIG. 2. Typical passivating curve.

Typical results for these analytical experiments are shown in Table I. The column titled "Equivalent Fe^{++}" gives the amount of ferrous ion equivalent to the coulombs passed during passivation. The next column lists the amount of ferrous ion which was found in the cell solution after passivation. The average of all values in the last column of Table I yields a value of 1 γ of Fe or 0.003 coulombs, which approaches the value reported by Kabanov (1). This is the amount of ferrous ion, as coulombs in the passivating process, in excess over the amount of iron determined in solution and per square centimeter of electrode surface. The results have an average deviation of 0.25 γ or about 30%.

The value of 0.003 coulomb/cm² required for passivation is far in excess of the quantity of electricity which is observed at the Flade region on reduction of the passive layer. For example, reduction of the passive layer in the 3.0 pH 0.1 *M* Na_2SO_4 solution at 14.5 μa/cm² requires 0.00016 coulomb/cm³ or less than $\frac{1}{10}$ that required for passivation. It

is known that the iron passive layer is anodic to iron, and exposure of bare iron during the reduction process most certainly increases local cell action which leads to spontaneous decay of the passive layer (2).

To determine the extent to which the passive layer could be reduced without exposing iron, the current efficiency for formation of the passive layer was determined. This was done by repeatedly reducing and reforming the passive layer until a constant value for the number of coulombs involved at the Flade region was obtained. Care was taken to apply anodic current just at the end of the arrest so that excessive currents would not be required for repassivation. When a constant value was obtained, a small reducing current was applied until a fraction of the Flade arrest was passed. The current was then reversed and a small anodic current applied for a short period. The current was reversed again and reduction allowed to proceed until the end of the arrest was reached. The difference between the constant coulomb numbers necessary to pass through the Flade region, and the number of coulombs initially passed cathodically gives the charge remaining in the surface at any point in the region.

For personal use only.

For a 100% efficient anodic current the number of coulombs actually required to pass the remainder of the arrest should be greater by an amount equal to the number of coulombs added anodically after the initial reduction. Figure 3 shows the results of an experiment in which 14.5 $\mu c/cm^2$ was added to the passive layer after various fractions of the arrest had been passed. The curve clearly shows the anodic current to be highly efficient up to a reduction of 70% of the Flade region. The open circles of Fig. 3 are results of the same experiment in which 0.05% *o*-phenanthroline was added to the cell solution. This treatment had no effect on efficiency of the anodic current.

Figure 4 shows the effect of additions of *o*-phenanthroline on the time required to achieve passivity when the passive layer is completely reduced. Presumably *o*-phenanthroline increases the time required for passivation due to chelation of the ferrous ions which are necessary to achieve the high potentials required for passivity (3). The high potentials are the result of precipitation of ferrous hydroxide on a ferrous salt. A cleaned coupon was used for each point of Fig. 4 so that equivalent roughness factors were involved for each passivation. Since 0.003 coulomb/cm^2 are involved in a formed passive layer but only 0.00016 coulomb/cm^2 are involved in the Flade region, the Flade region should be evident on reduction *only* if the passive layer is about 90% complete. If the Flade arrest is considered to involve a 1-electron process and passivation a 3-electron process, then the arrest should appear only if the passive layer is about 70% complete.

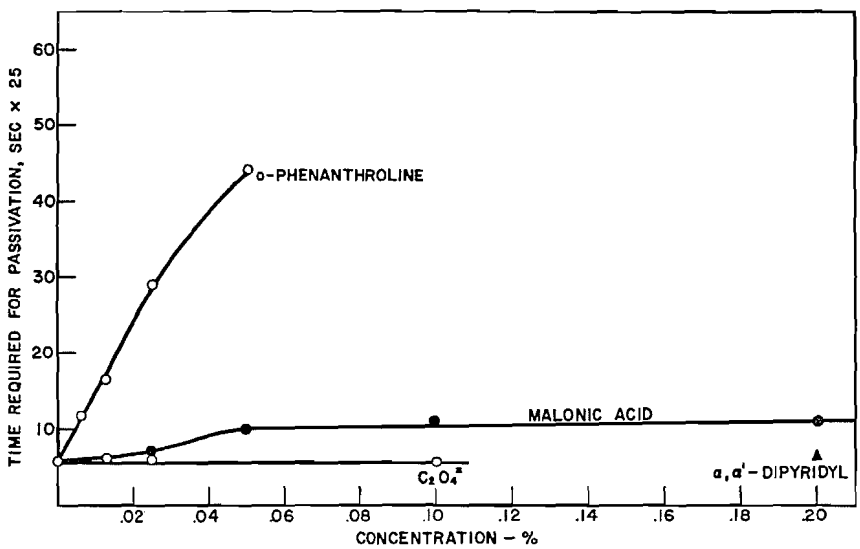

FIG. 4. Concentration chelating agent versus time required for passivation.

Additional evidence that the Flade region represents only a fraction of the passive layer is shown by the results in Fig. 5. This curve was obtained by plotting the anodic coulombs required to attain the reversible oxygen potential versus the fraction of Flade region achieved by cathodic reduction. When approximately 95% of the Flade region was passed passivity could no longer be attained by an anodic current of 14.5 $\mu a/cm^2$. When about 70% of the Flade region was passed the time required to reach the reversible oxygen potential increased, indicating that some iron was exposed and that local cell current began to increase. The flat portion of the curve in Fig. 5 is in accordance with the view that the thickness of the passive layer is proportional to the anodic potential

For personal use only.

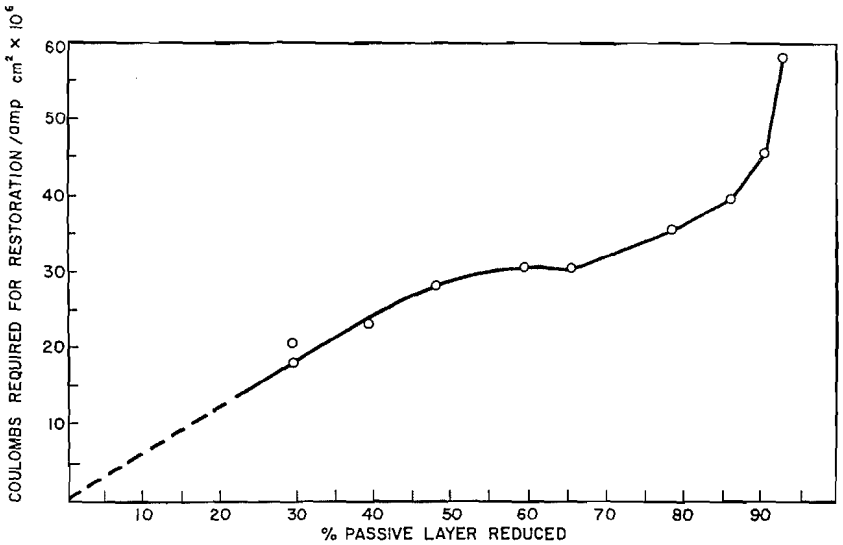

FIG. 5. Restoration of passive layer. Anodic c.d. = 12.9 μa/cm^2; cathodic c.d. = 14.2 μa/cm^2.

achieved. If only a small part of the passive layer is reduced at the Flade region, then a nearly constant number of coulombs is required to attain the oxygen potential after various fractions of the arrest have been passed. In these experiments the total number of coulombs involved in the arrest was calculated from the time at which the current was made cathodic to the end of the flat portion. For the low currents used, concentration polarization was very small and any resistance drop at the electrode surface was not detectable.

In constant current experiments such as these, the only arrest which appears in the charging curve is found at a potential corresponding to the Fe, Fe^{++} potential. Even if the Flade region represents the formation potential of the passive layer it is not surprising that a detectable arrest does not appear in this region during charging because of the high current involved. For example, the results of the previously described analytical experiments yielded a value of 0.003/cm^2 for the coulombs involved in the passive layer. For a passivating current of 70 ma/cm^2 only 1/35 second is required to pass 0.003 coulomb/cm^2 and, since some of the passive layer forms at potentials more anodic than that of the Flade region, only a portion of this short time would be involved in this arrest. To determine the potential at which a nearly complete passive layer had formed, the charging current was interrupted at various times and the potential then achieved was allowed to undergo open-circuit decay. Figure 6 shows the results of this experiment and indicates that a potential near the reversible oxygen potential must be achieved before a complete passive layer is formed. The Flade arrest on decay is visible only in the lower two charts where the potential achieved was 1.4 v. This result is in agreement with calculations made with the figures reported in Table I. Calculation of the time required, at the anodic current density employed, to account for all iron found in solution after passivation yields an average value corresponding to the achievement of 1.2 v. These results indicate that iron dissolution slows appreciably only on attainment of potentials more anodic than the Flade region.

To determine if the excess iron in solution after passivation was due to local cell action or if iron dissolution is necessary to achieve passivation, several chelating agents were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

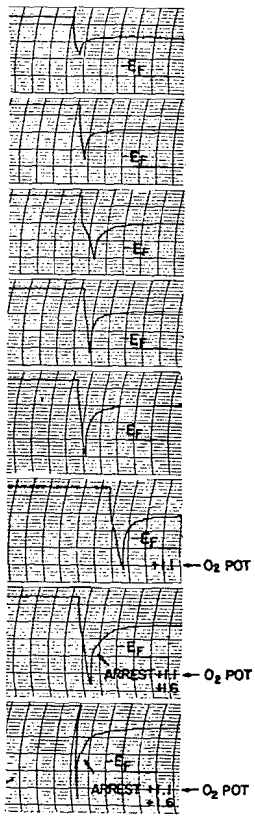

FIG. 6. Appearance of the Flade arrest in open-circuit decay. Anodic c.d. = 70.0 ma/cm²; chart speed = 2.5 cm/second.

added to the cell solution prior to passivation. These included *o*-phenanthroline, malonic acid, and α, α'-bipyridyl. As shown in Fig. 4 none had a significant effect except *o*-phenanthroline. In the first case the time required to achieve passivation is proportional to the *o*-phenanthroline concentration. The instability constant of the ferrous–*o*-phenanthroline complex is very small, i.e., approximately 10^{-21}. As pointed out by a previous experiment, additions of *o*-phenanthroline to the cell solution after the passive layer was formed had no effect on its reduction or reformation from a partially reduced state. Thus, oxidation of the chelating agent does not play a major role in the increased consumption of electricity during the passivating process. Apparently at least a portion of the iron dissolved in the anodic treatment of iron is necessary to achieve passivity.

DISCUSSION

Suitable corrections must be applied to the results of the analytical experiments in order to arrive at an exact figure for the coulombs involved in formation of the passive layer. Presence of hydrogen in the metal has an inhibiting effect on passivity as shown by others (4). Introduction of hydrogen by the initial cathodic treatment may be responsible for instability of the passive layer at potentials more cathodic than the oxygen potential during the passivating process. Also, the number of coulombs involved in competing electrode processes such as oxidation of ferrous ion or ferrous hydroxide is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

not known; however, the absence of arrests in the charging curve indicates that they do not take place to any notable extent. It was not possible to remove the iron electrode from the cell solution at the instant passivity was achieved and it is quite likely that the coupon, even though passive, corroded slightly, contributing to the amount of iron in solution, thereby making the results too small. Also, open-circuit decay of the electrode potential during the charging process indicates that some growth of the passive layer takes place after the beginning of oxygen evolution so that the number of coulombs involved in a complete passive layer is slightly larger than that obtained in the analytical experiments. If the Flade region represents only 10% of the passive layer as concluded from other experiments presented here, then growth of the passive layer above the oxygen potential should add this amount to the 0.003 coulombs obtained from the analytical experiments.

A complete passive layer is very stable and passivity in acid solutions can be maintained by anodic currents of less than 1 $\mu a/cm^2$ (5). Very few changes are involved at the Flade region on cathodic reduction of a passive layer maintained by such a low current. These results indicate that passivity can be achieved by less than a monolayer. The monolayer is probably composed of sorbed ions and dipoles held in place by appreciable force fields. An alternative explanation is the stabilization of a primary passive film by an adsorbed species (6). The role of adsorption in maintaining passivity is indicated by the rapid potential changes associated with the application of small currents at the Flade region, the absence of effect of a chelating agent on current efficiencies at the Flade region, and the small number of coulombs involved in formation of a passive layer.

CONCLUSIONS

Anodic dissolution of iron at a rapid rate is necessary to achieve passivity, and passivity can be deferred or prevented by the addition of a suitable chelating agent. Approximately 0.003 coulomb/cm^2 is involved in the passive layer; this amount of electricity is equivalent to a thickness of 15 Å of Fe_2O_3 based on projected areas. Coulombs involved at the Flade region represent only 10% of the passive layer and the remainder decays spontaneously when iron is exposed. Small anodic currents applied at the Flade region are completely efficient, indicating absence of local cell action and a passive film consisting of at least a monolayer.

THE THEORY OF FORMATION OF HIGH RESISTANCE ANODIC OXIDE FILMS[1]

L. YOUNG

ABSTRACT

Various models are considered for the growth of anodic oxide films (metal ions mobile). In general, a transition is expected, as the thickness of the film is increased, from control by the metal/oxide interface (Cabrera and Mott) with very thin films to control by the movement of ions through the body of the film (Verwey), with the concentration of mobile ions taking up the value (p, say) which gives electroneutrality. The field strength only varies with thickness in the transition region of thickness. Dewald's theory is the special case of p zero, which gives a field increasing continuously to infinite thickness. The high field production of Frenkel defects (with the vacant cation sites immobile and the interstitial ions mobile) as postulated by Bean, Fisher, and Vermilyea, and a slight mobility of oxygen ions are two processes which would allow p to vary with the field strength, and which would, therefore, give rise to "overshoot" in the transients in the field strength which occur when the applied current is suddenly changed. However, if the field strength is sufficiently great to produce Frenkel defects it would be expected to be sufficiently great to cause the vacancies to be mobile. This case is considered. Finally, it is noted that in an amorphous oxide it is difficult to maintain a distinction between lattice and interstitial ions, and, in fact, a range of site energies and jump distances would be expected. Some of the observed features (including "overshoot", and Tafel slope anomalies) of the kinetics for tantalum may, therefore, be due simply to the fact that the oxide is amorphous.

INTRODUCTION

This paper is concerned with developing the consequences of various models intended to represent the formation of the high ionic resistance type of anodic film in order to find crucial differences for experimental test. This type of film is formed on tantalum and niobium in most electrolytes and on aluminum, titanium, zirconium, hafnium, tungsten, uranium, silicon, germanium, and other metals or intermetallic compounds in certain electrolytes. It is distinguished from the type of anodic film used in storage batteries by the characteristic that electric field strengths of the order of 10^6 v cm^{-1} are produced in the oxide by anodic polarization, the resulting current being predominantly ionic. Part of the interest in the formation process lies in the connection with the formation of oxide films by reaction with oxygen ("tarnishing reaction"). The essential difference between the two processes is that in anodic oxidation only ions need cross the film for growth to occur,* but in the tarnishing reaction electrons must also move, since otherwise macroscopic separation of large electric charges would occur. In effect, the electrical circuit is closed within the oxide in the tarnishing reaction and externally in the anodic reaction. This means that the anodic kinetics should in principle be easier to interpret, in that there is no question, as there is in some tarnishing reactions (1), as to whether the ionic or the electronic current is rate determining. The anodic system is easier to investigate experimentally, since it has an extra degree of freedom: at a given temperature and concentration of reactants the rate of formation may still be varied (and, in fact, exactly controlled) by controlling the current through the oxide. In practice, it is only

[1]*Manuscript received July 8, 1958.*
Contribution from the British Columbia Research Council, University of British Columbia, Vancouver, B.C. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

**A "leakage" current is usually observed. This is due partly to an electronic current through the oxide and partly to ionic discharge in pores. However, this current has invariably been tacitly assumed to be independent of (that is, in parallel with) the ionic current, though, admittedly, ultraviolet irradiation, which would be expected to produce only an electronic current, also causes film growth.*

possible to discuss in a very provisional way whether a given metal behaves like a given model, since the experimental data are very restricted, and, even with the metals—tantalum, niobium, and zirconium—which have been at all extensively investigated, are incomplete or in dispute.

Basic Equations for the Ionic Current

All present theories treat ionic movement using models which are strictly applicable only to crystalline material. Thus they assume that either vacant anion or cation sites, or interstitial ions, are mobile, and that one vacancy or interstitial ion is exactly equivalent to another. Now, at least as far as X-ray diffraction is concerned, this type of film is normally amorphous. (Crystalline films can be produced, but detailed kinetic studies have not been made.) In an amorphous solid, it would seem difficult to make a distinction between interstitial and lattice ions. In fact, it may be necessary to abandon this distinction, and to consider the oxide as consisting of two random lattices (oxygen and metal), probably with a large concentration of vacancies in each lattice. There will be a distribution of mobilities because of the varying local environment of each ion. In other words, a given ion will encounter a range of jump distances and activation energies along its path through the oxide. Against this argument, there is, of course, the point that, even in an apparently amorphous lattice, there will be some degree of local order. For example, the detailed structures of tantalum and niobium pentoxide have not been worked out, but, if the structure reported (2) for one form of vanadium pentoxide is any guide, the lattice of the amorphous oxide may consist essentially of oxygen tetrahedra randomly linked to neighboring tetrahedra at an average of three points and with an average of one metal ion per tetrahedron.

The conventional equations, which are used to describe the ionic movement, apply only to either a few ions moving in a large number of empty sites, or a few vacancies moving in a nearly full lattice. This is because no allowance is made for the possibility that one carrier may block the path of another. It seems quite possible that this assumption of a very low concentration of the mobile species may fail. In particular, some theories postulate an exponential variation of carrier concentration with the field strength, with a large value appearing at accessible fields.

The same equations have been used to describe the movement both of interstitial ions and of vacant lattice sites. They were first applied to anodic oxide films by Verwey (3), who was, as it happens, considering specifically the movement of aluminum ions in the spinel structure γ-alumina, which has a large concentration of vacant cation sites at electroneutrality when the oxygen lattice is full. The conventional assumption is that the current at a given point x may be written

$$[1] \qquad i = 2anv \exp -(W-qaE)/kT - 2a[n+2a(\partial n/\partial x)]v \exp -(W+qaE)/kT,$$

where a = (mean) half jump distance for the ions, n = concentration of ions, v = vibration frequency of ions, W = activation energy at zero field, q = charge on the ions, and E = the field strength. The first term refers to the ions moving with the field, and the second term refers to ions moving against the field. The magnitudes of W and aq are such that, for the range of currents which is experimentally accessible at present, the second term is negligible (high field approximation). The concentration gradient needed to give a diffusion current comparable with the migration term is so large as to have little physical significance. The remaining term

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[2] $$i = 2an\nu \exp -(W-qaE)/kT$$

gives a relation between field strength and current density which is of the form

$$i = i_0 \exp \beta E.$$

The kinetic expressions 1 and 2 apply to an ion vibrating in simple harmonic motion in one dimension with a frequency ν, so that the chance of acquiring sufficient energy to jump the barrier on a given vibration is given by the Boltzmann factor. This treatment is, of course, an oversimplification. In particular, one would expect that success in jumping the barrier would depend on the correct phase relation with the vibration of neighboring atoms, and, perhaps, on sufficiently great amplitudes of their vibration. Unfortunately, even to allow for the accumulation of a critical energy in several degrees of freedom leads to cumbersome expressions, and still does not represent much greater correspondence with reality. The significance of ν and the possibilities of multiple jumps have been discussed recently by Ubbelohde (4) for ordinary diffusion. Multiple jumps are more likely in the present systems, since the ion continues to gain energy from the field so long as it moves. The transition state theory either provides the same final expressions by a more circuitous route, or leaves one with expressions, involving free energies and activity coefficients of imprecisely defined transition states, and these expressions, though of great generality, are not very amenable to experimental verification.

We have so far formulated equations for the ionic current at a point where the concentration of ions and the field strength are specified. A complete account of a given model is obtained when it is determined how these two quantities vary through the thickness of the oxide.

The present discussion will be chiefly restricted to the model in which metal ions carry most of the current. The alternative single carrier model in which oxygen ions carry most of the current gives analogous equations when treated using the conventional equations, but the two models differ in that adsorption effects may occur at the oxide/solution interface and structural effects (discussed below) may occur at the metal/oxide interface.

The discussion is confined to the rather idealized case that pores and fissures are not present in the oxide.

Interface Control

The interfaces were first taken into account by Mott and Cabrera (5), who considered (apparently intuitively) that the first barrier which metal ions have to surmount to enter the film will be higher than subsequent barriers encountered during passage through the film. The passage over this first barrier was treated in the same way as the jumps over the barriers within the film, but with the vital difference that the concentration of metal ions facing the barrier was assumed to be a constant, determined by the concentration of metal ions on the metal surface. Space charge was neglected so that the field strength was assumed to be constant through the film. The current over the entrance barrier is given by

[3] $$i = m_s\nu_s \exp -(W'-qa'E)/kT,$$

where m_s = surface concentration of metal ions, ν_s = their vibration frequency, W' = activation energy required to jump the first barrier with zero field, and a' = the half jump distance for this barrier. The concentration n_0 say of ions within the oxide adjusts itself so that the current given by 2 is equal to that given by 3, giving

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$[4] \qquad n_0 = \frac{(m_s\nu_s)^{a/a'}}{2a\nu} \exp\left(\frac{W - aW'/a'}{kT}\right) \cdot i^{1-a/a'}.$$

The kinetics are therefore determined by the entrance barrier. We may attempt to generalize the conditions under which the entrance barrier controls the kinetics. The required conditions are that space charge be negligible and that no upper limit be placed on n_0. The kinetics will then be controlled by the first barrier at which the backwards current is negligible (6). We introduce here an important parameter, the concentration (p, say) of mobile ions in the electrically neutral oxide. Apart from the improbable case that $n_0 \doteq p$, both n_0 and p must be small or the film must be very thin if the space charge is to be negligible. n_0 is certainly small in the original model, in which the first barrier is higher than later barriers. The significance of "small" will be clarified later.

Metal Ions Mobile, Space Charge Due to These Only

The theory proposed by Cabrera and Mott predicts that the Tafel slope $\partial E/\partial \log i$ is given by kT/qa', so that it should be proportional to the absolute temperature. This was reported not to be the case with tantalum (7, 6), niobium (8), and zirconium (9, 10), though it should be noted that the details of the behavior of tantalum as reported in recent investigations do not agree (6, 11, 12). Dewald (13) showed that an almost temperature-independent Tafel slope could appear if, as he claimed to be the case, the mobile metal ions were the only source of space charge. Actually, this assumption must be regarded as being made because it gives simple equations rather than because it would be expected to be true, as may be seen by putting it in the form that the concentration of the mobile ion near the interface given by 4 is assumed to be much greater than the critical value p which corresponds to electroneutrality. Poisson's equation gives

$$[5] \qquad \partial E/\partial x = 4\pi\, nq/\epsilon,$$

where ϵ is the dielectric constant of the oxide. The continuity equation for the current is

$$[6] \qquad \partial i/\partial x = \partial n/\partial t,$$

where t = time. Dewald puts $\partial i/\partial x = 0$. (The final result that $n(x)$ is not a function of the total thickness is derived directly from this initial assumption.) From [1] to [6], after two integrations,

$$[7] \qquad E = \frac{1}{\beta'} \log[i/m_s\nu_s \exp(-W'/kT)] + \frac{1}{\beta} \log(1 + \beta 4\pi\, qn_0x/\epsilon),$$

where

$$\beta = qa/kT \qquad \text{and} \qquad \beta' = qa'/kT.$$

This model exhibits a Tafel slope nearly independent of temperature over a certain region of temperature provided that certain conditions are fulfilled. Essentially, the space charge due to the ions causes a transition from control by the entrance barrier to control by the barriers within the oxide. However, the model also gives a field strength increasing with thickness. This has not been observed with tantalum or niobium though it is difficult to be sure that the small amount of variation required by the theory is absent. For example, the data given by Vermilyea (11, 14) for tantalum are inconclusive, because the ionic current was not shown to be constant, variations of surface area with thickness had not been shown to be absent, and the capacity had not been shown to measure thickness to the required accuracy. Some of these difficulties have been removed in subsequent work (15). When the integral rather than the differential field strength is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

considered, a certain degree of uncertainty is caused by our lack of knowledge of the inner potential differences between phases of different chemical composition. This point is not always recognized. The uncertainty may be conservatively reckoned as corresponding to about one volt, i.e. 1% in the field strength at 100 volts overpotential, and proportionately more for thinner films.

It may be noted that when (below) we introduce the more realistic assumption that the concentration of ions p corresponding to electroneutrality is not negligible, the transition occurs between Cabrera and Mott's case and Verwey's case (control by movement of metal ions through the electrically neutral oxide) with the field strength independent of thickness except in the transition region.

Dewald (12) has recently shown that his model—when treated using the conventional equations—does not predict the "overshoot" which is observed in the transients in the field strength when the current is suddenly changed. This would invalidate its application to tantalum and niobium. However, Willis, Adams, and van Rysselberghe (9) have suggested that these transients could be due to the sluggish opening and closing of growth spirals, which, effectively, is equivalent to a variation of m_s.

The evidence is thus fairly conclusively against the application of this model to tantalum and niobium, either with $p = 0$ (Dewald) or with p constant and not zero. By contrast, recent work (10) has shown that zirconium in addition to Tafel slope variations exhibits a marked increase in field strength with thickness, and fails to exhibit the overshoot in the transients, in agreement with the predicted behavior for $p \ll n_0$.

The effect that, with a non-zero concentration of carriers, the next site in the path of a given carrier may be already occupied may be allowed for by multiplying the right of (2) and (3) by $(1-n/N)$, where N is the total concentration of available sites. Variations of vibration frequencies and of the activation energies would remain to be taken into account. This modification introduces considerable complication, but does not explain the transients.

Field Production of Frenkel Defects

Bean, Fisher, and Vermilyea (16) have proposed for tantalum pentoxide films that Frenkel defects (lattice vacancy plus interstitial ion) are produced in the metal lattice by the high fields. They assume *ad hoc* that the interstitial ions are mobile and the vacancies are immobile. The idea that the field might produce lattice defects was considered as improbable in older work on conventional ionic conduction (17), but the greater field strengths in the present systems make it more feasible. In view of the amorphous nature of the oxide it can only represent an approximation to a real process. These authors appear to assume that the defect-producing process directly determines the concentration of interstitial ions. A more correct view is that the process creates a certain concentration of immobile negative space charge (associated with the vacant cation sites), and that any control of the concentration of mobile metal ions is due to this, in the way which is discussed in the next section.

Bean, Fisher, and Vermilyea postulated in addition that there is a quite sudden transition with increasing field strength in the half barrier width for the production of interstitial ions.* This gave an explanation for the sudden change from a half barrier width of 2.4 Å to one of 4.8 Å which Vermilyea (11) found in his second investigation of the kinetics. They seem to envisage that several barriers are taken at one jump,

**Unless the maxima and minima in the potential energy curve of an ion in transit are mirror images there will, of course, be a second-order variation of the half jump distance with field strength. Further sources of gradual variation of "a" with field strength are discussed later.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

though this is not stated explicitly. There is some disagreement on the experimental issues, and Dewald (12) has suggested that Vermilyea allowed insufficient time for the transients to decay. The present author's results (unpublished) suggest that the (apparent) jump distance (derived in a similar way) does vary with the field, but that there is no evidence for any sudden transition from a value a to $2a$. As a result of the variation of "a" with E, $(\partial E/\partial \log i)_E$ varies correctly with temperature, but $(\partial E/\partial \log i)_t$ is almost independent of temperature.

Both Vermilyea (18) and Dewald (12) have shown that this model can give "overshoot". The essential reason for this is that the concentration of carriers lags behind the field when the current is suddenly changed. More precisely, the concentration of negative charge (and hence the concentration of mobile ions) increases sluggishly with the field strength. The treatments given by these authors are, of course, not exact because they assume $n = p$ at all times.

Production of Frenkel Defects with Both Vacancies and Interstitial Ions Mobile

It seems reasonable to assume that if the field strength is sufficiently great to pull a lattice ion out of its position and place it in an interstitial position, it should also be able to move a lattice ion to an adjacent empty site. The assumption made by Bean, Fisher, and Vermilyea that vacant cation sites are immobile seems, therefore, inconsistent with the assumption of the creation of Frenkel defects. The more consistent model in which the vacancies are allowed to be mobile gives some interesting limiting cases. The equation for the rate of change of vacancy concentration at a given point acquires an extra term and becomes (in the form used by Dewald (12) in considering Bean, Fisher, and Vermilyea's model),

$$\partial m/\partial t = \partial i_m/\partial x + (N_0 - m)\gamma'' \exp -(W'' - Eqa'')/kT - i\sigma_m,$$

where m = concentration of vacancies; i_m = vacancy current (in ions); N_0 = total concentration of lattice sites; W'', ν'', and a'' the activation energy at zero field, vibration frequency, and half jump distance for the production of a Frenkel defect; and σ_m is the cross section for the capture of an interstitial ion by a vacancy. i_m is given by a term of the usual type.

If vacancies are not produced at the interface, $i_m(x = 0) = 0$. If the mobility of vacancies is sufficiently great with respect to their rate of production, their concentration falls to zero throughout. If not, m varies with x, and the field varies with thickness.

If vacancies are produced at the metal interface, as well as in the oxide, both constant and varying m and field are possible, according to the parameters, and the interface partly controls the kinetics over the range of fields where the vacancy current is important.

The Model in which Metal Ions Move in a Uniform Immobile Negative Space Charge

The significance of this model has been indicated in previous sections. We consider an immobile, uniform negative space charge given by $-pq$ where q is the charge on the *metal* ion. Poisson's equation is now

$$\partial E/\partial x = 4\pi\, q(n - p)/\epsilon,$$

where n, as before, is the concentration of metal ions. Using the continuity equation

$$\partial i/\partial x = 0$$

we obtain

$$(\partial n/\partial x) + n\beta(\partial E/\partial x) = 0.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

After integrating as in Dewald's theory, we obtain

$$[8] \qquad n = p/\{1-(1-p/n_0)\exp(-\beta 4\pi\, qpx/\epsilon)\}$$

and, after a second integration,

$$[9] \qquad E = E_0+\frac{1}{\beta}\log\{[n_0-(n_0-p)\exp(-\beta 4\pi\, qpx/\epsilon)]/p\}$$

where n_0 and E_0 are the values of n and E at $x = 0$, and are given by equations [4] and [3] respectively.

For large x, the field is given by

$$[10] \qquad E = E_0+(1/\beta)\log(n_0/p).$$

On substituting for E_0,

$$[11] \qquad E = \frac{1}{\beta}\{\log(i/2a\nu\, p)+W/kT\}.$$

The field then becomes independent of the interface and is determined by whatever determines p. This is the result which Verwey (3), Bean, Fisher, and Vermilyea (16), and Dewald (12) assume implicitly or, in Dewald's case, explicitly, to apply at all x. The validity of their assumption depends on p/n_0 and on the value of p, since this controls the characteristic length l (say) $= \epsilon/\beta 4\pi\, qp$ in equation [8]. For $l \simeq 10$ Å, $p \simeq 10^{21}$ metal ion equivalents per cm^3, assuming a typical value for a in $\beta = qa/kT$ of 3 Å. The total concentration of metal ions in the oxide is $2\rho L/M \simeq 10^{22}$, where ρ = density, L = Avogadro's number, and M = the molecular weight of the oxide. Thus for $l \simeq 10$ Å, a fraction of the order of 1 in 10 ions must be mobile and so on. In the theory of Bean, Fisher, and Vermilyea p varies exponentially with the field, so that it appears that at low fields when p is small, the space charge region should become important, and the assumption of no net space should break down. At high fields p will become rather large. In contrast with Dewald's model, the concentration of mobile metal ions may either fall below or rise above the value corresponding to electroneutrality. The possibility of the net space charge being either positive or negative means that the field strength in the interfacial region may either rise or fall in passing from the interfacial region towards the center of the oxide.

Consequences of the Amorphous Nature of the Oxide

It has been noted that in the amorphous oxide one would expect a range of types of site. Thus as the field is increased an increasing proportion of sites will stop acting as traps for the mobile ions. In particular, sites which have a short "a" for the exit of ions will become active as the contribution of the field (qaE) increases. The effect is, therefore, that p is expected to increase with the field strength so that "overshoot" will occur and in addition, changes in "a" and W with field strength are to be expected. The experimental observation of these features may need no further explanation than the fact that the oxide is amorphous. However, another source of variation in "a" with field strength is due to the obvious but never-mentioned fact that jumps occur in a cone of solid angle along the field direction. This cone will open as the field increases. The expectation that n and "a" change instantaneously with field strength seems to invalidate Vermilyea's method of obtaining "a" by transient studies (18), in which "a" is assumed to be independent of field strength.

Both Ions Mobile

It appears fairly certain that for the usual experimental conditions most of the current is carried through the films on tantalum and niobium by metal ions (19, 20). However, this does not exclude the occurrence of a slight mobility of oxygen ions, and this could be important because it provides another mechanism causing the concentration of negative ions (and hence p) to vary sluggishly with the field strength.

The steady-state condition is discussed first.

It is assumed that the oxygen ion current may be described by an equation of the same form as that which is used to describe the metal ion current. The limitations in this assumption have already been discussed. The subscripts + and − refer to metal and to oxygen ions, respectively. The current is now given as a charge flow rather than as ion flow:

$$i_+ = q_+ 2a_+n_+\nu_+ \exp(-W_+/kT) \exp \beta_+E,$$

where

[12] $$\beta_+ = q_+a_+/kT,$$

and similarly (with i_- and q_- as positive quantities)

[13] $$\begin{aligned} i_- &= q_- 2a_-n_-\nu_- \exp(-W_-/kT) \exp \beta_-E, \\ &= q_+ 2a_-p\nu_- \exp(-W_-/kT) \exp \beta_-E. \end{aligned}$$

As before, Poisson's equation gives

[14] $$\partial E/\partial x = 4\pi\, q_+(n-p)/\epsilon.$$

In the steady state, the continuity equation becomes

[15] $$(\partial i_+/\partial x) = (\partial i_-/\partial x) = 0.$$

Hence from [12] to [15],

[16] $$n_+ = n_+{}^0 \exp -\beta_+(E-E^0)$$

and

[17] $$p = p^0 \exp -\beta_-(E-E^0),$$

where n^0, p^0, and E^0 refer to values at $x = 0$.
From [14], [16], and [17]

[18] $$x = \int_0^x dE/\{(4\pi\, q/\epsilon)(n_+{}^0 \exp -\beta_+(E-E^0) - p \exp -\beta_-(E-E^0)\}.$$

Since $q_+ = 5e$ and $q_- = 2e$ it is probable that for tantalum $\beta_+ > \beta_-$. Hence, if the space charge near the metal is negative, so that E decreases with increasing x, both n_+ and n_- will increase with x, but n_+ will increase more rapidly, so that eventually the space charge must fall to zero. Conversely, if the space charge is initially positive, then the field at first increases, both n_+ and n_- decrease with distance but n_+ decreases more than n_- so that the space charge eventually becomes very small. Thus for large x we have n_+, n_-, and the field strength all constant. The model behaves essentially the same as that with p constant throughout the film. The difference is that p is determined by the field strength in the outer part of the oxide, since this field strength determines the rate of entry of negative ions into the oxide, and their rate of movement through the oxide.

The reaction at the oxide/solution interface by which O″ enters the oxide must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

essentially $H_2O = O''(\text{oxide}) + 2H^+$. The experimental data for tantalum show (1) that the kinetics are independent of the pH and of the electrolyte in dilute aqueous solutions, but (2) that the kinetics are affected by a variation of composition large enough to vary the activity of the H_2O species.

The entry of O'' may be described using equations similar in form to those used to describe the entry of metal ions at the other interface:

$$\begin{aligned} i_-(D) &= q_- m_l \nu_l \exp(-W_l/kT) \exp \beta_l E \\ &= q_- 2a_- n_-(D)\ \nu_- \exp(-W_-/kT) \exp \beta_-/kT, \end{aligned}$$

in which D = thickness of oxide, the subscript l refers to the oxide/solution boundary, and the field across the oxide/solution boundary is put equal to the field just inside the oxide. Hence,

$$n_-(D) = \frac{m_l \nu_l}{2a_- \nu_-} \exp\left(\frac{W_- - W_l}{kT}\right) \exp\left(\frac{Eq_-(a_l - a_-}{kT}\right).$$

The measured current is nearly equal to the metal ion current from equation [12] with n_+ put equal to $p(D)$.

$$i_+ = q_- 2a_+ \nu_+ \left(\frac{m_l \nu_l}{2a_- \nu_-}\right) \exp\left(\frac{W_- - W_l - W_+}{kT}\right) \exp E(\beta_+ + \beta_l - \beta_-).$$

This model has the peculiar characteristic that the kinetics are controlled by the metal/oxide interface when the film is very thin and space charge effects are negligible, and by migration through the oxide (with the concentration of mobile ions controlled by the oxide/solution interface) when the film is thick enough for space charge effects to have isolated the bulk of the film from the effects of the metal/oxide interface.

The mathematics of the non-steady state are complex, and only a qualitative discussion will be attempted.

The concentration of oxygen ions will either increase or decrease with increasing $E(D)$ according to whether β_l is greater or smaller than β_-. The first case will be assumed. Since it is assumed that the metal ions are far more mobile than oxygen ions, the metal ion distribution at each stage will be nearly in the steady-state condition appropriate to the instantaneous distribution of negatively charged ions. Suppose that after the system has come to a steady state at an applied current $I_1 \simeq i_+$, the current is suddenly increased to a new value I_2. The average field will first rise to a new value given by equation [11] with almost the same value of p as existed before I was increased. The process is that of charging a condenser with a leakage given by $i = i_0 \exp \beta E$, where $E \simeq V/D$. If V = voltage across the condenser of capacity C,

$$I(t) = CdV/dt + i_0 \exp(\beta V/D),$$

where $$I(t) = I_1 \text{ for } t \leqslant 0 \text{ and } I = I_2 \text{ for } t > 0,$$

we obtain $$I_2 t = (DC/\beta) \log\{(1 - I_2/I_1)/[1 - I_2/i_0 \exp(\beta V/D)]\}.$$

The time t for the condenser to charge up to a given fraction of its final charge is inversely proportional to the current density and independent of D.

As the field in the oxide increases, the rate of entry of oxygen ions also increases. As the concentration of oxygen ions builds up the field decreases and levels out at the new steady-state value. The decay of the overshoot should depend on the thickness of oxide, since the decay involves the movement across the oxide of something in the nature of a step function

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in the concentration of both ions, and the velocity of movement will tend to be independent of thickness. According to Dewald (12), with tantalum the decay does not depend on the thickness, so that the above model would appear (if our qualitative treatment is correct) not to apply to this metal.

Structural Effects at the Metal/Oxide Interface

Each time that a metal ion leaves the metal to enter the oxide it leaves a vacancy in the metal lattice and some degree of local misfit. This may cause the outer two or three layers of metal to become effectively amorphous. The effect will depend on the current density, since the diffusion within the metal surface will tend to repair the damage. The degree of directional bonding within the metal, and the presence of impurities will also affect this process. When the disarrangement is present, it will tend to remove the differences between the kinetics on different crystal faces that might be expected when the Cabrera–Mott theory applies.

SUMMARY

A great many different special cases are possible—movement by metal or oxygen, vacancies or interstitial ions, creation of defects by the field, interfacial barriers important or not important according to the relative values of various parameters, and so on. A few essential principles may, however, be formulated. In the first place, for metal ion movement the metal/oxide interface will control the kinetics unless sufficient space charge can accumulate near this interface to permit the field strength at the boundary to differ appreciably from the field strength further into the oxide. If the interface is, so to speak, isolated by space charge effects, the concentration of carriers in the main body of the film is controlled by whatever determines the net space charge density due to the non-mobile species. The field production of Frenkel defects, the movement of oxygen ions, and the range of sites due to the amorphous nature of the oxide could cause this background charge to vary with the field strength. When the background charge varies with the field strength, it becomes possible to have "overshoot" in the field transients. Variation of jump distance and hence of Tafel slope with field strength may be due to the variation of sites to be expected in an amorphous oxide, and to the fact that jumps occur at greater angles to the field direction as the field strength increases.

THE FORMATION AND PROPERTIES OF PASSIVE FILMS ON IRON[1]

MORRIS COHEN

ABSTRACT

A unified mechanism for the formation of passive films on iron in aqueous solutions is presented. The effects of water, oxygen, and oxidizing and non-oxidizing ions are considered. The γ-Fe_2O_3 film is formed first by the oxidation of water-formed magnetite and further thickening of the film takes place by the oxidation of diffusing Fe^{++} ion at the water surface of the oxide film. The main force leading to diffusion is the field set up by the adsorbed negative ion and the positive Fe^{++} ions at the surface of the metal. Some of the properties of the protective γ-Fe_2O_3 film and factors leading to its destruction are discussed.

When iron is exposed to aqueous solutions containing certain oxidizing ions such as chromate or nitrite, or buffering agents and oxygen, it becomes passive. Electron diffraction measurements and film stripping experiments indicate that the iron is covered by a thin film, composed mainly of γ-Fe_2O_3 (1, 2).

Although much has been published concerning the behavior and possible physical and chemical structure of these passive films on iron (3, 4, 5), very little data has been presented or possible mechanisms proposed to account for the formation of the films.

Since the behavior of passive films on iron is much the same, independent of the solution in which they are formed, there is probably a common general mechanism of formation. In this paper such a mechanism for the formation process and composition of passive films is developed and used to explain the build-up and break-down of the films.

1. Reactions of Iron with Water

(a) In the Absence of Oxygen

This reaction has been reviewed recently by V. J. Linnenbom (6). At room temperature he found evidence for ferrous hydroxide only. At higher temperatures some Fe_3O_4 was also found. In earlier work Schikorr (7) reports that $Fe(OH)_2$ converted slowly to magnetite at room temperature but this was not confirmed by Linnenbom. It is thermodynamically possible for iron to react with water to form either $Fe(OH)_2$ or Fe_3O_4.

When film-free iron is exposed to water, in all probability a film is formed which separates the iron from the water. If this film is formed by a heterogeneous reaction between the iron and the water then the composition of the film will probably approximate that of an anhydrous oxide. FeO is not stable below a temperature of 500° C, so that the most likely film is Fe_3O_4. This persists as a very thin film and the iron remains bright and silvery in appearance.

The rate of reaction of iron with oxygen-free water is very slow, of the order of 20 $\mu g/cm^2$ in 5 days (3). This rate is about the same in the presence of chloride ion. The reaction rate corresponds to the reaction of 56 Å of metal/day or a current of $2\times10^{-1}/\mu a\ cm^2$. The potential of the specimen, which corresponds to the equilibrium potential of iron in a saturated solution of $Fe(OH)_2$, indicates high hydrogen polarization. The mechanism of the reaction is probably that of diffusion of both Fe^{++} and electrons through a thin magnetite film of the order of 1 or 2 unit cells (8–16 Å) thick with the

[1]*Manuscript received July 10, 1958.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.
Issued as N.R.C. No. 4982.

rate of the reaction being controlled by the rate of formation of hydrogen. The very thin film of magnetite acts as a separator rather than a diffusion barrier and is stabilized by being in contact with the metal.

The reactions can be expressed as:

$$Fe \longrightarrow Fe^{++} + 2e,$$

$$\frac{2e + 2H_2O \longrightarrow 2OH^- + H_2}{Fe + 2H_2O \longrightarrow Fe(OH)_2 + H_2}.$$

The rapidly formed magnetite film is formed by the reaction:

$$3Fe + 4H_2O \longrightarrow Fe_3O_4 + 4H_2.$$

The magnetite thickens and becomes visible at higher temperatures or by the addition of certain other chemicals—that is when the rate of the reaction of $Fe^{++} \longrightarrow Fe_3O_4$ in contrast to $Fe^{++} \longrightarrow Fe^{++}$ hydrated is increased.

A diagram of the reactions of iron in oxygen-free water is shown in Fig. 1.

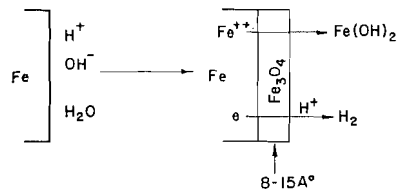

FIG. 1. Development of steady-state corrosion of iron in water. A thin film of magnetite is formed by direct reaction with water. Reaction continues by diffusion of ferrous ion into the solution and hydrogen formation.

(b) Absence of Oxygen but Presence of Oxidizing Anions

Four oxidizing ions—namely nitrite, chromate, molybdate, and tungstate—have been found to form films on iron in oxygen-free water. Of these, chromate forms a passive film at the lowest concentration. This film is of the order of 50–75 Å thick and contains both γ-Fe_2O_3 and Cr_2O_3 (8).

With nitrite solutions, at low concentrations thick films of Fe_3O_4 are formed. When the concentration of nitrite is increased to about 0.1 *N* a thin film of γ-Fe_2O_3, possibly containing some γ-FeO(OH), is formed (1).

Of the four oxidizing inhibitors the strongest oxidizing agent with respect to ferrous ion in neutral solution is chromate. The others react relatively slowly. All four inhibitors are poor cathodic depolarizers: nitrite ion is not reduced when exposed to cathodically polarized iron, while the reaction rate of iron with water, which is controlled by cathodic depolarization, is the same irrespective of the presence of low concentrations of molybdate and tungstate (3).

As in the presence of water alone, the instantaneous surface reaction of film-free iron is a heterogeneous one to form Fe_3O_4. Adsorption of the oxidizing anions on the films during the formation of the film leads to further oxidation to γ-Fe_2O_3. In the case of the chromate ion, where the reduction product is insoluble Cr_2O_3, this leads to the build-up of a film containing both Cr_2O_3 and γ-Fe_2O_3 in a ratio of about 1:3. The amount of chromium found in the film would correspond to a film about 50–75 Å thick (8).

In the case of nitrite the reduction products are soluble and at sufficiently high concentrations a film consisting mainly of γ-Fe_2O_3 is formed. At low concentrations (0.001 *N*) magnetite films of sufficient thickness to be visible are formed (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

With molybdate and tungstate visible magnetite films are also formed. However, if the iron is made anodic, γ-Fe_2O_3 films of a protective nature are formed. This may be due to an increase in oxidation rate by the discharge of hydroxyl ion to form oxygen and/or discharge of the anions at the metal oxide – solution interface.

This order of efficiency of the formation of passive films is probably related to the oxidizing power of the anions with respect to the oxidation of Fe^{++} to Fe^{+++}. The reaction of chromate ion with ferrous ion is very rapid, while that of nitrite, molybdate, and tungstate is relatively slow.

The γ-Fe_2O_3 which forms the main part of all the passive films is formed as the film grows. The first formed unit cell of Fe_3O_4 is oxidized to γ-Fe_2O_3 and further diffusion of Fe^{++} takes place through this γ-Fe_2O_3 film. The ferrous ion which reaches the oxide–solution interface is oxidized to ferric ion by the adsorbed oxidizing agent, thus leading to further thickening of the film. Although there is no direct contact between the iron and the solution the iron is oxidized to Fe^{++} by water in that the electrons are neutralized by H^+. The main force responsible for the diffusion of Fe^{++} through the γ-Fe_2O_3 is supplied by the electrostatic attraction between the adsorbed negative anion and positive metal ions in the lattice. This force is sufficient to allow a film of about 50–75 Å thick to form. The geometry of these reactions is shown in Fig. 2.

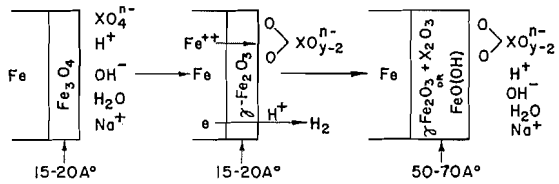

FIG. 2. Conversion of Fe_3O_4 to γ-Fe_2O_3 and further thickening of γ-Fe_2O_3 to form passive film. The attractive force between the anion and Fe^{++} depends on charge and thickness.

If the concentration of the passivating oxidizing agent is too low, oxidation of the ferrous ion takes place to magnetite only and a proportion of ferrous ion escapes into the solution. The magnetite film thickens considerably, probably because the cationic diffusion rate through magnetite is greater than that through γ-Fe_2O_3.

A number of oxidizing anions such as permanganate do not form passive films on iron. This could be due to either the physical nature of the reduction product and/or their ability to depolarize the cathodic reaction. The former is probably the more important in that a gelatinous reduction product interferes with the growth of the protective passive film. Because of depolarization of the hydrogen formation reaction some oxidizing anions may act as corrosion accelerators rather than passivating agents.

(*c*) *Presence of Oxygen*

Iron reacts rapidly with dry oxygen at room temperature to form a film of γ-Fe_2O_3 15–20 Å thick (10). At this thickness the reaction essentially ceases. If iron is exposed to water saturated with oxygen at normal pressures and temperatures the reaction continues at a relatively constant rate, the main products of the reaction being hydrated ferric oxides. If the specimen becomes covered with hydrated reaction product, so that there is a decrease in the oxygen concentration at the oxide–precipitate interface, visible films of magnetite are formed. The corrosion rate is very much higher than the rate in oxygen-free water, being of the order of 1.3 mg/cm^2 5 days or 13 μa/cm^2, or 65 times the rate in oxygen-free water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The initial reaction is the formation of a thin layer of magnetite as in the case of oxygen-free water. This thin layer of magnetite can then be oxidized to γ-Fe_2O_3 by reaction with adsorbed oxygen. At room temperature and pressure the solubility of oxygen in water is only 8 parts per million and owing to incomplete coverage by oxygen both the rate of oxidation to γ-Fe_2O_3 and further thickening of the γ-Fe_2O_3 film is slow. Fe^{++} ions continue to diffuse through the oxide into the solution where they are oxidized by dissolved oxygen to FeO(OH). These hydrated oxides are precipitated on the metal surface and form a diffusion barrier for the movement of oxygen to the metal surface. As in the case of the oxidizing anions, the lowered concentration of oxygen at the metal oxide – solution interface allows further growth of magnetite but does not oxidize the magnetite to γ-Fe_2O_3. The precipitate, being laid down unevenly, will tend to allow the formation of separate anodic and cathodic areas on the surface and the over-all corrosion current is sufficiently high and the pH sufficiently low to cathodically reduce any already formed γ-Fe_2O_3 (11). The above sequence of formation of Fe_3O_4, etc., will then be repeated. As well as oxidizing magnetite to γ-Fe_2O_3 the oxygen can also react with $(e + H^+)$ to form OH^- ions. This both accelerates the rate of corrosion and, at the normally low concentrations of oxygen in the solution, decreases the per cent of the surface area covered by oxygen. This lowered coverage leads to a decreased probability of the formation of a protective γ-Fe_2O_3 film.

At sufficiently high concentrations of oxygen it is possible to obtain protective passive films. This is related to a more rapid replenishment of the cathodically removed oxygen which leads to γ-Fe_2O_3 film growth rather than corrosion. The formation of a protective film thicker than 15–20 Å may be due in part to the field set up by the adsorption of some OH^- ions.

(*d*) *Presence of Oxygen and Oxidizing Ion*

In general the presence of oxygen decreases the concentration of oxidizing anion required to give passivity. Because of the presence of the anion the film still thickens to 50–75 Å. The main function of the oxygen in the case of the nitrite, molybdate, and tungstate is probably the oxidation to γ-Fe_2O_3 of some of the magnetite formed by the oxidation of ferrous ion by the anion.

(*e*) *Presence of Oxygen and Non-oxidizing Buffering Ion*

Iron is passive in air-saturated solutions containing relatively high concentrations of alkaline buffering agents such as Na_2CO_3, Na_3PO_4, and C_6H_5COONa. The passive film is mainly composed of γ-Fe_2O_3 with some hydrated oxide, and in the case of the phosphate, hydrated ferric phosphate (12). Most of the hydrated material appears to be located in rather thick inclusions which protrude above the oxide film (9). The salts would appear to serve two purposes. Firstly adsorption of the negative ion, by increasing the field strength across the oxide, leads to a sufficient thickening of the γ-Fe_2O_3 film formed by the reaction of O_2 with Fe_3O_4 to prevent further diffusion of iron ions. Secondly, where the film has not thickened, so that Fe^{++} ions continue to escape into the solution, the anodic pores are kept on the basic side. This decreases the rate of cathodic reduction and consequent thinning of the adjacent oxide. Since diffusion of ferrous ions through the porous precipitated plug of hydrated material is probably more rapid than through the oxide the plugs grow relatively thick before the reaction stops.

2. Reactions in the Presence of the Air-formed Film

As mentioned above, the air-formed film is γ-Fe_2O_3 of the order of 20 Å thick. In the presence of the passivating agent this film thickens, by the formation of more γ-Fe_2O_3

and possibly other hydrated products. Under borderline passivating conditions some of the film may be removed by cathodic reduction and either new film or plugs are formed in the manner outlined above.

3. Effect of an Applied Current

If the iron is made cathodic the γ-Fe_2O_3 film is reduced. At low cathodic current densities corrosion continues, probably through a layer of magnetite. At higher cathodic currents corrosion essentially ceases, probably with some redeposition of iron.

At low anodic currents the corrosion of iron is increased. At higher current densities passivity is often observed. This can be explained by a combination of the suppression of the cathodic reaction with its possibility of cathodic reduction of the γ-Fe_2O_3 and the direct discharge of oxygen on the metal surface. Because of the high overvoltage for oxygen evolution the equivalent pressure of oxygen at the metal surface is high and conditions for the formation of γ-Fe_2O_3 favorable. Oxidizing ions such as tungstate and molybdate will also be discharged at the anodic areas with a similar effect of apparent increased activity.

4. Properties of the Passive Film

Passive films have been stripped from iron by both chemical (13) and electrochemical (14) dissolution of the underlying metal. They are found to be mainly anhydrous γ-Fe_2O_3. They are chemically inert and dissolve in acid only with difficulty. The hydrated parts of the film are less inert than the anhydrous oxide. The film may be cathodically reduced to Fe^{++} ion which, at neutral and low pH's, is quite soluble. The film is a relatively good electronic conductor but a poor cationic conductor and the growth of the film appears to be controlled by the rate of cationic conduction.

The breakdown of the passive film probably takes place through the breakdown of pores in the anhydrous oxide film. Electron microscope and diffraction studies indicate that most of the passive films have discontinuities in the anhydrous oxide films which contain the less inert hydrated ferric oxides or other insoluble ferric salts. Diffusion of the solution through these rather porous precipitated plugs leads to the formation of acidity in the pores—particularly in the presence of such ions as chloride or sulphate. The ferric salts can be removed by the formation of soluble complexes with many ions. The combination of anodic current and acid conditions leads to undermining or cathodic reduction of the protective γ-Fe_2O_3 film.

It is rather surprising that there is such a large difference in the cationic diffusion properties of magnetite and γ-Fe_2O_3 as indicated by possible thicknesses of the two types of film. It is generally assumed that γ-Fe_2O_3 has essentially the Fe_3O_4 structure with cation vacancies (15). The diffraction patterns of the two oxides are very similar. The two oxides, however, behave quite differently chemically. Fe_3O_4 dissolves in acid very easily, while γ-Fe_2O_3 dissolves only with difficulty. On cathodic reduction γ-Fe_2O_3 is reduced completely to the ferrous state with high current efficiency, while magnetite is reduced with difficulty and very low current efficiency. In some X-ray diffraction studies in this laboratory it has been found that γ-Fe_2O_3 produced in several ways has d-values greater than 6 Å as well as two lines which do not appear in the Fe_3O_4 patterns. This would point to a somewhat different kind of ordered structure and may account for the different chemical and diffusional behaviors of the two oxides. This would also indicate that some recrystallization takes place in the conversion of Fe_3O_4 to γ-Fe_2O_3.

A second factor which may contribute to a difference in the growth rate and hence final thickness of the two oxides could be a difference in the rate of transfer of Fe^{++} ions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

across the metal–oxide interface. This would be partly related to a difference in the crystallographic arrangement of the oxides on the metal. Thin films of Fe_3O_4 show preferred orientation on iron, while γ-Fe_2O_3 films do not. The bulk of evidence shows that γ-Fe_2O_3, the main constituent of the passive film, is an inert material which in passivating solutions grows to a maximum thickness of 50–75 Å.

THE ELECTROCHEMICAL BEHAVIOR OF THE NICKEL – NICKEL OXIDE ELECTRODE

PART I. KINETICS OF SELF-DISCHARGE[1]

B. E. Conway and P. L. Bourgault

ABSTRACT

The nickel – nickel oxide electrode forms the positive plate in the charged nickel–cadmium battery. After "charging" the electrode to a chemical state represented by the non-structural formula NiO_x, where x can vary from about 1.4 to 1.8 depending on the current density and temperature, loss of oxygen and a fall of potential on open circuit occurs. In the present work this "self-discharge" effect has been examined by study of (i) the rate of decay of e.m.f. on open circuit, (ii) rate of oxygen evolution on open circuit, (iii) the electrochemical capacity of the electrode, and (iv) the build-up or charging curves for the electrode. The decay behavior has been studied in aqueous KOH solutions from 0.0015 to 15 *M*. Tafel slopes are obtained from the plots of e.m.f. vs. log (time of decay), and abrupt changes occur at certain electrode potentials which indicate changes of rate-determining mechanism in the self-discharge process. The slopes observed are interpreted in terms of a new scheme of consecutive reactions for anodic oxygen evolution by deducing, by means of the Christiansen method, the relevant Tafel slopes. It is shown that the scheme proposed uniquely accounts for the experimental behavior and that the change of mechanism observed in the self-discharge can only be explained if two consecutive and not alternative processes are involved. The dependence of the rates of self-discharge upon OH^- ion and water activity is deduced and the significance of these results is discussed.

INTRODUCTION

Interest in the behavior of the nickel – nickel oxide electrode arises from its use as the positive plate in the nickel–cadmium and nickel–iron batteries; at the same time, study of the system affords further insight into the fundamental kinetics of anodic processes, which in the case of the nickel system are complex owing to the existence of several possible oxidation states of the metal in corresponding hydrated oxides (1, 2). One of the features of interest is the loss of charge of the nickel oxide electrode when it is left standing in pure alkaline solution on open circuit. The loss of charge is accompanied by oxygen evolution and decay of e.m.f. of the electrode (e.g., measured with respect to the Hg/HgO electrode in the same solution). Hitherto, studies of the kinetics of decay have not been made rigorously and only somewhat arbitrary rate measurements have been obtained (i) by determining the total time required for the e.m.f. of the electrode to decay over about 0.6 v (3), and (ii) by determining the *total* volume of oxygen liberated from an electrode at the end of a period of 13 hours (4). Since it is clear that over the potential range studied (3) more than one process is involved in the decay, because the e.m.f.–time curve passes through an inflection, and since in the oxygen evolution process (4) the rate of oxygen evolution depends on the electrode potential, it must be concluded that the kinetic significance of "rates" measured by these procedures is unclear. Furthermore, the "rates" of self-discharge thus measured by these two procedures are found to be dependent in *opposite* senses upon the KOH or water activities in the solutions used. In the present work we have therefore attempted to make a more rigorous kinetic analysis of the self-discharge process by obtaining the decay of e.m.f. as a function of the theoretically significant *logarithm* of the time of decay, and relating this to the volume of

oxygen evolved, measured frequently during an over-all period of 10^5 to 10^6 seconds. Electrochemical capacities of the electrodes studied are obtained by several different methods involving the kinetics of the decay and charging processes.

EXPERIMENTAL

Electrodes

The electrodes used were similar to those utilized in the nickel–cadmium battery. Porous sintered pure nickel plaques having an average pore size of 1 μ (5) were impregnated under vacuum with a saturated solution of cobalt-free nickel nitrate prepared by recrystallization from A.C.S. analytical reagent grade material. The nickel hydroxide, $Ni(OH)_2$, was then precipitated in the sinter by immersion in 20% aqueous KOH solution purified as described below. The electrodes were then treated cathodically as described previously (6) and then washed in 10 changes of conductance water. The electrodes were finally charged anodically in the experimental solution (see below) until oxygen evolution occurred. The weight of oxide formed in the electrode was determined from the difference of the weights of the dry unimpregnated sinter and the oxide-impregnated one after drying at 80° C; under these conditions the oxide in the sinter is $Ni(OH)_2$. From this weight, the theoretical electrochemical capacity for a given degree of subsequent oxidation can be calculated.

Solutions

Conductance water was redistilled in CO_2-free nitrogen passed through liquid air traps containing charcoal. The steam was passed up a column of hard glass chips heated to 450° C. The water was then condensed into a second distillation vessel from which it was redistilled into a vessel containing solid A.C.S. analytical reagent grade KOH. This vessel was provided with a sintered glass bottom for filtering, and suitable exit and entry tubes for gas and solution. The KOH solution thus prepared was then recrystallized by immersion of the vessel in a refrigerated bath at −20° C; the mother liquor was forced out of the tube leaving crystals of the dihydrate of KOH. Further water was then distilled on to the recrystallized KOH from the second distillation stage. The solution thus obtained was then used to prepare potassium amalgam which was then reacted with more of the redistilled water until a suitable concentration of aqueous KOH was obtained. This solution was then passed into the experimental cell where it was pre-electrolyzed with a nickel anode, purified oxygen being bubbled through the solution. The pre-electrolysis current of 10^{-2} amp per apparent cm^2 was passed for 12 hours between the nickel anode and a charged nickel – nickel oxide electrode as cathode. This procedure was adopted in order that no hydrogen could be evolved cathodically and diffuse subsequently to the experimental charged nickel electrode, which might thereby be depolarized. Experiments were also made, in order to simulate battery conditions, in ordinarily purified solutions, i.e., without KOH regeneration by means of potassium amalgam. These experiments were carried out mainly in the higher range of concentrations of KOH as used in the nickel battery.

Cells

In dilute solutions ($< 0.1\ N$) it was found that use of the usual two-limb cell (7) with reference electrode and Luggin capillary lead to non-uniform charging* of the electrode, owing to asymmetry of the position of the electrode with regard to current

*By "charging" we signify the process of conversion of the initially precipitated $Ni(OH)_2$ to the non-stoichiometric higher hydrated oxide often referred to as nickel peroxide or NiO_2.

lines from the cathode. In order to overcome this difficulty, e.m.f. and oxygen volume measurements were made on electrodes charged in the cell shown in Fig. 1. The apparatus consisted in a central anodic compartment provided with two Hg/HgO reference electrodes and Luggin capillaries. The test electrode was situated at the center of two conical side limbs each communicating with a charged nickel – nickel oxide electrode used as a cathode. The field in which the test electrode was charged was thus relatively uniform, and uniform oxidation on both sides of the electrode was observed to occur. For stronger solutions it was found that an ordinary two-compartment cell with reference electrode and Luggin capillary could be satisfactorily used.

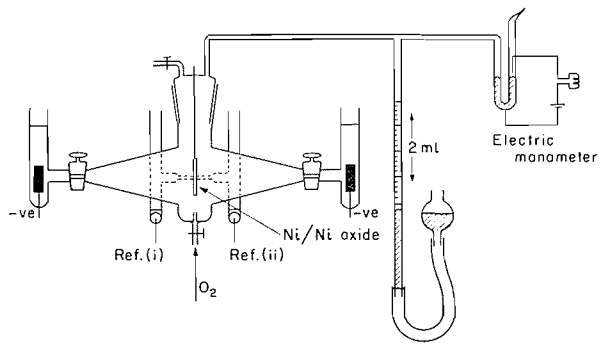

FIG. 1. Uniform field cell for oxygen evolution measurements.

Measurements of Oxygen Evolution

The rates of oxygen evolution on open circuit were measured after termination of charging, by closing off the cathode compartment by means of a stopcock, closing off the oxygen supply used for stirring the solution, and allowing the system to come into communication with a 2-ml gas pipette calibrated in 0.01-ml marks, readable to 0.003 ml and connected to a variable head of mercury. The pipette was also joined to one side of a constant-pressure manometer with an electrical device capable of indicating constancy of pressure to 0.2 mm Hg. Capillary tubing was used between the cell, the pipette, and the manometer in order to minimize dead space, which was about 7 ml; in oxygen volume measurements the cell was filled, within a few milliliters, up to the top of the glass cap. The oxygen volume could be measured to 0.003 ml. The whole apparatus was maintained in an air thermostat at 25° C constant to 0.05° C. The total oxygen volumes measured over periods of 2 to 3 days were from 2 to 5 ml. Volumes above 2 ml were determined as follows: 2 ml were initially collected and measured up to a certain time; the cell was closed off and the mercury brought back up to the zero volume mark, the 2 ml being rejected out of another stopcock. Communication was then remade to the cell and further oxygen collected; the total volume at various times was then calculated. Volumes were corrected to n.t.p. allowing for the vapor pressure of water over the various solutions used (8).

Electrical Measurements

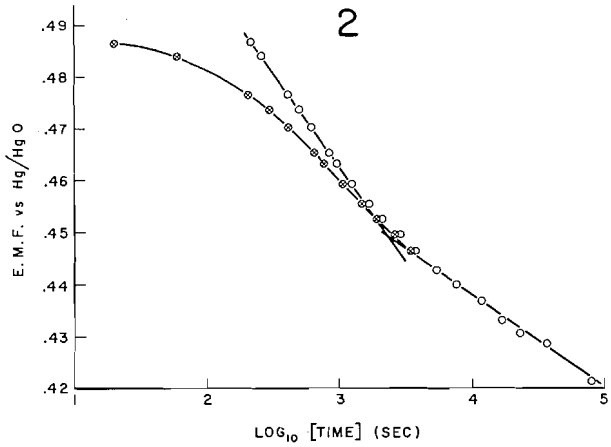
Potential measurements were made by means of a high impedance Doran pH-millivoltmeter and in some cases with a Tinsley potentiometer. Direct-current charging curves were obtained by manual potentiometric measurements and also in some cases by means of a high impedance recording electronic potentiometer. Short period e.m.f. decay curves were obtained by means of a Hewlett–Packard cathode ray oscillograph.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In these measurements in dilute solutions (< 0.01 N), a flow technique was used (flow rates up to 15 ml sec^{-1} past the electrode could be attained in a 2-cm diameter cell) in order to eliminate concentration polarization effects which otherwise influence the open-circuit decay behavior in the most dilute solutions during the first several seconds of decay.

RESULTS

Electromotive force decay curves were obtained at 25° C for the charged nickel – nickel oxide electrode at the following concentrations: 0.0015, 0.015, 0.145, 0.93, 2.9, 7.0, 9.4, and 14.6 M, and are shown in Figs. 2, 4, and 5, where the e.m.f. is plotted (see below) against logarithmic time plus a correction factor θ which is the time required for the electrode to decay from infinite positive potential to the potential at zero time, i.e., at the moment of beginning of the open-circuit decay measurements. Figures 3 and 6 show the corresponding oxygen volume measurements obtained at various times and plotted against the corresponding values of e.m.f. Figure 3 shows the dependence of volume of oxygen evolved in 7.1 M KOH solutions as a function of logarithmic time. At other



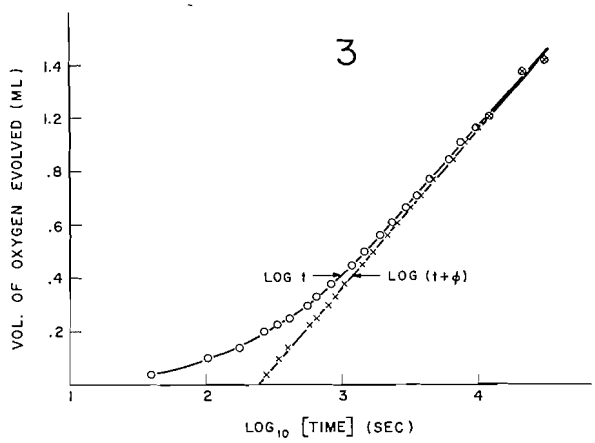


FIG. 2. Typical e.m.f. – log (time) relationship in 0.72 M KOH showing θ correction and corresponding electrode capacity.

FIG. 3. Oxygen evolution as a function of log (time) or log (time $+\phi$) where ϕ is analogous to θ in Fig. 2.

concentrations the oxygen evolution rates follow from the data in the Figs. 4 and 6. The decay curves show two linear regions having different Tafel slopes; the upper region has a slope of 0.039 ± 0.003 whilst that of the lower region is 0.021 ± 0.002. These values closely correspond, at 25° C, with Tafel slopes having values of 2.3 ($2RT/3F$) and 2.3 ($2RT/5F$), respectively, although the lower slope observed could correspond to the value 2.3 $RT/3F$. It is seen that the potential or time at which the change of slope occurs depends markedly upon the concentration of the KOH (Figs. 4, 5). The e.m.f. at the inflection point of the e.m.f. – log (time) lines is shown in Fig. 7 as a function of KOH concentration.

DISCUSSION

The results show that the self-discharge process occurs on open circuit with change of e.m.f. of the electrode and simultaneous evolution of oxygen. The self-discharge must hence proceed by an electrochemical mechanism analogous to that of corrosion, i.e., anodic and cathodic reactions are occurring simultaneously at a mixed potential. Usually either the cathodic or the anodic process is rate-determining and a potential corresponding to the rate of one or other of the processes, whichever is the faster, is set up. We have, therefore, to decide from the observed kinetics: (*a*) whether the anodic or the cathodic type of process is rate-determining and (*b*) having established this, what individual mechanism(s) in the net anodic or cathodic process determines its rate.

For an ordinary metal electrode for which the activation polarization behavior can be represented by the Tafel equation, it follows quite generally (9) that the decay of e.m.f. is logarithmic in the time of decay measured from the moment of cessation of the polarizing current. This relationship holds over wide ranges of time, except at very short times after interrupting the polarizing current or near the reversible potential for the process concerned. It has been shown (10) that the e.m.f., E, depends on the time of decay, t, according to

$$[1] \qquad dE/dt = -\frac{b}{2.303} \Big/ (t+\theta),$$

where b is the slope of the Tafel equation for the rate-determining process in decay and θ is as defined above, assuming a constant double-layer capacity. The integral form of equation [1] is

$$[2] \qquad E = E' - b \log (t+\theta),$$

where E' is the initial potential at $t = 0$ plus $b \log \theta$. E is thus logarithmic in $(t+\theta)$. θ can then be evaluated semiempirically from the e.m.f. – log (time) plots as that value of time which when added to the time, t, gives an initially linear e.m.f. – log $(t+\theta)$ plot, collinear with the relationship directly observed at higher times, e.g., for $t > ca.\ 10\ \theta$. When θ has been evaluated as above, the capacitance C of the double layer at the electrode can be obtained from

$$[3] \qquad \theta = \frac{b}{2.303} C/i,$$

where i is the polarizing current passing at the moment of commencement of the decay.

It may be expected that the decay of e.m.f. of the nickel oxide electrode should be analogous to that for the discharge of the double-layer condenser at a polarized metal electrode, except that the capacitance involved probably has a different origin and order of magnitude. We have therefore plotted the decay of e.m.f. as a function of log t and log

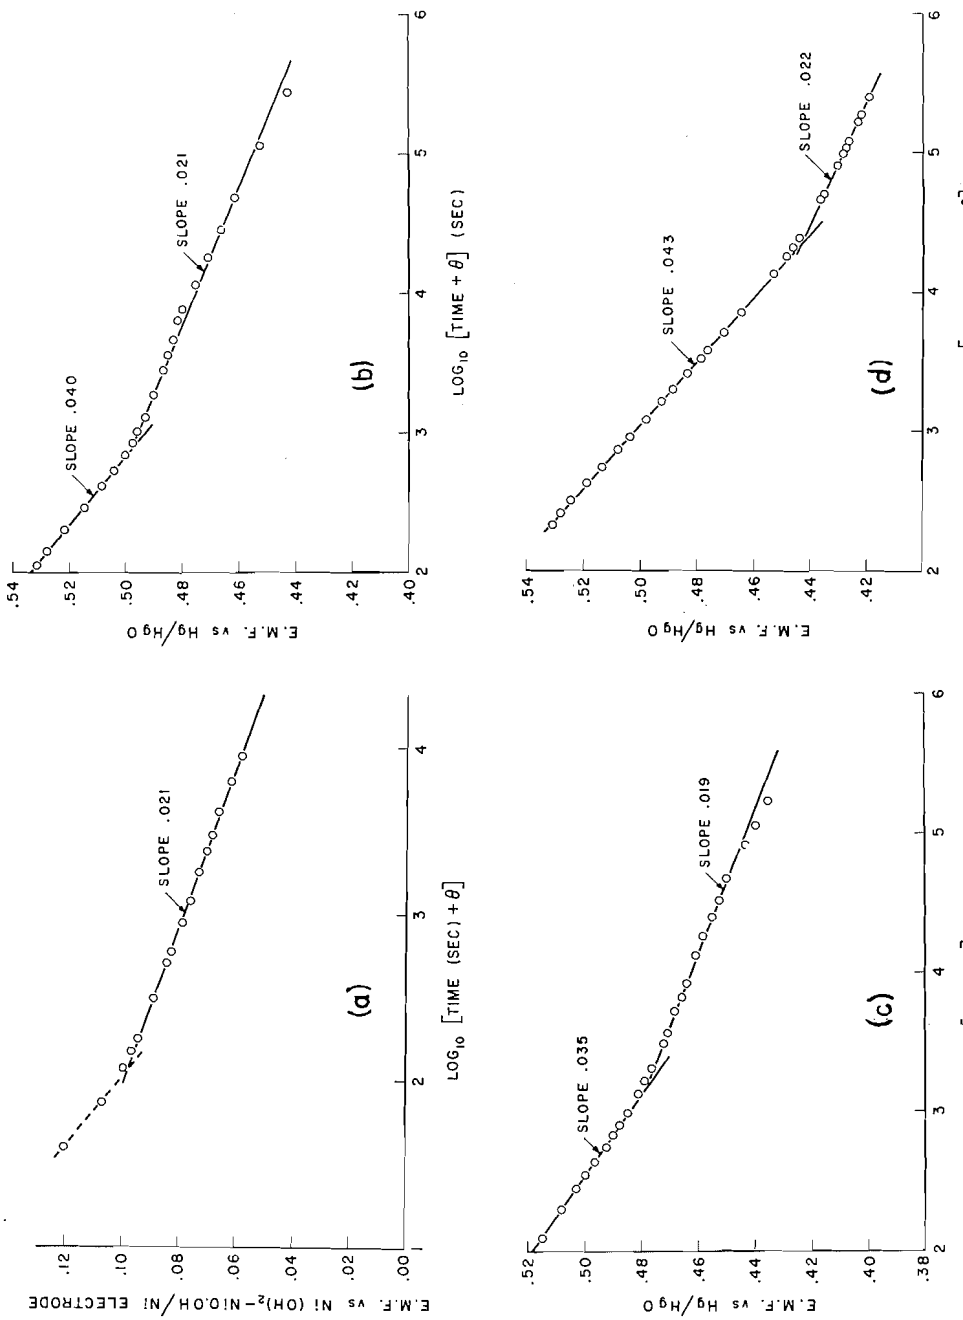

FIG. 4. Electromotive force decay lines at four low KOH concentrations. (*a*) 0.0015 *M*; (*b*) 0.015 *M*; (*c*) 0.145 *M*; (*d*) 0.93 *M*.

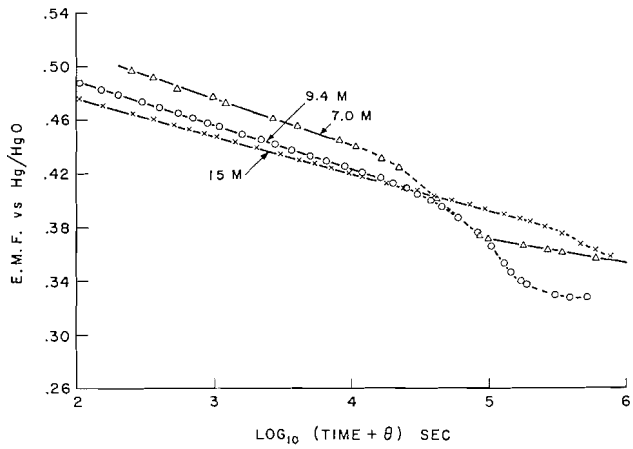

FIG. 5. Electromotive force decay lines at high KOH concentrations.

$(t+\theta)$ in Fig. 2 (see also Figs. 4 and 5) for the electrode in 0.72 M KOH. The plots of log t and log $(t+\theta)$ are identical beyond about $10^{3.4}$ seconds. A unique value of θ exists, which gives the theoretically expected linear behavior; its value for 0.72 M KOH in Fig. 2 is 200 seconds. In this figure it is clear that there are two linear–logarithmic regions and it must be emphasized that in this and other cases (see Fig. 4), no value of θ can be found which gives a *single* straight line for the e.m.f. – log (time) plots except in the one case of the behavior in 15 M KOH solution (Fig. 5). Any arbitrariness in the value of θ derived semiempirically and any consequent uncertainty in the slope of the decay line can be avoided by plotting the e.m.f., E, as a function of log Δt for constant decrements of E during decay intervals Δt. Tafel b values, the same as these calculated semi-empirically, are obtained. (We are indebted to Dr. R. Parsons for this suggestion.) The e.m.f. – log $(t+\theta)$ lines shown in Fig. 4 and Fig. 5, for a wide range of concentrations from 0.0015 to 15 M, indicate a complex behavior in which more than one rate-determining mechanism in the self-discharge is involved. The slopes of the e.m.f. – log (time) line (see Figs. 4 and 5) have the values given in Table I and are characteristic of several steps in processes previously discussed (11) for the anodic evolution of oxygen. The higher slope of 0.038 is also found in direct polarization measurements (12).

The plots of oxygen evolved during decay as a function of e.m.f. shown in Fig. 6 also

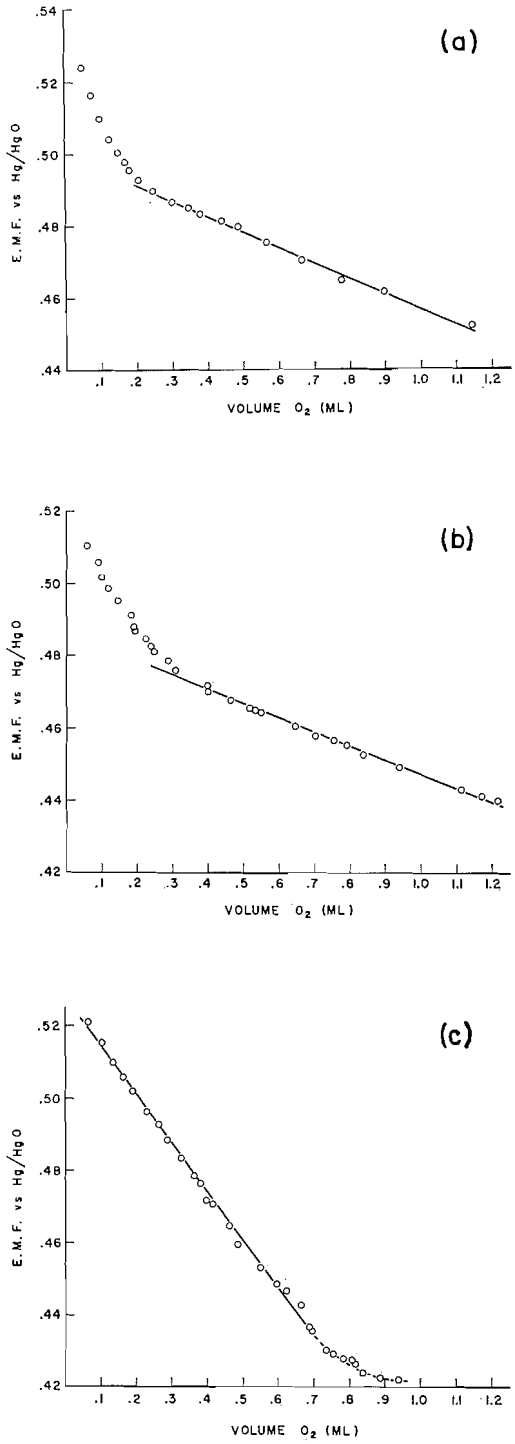

FIG. 6. Volumes of oxygen evolved on open circuit as a function of e.m.f. during decay. (*a*) 0.015 *M* KOH; (*b*) 0.145 *M* KOH; (*c*) 0.93 *M* KOH.

indicate changes of the potential-determining species during the self-discharge process. Thermodynamic investigations of this aspect of the behavior of the electrodes are in progress. It is apparent that both in the e.m.f. decay and in the corresponding oxygen evolution behavior, the process which comes in at later times (or lower e.m.f.'s) is more dependent upon KOH activity than the first process at earlier times. The first process, however, gives Tafel slopes of 0.038 in dilute solution but in the strongest solutions the value changes to 0.029.

Evaluation of Rates of Self-discharge

Comparison of the rates of the two processes at high and low e.m.f.'s can be made if we can obtain a measure of the exchange currents for these processes.

(*i*) *From E.M.F. Decay*

The rate of decay of the e.m.f., E, is given (10) by

$$[4] \qquad dE/dt = -\frac{i_0}{C}10^{\eta/b},$$

where i_0 is the exchange current for the rate-determining process in decay, C is the electrochemical capacity involved, η the oxygen overpotential,* and b the Tafel slope for the decay process obtained from the e.m.f. – log (time) plots. The values of η can be obtained from the values of e.m.f. experimentally measured with respect to the Hg/HgO electrode, since the reversible oxygen electrode is at 0.303 v more positive than the Hg/HgO electrode and its e.m.f. depends upon OH^- ion activity in the same way as does that of the Hg/HgO electrode.

From the logarithmic e.m.f. decay lines (Figs. 4, 5), we can obtain dE/d log (time) $(= -b)$; hence for a time t of decay required for the electrode to reach an overpotential η_t, equation [4] gives

$$[5] \qquad i_0 = -C\frac{dE}{dt}10^{-\eta/b} = \frac{Cb}{2.3t}10^{-\eta_t/b}.$$

The exchange current, and hence rate of self-discharge at any potential, is determined by the reciprocal of the time required to reach a given potential during decay.

From Figs. 4 and 5, values of t for various solutions can be obtained for chosen constant e.m.f. values and i_0 evaluated. The rates of self-discharge measured by $1/t_\eta$, for constant η, are shown in Fig. 8 for the range of concentrations studied and for the upper region of the decay lines. It is clear from Fig. 8 that the process at high positive potentials is much less dependent upon KOH activity than that at low potentials; at long times or low potentials the rate of self-discharge is approximately proportional to $(a_{OH^-})^2$; at shorter times or higher potentials the rate is proportional to a power of a_{OH^-} between $\frac{1}{2}$ and $\frac{1}{3}$.

(*ii*) *From Oxygen Evolution on Self-discharge*

From Figs. 2 and 6, the oxygen evolution rate, dV_{O_2}/dt, can be obtained from the slopes of the oxygen volume – e.m.f. lines and those of the e.m.f. – log (time) lines, since

$$[6] \qquad \frac{dV_{O_2}}{dt} = \left(\frac{dE}{dt}\right)\Big/\left(\frac{dE}{dV_{O_2}}\right) = \frac{1}{2.3t}\cdot\frac{dE}{d\log t}\Big/\frac{dE}{dV_{O_2}},$$

where t is again the time required to reach a given e.m.f. during oxygen evolution resulting from the self-discharge.† dV_{O_2}/dt can now be expressed as the anodic current, i_a, in

*We are here assuming that anodic processes are rate-determining in the self-discharge. That this is so, is indicated by the dependence of the rates upon OH^- and H_2O activity discussed below.

†dV_{O_2}/dt can, of course, be obtained directly by taking tangents to the oxygen volume – time curve; this procedure gives similar results to those obtained by means of equation [6], using appropriate values of the time, t.

self-discharge at the oxygen overpotential η, since $4F$ are required to evolve 22.4 l. of oxygen gas. Since the Tafel slope is found directly from the e.m.f. – log (time) plots, i_0 may readily be evaluated from the value of i_a at any suitable potential. The rates of self-discharge for the upper and lower potential regions may be expressed as current per unit weight of active material ($Ni(OH)_2$) in the electrode. Values thus calculated are also shown in Fig. 8 as a function of KOH activity and for two electrode potentials; the dependence of the rates of self-discharge (from oxygen evolution measurements) upon KOH activity for the two regions is seen to be similar to that calculated for e.m.f. decay rates, as would be expected.

(iii) Values of Exchange Current

From the above considerations, the values of i_0 for the self-discharge process, expressed with respect to unit weight of active material, are then obtained and are given in Table II for unit activity of KOH in solution. Agreement between the values obtained by the two methods is satisfactory and as good as the reproducibility usually obtained in other kinds of electrode–kinetic measurements (13). Owing to the nature of the impregnated electrodes, it is not possible to specify the total real interfacial area exposed to the solution; hence i_0 values cannot be stated in the usual way, i.e., in amperes per square centimeter. An upper estimate may, however, be made of the area available per gram of active material. The electrodes consist of sintered particles having a size of about 1 μ with 80% free space between them (5). If we regard the particles as spherical for the purposes of the calculation of the order of magnitude of the real accessible area, a value of 6000 cm^2 per cm^3 of sinter may be calculated. An electrode plate 3 in. $\times$ 1.0 in. $\times$ 0.04 in. can be impregnated with about 1 g of $Ni(OH)_2$; we can then calculate that there are about 10^4 cm^2 per gram of oxide. i_0 values per cm^2 are then about 10^{-11} and 10^{-13} amp cm^{-2} for the process occurring in the upper and lower potential regions, respectively. The main interest in the present determinations of i_0 and the rates of self-discharge is not their absolute magnitude but their *relative* values, which indicate that the process appearing at lower potentials has a lower electrochemical rate constant than that at higher potentials; the rate of the slower process is also more affected by electrode potential and by OH^- ion concentration than is that of the process occurring at more positive potentials.

TABLE II

Rates of self-discharge (i_0) at the reversible oxygen potential

Method	From e.m.f. decay	From O_2 evolution
Upper potential region	11.8×10^{-8} a.g.$^{-1}$	7.0×10^{-8} a.g.$^{-1}$
Lower potential region	3.5×10^{-10} a.g.$^{-1}$	4.3×10^{-10} a.g.$^{-1}$

Electrode Capacity

The electrochemical capacity involved in the self-discharge processes may be calculated in three ways: (i) from the θ correction in the determination of decay of e.m.f. using equation [3], (ii) from the volume of oxygen evolved as a function of e.m.f., i.e., from dV_{O_2}/dE, and (iii) from studies of d-c. charging on electrodes at which the self-discharge had virtually terminated (i.e. on electrodes still having a degree of oxidation approximately represented by the formula $NiO_{1.5}$). Values of electrode capacity obtained by the various methods are listed in Table III together with the ratios of "active" oxygen to nickel measured from the total charge which can be withdrawn from the electrode through an external circuit. From the active oxygen – nickel ratios in column 3 of Table III it is seen that the electrode is oxidized to the formal state $NiO_{1.57}$ in the strongest solution and to a smaller extent in more dilute solutions. The degrees of oxidation achieved with the present type of electrodes are thus somewhat less than that found by Wynne-Jones *et al.* (2, 3) for oxide films formed directly on nickel electrodes. The capacitance values calculated from θ, and oxygen evolution in the initial part of the decay are comparable as expected, since θ refers to this decay region. At longer times, the lower decay region (Fig. 2) gives higher capacities indicating that a different process

TABLE III

Electrode capacity and charge

(ii) Direct-current charging capacities in column 7 are given for the *initial* build-up of potential. At higher potentials in stronger solutions a more complex behavior is observed (Fig. 9).

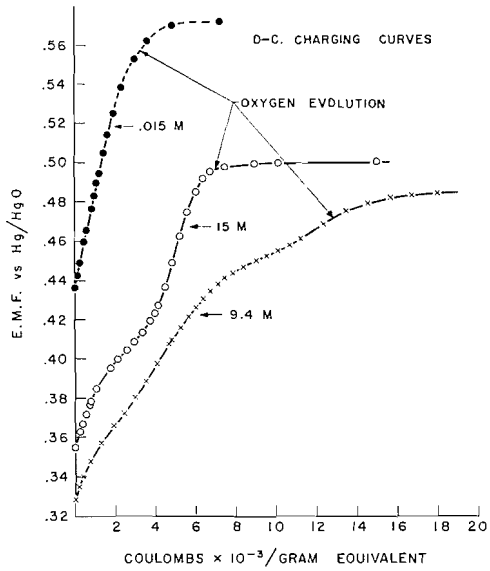

FIG. 9. Direct-current charging curves for the nickel oxide electrode at three KOH concentrations.

is probably involved. The d-c. charging capacities for dilute solutions are recorded for comparison.

Reaction Mechanisms in the Self-discharge Process

The electrode capacities measured under various conditions, including those from the θ constant in e.m.f. decay, are clearly several orders of magnitude too large to be identifiable with the interfacial double-layer capacity of the electrode. However, the kinetics of the discharge process are formally analogous to those observed (9) for decay of e.m.f. of a polarized electrode through discharge of the double-layer condenser. A mechanism must therefore be proposed whereby the active material in the bulk of the electrode can be involved in self-discharge and be electrically accessible to the solution, yet the kinetics of the process can be formally similar to those observed in the discharge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of the double-layer condenser on open circuit. The following general scheme involving a mixed Ni^{III} and Ni^{IV} non-stoichiometric hydrated oxide lattice* (1, 3, 14) meets these requirements:

$$Ni^{4+}.2O^{--}_{(surface)} + OH^- \rightarrow Ni^{4+}.2O^{--}_{(surface)} + OH_{(ads)} + e_{(lattice)} \quad [7]$$

$$Ni^{4+}.2O^{--}_{(surface)} + e_{(lattice)} \xrightarrow{\text{electron transfer}} Ni^{3+}.2O^{--}_{(surface)} \quad [8]$$

$$Ni^{3+}.2O^{--}_{(surface)} + H_2O \xrightarrow{\text{proton transfer}} Ni^{3+}.O^{--}.OH^-. \quad [9]$$

If there is electronic and protonic mobility in the lattice (3), $Ni^{4+}.2O^{--}$ can be regenerated in the surface of the oxide, since we can then write

$$Ni^{3+}.O^{--}.OH^-_{(surface)} + Ni^{4+}.2O^{--}_{(bulk)} \xrightarrow{e,\ H^+} Ni^{4+}.2O^{--}_{(surface)} + Ni^{3+}.O^{--}.OH^-_{(bulk)}. \quad [10]$$

Process [7] can then continue to occur by discharge of OH^- ions in the double layer until all Ni^{4+} is converted to Ni^{3+}; similar self-discharge of the $Ni^{3+}.O^{--}.OH^-$ phase to $Ni^{++}.2OH^-$ could also occur if the potential of the electrode remained positive to that of the reversible oxygen electrode.† Oxygen evolution through process [7] then proceeds by the *over-all* reaction

$$2OH_{(ads)} \longrightarrow H_2O + \tfrac{1}{2}O_2. \quad [11]$$

The rate-determining step in the anodic oxygen evolution process [7] with [11] is discussed below. Processes [8] and [10] involve electron shifts in the lattice and are likely to be very fast. The self-discharge rates are *increased* substantially by increasing KOH activity (Figs. 8, 9); hence process [9] is unlikely to be rate-determining, since with increasing KOH activity from 0 to 15 *M*, the water activity *falls* from unity to about 0.2 (8). Some step in the anodic oxygen evolution process in self-discharge is therefore rate-determining (cf. p. 300).

Rate-determining Steps in the Anodic Process

Two processes are likely to be involved, since two distinct slopes in the decay lines and in the e.m.f. – oxygen evolution plots are found (Figs. 2, 4, 5). These processes could be either consecutive or alternative; the one which is observed at lower electrode potentials has an exchange current of about 4×10^{-10} a.g^{-1} and a Tafel *b* value of about 0.021, whilst the other, observed at higher potentials, has an exchange current of about 9×10^{-8} a.g^{-1} and a Tafel *b* value of about 0.038. Since for two consecutive reactions, the slower determines the rate of the over-all reaction, whilst for two alternative reactions, it is the faster which predominates and hence kinetically characterizes the reaction, it follows from the above values of i_0 and *b* for the two processes concerned that they are *consecutive*. We therefore have to find a scheme of consecutive reactions which give amongst other possible slopes two leading to values of the Tafel *b* constant of 0.038 (2.3 $2RT/3F$) and

The constitution of the highest oxide of nickel is still under dispute (2, 15). It may be a peroxide of Ni^{II}(15) but this is hardly likely in view of the fact that the better characterized compound, β–NiO.OH, is formed as the electrode is charged, the highest state of oxidation being subsequently reached upon "overcharge". The higher oxides appear to be electrically conducting (2) otherwise the oxide electrode in the battery could hardly function in the necessary "reversible" manner. Such electronic conductivity would not be expected in a true peroxide lattice containing only Ni^{II} ions. In other kinds of compound the Ni^{IV} state is known to exist (16, 17).

†*In the studies of Wynne-Jones (3) on the nickel oxide electrode it appears that self-discharge occurred down to a potential of about zero volts with respect to the Hg/HgO electrode, i.e., 0.3 v negative to the oxygen reversible potential. In the present experiments the self-discharge of the electrode never continued below the reversible oxygen potential even after a period of a month. If depolarizers are, however, present, e.g., hydrogen, then further discharge can occur to lower potentials.*

For personal use only.

0.021 (2.3 $RT/3F$ and 2.3 $2RT/5F$ are both close to the experimental value). Inspection of the schemes given by Bockris (11) and Hackerman (18) shows that none gives both slopes in the *same* reaction scheme; but in different schemes (i.e., alternative pathways) processes leading to one or other of these slopes occur (11). We may examine, however, the following consecutive reaction schemes for anodic oxygen evolution, which have not previously been considered:

$$M + OH^- \rightarrow MOH + e, \quad [12]$$

$$MOH + OH^- \rightarrow MO + H_2O + e, \quad [13]$$

$$MO + MOH \rightarrow MHO_2, \quad [14]$$

$$MHO_2 + MOH \rightarrow M + H_2O + O_2; \quad [15]$$

here M signifies the electronically conducting bulk oxide phase rather than the base metal as previously considered (11), since the electrochemical oxygen evolution occurs at the surface of the oxide (19) rather than at that of the metal. The present treatment differs only from previous approaches in that we regard the transient radical species as adsorbed at the oxide–solution interphase rather than at the metal–solution interphase. At the same time, the OH^- ion being discharged may be adsorbed (see 18 and below).

For the series of consecutive reactions [12] to [15], the rates v are given by

$$\begin{aligned}
v_{12} &= k_{12}\, C_{OH^-}(1 - k'\, C_{MOH} - k''\, C_{MO}) e^{\Delta\phi F/2RT},\\
v_{-12} &= k_{-12}\, C_{MOH}\, e^{-\Delta\phi F/2RT},\\
v_{13} &= k_{13}\, C_{MOH}\, C_{OH^-}\, e^{\Delta\phi F/2RT},\\
v_{-13} &= k_{-13}\, C_{MO}\, e^{-\Delta\phi F/2RT},\\
v_{14} &= k_{14}\, C_{MOH}\, C_{MO},\\
v_{-14} &= k_{-14}\, C_{MHO_2},\\
v_{15} &= k_{15}\, C_{MHO_2}\, C_{MOH},
\end{aligned}$$

where C_{OH^-} is the concentration of hydroxyl ions in the double layer and $\Delta\phi$ is the potential difference between the electrode and the outer Helmholtz layer, k' and k'' are constants relating fractional surface coverage by intermediates to their surface concentrations (or activities). The symmetry factor for the charge-transfer steps is taken as 0.5 (cf. 13). In order to obtain the Tafel slopes for various rate-determining steps in the above scheme, we calculate the Christiansen coefficients w for each step as

$$\begin{aligned}
w_{12} &= k_{12}\, C_{OH^-}\, e^{\Delta\phi F/2RT},\\
w_{-12} &= k_{12}k'\, C_{OH^-}\, e^{\Delta\phi F/2RT} + k_{12}k''\, C_{OH^-}{}^2\, K_{13}\, e^{3\Delta\phi F/2RT} + k_{-12}\, e^{-\Delta\phi F/2RT},
\end{aligned}$$

if C_{MOH} and C_{MO} are both appreciable, i.e., if [14] is rate-determining; or as

$$w_{-12} = k_{12}k'\, C_{OH^-}\, e^{\Delta\phi F/2RT} + k_{-12}\, e^{-\Delta\phi F/2RT},$$

if only C_{MOH} is appreciable, i.e., if [13] is rate-determining. K_{13} is the quasi-equilibrium constant for [13] in the steady state if [14] is rate-determining. Other w values are

$$\begin{aligned}
w_{13} &= k_{13}\, C_{OH^-}\, e^{\Delta\phi F/2RT},\\
w_{-13} &= k_{-13}\, e^{-\Delta\phi F/2RT},\\
w_{14} &= k_{14}\, C_{MOH},\\
w_{-14} &= k_{-14},
\end{aligned}$$

and

$$w_{15} = k_{15}\, C_{MOH}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

If step [13] is rate-determining, the over-all velocity is then

$$v = \frac{k_{12}k_{13}\, C_{OH^-}{}^2\, e^{\Delta\phi F/RT}}{k_{12}k'\, C_{OH^-}\, e^{\Delta\phi F/2RT} + k_{-12}\, e^{\Delta\phi F/2RT}},$$

which at relatively low potentials gives

[16] $$v = K_{12}k_{13}\, C_{OH^-}{}^2\, e^{3\Delta\phi F/2RT};$$

and if [14] is rate-determining, and at relatively low potentials

[17] $$v = K_{12}{}^2K_{13}k_{14}\, C_{OH^-}{}^3\, e^{3\Delta\phi F/RT}$$

where K_{13} is the quasi-equilibrium constant for [13] when [14] is rate-determining. Equations [16] and [17] give the Tafel b constants as

$$b_{13} = 2.3\ (2RT/3F) \text{ and } b_{14} = 2.3RT/3F.$$

For [12] as the rate-determining step, b has the usual value of 2.3 $(2RT/F)$. The slopes for the decay in the low potential region could also be close to the value 2.3 $(2RT/5F)$ which differs from 2.3 $RT/3F$ by only 4 mv. The scheme in equations [12] to [15] could be modified by changing process [14] to a charge-transfer reaction as follows:

$$M + OH^- \rightarrow MOH + e, \quad [12]$$

$$MOH + OH^- \rightarrow MO + H_2O + e, \quad [13]$$

$$MO + OH^- \rightarrow MHO_2 + e, \quad [14a]$$

$$MHO_2 + MOH \rightarrow M + H_2O + O_2. \quad [15]$$

The mathematical analysis then gives the Tafel slope for process [14a], if it were rate-determining, as $b = 2.3\ (2RT/5F)$, with b for process [13] still as 2.3 $(2RT/3F)$.

The schemes in equations [12] to [15] through [14] or [14a] are the only ones which can be formulated (cf. 13, 21) in which there are *two consecutive* steps in a single reaction path having Tafel slopes in agreement with those observed in the present work, and from which the correct *sequence* of slopes (viz. 0.038 at higher potentials followed by 0.021 at lower potentials, if [14] becomes rate-determining) can be deduced. The reactions in either of the schemes [12] to [15] hence appear to offer a satisfactory explanation of the experimental results at present available. Distinction between [14] and [14a] as mechanisms for the low potential process must await a rather more accurate determination of the slopes. With decreasing electrode potential on decay, [14] can tend to become slower than [13], and hence rate-determining, since the rate of [14] is more strongly dependent $(e^{3\Delta\phi F/RT})$ on potential than of that of [13].

In very strong solutions the Tafel slope for the high potential process changes towards the value 0.029; this could occur (11, 18) if recombination desorption of adsorbed OH radicals replaced the discharge process indicated in reaction [13].

In the absence of excess electrolyte, e.g., K_2SO_4, not participating in the discharge reaction, all mechanisms should lead to rates independent of activity of OH^- ions (11). In the present work, however, the observed rates of both steps in the self-discharge are increased with increasing KOH activity. This effect probably arises from specific adsorption of OH^- ions on the surface of the polar oxide lattice, as has been indicated in the case of anodic processes at the iron electrode (18).

THERMODYNAMICS OF ADSORPTION IN IONIC SYSTEMS[1]

ROGER PARSONS

1. INTRODUCTION

Recently we have made measurements of the electrocapillary curve of mercury in aqueous solutions of potassium iodide at different temperatures (1). The object of this work was to increase our knowledge of the behavior of specifically adsorbed ions by determining the heat of adsorption. In the interpretation of these results, we drew an analogy between the mercury-solution system and the adsorption of a gas on a condensed phase. This enabled us to use the equations developed by Everett (2) for the calculation of the thermodynamic functions accompanying the adsorption process. A similar analogy has been used by Pethica (3) and his co-workers in considering adsorption of long-chain compounds at the air–solution interphase.

In the present paper we attempt to develop the thermodynamics of interphases between two phases containing charged particles in order to find out to what extent this analogy is justified.

2. THE COMPOSITION TERM IN THE CHARACTERISTIC EQUATION

The total differential of the energy (E) of any phase of c components is given by

$$[1] \qquad dE = TdS - pdV + \sum_{i=1}^{i=c} \mu_i \, dn_i$$

where T, p, S, and V are the temperature, pressure, entropy, and volume of the phase, and n_i is the number of moles of species i whose chemical potential in the phase is μ_i. For a plane interphase the corresponding equation is

$$[2] \qquad dE^\sigma = TdS^\sigma - pdV^\sigma + \gamma dA + \sum_{i=1}^{i=c} \mu_i \, dm_i,$$

where γ is the interfacial tension, A the area of the interphase, and m_i the number of moles of i in the interphase. We regard the interphase as a region of finite thickness comprising all the inhomogeneous region between the two phases (4).

Similar equations may be written for the other thermodynamic potentials, but at present we wish to concentrate attention on their common feature: the term

$$[3] \qquad \sum_{i=1}^{i=c} \mu_i \, dm_i.$$

For an ionic interphase the summation over all components is subject to the restriction that the interphase as a whole must remain electrically neutral. This condition may readily be incorporated in expression [3] so that [2] remains a complete differential. The form of expression [3] then, however, depends upon the nature of the interphase. For a perfectly non-polarizable interphase in which there is chemical equilibrium of one or more ionic species throughout the interphase, we may simply redefine our system in terms of $c-1$ components, each of which is a neutral complex of ions, i.e., a 'salt molecule'.

Thus, in the interphase between a zinc amalgam and an aqueous solution of zinc

[1]*Manuscript received June 29, 1958.*
Contribution from the Department of Physical and Inorganic Chemistry, The University, Bristol, England. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

chloride containing hydrochloric acid, there are six components which may be chosen as: Zn^{++}, Cl^-, H^+, H_2O, Hg^+, and e. For the total differential, we may choose the five $\mu\, dm$ terms corresponding to $ZnCl_2$, HCl, H_2O, Zn, and Hg. The electroneutrality condition is then automatically satisfied. The thermodynamics of such an interphase is then precisely of the same form as that for an interphase consisting of non-ionic components only (5).

On the other hand, this form is not obtained for an interphase in which there is no ionic equilibrium between one side of it and the other, such as in the perfectly polarized electrode. In order to study such an electrode it is necessary to combine it with a second electrode, which for thermodynamic convenience is reversible to one of the ions present in the interphase of the perfectly polarized electrode. The independent components can then be chosen, as before, as 'salt molecules', of which there will be $c-2$, leaving two ionic species, one on either side of the interphase. It is usually convenient to choose electrons as one of these, since one phase is normally a metal. The amount of each of these species in the interphase is then proportional to the charge on either side of the interphase (and may be positive or negative). Thus, we may write

$$z_{c-1}F\, m_{c-1} = Q^\alpha \qquad [4]$$

and

$$z_cF\, m_c = Q^\beta, \qquad [5]$$

where the $(c-1)$th component of valency z_{c-1} is left on the side of the interphase adjoining phase α and the cth on that adjoining phase β. Q^α is the electrical charge on the α side of the interphase and Q^β that on the β side. Since the interphase as a whole is electrically neutral,

$$Q^\alpha + Q^\beta = 0. \qquad [6]$$

Thus, for a perfectly polarized electrode the sum [3] becomes

$$\left(\frac{\bar{\mu}_{c-1}}{z_{c-1}} - \frac{\bar{\mu}_c}{z_c}\right)\frac{dQ^\alpha}{F} + \sum_{i=1}^{i=c-2} \mu_i\, dm_i. \qquad [7]$$

We note, by comparing the expression [3] for perfectly polarized and non-polarized electrodes, that for each the electroneutrality condition results in the loss of one degree of freedom.

It is convenient to express the coefficient of dQ^α in [7] in terms of more readily accessible quantities. It is here that the second electrode plays its part, since (if α is the metallic phase) we can find a relation between $\bar{\mu}_c$ and the electrochemical potential of the electrons in the reversible electrode. In general this coefficient, which we abbreviate as ϵ, is related to the measured e.m.f. E between these two electrodes through a constant K;

$$\left(\frac{\bar{\mu}_{c-1}}{z_{c-1}} - \frac{\bar{\mu}_c}{z_c}\right)\frac{1}{F} = \epsilon = E + K, \qquad [8]$$

where K is a sum of chemical potentials of neutral substances. For example, in the cell

$$\mathrm{Hg'} \mid \underset{(\mathrm{sat})}{\mathrm{Hg_2Cl_2}} \mid \mathrm{BaCl_2,\ HCl,\ H_2O} \mid {}^{\sigma} \mid \mathrm{Hg''} \qquad [9]$$

we have six components in the interphase: Ba^{++}, H^+, Cl^-, H_2O, Hg^+, and e^-. One choice of independent components would be $BaCl_2$, HCl, H_2O, Hg with Cl^-, and e^- regarded as constituting the charge. The constant K in [8] thus becomes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[10] $$K = \frac{\mu_{Hg} - \mu_{HgCl}}{(-1)F}.$$

3. CHARACTERISTIC EQUATIONS

In view of equations 2.7 and 2.8 we can write the analogue of 2.1 for a perfectly polarized electrode as

[1] $$dE^\sigma = TdS^\sigma - PdV^\sigma + \gamma dA + \epsilon dQ^\alpha + \sum_{i=1}^{i=c-2} \mu_i dm_i.$$

From equation [1] we may derive in the usual way complete differentials for the other characteristic thermodynamic potentials H^σ, F^σ, and G^σ. It has been pointed out by Guggenheim and by Everett (2) that, unlike a bulk phase, which has these four characteristic equations, a surface phase has eight. The additional four are defined in terms of the thermodynamic potentials $\mathfrak{E}$, $\mathfrak{H}$, $\mathfrak{F}$, and $\mathfrak{G}$ which are defined by equations such as*

[2] $$\begin{aligned} \mathfrak{E} &= E^\sigma - \gamma A, \\ &\vdots \quad\quad \vdots \\ \mathfrak{G} &= G^\sigma - \gamma A. \end{aligned}$$

The presence of the electrical energy term ϵdQ^α in the characteristic equation for a perfectly polarized electrode means that the number of characteristic equations is doubled again, since we can write equations for the thermodynamic potentials E_e, H_e, F_e, G_e, $\mathfrak{E}_e$, $\mathfrak{H}_e$, $\mathfrak{F}_e$, and $\mathfrak{G}_e$ which are defined by equations such as

[3] $$\begin{aligned} E_e &= E^\sigma - \epsilon Q^\alpha \\ &\vdots \quad\quad \vdots \\ \mathfrak{G}_e &= \mathfrak{G} - \epsilon Q^\alpha. \end{aligned}$$

For example,

[4] $$d\mathfrak{G}_e = -S^\sigma dT + V^\sigma dp - Ad\gamma - Q^\alpha d\epsilon + \sum_{i=1}^{i=c-2} \mu_i dm_i.$$

We may contrast [4] with the characteristic equations for the perfectly non-polarized electrode, since for the latter there is no term in Q^α and ϵ. Consequently, there are only eight characteristic equations which are the same as for a non-ionic interphase. The same is true if we restrict consideration of a perfectly polarized electrode to the condition $Q^\alpha = 0$ (the point of zero charge), since again the Q^α, ϵ term vanishes. This may be regarded as the state of affairs at an air–solution interphase.

4. HEATS OF ADSORPTION

It follows from Section 3 that just as there are four different heats of adsorption for a gas on a solid, there will be eight if the interphase is perfectly polarized. There is, however, a further complication due to the fact that we are necessarily dealing with a system of more than one adsorbed component. In dealing with a one-component system, Everett (2) was able to consider the adsorbed phase as a pure component and effectively to use in place of 3.1

[1] $$dE^\sigma = TdS^\sigma - PdV^\sigma + \gamma dA, \text{ etc.}$$

**To avoid confusion it must be noted that the quantities represented by 'German' capitals without subscripts are the same as those for which Everett (2) used 'Script' capitals.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

From equations of this type, we obtain heats of adsorption in two classes: at constant surface pressure and at constant amount adsorbed. There are no exact analogues for a multicomponent system.

We consider as an example the heat of adsorption related to 4.4. By cross-differentiating, we obtain

$$[2] \qquad \left(\frac{\partial \mu_j}{\partial T}\right)_{m_i,p,\gamma,\epsilon} = -\left(\frac{\partial S}{\partial m_j}\right)_{T,p,\gamma,\epsilon,m_i \neq m_j}.$$

Solving for dS the characteristic equation for $\mathfrak{H}_e$ and differentiating with respect to m_j while keeping T, p, γ, ϵ, and the other m_i constant, we obtain

$$[3] \qquad \left(\frac{\partial S}{\partial m_j}\right)_{T,p,\gamma,\epsilon,m_i \neq m_j} = \frac{1}{T}\left[\left(\frac{\partial \mathfrak{H}_e}{\partial m_j}\right)_{T,p,\gamma,\epsilon,m_i \neq m_j} - \mu_j\right],$$

whence

$$[4] \qquad \left[\frac{\partial(\mu_j/T)}{\partial T}\right]_{m_i,p,\gamma,\epsilon} = -\frac{\bar{\mathfrak{H}}_e}{T^2},$$

where $\bar{\mathfrak{H}}_{e,j} = (\partial \mathfrak{H}_e/\partial m_j)_{T,p,\gamma,\epsilon,m_i \neq m_j}$ is the interfacial partial molar electrochemical heat content of species j. The Clausius–Clapeyron equation is obtained from [4] by subtracting the corresponding equation for j in its standard state in the bulk phase. A complete analysis (which is too lengthy to present here) shows that all the Clausius–Clapeyron equations involve differentiating the chemical potential with respect to temperature at constant surface composition* and so all the corresponding heats are 'isosteric', although they differ according to which of three other pairs of variables are kept constant: (p,V), (γ,A), and (Q,ϵ). It must be emphasized that this conclusion applies to any type of interphase. Thus, it is only when we have a rather complete knowledge of the interfacial composition that we can determine heats of adsorption by means of the Clausius–Clapeyron equations.

5. THE GIBBS–DUHEM EQUATION

We can obtain the interfacial analogue of the Gibbs–Duhem equation from any of the characteristic equations by the usual methods

$$[1] \qquad S^\sigma dT - V^\sigma dp + A d\gamma + Q\alpha d\epsilon + \sum_{i=1}^{i=c-2} m_i d\mu_i = 0.$$

This equation is well known as the basic electrocapillary equation (6). However, there is one feature by which [1] differs from the equation normally employed: the term $Qd\epsilon$. This is usually written with the cell e.m.f. E in place of ϵ. These quantities are related by 2.8 and it is clear that while $d\epsilon$ can be equated to dE at constant temperature (cf. 2.10), this assumption is not correct where temperature variations are to be considered.

It is possible to eliminate two variables from [1] by taking into account the Gibbs–Duhem equations for the adjoining phases. We write these in the form:

$$[2] \qquad d\mu_1 = -\frac{S^\alpha}{n_1^\alpha} dT + \frac{V^\alpha}{n_1^\alpha} dp - \sum_{i \neq 1} \frac{n_i^\alpha}{n_1^\alpha} d\mu_i,$$

$$[3] \qquad d\mu_2 = -\frac{S^\beta}{n_2^\beta} dT + \frac{V^\beta}{n_2^\beta} - \sum_{i \neq 2} \frac{n_i^\beta}{n_2^\beta} d\mu_i,$$

**We have ignored here the effect of the neighboring phases on the number of degrees of freedom in equations like 3.4. For a perfectly polarized electrode this reduces the number of independent composition variables by two.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

and substitute in [1] the values of $d\mu_1$ and $d\mu_2$ the changes in the chemical potentials of the reference substances 1 and 2. If at the same time we divide through equation [1] by the area of the interphase A, we obtain:

$$[4] \qquad sdT-vdp+d\gamma+qd\epsilon+\sum_{i=3}^{i=c-2}\Gamma_i d\mu_i = 0,$$

where

$$[5] \qquad s = \left(S^\sigma-\frac{m_1}{n_1^\alpha}S^\alpha-\frac{m_2}{n_2^\beta}S^\beta\right)\Big/ A,$$

$$[6] \qquad v = \left(V^\sigma-\frac{m_1}{n_1^\alpha}V^\alpha-\frac{m_2}{n_2^\beta}V^\beta\right)\Big/ A,$$

$$[7] \qquad q = Q^\alpha/A,$$

$$[8] \qquad \Gamma_i = \left(m_i-\frac{m_1}{n_1^\alpha}n_i^\alpha\right)\Big/ A,$$

or

$$[9] \qquad \left(m_i-\frac{m_2}{n_2^\beta}n_i^\beta\right)\Big/ A.$$

It is frequently convenient to consider the adsorption of one substance taking as a starting point the system in the absence of this substance at the same T, p, ϵ, and μ_i for other components. If we consider the adsorption of component 3, then for the base system, equation [4] becomes

$$[10] \qquad s^\circ dT-v^\circ dp+d\gamma^\circ+q^\circ d\epsilon+\sum_{i=4}^{i=c-2}\Gamma_i^\circ d\mu_i = 0.$$

Subtracting [4] from [10], we obtain

$$[11] \qquad (s^\circ-s)dT-(v^\circ-v)dp+d\pi+(q^\circ-q)d\epsilon+\sum_{i=4}^{i=c-2}(\Gamma_i^\circ-\Gamma_i)d\mu_i-\Gamma_3 d\mu_3 = 0,$$

where $\pi = \gamma^\circ-\gamma$ is the surface pressure associated with component 3. We can use [11] to calculate the effect of component 3 on various properties of the interphase, e.g.,

$$[12] \qquad (\partial\pi/\partial\mu_3)_{T,p,\epsilon,\mu_i\neq\mu_3} = \Gamma_3,$$

$$[13] \qquad (\partial\pi/\partial T)_{p,\epsilon,\mu_i} = s-s^\circ,$$

$$[14] \qquad (\partial\mu_3/\partial T)_{p,\pi,\epsilon,\mu_i\neq\mu_3} = -(s-s^\circ)/\Gamma_3,$$

etc.

6. CHANGE OF VARIABLE TO ξ

In previous work we have argued that it is useful to consider changes in the composition of the interphase of a perfectly polarized electrode at a constant value of q. For convenience in calculation we have defined a new variable

$$[1] \qquad \xi = \gamma+qE.$$

However, it is evident from the foregoing that when temperature variation is to be considered, a better definition would be

$$[2] \qquad \xi = \gamma+q\epsilon.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Equation 5.4 then becomes

$$[3] \qquad sdT - vdp + d\xi - \epsilon dq + \sum_{i=3}^{i=c-2} \Gamma_i d\mu_i,$$

and the analogue of 4.11, if we consider introducing component 3 to the base system, this time keeping q and not ϵ constant, is

$$[4] \qquad (s^\circ - s)dT - (v^\circ - v)dp + d\Phi + (\epsilon^\circ - \epsilon)dq + \sum_{i=4}^{i=c-2} (\Gamma_i^\circ - \Gamma_i)d\mu_i - \Gamma_3 d\mu_3 = 0,$$

where

$$\Phi = \xi^\circ - \xi.$$

Again we can calculate the effect of component 3 on various properties of the interphase and obtain analogues of 5.12, 5.13, 5.14, etc.

$$[5] \qquad (\partial\Phi/\partial\mu_3)_{T,p,q,\mu_i \neq \mu_3} = \Gamma_3,$$

$$[6] \qquad (\partial\Phi/\partial T)_{p,q,\mu_i} = s - s^\circ,$$

$$[7] \qquad (\partial\mu_3/\partial T)_{p,\Phi,q,\mu_i \neq \mu_3} = -(s - s^\circ)/\Gamma_3.$$

Thus, we find that the same quantities may be calculated by two different routes. It is also evident that there is no advantage in principle in using [4] rather than 5.11, since the same quantities may be obtained from either. However, there may be practical advantages in a particular problem which would lead one to use one equation rather than the other.

It may be remarked here that our previous use of [1] in calculations from electrocapillary curves at different temperatures, which is incorrect in principle, has in fact led to no error because even with temperature varying

$$[8] \qquad E^\circ - E = \epsilon^\circ - \epsilon$$

and we have used equations based on equation [4] in which only $\epsilon^\circ - \epsilon$ appears.

7. APPLICATION TO EXPERIMENT

The systems used up to now consist of an aqueous electrolyte CA in contact either with air (3) or with mercury (1). Provided that the electrolyte has no tendency to hydrolyze so that the effect of the ionization of water may be neglected, the terms under the summation sign in 5.11 and 6.4 vanish. We identify component 3 with the electrolyte CA. Under these conditions 5.14 reduces, for the air–solution interphase to

$$[1] \qquad (\partial\mu_{CA}/\partial T)_{p,\pi} = -(s - s^\circ)/\Gamma_{CA},$$

while 6.7 for the mercury–solution interphase becomes

$$[2] \qquad (\partial\mu_{CA}/\partial T)_{p,\Phi,q} = -(s - s^\circ)/\Gamma_{CA}.$$

[1] and [2] are identical if $q = 0$, so that we need only consider [2]. The so-called integral or isotensile heats of adsorption, which have been obtained for these interphases, have been calculated from the expression

$$[3] \qquad \left[\frac{\partial(\mu_{CA} - \mu_{CA}^\circ)/T}{\partial T}\right]_{p,\Phi,q} = -\frac{\Delta h}{T^2}$$

where μ_{CA}° is the standard chemical potential of CA and

$$[4] \qquad \Delta h = h - H_{CA}^\circ.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

H_{CA}° is the heat content of CA in its standard state. Since it is well known that

$$[5] \qquad \left[\frac{\partial(\mu_{CA}^{\circ}/T)}{T}\right]_p = -\frac{H_{CA}^{\circ}}{T^2}$$

we need only investigate the meaning of the remaining part of [3] involving μ_{CA} and h. From [2] it follows that

$$[6] \qquad \left[\frac{\partial(\mu_{CA}/T)}{\partial T}\right]_{p,\Phi,q} = -\frac{1}{T^2}\left\{\frac{T(s-s^{\circ})}{\Gamma_{CA}}+\mu_{CA}\right\} = -\frac{h}{T^2}.$$

It is evident from [6] that h is none of the thermodynamic potentials defined above. Therefore, in general, the heat of adsorption obtained from [3] has no simple significance. However, if it is assumed that the change in the interfacial entropy when CA is adsorbed can be ascribed entirely to CA and also that it is a linear function of the amount adsorbed, then we can put

$$[7] \qquad \frac{s-s^{\circ}}{\Gamma_{CA}} = \left(\frac{\partial S\sigma}{\partial m_{CA}}\right)_{T,p},$$

and

$$[8] \qquad h = \bar{H}\sigma = \bar{\mathfrak{H}} = \bar{H}_e = \bar{\mathfrak{H}}_e,$$

i.e., the distinction between the various partial heat contents of the adsorbed phase vanishes. Thus, under these rather specialized conditions Δh has a satisfactory interpretation in terms of the change of a thermodynamic potential. For other conditions it would seem preferable to calculate the change in entropy of the interphase from 5.7 or 6.6 first, before attempting an interpretation in terms of a model.

On the other hand the isosteric heat of adsorption can be calculated from the rate of change of chemical potential with respect to temperature, if as well as the surface composition, one of each of the conjugate pairs of variables (γ,A), (q,ϵ) is kept constant (cf. 4.4). These conditions can be attained in practice, but if the surface concentration is obtained from interfacial tension measurements it is difficult to obtain accurate results.

Results of measurements of the Hg/KI(aq) system have previously been presented (1) in the form of curves of $-\Delta h$ and $[(s-s^{\circ})-\bar{S}_{KI}^{\circ}]/\Gamma_{KI}$ against Γ_{KI}, although they were originally interpreted as isotensile heat and differential entropy curves. At higher coverages it was found that the entropy was approximately independent of coverage. In this region, it follows from the above that the heats of adsorption are simply differences of heat content in the two states. At lower coverages the interpretation is more complex; consequently, it appears that no thermodynamic error has been made in the discussion of these results except at the low coverages.

A further important result of the above analysis is that the thermodynamic quantities, in particular the entropy, can be calculated for any point on the electrocapillary curve, whereas the previous method was in practice limited to the region of a negative charge on the mercury surface. We hope to present some of these results for specifically adsorbed systems in the near future.

THE ADSORPTION OF METHYLENE BLUE ON A POSITIVELY CHARGED MERCURY SURFACE[1]

J. M. Los and C. K. Tompkins

ABSTRACT

Direct measurement of the surface concentration Γ of methylene blue, adsorbed from a phosphate buffer solution onto an ideally polarized mercury electrode, has produced a Langmuir-type isotherm. The maximum value of Γ, Γ_m, was found to be dependent on the potential applied (E). Surface tension measurements showed that the rate-controlling process is not diffusion, but, presumably, the exchange of methylene blue cation (MB^+) with phosphate ions. A model for this process has been proposed. This allowed the calculation of the rate constant of adsorption (k_a) from the surface tension values as a function of time ($k_a \sim 5\times10^{-5}$ cm/sec; $dk_a/dE \sim 30\times10^{-5}$). There is some evidence for the occurrence of a consecutive process, most likely the combination of adsorbed MB^+ to dimers.

INTRODUCTION

It is well known that the presence of organic substances that will adsorb on mercury may change the characteristics of polarographic current–voltage waves of depolarizers. Even "reversible" waves can be affected. Much less is known about the effect on half-wave potential and limiting current that inorganic ions, mostly anions, may have. This problem should become interesting when the depolarizer is a big organic molecule, if it has to occupy a relatively large area of the electrode surface before electron transfer can take place. Alternatively, no adsorption of the compound may be needed for the latter, if only the electrons could be transferred by way of the Helmholtz part of the double layer. It is, therefore, of interest to find a compound which adsorbs more slowly than is required for reversibility (the rate constant of the electrode reaction at the latter's standard potential must be at least 10^{-2} cm sec^{-1} (1)). The experimental correlation between adsorption and reduction should thus enable one to decide upon the above-mentioned question of the mode of electron transfer.

The present paper will be concerned with an approach to this problem, namely a study of the kinetic parameters of adsorption of the compound methylene blue (MB^+Cl^-) on an ideally polarized mercury electrode, the solution being buffered by phosphate ($C_{HPO_4^=} = 0.05$; $C_{H_2PO_4^-} = 0.05$ moles/liter; pH is about 7).

The range of potentials available for ideal polarization is rather narrow. A polarogram shows that this range lies between anodic mercury dissolution, starting at +0.2 v (due to insolubility of Hg_2HPO_4, not of Hg_2Cl_2) and methylene blue reduction ($E_{\frac{1}{2}} \sim -0.2$ v; actually there is a small prewave, which, according to Brdicka (2), is due to the strong adsorption of reduced or leuco methylene blue). It was desirable to do measurements at more than one potential. The work presented here was done at −0.024 and +0.076 v (with respect to S.C.E.), i.e., 0.1 v apart.

MEASUREMENTS

Two types of measurements were performed, at 25° C.

(*1*) *Direct measurement of the surface concentration (excess) of methylene blue.*—This was achieved by means of an apparatus based on the principle of allowing the surface of many successive mercury drops at constant potential, to come to equilibrium with the

[1]*Manuscript received July 10, 1958.*
Contribution from the Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick. This paper was presented at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958.

surrounding methylene blue solution before the drops are dislodged and separated from the solution (together with their adhering double layer). Finally all unite and reject their skins of solution into a common pool. The concentration difference between this collected solution and the original one is then directly related to the actual surface excess. Although the essential features of this apparatus have been described previously (3), a few additional remarks need to be made concerning its operation (see Experimental Section).

(*2*) *Measurements of the surface tension by the drop-weight method, as a function of time, potential, and concentration.*—Craxford and McKay (4) have shown that this method yields values as precise as the capillary electrometer. Surface tension and surface concentration are, of course, related to each other by the Gibbs adsorption equation,

$$[1] \qquad d\gamma = -\sum_i \Gamma_i d\mu_i^{\alpha} - qdE,$$

where α is the solution phase. This equation may only be applied if equilibrium has been attained.

RESULTS

The experimental points of Fig. 1, which shows the results of the surface concentration (Γ) measurements, bear out that we have a Langmuir-type isotherm. Each point is an average of three to six measurements. This number was taken in order to test for differences with change in radius of the mercury drops, curvature of the solution–nitrogen interface, and drop time. Values of the latter around 3.6, 25, and 50 seconds were usually taken. Taking into account that the average deviation of a single measurement from the mean value was about 3–5%, no dependence on drop radius and interface curvature could be established. Apparently, at the lowest concentrations ($c \sim 10^{-8}$ moles/cm^3) the influence of the drop time has made itself felt (see Fig. 1). These particular points have, therefore, not been included in the least-square evaluation of the straight line.

Results of the surface tension (γ) measurements have been given as γ vs. t plots for five different concentrations in Fig. 2A (for -0.024 v) and Fig. 3A (for $+0.076$ v).

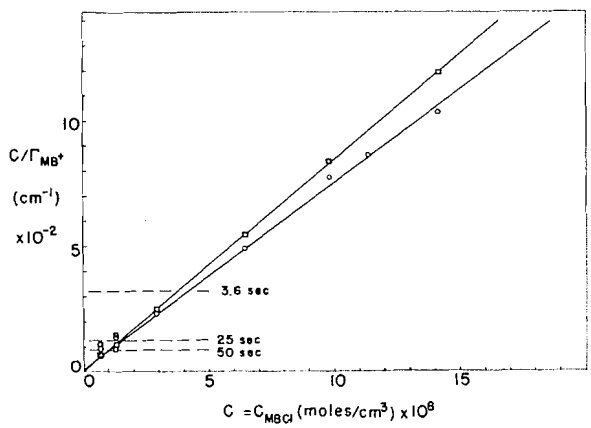

FIG. 1. The constants of the lines $c/\Gamma = a + bc$ are:
Lower line at -0.024 v: $b = (7.40 \pm 0.11) \times 10^9$ cm^2/mole; $a = 10 \pm 9$ cm^{-1}.
Upper line at $+0.076$ v: $b = (8.37 \pm 0.03) \times 10^9$ cm^2/mole; $a = 5 \pm 2$ cm^{-1}.
(Deviations are probable errors.) For broken lines see text.

DISCUSSION

Surface Concentration Measurements

At first glance (Fig. 1) these measurements seem to provide ample proof that equilibrium with the solution has been approached quite closely, except for the low concentration points with drop time around 3.6 seconds. Since the c/Γ vs. c lines go nearly through the origin (according to the surface tension measurements even more so than indicated by the intercept (a) values in the caption to Fig. 1), the isotherm must have a very steep ascending branch and for all concentrations measured Γ_e should be closely equal to Γ_m (Γ_e is the equilibrium value, Γ_m is the maximum value of the surface concentration). This means that the minimum time necessary to reach equilibrium may be calculated from the Ilkovic equation (5),

$$\Gamma_t = \frac{6}{7}(7/3)^{\frac{1}{2}}(D^{\frac{1}{2}}t^{\frac{1}{2}}/\pi^{\frac{1}{2}})c\ , \qquad [2]$$

where Γ_t is the maximum possible surface concentration at time t and D is the diffusion coefficient, here taken as 5×10^{-6} cm^2 sec^{-1}. The c/Γ_t values calculated from equation [2] for the drop times 3.6, 25, and 50 seconds, respectively, have been indicated in Fig. 1 by three horizontal broken lines. Measured points could not have reached equilibrium within 3.6, etc., seconds if they should fall below the corresponding line, and the reverse of this statement is approximately true as well. Whereas the low concentration points *included* in the calculation of the line had been taken at drop times 25 or 50 seconds, the corresponding 3.6-second points should have been at the level of the upper line. Of course, stirring of the solution by the falling drop invalidates equation [2] and speeds up the diffusion process. Such points, however, are of no value, since the potential of a falling drop changes rapidly if equilibrium has not been attained before it is released from the electrode.*

However, the surface tension measurements show clearly that a much slower process than diffusion must be rate-controlling, since γ continues to decrease for c/Γ values much in excess of the critical c/Γ values indicated by the horizontal lines in Fig. 1. From the analysis of the γ vs. t plots it follows that Γ_e would apply for drop times of 50 seconds and $c > 10\times10^{-8}$ moles/cm^3. The isotherm lines in Fig. 1 must therefore have the correct slope, while their intercepts could hardly be less within experimental error. Again considering the fact that the 3.6-second points are much lower than they should be, it follows that a mechanism other than stirring must be operating while the drops fall, so as to accelerate the surface adsorption.

Since $b = 1/\Gamma_m$ it follows that Γ_m (-0.024 v) $= 1.35\times10^{-10}$ and Γ_m ($+0.076$ v) $= 1.20\times10^{-10}$ moles/cm^2. These values have a precision of about 1%, and are in the sequence expected: the phosphate ions, in particular HPO_4^-, are more strongly held and the ions MB^+ more strongly repelled by the surface at the higher potential.

The Γ_m values correspond to an area/molecule of 1.22 Å^2 at -0.024 v and 1.39 Å^2 at $+0.076$ v, which values indicate that there is still phosphate left on the surface at "complete" coverage with MB^+. (A value of 90 Å^2 would probably be closer to the true area of a molecule.)

**The apparatus constructed by Kalousek and Blahnik (6), which is quite analogous to ours, has rapid dropping combined with a very long path of the drops through the solution. In principle, this long path should not be necessary.*

Surface Tension Measurements

Gibb's adsorption equation does not apply to non-equilibrium cases, such as the γ vs. t plots of Figs. 2A and 3A. In order to find the change of γ with time we must treat the adsorption layer as a separate phase (σ), theoretically in equilibrium with the surrounding solution (α) at infinite time only. For the surface phase then, we have at constant potential,

$$[3] \qquad d\gamma = -\sum_i \Gamma_i d\mu_i^{\sigma},$$

Γ_i being the surface concentration of species i and $\Gamma_i = \Gamma_i\ (t,c,E)$.

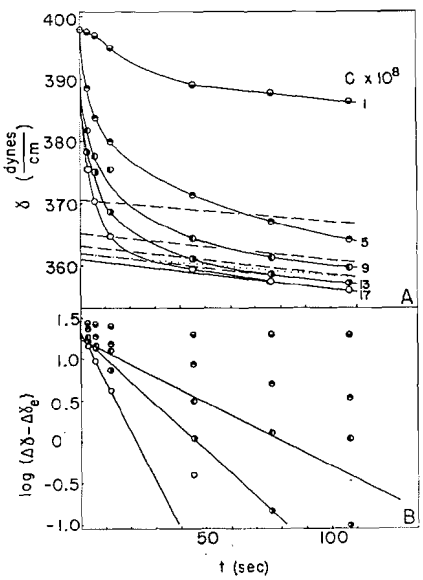

FIG. 2. A. γ vs. t plots for -0.024 v (S.C.E.). For broken and dotted lines see text.
B. Plot of points from 2A according to equation [12].

We now shall postulate the following model:

(*a*) If σ is considered as an ordinary phase, only differing from the latter in its property of surface tension, we may write,

$$[4] \qquad \mu_i^{\sigma} = \mu_i^{\sigma,0} + R^*T \ln \Gamma_i/\Gamma_{i,e},$$

where

$$[5] \qquad \mu_i^{\sigma,0} = \mu_i^{\alpha,0} + RT \ln a_{i,e}.$$

Equation [5] assures that $\mu_i^{\sigma} = \mu_i^{\alpha}$ for $\Gamma_i = \Gamma_{i,e}$. It can be shown quite generally that $R^* = Rd \ln a_i/d \ln \Gamma_i$. As a first approximation R^* will be taken as independent of Γ_i.

(*b*) Chloride ions do not adsorb in significant quantity. The only species entering into equation [3] is MB^+. Although these cations are known to dimerize to some extent in solution (the dimer concentration is about 1.2×10^{-8} at a total concentration of 10^{-7} moles/cm^3 (7)), we shall assume monomers (M) only.

(*c*) The rate of reaching equilibrium at the surface is entirely determined by the interchange of MB^+ with phosphate ions. Consequently, the volume concentration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

MB^+ is constant up to the surface ($c_M = c$) and the equilibrium to be established is

$$M^\alpha \underset{k_d}{\overset{k_a}{\rightleftharpoons}} M^\sigma.$$

(*d*) A Langmuir-type isotherm applies to the adsorption of M, as suggested by Fig. 1,

[6] $$c/\Gamma_e = a+bc,$$

where

$$a = a'/\Gamma_m = k_d/k_a\Gamma_m$$

and

$$b = 1/\Gamma_m.$$

(*e*) No surface activity coefficients will be considered. Constant ionic strength of the solution α does not guarantee the same in the surface phase.

(*f*) Expansion of the mercury drops, as used in the drop-weight method, will be neglected in the first analysis.

From (*a*), equation [4], we obtain

[7] $$d\mu_M{}^\sigma = R^*T\, d \ln \Gamma_M.$$

Substitution of equation [7] into equation [3] gives, considering (*b*) and (*c*),

[8] $$d\gamma = -R^*T\, d\Gamma_M.$$

Now we must find $\Gamma_M(t)$. According to (*c*),

$$\left(\frac{\partial \Gamma_M}{\partial t}\right)_{E,c} = k_a c(1-\theta) - k_d\theta.$$

Putting $\theta = \Gamma_M/\Gamma_m$, and substituting equation [6],

$$\left(\frac{\partial \Gamma_M}{\partial t}\right)_{E,c} = k_a c\left(1-\frac{\Gamma_M}{\Gamma_{M,e}}\right).$$

Upon integration:

[9] $$\Gamma_M = \Gamma_{M,e}(1-e^{-k_a c t/\Gamma_{M,e}}).$$

Now, substituting equation [9] into equation [8] and integrating:

[10] $$\Delta\gamma = -R^*T\Gamma_{M,e}(1-e^{-k_a c t/\Gamma_{M,e}}).$$

For $t \to \infty$, $\Delta\gamma \to \Delta\gamma_e$, and this establishes

[11] $$R^*T = -\Delta\gamma_e/\Gamma_e.$$

From equation [10] and equation [11] we derive,

[12] $$\log(\Delta\gamma - \Delta\gamma_e) = \log(-\Delta\gamma_e) - (k_a c/2.303\ \Gamma_e)t.$$

The surface tension falls off very rapidly at first, especially for the higher concentrations, but then it appears to decrease at a uniform rate. Rough calculations may show that this descent is too large to be caused by our postulate (*f*). We suggest that there may be a secondary process, slow compared with the one treated above. As a matter of fact, if we plot equation [12] as a straight line plot (Figs. 2B and 3B), we find that the best straight line can be obtained by correcting the experimental points of Figs. 2A and 3A

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

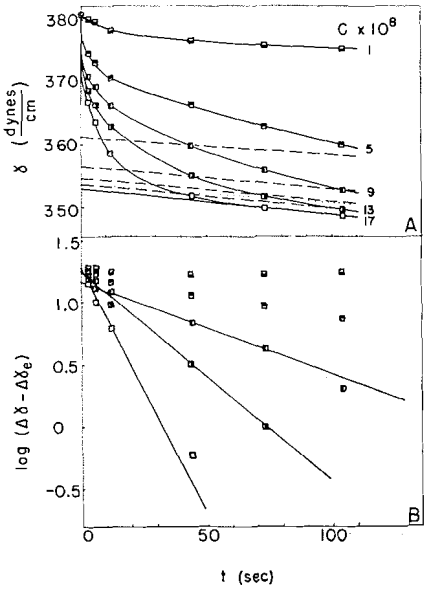

FIG. 3. A. γ vs. t plots for +0.076 v (S.C.E.). For broken and dotted lines see text.
B. Plot of points from 3A according to equation [12].

for this secondary process as indicated for the γ vs. t lines of $c = 17\times10^{-8}$. The extrapolation to $t = 0$ is not quite legitimate (see below), but this should not cause a large error. If one does not wish to admit that a consecutive process occurs, no correction is then made and $(\Delta\gamma_e) <$ smallest $\Delta\gamma$ measured. A plot according to equation [12] was found to deviate very much from a straight line in that case.

The following model would seem most logical in dealing with this secondary process:

(i) Dimers are produced on the surface in either one of two ways:

$$2\,M^\sigma \rightleftharpoons D^\sigma \text{ (homogeneous) or } M^\alpha + M^\sigma \rightleftharpoons D^\sigma \text{ (heterogeneous).}$$

(ii) This process is so slow with respect to the first one, that at times $t > t_1$, the equilibrium under (c) remains established.

(iii) Analogous to equation [4] we have,

$$\mu^\sigma{}_D = \mu_D{}^{\sigma,0} + R^*T \ln \Gamma_D/\Gamma_{D,e}, \qquad [13]$$

where

$$\mu_D{}^{\sigma,0} = 2\mu_M{}^{\sigma,0}.$$

Also, the postulates (b), (e), and (f) remain relevant.

The significance of (ii) and (e) is that $\Gamma_M = \Gamma_{M,e}$ and $\mu_M{}^\sigma = \mu_M{}^\alpha$, ($d\ \mu_M{}^\sigma = 0$) for constant c and E, so that equation [3] now becomes

$$\begin{aligned} d\gamma &= -\Gamma_D\, d\mu_D{}^\sigma \\ &= -R^*T\, d\Gamma_D \text{ (postulate (iii)).} \end{aligned} \qquad [14]$$

For the processes mentioned under (i) we obtain, respectively,

$$d\Gamma_D = k_2\Gamma_{M,e}{}^2\, dt, \qquad [15]$$

or

$$d\Gamma_D = k_2'\, \Gamma_{M,e} c\, dt. \qquad [16]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Note that these processes are pseudo-zeroth order for $t > t_1$. Substitution of equation [16] and equation [11] into equation [14] finally gives

$$\left(\frac{\partial\gamma}{\partial t}\right)_{c,E} = -k_2\Delta\gamma_e\Gamma_{M,e}, \qquad [17]$$

if the process is homogeneous. Alternatively, substituting equation [16] instead of equation [15], we obtain

$$(\partial\gamma/\partial t)_{c,E} = -k_2'\Delta\gamma_e c, \qquad [18]$$

if the process is heterogeneous ($\Delta\gamma_e$ is the equilibrium value for the first process).

In Figs. 2A and 3A we have assumed that the correct slope is given by the solid straight line through the lowest two points of $c = 17\times10^{-8}$. Since

$$\Delta\gamma_e = -\frac{RT}{b}\ln\frac{a+bc}{a} \qquad [19]$$

(substituting equation [6] into equation [1]), values of a may be calculated if the b values, previously given, are substituted. This yields

$$a(-0.024\text{ v}) = 0.02 \quad \text{and} \quad a(+0.076\text{ v}) = 0.11\text{ cm}^{-1}.$$

These a values should be free from the systematic error to which the pair obtained from the surface concentration measurements was subjected, although the precision is certainly very poor in both cases.

The other (broken) straight lines in Figs. 2A and 3A have been calculated: their intercepts from [19] and their slopes from [17] (the ratio of the slopes of a broken and a solid line equals the ratio of the corresponding $\Delta\gamma_e$ values, $\Gamma_{M,e} \cong \Gamma_m$). By doing this we see from Figs. 2A and 3A that the points of longest drop time for $c = 13\times10^{-8}$ may have reached equilibrium with the monomer, but none of the other points have.

If, on the other hand, equation [18] had been used for the calculation of the same slopes, the latter would have been much larger (i.e., less negative; see dotted line for $c = 13\times10^{-8}$) and certain experimental points would have fallen below the dotted lines, which makes no physical sense. Of course more experimental points are needed to establish the conclusion definitely, but pending the production of this evidence, we tentatively conclude that the dimerization process—if it occurs at all, i.e., if our second model is correct—must be the *homogeneous* one.

The straight-line plots of Figs. 2B and 3B according to equation [12] have intercepts ($\log - \Delta\gamma_e$) which are somewhat less than the ones calculated from the $\Delta\gamma_e$ values of Figs. 2A and 3A. Also, the k_a values calculated from the slopes seem to increase somewhat with concentration causing the rather large individual deviations in the values quoted below. Taking the straight lines for the three highest concentrations for each potential, these values of k_a are:

$$k_a(-0.024\text{ v}) = (7.5\pm2.5)\ 10^{-5}\text{ cm sec}^{-1},$$
$$k_a(+0.076\text{ v}) = (4.2\pm1.8)\ 10^{-5}\text{ cm sec}^{-1}.$$

The lower concentrations cannot be expected to follow equation [12], especially at small values of the drop time; their γ values must be high because of diffusion control, as is clearly shown in the figures.

The k_a values given above certainly would agree with the anticipated trend: higher for the smaller potential. It would seem, then, that methylene blue is a compound which might show irreversible features in its polarographic current–voltage wave (see Introduction).

For personal use only.

Values of $k_d = a\Gamma_m k_d$ are necessarily extremely inaccurate, but if the a values obtained from the surface tension measurements are used, these values are:

$$k_d(-0.024 \text{ v}) = 2\times10^{-15} \quad \text{and} \quad k_d(+0.076 \text{ v}) = 6\times10^{-16} \text{ mole cm}^{-2} \text{ sec}^{-1}.$$

EXPERIMENTAL

Surface Concentration Measurements

Reference will be made to Fig. 1 of ref. 3 throughout this section, which deals with further details on the operation of the apparatus used. The three sections, A, B, and C, which fit together with wide ground-glass joints, are assembled and the whole apparatus is placed in the thermostated water bath, as indicated in Fig. 1 (3). The connection to the Erlenmeyer flask outside the bath is made by way of a three-way stopcock (just above section A). The syphon (c) has a polyethylene section for flexibility. Connected to and vertically above the stopcock is a pear-shaped vessel, not shown. The Erlenmeyer flask contains sufficient solution to fill all the "dropping section" B, the siphon, and the flask itself to a height of about 1 cm. Before transferring the solution, the latter and the remainder of the glass apparatus are thoroughly washed with oxygen-free nitrogen by manipulating a set of stopcocks (not shown) in such a way that the nitrogen will pass through the tubular section in downward and upward directions alternatingly (the "head" A contains an extra outlet tube with stopcock, not shown). All but a small volume of the solution is next forced into the pear-shaped vessel above the apparatus, from which it can then flow into section B by gravity and extra nitrogen pressure. Simultaneously, a rather powerful stream of nitrogen is passed upward through capillary d in order to prevent any solution from entering this capillary. Both stopcocks above A are then closed and the nitrogen is shut off. The nitrogen overpressure in the small gas pocket above the solution in B will now force the solution downward into the capillary if the overpressure in C is slowly released through a stopcock on the side tube. Since the solution should not flow past the flare e it is necessary to open, simultaneously and carefully, the three-way stopcock toward the Erlenmeyer flask. The latter has been lowered a small distance to facilitate the operation, but after the solution has reached the flare e, it is raised till the surface of the solution in it is at the level of the bottom of the flare. It must be noticed that such a siphon is stable over a few (4–8) millimeters distance only, by virtue of the fact that the changing radius of the flare provides a balancing force of capillary "rise". Without the flare, the siphon would be completely unstable. An equally important function of the flare is that it allows the individual mercury drops to pass through the interface without difficulty.

The reference electrode ($Pt/Hg/Hg_2HPO_4/HPO_4^=, H_2PO_4^-$) had a fairly large mercury surface. It was filled to the top and then sealed, so that no liquid could flow into the methylene blue solution through the sintered glass disk. Its potential (+0.3105 v at 25° C with respect to S.C.E.) never changed more than a few ten thousandths of a volt throughout its period of use (many months).

The surface concentration, Γ_{MB^+}, is simply related to the concentration difference, Δc, between c_{MB^+} in the solution collected and the average in the dropping section B (before and after the period of dropping) by the equation

$$\Gamma_{MB^+} = v\Delta c/4\pi r^2_{Hg},$$

where Γ_{MB^+} is in moles/cm^2 and Δc in moles/cm^3. The volume of solution entrained per drop (v) is found from the total volume of solution collected (determined by weighing) over the total number of mercury drops (calculated from the drop time, which was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

usually quite constant, and the total duration of dropping), and the radius per drop (r_{Hg}) from the total weight of mercury collected. In order to collect 4 ml of solution in the tube f, ten to twenty thousand drops were required, depending on the radius of the dropping electrode and on the curvature of the solution–nitrogen interface at the flare (the more the interface was bulging downward, the larger v). There was no danger that part of the double layer should be stripped off when the mercury drops pierced the interface, since the value of v corresponds to a thickness of the entrained layer of 0.01 mm or so.

The determination of Δc was done with a Beckman D.U. spectrophotometer. At 620 mμ there is a strong absorption shoulder, but unfortunately Beer's law is known not to be obeyed (8), so before and after each analysis a calibration curve was determined by plotting $-\Delta \log T/\Delta c$ vs. Δc for four other methylene blue solutions, made at the same time as the solution used in the experiment.

Three runs could be done simultaneously in the same bath.

Surface Tension Measurements

These were generally performed under the same circumstances as described under "Surface Concentration Measurements". The mercury drops were collected in a little cup below the dropping electrode, from where they could be removed by suction without opening the apparatus. A 20-cm long capillary, diameter of bore ~50 μ, could be used for the measurements up to 120 seconds drop time, without putting in any constrictions. This is a much longer drop time than the Poiseuille equation would give. It is known (9) that solution can penetrate between mercury and a glass wall and that at certain heights in the capillary this film of solution can become quite thick, so as to form a natural constriction somewhere along the tube. Drop times are not very constant this way, but the results are just as reproducible as those of short drop times.

Materials

The methylene blue (Merck, reagent grade) was recrystallized from alcohol and dried *in vacuo* (not in an oven, because of slight decomposition at 110° C). The sodium phosphate salts were recrystallized from water and dried *in vacuo* over P_2O_5. Water redistilled from a quartz still was used throughout.

ω-HALOALKYL AND ω-AMINOALKYL SULPHIDES

CLEAVAGE OF THE ALKYL–SULPHUR BOND[1]

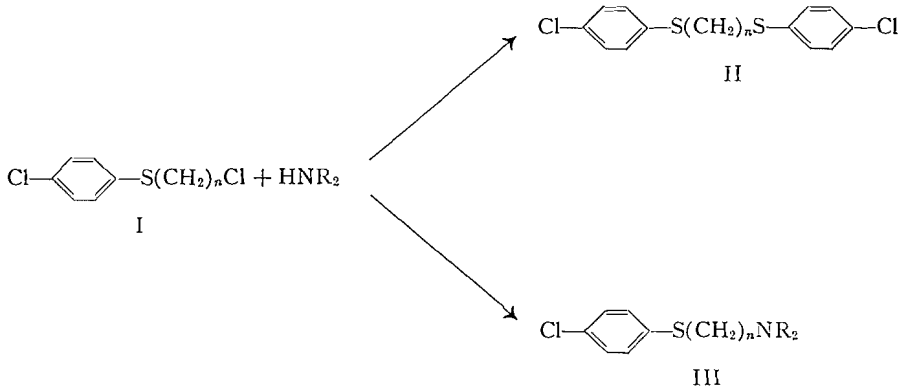
MARSHALL KULKA

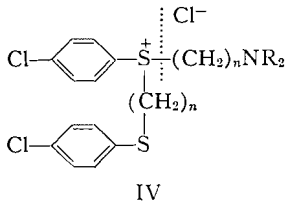
ABSTRACT

In the homologous series of *p*-chlorophenyl ω-chloroalkyl sulphides (I), the first and second members reacted abnormally with amines to yield 1,ω-bis(*p*-chlorophenylmercapto)alkanes (II). The fourth member of the series reacted normally to produce 4-aminobutyl *p*-chlorophenyl sulphide (III). The formation of II is explained on the basis of an alkyl–sulphur bond cleavage. The members of the *p*-chlorobenzyl series (VI) in general reacted with amines to form the expected aminoalkyl sulphides (VII). However, the *p*-chlorobenzyl chloroalkyl sulphides (VI) were thermally labile and decomposed to *p*-chlorobenzyl chloride and a sulphur component. A cyclic sulphur component originated from VI whose chloroalkyl carbon chain was 4, 5, or 6. The thermal degradation of VI is explained through a sulphonium salt cleavage.

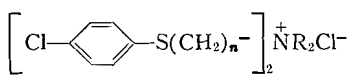
INTRODUCTION

It has been recently shown that *p*-chlorophenyl chloromethyl sulphide (I, $n = 1$) can undergo an unusual bimolecular reaction to form 2,8-dichloro-6H,12H-dibenzo(*b*,*f*)-1,5-dithiocin (1). Now another anomalous reaction of I has been discovered and is the subject





IV



V

[1]*Manuscript received September 18, 1958.*
Contribution from the Dominion Rubber Company Limited Research Laboratories, Guelph, Ontario.

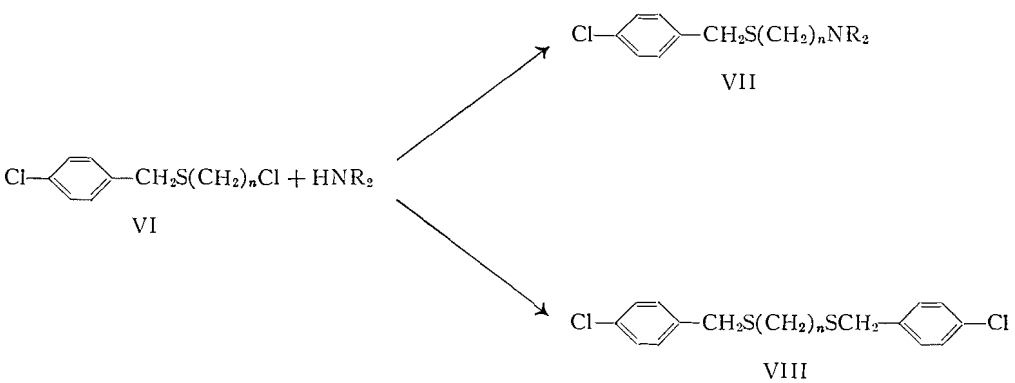
of this paper. When I (n = 1) was heated with ammonia, di-n-butylamine, or t-butylamine, the expected aminomethyl, p-chlorophenyl sulphide (III, n = 1), was not obtained. Instead, bis(p-chlorophenylmercapto)methane (II, n = 1) was the product.

On treatment of higher members of the homologous series of I with amines, it was found the 2-chloroethyl p-chlorophenyl sulphide (I, n = 2) also reacted abnormally in boiling di-n-butylamine to form 1,2-bis(p-chlorophenylmercapto)ethane (II, n = 2). However, when the temperature of the reaction was lowered to about 120° the only product was N,N-di-n-butylaminoethyl p-chlorophenyl sulphide (III, n = 2). Normal reaction only was indicated with higher members of the homologous series, since p-chlorophenyl 4-chlorobutyl sulphide (I, n = 4) with boiling di-n-butylamine gave p-chlorophenyl 4-di-n-butylaminobutyl sulphide (III, n = 4) in high yield. In this connection it was interesting to note that III (n = 2 and 4) forms a hydrochloride which is soluble in benzene and which distills readily without decomposition.

Any mechanism which attempts to explain the formation of II from I must take into account the observation that neither I nor III thermally decomposed to II, but that an equimolecular mixture of I and III on heating at 180° yielded II. This observation suggests two possible intermediates in the mechanism of the reaction, the sulphonium salt IV and the quaternary ammonium salt V, each of which could arise by the reaction of I with III. The dissociation of the sulphonium salt IV (indicated by the dotted line) would lead to II and chloroalkylamine. However, evidence is against this sulphonium salt mechanism since phenyl sulphides in general resist sulphonium chloride formation.

The formation of II (n = 1 and 2) from I might be attributed to a side reaction of I with p-chlorothiophenol in the presence of the amine. p-Chlorothiophenol could arise through an alkyl–sulphur bond cleavage of the quaternary ammonium salt V of I and III. A similar alkyl–sulphur bond cleavage has been experienced previously in the hydrazinolysis of β-p-chlorophenylmercapto-ethyl N,N-dimethyldithiocarbamate to p-chlorothiophenol (2).

The alkyl–sulphur bond in compounds of the benzyl series VI, unlike that of the phenyl series I, appeared to resist amine cleavage. Thus in the reaction of p-chlorobenzyl ω-chloroalkyl sulphides (VI) with amines only the normal products, VII, were formed and little if any of the neutral sulphides VIII could be detected.

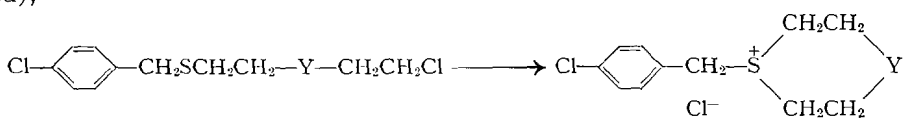


However, an alkyl–sulphur bond cleavage of a different nature was encountered in this series. It was found that the p-chlorobenzyl ω-haloalkyl sulphides (VI) were thermally

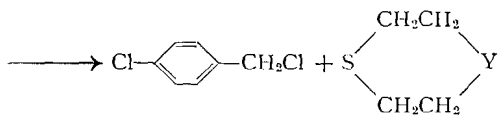
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

labile (unlike the members of the phenyl series I) and cleaved to *p*-chlorobenzyl chloride and a sulphur component. ω-Bromoalkyl *p*-chlorobenzyl sulphides were even more sensitive to heat and yielded *p*-chlorobenzyl bromide.

The lower members of the series VI could be distilled *in vacuo* with little if any decomposition but the higher members (n = 4 and 5) were too labile. Thus vacuum distillation of IX (Y = 0), IX (Y = CH_2), IX (Y = S), and IX (Y = 0) yielded *p*-chlorobenzyl chloride (XI) in each case together with tetrahydrothiophene (XII, Y = 0) (not isolated),



IX X



XI XII

pentamethylene sulphide (XII, Y = CH_2), 1,4-dithiane (XII, Y = S), and 1,4-oxathiane (XII, Y = 0) respectively. An attempt to prepare 4-bromo-2-butenyl *p*-chlorobenzyl sulphide from *p*-chlorobenzyl mercaptan and 1,4-dibromo-2-butene resulted in a mixture of *p*-chlorobenzyl bromide and a malodorous liquid which was probably dihydrothiophene.

The explanation for these reactions must involve sulphonium salt formation. Thus intramolecular sulphonium salt cyclization of IX could occur to form the ring X, which by dissociation would yield *p*-chlorobenzyl chloride (XI) and the cyclic sulphur compound (XII). Similar alkyl–sulphur bond cleavages with and without cyclizations have been reported by other workers (3, 4, 5). Bell, Bennett, and Hock (3) showed that mustard gas when heated at 180° yielded *p*-dithiane and ethylene dichloride. They proposed a mechanism for this reaction which consisted of both intermolecular and intramolecular sulphonium salt formation followed by dissociation.

An interesting example is provided of an alkyl–sulphur bond cleavage which must involve a seven-membered sulphonium salt ring (XIV). Thus when 2-β-chloroethoxy-5-methylbenzyl *p*-chlorobenzyl sulphide (XIII) was slowly distilled at 11 mm pressure, a

mixture of low-boiling compounds was obtained. These compounds proved to be *p*-chlorobenzyl chloride (XI) and 2,3-dihydro-7-methylbenzo(*f*)-1,4-oxathiepin (XV) (6).

EXPERIMENTAL

Bis(p-chlorophenylmercapto)methane (II, $n = 1$) *from p-Chlorophenyl Chloromethyl Sulphide* (I, $n = 1$)

To *p*-chlorophenyl chloromethyl sulphide (7) (20 g) was added *t*-butylamine (40 ml) and the solution was heated under reflux for 4 hours. The precipitated *t*-butylamine hydrochloride was filtered off from the cooled reaction mixture and the filtrate freed of excess *t*-butylamine by distillation. The residue was dissolved in benzene, the solution washed with water, and the solvent removed. The residue distilled at 160–162° (0.5 mm) and the distillate (12 g or 77%) when crystallized from methanol melted at 42–43° alone or in admixture with bis(*p*-chlorophenylmercapto)methane (8).

In another experiment *p*-chlorophenyl chloromethyl sulphide was heated in a sealed bomb with excess liquid ammonia at 50–55° for 15 hours. This yielded only bis(*p*-chlorophenylmercapto)methane.

1,2-Bis(p-chlorophenylmercapto)ethane (II, $n = 2$) *from p-Chlorophenyl 2-Chloroethyl Sulphide* (I, $n = 2$)

A solution of *p*-chlorophenyl 2-chloroethyl sulphide (20 g) and di-*n*-butylamine (40 ml) was heated under reflux for 5 hours. The excess di-*n*-butylamine was removed *in vacuo* and the residue was crystallized from methanol. The white prisms (9 g) melted at 92–93° and did not depress the melting point of 1,2-bis(*p*-chlorophenylmercapto)ethane (9).

In another experiment *p*-chlorophenyl 2-chloroethyl sulphide was heated in a sealed bomb with methylamine at 140° for 6 hours. The product was 1,2-bis(*p*-chlorophenylmercapto)ethane.

2-(Di-n-butylamino)ethyl p-Chlorophenyl Sulphide (III, $n = 2$, R = C_4H_9)

A solution of *p*-chlorophenyl 2-chloroethyl sulphide (50 g) and di-*n*-butylamine (100 ml) was heated at 115–125° for 18 hours. The excess di-*n*-butylamine was removed *in vacuo*, the residue dissolved in benzene, and the solution washed with dilute hydrochloric acid. The benzene was removed and the residue distilled yielding a very viscous distillate (52 g) boiling at 160° (0.5 mm). When it was rubbed and warmed, it solidified and the white solid melted at 86–88°. This proved to be the hydrochloride of 2-(di-*n*-butylamino)-ethyl *p*-chlorophenyl sulphide (it is rather unusual that an amine salt should distill and be soluble in benzene). Anal. Calc. for $C_{16}H_{27}NCl_2S$: C, 57.14; H, 8.03. Found: C, 56.68; H, 7.79.

The free base was liberated from the hydrochloride by dissolving the latter in benzene and shaking with aqueous sodium hydroxide. 2-(Di-*n*-butylamino)ethyl *p*-chlorophenyl sulphide boiled at 137–140° (0.5 mm), $n_D^{20} = 1.5350$ and remained a colorless mobile liquid. Anal. Calc. for $C_{16}H_{26}NClS$: C, 64.11; H, 8.68. Found: C, 63.58, 63.27; H, 8.34, 8.52.

In another experiment when *p*-chlorophenyl 2-chloroethyl sulphide was heated with di-*n*-butylamine at 130–150° for 5 hours, a mixture of 2-(di-*n*-butylamino)ethyl *p*-chlorophenyl sulphide and 1,2-bis(*p*-chlorophenylmercapto)ethane was obtained.

4-(Di-n-butylamino)butyl p-Chlorophenyl Sulphide (III, $n = 4$, R = C_4H_9)

A solution of *p*-chlorophenyl 4-chlorobutyl sulphide (1) (17 g) and di-*n*-butylamine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

(50 ml) was heated under reflux for 5 hours. The excess amine was removed *in vacuo*, the residue was dissolved in benzene, and the solution washed with aqueous sodium hydroxide and with water. Removal of the solvent and distillation of the residue yielded a colorless liquid (18 g), b.p. = 155° (0.5 mm); $n_D^{22} = 1.5288$. Anal. Calc. for $C_{18}H_{30}NClS$: C, 65.95; H, 9.16. Found: C, 65.43; H, 8.98.

2-(Diethylamino)ethyl p-Chlorophenyl Sulphide (III, $n = 2$, R = C_2H_5)

A solution of *p*-chlorophenyl 2-chloroethyl sulphide (20 g) and 98% diethylamine (35 ml) was heated at 120–130° in a sealed bomb for 6 hours. The product which was worked up as above boiled at 163–165° (11 mm); $n_D^{22} = 1.5535$. The yield was 12 g. Anal. Calc. for $C_{12}H_{18}NClS$: C, 59.14; H, 7.39. Found: C, 58.81, 59.25; H, 7.53, 7.50.

2-Aminoethyl p-Chlorophenyl Sulphide (III, $n = 2$, R = H)

To a solution of sodium hydroxide (10 g) in water (100 ml) was added *p*-chlorothiophenol (16 g) and 2-bromoethylamine hydrobromide (20 g) in water (30 ml). The resulting solution was heated on the steam bath for ½ hour and the precipitated oil was extracted with benzene. The benzene solution was washed with water, the solvent removed, and the residue distilled, b.p. = 152° (11 mm); $n_D^{25} = 1.6025$. The yield was 15 g. Anal. Calc. for $C_8H_{10}NClS$: C, 51.20; H, 5.33. Found: C, 50.27, 50.87; H, 5.25, 5.31.

2-Aminoethyl Pentachlorophenyl Sulphide

This was prepared in 60% yield from pentachlorobenzenethiol and 2-bromoethylamine hydrobromide as above. The white prisms crystallized from benzene – petroleum ether and melted at 89–90°. Anal. Calc. for $C_8H_6NCl_5S$: C, 29.46; H, 1.81. Found: C, 30.17, 29.81; H, 2.23, 2.12.

p-Chlorobenzyl 2-(Di-n-butylamino)ethyl Sulphide (VII, $n = 2$, R = C_4H_9)

A solution of *p*-chlorobenzyl 2-chloroethyl sulphide (9) (20 g) and di-*n*-butylamine (40 ml) was heated under reflux for 3 hours. The excess amine was removed *in vacuo*, the residue dissolved in benzene and washed with water. The solvent was removed and the residue fractionally distilled. The first fraction consisted of low-boiling material. The second fraction (7 g), which boiled at 137–140° (0.5 mm); $n_D^{27} = 1.5320$, was the required *p*-chlorobenzyl 2-(di-*n*-butylamino)ethyl sulphide. Anal. Calc. for $C_{17}H_{28}NClS$: C, 65.07; H, 8.93. Found: C, 65.26; H, 8.75.

The third fraction (3 g) boiled at 180–210° (0.5 mm) and the distillate on crystallization from methanol yielded white prisms (1.2 g) which melted at 74–76° alone or in admixture with 1,2-bis(*p*-chlorobenzylmercapto)ethane (9).

Pyrolysis of p-Chlorobenzyl 5-Chloropentyl Sulphide (VI, $n = 5$)

The crude *p*-chlorobenzyl 5-chloropentyl sulphide (40 g) (see below) was distilled at 12 mm first, and the distillate was then fractionated.

Fraction 1 consisted of 9 g of colorless malodorous liquid boiling at 140°; $n_D^{20} = 1.5060$. These properties agree with those of pentamethylene sulphide (10, 11). When a portion of fraction 1 was dissolved in acetic acid and treated with 30% hydrogen peroxide, pentamethylene sulphone (12), m.p. 96–97°, was formed.

Fraction 2 consisted of 19 g of colorless lachrymatory liquid; $n_D^{20} = 1.5560$ boiling at 87–89° (11 mm). It solidified on cooling and melted at 29°. Recrystallization from petroleum ether yielded long white needles melting at 29–30° alone or in admixture with *p*-chlorobenzyl chloride.

Pyrolysis of p-Chlorobenzyl 4-Chlorobutyl Sulphide (VI, $n = 4$)

Crude *p*-chlorobenzyl 4-chlorobutyl sulphide was prepared and pyrolyzed as above. *p*-Chlorobenzyl chloride was obtained in 74% yield but no tetrahydrothiophene could be isolated.

Pyrolysis of p-Chlorobenzyl 4-Bromo-2-butenyl Sulphide

To a stirred solution of potassium hydroxide (11 g) in methanol (200 ml) and *p*-chlorobenzyl mercaptan (30 g), cooled to 0°, was added a chilled solution of 1,4-dibromo-2-butene (100 g) in benzene (100 ml). The reaction mixture was stirred with cooling at 5–10° for 1 hour. The precipitated potassium bromide was filtered off and the solvents were removed from the filtrate. The residue was dissolved in benzene, the solution washed with water, and the solvent removed. The residue was distilled at 11 mm and the distillate then fractionated. Fraction 1 was a colorless malodorous liquid boiling at 40–60° (11 mm) and was probably dihydrothiophene. Fraction 2, boiling at 60–95° (11 mm), consisted mainly of 1,4-dibromo-2-butene. Fraction 3 (14 g) boiled at 95–102° (11 mm) and on crystallization from methanol yielded white needles melting at 49–50° alone or in admixture with *p*-chlorobenzyl bromide (13).

β-p-Chlorobenzylmercaptoethyl 2-Hydroxyethyl Sulphide

To a solution of potassium hydroxide (6 g) in methanol (100 ml) was added 2-mercaptoethanol (9 ml) and *p*-chlorobenzyl 2-chloroethyl sulphide (9) (20 g). The resulting solution was heated under reflux for 2 hours and then the methanol distilled off. The residual oil was extracted with benzene, the solution washed with water, and the solvent removed. The residue distilled at 175–178 (0.5 mm) yielding 19 g of a colorless liquid, $n_D^{26} = 1.5992$. Anal. Calc. for $C_{11}H_{15}OClS_2$: C, 50.28; H, 5.71. Found: C, 50.59; H, 5.82.

β-o-Chlorobenzylmercaptoethyl 2-Hydroxyethyl Sulphide

This was prepared in 87% yield from *o*-chlorobenzyl 2-chloroethyl sulphide as above, b.p. = 170–175° (0.5 mm); $n_D^{22} = 1.6020$. Anal. Calc. for $C_{11}H_{15}OClS_2$: C, 50.28; H, 5.71. Found: C, 50.55; H, 5.76.

Pyrolysis of β-p-(IX, Y = S) *and β-o-Chlorobenzylmercaptoethyl 2-Chloroethyl Sulphide*

A solution of *β-o*-chlorobenzylmercaptoethyl 2-hydroxyethyl sulphide (30 g), benzene (100 ml), and thionyl chloride (12 ml) was heated under reflux for 2 hours. The benzene and excess thionyl chloride were removed *in vacuo* and the residue was slowly distilled at 11 mm. The distillate was cooled and the white malodorous precipitate (6 g) filtered, washed with cold methanol, and dried. It sublimed readily and melted at 111–112°. This was *p*-dithiane (14).

The filtrate on distillation yielded *o*-chlorobenzyl chloride.

When *β-p*-chlorobenzylmercaptoethyl 2-hydroxyethyl sulphide was converted to the 2-chloroethyl derivative IX, (Y = S) with thionyl chloride and treated as above, a separable mixture of *p*-dithiane and *p*-chlorobenzyl chloride was obtained.

Pyrolysis of β-p-Chlorobenzylmercaptoethyl 2-Chloroethyl Ether (IX, Y = 0)

β-p-Chlorobenzylmercaptoethyl 2-chloroethyl ether (10 g) (see below) was heated at 160–170° for 7 hours. A malodorous liquid (3 g) distilled into the receiver which on redistillation boiled at 147–150°; $n_D^{22} = 1.5070$. The properties of this compound are in agreement with those given for 1,4-oxathiane (15, 16).

The residue on distillation yielded 5 g of *p*-chlorobenzyl chloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Pyrolysis of 2-β-Chloroethoxy-5-methylbenzyl p-Chlorobenzyl Sulphide (XIII)

To a solution of potassium hydroxide (5 g) in methanol (100 ml) was added *p*-chlorobenzyl mercaptan (11 g) and 2-β-chloroethoxy-5-methylbenzyl chloride (6) (15 g) in that order. The resulting reaction mixture was heated under reflux for 15 minutes. The methanol was removed, the residue dissolved in benzene, the solution washed with water, and the solvent removed. The residue was distilled slowly at 11 mm pressure up to 200° and the distillate was fractionated. Fraction 1 (5 g) which boiled at 80–135° (11 mm) was treated with thiourea in ethanol. The resulting isothiuronium salt melted at 205–207° and did not depress the melting point of the isothiuronium salt of *p*-chlorobenzyl chloride. Fraction 2 (9 g) boiled at 135–150° (11 mm) and when crystallized from methanol yielded white prisms melting at 45–46° alone or in admixture with 2,3-dihydro-7-methylbenzo(*f*)-1,4-oxathiepin (XV) (6).

Preparation of ω-Chloroalkyl Sulphides

These were prepared by the method used for 2-chloroethyl aryl and aralkyl sulphides previously described (9).

(*a*) *p-Chlorobenzyl 3-chloropropyl sulphide* (VI, $n = 3$) was obtained in 87% yield from 1,3-dichloropropane and *p*-chlorobenzyl mercaptan, b.p. = 115–118 (0.5 mm); $n_D^{22} = 1.5720$. Anal. Calc. for $C_{10}H_{12}Cl_2S$: C, 51.06; H, 5.10. Found: C, 50.63, 50.91; H, 4.89, 4.64.

(*b*) *p-Chlorobenzyl 3-bromopropyl sulphide* was prepared in 60% yield from 1,3-dibromopropane and *p*-chlorobenzyl mercaptan, b.p. = 120–125° (0.5 mm); $n_D^{22} = 1.5884$. Anal. Calc. for $C_{10}H_{12}ClBrS$: C, 42.93; H, 4.29. Found: C, 42.21, 42.27; H, 3.39, 3.50.

(*c*) *p-Chlorobenzyl 2-bromoethyl sulphide* could not be prepared in pure form because pyrolysis occurred during distillation to form *p*-chlorobenzyl bromide.

(*d*) *n-Amyl 4-chlorobutyl sulphide* was prepared in 20% yield from *n*-amyl mercaptan and 1,4-dichlorobutane, b.p. = 120–130° (11 mm); $n_D^{23} = 1.4775$. Anal. Calc. for $C_9H_{19}ClS$: C, 55.53; H, 9.76. Found: C, 56.33, 56.74; H, 9.75, 9.84.

(*e*) *β-p-Chlorobenzylmercaptoethyl 2-chloroethyl ether* (IX, Y = 0) was prepared in 75% yield from *p*-chlorobenzyl mercaptan and excess β,β′-dichloroethyl ether, b.p. = 137–140° (0.5 mm); $n_D^{22} = 1.5618$. Anal. Calc. for $C_{11}H_{14}OCl_2S$: C, 49.81; H, 5.28. Found: C, 49.94, 49.82; H, 5.08, 5.12.

(*f*) *p-Chlorobenzyl 5-chloropentyl sulphide* (VI, $n = 5$) was prepared from *p*-chlorobenzyl mercaptan and 1,5-dichloropentane (17). No attempt was made to distill the crude product because it pyrolyzed very readily.

(*g*) *Crude p-chlorobenzyl 4-chlorobutyl sulphide* (VI, $n = 4$) was prepared similarly.

o-Chlorobenzyl 2-Hydroxyethyl Sulphide

To a stirred mixture of sodium hydroxide (70 g) in 2-mercaptoethanol (200 ml) and benzene (200 ml) was added, over ½ hour, a solution of *o*-chlorobenzyl chloride (250 g) in benzene (150 ml). The reaction mixture boiled vigorously. It was heated under reflux for 2 hours, washed with water, the solvent removed, and the residue distilled, b.p. = 175–178° (11 mm); $n_D^{20} = 1.5832$. The yield was 293 g. Anal. Calc. for $C_9H_{11}OClS$: C, 53.33; H, 5.43. Found: C, 53.73; H, 5.58.

o-Chlorobenzyl 2-Chloroethyl Sulphide

To a stirred solution of *o*-chlorobenzyl 2-hydroxyethyl sulphide (200 g) in benzene (250 ml) was added, over ½ hour, thionyl chloride (125 g) with cooling. The reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

mixture was heated under reflux for 1 hour, the solvent removed, and the residual oil distilled, b.p. = 155–158° (11 mm); n_D^{23} = 1.5827. The yield was 190 g. Anal. Calc. for $C_9H_{10}Cl_2S$: C, 48.87; H, 4.52. Found: C, 48.76; H, 4.05.

β-p-t-Butylphenoxyethyl 2-Hydroxyethyl Sulphide

This was prepared in 90% yield from *p-t*-butylphenyl 2-chloroethyl ether and 2-mercaptoethanol in the same way as was *o*-chlorobenzyl 2-hydroxyethyl sulphide above. The colorless liquid boiled at 205–210° (11 mm); n_D^{23} = 1.5410. Anal. Calc. for $C_{14}H_{22}O_2S$: C, 66.14; H, 8.66. Found: C, 65.49; H, 8.86.

β-p-t-Butylphenoxyethyl 2-Chloroethyl Sulphide

This was prepared in 94% yield by treatment of *β-p-t*-butylphenoxyethyl 2-hydroxyethyl sulphide with thionyl chloride. It distilled at 145–148° (0.5 mm) as a colorless liquid, n_D^{22} = 1.5400. Anal. Calc. for $C_{14}H_{21}OClS$: C, 61.65; H, 7.70. Found: C, 61.83; H, 7.79.

Preparation of the Aminoalkyl Sulphides

These were prepared by the same method as was (*a*).

(*a*) *p-Chlorobenzyl 2-aminoethyl sulphide* (VII, $n = 2$, R = H) was prepared by the addition of liquid ammonia (about 100 ml) to 30 g *p*-chlorobenzyl 2-chloroethyl sulphide cooled by dry ice, and the reaction mixture was sealed in a hydrogenation bomb and heated at 135–140° for 6 hours. The excess ammonia was allowed to evaporate, the residue treated with aqueous sodium hydroxide and extracted with benzene. The benzene solution was washed with water, the solvent removed, and the residue distilled. Most of it (20 g) distilled at 103–105° (0.2 mm) as a colorless liquid; n_D^{25} = 1.5850. Anal. Calc. for $C_9H_{12}NClS$: C, 53.59; H, 5.95. Found: C, 52.83, 53.01; H, 5.83, 6.02. The residue from the distillation on treatment with hydrochloric acid and crystallization from methanol yielded 3 g of bis(*β-p*-chlorobenzylmercaptoethyl)amine hydrochloride melting at 140–141°. Anal. Calc. for $C_{18}H_{21}NCl_2S_2$: C, 51.07; H, 5.20. Found: C, 51.22, 51.32; H, 5.26, 5.36.

(*b*) *o-Chlorobenzyl 2-aminoethyl sulphide* was prepared from *o*-chlorobenzyl 2-chloroethyl sulphide in 76% yield. The almost colorless liquid boiled at 160–165° (13 mm); n_D^{24} = 1.5862. Anal. Calc. for $C_9H_{12}NClS$: C, 53.59; H, 5.95. Found: C, 53.86, 53.38; H, 5.56, 5.93.

(*c*) *β-p-Chlorobenzylmercaptoethyl 2-aminoethyl ether* was prepared from *β-p*-chlorobenzylmercaptoethyl 2-chloroethyl ether in 45% yield. It distilled as a colorless liquid boiling at 135–137° (0.5 mm); n_D^{22} = 1.5640. Anal. Calc. for $C_{11}H_{16}NOClS$: C, 53.77; H, 6.42. Found: C, 53.68, 52.97; H, 6.25, 6.21.

(*d*) *p-Chlorobenzyl 5-aminopentyl sulphide* (VII, $n = 5$, R = H) was prepared in 25% yield from crude *p*-chlorobenzyl 5-chloropentyl sulphide. It distilled at 145–150° (0.5 mm); n_D^{25} = 1.5580. Anal. Calc. for $C_{12}H_{18}NClS$: C, 59.14; H, 7.39. Found: C, 58.94, 59.41; H, 7.10, 7.14.

(*e*) *p-Chlorobenzyl 3-amino-2-hydroxypropyl sulphide* was prepared from *p*-chlorobenzyl 3-chloro-2-hydroxypropyl sulphide (9) in 68% yield. It distilled at 170–175° (0.5 mm) and crystallized from ether containing a little methanol as white prisms which melted at 85–86°. Anal. Calc. for $C_{10}H_{14}NOClS$: C, 51.84; H, 6.04. Found: C, 51.96; H, 5.80. The residue from the distillation crystallized from methanol to yield bis(1-*p*-chlorobenzylmercapto-2-hydroxypropyl)amine melting at 97–100°. Anal. Calc. for $C_{20}H_{25}NO_2Cl_2S_2$: C, 53.81; H, 5.60. Found: C, 54.25, 53.85; H, 5.47, 5.31.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

(*f*) *p-Chlorobenzyl 3-aminopropyl sulphide* (VII, $n = 3$, R = H) was prepared from *p*-chlorobenzyl 3-chloropropyl sulphide in 67% yield. It distilled as a colorless liquid with b.p. = 112–115° (0.5 mm); $n_D^{22} = 1.5754$. Anal. Calc. for $C_{10}H_{14}NClS$: C, 55.68; H, 6.49. Found: C, 54.91, 55.13; H, 6.47, 5.99.

(*g*) *n-Amyl 4-aminobutyl sulphide* was prepared from *n*-amyl 4-chlorobutyl sulphide in 42% yield. It distilled as a colorless liquid with b.p. = 112° (11 mm); $n_D^{23} = 1.4790$. Anal. Calc. for $C_9H_{21}NS$: C, 61.71; H, 12.00. Found: C, 60.99, 61.17; H, 11.91, 12.17.

(*h*) *n-Dodecyl 2-aminoethyl sulphide* was prepared from *n*-dodecyl 2-chloroethyl sulphide (18) in 50% yield. It distilled as a yellow liquid with b.p. = 120–123° (0.5 mm); $n_D^{23} = 1.4755$. Anal. Calc. for $C_{14}H_{31}NS$: C, 68.57; H, 12.65. Found: C, 68.56, 68.76; H, 12.21, 12.62.

(*i*) *β-p-t-Butylphenoxyethyl 2-aminoethyl sulphide* was prepared from *β-p-t*-butylphenoxyethyl 2-chloroethyl sulphide in 73% yield. It distilled as an almost colorless liquid with b.p. = 138–140° (0.5 mm); $n_D^{24} = 1.5400$. Anal. Calc. for $C_{14}H_{23}NOS$: C, 66.40; H, 9.09. Found: C, 66.44; H, 9.16.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY ULTRAVIOLET LIGHT ABSORPTION

PART II. THE EFFECT OF SOLVENT–SOLUTE INTERACTIONS ON THE INTERMOLECULAR HYDROGEN BOND IN BENZOIC ACIDS[1]

W. F. Forbes and A. R. Knight

ABSTRACT

The concentration dependence of some electronic absorption bands, which has previously been ascribed to intermolecular hydrogen bonding, is reinvestigated. The concentration dependences are compared for a number of substituted benzoic acids in inert solvents, and in solvent mixtures containing various amounts of ether. The results are discussed in terms of current theories of hydrogen bonding.

INTRODUCTION

In Part I (1) of this series it was found convenient to classify environmental influences affecting ultraviolet absorption spectra as follows: (i) intermolecular hydrogen bonding acting between solute molecules only; (ii) intermolecular hydrogen bonding acting between solute and solvent molecules; and (iii) solvent–solute interactions which do not involve hydrogen bonding.

The first of these effects was shown in Part I to be qualitatively susceptible to spectral analysis, and the concentration dependence of the electronic spectra of benzoic acids in cyclohexane media was ascribed to intermolecular hydrogen bonding. The next aim was to obtain quantitative relations between absorption spectra and solution concentrations for these and other substituted benzoic acids. It was then found that a number of substituted benzoic acids were not sufficiently soluble in cyclohexane to permit the determination of the concentration dependence of their spectra, and ether had to be added in order to obtain solution. The characteristic concentration dependence was still obtained under these conditions, but the question arose whether addition of ether affects the dimeric hydrogen bond, or whether addition of small amounts of ether does not unduly disturb the spectral effect associated with the formation of the dimeric hydrogen bond. In order to decide, the spectra of a number of cyclohexane-soluble benzoic acids were determined in cyclohexane and in solvent mixtures containing various proportions of cyclohexane and ether.

EXPERIMENTAL

The ultraviolet absorption spectra were determined as previously described in this series (1). For each compound the concentration dependence was determined at least in duplicate. A considerable extension of the concentration range was achieved by using progressively more concentrated solutions in the solvent cell instead of pure solvents. By using solutions of biphenyl in cyclohexane, which do not show any appreciable concentration dependence, it was shown that this modification does not introduce any additional errors.* By extremely careful manipulation, ϵ_{max} values could be measured with a precision estimated to be $\pm 2\%$ or better, and the day-to-day reproducibility was also well within this margin. Results are listed in Figs. 2, 3, 4, and 5 where the vertical brackets indicate the $\pm 2\%$ reproducibility.

[1]*Manuscript received September 15, 1958.*
Contribution from the Memorial University of Newfoundland, St. John's, Newfoundland.
**We are indebted to Dr. O. H. Wheeler for suggesting this modification to us.*

Solvent mixtures were prepared by mixing together the corresponding volume percentages. The cyclohexane used was Fisher Certified Reagent, spectroanalyzed, and the ethyl ether used was Eastman white label, spectrograde. No evidence was found to indicate the presence of traces of acids or base in the solvents. The benzoic acids were purified by standard methods and carefully dried. Elemental analyses showed the absence of any appreciable amounts of water of crystallization in the benzoic acids. For example, *p*-toluic acid analyzed for C, 70.7% (calc. C, 70.6%), whereas $C_8H_8O_2.H_2O$ requires C, 62.3%.

THE EFFECT OF ADDITION OF ETHER ON THE O–H---O BOND IN BENZOIC ACID DIMERS

The absorption spectrum of benzoic acid in cyclohexane solution at different concentrations is shown in Fig. 1.

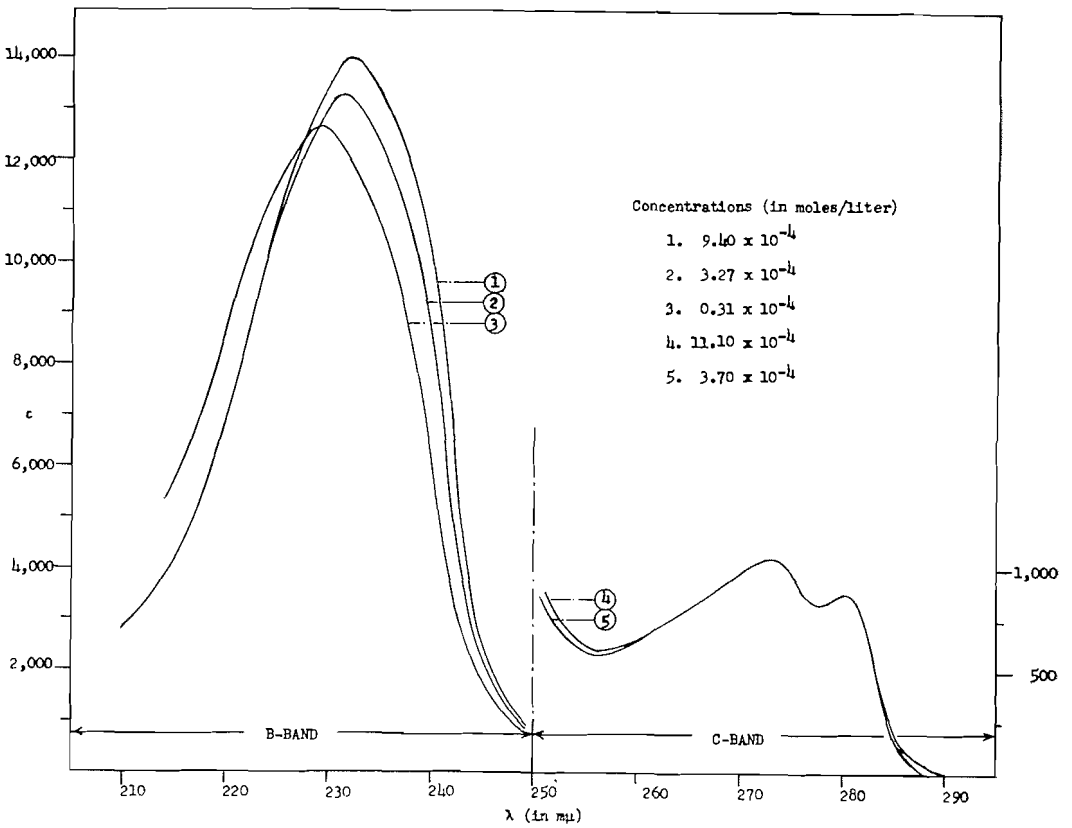

FIG. 1. The effect of concentration on the ultraviolet absorption spectrum of benzoic acid in cyclohexane solution. The description of the absorption bands as *B*- and *C*-bands follows the nomenclature adopted in Part I (1, cf. also ref. 2).

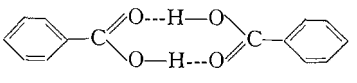
The following observations lead us to ascribe this concentration dependence to intermolecular hydrogen bonding between solute molecules, that is, to dimerization as shown in I:



I

(i) A similar concentration dependence is not observed for a number of other molecules within the investigated concentration range (1).

(ii) The concentration dependence practically disappears for methyl benzoate (1, 3). Hence, the hydroxyl group is necessary.

(iii) The concentration dependence for benzoic acid relates with the supposed dimerization of benzoic acids at concentrations similar to those of the present investigation (cf. refs. 4, 5).

(iv) Addition of ether decreases the concentration dependence (see Figs. 2, 3, 4, and 5).

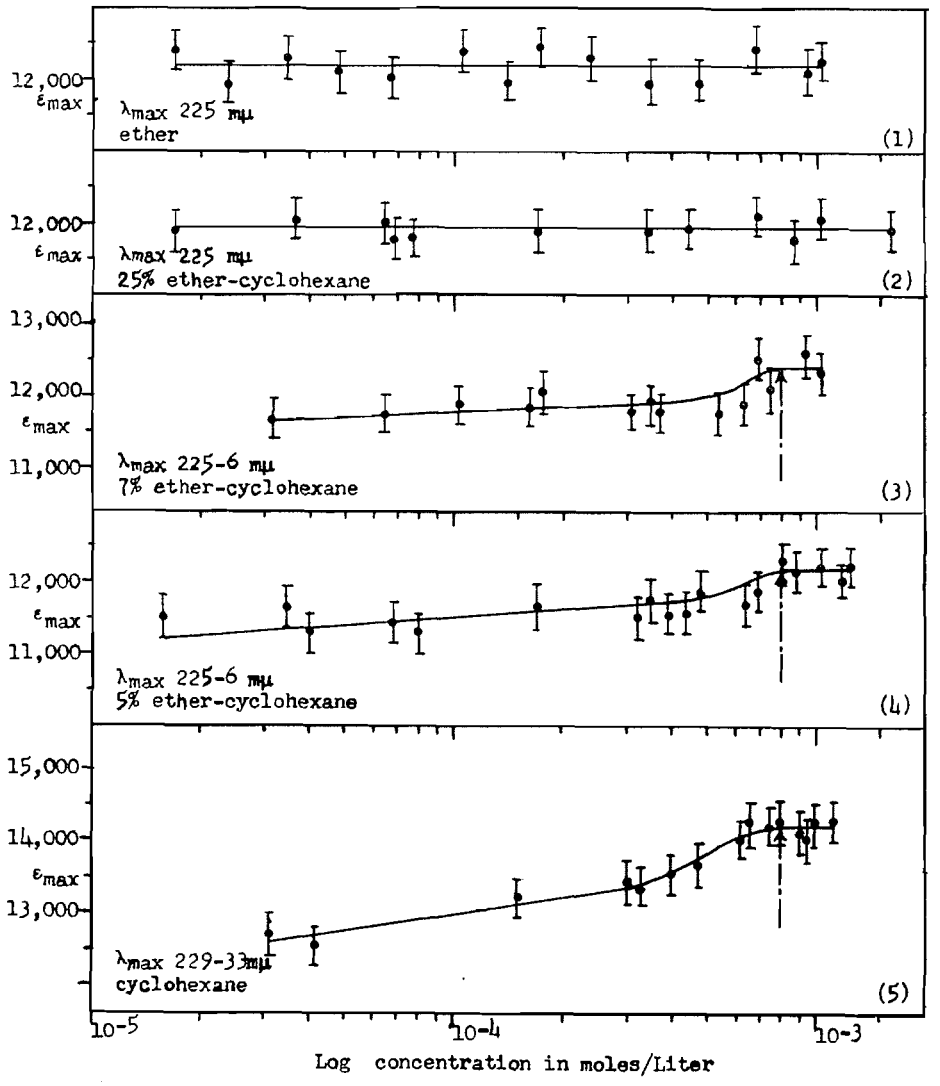

FIG. 2. The variation of ϵ_{max} on changing the concentration of acid for benzoic acid in (1) ether solution, (2) cyclohexane solution containing 25% ether, (3) cyclohexane solution containing 7% ether, (4) cyclohexane solution containing 5% ether, and (5) cyclohexane solution. In this and subsequent figures the lower λ_{max} value shown indicates the maximal wavelength at the smallest concentration, and the higher λ_{max} value indicates the maximal wavelength at the largest concentration. In this way, for example in Fig. 2 for benzoic acid in cyclohexane solution, λ_{max} 229 mμ represents the maximal wavelength for the most dilute solution.

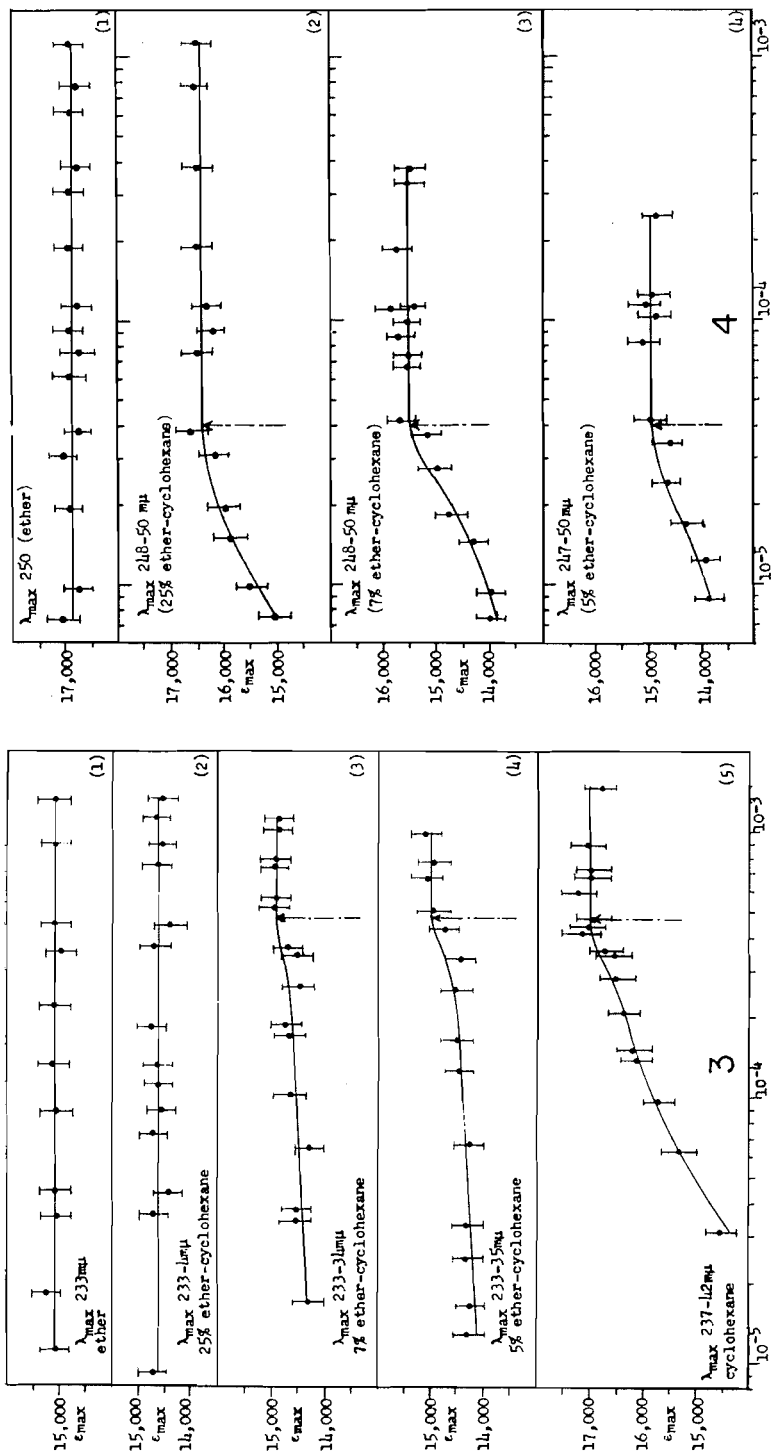

FIG. 3. The variation of ϵ_{max} on changing the concentration of acid for *p*-toluic acid in (1) ether solution, (2) cyclohexane solution containing 25% ether, (3) cyclohexane solution containing 7% ether, (4) cyclohexane solution containing 5% ether, and (5) cyclohexane solution.

FIG. 4. The variation of ϵ_{max} on changing the concentration of acid for *p*-hydroxybenzoic acid in (1) ether solution, (2) cyclohexane solution containing 25% ether, (3) cyclohexane solution containing 7% ether, and (4) cyclohexane solution containing 5% ether.

This indicates a competitive intermolecular hydrogen bonding, and hence indirectly suggests solute–solute hydrogen bonding as an explanation of the observed concentration dependence.

(v) Intramolecular hydrogen bonding in salicylic acid apparently reduces the strength of the dimeric hydrogen bond (cf. Figs. 2 and 5, and subsequent discussion). Since various forms of hydrogen bonding would be expected to compete with each other, this again indicates that association is responsible for the observed concentration dependence (cf. ref. 6).

Figure 1 also shows that the shape of both *B*- and *C*-bands remains approximately similar on changing the solute concentration; similar curves are also obtained for the substituted benzoic acids on changing the concentration. Consequently, maximal molecular extinction coefficients (ϵ_{max}) are used as a first approximation to measure the actual absorption intensities. Figure 2 shows the observed changes in ϵ_{max} with solute concentration for benzoic acid in cyclohexane solution and in various cyclohexane–ether solvent mixtures.

Figure 2 shows that it is possible to determine the concentration above which the values of ϵ_{max} become approximately independent of concentration changes. These values, as shown in Figs. 2, 3, 4, and 5 by vertical arrows, are assumed to represent the concentrations below which the particular benzoic acids exist appreciably in the monomeric form. Figure 2 also shows that in ether solution no concentration dependence is observed. On the other hand, in cyclohexane solution containing 5% of ether, a concentration dependence is observed, and generally, in solutions containing intermediate percentages of ether, intermediate concentration dependences are observed.

It also follows from the argument set out in the previous paragraph, that the *lower* the concentration at which a particular benzoic acid begins to exist appreciably in the monomeric form, the *stronger* will be the dimeric hydrogen bond. Figures 3 and 4 show

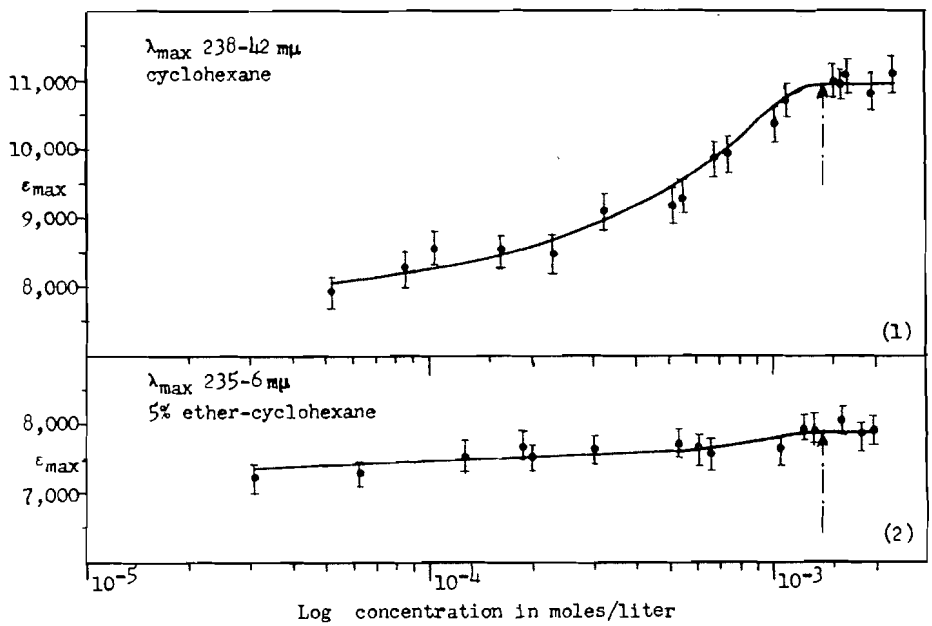

FIG. 5. The variation of ϵ_{max} on changing the concentration of acid for salicyclic acid in (1) cyclohexane, (2) cyclohexane solution containing 5% ether.

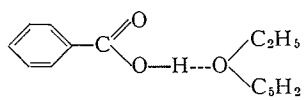
that a *p*-methyl- or a *p*-hydroxyl-group in benzoic acid apparently has this effect of strengthening the dimeric hydrogen bond, and the *p*-hydroxyl group appears to be more effective than the *p*-methyl group. Further, for *p*-hydroxybenzoic acid the concentration dependence, ascribed to intermolecular hydrogen bonding, is readily discernible in 25% ether (see Fig. 4), whereas for benzoic and *p*-toluic acid no concentration dependence could be observed under those conditions (see Figs. 2 and 3).

The effect of solute concentration on the maximal extinction coefficient of salicylic acid is shown in Fig. 5. Figure 5 indicates that the intramolecular hydrogen bond in salicylic acid decreases the strength of the dimeric hydrogen bond in this acid, compared with benzoic acid or *p*-hydroxybenzoic acid. On addition of 5% of ether to the solution of salicylic acid in cyclohexane the concentration dependence is only recognized with difficulty, whereas under similar conditions the concentration dependence in benzoic acid may readily be discerned (see Figs. 2 and 5).

DISCUSSION

Three conclusions may be reached from the data. First, the vertical arrows in Figs. 2, 3, 4, and 5, indicating the appearance of monomeric forms, occur at approximately the same concentration, irrespective of whether a small amount of ether has been added to the solvent or not. Hence in comparing the relative strengths of the dimeric hydrogen bond for substituted benzoic acids by this method, *the concentration dependence may be determined either in cyclohexane or in cyclohexane containing small amounts of ether.* This allows the extension of the comparison to benzoic acids which are only slightly soluble in cyclohexane; applications of this extension will be reported in Part III of this series.

Secondly, as expected (cf. ref. 4), for the four benzoic acids studied, *the dimeric hydrogen bond is stronger than any competing intermolecular hydrogen bonding occurring between benzoic acid and ether molecules.* This follows because if hydrogen-bonded forms of type II were to compete with dimeric forms of type I and if in addition the intermolecular



II

hydrogen bond in II were stronger than the bond in I, structures of type II would be formed preferentially. It would then be inconceivable that the very small amounts of benzoic acid present in cyclohexane solution, containing relatively large amounts of ether, would have the opportunity to dimerize to any appreciable extent. However, dimerization occurs, and hence the initial conclusion follows.

Notwithstanding the conclusion deduced in the previous paragraph, the spectra of the three benzoic acids in 100% ether are believed to correspond to the spectra of monomeric forms. We arrive at this conclusion thus: the absence of concentration dependence in 100% ether suggests that there is present predominantly only one molecular species of acid. At the same time, there is no evidence that, for example, in benzoic acid dimerization predominates below an acid concentration of *ca.* 8×10^{-4} moles/l. (see Fig. 2). Hence the absorption in the concentration region below 8×10^{-4} moles/l. can hardly correspond to dimer absorption, and consequently, since only one acid species is believed to be present, this is assumed to be a monomeric species. A satisfactory way to account for these two, apparently contradictory, observations—that is, that the dimeric hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

bond is stronger than the ether – benzoic acid linkage while at the same time the observed spectra are frequently ascribed to ether – benzoic acid hydrogen-bonded complexes—is to postulate that *neither the dimeric hydrogen bond between benzoic acid molecules nor the intermolecular hydrogen bond between acid and ether molecules represents a stable hydrogen-bonded complex under the conditions of the experiment.* That is, it is assumed that both intermolecular bonds are continuously formed, broken, and re-formed; and the characteristic spectral effect, ascribed to intermolecular hydrogen bonding, will only be observed if bond formation occurs sufficiently often or if the bond formed is sufficiently strong. According to this view benzoic acid molecules, in solution containing large amounts of ether, are sufficiently surrounded by ether molecules so that the spectral effect, ascribed to dimerization, is no longer observed. According to this view also, a stronger dimeric hydrogen bond, as has been postulated in *p*-hydroxybenzoic acid compared with benzoic acid, would be anticipated to require a greater ether concentration to obscure the concentration dependence ascribed to dimerization; whereas a weaker dimeric hydrogen bond, as has been postulated in salicylic acid, would be anticipated to require a smaller ether concentration to achieve the same effect. That these predictions are borne out is indicated from Figs. 2, 4, and 5. Finally, the hypothesis receives indirect support from the work of Coggeshall and Lang (7), who showed the absence of spectral changes for solutions of phenol or aniline at different temperatures, although the temperature change was quite adequate to destroy any hydrogen-bonded complexes. They conclude that for these compounds spectral differences between solutions in polar and non-polar solvents do not depend on stable hydrogen-bonded complexes.

ACKNOWLEDGMENTS

The authors are pleased to acknowledge the assistance of Miss V. M. Walsh and Mr. J. F. Templeton in some of the preliminary work, and they are indebted to Mr. J. C. Dearden for a number of valuable discussions.

THE QUENCHING OF POTASSIUM RESONANCE RADIATION BY HYDROCARBONS[1]

E. A. CHERNIAK[2] AND W. M. SMITH

ABSTRACT

The quenching of the resonance radiation of potassium by some unsaturated and saturated hydrocarbons has been examined at 67° C. The behavior was found to be almost identical with that previously observed with sodium, the saturated hydrocarbons quenching to a negligible extent, the unsaturated hydrocarbons exhibiting cross sections with potassium not significantly different from those exhibited towards sodium.

INTRODUCTION

An examination of the quenching of excited potassium ($4^2P \rightarrow 4^2S$) by hydrogen and deuterium was described in an earlier publication (1). We report here on an extension of the measurements to quenching by some saturated and unsaturated hydrocarbons, work undertaken with a view to obtaining information about the comparative behavior of the various excited alkali metals.

METHOD

The method used to measure the cross sections for the quenching process was the same as that described before (1) except that pyrex resonance vessels were used during all measurements. The features of the method are as follows. Potassium atoms in the 4^2P state are produced at constant rate by irradiation of potassium vapor in a resonance vessel by a filtered beam from a G.E. K-1 lamp. The intensity of the "resonance radiation" (due to return of the excited atoms to the 4^2S state) is estimated in the presence and in the absence of quenching gas. The ratio of these intensities is known as the quenching ratio Q and its values for various pressures of quenching gas are the primary data from which a cross section σ^2 may be estimated (1). Also required is the mean life of a 4^2P potassium atom, and we have taken Stephenson's value 2.71×10^{-8} seconds (2). All measurements were made at $66.7 \pm 0.4°$ C.

MATERIALS

Potassium was purified and introduced into the quenching vessels in the manner described previously (1).

Methane was prepared by the reduction of ethanolic methyl iodide by a zinc–copper couple (3). The gas was passed through fuming sulphuric acid, and potassium hydroxide solution, and was collected for intermediate storage over water in an aspirator bottle. This gas was then passed through a dry-ice trap, fractionally distilled with the aid of liquid air, and dried over potassium before final storage.

Propane was Phillips Research Grade hydrocarbon.

Ethene was from two sources. One sample was Matheson C.P. grade. The other was made by dehydrating ethanol with freshly prepared pyrophosphoric acid (4). The impure ethene was then dried and fractionally distilled as was the methane.

The butenes were Phillips Research Grade hydrocarbons.

RESULTS

It was found that the unsaturated hydrocarbons quench strongly, and that the saturated hydrocarbons quench to an almost negligible extent. Data for the unsaturated hydrocarbons are summarized in Figs. 1 and 2 as plots of $1/Q$ against pressure. These data are in reasonable accord with the Stern-Volmer relation (a linear relation between $1/Q$ and pressure). On the other hand, the saturated hydrocarbons methane and propane led to a significant increase rather than a decrease in the intensity of the resonance radiation. At a pressure of 5 mm of mercury the quenching ratios were 1.03 and 1.10 respectively. Apparently these gases were leading to an increase in the rate of production

For personal use only.

of excited potassium atoms, probably through broadening of the absorption line of the potassium vapor. It is not possible to estimate quenching cross sections for methane and propane from these data, but they must be very small.

Cross sections (σ^2) for quenching by the unsaturated hydrocarbons estimated from the data summarized in Figs. 1 and 2 are given in Table I, along with previously reported values for the quenching of excited potassium by hydrogen (1), and the quenching of excited sodium (5) by all those substances whose behavior with potassium are recorded.

TABLE I

Quenching cross sections ($cm^2 \times 10^{16}$)

Gas	With potassium	With sodium
Ethene	44	44[a]
Butene-1	57	58[a]
cis-Butene-2	57	
trans-Butene-2	57	58[a]
Hydrogen	1.56[b]	7.4[a]

[a]From ref. 5.
[b]From ref. 1.

The cross sections were estimated from values of the slopes of the plots of $1/Q$ against pressure, the effects of added gas on the rate of production of excited atoms being ignored. We do not have data which would enable corrections to be made for this effect, but the fact that methane and propane do apparently increase the absorption suggests that the true values of $1/Q$ and σ^2 for the unsaturated hydrocarbons may be a little greater than recorded in the table. The data for the different butenes have been grouped together in determining a single slope and a single cross section.

DISCUSSION

The hydrocarbons which were investigated exhibit quenching characteristics towards excited potassium (4^2P) which are almost identical with those exhibited by the same gases towards sodium (3^2P) in spite of the difference in the excitation energies of the two metals. On the other hand hydrogen was previously found to exhibit significantly different behavior with the two metals (1).

The data for the saturated and unsaturated hydrocarbons indicate that it is the unsaturated center which is decisive in controlling quenching efficiency. As has been pointed out by Laidler (6) there is no excited singlet level in the alkenes low enough to be excited by either alkali atoms in the ^2P state. It follows that the electronic state of the hydrocarbons does not change in a quenching encounter, and that the electronic excitation energy of potassium is transferred directly into vibrational and rotational.

Theories developed by Laidler (7) and Magee and Ri (8) for processes involving degradation of electronic excitation energy of the excited alkali metals to vibrational and translational suggest that quenching occurs with high cross section only when the excited atom, and quenching molecule, are held in association for periods much in excess of the time of a normal collision, the magnitude of the quenching cross section depending on the probability of change of electronic state during the lifetime of the complex as well as on the cross section for complex formation. No attempt was made to estimate the probability of change of electronic state, and it was assumed that it approached unity unless the rotational energy was unduly high. Magee and Ri's treatment of quenching

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of the excited alkali metals by hydrogen led to such a picture, and also to the prediction that potassium would be quenched by hydrogen less effectively than sodium, essentially because the smaller stability of the complex involving potassium implied a smaller cross section for the association reaction yielding the complex.

The large values of the quenching cross sections for processes involving the alkenes suggest that the probability of change in electronic state approaches unity, and along with the nearly identical values exhibited by a given alkene with both alkali metals, could be taken to imply that the interactions leading to complex formation are very similar. However, cross sections for complex formation considerably in excess of the values implied by atomic radii appear possible, particularly where there are strong ionic contributions to the interaction and it may be that the cross sections for complex formation are somewhat greater than the admittedly large values noted for quenching and that the probabilities of electronic transition are appreciably less than unity. If this were so, the increase in quenching cross sections with increasing molecular weight of the alkene might be due in part to an associated increase in the probability of electronic transition during the lifetime of the complex. It would be enlightening in this connection to have independent means, experimental or theoretical, for estimating the cross sections for complex formation between the alkenes and excited alkali metals in the gas phase.

BROMINATION OF STEROID 20-KETALS[1]

ARTHUR A. AMOS AND P. ZIEGLER

ABSTRACT

Bromination of 3α,12α-diacetoxypregnan-20-one ethylene ketal provided in good yield the corresponding 21-monobromo compound. This product, on acid hydrolysis and subsequent acetolysis, gave the known 3α,12α,21-triacetoxypregnan-20-one. Acid hydrolysis of the bromoketal, followed by Faworsky rearrangement, led to 3α,12α-diacetoxy-17α-methyletiocholanic acid methyl ester.

In order to prepare 11-keto steroids from the readily available 3α,12α-diacetoxypregnan-20-one (I*b*), it had been planned to apply the elegant Glaxo procedure (1, 2) to 3α-acetoxy-12,20-diketopregnane 20-ethylene ketal (VIII*b*), obtained from I. However, when VIII*b* was treated with varying amounts of bromine in methylene chloride at low temperature and in the presence of calcium oxide, the reaction products consisted of mixtures of brominated 20-keto steroids. At no time could VIII*b* be brominated exclusively at C-11; it was apparent that, during the reactions, the ketal group was removed and that bromine also had been substituted at C-17 and/or C-21. It had been observed before (3) that 3β-acetoxy-12,20-diketoallopregnane 12-ethylene ketal could be brominated at C-17, but only with simultaneous hydrolysis of the 12-ketal group. As will be seen later on, 3α,12α-diacetoxypregnan-20-one ethylene ketal (II*b*) could be brominated, under the same conditions as described above, to the corresponding 21-bromoketal (III); this reaction had no effect on the ketal group which remained intact. It is therefore assumed that α-monobromination of the ketal II*b* proceeded by a free radical mechanism during which the substitution of bromine at C-21 and the formation of hydrogen bromide took place without preliminary or concurrent formation of hydrogen ions. The hydrogen bromide did not dissociate rapidly in methylene chloride and the protons that did form were immediately taken up by the calcium oxide. On the other hand, α-brominations of ketones proceed via the enol form of the ketone by an ionic mechanism, during which protons as such are believed to be transferred. In the bromination of VIII*b*, enolization of the 12-keto group and subsequent bromination at C-11 probably produced hydrogen ions in proximity of the 20-ketal group, which then rapidly decomposed. The liberated 20-keto steroid then reacted with more bromine at C-17 and C-21.

Very little information is available on the bromination of ketals. Sapogenins react with bromine in the spiroketal side chain at C-23 giving compounds in which the bromine atom is in the α-position to the potential carbonyl group (4). Similarly, aliphatic acetals react with bromine (5, 6, 7) or N-bromosuccinimide (8) to yield the corresponding α-bromoacetals. An indication that steroidal 3-ketals react with bromine at C-4 has been reported (9). When 3α,12α-diacetoxypregnan-20-one ethylene ketal (II*b*) was brominated, only 1 mole of bromine was taken up, and there was obtained 70–80% of a crystalline monobromo derivative. This compound did not exhibit a ketone band in the ultraviolet region, and it was therefore assumed that the 20-ketal structure had remained unchanged during bromination; elemental analyses indicated structure III or the corresponding 17-bromo isomer. The latter formulation was at first preferred mainly because the reaction of 3α,12α-diacetoxypregnan-20-one (I*b*) with 1 mole of bromine has been reported (10) to provide predominantly the 17-bromo derivative of I*b*. This is in agreement with other

data (11, 12) which indicate that 20-keto steroids with equimolar amounts of bromine provide the related 17-bromo compounds. The bromoketal III was then found to yield, after treatment with 80% acetic acid and subsequent acetolysis, the known (13) 3α,12α,21-triacetoxypregnan-20-one (V); this clearly proved that the bromine atom in III was attached to C-21, and that compounds I*b* and II*b* react in a different manner towards bromine.

The bromoketal III was then converted quantitatively, by vigorous acid hydrolysis, to the bromoketone IV; carbon and hydrogen analyses for this compound did not correspond to the assigned empirical formula, a finding which had been made previously (13) when IV was obtained by an entirely different route. This discrepancy was ascribed to partial decompositon during recrystallization. The identity of IV was verified by its conversion to V by acetolysis and acetylation. As expected, the bromoketone IV underwent a Faworsky rearrangement upon mild alkaline treatment to afford, after acetylation, the known (10, 14) methyl 3α,12α-diacetoxy-17α-methyletiocholanate (VI*b*). This type of rearrangement has been described both in the case of 17- and 21-halogenated 20-keto steroids (15).

Preliminary results show that ketals, closely related to II*b* but which lack the 12α-acetoxy group, cannot be monobrominated at C-21 in good yield. Thus 3α-acetoxypregnan-20-one ethylene ketal with equimolar amounts of bromine yields a dibromoketal of as yet unknown constitution.

EXPERIMENTAL*

3α,12α-Diacetoxypregnan-20-one Ethylene Ketal (II*b*)

Compound I*b* (10 g) and *p*-toluenesulphonic acid (0.25 g), dissolved in a mixture of dry benzene (150 ml) and ethylene glycol (20 ml), were stirred and refluxed for 16 hours. During this time 1.05 ml of water was collected in a Dean-Stark trap. The reaction mixture was then neutralized by addition of sodium bicarbonate (2.2 g), the solvents were evaporated *in vacuo*, and the residue was taken up in water and ether. The ether extract, after being washed with water, dried over sodium sulphate, and evaporated, provided the crude products (10.8 g) which crystallized readily from methanol to yield 8.75 g (80%) of crystals, m.p. 141–142°. One crystallization from ether–hexane and three from methanol gave pure II*b*, m.p. 145–146° and $[\alpha]_D^{25}$ +124.2° (*c*, 0.512, ethanol). Anal. Calc. for $C_{27}H_{42}O_6$: C, 70.09; H, 9.15; O, 20.77. Found: C, 69.79; H, 9.21; O, 21.00.

3α,12α-Dihydroxypregnan-20-one Ethylene Ketal (II*a*)

The diacetoxyketal II*b* (10 g) was saponified by refluxing for 17 hours with potassium hydroxide (10 g), water (5 ml), and ethanol (95 ml). The solution was cooled to 20°, poured into water (600 ml), and the gummy mixture was stirred for ½ hour. The solid was then filtered off, washed with water, and dried to yield 8.05 g (98.5%) of product, m.p. 157–158°. After three recrystallizations from ether, this material had m.p. 157–159° but did not give satisfactory elemental analyses. It was dissolved in benzene, the solvent was distilled off, and the residue was crystallized twice from ether–iso-octane to give m.p. 146.5–148° and $[\alpha]_D^{25}$ +82.8° (*c*, 0.528, ethanol). Anal. Calc. for $C_{23}H_{38}O_4$: C, 72.97; H, 10.12. Found: C, 73.19, 73.10; H, 10.36, 10.28.

3α-Acetoxy-12α-hydroxypregnan-20-one Ethylene Ketal (VII)

Compound II*a* (2 g) was acetylated at 25° with pyridine (1.35 ml) and acetic anhydride (0.81 ml). After 20 hours the solution was diluted with water and ether, the solvent

**Microanalyses were kindly performed by Mr. E. Thommen, Basel, Switzerland.*

extract was washed several times with water, dried, and evaporated. The residue (2.4 g) crystallized from ether–hexane to provide 1.55 g (70%) of product, m.p. 154–156°. Three recrystallizations from methanol gave pure VII, m.p. 163–164° and $[\alpha]_D^{25}$ +72° (*c*, 0.541, ethanol). Anal. Calc. for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59; O, 19.02. Found: C, 71.46; H, 9.74; O, 19.22.

3α-Acetoxy-12,20-diketopregnane 20-Ethylene Ketal (VIII*b*)

Compound VII (3 g) in *t*-butanol (45 ml) and pyridine (1.35 ml) was oxidized with N-bromosuccinimide (2.47 g) at 20° under constant stirring. After 6 hours the orange-red solution was poured into water (200 ml), the mixture was stirred briefly, then refrigerated overnight. The solid was filtered off, washed with dilute sodium sulphite solution and then with water. The dry material (3 g), m.p. 195–200°, was crystallized first from ethyl acetate, then from ether to afford VIII*b*, m.p. 226–228° and $[\alpha]_D^{25}$ +111.8° (*c*, 0.214, ethanol). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.73; H, 9.15; O, 19.11. Found: C, 71.85, 71.92; H, 9.35, 9.27; O, 19.02.

3α-Hydroxy-12,20-diketopregnane 20-Ethylene Ketal (VIII*a*)

Saponification of VIII*b* by refluxing with methanolic potassium hydroxide and subsequent isolation by precipitation with water, afforded quantitatively crude VIII*a*, m.p. 166–168°. Several recrystallizations from ethyl acetate gave the analytical specimen, m.p. 171–172° and $[\alpha]_D^{25}$ +105.5° (*c*, 0.679, ethanol). Anal. Calc. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64. Found: C, 73.30, 73.40; H, 9.81, 9.78.

Bromination of 3α-Acetoxy-12,20-diketopregnane 20-Ethylene Ketal (VIII*b*)

The reactions were carried out in methylene chloride at 0° to −10° in the presence of calcium oxide. With stirring, 1–4 molar equivalents of bromine was added within 10–20 minutes, whereupon the mixtures were poured into dilute sodium bicarbonate solution. The organic solvent extracts were then washed with water, dried, and evaporated to a residue.

Using 1, 2.4, 3, or 4 molar equivalents of bromine and resorting to fractional crystallization of the crude reaction products, two compounds could be isolated. The first of these had m.p. 210–213° (decomp.), $[\alpha]_D^{25}$ −19.1° (*c*, 0.404, chloroform), and contained 42.64% C, 4.31% H, and 42.6% Br. On refluxing with 80% acetic acid, the material remained unchanged which indicated that the ketal group was hydrolyzed during bromination. The same product, having m.p. 212–215° (decomp.) and $[\alpha]_D^{25}$ −19.2° (*c*, 0.414, chloroform), was also obtained when 3α-acetoxypregnan-12,20-dione was brominated under similar conditions. The second compound, isolated in only small amounts, had m.p. 200–202° (decomp.) and $[\alpha]_D^{25}$ −31.8° (*c*, 0.432, chloroform). Since monobromination of VIII*b* at C-11 could not be effected, these experiments were discontinued.

3α,12α-Diacetoxy-21-bromopregnan-20-one Ethylene Ketal (III)

To a solution of II*b* (10 g) in methylene chloride (170 ml) there was added calcium oxide (4.35 g), and the mixture was cooled to −10°. With constant stirring, a solution of bromine (4.66 g; 1.34 molar equivalents) in methylene chloride (30 ml) was added dropwise and, after ½ hour, the red mixture was poured into water (150 ml) containing sodium bicarbonate (8 g). The organic solvent extract was washed with sodium thiosulphate solution, then with water, dried over sodium sulphate, and evaporated. Crystallization of the residue (12.6 g) from aqueous methanol provided 8.2 g (74%) of product, m.p. 138–140°. Repeated recrystallization from methanol gave pure III, m.p. 145–147° and $[\alpha]_D^{25}$ +100.7° (*c*, 0.35, ethanol). Anal. Calc. for $C_{27}H_{41}O_6Br$: C, 59.88; H, 7.63; Br, 14.76. Found: C, 59.91, 59.78; H, 7.60, 7.71; Br, 14.80.

For personal use only.

3α,12α-Dihydroxy-21-bromopregnan-20-one (IV)

Compound III (6 g) was refluxed for 1¼ hours with methanol (60 ml) and concentrated hydrochloric acid (3 ml). Dilution with water (100 ml) produced a precipitate which was filtered off, washed with water, and dried; the solid (4 g; 94%), m.p. 147–150°, was crystallized once from aqueous methanol and twice from ether to afford a sample for analysis, m.p. 147–150°, $[\alpha]_D^{25}$ +151° (*c*, 0.284, chloroform). Anal. Calc. for $C_{21}H_{33}O_3Br$: C, 61.01; H, 8.05. Found: C, 64.74, 64.43; H, 8.56, 8.88. This compound has been reported (13) to have m.p. 148–150°, $[\alpha]_D^{25}$ +148.5° (*c*, 0.793, chloroform), and giving the following analyses: C, 64.57; H, 8.85; Br, 17.54.

3α,12α,21-Triacetoxypregnan-20-one (V)

(*a*) *From* III.—The bromoketal III (2.5 g) was heated on the steam bath for 2¼ hours with 80% acetic acid (65 ml) in order to hydrolyze the ketal grouping. After addition of water, the products were extracted with ether, the ether extract was washed with dilute sodium bicarbonate and then with water. The residue (2.3 g) from evaporation of solvent was refluxed for 16 hours with potassium acetate (9.2 g), potassium iodide (35 mg), acetic acid (1.4 ml), and acetone (138 ml). After the mixture had been cooled the salts were filtered off, the filtrate was evaporated to a small volume, and the residue was taken up in ether and water. From the ether extract a gum (2.3 g) was obtained, which crystallized from ether–hexane to yield 0.89 g of material, m.p. 143–148°. Four recrystallizations gave pure V, m.p. 151–152° and $[\alpha]_D^{25}$ +151.7° (*c*, 0.23, acetone). Anal. Calc. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 68.16, 68.24; H, 8.33, 8.37. This compound was reported (13) to have m.p. 153–153.5° and $[\alpha]_D^{25}$ +159.5° (*c*, 1.03, acetone).

(*b*) *From* IV.—Compound IV (100 mg) was refluxed for 17 hours with freshly fused potassium acetate (200 mg), potassium iodide (5 mg), acetic acid (0.25 ml), and acetone (10 ml). The cooled solution was diluted with water, extracted with ether, and the solvent extract was washed and dried. Acetylation of the residue (90 mg) with pyridine (2.5 ml) and acetic anhydride (5 ml) at 25° for 18 hours, followed by solvent extraction of the products and working up in the usual manner, yielded a gum which crystallized from ether–hexane. There was obtained 81 mg (71.5%) of V, m.p. 148–152°, giving no depression in melting point on admixture with a sample of V obtained in the previous experiment.

3α,12α-Diacetoxy-17α-methyletiocholanic Acid Methyl Ester (VI*b*)

Compound IV (1 g) was dissolved in methanol (75 ml), a solution of sodium hydroxide (0.8 g) in water (25 ml) was added, and the resulting solution was kept at 25° for 20 hours. After neutralization of the alkali with acetic acid (1.2 ml), most of the methanol was evaporated, and the products were taken up in ether and water. The solvent extract, after having been washed with water, dried, and evaporated, provided a residue (0.95 g); this was acetylated at 20° with pyridine (2.5 ml) and acetic anhydride (5 ml) to afford, subsequent to the usual work-up, 1.08 g of material which failed to crystallize. Chromatography on alumina finally yielded 0.15 g of crystals, m.p. 160–162°, eluted from the column with benzene–hexane (2:3 and 3:2). One recrystallization from hexane gave pure VI*b*, m.p. 163–164° and $[\alpha]_D^{25}$ +121.9° (*c*, 0.305, chloroform). This compound has been reported (10, 14) to have m.p. 161–161.5°, 163–165°, and $[\alpha]_D^{25}$ +117.4° (*c*, 0.78, chloroform).

3α,12α-Dihydroxy-17α-methyletiocholanic Acid Methyl Ester (VI*a*)

Saponification of VI*b* (100 mg) with 5% methanolic potassium hydroxide (10 ml) for 4 hours at reflux temperature and precipitation of the product by addition of water

(40 ml) gave crude VI*a* (80 mg), having double m.p. 95–100° and 155–156°. This was crystallized from ether–hexane to yield the pure compound, m.p. 155–157° and $[\alpha]_D^{25}$ +51.1° (*c*, 0.351, chloroform). The literature (10) reports m.p. 152–152.5° and $[\alpha]_D^{22}$ +42.3° (*c*, 0.79, chloroform).

STERIC INHIBITION OF RESONANCE

I. 9-NITROANTHRACENE AND 9,10-DINITROANTHRACENE[1]

JAMES TROTTER[2]

ABSTRACT

Detailed X-ray analyses of the crystal structures of 9-nitroanthracene and 9,10-dinitroanthracene have shown that the nitro groups are tilted out of the planes of the aromatic rings by 84.7° in the nitro derivative and 63.7° in the dinitro. The decreases in resonance interaction resulting from these deviations from coplanarity have been correlated with the characteristic vibration frequencies of the nitro groups.

INTRODUCTION

Examination of some of the physical properties of the nitro and acetyl derivatives of durene and mesitylene suggests that the steric effect of the methyl groups prevents the attainment of a completely coplanar configuration, and reduces the resonance interaction between the aromatic π-electrons and the substituent nitro and acetyl groups. Consideration of Raman and infrared frequencies, dipole moments, ultraviolet spectra, acid-base strengths, and rates of reaction indicates a great amount of inhibition of resonance in this type of molecule (1). Few direct measurements of the deviations from coplanarity have been made however.

Huse and Powell (2) have investigated the crystal structure of picryl iodide (I) by X-ray diffraction methods; their results indicate that the para-nitro group is coplanar with the benzene nucleus and, owing to resonance with ionic structures (II), the para C–N bond length (1.35 Å) is much shorter than the normal single bond distance, but the planes of the ortho-nitro groups are approximately at right angles to the benzene ring, there is no resonance with the aromatic π-electrons, and the ortho C–N bond length (1.45 Å) corresponds closely to the single bond distance. The molecular geometry and dimensions have not been determined very accurately, however, owing to the presence of the heavy iodine atom.

Francel (3) has investigated the infrared spectra of five ortho-substituted nitrobenzenes in the solid state using polarized radiation. The polarization of the absorption band arising from the asymmetric NO_2 stretching vibration in *o*-nitrobromobenzene indicates that the nitro group is rotated well out of the plane of the benzene ring owing to the steric effect of the bromine atom, and is probably almost perpendicular to the ring. The polarization of the bands in the corresponding chloro derivative is assumed to indicate a smaller angle between the benzene ring and the nitro group, which would be expected because of the difference in the van der Waals radii of chlorine and bromine. Again, however, no accurate measure of the deviation from coplanarity has been possible.

The present investigations, which are confined chiefly to nitro derivatives, were undertaken to obtain accurate measurements of the tilts of the planes of the substituent groups out of the aromatic planes, using X-ray diffraction methods, and to correlate these values with the reduction in resonance interaction, the bond lengths in the molecules, the infrared frequencies, dipole moments, and other physical data.

Such steric effects and resonance inhibition should be observable also in 9- and 9,10-substituted anthracenes, where the environments of the substituent groups are very similar to those in durene and mesitylene derivatives. Contributions to the ground state of the 9-nitroanthracene molecule from structures such as III and IV would be greatest when the nitro group is coplanar with the anthracene nucleus, but this involves distances which are much less than the usual van der Waals separations, between the oxygen atoms and the hydrogen atoms bonded to carbons 1 and 8. It would be expected that the strain due to this 'overcrowding' would be relieved by rotation of the nitro group about the C–N bond. Jones (4, 5) has examined the ultraviolet spectra of certain 9,10-diarylanthracenes, and observes that the introduction of phenyl groups, for example, at positions 9 and 10 causes very little change in the anthracene spectrum, and indeed methyl groups actually produce a greater displacement towards longer wavelengths. He concludes that the phenyl groups are hindered to such an extent that they probably lie more or less perpendicular to the main plane of the anthracene nucleus.

The infrared spectra of 9-nitroanthracene and 9,10-dinitroanthracene have now been measured, and the characteristic nitro group vibration frequencies have been correlated with the angles between the planes of the nitro groups and the anthracene nuclei. These angles have been determined by accurate X-ray analyses of the crystalline materials. Extension of these investigations to durene and mesitylene derivatives will be described in subsequent communications.

EXPERIMENTAL

Preparation and Purification of Materials

Commercial 9-nitroanthracene was purified by chromatography on alumina and crystallization from petroleum ether, giving yellow crystals melting at 146°. From this material 9,10-dinitroanthracene was prepared by nitration with nitric acid in acetic anhydride, and then purified by chromatography and crystallization, giving yellow crystals, melting point 310°. Crystals of each substance grown by slow crystallization from petroleum ether were suitable for the X-ray examinations.

Infrared Spectra

The spectra measured (Fig. 1) were those of 1 mg of the pure solids dispersed in potassium bromide disks of thickness 1 mm and weighing 400 mg as observed with a Perkin–Elmer model 21 infrared spectrophotometer with a rock salt prism. The peak positions of the NO_2 symmetrical stretching frequencies in the region of 1370 cm^{-1} were more accurately determined using a Perkin–Elmer spectrometer model 12C, but these more accurate values agreed closely with the previously measured frequencies.

X-Ray Analyses

Crystals of 9-nitroanthracene are monoclinic with four molecules in a unit cell of dimensions $a = 7.49$, $b = 13.77$, $c = 11.44$ Å, $\beta = 115°11'$, space group $P2_1/a$. The structure was determined from projections along the three principal crystallographic axes. The nitro group is very markedly tilted out of the plane of the anthracene nucleus about the C–N bond, the angle between the planes of the aromatic ring and of the nitro group being 84.7°. Figure 2 shows a projection of the structure along the c-axis; the individual atoms are not separately resolved in this projection, but the large deviation from coplanarity is well illustrated.

9,10-Dinitroanthracene is triclinic with one molecule in a unit cell of dimensions $a = 3.95$, $b = 8.68$, $c = 8.76$ Å, $\alpha = 106°46'$, $\beta = 98°59'$, $\gamma = 98°01'$, space group

$P\bar{1}$. In the projection along the short a-axis all the atoms are very well resolved. Figure 3 shows a projection of the structure along the b-axis, in which the resolution of the individual atoms is not so good, but which shows very clearly the tilt of the nitro groups. The molecule is centrosymmetrical and the angle between the planes of a nitro group and the aromatic nucleus is in this case 63.7°. This deviation from planarity is just sufficient to increase the separations between the oxygen atoms and neighboring carbon and hydrogen atoms to the normal van der Waals distances. Full details of the crystal structure analyses are published elsewhere (6, 7).

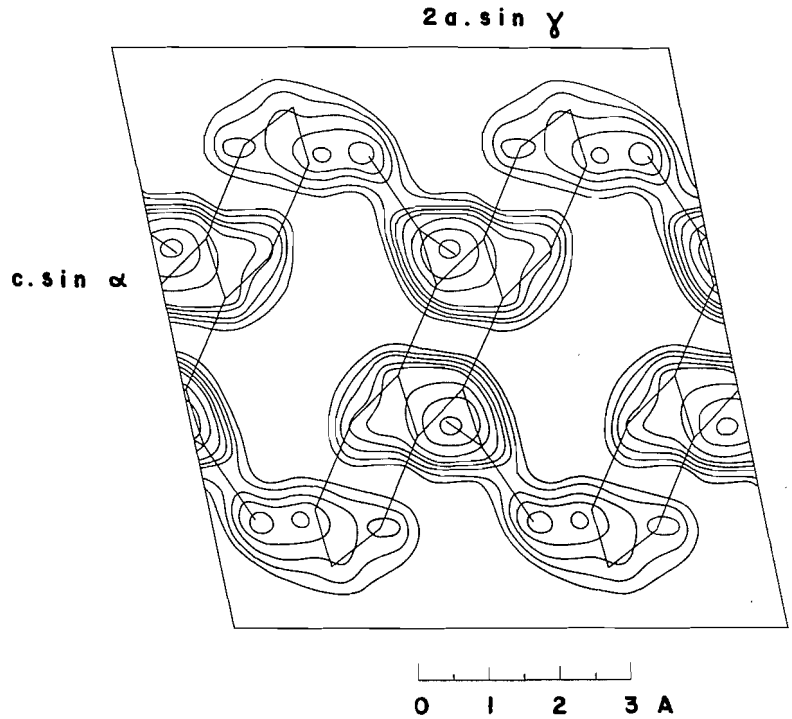

FIG. 3. Projection of the 9,10-dinitroanthracene structure along the b-axis, showing the nitro-group tilts.

DISCUSSION

The spectra of 9-nitroanthracene and 9,10-dinitroanthracene in the range 2000 cm^{-1} to 600 cm^{-1} are shown in Fig. 1, and the peak positions and intensities of the absorption bands are listed in Table I. The maxima at 1374 cm^{-1} in 9-nitroanthracene and at 1367 cm^{-1} in 9,10-dinitroanthracene can be assigned to the NO_2 symmetrical stretching vibrations, the intensity of the absorption in the dinitro compound being about double that in the mononitro derivative. The NO_2 asymmetrical stretching vibrations cannot be assigned quite so unambiguously. In 9,10-dinitroanthracene there are bands of about equal intensity at 1519 cm^{-1} and 1542 cm^{-1}, while in the 9-nitro there is a band at 1519 cm^{-1} corresponding in intensity to that of the dinitro derivative and a shoulder at 1540 cm^{-1} of about half this intensity, and on this basis the bands around 1540 cm^{-1} have been assigned to the NO_2 asymmetrical stretching vibrations.

The C–N stretching frequency in nitromethane (8) is at 918 cm^{-1}, although it is at rather lower frequencies in the higher nitroparaffins (at 804 cm^{-1} in 1-nitropropane for

example), while in aromatic nitro compounds (9) it is at 849 cm^{-1}. The absorption maxima at 836 cm^{-1} and 831 cm^{-1} in the meso-nitroanthracenes can be assigned to the C–N stretching vibrations. The strong absorption at 890 cm^{-1} in the mononitro derivative, which is not observed in the dinitro, corresponds to the C_{10}–H out-of-plane vibration.

In Table II the characteristic nitro group frequencies in 9-nitroanthracene and 9,10-dinitroanthracene are compared with those in nitromethane and those in typical aromatic nitro compounds (9). In aromatic nitro compounds contributions from ionic structures of type V lead to a decrease in the force constant of the N–O bonds and a consequent decrease in the NO_2 symmetrical and asymmetrical stretching frequencies (1349 cm^{-1} and 1518 cm^{-1}) compared with non-conjugated nitro compounds (1377 cm^{-1} and 1586 cm^{-1} in nitromethane). The frequency of the NO_2 symmetrical stretching vibration in 9-nitroanthracene is much higher than in nitrobenzene, and nearly equal to the frequency in nitromethane, corresponding to a negligible amount of resonance interaction between the nitro group and the anthracene nucleus. In 9,10-dinitroanthracene the band is at 1367 cm^{-1}, indicating a very marked reduction in resonance interaction compared with nitrobenzene, but also suggesting that the resonance is not inhibited to such an extent as in the 9-nitro derivative.

These frequencies are in accord with the tilts of the nitro groups out of the aromatic planes, which are given in the final column of Table II. The tilt has been assumed to be zero in nitrobenzene, although this is not quite certain; X-ray crystal analyses of *p*-dinitrobenzene for example have shown that the nitro group is tilted 9°25′ out of the plane of the benzene ring in this molecule (10). Resonance interaction is at a maximum in nitrobenzene (corresponding to $\theta = 0°$) and zero in nitromethane (corresponding effectively to $\theta = 90°$). The frequencies of the NO_2 symmetrical stretching vibrations indicate that resonance between aromatic rings and nitro groups is almost completely inhibited

TABLE II

Characteristic nitro-group frequencies (cm^{-1}) and deviations from coplanarity

Molecule	NO_2 stretching		C–N stretching	NO_2 tilt (θ in degrees)
	Symmetrical	Asymmetrical		
Nitromethane	1377	1586	918	90
9-Nitroanthracene	1374	1540	836	84.7
9,10-Dinitroanthracene	1367	1542	831	63.7
Aroamtic nitro compounds	1349	1518	849	0

in 9-nitroanthracene ($\theta = 85°$) and inhibited to a large extent in 9,10-dinitroanthracene ($\theta = 64°$). The NO_2 asymmetrical stretching vibrations in 9-nitro and 9,10-dinitroanthracene are also in accord with resonance inhibition, although quantitatively the agreement is not so good.

Resonance inhibition decreases the weight of ionic structures such as III and IV, and the resulting decrease in the force constant of the C–N bond should lead to lower frequencies for the C–N stretching vibration in 9-nitroanthracene and 9,10-dinitro-

anthracene than in nitrobenzene, in agreement with the observed frequencies. The C–N stretching frequency in nitromethane would then appear to be anomalous, but the higher frequency in this case is not unexpected as the carbon atom can vibrate more freely than those in the more rigid aromatic molecules.

The characteristic NO_2 vibration frequencies in meso-nitroanthracenes then indicate a marked inhibition of the resonance interaction between the nitro groups and the aromatic π-electrons, in complete agreement with the effect which would be predicted from a measure of the tilts of the nitro groups out of the aromatic planes. For the NO_2 symmetrical stretching frequencies the results would appear to be semiquantitative, but this is probably fortuitous, since only qualitative agreement is obtained with the other characteristic vibrations. Only qualitative agreement is to be expected of course, since the nitro-group frequencies are not entirely independent of the remainder of the molecule, and small frequency variations are observed among quite similar aromatic molecules where no steric effects are involved. Quantitative information concerning the resonance interaction may be obtained from an examination of the bond lengths in these molecules, since structures of types III and IV would impart a considerable amount of double bond character to the C–N bond, reduce the double bond character of the N–O bonds, and also influence the bond lengths in the aromatic rings. Discussion of these quantitative relations obtainable from a study of the bond length variations will be given in later communications.

ACKNOWLEDGMENTS

The author wishes to thank Dr. W. G. Schneider for samples of 9-nitroanthracene and 9,10-dinitroanthracene, and Mr. R. Lauzon for recording the infrared spectra.

THE SYNTHESIS OF 4-*O*-β-D-GALACTOSYL-D-GLUCOSE (LACTOSE)[1]

E. J. C. CURTIS AND J. K. N. JONES

ABSTRACT

4-*O*-β-D-Galactosyl-D-glucose (lactose) has been synthesized using a modification of the Koenigs–Knorr reaction.

INTRODUCTION

4-*O*-β-D-Galactosyl-D-glucose (lactose) occurs in all mammalian milk to the extent of about 5%. It has also been reported in the long-styled pollen of forsythia flowers. It was prepared in 1942 by Haskins, Hann, and Hudson (1) from epilactose (4-*O*-β-D-galactosyl-D-mannose), but has not previously been synthesized directly.

One of the most useful methods of disaccharide synthesis is that due to Koenigs and Knorr (2). They prepared tetra-*O*-acetyl-α-D-glucopyranosyl-bromide and found that this, in the presence of silver carbonate or dry pyridine, reacted with methanol to form methyl-β-D-glucopyranoside. The reaction—essentially the elimination of hydrogen halide between a glycosyl halide and a hydroxyl group—was adapted for disaccharide synthesis by Helferich (3) and by Hudson (4). They allowed the acetobrom sugar to react with a suitably substituted sugar derivative in a dry inert medium in the presence of silver carbonate or silver oxide. With modern refinements—use of "Drierite" as drying agent and small amounts of iodine as catalyst—good yields can be obtained in the case of $1 \rightarrow 6$ linked hexose disaccharides, where a primary hydroxyl group is involved. However, up to the present only small yields have been obtained in the case of disaccharides where a secondary hydroxyl group is involved. This is due to the lesser reactivity of the secondary hydroxyl group and to steric hindrance by the alcohol component due to the presence of the hemiacetal ring and the substituent groups. It was thought that this second factor might be lessened—and thus greater yields obtained—by the use of an open-chain sugar derivative as the alcohol reactant. Here the accessibility of the hydroxyl group is much greater than in the corresponding ring compound.

In the present work 2,3-5,6-di-*O*-isopropylidene-D-glucose diethyl acetal was condensed with acetobrom-D-galactose under standard Koenigs–Knorr conditions (5). The reaction mixture was boiled with sodium hydroxide solution to remove acetyl groups from the product and to destroy excess acetobrom-galactose, cooled, and deionized. Hydrolysis of isopropylidene and acetal groups was carried out with hot dilute acetic acid. The resulting mixture of mono- and di-saccharides was separated by charcoal- and paper-chromatography. Lactose was obtained crystalline in 35% yield, which is well in excess of the yields usually obtained from Koenigs–Knorr syntheses where a secondary hydroxyl group is involved. Two other disaccharide fractions were obtained in small yield. These have not been completely identified but presumably result from isomers of 2,3-5,6-di-*O*-isopropylidene-D-glucose diethyl acetal. These are inevitably present in small amount as a result of the method of preparation of this compound (via a mercaptal mixture (8) consisting mainly of the 2,3-5,6-di-*O*-isopropylidene derivative).

EXPERIMENTAL

Optical rotations were measured in water at 21°±2° C. The following solvent systems (v/v) were used to separate sugars on paper chromatograms: (A) ethyl acetate: acetic acid: formic acid: water, 18:3:1:4; (B) *n*-butanol:ethanol: water, 3:1:1. Sugars were

[1]*Manuscript received August 11, 1958.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

detected with the *p*-anisidine hydrochloride spray (6). Solutions were concentrated under reduced pressure at 40° C.

D-*Glucose Diethyl Thioacetal* (*Ref. 7*)

D-Glucose (60 g), ice-cold ethanethiol (60 ml), and ice-cold concentrated hydrochloric acid (60 ml) were shaken together in a stoppered flask, and left at room temperature. After 3 hours the material had formed a crystalline mass. Methanol (*ca.* 300 ml) was added and sufficient lead carbonate to neutralize the solution, which was then filtered and the precipitate washed with boiling methanol. The crude product crystallized from the filtrate on cooling and was recrystallized from methanol. Yield: 62 g (65%), m.p. 119–120° C.

Di-O-isopropylidene-D-*glucose Diethyl Thioacetal* (*Ref. 8*)

Glucose diethyl thioacetal (36 g) was added to a mixture of dry acetone (350 ml) and concentrated sulphuric acid (8.5 g) and the resulting solution was left at room temperature for 72 hours. The solution was neutralized with a solution of barium hydroxide in methanol, and filtered. The filtrate was evaporated to a pale yellow mobile syrup. Yield: 35 g.

Di-O-isopropylidene-D-*glucose Diethyl Acetal*

The method used was similar to that employed by Wolfrom *et al.* (9) in the preparation of D-galactose diethyl acetal pentaacetate. Di-*O*-isopropylidene-D-glucose diethyl thioacetal (40 g), mercuric oxide (80 g), and lead carbonate (20 g) were added to dry ethanol (400 ml) and the solution heated to 70–80° C while it was being stirred. A solution of mercuric chloride (176 g) in dry ethanol (300 ml) was then added and the solution stirred for 5 hours at 70–80° C with occasional addition of mercuric oxide. The solution was filtered hot and the precipitate washed with hot ethanol. The filtrate was evaporated to a small volume and then diluted with chloroform (400 ml). This chloroform solution was extracted with water until chloride-free and dried over Drierite. Filtration and subsequent evaporation yielded a syrup (30 g), which was purified by distillation, a fraction (22 g) being collected with b.p. 130–140° C at 0.05 mm.

Condensation of Di-O-isopropylidene-D-*glucose Diethyl Acetal with Acetobromo*-D-*galactose*

Di-*O*-isopropylidene-D-glucose diethyl acetal (15 g, 0.0449 mole) was dissolved in dry, alcohol-free chloroform (200 ml) and to the solution were added Drierite (20 g), silver oxide (20 g), and glass beads (35 g). The solution was shaken in the dark. After 4 hours acetobrom-D-galactose (46 g, 0.112 mole) in dry, alcohol-free chloroform (150 ml) and iodine (1 g) were added and the shaking continued. After 42 hours a test for ionizable bromine was negative. The solution was filtered, evaporated to a syrup, and dissolved in a solution of sodium hydroxide (20 g) in methanol (400 ml). This was heated under reflux for 3.5 hours, cooled, and de-cationized on Amberlite IR-120 resin in the cold. The acidic eluate was heated at 65° C for 1 hour in order to hydrolyze isopropylidene and acetal groups, and then de-ionized by passage through a column of Duolite A-4 resin. Concentration of the eluate yielded a syrup (20 g) which was shown by paper chromatography to consist, in addition to glucose and galactose, of a main fraction with R_{gal} 0.45 (solvent A) and 0.28 (solvent B) and two much smaller spots running slightly in front of, and behind, this spot.

A portion of the syrup (8.1 g) was fractionated on a column of Darco charcoal (4×5 cm) (10). Elution with water removed all the monosaccharide and in the final stages a faint trace of the slower-moving components: subsequent elution with ethanol/water (5:95) removed the bulk of the slower-moving components (2.9 g). This latter syrup

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

was dissolved in a little moist methanol, nucleated with authentic lactose, and the solvent allowed to evaporate at room temperature. Part of the material crystallized, 1.8 g being obtained. It was recrystallized from moist methanol and was found chromatographically to be a single substance indistinguishable from lactose. Hydrolysis yielded galactose and glucose in equal amounts. It had m.p. 201–202° C undepressed by admixture with an authentic specimen of lactose monohydrate, and $[\alpha]_D$ +86.3 (5 min) → +58.1° (16 hr). The infrared spectra of the material and of authentic lactose monohydrate were identical. Calculated for $C_{12}H_{22}O_{11}.H_2O$: C, 40.00%; H, 6.67%. Found: C, 40.19%; H, 6.82%.

Part of the syrup which failed to crystallize (0.6 g) was separated on filter paper (Whatman No. 3 MM). A further quantity of lactose (0.20 g) was obtained in addition to two other fractions: I (51.2 mg) and II (49.9 mg). Fraction I had R_{gal} 0.33 (solvent A) and 0.15 (solvent B) while II had R_{gal} 0.47 (solvent A) and 0.32 (solvent B). Both fractions yielded galactose and glucose in equal amounts on hydrolysis.

Periodate Oxidation of Fractions I and II

Portions of fractions I and II were oxidized with aqueous sodium metaperiodate solution using standard procedures. The periodate uptake was estimated by the method of Neumüller and Vasseur (11) and the formic acid liberation by that of Andrews *et al.* (12).

The molar periodate consumptions per mole of disaccharide were as follows: fraction I, 3.90 (after 25 min), 4.44 (1 hr), 4.75 (3.5 hr), and 4.83 (22 hr); fraction II, 2.35 (0.5 hr), 2.84 (1 hr), 3.08 (4 hr), and 3.56 (22 hr). The molar productions of formic acid were: fraction I, 3.77 (after 40 min), 4.29 (1.5 hr), 4.92 (4 hr), and 5.34 (22.5 hr); fraction II, 1.01 (40 min), 1.25 (1.5 hr), 1.41 (4 hr), and 2.12 (22.5 hr). Extrapolation of the flat part of the curve to zero time gave values of: fraction I, periodate uptake = 4.78 moles per mole of sugar, formic acid production = 4.41 moles per mole; fraction II, periodate uptake = 2.95 moles per mole sugar, formic acid production = 1.17 moles per mole.

The figures for fraction I are difficult to interpret. The large amount of formic acid could not have come from any normal type of sugar and it may be that this fraction is a mixture of disaccharide and some other material. The figures for fraction II—where the slope of the flat part of the periodate and formic acid curves indicates that over-oxidation was taking place—are those to be expected of a 1 → 3 linked hexopyranose disaccharide. Crystalline derivatives of fractions I and II have not yet been obtained.

THE INFRARED SPECTRA OF SOME CYCLIC MALONATES[1]

R. A. ABRAMOVITCH

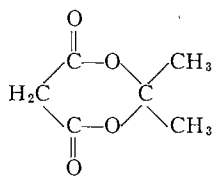
ABSTRACT

The infrared spectra of isopropylidene malonate and some of its derivatives have been examined and compared with those of open-chain malonate esters and of 5,5-dimethylcyclohexane-1,3-dione. Two bands in the carbonyl stretching region are attributed to vibrational coupling of the carbonyl groups in the cyclic esters. There is no evidence that isopropylidene malonate exists in the enolic form either in the solid state or in chloroform solution. This cyclic ester structure for "Meldrum's acid" is thus confirmed.

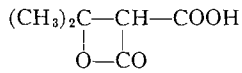
In an investigation of the infrared spectra of a number of malonate esters it was shown (1) that most of them exhibited two ester carbonyl stretching bands, and that these were not due to enolization and conjugate chelation, or to association. It was not possible, at that stage, to decide whether these double carbonyl bands were due to vibrational coupling or to rotational isomerism, or yet perhaps to another still unknown cause.

It was of interest to determine whether, in the absence of the possibility of rotational isomerism, two ester carbonyl groups beta- to each other could undergo vibrational coupling. For this purpose the spectra of isopropylidene malonate and some of its derivatives have been examined, since apart from ethylene glycolyl malonate (2) (which is not unambiguously characterized), no other simple cyclic esters of malonic acid seem to be known. Vibrational coupling does not appear to have been observed in cyclic 6-membered β-diketones: here, enolization with intermolecular chelation has been reported (3). The carbonyl groupings, which are beta- to each other, in cyclic anhydrides are known to undergo coupling (4), and it has recently been suggested that this type of interaction also occurs in substituted isatoic anhydrides (5) though in this case the carbonyl groups are different in nature and one would have expected each to exhibit its own stretching frequency.

Isopropylidene malonate (I) poses an interesting structural problem which was largely clarified by the work of Davidson and Bernhard (6). The cyclic ester, also known as "Meldrum's acid", is prepared by the action of acetone on malonic acid in a cold acetic anhydride – sulphuric acid medium, and was originally attributed the structure of β,β-dimethyl-β-propiolactone-α-carboxylic acid (II). On the basis of chemical evidence Davidson and Bernhard were able to suggest structure (I) for the product and structure (III) for the dimethylated derivative.



(I)



(II)

They compared the reactions of the cyclic ester with those of 5,5-dimethylcyclohexane-1,3-dione (IV) and attributed the acidity of the ester (pK_a 5.1) to enolization (($I \rightleftarrows V$) in the same way as the acidity of 5,5-dimethylcyclohexane-1,3-dione (pK_a 5.2) is

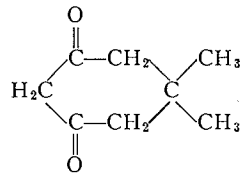
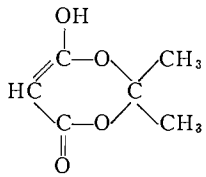
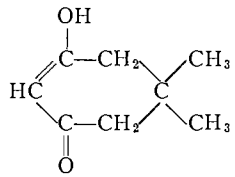
(III)



(IV)



(V)



(VI)

attributed to a similar enolization (IV $\rightleftarrows$ VI). In fact, the dione (IV) is 95% in the enolic form in water solution (7). On the other hand, isopropylidene dimethylmalonate, which cannot exist in an enolic form, exhibits no acidic properties (6). It should be pointed out, however, that diethyl malonate itself is not enolized to any appreciable extent ((1), and references cited therein).

EXPERIMENTAL

Isopropylidene malonate and isopropylidene dimethylmalonate were prepared by the method of Davidson and Bernhard (6). Isopropylidene malonate could be recrystallized either from acetone–water, or more conveniently from water or anhydrous carbon tetrachloride giving needles, m.p. 96°. 5,5-Dimethylcyclohexane-1,3-dione had m.p. 147–148.5°.

Isopropylidene ethylmalonate.—To a suspension of ethylmalonic acid (6.6 g) in acetic anhydride (6 ml) was added concentrated sulphuric acid (0.2 ml) with stirring. Most of the solid dissolved. Acetone (4 ml) was added dropwise to the suspension kept at 20–25° and the resulting solution was kept in the refrigerator overnight. The solid which separated was filtered and washed repeatedly with ice water, and the filtrate and washings combined to give a further amount of isopropylidene ethylmalonate. The product (6.09 g), m.p. 108–109° (depressed to 86–88° on admixture with ethylmalonic acid, m.p. 111°), was recrystallized from distilled water giving long, colorless needles, m.p. 108–109°. Found: C, 55.5; H, 7.1. Calc. for $C_8H_{12}O_4$: C, 55.8; H, 7.0.

Isopropylidene deuteromalonate.—An attempt to replace the reactive hydrogen atoms by sodium (with sodium ethoxide) followed by evaporation to dryness and treatment with D_2O, as in the case of diethyl ethylmalonate (1), only led to hydrolysis of the cyclic ester. Exchange of the active hydrogens of isopropylidene malonate took place readily when the compound was recrystallized from 99.9% deuterium oxide; seven such recrystallizations gave the deuterated ester as flat needles, m.p. 93–94°.

Infrared spectra.—A Perkin–Elmer model 21 double beam spectrophotometer with sodium chloride optics was used. The chloroform used for the solution spectra was AnalaR grade, dried and redistilled before use. The solution cell thickness was 0.028 mm and the concentrations were in the range of 20–22 mg/ml. Carbon tetrachloride was also of AnalaR grade and was dried before use.

RESULTS

The 3–5 μ region.—5,5-Dimethylcyclohexane-1,3-dione is the only compound which shows OH stretching absorption in that region: in the solid state a very broad band is observed at 2505 cm^{-1} with a shoulder at 2380 cm^{-1}. These bands are attributed to the enolic OH group, which is strongly intermolecularly bonded. The intensities of these bands are decreased considerably in dilute chloroform solution and vanish altogether at high dilution. Isopropylidene deuteromalonate exhibits a band at 2155 cm^{-1} (Nujol mull) attributed to the CD_2 vibration, indicating that at least a large proportion of the active hydrogen atoms have been exchanged for deuterium; if only one of the two hydrogen atoms had been replaced no appreciable band corresponding to the tertiary C—D stretching mode would have been observed (1). None of the other compounds examined showed any O—H stretching bands either in the solid state or in chloroform solution.

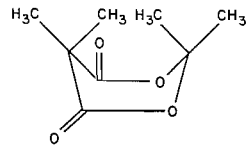
The 5–6 μ region.—The cyclic malonates exhibited two bands in this region above 1730 cm^{-1} whether in the solid state or in solution. In the solid state 5,5-dimethylcyclohexane-1,3-dione exhibited only a single broad band at 1612 cm^{-1}, whereas in dilute chloroform solution three bands were observed at 1733 (m), 1710 (s), and 1612 cm^{-1} (s) (broad). Bellamy and Beecher (8) reported bands at 1733, 1706, and 1603 cm^{-1} which they attributed to the keto, free enol, and intermolecularly chelated forms respectively. Though the positions of the double maxima of the cyclic malonates are altered on going from the solid state to the solutions, or, in the case of isopropylidene dimethylmalonate on changing from a chloroform solution to a carbon tetrachloride solution, $\Delta\nu_{C=O}$ for each individual compound remains approximately the same. The effect of deuteration does not change the mean of the positions of the two bands of isopropylidene malonate in chloroform solution though the positions of the bands themselves are altered, as is also $\Delta\nu_{C=O}$ (which becomes closer to that of isopropylidene dimethylmalonate).

DISCUSSION

Structure (II) for "Meldrum's acid" is eliminated owing to absence of the broad peaks characteristic of the carboxyl group in the 3–4 μ region, as well as of a band at around 1700 cm^{-1}. It is clear, however, that neither in the solid state nor in chloroform solution is isopropylidene malonate (I) enolized to any appreciable extent. This is shown by the absence of any O—H stretching bands, whether bonded or unbonded, by the absence of a definite band corresponding to an α,β-unsaturated ester carbonyl group as would be present in the free enol, as well as by the non-appearance of a band corre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

sponding to a chelated ester carbonyl group. Also, since isopropylidene dimethylmalonate shows two bands above 1730 cm^{-1} these cannot be due to an equilibrium between keto and enol forms. The possibility that the two bands are due to different conformations of the 6-membered ring is rendered very unlikely by the fact that in isopropylidene dimethylmalonate there would be large 1,4-interactions in the boat form (VII).



(VII)

Vibrational coupling is, therefore, the most logical answer. The fact that vibrational coupling can occur in cyclic malonates where rotational isomerism is not possible does not, however, mean that this is necessarily the explanation for the appearance of two ester carbonyl bands in open-chain malonates; all it does show is that coupling can occur between suitably situated ester carbonyl groups beta- to each other. The acidity of isopropylidene malonate must be due to the ease with which it undergoes enolization *in the presence of base.*

The difference in behavior between malonates and β-diketones is interesting. The greater degree of enolization of β-diketones has been attributed to the larger —M effect of the acyl group over that of the ester group (9) as well as in the added stabilization due to internal hydrogen bonding of the enol form (10). The cyclic β-diketone 5,5-dimethylcyclohexane-1,3-dione is enolized to an even larger extent than acetylacetone and this may be due to greater steric ease of intermolecular hydrogen bonding between two molecules of the enol existing in semichair conformations. It is tempting, therefore, to suggest that, since cyclic malonates are not enolized to any appreciable extent in the solid state or in solution whereas 5,5-dimethylcyclohexane-1,3-dione is almost completely enolized and intermolecularly chelated in the solid state, ketonic carbonyl groups have a greater tendency to undergo hydrogen bonding than similarly situated ester carbonyl groups. This could be rationalized if it were assumed that ease of hydrogen bonding in such cases depended among other things on the availability of electrons at the oxygen atom, since in ketones the alkyl group has a +I effect whereas in ester groups the alkoxyl group has a −I effect.

Some comments may also be made about the two bands at 1733 and 1710 cm^{-1} in the spectrum of 5,5-dimethylcyclohexane-1,3-dione in chloroform solution, which were previously observed by Bellamy and Beecher (8) at 1733 and 1706 cm^{-1}, and which they attributed to the unenolized keto form and to the free enol respectively. These authors observed that the band at 1603 cm^{-1}, due to the intermolecularly chelated form, vanished on great dilution owing to the breaking of the intermolecular hydrogen bonds, as expected. They found, however, that the 1710 cm^{-1} band also vanished at very high dilutions; they suggested that this band was due to the free enol form and that at these high dilutions in non-polar solvents the compound existed only in the keto form. If, after breaking the intermolecular hydrogen bonds by solution in chloroform, the free enol form were stable in that solvent it is difficult to see why further dilution with the same solvent should have rendered this form less stable. On the other hand, it is not stated whether after dilution a proportionally greater cell thickness was used in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

measurements. It may be possible that the two bands at 1733 and 1710 cm^{-1} are again due to vibrational coupling of the two unenolized carbonyl groups. A 6-membered ring ketone normally absorbs at *ca.* 1720–1710 cm^{-1} (though this might conceivably be raised to 1733 cm^{-1} if a strongly electron-attracting substituent is attached to the α-carbon atom as is the case here); an α,β-unsaturated 6-membered ring ketone, on the other hand, might be expected to absorb below 1700 cm^{-1} (11). The position of the two bands observed would fit in with the trend of one band being above, the other below, the common frequency in cases where vibrational coupling occurs (12).

ACKNOWLEDGMENTS

The author wishes to thank Dr. L. C. Leitch for a generous gift of deuterium oxide and the National Research Council for a grant-in-aid of this research. Useful discussions with Drs. J. M. Pepper and R. A. Heacock are gratefully acknowledged.

PERACETIC ACID OXIDATION OF HALOGENATED AZOBENZENES[1]

PAUL E. GAGNON AND BRIAN T. NEWBOLD[2]

ABSTRACT

A series of dihalogenated and five tetrachloroazobenzenes were oxidized to the corresponding azoxy compounds by means of 30% hydrogen peroxide in glacial acetic acid, the reaction being carried out at about 60–70° C, for 24 hours.

As expected, the yields, in general, obtained from azobenzenes containing substituents in the 2,2′-positions were lower than those from compounds having substituents in the 3,3′- and 4,4′-positions, which gave very good results.

INTRODUCTION

One of the most useful methods for the preparation of azoxybenzenes is the reduction of the appropriate nitrobenzene with a suitable reagent. However, azoxy compounds have also been obtained by oxidation of amines by means of peracids. For example, aniline when oxidized with an equimolar quantity of perbenzoic acid (1), or with peracetic acid (2), gave rise to azoxybenzene. D'Ans and Kneip (2) stated that primary amines can give rise to azo and azoxy compounds when treated with concentrated peracids under various conditions. Later, Greenspan (3) obtained a much better yield, 85%, of azoxybenzene from aniline by oxidation with 45% peracetic acid.

A third method of obtaining azoxybenzenes is the oxidation of the corresponding azobenzenes. For instance, azobenzene gave azoxybenzene when treated with an acetic acid solution of chromic acid in a sealed tube at 150–250° C (4) and 4,4′-dinitroazoxybenzene was obtained from the azo compound by the action of fuming nitric acid at room temperature (5).

The direct oxidation of azobenzenes to azoxybenzenes by means of organic peracids has been a subject of interest for many years. Angeli and others (6, 7, 8, 9) studied this reaction. For example, when azobenzene was treated for several days with peracetic acid, made by combining glacial acetic acid with 30% hydrogen peroxide, azoxybenzene was obtained (6). In a review (10), Swern states that this reaction proceeds readily under mild conditions and quantitative yields are frequently obtained, and he lists the azoxybenzenes prepared by this method up to 1949. In recent work, azobenzene was also oxidized by perbenzoic acid (11).

There are some examples of peracid oxidation of halogenated azobenzenes mentioned in the literature. For instance, 4-bromo-, 4,4′-dibromo-, and 2-bromo-4-nitro-azobenzene have been oxidized to the corresponding azoxy compounds by 30% hydrogen peroxide in glacial acetic acid (12, 13). Badger *et al.* (14) recently oxidized 3-bromo-, 4-bromo-, and 4-chloro-azobenzene with perbenzoic acid. However, only one dichloroazobenzene, namely, the 4,4′-derivative, has been oxidized to the azoxy compound by means of peracetic acid (15). Recently (16), 3,3′- and 4,4′-difluoroazoxybenzenes were prepared from the azo compounds by oxidation with peracetic acid using the method of Angeli.

The main object of the present work was to oxidize a series of dihalogenated and tetrachloroazobenzenes to the corresponding azoxy derivatives by means of 30% hydrogen peroxide in glacial acetic acid and to compare the yields obtained.

THEORETICAL PART

In the present work, many oxidations of dihalogenated azobenzenes were carried out using 30% hydrogen peroxide in glacial acetic acid. The manner in which the hydrogen peroxide was added to the solution of the azo compound was found to be important. The best results were obtained when most of the hydrogen peroxide was added regularly in small portions during the first 2 hours. The solubility of the azobenzene in glacial acetic acid was of considerable importance. It was found that the azobenzenes which were very soluble were the most easily oxidized. The time of the reaction was also critical, for instance, when the period of heating at 60–70° C was only a few hours, the yields of the azoxy derivatives were low. Therefore, the period of heating for the oxidations described in this work was extended to 24 hours.

The experimental conditions for the best yields of the dihalogenated azoxybenzenes are given in Table I. It is seen that only a low yield, 28%, of 2,2′-dichloroazoxybenzene was obtained, and that almost half of the starting material was recovered. It is evident that 2,2′-dichloroazobenzene was quite stable to oxidation with peracetic acid. Bigelow *et al.* (17) found that 4-amino-azobenzene was very difficult to oxidize, there being incomplete oxidation even after 6 days of refluxing in 30% hydrogen peroxide. In the present work, however, very good yields of 3,3′- and 4,4′dichloroazoxybenzene were obtained.

TABLE I

Oxidation of halogenated azobenzenes

Azobenzenes	Amount, g	30% H_2O_2, ml	CH_3COOH, ml	Temp., °C	Azoxy compound Yield, %	M.p., °C	Lit. m.p., °C		Starting material rec., %
				Dihalogenated azobenzenes					
2,2′-Dichloro-	2.000	41	150	60–70	28	56	56	(23)	47
3,3′-Dichloro-	2.000	41	200	62–75	93	98–99	97	(24)	Nil

3,3′-Dibromo-	0.300	10	50	64–65	Quant.	111–112	111.5	(26)	"
4,4′-Dibromo-	0.202	16	100	65–68	Quant.	171–171.5	172	(27)	"
3,3′-Diiodo-	0.200	10	100	62–67	96	116–117	117–118	(20)	"
				Tetrachloroazobenzenes					
2,2′;3,3′-Tetrachloro-	0.042	20	150	66–70	71	136–138	—	*	Nil
2,2′;4,4′- "	0.098	30	100	65–67	26	128–129	130.5	(20)	72
2,2′;5,5′- "	0.088	35	100	65–68	25	145–146	147	(28)	75
3,3′;4,4′- "	0.160	22	150	62–68	98	137.5–138.5	137–138	(29)	Nil
3,3′;5,5′- "	0.095	20	150	61–70	71	172–173	171–172	(30)	"

*2,2′;3,3′-Tetrachloroazoxybenzene also prepared from 2,2-dichloronitrobenzene using dextrose in alkaline medium was pale yellow, m.p. 138–138.5° C. Yield, 2%. Anal. calc. for $C_{12}H_6N_2OCl_4$: Cl, 42.20%. Found: Cl, 41.22%.

By contrast, the yield of 2,2′-dibromoazoxybenzene was low, 13%, and there was apparently considerable complete oxidation, there being no recovery of unreacted starting material. Bigelow *et al.* (17) showed that both 4-nitro-4′-hydroxyazobenzene and 4-hydroxyazobenzene were completely oxidized to carbon dioxide and nitrogen by prolonged refluxing with 30% hydrogen peroxide. Quantitative yields of 3,3′- and 4,4′-dibromoazoxybenzene were obtained in the present study. As shown in Table I, the yield of 3,3′-diiodoazoxybenzene was very good, but here again, in some experiments, considerable decomposition occurred.

As far as we know, there are no instances of oxidation of tetrachloroazobenzenes with

peracetic acid that have been recorded in the literature. In the present work, five tetrachloroazoxybenzenes were prepared from the azo compounds by oxidation with 30% hydrogen peroxide in glacial acetic acid. The solubility of the tetrachloroazobenzene in glacial acetic acid, the manner in which the hydrogen peroxide was added, and the time of heating were of importance.

The experimental conditions and best results are given in Table I. It is seen that the yield of 2,2′;3,3′-tetrachloroazoxybenzene, which is described for the first time, was 71%, whereas the yields of 2,2′;4,4′- and 2,2′;5,5′-tetrachloroazoxybenzene were only 26 and 25% respectively. By comparison, both 3,3′;4,4′- and 3,3′;5,5′-tetrachloroazobenzene gave good yields of the azoxy derivatives.

In general, it may be said that oxidation of halogenated azobenzenes with peracetic acid is a good method for the preparation of azoxybenzene derivatives having no substituents in the 2,2′-positions.

EXPERIMENTAL PART*

Preparation of Halogenated Azobenzenes

The halogenated azobenzenes were prepared from the corresponding nitrobenzenes by standard methods given in the literature. For example, 4,4′-dichloroazobenzene was made by reducing 4-chloronitrobenzene with magnesium and absolute methanol (18). In the case of 3,3′;4,4′-tetrachloroazobenzene, the azoxy compound (19) was reduced with zinc dust and sodium hydroxide, followed by oxidation in air, as previously described (20).

Peracetic Acid Oxidation

The procedure followed was essentially the same in every case; therefore the preparation of only one compound needs to be described in detail.

4,4′-Dichloroazobenzene (0.512 g) was dissolved in glacial acetic acid (200 ml) at 80° C, and then 30% hydrogen peroxide (2 ml) was added. Further additions of 30% hydrogen peroxide (2 ml) were made every 15 minutes during the first 2 hours, when a further 5 ml was added. The heating was continued at about 65° C, then after 3 hours, 3 ml of 30% hydrogen peroxide was added. To complete the reaction, after 19 and 20 hours 2- and 5-ml portions of hydrogen peroxide, respectively, were added. Heating was continued until the 24-hour period was over, the solution being then allowed to cool to room temperature. The original orange color had changed to pale yellow. The solution was poured into an excess of water (300 ml) and a pale yellow product separated out. It was washed with water and dried. Crude yield, 89%. The 4,4′-dichloroazoxybenzene was recrystallized several times from ethanol as pale yellow needles, m.p. 154–155° C, alone or with an authentic sample (lit. m.p. 155–156° C (21)).

In some cases, the aqueous filtrate, obtained after precipitation with water and filtration, yielded a small amount of product after standing in a refrigerator. In some experiments, precipitation took place after several portions of hydrogen peroxide had been added and glacial acetic acid was used to restore the solution. In cases where there was incomplete oxidation, that is, where a mixture of azoxy compound and starting material was obtained, separation was achieved either by crystallization or chromatography. The latter method was used particularly for the separation of products obtained from the oxidation of the tetrachloroazobenzenes. The chromatography was carried out with columns containing a (4:1) mixture of salicylic acid – celite as absorbant. The celite was celite 535. The products were placed on the column in ligroin solution and

**All melting points are uncorrected.*

For personal use only.

development was carried out with ligroin (b.p. 66–75° C). Elution was achieved with 95% ethanol. The azoxy compound was absorbed high on the column as a yellow band and the starting material (orange band) moved down to the bottom or was passed into the filtrate. The products separated by chromatography were further purified by recrystallizations from ethanol. In order to verify the oxidation method used in the present work, azobenzene was employed as a reference compound. Azobenzene (2 g), glacial acetic acid (50 ml), 30% hydrogen peroxide (18 ml) were heated at 65° C for 24 hours. The crude yield of azoxybenzene was 83%: m.p. 35–36° C, alone or with an authentic sample (lit. m.p. 35.5–36.5° C (22)).

The experimental details and results for all the halogenated azoxybenzenes prepared are given in Table I.

ACKNOWLEDGMENT

The authors wish to express their sincere thanks to Dr. Karl F. Keirstead, who gave them some halogenated azo- and azoxy-benzene samples.

A NEW SPECTROPHOTOMETRIC PROCEDURE FOR PLATINUM WITH TIN (II) CHLORIDE[1]

S. S. Berman and E. C. Goodhue

ABSTRACT

A spectrophotometric procedure has been developed for microgram quantities of platinum utilizing an absorption peak at 310 mμ formed when platinum salts react with tin (II) chloride. The method offers a 5-fold increase in sensitivity over the conventional platinum – tin (II) chloride procedure. Several factors influencing the intensity and stability of the absorbing species, whose nature is unknown, are described. Palladium and rhodium produce gross interferences, but small quantities of iridium, iron, copper, and chromium can be tolerated. The procedure is applicable to fumed sulphuric acid solutions of platinum and to solutions of platinum in nitric acid. The recommended concentration range is 0.4 to 6 p.p.m. when measurements are made in 1.0-cm cells.

INTRODUCTION

Tin (II) chloride has long enjoyed wide use as a satisfactory colorimetric reagent for platinum. The earliest reported application was in 1921 by Davis (1). Several workers have since investigated this reagent (2, 3, 4, 5, 6, 7), the most extensive report being produced by Ayres and Meyer (4). In spite of its relatively low sensitivity tin (II) chloride has been preferred in many laboratories because it offered a wide freedom from interference and range of applicability. Two other reagents have also found a wide use. These are potassium iodide (3) and *p*-nitrosodimethylaniline (8). The potassium iodide procedure is less sensitive than that involving tin (II) chloride and suffers gross interferences. The *p*-nitrosodimethylaniline method is the most sensitive procedure for platinum published to date. It is fairly tolerant to the presence of some base metals but is not applicable to solutions of platinum in sulphuric acid and the conditions for the development of the colored species must be followed rather rigorously. (The diacetoimidoplatinum method of Barkovskiĭ and Kul'berg (9) has been reported in Chemical Abstracts (10) to be applicable to platinum concentrations "varying between 25 and 90 μg per liter". However, a study of the original paper has shown that this should have read "250 to 900 μg per ml".)

A comparison of the sensitivities of some of the usefully developed spectrophotometric procedures for platinum is given in Table I.

Ayres and Meyer (4) in their examination of the tin (II) chloride procedure (absorption maximum at 403 mμ) noted the existence of a second absorption peak at about 310 mμ

TABLE I

Sensitivity of spectrophotometric methods for platinum

Method	Molar absorptivity
Thiosemicarbazide (13)	2.46
Diacetoimidoplatinum (9)	2.4×10^2
Potassium iodide (3)	6.05×10^3
Tin (II) chloride (403 mμ) (4)	7.83×10^3
Hexachloroplatinate (14)	8.40×10^3
Phenylthiosemicarbazide (15)	1.35×10^4
Tin (II) chloride (310 mμ)	3.95×10^4
p-Nitrosodimethylaniline (8)	5.29×10^4

Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5008.

but stated that the absorption of the reagent blank was so great below 325 mμ as to render this peak unsuitable for use. The authors have succeeded in establishing conditions whereby this absorption peak can be used as the basis for a precise and sensitive determination of platinum. This was done primarily by a gross reduction in the quantity of tin (II) chloride used to produce the absorbing species, and the addition of sulphuric and perchloric acids to stabilize the species and affect a hypsochromic shift in the absorption band due to the tin (II) chloride reagent. A spectral curve (A) of a solution containing 3.92 p.p.m. of platinum treated by the procedure described below is shown in Fig. 1. The absorbance at 310 mμ is five times that at 403 mμ, and the spectral curve (B) of the reagent blank against water shows that the absorbance of the blank is quite low at 310 mμ.

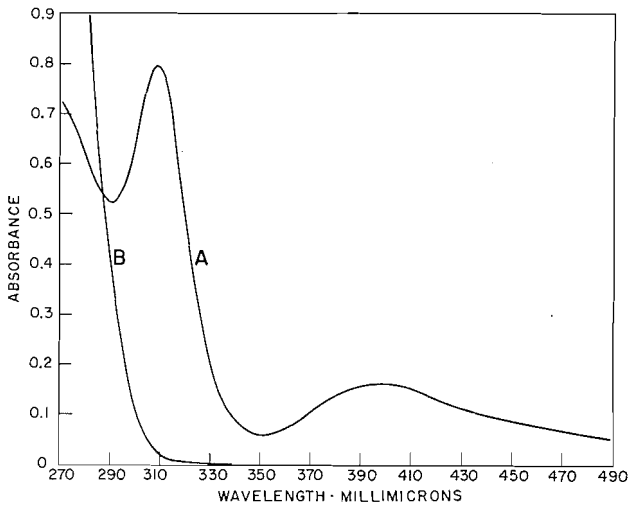

FIG. 1. A: Spectral curve of a solution containing 3.92 p.p.m. platinum against a reagent blank.
B: Spectral curve of the reagent blank against water.

EXPERIMENTAL

Apparatus and Solutions

Absorption measurements were made with a Beckman Model DU quartz spectrophotometer equipped with a hydrogen lamp source and matched 1.00-cm quartz cells. Spectral curves and some studies of the stability of the absorbing species under various conditions were made with a Beckman Model DK-1 recording spectrophotometer.

A standard platinum solution was prepared by dissolving pure platinum sponge in aqua regia, evaporating several times to dryness with hydrochloric acid, and then dissolving the residue and diluting with 0.1 *M* hydrochloric acid. The solution was standardized by precipitation with 4-phenylthiosemicarbazide (11). A 5-ml aliquot of this solution was diluted to 1000 ml with 0.1 *M* hydrochloric acid. The resulting solution contained 9.80 μg of platinum per milliliter of solution.

The reagent was a 2% w/v solution of tin (II) chloride dihydrate in 1.5 *M* hydrochloric acid. The reagent was prepared by dissolving the tin (II) chloride in concentrated hydrochloric acid and then diluting the solution with water.

All chemicals used were of analytical reagent grade.

DEVELOPMENT OF THE METHOD

Preliminary experiments using 5-ml aliquots of the dilute stock platinum solution, 5 ml of concentrated hydrochloric acid, and 2 ml of the reagent solution diluted to 25 ml with water, showed that a stable absorption peak was produced at 310 mμ. The absorbance of the reagent blank measured against water was 0.080. A slit width of about 0.3 mm was required when making measurements on the platinum solutions against a reagent blank.

However, very erratic results were obtained when the stock solution was treated in any way prior to the development of the color in an effort to simulate an actual sample in practice (e.g. boiling with hydrochloric acid, addition of sulphuric acid). Furthermore, it was found that in all these cases the absorption species was not stable, tending to fade rather rapidly, the rate of fading being proportional to the amount of light to which the sample was subjected. The addition of perchloric acid to the system prior to the addition of the reagent succeeded in stabilizing the color but did not increase the precision.

It was found that very precise results could be obtained, regardless of prior treatment of the platinum solution, if sulphuric acid was added and the solution heated to expel all volatile acids (care being taken not to fume the sample).

THE REAGENT

There was no difference in the absorbance produced when 1, 2, or 4 ml of reagent were used. However, 0.5 ml of reagent was insufficient to produce maximum absorbance. In order to keep the absorbance of the reagent blank at 310 mμ at a minimum, 2 ml was chosen as the optimum quantity.

Some experiments were carried out in which the hydrochloric acid concentration of the reagent was 3 *M* instead of 1.5 *M*. This difference in acid concentration had no apparent effect on the absorbance of the resulting solutions.

Low results were sometimes obtained when the color was developed with reagent solution that was one or two days old. It is therefore recommended that fresh reagent solution be prepared daily.

EFFECT OF PERCHLORIC ACID

The addition of concentrated perchloric acid (70–72%) had the effect of stabilizing the system. Solutions which contained no perchloric acid faded quickly, especially when exposed to light.

Some experiments were carried out in which the solutions were entirely shielded from light. The rate of fading was much less in these cases but still too fast to produce reliable results. The same phenomenon was noticed by one of the authors (S.S.B.) in the development of a similar spectrophotometric procedure for rhodium with tin (II) bromide (12). In this case perchloric acid also stabilized the system.

No differences in absorbance were apparent when quantities of concentrated perchloric acid ranging from 5 to 10 ml were used. Five milliliters was chosen as the optimum amount.

When 5 ml of concentrated perchloric acid was used the yellow color of the solution developed totally within a few minutes of the addition of the reagent. The absorbance was stable for at least 4 hours and decreased by only a few per cent in 18 hours.

Another effect of the addition of perchloric acid was to produce a hypsochromic shift in the absorption band due to the tin (II) chloride reagent. The absorbance of the reagent blank containing 5 ml of perchloric acid measured against water at 310 mμ

was 0.020. Slit widths of only about 0.13 mm were required when making absorbance measurements against reagent blanks.

EFFECT OF SULPHURIC ACID

After the preliminary experiments it was evident that all platinum solutions would have to be pretreated in some manner in order to convert the platinum to some species which would react favorably with the tin (II) chloride reagent.

Boiling with hydrochloric acid and with aqua regia were tried unsuccessfully.

It was found, however, that if sulphuric acid and hydrochloric acid were added to the platinum solution and the solution heated, but not fumed, until all the hydrochloric acid was evolved, quite reproducible results could be obtained regardless of the previous history of the sample.

Quantities of concentrated sulphuric acid ranging from 5 to 10 ml produced no differences in the absorbance of replicate samples. Six milliliters was chosen as the optimum value as less than 5 ml proved to be inadequate (low results being obtained) and there is always the danger of losing some acid by fuming.

Fumed samples generally gave low results unless the precaution was taken of adding several milliliters of concentrated hydrochloric acid again and boiling until the volatile acid had been expelled.

Several samples which were fumed quite strongly and then treated with hydrochloric acid as described above gave excellent results.

RECOMMENDED PROCEDURE

Transfer the solution containing the platinum to a small beaker. Add 6 ml of concentrated sulphuric acid and 5 ml of concentrated hydrochloric acid. Cover and boil the solution gently on a hot plate until all the hydrochloric acid is expelled taking care not to bring the solution to fumes of sulphuric acid. Cool and transfer the sulphuric acid solution to a 25-ml volumetric flask with a small quantity of water. Add 5 ml of concentrated perchloric acid followed by 2.0 ml of the reagent. Dilute to volume with water and mix thoroughly. Measure the absorbance at 310 mμ using a reagent blank for comparison.

PRECISION ATTAINABLE

The mean absorbance of 12 replicate samples each containing 49.0 μg of platinum in a final volume of 25 ml was 0.397. The mean deviation of these results was 0.002 or 0.5%.

ADHERENCE TO BEER'S LAW

The solutions adhered to Beer's law throughout the whole range of concentrations tested, which was from 0.4 to 6 p.p.m. This is demonstrated in Table II.

A solution containing 0.078 p.p.m. of platinum was prepared and the absorbance measured in 5-cm quartz cells. The absorbance was 0.080 giving an absorbance to

TABLE II

Adherence to Beer's law

P.P.M. Pt (C)	Absorbance (A)	Ratio A/C
0.392	0.081	0.206
1.18	0.240	0.202
1.96	0.397	0.201
3.92	0.796	0.202
5.88	1.190	0.201

For personal use only.

concentration ratio (when corrected for the longer path length) of 0.204. This agreed very well with the ratios obtained for the more concentrated solutions and indicated that the procedure was quite applicable for these small quantities of platinum.

The recommended range for this procedure is 0.4 to 6 p.p.m. when measurements are made in 1-cm cells, and 0.08 to 1.2 p.p.m. when measurements are made in 5-cm cells.

INTERFERENCES

Gross quantities of nitric acid can be tolerated as this acid is expelled along with the hydrochloric acid in the pretreatment of the sample.

Several metals commonly associated with platinum were tested to ascertain their effect on the procedure. The results of these tests are shown in Table III. In each case the metal was added prior to the sulphuric acid – hydrochloric acid treatment of the sample.

TABLE III

Effect of diverse metals on 49.0 μg Pt

Metal added	Absorbance

47.8 μg Pd^{++}	0.741
45.4 μg Ir^{++++}	0.410
49.9 μg Rh^{+++}	0.890
1.0 mg Cu^{++}	0.410
1.0 mg Ni^{++}	0.355
1.0 mg Fe^{+++}	0.406
1.0 mg Cr^{+++}	0.399

It is apparent that small quantities (up to 1 mg) of chromium, iron, and copper and equivalent amounts of iridium produce a maximum error of 3% in the estimation of platinum.

EFFECT OF USING A TUNGSTEN LAMP AND COREX CELLS

All the work reported above was done using a hydrogen lamp source and quartz cells, since 310 mμ is beyond the recommended limit (320 mμ) for Corex-glass cells. Since many laboratories do not have an ultraviolet accessory it was decided to test the procedure using a tungsten lamp source and Corex-glass cells. It was found that measurements could be made quite conveniently, the only effect being the increase in slit width from 0.13 to 0.34 mm due to the loss of energy at this wavelength.

MICROCALORIMETRY OF ADSORPTION OF WATER VAPOR ON LEAD DI-IODIDE[1]

HENRY M. PAPÉE[2]

ABSTRACT

Using a microcalorimeter of the Calvet type, measurements of the total heat of adsorption of water vapor on microcrystals of lead di-iodide have been made. By comparing the results obtained with those relating to the kinetic process of surface sintering by water vapor, heats for the process of sintering were calculated. The same sintering characteristics were found for preheated and unheated samples, but it was found that the heated product adsorbs more water than the original salt. Qualitative experiments on lead mono-iodide show a different pattern of heat evolution with time, and the over-all process requires more water to reach completion than in the case of di-iodide. The heats evolved are much greater, probably partly due to the reaction of water with the surface.

INTRODUCTION

The activity of lead iodide crystals towards ice nucleation and cloud precipitation (1, 2, 3, 4, 5) has recently resulted in studies with the object of gaining insight into the mechanism of the process. Much information was obtained by Birstein (6), who studied the process using conventional adsorption techniques and established that a considerable number of layers of water molecules can be formed on lead iodide particles. A study of the phenomenon by use of microcalorimetry was attempted in this laboratory under a U.S.A.F. contract, with the object of directly measuring the energies of the steps involved.

EXPERIMENTAL

Apparatus

A microcalorimeter of the Tian–Calvet type was used, and the general pattern of the experimentation followed closely that used recently in this laboratory for the study of the process of adsorption of water vapor on sodium chloride microcrystals (7).

Reagents

Pure lead di-iodide of large specific surface areas was prepared by a method previously described, and the specific areas of the product were changed, when required, by heating (8).

Procedure

Three series of experiments* were carried out as follows:

Series 1.—In this series of measurements, the microcalorimetry was carried out using different amounts of salt originating from a batch product of an initial surface area of 2.05 m^2/g. The original material was never heated above 25° C.

Series 2.—The work was done on samples of different specific surface areas. These were obtained by heating the original product under vacuum.

Series 3.—Two measurements were carried out on samples of lead mono-iodide. This product was obtained from the di-iodide by thermal decomposition at 240° C under dry nitrogen and at atmospheric pressure. The product obtained in this way had been outgassed by pumping it to a high vacuum for several days at 25° C.

RESULTS

The admission of water vapor into the cell containing lead iodide leads to a pattern of heat evolution with time, such as the one shown in Fig. 1. The process is slow and takes several hours to finish. Since it is to be expected that an initial fast process of adsorption will be followed by a slow process of sintering of the surface, and since the kinetic aspect of this second phenomenon is known, heats corresponding to both processes can be estimated graphically from the experimental curves.

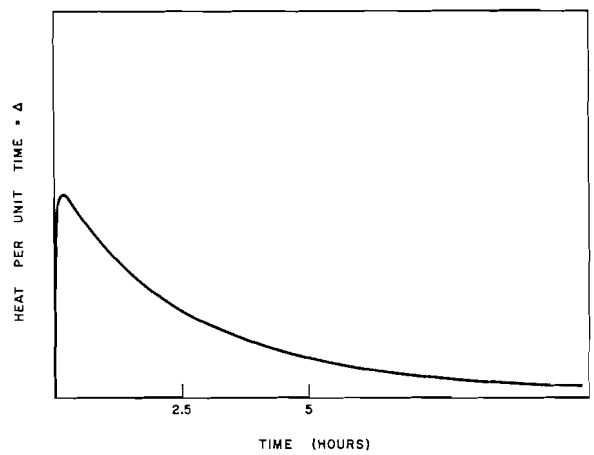

FIG. 1. Schematic plot of rate of heat evolution against time.

The decrease of lead iodide surface with time upon hydration has been shown previously (8) to follow a first-order pattern according to the equation

$$[1] \qquad \log(S-S_\infty) = -0.245t+A.$$

The symbols used in this paper are:

S: specific surface in meters^2 per gram, at time t,
t: time in hours,
S_0: initial specific surface of the product,
S_∞: specific surface of the product after long exposure to water vapor,
Q: heat of sintering,
A, a, b: constants,
w: weight of salt used in experiment,
Δ: deviation of galvanometer, approximately equal to (rate of heat evolution) $\times$ (proportionality constant).*

1st Series

The values of S_0 and S_∞ in this series were determined by B.E.T. nitrogen adsorption, and were $S_0 = 2.05$ and $S_\infty = 0.82$. Constant A of equation [1] is therefore $A = 0.090$ and

$$[2] \qquad S-S_\infty = \exp\{2.303(-0.245t+0.090)\}.$$

The process of heat evolution representative of the sintering of the crystalline surface under exposure to water vapor will follow the general equation

**Because of the slowness of the process this approximation is very good.*

$$[3] \qquad \frac{dQ}{dt} = a\left(w\frac{d(S-S_\infty)}{dt}\right) = b\Delta\,.$$

Substituting eq. [2] in [3] and taking logarithms

$$[4] \qquad \log\Delta = \log((-a/b)0.564)+\log w-0.245t+0.090$$

or

$$[4'] \qquad \log\Delta = \log w-0.245t+K$$

in which the constant K contains all constants of eq. [4].

Figure 2 shows a series of calorimetric heat evolution curves in logarithmic form and represents examples of patterns obtained when working with different amounts of substance. The dotted line through the origin represents a line of gradient -0.245, which was obtained by measuring the kinetics of sintering by B.E.T. nitrogen estimation of surfaces at different times. Good agreement between the two methods can be seen.

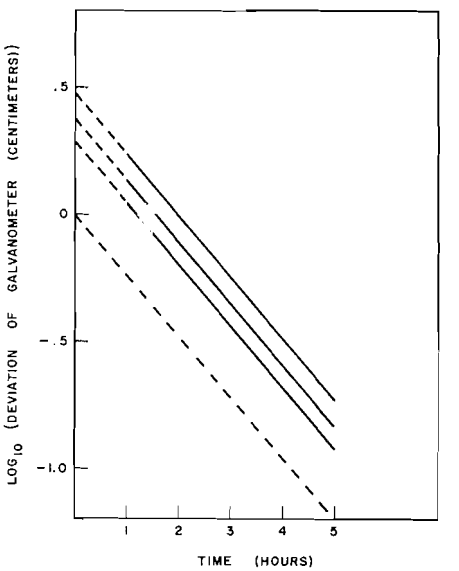

FIG. 2. Plot of decimal logarithm of rate of heat evolution against time, in microcalorimetry salt container. The lines represent experiments with different weights of the product. The dotted line gives the slope of the process as obtained by other means, and using B.E.T. surface measurements.

It was noticed that the curves become linear after about 30 minutes, initial irregularities being partly due to the heat of adsorption which superposes itself on the heat of sintering of the surface. Furthermore, for rapid initial heat evolution, the expression for Δ is no longer accurate enough (see also ref. 9). Because of this, the curves are shown after the first hour has elapsed, by which time they obey with good approximation the law of eq. [1].

Extrapolating the plots to zero time, the hypothetic value of the parameter Δ at the start of the process can be obtained. Under such conditions eq. [4'] becomes

$$[4''] \qquad [\log\Delta]_{t=0} = \log w+K.$$

Thus constant K can be obtained. Based on 9 experimental values it is found to be:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$K = -0.08 \pm 0.02.$$

Substitution of the value for K in eq. [4′] gives, for unit weight of salt,

[4‴] $$\Delta = 10^{(-0.245t-0.08)}.$$

Taking the calibration coefficients of the instrument into account, and integrating eq. [4‴] between zero and infinite time, the value of 0.084 ± 0.006 cal/g is obtained, and corresponds to the sintering of the surface of 1 g of lead di-iodide from 2.05 to 0.82 m^2/g.*

The over-all heat of the process is obtained by planimetric integration of the recorded curves. The results obtained are shown in Fig. 3. The heat evolved by 1 g of di-iodide when put in contact with water vapor is given by the slope of the line and is found to be 0.179 ± 0.007 cal.

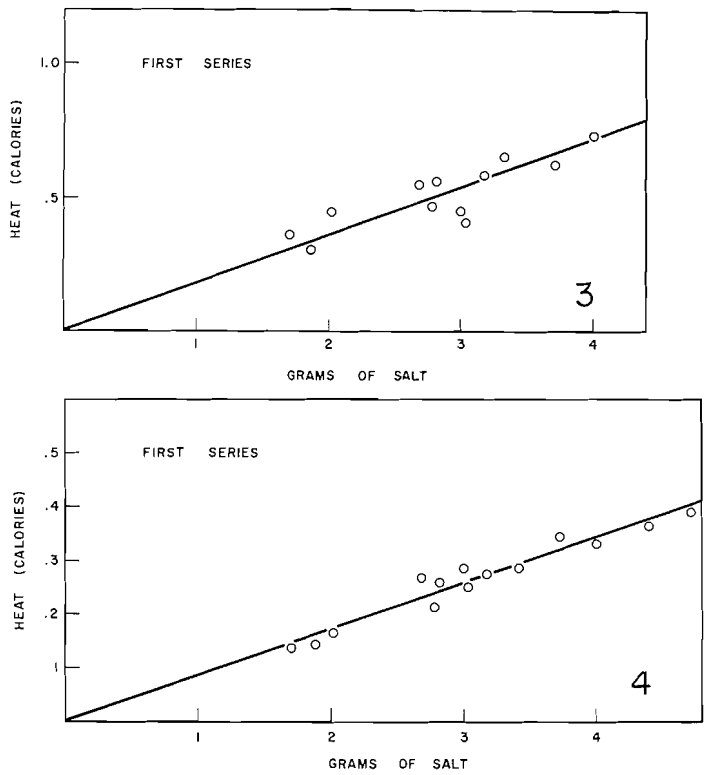

FIG. 3. Plot of over-all heat obtained by planimetric integration of areas under curves recorded, for cell in which salt was contained, against weight of salt.
FIG. 4. Plot of heat absorbed in cell from which water was evaporating, against weight of salt.

The evaporation of water necessary to induce the process described above was followed simultaneously, and the recorded curves showed rapid initial evaporation of water, but this was of short duration and only very small amounts of water evaporated per unit time after several hours. No relationship between kinetics of sintering and the amount of water used could be established. The heats of evaporation of water were therefore estimated by planimetric integration of the area obtained experimentally, and the

The values quoted in the present paper are 'thermochemical' calories, equal to 4.1840 joules. The instrument was calibrated electrically.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

results representing the over-all process are shown in Fig. 4. The slope of the line gives the heat of evaporation of water required for the process of adsorption on, and sintering of, the salt, and is 0.086 ± 0.002 cal/g.

Since the specific surface of the salt is equal to 0.82 m^2/g, at the end of the process, the amount of the water adsorbed by unit surface will be deduced from the heat absorbed and the latent heat of evaporation of water. The heat of evaporation of the amount of water used in the process just discussed is

$$(0.086 \pm 0.002)/0.82 = 0.105 \pm 0.0024 \text{ cal/m}^2$$

and assuming 10.6 $Å^2$ for the area occupied by a water molecule, the coverage is calculated to be 0.68 ± 0.02 layers.

*2nd Series**

Since samples of different initial surface areas were used in this case, eq. [1] will become

$$[5] \qquad (S - S_\infty) = (S_0 - S_\infty) \exp(-0.5642t),$$

which after substitution in eq. [3] becomes on taking logarithms

$$[6] \qquad \log \Delta = -0.245t + \log\{w(S_0 - S_\infty)\} + K$$

where K is constant.

Experiments were performed on 4 batches of salt, each of which was heated for 24 hours, to a different temperature. The specific areas of the products were determined by B.E.T. nitrogen adsorption both before exposure to water vapor and after long periods of exposure. Plots of ($\log \Delta$) against time were found to follow linear patterns of the type previously discussed and the gradients of the lines were the same as before. From these K is obtained following the method previously described. Seven separate runs give $K = -0.25 \pm 0.03$. This shows that sintering of lead di-iodide crystals that were moderately heated under vacuum by exposure to water vapor proceeds along a pattern similar to that of unheated salt. Substitution of the calculated value of K in eq. [6] leads after rearrangement and integration of Δ between zero and infinite time to a value of 0.056 ± 0.006 cal and represents the heat that is developed when 1 g of

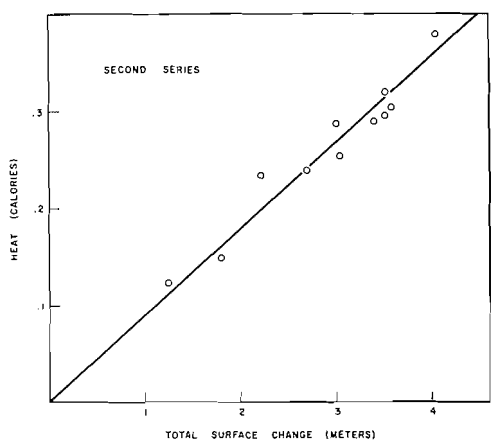

FIG. 5. Plot of over-all heat obtained by planimetric integration of areas under curves recorded for cell in which salt was contained, against $w(S_0 - S_\infty)$.

**Salt sintered by heat under vacuum in the range between 50 and 150° C.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

salt sinters by 1 m². Planimetric integration of the over-all phenomenon leads to results shown in Fig. 5, where the heat obtained is plotted against $w(S_0-S_\infty)$. The over-all heat that is evolved when the total surface changes by 1 meter is obtained from the slope of the line, and is 0.089 ± 0.002 cal.

As in the previous series, the heats of evaporation of water required to induce the phenomena described above were estimated by planimetric integration of the over-all areas under the curve. In contrast to Series 1, the phenomenon seemed to last longer, and the rate of heat evolution after 24 hours, although very small, could still be detected, and was fairly constant over the last 10 hours. However, no counterpart of this could be detected in the salt container. The heats are given in Fig. 6, which shows furthermore that the amount of water used in the process is a function not of the surface change but of the final surface S_∞.

The slope of the line gives the heat per unit surface, and is in this case 0.278 ± 0.004 cal/m² and the corresponding coverage is 1.79 ± 0.03 layers.

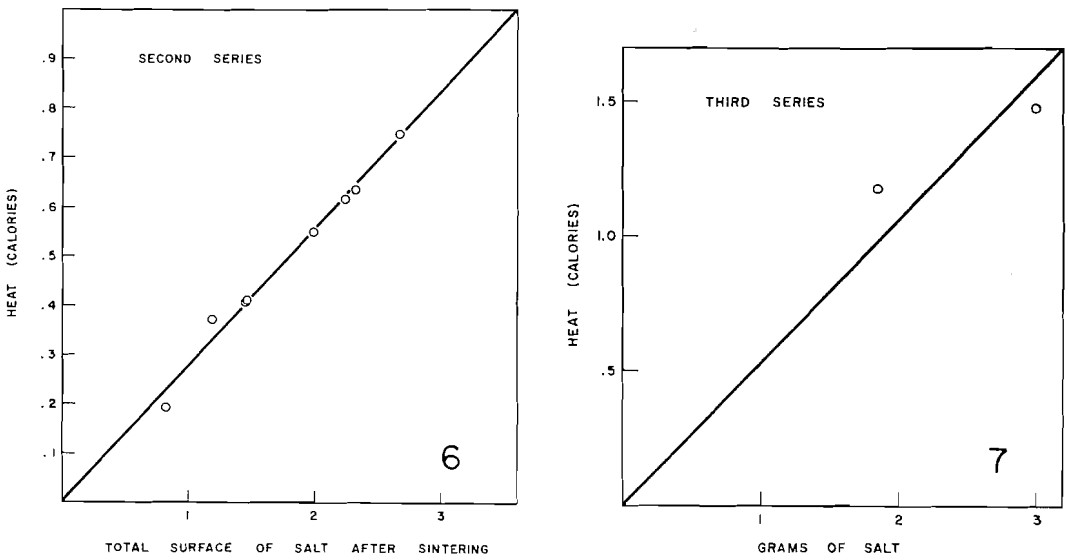

FIG. 6. Plot of heat absorbed in cell from which water was evaporating against product of weight of salt multiplied by its surface area after hydration.
FIG. 7. Plot of over-all heat evolved in salt container against weight of salt.

3rd Series

Although the conversion of the lead di-iodide by heating at 240° under dry nitrogen gave a mono-iodide 98.6% pure, it is not certain whether the subsequent outgassing in vacuum at 25° C liberated completely the surface of the product from elementary iodine which must have certainly been adsorbed there. The results reported in this series are therefore to be considered only as a by-product of the main experimentation, and are reported for the purpose of a tentative comparison with the previous data. Furthermore, the preparation of lead iodide for cloud-seeding experiments (cf. refs. 1, 2, 3, 4, 5) must invariably result in partial alteration of the salt (8). It is thought therefore that a brief discussion of the results obtained in this series is justified, since it might be helpful towards further studies of the subject.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Two runs were made on samples originating from the same batch. This consisted of salt of specific surface area of 0.84_5 m²/g. No determinations were made of the surface after hydration.

Plots of [log Δ] against time in both cases gave straight lines of gradients -0.12_2 hours^{-1}.

Heats evolved in the salt cell were estimated planimetrically and are plotted in Fig. 7 against the weight of salt. The line was fixed through the origin, and its gradient is 0.53 ± 0.06 cal/g.

Finally, the heat absorbed in the water container is given in Fig. 8 as a function of the amount of salt on which adsorption was carried out. The slope of the line is 0.31 ± 0.08 cal/g $= 0.4 \pm 0.1$ cal/m². This corresponds to the amount of water required to form 2.4 ± 0.61 layers.

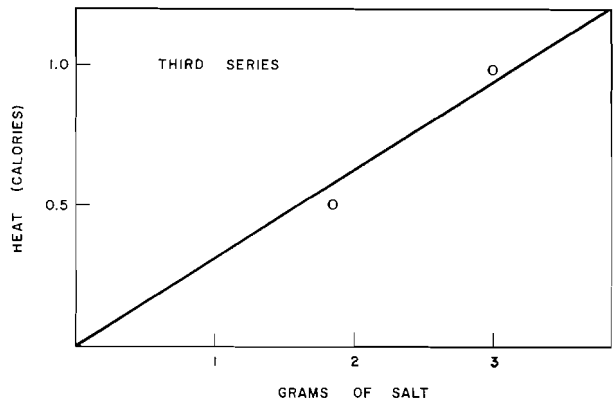

FIG. 8. Plot of heat absorbed in cell from which water was evaporating, against weight of salt.

DISCUSSION

The results obtained are summarized in the table.

Series	Nature of salt	Heat of sintering of surface under exposure to water vapor, cal/m²	Total heat measured, cal/m²	Heat of evaporation of water, cal/m² of sintered salt	Water coverage layers
1	PbI_2 salt handled only at temperatures below 25° C	0.068 ± 0.005	0.145 ± 0.006	0.105 ± 0.002	0.68 ± 0.02
2	PbI_2 salt heated between 50 and 150° C before adsorption measurements	0.056 ± 0.006	0.089 ± 0.002	0.278 ± 0.004	1.79 ± 0.03
3	PbI obtained from PbI_2 by thermal decomposition		0.53 ± 0.06	0.31 ± 0.08	2.4 ± 0.6

It can be seen that for PbI_2 no difference in the kinetic pattern of sintering of the surface by exposure to water vapor takes place, whether the surface was moderately heated or not, since the rate plots obey the same law. As expected, this is different in case of lead mono-iodide, although the general pattern probably remains of the first order with respect to surface.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In the case of preheated samples, the results are slightly lower than in the case of samples that were handled at room temperature. It is interesting to note, however, that the product which has been 'activated' by heat adsorbs a considerably larger amount of water than a non-activated salt. Since the heat evolved in the salt container in the first two series of experiments does not indicate condensation of water on the surface, or chemical reaction such as hydrolysis etc., this result can be tentatively interpreted in terms of 'electrostriction' of water molecules around charges appearing in the original area of imperfections induced by heat, after the surface is placed in contact with water vapor. Detailed analysis of the absorption of heat in the water container with time is indicative of a similar pattern. It can be seen that the rate drops almost to zero after a few hours, and then gradually slightly increases. A slow downward trend of the rate is observed again after about 20 hours, but a small process of heat absorption can be detected in most cases even after the period of 24 hours. If similar mechanism occurs in the case of silver iodide, which, like lead iodide is known to be an excellent ice-nucleating agent, the time lag (10) in formation of ice crystals after injection into supercooled water vapor might tentatively be explained along these lines.

The heat evolved in the salt container is much larger in the case of lead mono-iodide, than in the case of the previous series. Although the amount of water used in the process is also larger it does not explain the difference between the values obtained and those related to the process occurring on lead di-iodide. The result points therefore to

(i) a different heat of sintering of the surface of the product; and/or,
(ii) condensation of water on the surface; and/or,
(iii) hydrolysis of the salt.

The number of water layers on the surface is found to be very small in comparison with the measurements of Birstein (6) and the heats obtained, although of the same order of magnitude, are lower than his isosteric data. This might be due to one or both of the following factors:

(i) Small leaks in our calorimetry system, which would reduce the number of layers adsorbed.
(ii) Small temperature differences between the source of water vapor and the salt in Birstein's system. Calibration evidence points in our case to a thermal stability of the apparatus to within 10^{-5} degrees centigrade over long time periods.

Since all of our experiments were performed in the same system, and without disturbing the apparatus, it is thought that experimental abnormalities would show up in individual cases, and major leaks would be therefore easily detected. No sign of this was found during the experimentation. Furthermore, as implied previously, the process does not appear to be controlled by diffusion of H_2O. Because of this controversy, however, it appears that the relative behavior towards adsorption of water vapor of the three products under study is of more immediate significance than the direct data obtained.

ACKNOWLEDGMENTS

The author is indebted to Drs. G. C. Benson, J. A. Morrison, and A. R. Blake of the National Research Council for many helpful discussions, and to Professor K. J. Laidler of this Department for reading the manuscript and his interest in this project. POTATO X VIRUS

PART III. LIGHT SCATTERING STUDIES[1]

M. E. REICHMANN

ABSTRACT

Light scattering studies were made on a non-aggregated potato X virus preparation. The data are consistent with a cylindrical model 5400 Å long having a molecular weight of 35×10^6. The weight average length of 4700 Å was determined from the high angle measurements. The low value of the weight average length, as compared with the length of the most frequent particle from electron microscopy, is interpreted in terms of a slight tendency to aggregate side-by-side. The insignificant extent of this aggregation is demonstrated by a direct evaluation of the weight average diameter. The value of 109 Å obtained is only 9% higher than the number average diameter reported in the literature.

INTRODUCTION

The spontaneous end-to-end aggregation of potato X virus in the process of purification has been the main obstacle in physicochemical studies of its properties in solution. The molecular weight of this virus has not been previously determined. The value of 37.5×10^6 used by Niu *et al.* (1) from data of Bode and Kohler (2) does not appear in the original paper, and was probably calculated from the electron microscope dimensions. These dimensions have now been corrected by Bode and Paul (3). Loring estimated the molecular weight to be 26×10^6 from sedimentation and viscosity measurements (4). Assuming a cylindrical shape, Loring also derived the dimensions of the virus particle as being 98 Å in diameter and 4330 Å in length.

From flow-birefringence studies on the virus in untreated tobacco sap and from a partially fractionated preparation, we reported a particle length of 5400–6200 Å (5).

The diameter of the dry virus particle has been determined from electron micrographs as 160 Å (6) and 100 Å (7). More recently, the length of the most probable particle has been given as 5000–5250 Å, and the diameter of 100 Å was confirmed (3).

In a previous publication, we reported a method for preparing purified, non-aggregated potato X virus from tobacco sap (8). The availability of this method facilitated further studies of the properties of the virus in solution, which are the subject of this paper.

MATERIAL AND METHODS

The method of virus preparation used in these studies has been described (8). Virus concentrations were determined by nitrogen analysis and checked by measurements of optical density at 260 mμ in 0.1 phosphate buffer pH 5.7 (8).

The angular distribution of the intensity of scattered light was measured in a Brice–Phoenix Universal Light Scattering Photometer manufactured by Phoenix Precision Instrument Co., Philadelphia, Penn. (9), using the cylindrical cell furnished with the instrument. The symmetry of the envelope of the cell was checked with a fluorescein solution and the cell was calibrated with a Ludox solution (10, 11). Reflectance corrections (12, 13) were made as described in other publications (10, 11). Dust-free solvents were obtained by filtration through a U.F. sintered-glass filter. Dust was removed from the virus solution by centrifuging the stock solutions in a Servall centrifuge at $15{,}000\times g$ for 30 minutes. A small amount of virus was precipitated under these conditions. Light

[1]*Manuscript received September 22, 1958.*
Contribution No. 6, Chemistry Division, Science Service, Canada Department of Agriculture Research Laboratory, Vancouver, B.C.

scattering measurements were therefore also made on solutions that were centrifuged 20 and 60 minutes. Within the error of the experiment the same data were obtained, indicating that no fractionation of the virus material had taken place. Although the light scattering measurements were made at room temperature, the virus stock solution was kept in the cold. The manner in which dilutions were made has been described (14).

The specific refractive index increment, dn/dc, was determined with a Brice–Speiser differential refractometer (15). As mentioned previously (8), the non-aggregated virus was insoluble in water in the absence of electrolytes. Errors can be anticipated in refractive index increments determined in the presence of electrolytes as a result of differences in electrolyte concentrations between dialyzate and solvent due to the Donnan term. It was therefore preferable to measure the refractive index increment of an aggregated preparation obtained by 5 cycles of high and low speed centrifugation in distilled water. The dn/dc value found was 0.189 ± 0.004.

THEORETICAL CONSIDERATIONS

The relationship between the angular distribution of the intensity of scattered light and the molecular parameters in the case of rigid rods has been discussed (16). It has been shown that the weight average molecular weight and the z average length can be determined provided that the parameter $x^2 = (2L\pi/\lambda' \sin \theta/2)^2$ does not exceed 15 in the low angle range of measurements. Table I gives the values of x and x^2, for a monodisperse rod whose length L is 5000 Å, in the angular range $\theta = 30°$–$90°$ at a wave length $\lambda' = 3280$ Å ($= 4360$ Å/1.33). Between the angles 30° and 50°, x^2 is smaller than 15 and Kc/R_θ should be linear in $\sin^2 \theta/2$. In the case of a polydisperse system with a number average length of 5000 Å, the downward curvature will set in at lower angles, depending on the width of the distribution function (17). It should, however, be possible to determine the z average length and the weight average molecular weight of potato X virus, provided only that the polydispersity is not too great.

TABLE I

Theoretical values of the parameter x (see text) for angles at which light scattering measurements were made. Monodisperse rigid rods 5000 Å long. Wave length (4360/1.33) Å

θ	x	x^2
30°	2.50	6.25
35°	2.90	8.40
40°	3.30	10.90
45°	3.70	13.70
50°	4.10	16.80
60°	4.80	23.00
70°	5.50	30.25
80°	6.20	38.45
90°	6.80	46.25

From the asymptotic value of Kc/F_θ vs. $\sin \theta/2$, the number average length and molecular weight can be determined (18, 19, 20). In addition, if the weight average molecular weight is known, the weight average length can also be evaluated (16). The approximations made in the theoretical treatment require that $x > 2$. As can be seen from Table I this condition is fulfilled for a monodisperse particle 5000 Å long over the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

entire range of angles tabulated. In the case of polydispersity the smaller particles may contribute significantly to the scattering and cause a deviation from linearity at low angles.

RESULTS AND DISCUSSION

Figures 1 and 2 represent typical Zimm plots of the angular distribution of the intensity of light scattered by four different virus concentrations in 0.1 M potassium chloride and 0.005 M sodium citrate, respectively. The plots are practically linear between 30° and 50°, and the weight average molecular weight and z average length were determined from the intercept and slope respectively. To check the reproducibility of the purification procedure three different virus preparations were investigated. The molecular weights were $34–36\times10^6$ and the length was 5300–5500 Å. Within the error of the experiment, the data in 0.005 M sodium citrate were the same as in 0.1 M potassium chloride. Therefore, no change in shape occurred, although the net charge on the virus particles increased as indicated by the increase of the second virial coefficient. The rigidity of the virus particle, as demonstrated previously by flow-birefringence measurements (5), was thus confirmed.

Figure 3 represents a plot of $(Kc/R_\theta)_{c=0}$ vs. sin $\theta/2$ corresponding to the data in Fig. 1. The linear relationship was followed. The slope of the regression line corresponds to

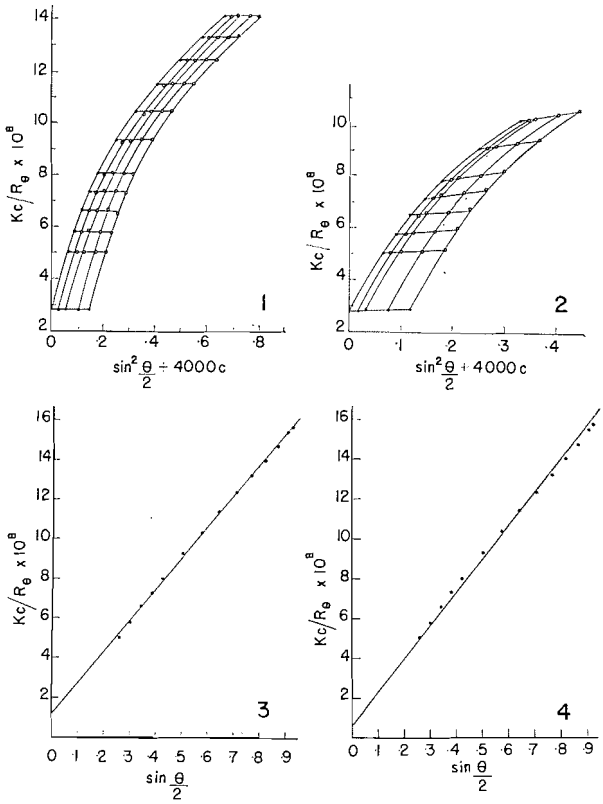

FIG. 1. Typical Zimm plot of light scattering data of potato X virus in 0.1 M potassium chloride.
FIG. 2. Typical Zimm plot of light scattering data of potato X virus in 0.005 M sodium citrate.
FIG. 3. The angular distribution of the intensity of scattered light from potato X virus solutions in 0.1 M potassium chloride as a function of sin $\theta/2$. Virus concentration was extrapolated to zero. Solid line is regression line: $(Kc/R_\theta)_{c=0} = (0.12+1.60 \sin \theta/2)\times10^{-7}$.
FIG. 4. Same data as in Fig. 3. Solid line is regression line with average slope 1.675×10^{-7} (see text).

1.60×10^{-7}. Taking the weight average molecular weight from Fig. 1 as 35.7×10^6 a weight average length of 4700 Å was calculated. From the best fit of the experimental values of $1/P$ vs. $\sin^2\theta/2$ with a theoretical curve at high angles, the value of 4800 Å was derived. As could be anticipated (16) this value is very close to the weight average length.

The uncertainty in the determination of number averages has been discussed (16). This can be illustrated with the data in Fig. 3. From the intercept and slope of the straight line in Fig. 3 the following number averages were derived: molecular weight 17×10^6, length 2200 Å. Obviously these data are unreasonably low. A more reasonable value can be obtained in the following manner. Taking the best straight lines through the points between 30° and 60° and between 90° and 135° separately, an average slope of 1.675×10^{-7} can be evaluated. Using this as the slope, the regression line through all the points will be given by $(Kc/R_\theta)_{c=0} = (0.063+1.675\sin\theta/2)\times10^{-7}$ (Fig. 4). The number average molecular weight and length from this line would be 32×10^6 and 4400 Å respectively. It should be noticed that while the slope has been changed by 5%, the molecular parameters increased by a factor of two. On the other hand the weight average length from Fig. 4 would be 4900 Å, not very different from the value derived from Fig. 3.

It was somewhat surprising that the weight average length was found to be lower than the most probable particle length as determined from electron microscopy. Inspection of light scattering data on tobacco mosaic virus will show that a similar discrepancy can also be found there (21, 22). We have pointed out that this can be anticipated in the case of polydispersity in thickness (16). The low value of the number average length could therefore be interpreted as indicating a tendency for side-to-side aggregation. The extent of this aggregation can be estimated by evaluating the radius of the cylinder, rather than the weight average length, from the slope in Fig. 3. The particle width determined from this slope should be independent of the distribution of length (19) and if the shape is known, can be determined unambiguously. Assuming a cylindrical shape the weight average radius is given by (16): $\sqrt{(r^2)_w} = \sqrt{4/\pi\rho N\lambda'\times(\text{slope})} = 54.5$ Å giving a diameter of 109 Å. This is only 9% higher than the number average value determined with the electron microscope.

The difference between the weight average and z average length, a measure of the total polydispersity, was relatively small (15%). We would therefore anticipate a sharp distribution function of lengths in our preparation.*

Assuming a cylinder 5100 Å long, 100 Å in diameter (3), with a partial specific volume of 0.73 ml/g (23), the predicted molecular weight is 33×10^6, in good agreement with the light scattering data. The value of 26×10^6 calculated by Loring (4) can be considered only as a rough estimate. The sedimentation constant and viscosity on which this estimate was based were determined at finite concentrations and the viscosity was measured at relatively high gradients (Ostwald Viscometer). From what is known about the dependence of the sedimentation constant on concentration and the viscosity on gradient in the case of large elongated particles, it is obvious that both values must have been too low. This is also apparent from the particle length derived from these data, which is 4330 Å.†

Finally, it should be mentioned that as in the case of tobacco mosaic virus (21), the

*A comparison with a uniform tobacco mosaic virus preparation can be made (21, 22). The difference in length determined from high values of $1/P$ and from the limiting slope of this function was 10%. In our potato X virus preparation the difference was 13% (4800 Å and 5460 Å).

†We have also determined the molecular weight from sedimentation–diffusion measurements. Because of the very slow rate of diffusion, the diffusion constant could not be determined accurately. We found, however, that at low virus concentrations the boundary remained Gaussian over a period of 8 days in the Spinco electrophoresis–diffusion apparatus. We obtained $D_{20} = 3.2\times10^{-8}$. The molecular weight obtained from this value and $S_{20} = 117.8\times10^{-13}$ (8) was 33×10^6.

light scattering particle length of potato X virus is significantly lower than the hydrodynamic length determined from flow birefringence (5). The inadequacy of the ellipsoid of revolution to represent a cylinder has been discussed in detail (21). Since the same considerations apply in the case of potato X virus, a similar discrepancy between the light scattering and flow-birefringence length can be anticipated.

FREE RADICALS BY MASS SPECTROMETRY

XV. THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF FORMIC ACID, ACETIC ACID, AND METHYL FORMATE[1]

P. KEBARLE[2] AND F. P. LOSSING

ABSTRACT

The $Hg(^3P_1)$ photosensitized decomposition of formic acid proceeds by two intramolecular rearrangement reactions, leading respectively to H_2O and CO, and to H_2 and CO_2. No free radicals are produced. The decomposition reactions of methyl formate and of acetic acid proceed predominantly by the formation of free radicals, but intramolecular rearrangements also occur to a significant extent. For both these latter compounds the evidence suggests the occurrence of two modes of dissociation into free radicals:

$$RC(=O)—OR' + Hg^* \rightarrow RC(=O) + OR' + Hg$$

$$RC(=O)—OR' + Hg^* \rightarrow R + C(=O)—OR' + Hg.$$

No evidence for the alternative mode of dissociation

$$RC(=O)—OR' + Hg^* \rightarrow RC(=O)—O + R' + Hg$$

was found.

INTRODUCTION

In the photolytic decomposition of molecules of the type RCOOR′, several types of primary steps appear to occur. A bond rupture to give two free radicals may occur at one of several bonds, and an intramolecular shift of a hydrogen atom to give two molecular products appears to be also an important mode of decomposition.

The simplest molecule of the RCOOR′ type, formic acid, has been examined both by direct photolysis and by mercury photosensitization. Ramsperger and Porter (1) found that in the region 2260 Å – 2500 Å two molecular rearrangements occurred:

$$HCOOH + h\nu \rightarrow CO + H_2O\ (64\%), \quad [1]$$

$$HCOOH + h\nu \rightarrow CO_2 + H_2\ (36\%). \quad [2]$$

Reaction [1] accounted for 64% of the molecules reacted, and reaction [2] accounted for the remainder.

Bates and Taylor (2) examined the mercury-photosensitized decomposition at 2537 Å and found a similar situation:

$$Hg^* + HCOOH \rightarrow Hg + CO + H_2O\ (76\%), \quad [3]$$

$$Hg^* + HCOOH \rightarrow Hg + CO_2 + H_2\ (24\%). \quad [4]$$

The same products were found by Herr and Noyes (3). A more comprehensive examination of the direct photolysis over the region 1900–2540 Å was made by Gorin and Taylor (4). They found the ratio of reaction [1] to reaction [2] to vary with wavelength, shorter wavelengths and higher temperatures favoring reaction [2]. Molecules of the dimeric

[1]*Manuscript received September 16, 1958.*

[2]*National Research Council of Canada Postdoctorate Fellow 1956–58.*

form of formic acid $(HCOOH)_2$ decomposed solely into CO_2 and H_2 at all wavelengths used. From experiments with parahydrogen the authors concluded that a primary split

$$HCOOH + h\nu \rightarrow H + COOH \quad [5]$$

did not occur to any significant extent. A similar conclusion was reached by Burton (5), who found that antimony mirrors were not removed in the direct photolysis. The only evidence for a free radical mode of dissociation comes from the observations of Terenin (6) of the OH radical in emission during photolysis.

The next simplest molecules of the RCOOR′ type are methyl formate, $HCOOCH_3$, and acetic acid, CH_3COOH. Very little data is available on the photodecomposition of methyl formate. Ausloos (7) found the photolysis of liquid methyl formate to yield CH_4, CO_2, CO, and H_2 as products. No runs on gaseous methyl formate were reported.

The photolysis of CH_3COOH was examined by Burton (8), who, on the basis of mirror removal experiments, rejected the primary split

$$CH_3COOH + h\nu \rightarrow CH_3 + COOH \quad [6]$$

in favor of the process

$$CH_3COOH + h\nu \rightarrow CH_3COO + H. \quad [7]$$

No CH_3 radicals or radicals such as CH_3CO which would decompose to form CH_3 could be detected. A molecular process

$$CH_3COOH + h\nu \rightarrow CH_4 + CO_2 \quad [8]$$

was reported by Farkas and Wansbrough-Jones (9). A recent investigation of the photolysis by Ausloos and Steacie (10) using deuterium labelling provides good evidence that reaction [8] occurs to the extent of about 10%. Three other primary processes were possible, reactions [6], [7], and a split into acetyl and hydroxyl radicals:

$$CH_3COOH \rightarrow CH_3CO + OH. \quad [9]$$

From the behavior with temperature, it was evident that dimers $(CH_3COOH)_2$ played no part in the primary process.

EXPERIMENTAL

The reactor and mercury lamp have been described in previous publications (11, 12). A new ion source, similar in some respects to that used by Leger in a rapid-scan mass spectrometer (13), was constructed for this work and is shown in Fig. 1. It possessed a number of features designed to improve the sensitivity of detection for oxygenated radicals. The plates of the source were rectangular in shape, 2 in. long by $\frac{5}{8}$ in. wide. The side walls of the ionization chamber facing the orifice and the pumping lead consisted only of tungsten mesh screen of high transparency (> 90%). Owing to the open construction of the ionization chamber relatively little obstruction was placed in the flight path of a molecule from the orifice to the pumping lead, and the proportion of radicals ionized after colliding with surfaces should consequently be much less than in the design used previously. Although this feature is probably of little advantage for radicals which are not reactive toward metal surfaces, such as the alkyl radicals (14), it might be expected that oxygenated radicals are more sensitive to such collisions. A further advantage, that fewer molecules are able to enter the analyzer tube, permitted a higher differential pressure to be maintained between the ionization chamber and the analyzer tube. A rough estimate based on the ratio of the pressures in the pumping leads in the two designs indicated a four- or five-fold improvement in this ratio.

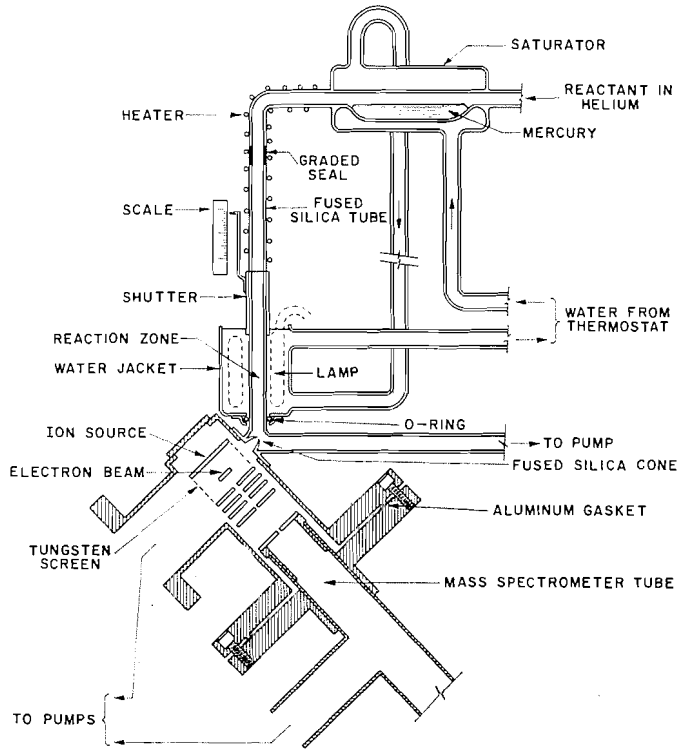

FIG. 1. Diagram of photochemical reactor and mass spectrometer ion source.

MATERIALS

The formic acid, methyl formate, and acetic acid were samples of commercial grades of high purity which were carefully degassed before using. The deuterated methyl formate and acetic acid were kindly supplied by Dr. L. C. Leitch.

RESULTS AND DISCUSSION

Before discussing the results in detail, it will not be amiss to point out some differences in reaction conditions between the reactor used in this work and those used in conventional photochemical experiments. In previous investigations using the same apparatus a number of compounds were found to decompose by a primary split into free radicals. In all these cases no evidence was found for the occurrence of reactions between free radicals and the parent compound. The reason for this is easily understood. Such abstraction reactions require an activation energy of 8–10 kcal/mole while radical combination and disproportionation reactions require considerably less, probably 0–1 kcal/mole. At 55° C the rate constant for abstraction reactions is consequently only 10^{-5} to 10^{-6} as large as for radical–radical reactions. In conventional photochemical systems this large factor is counterbalanced by the very small steady-state concentration of radicals relative to the parent compounds, and an abstraction reaction may consequently be of great importance. In the reactor used in this work the situation is quite different. For example, in the mercury-photosensitized decomposition of acetone (12) the concentration of methyl radicals was about $\frac{1}{10}$ of the concentration of acetone during most of the contact time. With such relatively high concentrations of radicals, radical–radical interactions will be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

at least 10^4 times faster than reactions of radicals with the parent compound, and the formation of radicals or other products by such reactions can be neglected.

The situation is similar in many respects to that produced in the flash photolysis experiments of Khan, Norrish, and Porter (15) in which radical–radical reactions were considered to predominate. It is of interest to note that in the flash experiments the average decomposition was about 1% for a flash duration of about 10^{-4} second. No chains were found to participate and the entire decomposition resulted from the primary act. In the present system the extent of decomposition was 10–20% of the parent compound in a time of 10^{-3} second. The rates of radical production and consequently the ratio of concentrations of radicals and parent compound in the two reaction systems are, therefore, of about the same order.

A further consequence of the high concentration of radicals in the present experiments is the possibility of reaction of a radical with an excited mercury atom, leading to dissociation of the radical. Such reactions had to be postulated for allyl radicals (11) and for acetyl radicals (12) to explain the formation of certain products.

Formic Acid

In the mercury photosensitized decomposition of formic acid vapor, only four products were found: CO, H_2O, CO_2, and H_2. No free radicals could be detected. The amounts of products formed at two partial pressures of formic acid, and at various positions of the shutter (i.e. various exposure times) are given in Table I. Some difficulties were encountered in measuring the sensitivity coefficients for formic acid and for water, on account of the absorption effects of the glass surfaces in the sample line, and the mass balances of the products are therefore somewhat different from 100%. The analysis of formic acid and of the products at short exposure times were quite uncertain since only small changes in the composition were produced. The amounts of HCOOH decomposed and of products formed are shown in Figs. 2 and 3, as a function of the exposure time. It is evident that within the experimental error $\phi_{CO} = \phi_{H_2O}$ and $\phi_{CO_2} = \phi_{H_2}$. The equality of these pairs of products and the lack of variation with exposure time indicates that the only modes of decomposition are the two intramolecular rearrangement reactions found in earlier work, reactions [3] and [4]. From the present data the ratio of occurrence of these two reactions is about $\phi_3/\phi_4 \approx 70/30$. This ratio is slightly different from the

ratio 76–24 found by Bates and Taylor, but in view of the uncertainty in the analysis of HCOOH and H_2O in the present work it is not entirely certain that the difference is significant. The present work does, however, confirm the view that a dissociation into free radicals or into an atom and a free radical occurs to a very small extent or not at all.

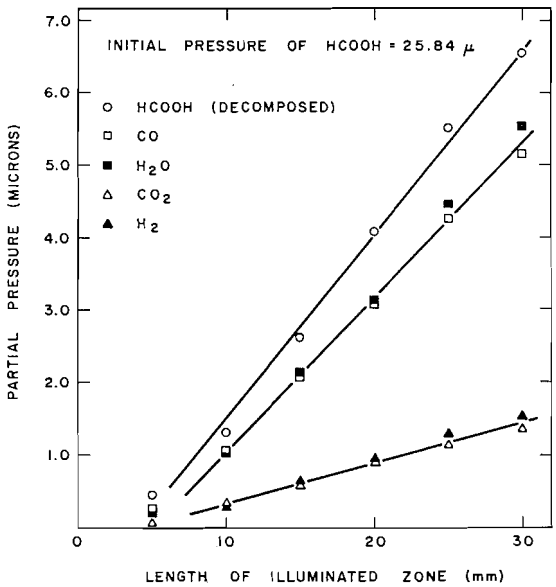

FIG. 3. Products from mercury-photosensitized decomposition of formic acid vapor.

Methyl Formate

The distribution of products formed by the mercury-photosensitized decomposition of methyl formate with different lengths of illuminated zone are given in Table II. In addition to these products very small amounts of methyl acetate and dimethyl ether were also produced. Two other minor products could be detected only by their parent peaks at mass 58 and mass 62. A search for free radicals was made using initial pressures

of methyl formate two or three times higher than in the quantitative experiments. Using low electron energies, at which only parent ions should be formed, the peaks at mass 15, 29, 31, and 59 were found to increase when the lamp was on. These mass numbers correspond to the parent ions of CH_3, CHO, CH_3O, and $COOCH_3$ radicals. The presence of these radicals is also indicated by the formation of a number of products which evidently arise from the corresponding radical–radical interactions. Ethane undoubtedly was formed by the combination of two methyl radicals, the dimethyl ether from the combination of a methyl and a methoxy radical, and the methyl acetate from the combination of a methyl and a $COOCH_3$ radical. The unidentified peaks at mass 58 and mass 62 might be the parent peaks of glyoxal, the dimer of CHO radical, and dimethyl peroxide, the dimer of CH_3O, but a positive identification could not be made.

In order to obtain a further confirmation for some of these findings a separate experiment was carried out in which mercury dimethyl was added to the helium stream carrying the methyl formate. With the lamp on, a small additional increase in the peaks at mass 74 and mass 43 was observed. The increased portions of these peaks had a ratio mass 74/mass 43 = 0.15. The ratio of these peaks in the mass spectrum of methyl acetate measured in a separate experiment was 0.18. An increase was also observed for the mass 46 and 45 peaks, in the ratio mass 46/mass 45 = 0.34. The ratio for dimethyl ether measured separately was 0.40. Although the agreement is somewhat approximate, there can be little doubt that the corresponding increases in the peaks were caused by the formation of methyl acetate and dimethyl ether by reaction of $COOCH_3$ and OCH_3 radicals with the additional CH_3 radicals provided by the decomposition of mercury dimethyl.

The presence of the CH_3O and HCO radicals indicate that the following primary step must occur:

$$Hg^* + HCOOCH_3 \rightarrow Hg + HCO + OCH_3. \qquad [10]$$

The presence of the $COOCH_3$ radical suggests the occurrence of a second primary dissociation process:

$$Hg^* + HCOOCH_3 \rightarrow Hg + H + COOCH_3. \qquad [11]$$

The formation of the $COOCH_3$ radical by a primary step, and not by abstraction of a H atom from methyl formate by one of the radicals produced in reaction [10] depends on the validity of the discussion given above concerning the occurrence of radical–substrate reactions.

The presence of methyl radicals might result from a third primary mode of dissociation:

$$Hg^* + HCOOCH_3 \rightarrow Hg + HCOO + CH_3. \qquad [12]$$

It is not necessary, however, to postulate this reaction since the dissociation of the $COOCH_3$ radical by the reaction:

$$COOCH_3 \rightarrow CO_2 + CH_3 \qquad [13]$$

might be expected to be quite rapid at 55° C. Although the strength of the COO—CH_3 bond is unknown, it can be shown from thermochemical data that it cannot be very strong. From the relation

$$D(H—COOCH_3) + D(COO—CH_3) = \Delta H_f(H) + \Delta H_f(CH_3) + \Delta H_f(CO_2) - \Delta H_f(HCOOCH_3)$$

and standard thermochemical data, the sum of the two bonds is 73.6 kcal/mole. Since it might be expected that the C—H bond alone must be nearly this strong, D(COO—CH_3)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

must be certainly not greater than 10–15 kcal/mole. It is rather surprising that the $COOCH_3$ radical could be detected at all in the present experiments.*

The quantitative data given in Table II were obtained from the mass spectra of the products in the reaction stream taken with 50-v electrons. After subtracting the contributions of the stable reaction products from the mass spectra, a small residual peak remained for mass 59, and somewhat larger ones for mass 31, 29, and 15. It is probable that these peaks were caused by the presence of the $COOCH_3$, CH_3O, CHO, and CH_3 free radicals. Since the mass spectrum of the CH_3O radical is not known, its contribution to the mass 15 peak could not be evaluated. Thus the concentration of the CH_3 radical, which is the only one whose sensitivity coefficient is known, could not be determined. The mass balances given in Table II therefore do not include free radical contributions. Contributions from the minor products methyl acetate, dimethyl ether, and the tentatively identified methyl peroxide and glyoxal are also not included.

Two approximate relations between the amounts of the various products given in Table II can be seen:

$$[CO] \approx [CH_3OH] + [CH_2O] \qquad \text{I}$$

$$[CO_2] \approx [CH_4] + [C_2H_6]. \qquad \text{II}$$

TABLE III

Product balances—methyl formate

Length of illuminated zone (mm)	Methyl formate		Products (μ)			
	Initial pressure (μ)	% Decomposed	[CO]	$[CH_3OH + CH_2O]$	$[CO_2]$	$[2\,C_2H_6 + CH_4]$*
20	19.87	12.73	1.86	1.75	.331	.273
25	19.87	16.76	2.23	2.24	.441	.340
30	19.87	19.48	2.80	2.64	.490	.440

*This sum should include $[CH_3]$, which could not be measured.

Numerical values for these product balances are given in Table III. Product balance I can be related to the primary reaction [10] if it is assumed that all of the HCO radicals produced by [10] are converted to CO by subsequent reactions, and that essentially all the CH_3O radicals disproportionate to CH_3OH and CH_2O. Similarly, product balance II will hold provided that essentially all the $COOCH_3$ radicals produced by reaction [11] are converted by subsequent reactions to CO_2, C_2H_6, and CH_4. A reaction mechanism fulfilling the requirements of product balances I and II is given below:

$$Hg^* + HCOOCH_3 \rightarrow Hg + HCO + OCH_3 \qquad [10]$$

$$Hg^* + HCOOCH_3 \rightarrow Hg + H + COOCH_3 \qquad [11]$$

$$COOCH_3 \rightarrow CO_2 + CH_3 \qquad [13]$$

$$Hg^* + OCH_3 \rightarrow Hg + H + CH_2O \qquad [14]$$

$$Hg^* + HCO \rightarrow Hg + H + CO \qquad [15]$$

$$2CH_3O \rightarrow CH_3OH + CH_2O \qquad [16]$$

$$2HCO \rightarrow H_2 + 2CO \qquad [17]$$

**Some further support for the instability of* $COOCH_3$ *is given by a comparison with the* CH_3CO *radical. From the relation:*

$$D(H—COCH_3) + D(CO—CH_3) = \Delta H_f(H) + \Delta H_f(CH_3) + \Delta H_f(CO) - \Delta H_f(CH_3CHO)$$

the sum of the two bonds is 97.5 kcal/mole. If, as might reasonably be expected, $D(H—COCH_3)$ *is not much less than* $D(H—COOCH_3)$ *it is evident that* $D(COO—CH_3)$ *is significantly weaker than* $D(CO—CH_3)$.

$$CH_3O + HCO \rightarrow CH_3OH + CO \quad [18]$$

$$CH_3O + HCO \rightarrow 2CH_2O \quad [19]$$

$$H + CH_3O \rightarrow CH_2O + H_2 \quad [20]$$

$$H + HCO \rightarrow CO + H_2 \quad [21]$$

$$CH_3 + CH_3O \rightarrow CH_4 + CH_2O \quad [22]$$

$$CH_3 + HCO \rightarrow CH_4 + CO \quad [23]$$

$$2CH_3 \rightarrow C_2H_6 \quad [24]$$

The evidence for reactions [10], [11], and [13] has been discussed. It is evident that with at least four free radicals, H atoms, and excited mercury atoms present as reactive species it is not possible to distinguish between alternative methods of producing many of the secondary products. The reactions listed above are all probable ones, but other modes of radical–radical interaction may, of course, occur. Reactions [14] and [15], for which there is no direct evidence, were included on the basis of previous work on the decomposition of acetone (12), using the same apparatus, in which the formation of ketene could only be explained by the reaction of acetyl radicals with excited mercury atoms. Reactions [16] to [23] are radical disproportionation steps, all of which may not be active in the mechanism. However, since products of radical combination, with the exception of ethane, were found only in minute amounts, it is to be expected that disproportionation reactions must account for the largest part of the products found.

In the preceding discussion the possibility of a dissociation involving an intramolecular rearrangement was not considered. It is clear that product balance I will still hold if part of the decomposition proceeds by the reaction

$$Hg^* + HCOOCH_3 \rightarrow Hg + CH_3OH + CO \quad [25]$$

since for every CO molecule one CH_3OH molecule is also produced. Similarly, product balance II will be obeyed if the intramolecular rearrangement

$$Hg^* + HCOOCH_3 \rightarrow Hg + CH_4 + CO_2 \quad [26]$$

is one of the primary reactions. These are analogous to reactions [3] and [4] respectively, as found to occur in the decomposition of formic acid. In order to establish whether methyl formate decomposes partly by reaction [25] some experiments were carried out using mixtures of $HCOOCH_3$ and $DCOOCD_3$. The total pressure of the two isomers in the helium stream was kept approximately equal to the pressure of methyl formate used in the previous experiments. In a series of runs, the mole fraction of deuterated methyl formate was varied from unity to almost zero. For each composition the amount of CD_3OD formed and the percentage of decomposition of $DCOOCD_3$ were measured. In these experiments the length of the illuminated zone was 30 mm. The results are summarized in Table IV. A plot of the ratio CD_3OD formed/$DCOOCD_3$ decomposed versus the mole fraction of $DCOOCD_3$ is shown in Fig. 4. If CD_3OD were formed entirely by the intramolecular rearrangement reaction [25], the ratio would not be affected by the addition of $HCOOCH_3$. Conversely, if CD_3OD were formed entirely by a free radical process, the ratio should approach zero as the mole fraction of $DCOOCD_3$ approaches zero. The observed dependence shows an intermediate behavior indicating the participation of both a molecular and a free radical process. The ratio obtained by extrapolation is approximately 0.12. Thus about 12% of the methyl formate decomposes by the rearrangement reaction [25]. In the experiments with $HCOOCH_3$ reported in Table II (for a 30-mm illuminated zone) the yield of CO was 72.4% of the methyl formate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

decomposed. Since the yield of CO represents the fraction of methyl formate decomposing by reactions [10] and [25], it follows that the methyl formate decomposing by reaction [10] alone is approximately $72.4-12.0 = 60.4\%$.

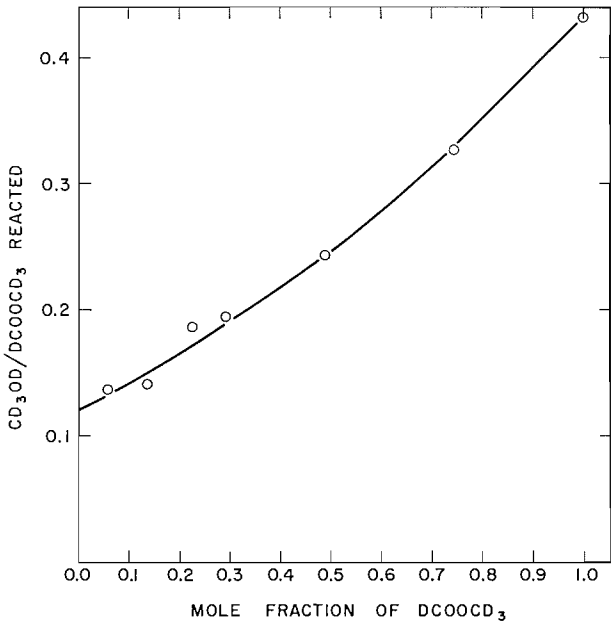

FIG. 4. Formation of CD_3OD in $DCOOCD_3$–$HCOOCH_3$ mixtures.

TABLE IV

CD_3OD Production in $DCOOCD_3$–$HCOOCH_3$ mixtures

$DCOOCD_3$ (μ), initial	$HCOOCH_3$ (μ), initial	Mole fraction $DCOOCD_3$	$DCOOCD_3$ decomposed		CD_3OD formed	CD_3OD formed
			μ	%	(μ)	$DCOOCD_3$ decomposed
1.21	19.6	.058	.226	18.7	.031	.137
2.64	16.7	.136	.516	19.5	.073	.141
4.89	16.7	.226	.909	18.6	.170	.187
6.94	16.7	.293	1.37	19.7	.266	.194
8.48	8.8	.490	1.81	21.3	.440	.243
14.97	5.1	.747	2.96	19.8	.968	.327
20.93	0.0	1.00	4.05	19.3	1.75	.432

Similarly, the methyl formate decomposing by reactions [11] and [26] should be equal to the yield of CO_2, that is 12.7% (Table II). Assuming that all the methane is formed by reaction [26] an upper limit for the participation of this reaction would be given by the methane yield, which is 4.8%. Since methane could also be formed by reactions [22] and [23], it is probable that the true extent for the occurrence of reaction [26] is much smaller than 4.8%, and possibly zero.

Acetic Acid

The yields of products obtained in the mercury-photosensitized decomposition of acetic acid are given in Table V. The full intensity of the lamp was used in this experiment by withdrawing the shutter completely out of the reaction zone. The principal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

products were water, carbon dioxide, ketene, methane, ethane, methyl radicals, and acetone. The formation of a polymeric substance on the walls of the reactor, which was visible as a brown stain after several minutes' exposure, may account for the deficiency in the mass balances given in Table V. This deposit may result from the polymerization of the ketene formed in the reaction. In the mercury-photosensitized reaction of acetone (12) in which ketene was a product, a similar deposit was formed.

TABLE V

Decomposition of acetic acid

Acetic acid (μ) present		Acetic acid decomposed		Products (μ)								Mass balance (%) for:		
Lamp off	Lamp on	μ	%	CO_2	CO	C_2H_6	H_2O	CH_4	CH_3	Acetone	Ketene	O	C	H
7.35	6.12	1.23	16.7	0.461	0.260	0.224	0.654	0.231	0.073	0.015	0.292	87.7	87	91.6

Using electrons of low energy, the only radical which could be detected was methyl. However, the formation of acetone as a product can be explained only by the presence of acetyl radicals, which must have been present in concentrations too low to detect. Addition of mercury dimethyl to the reaction stream caused an increase in the amount of acetone formed, thus confirming the presence of CH_3CO radicals. The presence of CH_3CO radicals, together with the formation of substantial amounts of water, indicates that the following step must occur:

$$Hg^* + CH_3COOH \rightarrow Hg + CH_3CO + OH. \quad [27]$$

Although the CH_3 radicals detected might arise by dissociation of CH_3CO, the presence of large amounts of CO_2 together with the fact that the yield of CO is not nearly twice the yield of ethane indicates that a second primary process, in which CH_3 radical and a radical ultimately forming CO_2 are produced, must occur: one possibility is that this reaction is the following:

$$Hg^* + CH_3COOH \rightarrow Hg + CH_3 + COOH. \quad [28]$$

CO_2 would then be formed by the decomposition of the COOH radical as follows:

$$COOH \rightarrow CO_2 + H. \quad [29]$$

Reaction [29] appears to be a much more probable mode of dissociation of COOH than the more frequently proposed dissociation into CO and OH, since $\Delta H_f(CO_2)+\Delta H_f(H)$ is some 25 kcal/mole less than $\Delta H_f(CO)+\Delta H_f(OH)$. A difference in dissociation energy of this magnitude between the O—O and O—H bonds in COOH should be sufficient to ensure that COOH dissociates mainly by reaction [29]. However, an alternative primary decomposition step

$$Hg^* + CH_3COOH \rightarrow Hg + CH_3COO + H \quad [30]$$

would ultimately form CH_3 and CO_2 by dissociation. Reaction [30] was proposed by Burton (8) and by Ausloos and Steacie (10) as the primary dissociation step in the direct photolysis. A search for the $CH_3C\dot{O}O$ radical, using low electron energies, showed no indication of its presence. In experiments in which mercury dimethyl was added to the reaction stream, no sign of methyl acetate, the combination product of $CH_3C\dot{O}O$ and CH_3, could be found. It must be concluded that either the $CH_3C\dot{O}O$ radical was not formed in appreciable amounts, or alternatively that this radical has an extremely short lifetime at 55° C. (Care should be taken to distinguish between this radical, $CH_3C\dot{O}O$, and the isomeric radical $\dot{C}OOCH_3$ produced from methyl formate.) Since four

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

radical products can result from these primary steps, 10 radical recombination products are possible. Two of these lead to re-formation of acetic acid. A search was made for the parent peaks of the other eight, but aside from acetone and ethane no other recombination products could be detected. The observed products must then arise mainly by radical decomposition and disproportionation reactions. The following set of reactions appear probable:

$$COOH \rightarrow CO_2 + H \quad [29]$$

$$Hg^* + COOH \rightarrow Hg + CO_2 + H \quad [31]$$

$$CH_3CO \rightarrow CH_3 + CO \quad [32]$$

$$Hg^* + CH_3CO \rightarrow Hg + CH_2{=}CO + H \quad [33]$$

$$COOH + CH_3 \rightarrow CH_4 + CO_2 \quad [34]$$

$$COOH + OH \rightarrow H_2O + CO_2 \quad [35]$$

$$2CH_3 \rightarrow C_2H_6 \quad [24]$$

$$CH_3 + COCH_3 \rightarrow CH_3COCH_3. \quad [36]$$

Reactions [29] and [32] could be either thermal decompositions or decompositions of excited radicals produced in the primary splits. Reactions [31] and [33] have been assumed on the basis of previous experience with the apparatus as discussed above. Reactions [34] and [35] are plausible disproportionation reactions, and reactions [24] and [36] account for the formation of ethane and acetone.

These reactions lead to a number of relations between the yields of various products which can be compared with the analytical results. There are two modes of formation of methyl radicals, the primary reaction [28] and the decomposition reaction [32]. Since all the COOH produced by reaction [28] is evidently converted to CO_2 by subsequent reactions, the sum of the yields of CO and CO_2 should equal the total amount of methyl formed, that is:

$$[CO] + [CO_2] = [CH_3] + [CH_4] + 2[C_2H_6] + [CH_3COCH_3].$$

From Table V $[CO] + [CO_2] = 0.752\ \mu$, and the total methyl yield is $0.721\ \mu$, in reasonable agreement. The OH radicals produced by the primary step [27] are evidently all converted to H_2O. The quantity of H_2O should then be equal to the sum of the products derived from CH_3CO radicals, i.e.

$$[H_2O] = [CH_2{=}CO] + [CO] + [CH_3COCH_3].$$

From Table V, $[H_2O] = 0.65\ \mu$ and the sum of the acetyl products is 0.57. If allowance is made for the fact that some ketene may have polymerized, this agreement is reasonably close.

However, these two product balances would also apply if part of the primary decomposition occurred by one or both of the intramolecular rearrangement steps:

$$Hg^* + CH_3COOH \rightarrow Hg + CH_4 + CO_2, \quad [37]$$

$$Hg^* + CH_3COOH \rightarrow Hg + H_2O + CH_2{=}CO. \quad [38]$$

In order to determine the extent to which these reactions occur, an attempt was made to carry out experiments with CD_3COOD–CH_3COOH mixtures similar to those with deuterated methyl formate. It was found that the acidic hydrogen and deuterium atoms exchanged so rapidly in the reaction system that useful experiments with mixtures could not be carried out. It is possible, however, to set upper limits to the extent of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

these reactions from an examination of the data in Table V. The proportion of acetic acid decomposing by reactions [28] and [37] should be given by the yield of CO_2, that is, 37.5%. On the assumption that all the methane was produced by reaction [37], the upper limit for the occurrence of this reaction is 18.8%, and a lower limit for sum of reactions [28] and [30] is 37.5% − 18.8%, i.e. 18.7%. Since methane could also be produced by reaction [34] the actual extent was probably significantly less. The proportion of acetic acid decomposing by the primary reactions [27] and [38] should be given by the yield of H_2O, that is, 53%. On the assumption that all the ketene was formed by reaction [38], this reaction accounted for 23.7%, and a lower limit for reaction [27] would be 29.3%. The approximate extent of the various primary processes can be summarized as follows:

$$Hg^* + CH_3COOH \rightarrow Hg + CH_3CO + OH \quad \sim 29\% \quad [27]$$

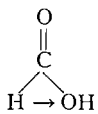
$$\rightarrow \begin{cases} Hg + CH_3 + COOH \\ Hg + CH_3COO + H \end{cases} \sim 18\% \quad \begin{cases} [28] \\ [30] \end{cases}$$

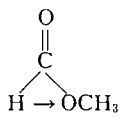
$$\rightarrow Hg + CH_4 + CO_2 \quad \sim 19\% \quad [37]$$

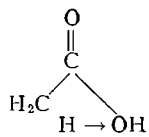
$$\rightarrow Hg + H_2O + CH_2{=}CO \sim 24\%. \quad [38]$$

CONCLUSION

It is evident that the modes of mercury-photosensitized decomposition of compounds of the type $R\overset{\overset{O}{\|}}{C}OR'$ do not by any means conform to a pattern. It is quite surprising that although HCOOH decomposes solely by molecular rearrangement reactions, methyl formate and acetic acid decompose predominantly by a split into free radicals. Two parallels in behavior can, however, be observed. In all three compounds the molecular rearrangement involving the transfer of a hydrogen atom to the oxygen atom of the hydroxy- or methoxy-group occurs with a greater probability than other molecular rearrangements. This reaction may be visualized as follows for the three compounds:







Secondly, in methyl formate and acetic acid the present experiments indicate that the predominating mode of dissociation into free radicals is the recation:

$$R\overset{\overset{O}{\|}}{C}OR' \rightarrow R\overset{\overset{O}{\|}}{C} + OR'. \quad [39]$$

Of secondary importance is the reaction:

$$R\overset{\overset{O}{\|}}{C}OR' \rightarrow R + \overset{\overset{O}{\|}}{C}OR'. \quad [40]$$

It may be noted further that when R is H, reaction [39] is much faster than [40], but when R′ is H the difference in rate is much smaller.

It is evident from the tables that the amount of formic acid decomposed is considerably greater than the amounts of methyl formate and acetic acid decomposed in an equal time under the same conditions. Provided that the quenching cross sections of the three compounds are not greatly different, it appears that the formic acid molecule

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

possesses a much greater facility for molecular rearrangements than do methyl formate or acetic acid. The lack of a free radical mode of decomposition for formic acid is therefore probably a consequence of the rapidity with which molecular rearrangements can occur. On the basis of structural considerations it is not clear why formic acid and methyl formate should differ so greatly in this respect.

DÉRIVÉS DU TRIMÉTHYL-1,8,8 BICYCLO[3,2,1]OCTANE

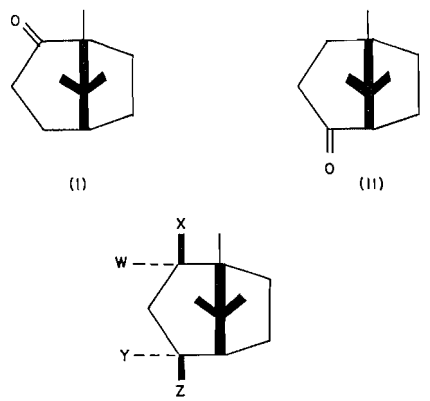
III. SYNTHÈSE DES TRIMÉTHYL-1,8,8 BICYCLO[3,2,1]OCTANOLS-2α ET -2β ET DES TRIMÉTHYL-5,8,8 BICYCLO[3,2,1]OCTANOLS-2α ET -2β[1]

H. Favre, M. Lefebvre[2] et (en partie) J-C. Richer[3]

RÉSUMÉ

Le (+)-triméthyl-1,8,8 bicyclo[3,2,1]octanol-2α et le (+)-triméthyl-5,8,8 bicyclo[3,2,1]-octanol-2α ont été préparés en réduisant par le sodium et l'alcool le (−)-homocamphre et le (+)-homoépicamphre respectivement. L'hydrogénation catalytique de ces cétones par le platine dans l'acide acétique conduit au (−)-triméthyl-1,8,8 bicyclo[3,2,1]octanol-2β et au (+)-triméthyl-5,8,8 bicyclo[3,2,1]octanol-2β respectivement. Les rendements stériques de ces opérations sont supérieurs à 90%. Les configurations ont été attribuées à la suite de l'analyse des modes de formation, des pouvoirs rotatoires et des vitesses d'oxydation chromique des alcools.

Nous rapportons dans ce mémoire des travaux relatifs à la réduction du (−)-homocamphre (I) et du (+)-homoépicamphre (II)[4] et à la détermination de la configuration de chacun des 4 alcools[5] (III–VI) obtenus. L'obtention des alcools stériquement purs n'offre pas de grandes difficultés. Pour chaque cétone la réduction par le sodium et l'éthanol conduit en prépondérance à l'un des épimères (alcool au sodium), tandis que l'autre s'obtient facilement par l'hydrogénation catalytique sur platine dans l'acide acétique (alcool au platine). Après chaque réduction, l'alcool brut fut transformé en *p*-nitrobenzoate; ce dérivé fut cristallisé jusqu'à point de fusion et pouvoir rotatoire constants, puis saponifié. Les quatre alcools obtenus de cette manière (Tableau I) sont



III.	W = OH; X,Y,Z = H	Triméthyl-1,8,8 bicyclo[3,2,1]octanol-2α
IV.	X = OH; W,Y,Z = H	Triméthyl-1,8,8 bicyclo[3,2,1]octanol-2β
V.	Y = OH; W,X,Z = H	Triméthyl-5,8,8 bicyclo[3,2,1]octanol-2α
VI.	Z = OH; W,X,Y = H	Triméthyl-5,8,8 bicyclo[3,2,1]octanol-2β

[4]*Pour la préparation de ces cétones, voir (1, 2).*
[5]*La nomenclature est celle en vigueur pour les dérivés du nortropane (aza-8 bicyclo[3,2,1]octane) et les composés apparentés (3). Les formules spatiales III A–VI A et III B–VI B représentées plus loin sont équivalentes aux formules III–VI.*

stériquement purs à la chromatographie sur alumine; chacun donne naissance à un *p*-nitrobenzoate en tous points semblable à celui qui servit à la purification. Chaque alcool fut oxydé par l'acide chromique en homocamphre ou en homoépicamphre, suivant son origine. Il convient de relever que les alcools épimères ne donnent pas de dépression de point de fusion en mélange, alors que leurs dérivés (esters) mentionnés plus haut en donnent. Une observation semblable avait été faite pour les cétones I et II (1).

TABLEAU I

Description des alcools III–VI

Alcools	P.f.	Rendements en alcools	Rendements stériques	$[\alpha]_D$*
Alcool au sodium III	212°	97%	94%	+17.9°±2.0°
Alcool au platine IV	234–235°	93%	90–95%	−29.2°±2.0°
Alcool au sodium V	166°	94%	92%	+35.9°±2.0°
Alcool au platine VI	206°	87%	97%	+43.9°±2.0°

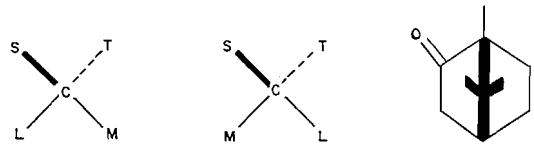
*Benzène.

Le succès de la réduction catalytique dépend de la position du groupe méthyle pontal (position 1 ou 5) par rapport au groupe carbonyle à réduire. Ainsi l'homoépicamphre est aisément réduit par le platine dans l'acide acétique glacial et tout aussi aisément par le platine ou le nickel de Raney dans l'alcool (sans pression et 25°). L'homocamphre, dont le groupe carbonyle est adjacent au méthyle pontal, n'est réduit à une vitesse appréciable que par le platine dans l'acide acétique. Lorsque la réduction a lieu, le rendement stérique est toujours supérieur à 90%. La réduction par le sodium et l'éthanol procède sans difficultés: les rendements en alcools et les rendements stériques sont les mêmes pour la réduction de l'homocamphre et de l'homoépicamphre. Les rendements stériques (Tableau I) ont été déterminés par l'analyse du pouvoir rotatoire des alcools bruts; celui de la réduction de l'homocamphre au platine a dû être estimé, car l'alcool brut contenait des traces de cétone décelées par spectroscopie infrarouge.

Pour déterminer les configurations et les conformations respectives des quatre alcools III à VI, nous avons appliqué plusieurs méthodes. Celles qui font appel aux modes de formation des alcools, à leurs rotations moléculaires et à leurs vitesses d'oxydation chromique seront discutées ici. Les réactions d'élimination des groupes —OH et de leurs esters feront l'objet de mémoires séparés en raison de leur complexité.

Nous appliquerons en premier lieu la méthode des rotations moléculaires de Bose et Chaterjee (4). La règle stipule que si les configurations absolues de deux composés alicycliques épimères peuvent être ramenées aux configurations VII et VIII, l'épimère VII sera plus dextrogyre que l'épimère VIII, pour autant que L, M, S et T représentent l'ordre décroissant de l'encombrement stérique des substituants ou des parties de la molécule adjacents au carbone asymétrique.

Comme la configuration absolue de l'homocamphre (I) et de l'homoépicamphre (II)



(VII) (VIII) (IX)

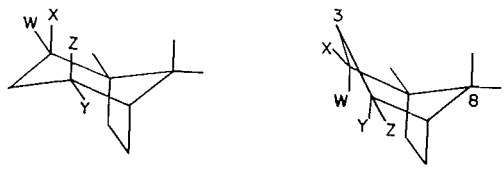
est connue avec certitude—puisque ces cétones sont dérivées (1, 2) du (+)-camphre (configuration absolue (5, 6), formule IX) par un procédé qui ne saurait provoquer d'inversion de configuration—nous pouvons connaître L et M pour les quatre alcools III à VI en question; L est l'atome de pont et M le groupe méthylène en position 3. En posant: —OH = S et —H = T, nous arrivons aux configurations suivantes:

Série de l'homocamphre: l'alcool au sodium, plus dextrogyre que l'alcool au platine, reçoit la configuration VII et par suite, la formule III. L'alcool au platine sera IV.

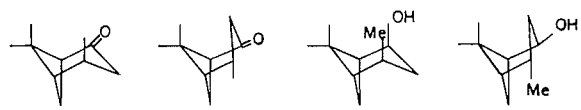
Série de l'homoépicamphre: l'alcool au platine, étant le plus dextrogyre, reçoit la configuration VII, donc VI. L'alcool au sodium sera V.

En fait, les formules III à VI peuvent être transposées en formules spatiales, qui se rattachent à deux conformations que nous appelons A et B.



I A	W,X = = O (cétone); Y,Z = —H	I B
II A	Y,Z = = O (cétone); W,X = —H	II B
III A	W = —OH; X,Y,Z = —H	III B
IV A	X = —OH; W,Y,Z = —H	IV B
V A	Y = —OH; W,X,Z = —H	V B
VI A	Z = —OH; W,X,Y = —H	VI B

La conformation B (cyclohexanique bateau) est certainement moins stable que la conformation A (cyclohexanique chaise), en raison principalement de l'interférence prononcée du groupe méthyle en position 8 (flagpole, *fp*) avec l'hydrogène (*fp*) en position 3. Nous avançons ceci en tenant compte de l'analogie qui existe entre les dérivés du triméthyl-1,8,8 bicyclo[3,2,1]octane et les verbanones. Bose a montré (7) que la *cis*-verbanone réagit sous sa conformation X C (analogue à I A et II A) plutôt que X D (analogue à I B et II B); voir aussi (8). Bose laisse toutefois ouverte la question de savoir si le néoisoverbanol a la conformation XI C ou XI D, XI C pouvant être défavorisée en raison des trois substituants axiaux.



X C X D XI C XI D

Nous ne retenons ainsi pour l'homocamphre (I) et l'homoépicamphre (II) que les conformations I A et II A respectivement, où le groupe carbonyle à réduire se présente comme celui d'une cyclohexanone chaise. De nombreux exemples supportent le fait que la réduction d'un groupe carbonyle par le sodium et l'alcool engendre un groupe —OH équatorial. Les hydroxyles des deux alcools au sodium seraient ainsi équatoriaux et leurs configurations α. Les alcools au platine seraient par conséquent les alcools axiaux, de configuration β, ce qui est conforme à ce que l'on sait de l'hydrogénation catalytique qui conduit, dans des conditions expérimentales ne favorisant pas une isomérisation, à la fixation de l'hydrogène sur le côté le plus dégagé de la molécule: généralement le groupe—OH est axial. Pour de nombreuses références, voir (7, 9, 10, 11, 12).

TABLEAU II
Vitesses d'oxydation chromique et fréquences de vibration C—O des alcools III à VI

Alcools	Vitesses d'oxydation relatives à celle du cyclohexanol	Fréquences de vibration* C—O, cm^{-1}
Cyclohexanol	1	
Alcool au sodium III	5.7	1044 (f), 1033 (f), 1013 (F)
Alcool au platine IV	111.8	1029 (F), 1005 (F)
Alcool au sodium V	6.5	1038 (F)
Alcool au platine VI	125.0	1044 (F)

*Mesurées dans le sulfure de carbone. (F) signifie bande forte, (f) bande plus faible.

À la suite des premiers travaux de Vavon (13) concernant la vitesse de l'oxydation chromique des alcools secondaires en cétones, Barton (14, 15) a fait remarquer que les groupes —OH axiaux étaient oxydés plus rapidement que les hydroxyles équatoriaux. Schreiber et Eschenmoser (16) ont interprété ce fait en termes d'interactions entre atomes non liés et de décompression stérique lors du passage des esters chromiques aux cétones, la décompression stérique, par suite la vitesse d'oxydation, étant plus grande pour une conformation axiale, plus comprimée qu'une conformation équatoriale.

Les résultats[6] rapportés au Tableau II montrent que les deux alcools au platine sont oxydés environ 20 fois plus rapidement que les deux alcools au sodium; ces résultats sont donc bien en accord avec les conformations IV A et VI A pour les alcools au platine (groupes —OH axiaux) et avec les conformations III A et V A pour les alcools au sodium (groupes —OH équatoriaux).

En définitive, l'analyse des modes de formation des alcools III à VI, de leurs pouvoirs rotatoires et de leurs vitesses d'oxydation chromique, contribue à former un faisceau d'indices favorables à l'interprétation suivante: les alcools sont formés à partir des cétones de conformation A (I A et II A, cyclohexanique chaise) et existent sous cette conformation en tant qu'alcools axiaux (IV A et VI A, alcools au platine) et alcools équatoriaux (III A et V A, alcools au sodium).

Nous rapportons au Tableau II les fréquences des vibrations C—O des quatre alcools III à VI; nous les avons mesurées dans le but de les comparer aux valeurs moyennes déduites par Cole, Jones et Dobriner (17) pour les alcools stéroides axiaux (996–1036 cm^{-1}) et équatoriaux (1038–1044 cm^{-1}). Les alcools III et IV issus de l'homocamphre montrent plusieurs bandes et il n'est pas possible d'en choisir une plutôt que l'autre pour appliquer la règle. L'inversion observée pour les triméthyl-5,8,8 bicyclo[3,2,1]-octanols-2α et -2β (V et VI) n'est donc plus significative et ne saurait être retenue pour invalider les conclusions tirées plus haut au sujet de la conformation de ces alcools.

PARTIE EXPÉRIMENTALE[7]

L'homocamphre utilisé dans les sections 1 et 2 a été préparé selon (1).

1. Triméthyl-1,8,8 bicyclo[3,2,1]octanol-2β (IV)

1.1. Préparation de l'alcool brut

(*a*) On procède à l'hydrogénation préalable de 100 mg de PtO_2 dans 10 ml d'acide acétique glacial, puis à l'hydrogénation proprement dite de 2.0 g d'homocamphre dissous

[6]*Nous avons choisi la valeur arbitraire de 1 pour le cyclohexanol; on pourra ainsi rapprocher les vitesses d'oxydation des alcools III à VI de celles données par Schreiber et Eschenmoser pour divers cholestanols (16).*

[7]*Les points de fusion (p.f.) ont été déterminés dans des tubes capillaires dans un bloc chauffé électriquement et en utilisant un thermomètre étalonné avec les standards du Bureau des Standards de Washington. Les spectres infrarouges ont été mesurés à l'aide d'un spectromètre "Perkin–Elmer" modèle 112, à simple faisceau et parcours double, prisme* NaCl. *Les analyses carbone–hydrogène sont de Geller Laboratories, Hackensack, N.J.; celles d'azote sont de M. Lefebvre. Les valeurs des pouvoirs rotatoires* $[\alpha]_D$ *sont à* $\pm 2°$ *près.*

For personal use only.

dans 30 ml d'acide acétique glacial. Il y a absorption de 235 ml d'hydrogène en $4\frac{1}{2}$ h (calculé pour $1H_2$: 245 ml; 748 mm, 23°). On reprend le tout par de l'éther, extrait l'acide acétique par des lavages avec une solution aqueuse de soude caustique à 10%. Après les lavages habituels jusqu'à neutralité, séchage et évaporation de l'éther, le résidu est sublimé pour donner 1.89 g (93%) d'alcool brut, p.f. 235°; $[\alpha]_D^{23} = -32.4°$ ($c = 3.93$; benzène).

(*b*) En 8 heures, il n'y eut aucune absorption lorsque 5 g d'homocamphre furent agités en atmosphère d'hydrogène en présence de 5 g de nickel de Raney dans 50 ml d'éthanol 95% et 10 ml de solution alcoolique de soude 10%. De même, en 1 heure, aucune absorption d'hydrogène n'eut lieu ne présence de platine dans l'éthanol 95%.

1.2. Purification de l'alcool brut

L'alcool brut (3.8 g) est chauffé à l'ébullition à reflux durant 2 heures dans 30 ml de pyridine sèche avec 6.5 g de chlorure de *p*-nitrobenzoyle. Après refroidissement, on précipite l'ester par addition d'eau. Le solide est essoré et repris dans de l'éther. On lave (HCl 10%, NaOH 10% puis eau). On sèche, évapore le solvant et cristallise le résidu dans du méthanol jusqu'à point de fusion et pouvoir rotatoire constants. On a 6.5 g (91%) de *p*-nitrobenzoate p.f. 123–124°, $[\alpha]_D^{23} = -96.6°$ ($c = 3.97$; benzène). On en saponifie 4.0 g par chauffage à reflux durant 2 heures avec 4.0 g de NaOH dans 25 ml d'éthanol et 25 ml d'eau. On isole à la manière habituelle 1.3 g de triméthyl-1,8,8 bicyclo[3,2,1]-octanol-2β régénéré. Cet alcool régénéré (2.050 g) est adsorbé sur 60 g d'alumine Merck pour chromatographie. Des élutions de 100 ml chacune ont donné:

(A) Fractions 1–14, éther de pétrole, p.é. 30–40°, 0.685 g, p.f. 234–235°, $[\alpha]_D^{23} = -29.2°$;

(B) Fractions 15–24, éther de pétrole–benzène 1–1, 1.140 g, p.f. 234–235°, $[\alpha]_D^{23} = -28.7°$;

(C) Fractions 25–26, benzène, 0.139 g, p.f. 233–234°, $[\alpha]_D^{23} = -26.4°$. Pour $[\alpha]_D^{23}$: $c = 4.0$; benzène.

Un échantillon de triméthyl-1,8,8 bicyclo[3,2,1]octanol-2β a été sublimé pour l'analyse; p.f. 234–235°, $[\alpha]_D^{23} = -29.2°$ ($c = 4.0$; benzène). Calculé pour $C_{11}H_{20}O$: C, 78.51; H, 11.98%. Trouvé: C, 78.33; H, 12.06%. Spectre infrarouge: bandes à 1029 et 1005 cm^{-1} (CS_2/0.03 *M*).

1.3 p-Nitrobenzoate

L'alcool pur (350 mg) et 420 mg de chlorure de *p*-nitrobenzoyle sont chauffés à reflux durant 2 heures dans 5 ml de pyridine sèche. On isole à la manière habituelle 489 mg de *p*-nitrobenzoate, paillettes incolores, p.f. 125° (éthanol 95%), $[\alpha]_D^{23} = -84.5°$ ($c = 4$; chloroforme). Calculé pour $C_{18}H_{23}O_4N$: C, 68.12; H, 7.30; N, 4.41%. Trouvé: C, 68.19; H, 7.55; N, 4.35%.

1.4. Oxydation chromique

L'alcool (360 mg) et 150 mg d'anhydride chromique sont dissous dans 10 ml d'acide acétique glacial. La solution s'échauffe un peu. On abandonne à température de la pièce pendant 3 heures. On ajoute ensuite 30 ml d'eau et neutralise avec du bicarbonate de sodium (solution aqueuse à 10%). On extrait à l'éther et isole à la manière habituelle 353 mg de cétone brute que l'on traite par 423 mg de dinitro-2,4 phénylhydrazine en solution dans 8 ml de méthanol contenant 4% d'acide chlorhydrique conc. On obtient, après une précipitation lente, 641 mg de dinitro-2,4 phénylhydrazone brute que l'on cristallise dans l'acide acétique glacial. On retrouve 452 mg de dinitro-2,4 phénylhydrazone d'homocamphre, p.f. 238–239° seule ou en mélange avec un échantillon de dinitro-2,4 phénylhydrazone d'homocamphre authentique (1).

2. Triméthyl-1,8,8 bicyclo[3,2,1]octanol-2α (III)

2.1. Préparation de l'alcool brut

Dans un ballon à trois tubulures surmonté d'un agitateur mécanique et d'un réfrigérant, on introduit 9.6 g (0.057 mole) d'homocamphre et 150 ml d'alcool isobutylique. On porte à l'ébullition et ajoute, par portions de 0.5 g environ, 15.0 g (0.65 mole) de sodium. Après l'addition, on chauffe encore 5 heures à reflux, avec agitation. On ajoute de l'eau (30 ml) et distille sous vide. On retrouve 9.36 g (après sublimation) d'alcool brut, à odeur camphrée, p.f. 208–216°, $[\alpha]_D^{23} = +15.1°$ ($c = 4.0$; benzène). Rendement: 97%.

Un essai semblable effectué à partir de 4.0 g d'homocamphre dans 100 ml d'éthanol anhydre et 8 g de sodium a donné 3.9 g (97%) d'alcool brut, après sublimation, p.f. 207.5–209.5°, $[\alpha]_D^{23} = +14.6°$ ($c = 4.00$; benzène).

2.2. Purification de l'alcool brut (Mode opératoire 1.2)

Le *p*-nitrobenzoate brut fond à 127–128°, $[\alpha]_D^{23} = +32.9°$ ($c = 4.00$; benzène). Il est saponifié et donne l'alcool régénéré, p.f. 212–213°, $[\alpha]_D^{23} = +16.5°$ ($c = 4.12$; benzène), qui est chromatographié sur alumine; trois fractions principales sont recueillies:

(A) 29%, éther de pétrole–benzène 4–1 (p.é. 30–40°), p.f. 213–215°, $[\alpha]_D^{23} = +15.7°$;

(B) 40%, éther de pétrole–benzène 1–1, p.f. 212°, $[\alpha]_D^{23} = +17.3°$;

(C) 27%, benzène, p.f. 212°, $[\alpha]_D^{23} = +17.9°$. (Pour tous les pouvoirs rotatoires: $c = 4.00$; benzène.)

La fraction (C) fut analysée. Calculé pour $C_{11}H_{20}O$: C, 78.51; H, 11.98%. Trouvé: C, 78.43; H, 12.08%. Le point de fusion de mélange avec l'alcool épimère p.f. 234–235° (voir section 1.2) est de 216.5–220°. Spectre infrarouge: bandes à 1013, 1033 et 1044 cm^{-1} (CS_2/0.03 *M*).

2.3. p-Nitrobenzoate (Préparation, voir 1.3)

Aiguilles incolores (méthanol), p.f. 127–128°, $[\alpha]_D^{23} = +35.0°$ ($c = 4$; chloroforme). Calculé pour $C_{18}H_{23}O_4N$: C, 68.12; H, 7.30; N, 4.41%. Trouvé: C, 68.45, 68.03; H, 7.11, 7.31; N, 4.42%.

2.4. Oxydation chromique (Mode opératoire, voir 1.4)

La dinitro-2,4 phénylhydrazone obtenue fond à 238–238.5° seule et 237–239° en mélange avec la dinitro-2,4 phénylhydrazone de l'homocamphre (1).

3. Triméthyl-5,8,8 bicyclo[3,2,1]octanol-2β (VI)

3.1. Préparation de l'alcool brut

(*a*) L'homoépicamphre (5.0 g) dissous dans 50 ml d'éthanol 95% est hydrogéné en présence de 5.0 g de nickel de Raney et 10 ml d'une solution alcoolique de NaOH à 5%. En 24 heures, il y a absorption de 725 ml d'hydrogène (calculé pour $1H_2$: 729 ml; 760 mm, 23°). On essore le catalyseur, évapore le filtrat, on reprend le résidu par de l'éther. Après les lavages habituels, on sèche et évapore l'éther; le résidu est sublimé: 4.72 g d'alcool brut (93%), p.f. 207–208.5°, $[\alpha]_D^{23} = +42.8°$ ($c = 4.04$; benzène).

(*b*) L'homoépicamphre (2 g) est hydrogéné en présence de 60 mg de PtO_2, hydrogéné au préalable, dans 40 ml d'acide acétique glacial. Au bout de 3 heures, l'hydrogénation est terminée; absorption: 285 ml (calculé pour $1H_2$: 296 ml; 748 mm, 23°). On essore le catalyseur, reprend la solution par de l'éther, que l'on lave avec une solution aqueuse de NaOH 10%. On extrait à la manière habituelle 1.76 g (87%) d'alcool brut (sublimé), p.f. 205–206°, $[\alpha]_D^{23} = +43.4°$ ($c = 4.0$; benzène).

3.2. Purification de l'alcool brut

Le *p*-nitrobenzoate se présente sous forme de paillettes après cristallisation dans l'éthanol. Il fond à 137–138°, $[\alpha]_D^{23} = +78.5°$ ($c = 4$; chloroforme). Calculé pour

$C_{18}H_{23}O_4N$: C, 68.12; H, 7.30; N, 4.41%. Trouvé: C, 68.24; H, 7.31; N, 4.39%. Après saponification, on retrouve un triméthyl-5,8,8 bicyclo[3,2,1]octanol-2β (VI) homogène à la chromatographie sur alumine: p.f. 206°; $[\alpha]_D^{23} = +43.9°$ ($c = 4.0$; benzène). Calculé pour $C_{11}H_{20}O$: C, 78.51; H, 11.98%. Trouvé: C, 78.27; H, 11.81%. Spectre infrarouge: bande à 1044 cm^{-1} (CS_2/0.03 *M*).

3.3. Oxydation chromique

L'alcool (504 mg) donne 659 mg de dinitro-2,4 phénylhydrazone d'homoépicamphre, p.f. 178–178.5°, seule ou en mélange avec la dinitro-2,4 phénylhydrazone de l'homoépicamphre (1).

4. Triméthyl-5,8,8 bicyclo[3,2,1]octanol-2α (V)

4.1. Préparation de l'alcool brut

Selon le mode opératoire 2.1, 12 g d'homoépicamphre sont réduits par 20 g de sodium dans 200 ml d'éthanol anhydre. On obtient 11.3 g (94%) d'alcool brut sublimé, p.f. 172–173°, $[\alpha]_D^{23} = +36.4°$ ($c = 4.03$; benzène).

4.2. Purification de l'alcool brut (Mode opératoire 1.2)

Le *p*-nitrobenzoate pur fond à 120°, $[\alpha]_D^{23} = +24.5°$ ($c = 4$; chloroforme). Calculé pour $C_{18}H_{23}O_4N$: C, 68.12; H, 7.30; N, 4.41%. Trouvé: C, 68.28; H, 7.39; N, 4.33%. Après saponification, on retrouve un triméthyl-5,8,8 bicyclo[3,2,1]octanol-2α (V) homogène, p.f. 166°, $[\alpha]_D^{23} = +35.9°$ ($c = 4.0$; benzène). Calculé pour $C_{11}H_{20}O$: C, 78.51; H, 11.98%. Trouvé: C, 78.25; H, 11.82%. Le p.f. de cet alcool avec l'épimère p.f. 206° (alcool VI, section 3.2) est de 179–185°. Spectre infrarouge: bande forte à 1038 cm^{-1} (CS_2/0.03 *M*).

4.3. Oxydation chromique (Mode opératoire, voir 1.4)

L'alcool V (504 mg) donne 632 mg de dinitro-2,4 phénylhydrazone d'homoépicamphre, p.f. 177.5°, seule ou en mélange avec la dinitro-2,4 phénylhydrazone de l'homoépicamphre (1).

5. Mesures des vitesses d'oxydation chromique

La mesure de la disparition de l'acide chromique se fait dans un spectrophotomètre Beckman DK1, ajusté à la longueur d'onde de 3500 Å. Une courbe de calibration de la densité optique des solutions de CrO_3, à cette longueur d'onde, a d'abord été tracée en fonction de la concentration. La vitesse d'oxydation a ensuite été mesurée grâce à la variation de la densité optique de la solution en fonctions du temps.

À partir d'une solution mère d'acide acétique aqueux à 90.9% (volume/volume) maintenue à température constante (24.9°±0.1°), on prépare: (*a*) une solution de CrO_3 environ 1.05×10^{-3} *M* que l'on place dans le bain à température constante; (*b*) une solution contenant les alcools à oxyder; cette solution est préparée juste avant l'oxydation. Au temps zéro, on mélange rapidement les solutions (*a*) et (*b*) de manière à obtenir environ 50 ml en tout; on en remplit une cellule en quartz que l'on place dans la chambre de mesures d'un spectrophotomètre Beckman DK1; ces diverses opérations prennent de 20 à 30 secondes depuis le temps zéro. La technique varie ensuite un peu, selon la rapidité de l'oxydation: (1) pour les oxydations lentes, allant jusqu'à 60 minutes, on conserve la solution contenant l'alcool et le CrO_3 dans le bain à température constante; on en prélève des échantillons de temps en temps, que l'on place dans la chambre de mesures du spectrophotomètre et dont on mesure la densité optique; on assure ainsi l'uniformité de la température au cours de l'expérience; (2) pour les oxydations rapides, ne dépassant pas 5 minutes, tous les points de la courbe sont enregistrés automatiquement sur le papier qui se déroule sans interruption; comme la température de la chambre de mesures du spectrophotomètre est voisine de 25°, les variations de température sont négligeables.

Les résultats et les données expérimentales sont rapportés au Tableau III. La vitesse $v = -d\ CrO_3/dt$ a été déterminée par la méthode graphique et les valeurs de v données sont les valeurs de la vitesse extrapolée au temps zéro.

TABLEAU III

Détail des déterminations des vitesses d'oxydation chromique

Alcools	Concentrations molaires des alcools	Concentrations molaires en CrO_3	$v = -d\ CrO_3/dt$ mole×litre^{-1}×min^{-1}
Cyclohexanol	7.136×10^{-4}	10.22×10^{-4}	2.80×10^{-6} (lente)
Alcool au sodium III	7.162×10^{-4}	10.85×10^{-4}	16.0×10^{-6} (lente)
Alcool au platine IV	7.013×10^{-4}	10.76×10^{-4}	330.0×10^{-6} (rapide)
Alcool au sodium V	7.108×10^{-4}	10.76×10^{-4}	18.4×10^{-6} (lente)
Alcool au platine VI	7.111×10^{-4}	10.77×10^{-4}	350.0×10^{-6} (rapide)

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada de son aide financière (subvention de recherche, H.F., et bourse d'études, J-C.R.) et l'Office de Recherches Scientifiques de la Province de Québec d'une bourse d'études, M.L.

DÉRIVÉS DU TRIMÉTHYL-1,8,8 BICYCLO[3,2,1]OCTANE

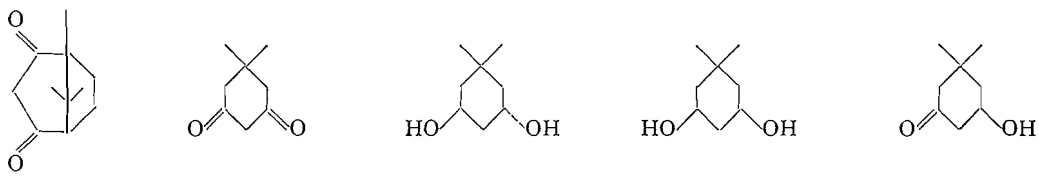
IV. DÉTERMINATION DES CONFIGURATIONS DES DEUX DIMÉTHYL-5,5 CYCLOHEXANEDIOLS-1,3[1]

H. Favre et J-C. Richer[2]

RÉSUMÉ

À la suite de l'analyse des modes de formation et des vitesses d'oxydation chromique des diméthyl-5,5 cyclohexanediols-1,3, les auteurs attribuent la configuration *cis* au diol p.f. 149–151° et la configuration *trans* à l'isomère p.f. 106–107.5°.

Au cours de l'étude de la réduction catalytique de la triméthyl-1,8,8 bicyclo[3,2,1]-octanedione-2,4 (I) (1) nous avons utilisé le dimédon (II) comme substance modèle. Nous avons obtenu avec un rendement de 95% un seul des deux diméthyl-5,5 cyclo-



I II III IV V

hexanediols-1,3 stéréoisomères (p.f. 106–107.5°, III), en opérant à pression atmosphérique et à 25°, en présence de nickel de Raney dans l'éthanol. Les deux diméthyl-5,5 cyclohexanediols-1,3 sont connus à la suite de réductions chimiques ou catalytiques (Tableau I); à notre connaissance, leurs configurations respectives, *cis* et *trans*, ne le sont pas; ce travail a pour but de les déterminer.

TABLEAU I

Réductions du dimédon conduisant aux diméthyl-3,3 cyclohexanediols-1,3

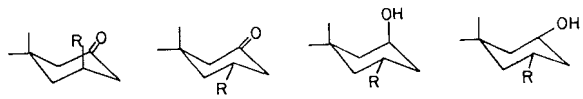
Nous avancerons d'abord quelques considérations concernant le mécanisme de l'hydrogénation catalytique. Dans tous nos essais, l'hydrogénation prenait fin après absorption de deux moles d'hydrogène. En interrompant la réaction après fixation d'une

[1]*Manuscrit reçu le 27 août, 1958.*
Contribution du Département de Chimie de l'Université de Montréal, Montréal, P.Q. Ce mémoire est tiré de la thèse de doctorat de J-C. Richer; il fut présenté au 41e Congrès annuel de l'Institut de chimie du Canada à Toronto, les 26–28 mai, 1958.
[2]*Boursier du Conseil national de Recherches du Canada, 1954–1958. Adresse actuelle: Department of Chemistry, University of Notre Dame, Notre Dame, Ind.*

mole d'hydrogène seulement, nous avons pu mettre en évidence la présence de la diméthyl-5,5 cyclohexanolone-3,1 (V) dans le milieu, à côté du dimédon non réduit et du diol III. En pratique, nous avons isolé le produit de déshydratation du β-cétol V, la diméthyl-5,5 cyclohexène-2 one-1. Cette formation de β-cétol était connue pour la réduction de nombreuses β-dicétones aliphatiques (6). Nous l'avons montrée pour étayer notre raisonnement. Nous formulons ainsi la réaction d'hydrogénation: la réduction catalytique du dimédon conduit d'abord à la diméthyl-5,5 cyclohexanolone-3,1 (V) qui se détache du catalyseur pour s'y fixer à nouveau et se faire réduire en diol. La configuration du diol obtenu dépendra de la conformation du β-cétol V, si aucune isomérisation n'a lieu. Il y a alors une analogie entre la réduction de ce β-cétol et celle de la triméthyl-3,3,5 cyclohexanone-1 (VI A) étudiée en détail par Wicker (7, 8, 9). Cet auteur a montré que dans des conditions douces (température basse, peu de catalyseur alcalin susceptible de provoquer des isomérisations), la cétone VI conduisait principalement à l'alcool *trans* VII (88% de *trans* pour 12% de *cis*); la triméthyl-3,3,5 cyclohexanone serait réduite sous la conformation VI A de préférence à VI B à cause de l'interférence des deux groupes méthyle axiaux 3 et 5; la fixation de l'hydrogène se fait de façon à donner l'alcool axial.



V B R = OH V A R = OH III R = OH IV R = OH
VI B R = CH_3 VI A R = CH_3 VII R = CH_3 VIII R = CH_3

Ainsi, la conformation V A, préférée à V B pour la diméthyl-5,5 cyclohexanolone-3,1,[3] conduira au diol III *trans*, groupes —OH *a*—*e*, à la condition qu'il n'y ait pas d'isomérisation consécutive à la formation du diol. Nous avons mis en oeuvre un nickel de Raney traité par du chloroforme. Cornubert et ses collaborateurs (12, 13, 14, 15) ont montré que le chloroforme et d'autres composés organiques halogénés abaissaient considérablement l'aptitude du nickel de Raney à réduire les groupes carbonyle; l'explication donnée est que le chloroforme engendre avec le nickel de l'acide chlorhydrique qui neutralise la soude fixée par le catalyseur. Comme nous n'avons pas utilisé les quantités prescrites par Cornubert pour contraindre le nickel et l'empêcher de réduire les groupes carbonyle, mais seulement des quantités modérées n'empêchant pas la réduction, nous pensons que notre nickel s'approchait de la neutralité et puisque nous n'avons opéré ni sous pression ni à température élevée, une isomérisation n'était plus à craindre et une configuration *trans* (III) se justifie pour le diol p.f. 106–107.5°. Le diol p.f. 149–151° est alors le diol *cis*.

Nous avons tenté de corroborer ces configurations par deux méthodes:

1. La résolution en antipodes optiques qui fait de l'isomère dédoublable l'isomère *trans*. Nous avons réussi à préparer le bi-phtalate acide de l'isomère p.f. 106–107.5° (*trans*, donc dédoublable, selon nos considérations antérieures), mais nous n'avons pu en cristalliser les sels de strychnine ou de brucine.

2. L'étude infrarouge des ponts hydrogène internes, à la manière de Kuhn (16), qui a montré que le cyclohexanediol-1,3 *cis*, en solution 0.005 *M* dans le tétrachlorure de carbone, présente deux bandes, 3619 et 3544 cm^{-1}, attribuées respectivement aux groupes —OH libres et —OH liés par un pont hydrogène; l'isomère *trans* ne présente qu'une

[3]*Dans son exposé sur la prééminence des formes équatoriales, Cornubert (10) démontre que le diméthyl-3,3 cyclohexanol existe sous la forme* —OH *équatorial. Eliel et Lukach (36) arrivent à la même conclusion. Nous trouvons dans ces travaux la justification de notre avancé.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

bande, 3620 cm^{-1}, la distance séparant les hydroxyles axial et équatorial ne permettant pas la formation d'un pont hydrogène interne. Cette méthode est inappliquable au cas des diméthyl-5,5 cyclohexanols-1 *cis* et *trans*, car les deux isomères ne montrent qu'une bande: 3621 cm^{-1} pour l'isomère p.f. 149–151° et 3627 cm^{-1} pour l'isomère p.f. 106–107.5°.

Nous nous sommes alors tournés vers l'étude cinétique de l'oxydation chromique des deux diols III et IV, en nous inspirant des travaux de Vavon (17) et de Winstein (11) (indiquant que les alcools cyclohexaniques axiaux s'oxydent plus rapidement que les alcools équatoriaux (18, 19)), et de Schreiber et Eschenmoser (20) (montrant que la vitesse d'oxydation est proportionnelle à la compression stérique du système; en particulier, qu'un groupe méthyle axial porté par un carbone en β de celui qui porte le groupe —OH augmente considérablement la vitesse de l'oxydation de l'alcool axial, celle de l'alcool équatorial étant sensiblement la même que s'il n'y avait pas le groupe méthyle: cas des cholestanols-2α et -2β, et -3α et -3β).

Nous avons ainsi commencé par mesurer les vitesses d'oxydation des cyclohexanediols-1,2, -1,3 et -1,4 *cis* et *trans* dont les configurations sont bien connues. Les résultats (Tableau II) appellent les commentaires suivants: (*a*) les diols-1,2 *cis*, -1,3 *trans* et -1,4 *cis* s'oxydent plus rapidement que leur isomère *trans*, *cis* et *trans* respectif; (*b*) les diols qui s'oxydent plus rapidement présentent nécessairement un groupe —OH axial et l'autre équatorial; nous en concluons que les diols qui s'oxydent plus lentement le font sous leur conformation diéquatoriale et non diaxiale.

TABLEAU II

Vitesses d'oxydation chromique des cyclohexanediols

Alcools*	Conformations†	Concentrations molaires en alcool	Concentrations molaires en CrO_3	$v = -d CrO_3/dt$‡ mole $\times litre^{-1} \times min^{-1}$

Diméthyl-5,5 cyclohexanediol-1,3 *trans*, p.f. 106–107.5° III	$a-e$	3.542×10^{-4}	10.60×10^{-4}	20.00×10^{-6}

*On trouve à la suite des diols les références bibliographiques concernant leurs configurations et leurs modes de préparation. Les points de fusion de ces diols sont identiques à ceux décrits dans la littérature.

†Pour les conformations du cyclohexanol, voir (10, 11).

‡Acide acétique aqueux, 90.9% (v/v); $t = 24.9° \pm 0.1°$.

Il est clair que ces résultats sont essentiellement approchés. Winstein (11) considère que la réaction d'oxydation est la résultante de plusieurs réactions ayant des vitesses distinctes: (*a*) estérification (réaction d'équilibre, rapide); (*b*) formation de la cétone (réaction lente); (*c*) réactions secondaires, par exemple oxydation de la cétone formée (vitesses inconnues). Dans le cas des diols-1,3 qui nous intéressent, ces réactions secondaires peuvent être extrêmement complexes; les β-cétols issus des diols-1,3 *cis* et *trans*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

pouvant (*a*) s'oxyder en dicétone, susceptible elle-même d'être oxydée, (*b*) se déshydrater en cétone α,β-éthylénique, aussi oxydable. De toute façon, nous avons déterminé la vitesse d'oxydation d'une manière simple, en extrapolant graphiquement au temps zéro les vitesses données par l'équation $v = -d\ CrO_3/dt$, et nous ne tirerons de la comparaison des vitesses d'oxydation que des renseignements qualitatifs, d'autant plus que nous prenons pour acquis que l'acide chromique oxydera l'un et l'autre des groupes hydroxyle,[4] ce qui rend toute étude quantitative prématurée. Les cyclohexanediols-1,3, dont l'isomère *trans* s'oxyde 1.9 fois plus rapidement que l'isomère *cis*, nous serviront de point de comparaison pour interpréter les résultats de l'oxydation des diméthyl-5,5 cyclohexanediols-1,3 (III et IV). De ces derniers, l'isomère p.f. 106–107.5° s'oxyde 8.3 fois plus rapidement que l'isomère p.f. 149–151°. Nous interprétons ceci en faisant du premier de ces diols l'isomère *trans*, $a-e$, et du deuxième le diol *cis*, oxidé sous sa forme $e-e$. Nous retrouvons non seulement la différence attendue entre les vitesses d'oxydation, mais encore une accélération notoire de la vitesse du diol diméthylé *trans* (III) par rapport à celle du cyclohexanediol-1,3 *trans*, bien en accord avec la présence d'un groupe méthyle axial sur le carbone en β de celui qui porte le groupe —OH axial. Les configurations déduites de l'oxydation chromique sont donc les mêmes que celles tirées plus haut du mécanisme de l'hydrogénation catalytique.

PARTIE EXPÉRIMENTALE[5]

Le dimédon mis en oeuvre a été cristallisé plusieurs fois dans l'éthanol 95%; il fond à 149–150°.

1. Réduction du dimédon en diméthyl-5,5 cyclohexanediol-1,3 trans (III)

Le dimédon (7.28 g) dissous dans 150 ml d'éthanol 95% est introduit dans un ballon à hydrogéner contenant 7.5 g de nickel de Raney; (préparation voir (37)); on ajoute 50 mg de chloroforme (sous forme d'une solution alcool-chloroforme 90–10) et secoue en atmosphère d'hydrogène. Au bout de 42 heures, la réaction s'arrête d'elle-même. On essore le catalyseur, le lave avec un peu de méthanol, évapore le filtrat à pression ordinaire, puis sous vide de 11 mm. Le résidu est repris par de l'éther et lavé avec une solution aqueuse de NaOH 10% puis à l'eau. On sèche sur sulfate de sodim, évapore l'éther et chromatographie le résidu, dissous dans du benzène, sur 100 g d'alumine Merck pour chromatographie; 300 ml de benzène éluent 3.5 g de composés en partie cristallisés, puis 700 ml de benzène éluent 0.209 g de diol p.f. 105–107°; finalement, 350 ml de méthanol éluent 3.7 g de diol p.f. 106–108°. La fraction partiellement cristalline est reprise dans de l'éther de pétrole et adsorbée sur 100 g d'alumine; l'élution par 600 ml de chloroforme donne 0.256 g de liquide brun, puis 300 ml de méthanol éluent 3.2 g de diol p.f. 106–108°. Le diméthyl-5,5 cyclohexanol pur fond à 106–107.5°, après cristallisation dans l'éther. Calculé pour $C_8H_{16}O_2$: C, 66.63; H, 11.18%. Trouvé: C, 66.99; H, 11.06. Le rendement en diol brut est de 95%.

Si l'on ajoute des quantités de chloroforme représentant 7.5, 14 ou 25% de la quantité de nickel de Raney, il n'y a pas d'absorption d'hydrogène.

[4]*Gallagher et Long (35) ont bien démontré ce fait en étudiant l'oxydation chromique de l'ester méthylique de l'acide cholique; bien que réagissant avec des vitesses différentes, les trois groupes* —OH *sont oxydés, et l'oxydation préférentielle de l'hydroxyle en position 7 ne se fait qu'avec un rendement de 40%.*

[5]*Les points de fusion ont été déterminés en tubes capillaires, le thermomètre étant étalonné avec des substances provenant du Bureau des Standards de Washington. Les spectres infrarouges ont été mesurés à l'aide d'un spectrophotomètre "Perkin–Elmer", modèle 112, à simple passage et double faisceau, optique* LiF.

For personal use only.

2. Hydrogénation interrompue: préparation de la diméthyl-5,5 cyclohexène-2 one-1

Le dimédon (5.27 g) est hydrogéné dans 80 ml d'éthanol contenant 90 mg de chloroforme, en présence de 4.5 g de nickel de Raney, jusqu'à fixation de 1.02 mole d'hydrogène; la réaction est interrompue, le catalyseur essoré et lavé avec du méthanol, le filtrat évaporé; le résidu est entraîné par de la vapeur d'eau après adjonction de 50 ml carbonate de sodium (sol. aqueuse 10%). On examine séparément le distillat et les eaux alcalines.

(*A*) *Le distillat.*—Il est saturé par du chlorure de sodium et extrait à l'éther. Les solutions éthérées de plusieurs extractions sont réunies, séchées et évaporées; le résidu est traité par de l'acétate de semicarbazide dans du méthanol. On recueille 125 mg de semicarbazone de diméthyl-5,5 cyclohexène-2 one-1, p.f. 191–192.5° (méthanol) seule ou en mélange avec une semicarbazone de diméthyl-5,5 cyclohexène-2 one-1. Analyse: calculé pour $C_9H_{15}ON_3$: N, 23.19%. Trouvé: N, 23.35%.

(*B*) *Des eaux alcalines.*—On extrait par l'éther le diméthyl-5,5 cyclohexanediol-1,3, p.f. brut 101–103° (1.7 g) et après adjonction d'acide chlorhydrique, le dimédon qui n'a pas réagi (2.1 g).

3. Détermination des vitesses d'oxydation chromique

Le mode opératoire est celui décrit en détail dans la partie III de cette série (37) et les résultats sont rapportés au Tableau II. Les composés ont été préparés selon les travaux antérieurs dont référence est faite au Tableau II.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada d'une subvention de recherche (H.F.) et d'une bourse d'études (J-C.R.).

DÉRIVÉS DU TRIMÉTHYL-1,8,8 BICYCLO[3,2,1]OCTANE

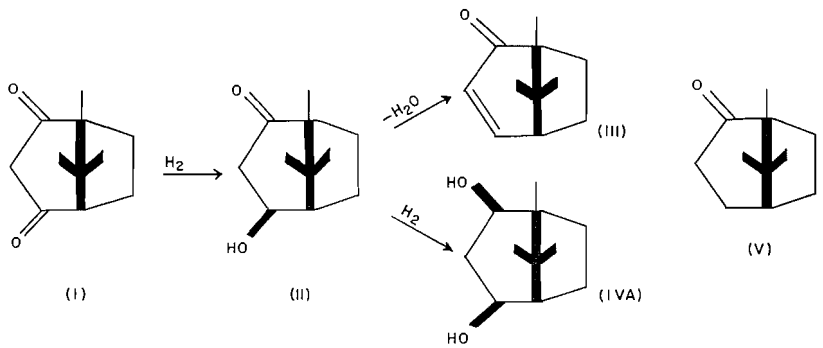
V. RÉDUCTIONS CATALYTIQUE ET CHIMIQUE DE LA TRIMÉTHYL-1,8,8 BICYCLO[3,2,1]OCTANEDIONE-2,4[1]

H. FAVRE ET J-C. RICHER[2]

RÉSUMÉ

Les auteurs montrent que la triméthyl-1,8,8 bicyclo[3,2,1]octanedione-2,4 est réduite: en triméthyl-1,8,8 bicyclo[3,2,1]octanediol-2β,4β en présence de nickel de Raney et de soude caustique; en triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2, ou directement en homocamphre, en présence de nickel de Raney et de très petites quantités de chloroforme, par l'intermédiaire de la triméthyl-1,8,8 bicyclo[3,2,1]octanol-4β one-2; en un mélange de triméthyl-1,8,8 bicyclo[3,2,1]octanediols-2α,4α; -2α,4β et probablement -2β,4α par le sodium dans l'éthanol. Les configurations des diols furent assignées à la suite de l'analyse de leurs modes de formation, de leurs vitesses d'oxydation chromique et des rotations moléculaires de leurs di-*p*-nitrobenzoates.

Rupe et Frey (1) ont hydrogéné la triméthyl-1,8,8 bicyclo[3,2,1]octanedione-2,4 (I) en présence d'un catalyseur de nickel dans l'éthanol aqueux à 50%. A température de 60–70° et sous pression de 90 atmosphères, ils ont obtenu un composé p.f. 276–279° qui n'a pas été étudié, et qui est décrit simplement comme un "dimère". A température et à pression ordinaires, en présence de carbonate de sodium, ces auteurs ont obtenu la triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (III) avec un rendement de 87.5%; le β-cétol II est postulé comme intermédiaire.



En reprenant les essais du Rupe et Frey, dans le but d'obtenir de l'homocamphre, nous n'avons obtenu que peu ou pas du tout de la cétone α,β-éthylénique III, mais principalement un composé p.f. 279–284°; nous utilisions un catalyseur de nickel de Raney (dans leur mémoire, Rupe et Frey n'indiquent ni la nature ni le mode de préparation de leur nickel). Après avoir caractérisé le composé inconnu, p.f. 279–284°, comme un des 4 triméthyl-1,8,8 bicyclo[3,2,1]octanediols-2,4 stéréoisomères (nous montrons plus loin dans cet article que c'est l'isomère 2β,4β (IV A) répondant à la formule $C_{11}H_{20}O_2$, donnant un di-*p*-nitrobenzoate bien cristallisé, p.f. 213–215°), nous nous sommes attachés à préciser les conditions opératoires pouvant conduire fidèlement soit au diol IV A, soit à la cétone α,β-éthylénique III. On trouve au Tableau I les résultats de cette étude.

Les hydrogénations ont été effectuées dans des conditions contrôlées, le nickel de

5	20.0 g	12 g	(*a*) 0.9% Chloroforme (*b*) 1 mole NaOH	1.03 mole 0.78 mole	20 heures 30 minutes	92% Homocamphre V 5% Diol IV A
6	5.0 g	3 g	(*a*) Nil (*b*) 1 mole NaOH	1.07 mole 0.72 mole	22 heures 45 minutes	82% Homocamphre V 12% Diol IV A

*La quantité de soude ajoutée est exprimée en mole par mole de dicétone I. Le pourcentage de chloroforme est relatif au poids de nickel de Raney mis en oeuvre.

†Exprimé en mole par mole de dicétone I.

‡Cétones = fractions cétoniques pouvant contenir de l'homocamphre et de la triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (III) et peut-être d'autres cétones.

Raney mis en oeuvre étant l'objet d'une attention particulière: il fut préparé à partir d'un alliage AN 50 selon le mode décrit dans la partie expérimentale, et fut utilisé rapidement après sa préparation; des échantillons vieux de quelques semaines ne permettent pas de reproduire les résultats.

Delépine et Horeau (2) ont montré que l'activité réductrice du nickel de Raney envers les cétones et l'acétylacétone était accrue par des adjonctions de petites quantités de soude caustique au milieu, tandis que Cornubert et ses collaborateurs (3, 4, 5, 6, 7) ont rapporté l'influence inhibitrice du chloroforme et d'autres dérivés organiques halogénés sur la réduction des groupes carbonyle. Nous nous sommes inspirés de ces observations pour choisir les agents appelés à modifier l'activité du nickel de Raney et à rendre ce catalyseur spécifique et fidèle.

L'addition de soude caustique favorise nettement la formation du diol IV A (essai 1, Tableau I); les rendements en diols dépendent directement de la quantité de soude introduite, car le sel sodé de la dicétone n'est pas réduit comme le montre l'essai 2 (Tableau I).

L'addition massive de chloroforme inhibe complètement la réduction (voir réduction du dimédon (8)); par contre, l'adjonction de quantités ne dépassant pas 2%[3] du poids du catalyseur mis en oeuvre permet la réduction du carbonyle en position 4 et inhibe avec satisfaction celle du carbonyle en position 2. Ce mode opératoire nous a permis d'obtenir:

(1) Le β-cétol intermédiaire II (hydrogénation 3) en évaporant avec précaution le solvant débarrassé du catalyseur lorsque la réduction s'arrête d'elle-même après absorption de 1.0 mole d'hydrogène; ce β-cétol est un composé très instable, p.f. 249–250°,

[3]*Nous avons adopté les termes suivants: nickel "ordinaire", pour le nickel utilisé tel que préparé selon notre méthode; nickel "modéré", lorsque le nickel "ordinaire" est traité par des quantités de chloroforme ne dépassant pas 2% de son poids. Cornubert appelle nickel "contraint" le nickel inapte à réduire les groupes carbonyle.*

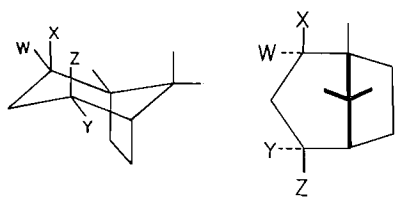
spectre infrarouge, bandes à 3455 (—OH) et 1705 (C = 0) cm^{-1}, perdant facilement une molécule d'eau par sublimation ou par entraînement à la vapeur d'eau.

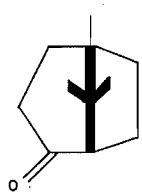
(2) La triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (III) (hydrogénation 4) avec un rendement de 94% (9, 1).

(3) L'homocamphre (V). Dans ce cas (hydrogénation 5), après absorption d'une mole d'hydrogène et arrêt spontané de la réaction, on introduit dans le milieu réactionnel une mole de soude caustique en solution dans l'éthanol 95%. Il se produit un échauffement de la solution avec élimination d'une molécule d'eau du β-cétol II; l'absorption d'hydrogène reprend aussitôt, et bien que l'absorption ne corresponde alors qu'à 0.78 mole d'hydrogène, on isole l'homocamphre (V) avec un rendement de 94%. Cet homocamphre est très pur et son mode de préparation est le plus simple de tous ceux décrits jusqu'ici (9). L'hydrogénation 6 présente un certain intérêt; elle fut réalisée avec un nickel de Raney "ordinaire" (sans adjonction de soude ou de chloroforme); elle démontre clairement l'influence inhibitrice du chloroforme sur la réduction du carbonyle en position 2 (cf. hydrogénation 5). Elle montre aussi que l'adjonction de soude doit se faire au début de l'hydrogénation si l'on veut obtenir un bon rendement en diol IV A (comme dans l'hydrogénation 1). L'emploi du nickel de Raney "ordinaire" reste cependent fort aléatoire: de nombreux essais ont donné des quantités variables du diol IV A et de la cétone α,β-éthylénique III. Ces essais peu intéressants en raison du manque de fidélité du catalyseur ne sont pas rapportés dans ce mémoire.



IV A X,Z = OH; W,Y = H
IV B W,Y = OH; X,Z = H
IV C X,Y = OH; W,Z = H
IV D W,Z = OH; X,Y = H

VI X = OH; W,Y,Z = H
VII W = OH; X,Y,Z = H
VIII Y = OH; W,X,Z = H
IX Z = OH; W,X,Y = H



X

Les produits de la réduction de la dicétone I par le sodium dans l'éthanol ont été séparés en produit acide (dicétone I de départ non entrée en réaction) 58.1% et en composés neutres, 39.9%, qu'une chromatographie sur alumine a séparés en:

(1) 4.1% d'un solide jaune non étudié;

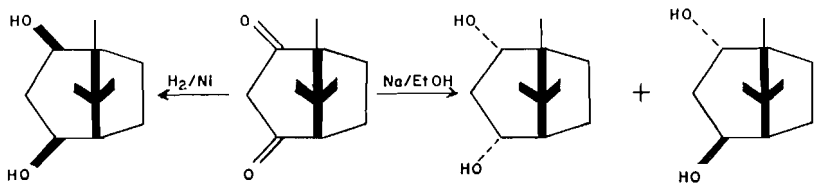
(2) 5.5% d'un solide incolore, p.f. 171–173°, $[\alpha]_D^{23} = +23.6°$, correspondant à la formule $C_{11}H_{20}O$. Ce résultat d'analyse et la facilité avec laquelle ce solide s'élue de l'alumine indiquent qu'il doit être un mélange des monoalcools VI–IX;

(3) 20.4% d'un solide incolore, p.f. 250–255°, $[\alpha]_D^{23} = +7.2°$ donnant un di-*p*-nitrobenzoate p.f. 211–212.5°, $[\alpha]_D^{23} = +70.0°$ dont on tire par saponification le diol IV D, p.f. 237–239°, $[\alpha]_D^{23} = -9.0°$;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

(4) 68.4% de diol IV B, p.f. 234–236°, $[\alpha]_D^{23} = +32.7°$, dont le di-*p*-nitrobenzoate fond à 221–224°, $[\alpha]_D^{23} = +37°$.

Nous avons en main trois des quatre triméthyl-1,8,8 bicyclo[3,2,1]octanediols-2,4 stéréoisomères; nous les considérons comme stériquement purs; leurs di-*p*-nitrobenzoates donnent des dépressions de point de fusion en mélange. À la suite de l'analyse de leurs modes de formation, de l'application à leurs di-*p*-nitrobenzoates de la méthode des différences de rotation moléculaire et de leurs vitesses d'oxydation chromique, nous leur avons attribué les configurations suivantes:



IV A p.f. 279–284° | I | IV B p.f. 234–236° | IV D p.f. 237–239°

Nous pensons aussi avoir en main un mélange des diols IV D et IV C dont le p.f. est de 250–255° (réduction chimique, fraction 3 brute), car le comportement chromatographique de ce mélange semble montrer que l'isomère IV D, qui le constitue en partie, n'est pas accompagné des diols IV A et IV B.

Nous examinerons dans l'ordre les modes de formation, la méthode des différences des rotations moléculaires et les vitesses d'oxydation des diols.

L'hydrogénation catalytique de la triméthyl-1,8,8 bicyclo[3,2,1]octanedione-2,4 (I) est stéréospécifique. Elle rappelle les hydrogénations de l'homocamphre (V) et de l'homoépicamphre (X) qui conduisent aux monols VI et IX de configuration β, —OH axial (10). Il semble raisonnable d'attribuer la configuration -4β au β-cétol intermédiaire (II) et d'envisager que la réduction du groupe C = 0 de ce cétol conduira comme celle de l'homocamphre à un groupe —OH axial. Le diol qui se formera sera ainsi diaxial ou -2β,4β (IV A)[4]; ceci est vrai pour autant qu'il n'y ait pas d'isomérisation des groupes —OH axiaux en groupes équatoriaux; nous voyons l'absence de toute isomérisation dans le fait que nous avons obtenu (voir mémoire antérieur (10)) le même rendement stérique en alcool axial au cours de la réduction de l'homoépicamphre, en mettant en oeuvre le platine dans l'acide acétique et le nickel de Raney en présence de soude.

Nous avançons également par analogie que le diol p.f. 234–236° qui se forme en quantité prépondérante lors de la réduction par le sodium et l'éthanol est le diol-2α,4α (IV B), puisque l'homocamphre (V) et l'homoépicamphre (X) engendrent principalement les monols de configuration α (VII et VIII)(10).

L'examen des rotations moléculaires des di-*p*-nitrobenzoates donne les conclusions suivantes. Utilisant la valeur $[M]_D = +24°$ pour la rotation moléculaire du triméthyl-1,8,8 bicyclo[3,2,1]octane[5] et les valeurs des rotations moléculaires des *p*-nitrobenzoates des triméthyl-1,8,8 et -5,8,8 bicyclo[3,2,1]octanols-2α et -2β décrites dans la partie III de cette série (10), nous pouvons calculer[6] les valeurs des rotations moléculaires des di-*p*-nitrobenzoates des quatre diols (voir Tableau II).

Nous remarquons alors une correspondance convenable entre les valeurs calculées

[4]*Nous ne retenons que la conformation "cyclohexane chaise" pour les diols-2,4 du triméthyl-1,8,8 bicyclo [3,2,1]octane; voir (10).*

[5]*Travaux de notre laboratoire non-publiés. Cet hydrocarbure a été préparé à partir du (+) camphre, sans inversion de configuration.*

[6]*Nous trouvons une justification de cette manière de procéder dans les travaux de Striebel et Tamm (11).*

octanediol-2α,4α (IV B) (Na + EtOH)		+178°±10°		+160°±15°

TABLEAU III

Vitesses d'oxydation chromique comparées des monols et des diols dans les positions 2 et 4 du triméthyl-1,8,8 bicyclo[3,2,1]octane

Composés	Conformations des groupes OH	Concentrations molaires en monol ou diol	Concentrations molaires en CrO_3	$v = -d\ CrO_3/dt$* mole×litre^{-1}×min^{-1}
Triméthyl-1,8,8 bicyclo[3,2,1]octanol-2β (VI)	*a*	7.013×10^{-4}	10.76×10^{-4}	330×10^{-6}
octanol-2α (VII)	*e*	7.162×10^{-4}	10.85×10^{-4}	10×10^{-6}
Triméthyl-5,8,8 bicyclo[3,2,1]octanol-2β (IX)	*a*	7.111×10^{-4}	10.77×10^{-4}	350×10^{-6}
octanol-2α (VIII)	*e*	7.108×10^{-4}	10.76×10^{-4}	18.4×10^{-6}
Triméthyl-1,8,8 bicyclo[3,2,1]octane diol-2β,4β (IV A)	*a*−*a*	3.557×10^{-4}	10.66×10^{-4}	300×10^{-6}
diol-2α,4α (IV B)	*e*−*e*	3.550×10^{-4}	10.58×10^{-4}	12×10^{-6}
diol-2α,4β (IV D)	*a*−*e*	3.550×10^{-4}	10.67×10^{-4}	120×10^{-6}
Mélange, p.f. 250–255°, $[\alpha]_D^{23} = +7.2°$		3.550×10^{-4}	10.69×10^{-4}	110×10^{-6}

*Dans l'acide acétique aqueux 90.9% (v/v); $t = 24.9°\pm0.1°$.

et observées si nous faisons du diol p.f. 234–236° le diol diéquatorial (IV B) et du diol p.f. 237–239° l'isomère 2α,4β (équatorial en 2 et axial en 4) (IV D). La correspondance est encore bonne si l'isomère p.f. 279–284° (catalytique) est le diol-2β,4β (IV A); la différence s'explique par un effet de voisinage.

Finalement, l'étude des vitesses d'oxydation chromique (Tableau III) donne les résultats suivants. Avec Lefebvre (10), nous avons montré que les monols axiaux VI et IX s'oxydent par l'acide chromique plus rapidement que les monols équatoriaux VII et VIII. Nous avons montré également (8) que le cyclohexanediol-1,3 *trans* ($a-e$) s'oxyde plus rapidement que l'isomère *cis* (oxydé sous sa forme $e-e$); malgré son caractère empirique, la méthode est applicable à l'étude des diols-1,3. En l'appliquant à l'élucidation des configurations des diols IV qui font l'object de cette étude, nous n'avions plus affaire à des cyclohexanes convertibles, mais à un système rigide. Théoriquement, donc, nous pouvons prévoir que les diols IV A à IV D se diviseront en trois groupes: (1) diol $a-a$; (2) diol $e-e$ et (3) les deux diols $a-e$ —et que ces trois groupes s'oxyderont avec des vitesses différentes, respectivement grande, petite et moyenne; nous admettons que les deux groupes hydroxyle[7] des diols s'oxydent l'un aussi bien que l'autre.

On remarque (Tableau III) que l'accord est bon, compte tenu de la réduction en concentration molaire des diols, entre les valeurs des monols VI–IX et des 2 diols IV A et IV B et que les configurations assignées sont les mêmes que celles déduites plus haut des modes de formation et des pouvoirs rotatoires. Le diol qui s'oxyde avec la vitesse intermédiaire aura l'un de ses groupes axial et l'autre équatorial; son di-*p*-nitrobenzoate, par son pouvoir rotatoire, en fait le diol-2α,4β (IV D) (voir plus haut).

Nous avons oxydé également le mélange des diols p.f. 250–255°; sa vitesse, semblable à celle du diol axial-équatorial, -2α,4β, nous fait supposer que ce mélange est formé des diols-2α,4β et -2β,4α, comme le comportement chromatographique nous l'avait fait supposer plus haut.

Nous avons mesuré[8] le spectre infrarouge du diol diaxial dans le but de voir à la manière de Kuhn (14) si les groupes —OH pouvaient former un pont hydrogène intramoléculaire; nous n'avons trouvé qu'une bande dans la région caractéristique, à 3630 cm^{-1}; le diol diéquatorial présente également une seule bande à 3627 cm^{-1}.

Nous en concluons que le groupe méthyle axial ne permet pas la formation d'un pont hydrogène intramoléculaire; un tel pont se serait manifesté par une bande de fréquence plus basse que 3630 cm^{-1}. Rappelons qu'un pont hydrogène intramoléculaire ne se forme pas chez le diméthyl-5,5 cyclohexanediol-1,3 *cis* (8). Ces faits nous amènent à considérer un point qui a retenu tout particulièrement notre attention au cours de ce travail. Alors que l'homocamphre n'est pas hydrogénable par le nickel de Raney en présence de soude caustique (10), l'hydroxy-4 homocamphre (II) l'est. La seule explication que nous puissions offrir est que dans l'hydroxy-cétone, l'interaction OH—CH_3 diaxiale modifie la conformation cyclohexanique chaise du squelette au point de rendre l'hydrogénation du groupe cétonique suffisamment rapide pour devenir effective. Nous tentons actuellement de démontrer jusqu'où peut aller cette déformation de conformation dont le stade ultime serait une forme cyclohexanique bateau (voir le IIIe mémoire de cette série (10)).

PARTIE EXPÉRIMENTALE[9]

La (−) triméthyl-1,8,8 bicyclo[3,2,1]octanedione-2,4 (I) a été préparée selon (1, 9).

[7]*L'oxydation chromique de l'acide cholique justifie cet avancé (8, 12).*

[8]*Optique* LiF.

[9]*Les points de fusion (p.f.) ont été déterminés en tubes capillaires, le thermomètre étant étalonné avec des substances de p.f. connu (Bureau des Standards de Washington). Les spectres infrarouges ont été mesurés à l'aide d'un spectromètre Perkin–Elmer, modèle 112, à simple faisceau et parcours double (sauf indication contraire, prisme* NaCl). *Les analyses sont de Geller Laboratories, Hackensack, et de W. Manser, Herrliberg.*

1. Hydrogénation catalytiques

Préparation du nickel de Raney

L'alliage AN 50 (50 g) est ajouté par petites portions à 800 ml de soude caustique 20% à température de 0°–5°. Après l'addition, le tout est chauffé sur un bain-marie durant deux heures. La solution de soude est décantée et remplacée par 400 ml de solution fraîche. Le chauffage au bain-marie est continué pendant une heure. Par décantations successives, le nickel est lavé 20 fois avec l'eau du robinet (portions de 800 ml), trois fois avec de l'éthanol 95% distillé dans un appareil de verre Pyrex. Le catalyseur est conservé dans de l'éthanol 95%.

Nous décrivons les essais dans l'ordre donné au Tableau I (partie théorique).

Hydrogénation No. 1—Nickel de Raney + soude caustique: obtention du triméthyl-1,8,8 bicyclo[3,2,1]octanediol-2β,4β IV A

La dicétone I (12.5 g, 0.0694 mole) et 1.39 g de NaOH (0.0348 mole) en solution dans 150 ml d'éthanol 95% sont hydrogénés en présence de 12.0 g de nickel de Raney. En 25 heures, il y a absorption de 1720 ml d'hydrogène (calculé pour $1H_2$: 1710 ml, pour 750 mm et 23°). Le catalyseur est essoré; la solution alcoolique est évaporée et le résidu soumis à l'action de la vapeur d'eau.

La fraction volatile, extraite à l'éther, représente 700 mg (5.6%); il s'agit de cétones qui n'ont pas été étudiées.

La solution alcaline qui contient les composés non volatils est extraite par de l'éther, puis acidifiée par HCl (rouge Congo); une extraction au chloroforme permet de retrouver 5.9 g de dicétone (47%) qui n'a pas réagi. La solution éthérée contient les composés neutres dont on retire par chromatographie sur alumine et élution par le chloroforme 81% de triméthyl-1,8,8 bicyclo[3,2,1]octanediol-2β,4β (IV A) très pur; les fractions éluées par le benzène et le mélange benzène-chloroforme 1-1, précédant l'élution par le chloroforme pur, n'ont pas été étudiées. Le diol pur présente les constantes suivantes: p.f. 279–284°, $[\alpha]_D^{22} = -17.4°$ ($c = 4.09$; éthanol/95%).

Calculé pour $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%. Trouvé: C, 71.87; H, 10.94%. En chauffant le diol avec du chlorure de *p*-nitrobenzoyle dans de la pyridine sèche le di-*p*-nitrobenzoate précipite sous forme d'aiguilles qui se transforment en paillettes par cristallisation dans le chloroforme-éthanol: p.f. 213–215°, $[\alpha]_D^{23} = +4.16°$ ($c = 2.97$; chloroforme). Calculé pour $C_{25}H_{26}O_8N_2$: C, 62.23; H, 5.43; N, 5.81%. Trouvé: C, 62.34; H, 5.46; N, 5.52, 5.80%. Poids moléculaire du di-*p*-nitrobenzoate, déterminé dans le camphre, 432; valeur théorique: 482.

Hydrogénation No. 2—Nickel de Raney + soude caustique

Si l'on hydrogène 10.0 g de dicétone I (0.055 mole) en présence de 2.22 g de NaOH (0.055 mole) et de 12 g de nickel de Raney, dans 85 ml d'éthanol 95%, en 25 heures, il y a absorption de 310 ml d'hydrogène. On retrouve, selon le mode opératoire de l'hydrogénation No. 1, 91% de cétone qui n'a pas réagi, 5% de diol IV A brut p.f. 267–276° et 2% de cétones (non étudiées).

Hydrogénation No. 3—Nickel de Raney + chloroforme: obtention de la triméthyl-1,8,8 bicyclo[3,2,1]octanol-4β one-2 (II)

Dans un ballon à hydrogéner on introduit 5.022 g de dicétone I, 50 ml d'éthanol 95% et 5 g de nickel de Raney; on ajoute alors 0.75 ml d'une solution éthanolique de chloroforme à 10% (soit 75 mg de chloroforme) et on procède à l'hydrogénation. En 20 heures il y a fixation de 710 ml d'hydrogène (calculé pour $1H_2$: 698 ml; 774 mm et 26°). On essore le catalyseur et sépare la solution alcoolique en deux portions égales.

La première portion est évaporée sur un bain-marie; le résidu est rendu alcalin et

entrainé à la vapeur d'eau; on recueille la triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 p.f. 174–176° (pour la caractérisation de ce composé voir (9) et dans ce travail l'hydrogénation No. 4).

La deuxième portion est évaporée à 25°, puis séchée sous vide poussé à cette température. La triméthyl-1,8,8 bicyclo[3,2,1]octanol-4β one-2 se présente sous la forme d'un solide incolore et amorphe, p.f. 249–250°. L'analyse centésimale est satisfaisante en raison des conditions rudimentaires d'isolement du composé: calculé pour $C_{11}H_{18}O_2$: C, 72.52; H, 9.96%. Trouvé: C, 71.05; H, 9.85%. Ce β-cétol perd une molécule d'eau si on le sublime; les fractions de tête de la sublimation fondent à 180–182° et leur spectre infrarouge présente une bande à 1678 cm^{-1}, caractéristique d'une cétone α,β-éthylénique. Les fractions de queue de la sublimation fondent à 242–244°: leur spectre infrarouge montre la présence du groupe —OH (3455 cm^{-1}) et de la cétone saturée (1705 cm^{-1}), dans le Nujol.

Hydrogénation No. 4—Nickel de Raney + chloroforme: obtention de la triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (III)

La dicétone I (9.854 g) est hydrogénée, en présence de 5 g de nickel de Raney modéré par adjonction de 0.7 ml d'une solution de chloroforme-éthanol 10–90, dans 100 ml d'éthanol 95%. En 25 heures il y a absorption de 1265 ml d'hydrogène (calculé pour $1H_2$: 1300 ml; 745 mm et 25°). On essore le catalyseur, distille l'alcool à pression ordinaire, ajoute 100 ml d'une solution de Na_2CO_3 10% au résidu et entraîne à la vapeur d'eau. Le solide qui est entraîné est repris par de l'éther qui après séchage est évaporé. Le résidu (8.22 g, 94%) est sublimé. La triméthyl-1,8,8 bicyclo[3,2,1]octène-3 one-2 (III) fond à 176.5–178°, $[\alpha]_D^{23} = -54.9°$ ($c = 3.93$; benzène). Calculé pour $C_{11}H_{16}O$: C, 80.44; H, 9.82%. Trouvé: C, 80.37; H, 9.84%. La dinitro-2,4 phénylhydrazone fond à 191–192.5°. L'homocamphre qui résulte de la réduction de la double liaison fond à 191–191.5°, $[\alpha]_D^{23} = -111.4°$ ($c = 4.32$; benzène). Pour fins de comparaison, voir (9, 1). Les composés non volatils avec la vapeur d'eau ont été séparés en: (*a*) triméthyl-1,8,8 bicyclo[3,2,1]-octanediol-2β,4β (IV A), p.f. 280–281.5° (rendement 4%); (*b*) dicétone I qui n'a pas réagi (2%).

Hydrogénation No. 5—Nickel de Raney + chloroforme: obtention de l'homocamphre

La dicétone I (20 g) est hydrogénée dans 200 ml d'éthanol 95%, en présence de 12 g de nickel de Raney modéré par adjonction de 1.08 ml d'une solution à 10% de chloroforme dans l'éthanol 95% (soit 108 mg de chloroforme). En 20 heures il se fixe 2825 ml d'hydrogène (calculé pour $1H_2$: 2750 ml; 749 mm et 23°). Lorsque l'absorption s'arrête, on indroduit dans le milieu 44.4 ml d'une solution à 10% de NaOH dans l'éthanol 95% (1 mole de NaOH par mole de dicétone I). Il y a dégagement de chaleur et le tout, remis en présence d'hydrogène, absorbe alors 2140 ml d'hydrogène en 30 minutes. On essore le catalyseur, évapore lentement l'éthanol du filtrat à travers une colonne de Widmer. Le résidu est repris dans de l'éther qui est séché sur sulfate de sodium et évaporé (colonne de Widmer). L'homocamphre brut pèse 17.92 g. On le chromatographie sur alumine Merck pour chromatographie. Pour 41 g on utilise 300 g d'alumine; l'élution par 2250 ml de benzène donne 38.54 g d'homocamphre pur, p.f. 191–192°, $[\alpha]_D^{23} = -112.2°$ ($c = 2.97$; benzène) et 2.22 g de triméthyl-1,8,8 bicyclo[3,2,1]octanediol-2β,4β (IV A), p.f. 275–280°.

Hydrogénation No. 6—Nickel de Raney sans adjonction

La dicétone I (5.0 g; 0.0275 mole) est hydrogénée dans 50 ml d'éthanol 95% en présence de 3 g de nickel de Raney. En 22 heures il se fixe 740 ml d'hydrogène (calculé pour $1H_2$:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

686 ml; 754 mm et 25°). Ce temps écoulé, on introduit dans le milieu 1.11 g de NaOH (0.0227 mole) sous forme d'une solution alcoolique) et l'on reprend l'hydrogénation. Il y a alors absorption de 495 ml d'hydrogène. On essore le catalyseur, évapore l'alcool du filtrat, reprend par de l'éther que l'on sèche sur sulfate de sodium anhydre. On recueille après distillation de l'éther 4.458 g de composés neutres que l'on chromatographie sur 130 g d'alumine Merck pour chromatographie. L'élution par 600 ml de benzène donne 3.658 g d'homocamphre, $[\alpha]_D^{23} = -114°$ ($c = 4.95$; éthanol); 40 mg sont élués ensuite des mélanges benzène-chloroforme; le triméthyl-1,8,8 bicyclo[3,2,1]octanediol-2β,4β (IV A) est finalement élué par 300 ml de méthanol: 517 mg, p.f. 276–280°.

2. Réduction chimique (sodium et éthanol) de la dicétone I

À une solution de 20.78 g (0.1156 mole) de dicétone I dans 500 ml d'éthanol anhydre, on ajoute par petites portions 36 g (1.564 mole) de sodium. Lorsque le sodium a fini de réagir, on ajoute 40 ml d'eau et distille l'éthanol à travers une colonne de Widmer. Le résidu est repris par de l'eau et extrait par du chloroforme. Les fractions chloroformiques réunies sont séchées sur du sulfate de sodium et évaporées à travers une colonne de Widmer: on recueille 8.455 g de composés neutres, que l'on met en suspension dans 850 ml d'un mélange benzène-chloroforme 1-1 et que l'on introduit dans un tube à chromatographie contenant 250 g d'alumine Merck pour chromatographie. La partie insoluble du mélange se trouve reposer au sommet de la colonne d'alumine; on procède alors à l'élution par des portions de 850 ml de solvant.

Chromatographie I

Fractions	Eluant	Quantité éluée	P.f.
1	Benz-chlor 1-1	0.025 g	
2	Benz-chlor 1-2	0.225 g	
3	Benz-chlor 1-4	0.738 g	184–186°
4	Chloroforme	1.034 g	265–267°
5	Chloroforme	1.260 g	235–238°
6–12	Chloroforme	5.175 g	236–238°

Les fractions 6–12 sont sublimées et constituent le triméthyl-1,8,8 bicyclo[3,2,1]-octanediol-2α,4α (IV B), p.f. 234–236°, $[\alpha]_D^{23} = +32.7°$ ($c = 3.82$; éthanol 95%). Calculé pour $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%. Trouvé: C, 71.49; H, 10.80%. On en prépare un di-*p*-nitrobenzoate, p.f. 221–224°, $[\alpha]_D^{23} = +37.0°$ ($c = 2.91$; chloroforme). Calculé pour $C_{25}H_{26}O_8N_2$: C, 62.23; H, 5.43; N, 5.81%. Trouvé: C, 62.37; H, 5.38; N, 5.67%.

Les fractions 3, 4 et 5 de la chromatographie I sont mises en solution dans 300 ml de benzène et adsorbées sur 90 g d'alumine. L'élution par des portions de 300 ml de solvent donne:

Chromatographie II

Fractions	Eluant	Quantité éluée	Caractéristiques
1–2	Benzène	0.085 g	
3–5	Benz-chlor Jusqu'à 1-1	0.438 g	$[\alpha]_D^{23} = +22.1°$ ($c = 3.6$; benz)

A NEW MOLECULAR REARRANGEMENT

IV. FURTHER OBSERVATIONS ON THE CHEMISTRY OF 1-NITRO-2,3,5,6-TETRAHYDRO-1(H)-IMIDAZ(1,2-a)IMIDAZOLE AND 1-(β-CHLOROETHYL)-2-IMIDAZOLIDONE[1]

A. F. McKay and M.-E. Kreling

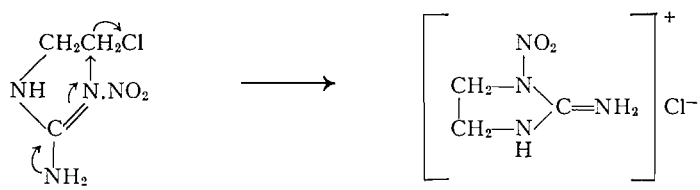
ABSTRACT

Chlorination of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine gives a mixture of 1-(β-chloroethyl)-2-nitriminoimidazolidine and 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride. The other products, 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride and 1-(β-nitraminoethyl)-2-imidazolidone, isolated during the original study of the chlorination of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine are formed by the action of ethanol on 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride. Amines add to 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate to give the corresponding 1-(β-nitraminoethyl)-2-substituted amino-2-imidazoline nitrates. These reactions and the aminolysis of 1-(β-chloroethyl)-2-imidazolidone are described in detail.

INTRODUCTION

The present work was directed to a comparison of the chemical properties of 1-(β-chloroethyl)-2-nitroguanidine (1) with 1-(β-chloroethyl)-2-nitriminoimidazolidine (2) and to an attempt to find an explanation for the origin of the products isolated from the reaction of thionyl chloride with 1-(β-hydroxyethyl)-2-nitriminoimidazolidine (2).

The cyclization of 1-(β-chloroethyl)-2-nitroguanidine to 1-nitro-2-iminoimidazolidine hydrochloride (or its tautomer, 1-nitro-2-amino-2-imidazolinium chloride) was described first in 1950 (1). This cyclization occurred at the melting point of the compound or it could be effected by heating the compound with an inert solvent. A carbonium ion mechanism was suggested (3, 4) for this cyclization reaction but it was noted that this suggestion was premature owing to the absence of kinetic data. Later the kinetic data were supplied by the work of Boyars, Sager, and Skolnik (5). They found that the relative rates of cyclization of the 1-β-substituted-2-nitroguanidines were 1-β-bromoethyl- > 1-β-chloroethyl- > 1-β-nitroxyethyl-. These relative rates of reaction are in agreement with the bond energies for C–Br, C–Cl, C–O covalent links which would be expected in a carbonium ion mechanism. However, since the rate of cyclization of 1-(β-nitroxyethyl)-2-nitroguanidine was greater than the cyclization rate of 1-(β-nitroxypropyl)-2-nitroguanidine, an internal Sn_2 mechanism rather than a carbonium ion mechanism was favored. Further evidence for the internal Sn_2 mechanism was established by a demonstration (6) of the lack of salt effect on the cyclization rate. Thus the cyclization of 1-(β-chloroethyl)-2-nitroguanidine is considered to occur by a backside approach of the nitrimino group to the substituted side chain as follows:



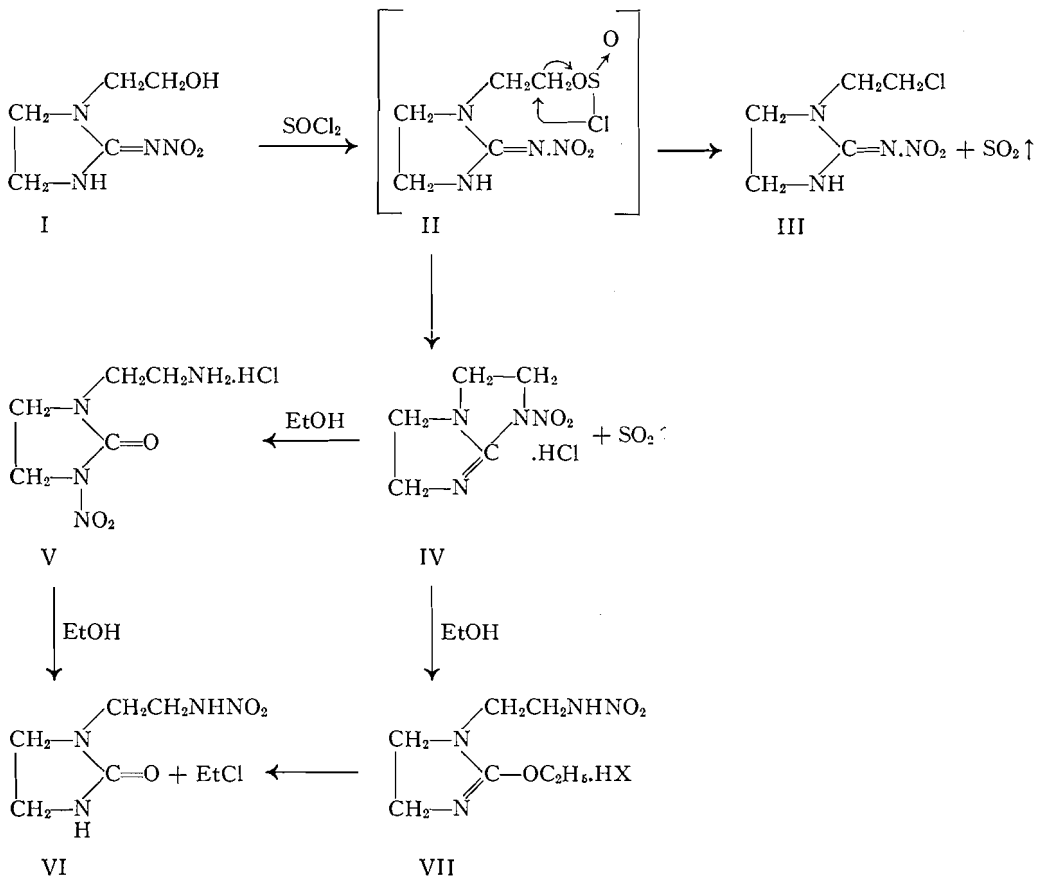
[1]*Manuscript received May 14, 1958.*
Contribution No. 21 from the L. G. Ryan Research Laboratories of Monsanto Canada Limited, Montreal, Quebec.

If cyclization of 1-(β-chloroethyl)-2-nitriminoimidazolidine to 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride occurred in a similar manner, it would provide an explanation for some of the products obtained in the reactions (2, 7) of the former compound.

DISCUSSION

A study of the chemical properties of 1-(β-chloroethyl)-2-imidazolidone (III), 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride (V), and 1-(β-nitraminoethyl)-2-imidazolidone (VI) obtained (2) from the reaction of thionyl chloride with 1-(β-hydroxyethyl)-2-nitriminoimidazolidine has indicated that the origin of these products may be represented as shown in Chart I. The mechanism for the chlorination of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine (I) to 1-(β-chloroethyl)-2-nitriminoimidazolidine (III) is assumed to be similar to that suggested (8) for the chlorination of alcohols with thionyl chloride.

CHART I



Since 1-(β-chloroethyl)-2-nitriminoimidazolidine (III) was recovered unchanged in 90% yield after it was heated under reflux for 4 hours in benzene containing dry hydrogen chloride and thionyl chloride, it cannot be considered the precursor of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride (IV) or 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride (V). We could find no evidence for the cyclization of 1-(β-chloroethyl)-2-nitriminoimidazolidine (III) under the conditions (1) used successfully in the cyclization of 1-(β-chloroethyl)-2-nitroguanidine. Thus the bicyclic compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

IV would have to arise from II or an active intermediate in the chlorination of I to III.

1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate was converted into 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride by heating with moist benzene containing hydrogen chloride. Therefore the bicyclic compound (IV) could give rise to 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride (V). Moreover, 1-(β-nitraminoethyl)-2-imidazolidone (VI) also must arise from one of the products of the thionyl chloride reaction during their isolation because primary nitramines are unstable in the presence of acid chlorides even under anhydrous conditions (9, 10, 11, 12, 13, 14, 15). It has been shown that both 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (16) and 1-(β-aminoethyl)-3-nitro-2-imidazolidone nitrate (7) on refluxing with ethanol give good yields of 1-(β-nitraminoethyl)-2-imidazolidone (VI). 1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate in the presence of warm ethanol (50° C) gives a new compound whose analysis and properties agree with the structure, 1-(β-nitraminoethyl)-2-ethoxy-2-imidazolinium nitrate (VII, X = NO_3). The latter compound VII on heating under reflux in absolute ethanol is converted in good yield into 1-(β-nitraminoethyl)-2-imidazolidone (VI). On heating 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride (V) with ethanol, ethyl chloride forms and the unstable free base rearranges to the more stable compound (VI).

When 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate was heated in benzene containing hydrogen chloride and thionyl chloride it was converted into 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride. Thus the hydrochloride salt of the bicyclic compound (IV) is stable under the conditions previously (2) used in the chlorination of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine. Since both the 1-(β-chloroethyl)-2-nitriminoimidazolidine and the bicyclic compound IV are stable under these conditions, a method was developed for their isolation from the reaction of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine with thionyl chloride. The crude crystalline product from the chlorination reaction was washed with water leaving behind the water insoluble 1-(β-chloroethyl)-2-nitriminoimidazolidine (59% yield). The aqueous filtrate on treatment with aqueous picric acid solution gave a crystalline picrate of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole (41% yield). It is now apparent that the products produced directly in the reaction of 1-(β-hydroxyethyl)-2-nitriminoimidazolidine with thionyl chloride are 1-(β-chloroethyl)-2-nitriminoimidazolidine (III) and 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride (IV). The other products, 1-(β-aminoethyl)-3-nitro-2-imidazolidone hydrochloride and 1-(β-nitraminoethyl)-2-imidazolidone, isolated during the original (2) study of this chlorination reaction, were formed by the reaction of the bicyclic compound with ethanol.

1-(β-Chloroethyl)-2-nitriminoimidazolidine (III) has been converted (7) into 1-(β-nitraminoethyl)-2-benzylamino-2-imidazolinium chloride (VIII) by heating with benzylamine in the presence of water.

A carbonium ion mechanism giving a bicyclic intermediate was suggested for this reaction. On the basis of this proposal it was considered that 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole might provide a more favorable starting material for the preparation of 1-(β-nitraminoethyl)-2-substituted amino-2-imidazoline salts (VIII). This proved to be the case and the compounds prepared by this method are described in Table I. However the successful use of a proposed bicyclic intermediate in a reaction does not provide unequivocal proof of its importance in the reaction mechanism. The concerted mechanism with ring opening (IX → VIII) offers an equally plausible mechanism for this reaction.

A further study was made of the reaction between methanolic potassium hydroxide and 1-(β-chloroethyl)-2-imidazolidone (X). This reaction gives several products, which is considered typical (17) of reactions involving carbonium ion intermediates. However, the number of products produced in a reaction involving a carbonium ion intermediate depend to some extent on the concentration of reactants and reaction conditions. The products identified from the reaction of 1-(β-chloroethyl)-2-imidazolidone with methanolic potassium hydroxide were Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene (XII), 1(-β-methoxyethyl)-2-imidazolidone (XV), and 1-vinyl-2-imidazolidone (XIV).

Freshly distilled samples of Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene (XII) on standing deposited crystals (XIII), which melted at 249–252° C. It appears that the bicyclic compound is converted slowly into the latter compound by absorbed moisture. Δ^7-1-Oxa-4,7-diazabicyclo(3.3.0)octene (XII) was considered (18) a possible intermediate in the formation of 1-(β-hydroxyethyl)-2-iminoimidazolidine (or its tautomer, 1-(β-hydroxyethyl)-2-amino-2-imidazoline) from 1-(β-chloroethyl)-2-imidazolidone (X). The bicyclic compound XII could arise from a carbonium ion intermediate (XI). This intermediate XI would also explain the formation of 1-(β-aminoethyl)-2-imidazolidone in the reaction of X with ammonia. If, however, we considered the concerted mechanism with ring opening (XVII → XVIII) for the formation of 1-(β-hydroxyethyl)-2-amino-2-imidazoline (XVIII, R = H) from the reaction of ammonia with XI, then another mechanism[2] must be operative in this reaction to produce the second product 1-(β-aminoethyl)-2-imidazolidone (XVI, R = H).

Δ^7-1-Oxa-4,7-diazabicyclo(3.3.0)octene (XII) on treatment with benzylamine gave 1-(β-hydroxyethyl)-2-benzylamino-2-imidazoline (XVIII, R = benzyl).

EXPERIMENTAL[3]

1-(β-Nitraminoethyl)-2-ethoxy-2-imidazolinium Nitrate

A freshly prepared sample of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (7) (10 g, 0.046 mole) was dissolved in absolute ethanol (500 ml) at 50° C. Although this solution was cooled immediately in freezing mixture only 2.2 g (22%) of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (m.p. 149–151° C with decomposition) was recovered. After the filtrate was concentrated to a volume of 200 ml, a second crystalline compound (m.p. 116–119° C with decomposition) was obtained, yield 5.1 g (42%). The melting point was raised to 124–125.5° C with decomposition by one crystallization from ethanol–ether (2:1) solution. Anal. Calc. for $C_7H_{15}N_5O_6$: C, 31.70; H, 5.70; N, 26.42%. Found: C, 31.90; H, 5.75; N, 26.41%.

1-(β-Nitraminoethyl)-2-imidazolidone from 1-(β-Nitraminoethyl)-2-ethoxy-2-imidazolinium Nitrate

1-(β-Nitraminoethyl)-2-ethoxy-2-imidazolinium nitrate (215 mg, 0.81 mm) was heated under reflux in absolute ethanol (5 ml) for 2 hours. Removal of the ethanol *in vacuo* gave a crystalline product melting at 176–180° C with decomposition. One crystallization from absolute ethanol (7 ml) raised the melting point to 180–182.5° C with decomposition, yield 133 mg (94%). A mixture melting point determination with a known sample of 1-(β-nitraminoethyl)-2-imidazolidone (7) was not depressed.

[2]*The Referee has suggested that the reaction between ammonia and 1-(β-chloroethyl)-2-imidazolidone represents a competition between* Sn_2 *and elimination reactions. This is certainly a possibility.*

[3]*All melting points are uncorrected. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois.*

1-(β-Nitraminoethyl)-2-substituted Amino-2-imidazolines

The properties of the 1-(β-nitraminoethyl)-2-substituted amino-2-imidazoline salts prepared by the reaction of amines with 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)-imidazole nitrate are described in Table I. Since the conditions for these reactions are very similar, only the preparation of 1-(β-nitraminoethyl)-2-(*p*-anisidino)-2-imidazoline nitrate is described below in detail.

1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (657.5 mg, 0.003 mole) and *p*-anisidine (369 mg, 0.003 mole) in absolute ethanol (8 ml) were heated under reflux for 3 hours. After removal of the solvent *in vacuo*, a hard gum was obtained, yield 1.025 g (100%). Trituration with acetone gave 984 mg (96%) of crystalline product melting at 115–118° C with decomposition. Four crystallizations from ethanol–ether (5:3) solution raised the melting point to 118.5–120° C with decomposition.

An oily picrate, which crystallized slowly on standing in the refrigerator for 2 weeks, was obtained in the usual way from water in 78% yield. Two recrystallizations from water raised the melting point from 120 to 122° C to a constant value of 121–122° C.

Stability of 1-(β-Chloroethyl)-2-nitriminoimidazolidine

1-(β-Chloroethyl)-2-nitriminoimidazolidine (235 mg) in absolute ethanol (7 ml) was heated under reflux for 7 hours. The solution on cooling deposited crystals melting at 142–144° C with decomposition, yield 178 mg (76%). The crystals were identified as unchanged starting material by a mixed melting point determination.

1-(β-Chloroethyl)-2-nitriminoimidazolidine (188 mg) was also recovered in 90% yield after it was refluxed for 4 hours in a benzene solution containing dry hydrogen chloride (200 mg) and thionyl chloride (150 mg).

1-(β-Aminoethyl)-3-nitro-2-imidazolidone Nitrate from 1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole Nitrate

1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (1 g, 0.0046 mole) in benzene (50 cc) saturated with hydrogen chloride was heated under reflux for 8.5 hours. After the solvent was decanted from the insoluble oil (0.76 g) the oil was triturated with warm (40° C) ethanol. The crystals (m.p. 155–159° C with decomposition) were recovered by filtration, yield 0.36 g (38%). The crystals were purified by solution in water and precipitation with ethanol. The pure product melted at 160.5° C with decomposition alone and on admixture with a known (7) sample of 1-(β-aminoethyl)-3-nitro-2-imidazolidone nitrate.

The picrate (m.p. 198° C decomposition) was prepared in the usual manner from water. It did not depress the melting point of a known (7) sample of the picrate of 1-(β-aminoethyl)-3-nitro-2-imidazolidone.

Stability of 1-Nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole Hydrochloride in Benzene – Thionyl Chloride Medium

Thionyl chloride (5 ml) was added to dry benzene (15 ml) and then 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole nitrate (0.57 g, 0.0026 mole) was added portionwise at room temperature. A vigorous reaction occurred and brown fumes were evolved. Although the reaction was complete in 15 minutes, the solution was held at 55° C for a further 6 hours. At the end of this time the solution was cooled and the crystalline precipitate was recovered by filtration, yield 0.49 g (98% based on 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole hydrochloride). The melting point was raised from 130–135° C with decomposition to 137–139° C with decomposition by solution in ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

at room temperature and precipitation with ether. This sample gave low chlorine values on analysis so it was characterized as its picrate.

The picrate was formed in 50% yield in the usual manner from aqueous solution. It melted at 150–151° C alone and on admixture with a known (16) sample of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole picrate.

Chlorination of 1-(β-Hydroxyethyl)-2-nitriminoimidazolidine

1-(β-Hydroxyethyl)-2-nitriminoimidazolidine (2, 19) (1.74 g, 0.01 mole) was chlorinated with thionyl chloride in benzene under the conditions previously (2) described. At the end of the reaction period the crystalline starting material had been transformed into a colorless oil which crystallized after a small amount of benzene had been evaporated *in vacuo* at 50° C. The hygroscopic crystals were collected by filtration and dried *in vacuo*, yield 1.87 g (98%). A sample (0.74 g) of the crude product was suspended in water. The water insoluble crystalline product (m.p. 142–143° C) was collected by filtration and dried, yield 0.44 g (59%). A mixed melting point determination with a known (2) sample of 1-(β-chloroethyl)-2-nitriminoimidazolidine (m.p. 142.5–143.5° C) gave no depression.

The filtrate from 1-(β-chloroethyl)-2-nitriminoimidazolidine on treatment with aqueous picric acid yielded a crystalline picrate (m.p. 150–151.5° C). A mixture melting point with a known sample of 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz(1,2-a)imidazole picrate (m.p. 151° C) was not depressed.

The yield of picrate was 306 mg. Since pure 1-nitro-2,3,5,6-tetrahydro-1(H)-imidaz-(1,2-a)imidazole hydrochloride under the same conditions gives a 50% yield of picrate, this yield of picrate corresponds to the presence of 304 mg (41%) of bicyclic hydrochloride.

Δ^7-1-Oxa-4,7-diazabicyclo(3.3.0)octene

A methanolic solution of potassium hydroxide (533 ml of 1.69 *N* solution) was added dropwise over a period of 1.5 hours to a solution of 1-(β-chloroethyl)-2-imidazolidone (18) (133 g, 0.9 mole) in absolute methanol (300 ml). This reaction mixture was heated under reflux for 5 hours after which it was worked up as previously (18) described. The volume of the final chloroform solution was 265 ml. A portion (29.4 ml) of the chloroform extract on evaporation gave 11.9 g of yellowish oil. This oil on treatment with aqueous picric acid solution yielded 6.7 g (18.5%) of crude (m.p. 134–138° C) Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene picrate. One crystallization from acetone–ether (3:1) solution raised the melting point to 145–146.5° C. This picrate did not depress the melting point of a known (18) sample of Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene picrate (m.p. 144.5–145.5° C).

The residual oil (21.8 g) from another portion (55 ml) of the chloroform extract was distilled *in vacuo*. The following four fractions were obtained: (1) 1.69 g of crystals (b.p. 78–80° C/0.07 mm), (2) 0.9 g of liquid containing some crystals (b.p. 82–88° C/0.06 mm), (3) 2.18 g of turbid liquid (b.p. 92–95° C/0.06 mm), and (4) 15.26 g of a low melting crystalline material (b.p. 98–100° C/0.06 mm).

A small sample of fraction 1 on treatment with a saturated aqueous picric acid solution gave Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene picrate (m.p. 145–146° C) in 86% yield. Two samples (1.3 g) of Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene (both samples originally contained 86–87% bicyclic compound by picrate analyses), which had been standing for 2 weeks, were combined and redistilled *in vacuo*. It was noted that most of the originally low melting solid had been converted into a high melting solid which was no longer distillable. Only 0.3 g (b.p. 76–78° C/0.07 mm) of distillate was obtained. This small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

sample of Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)octene was redistilled for analysis. Anal. Calc. for $C_5H_8N_2O$: C, 53.55; H, 7.19; N, 24.99%. Found: C, 53.25; H, 7.09; N, 24.63%.

The residue from the distillation of bicyclic compound was crystallized from chloroform–hexane solution, yield 0.35 g (27% by weight). The melting point was increased from 237–241° C to 249–252° C by two crystallizations from chloroform–hexane solution. Anal. Calc. for $C_{10}H_{18}N_4O_3$: C, 49.57; H, 7.49; N, 23.13%. Found: C, 49.90; H, 7.38; N, 23.45%.

Iodometric titrations of fractions 3 and 4 indicated that they contained 58.7 and 50.8% respectively of the 1-vinyl-2-imidazolidone compound. Fractions 3 and 4 on treatment with dinitrophenylhydrazine in acid solution gave 56% and 47.2% yields respectively of the dinitrophenylhydrazone of acetaldehyde. The dinitrophenylhydrazone melted at 151–152° C with sintering at 149° C after several crystallizations from aqueous methanol. Anal. Calc. for $C_8H_8N_4O_4$: C, 42.86; H, 3.60; N, 24.99%. Found: C, 43.32; H, 3.51; N, 25.13%. The formation of the dinitrophenylhydrazone of acetaldehyde from fractions 3 and 4 agrees with the observation of Reppe (20) that vinyl groups attached to nitrogen are split off as acetaldehyde under the influence of weak acids.

Reaction of Δ^7-1-Oxa-4,7-diazabicyclo(3.3.0)octene with Benzylamine

Benzylamine (0.086 g, 0.008 mole) was added to Δ^7-1-oxa-4,7-diazabicyclo(3.3.0)-octene (0.09 g, 0.008 mole) in absolute ethanol (5 ml). The mixture was allowed to stand at room temperature overnight after which it was evaporated to dryness *in vacuo* at 40° C. A pink-colored semicrystalline oil was obtained, yield 120 mg.

A portion (40 mg) of this oil on treatment with aqueous picric acid solution gave a 68% yield of crystalline picrate (m.p. 116–119° C). Crystallization from ethanol raised the melting point to 122.5° C. This picrate did not depress the melting point of a known sample of 1-(β-hydroxyethyl)-2-benzylamino-2-imidazoline picrate (21).

CO-ORDINATION COMPOUNDS OF NICKEL(II)

PART I. THE SPECTRA OF SALICYLALDIMINE DERIVATIVES OF NICKEL(II) IN SOME ORGANIC SOLVENTS[1]

H. C. Clark and R. J. O'Brien

ABSTRACT

Measurements of the ultraviolet and visible absorption spectra of bis-N-methyl-salicylaldimine nickel(II) and its 5-chloro and 5-bromo derivatives in benzene, chloroform, carbon tetrachloride, and cyclohexane solutions at temperatures between 15° and 45° C are reported. The results confirm the occurrence of a temperature dependent equilibrium between dia- and para-magnetic forms. The nature of the paramagnetic form is discussed in terms of the recent developments of the ligand field theory. The effect on the equilibrium of substitution of chlorine or bromine in the five position of the salicylaldehyde molecule is also discussed.

INTRODUCTION

The co-ordination compounds formed between nickel and various salicylaldimines are generally highly colored, diamagnetic solids with square planar configurations. Willis and Mellor (1) found that the addition to these complexes of organic solvents such as pyridine, dioxan, benzene, and chloroform caused changes to paramagnetism, magnetic moments of between 1 and 3 Bohr magneton being observed at room temperature. These magnetic moments are independent of concentration, but measurements over a wide temperature range have shown (2, 3) that in many of these solutions, a temperature dependent equilibrium occurs between dia- and para-magnetic forms, the latter being favored at low temperatures. The paramagnetic species may be (1) octahedral with two co-ordination sites occupied by solvent molecules, (2) tetrahedral, or (3) square planar but with unpaired electrons. Tetrahedral nickel(II) complexes, although long postulated theoretically, have only recently been isolated (4) and the existence of such complexes in solution now seems more probable. Square planar paramagnetic complexes can be predicted only from ligand field theory and have not been isolated as yet.

Later work on the absorption spectra of nickel–salicylaldimine complexes in organic solvents (5) generally supported the magnetic evidence of a temperature dependent equilibrium between dia- and para-magnetic forms, but there were several important exceptions. Further spectral measurements as reported below, and also by Sacconi, Paoletti, and Del Re (6) provide assistance in explaining these exceptional cases.

EXPERIMENTAL

The complexes were prepared by the method described previously (3, 7) in which bis-salicylaldehyde nickel(II) or its 5-chloro or 5-bromo derivative was gradually added to a saturated alcoholic solution of methylamine. It was interesting to note that in the early stages of the preparation, when a large excess of methylamine was present, a light green flocculent precipitate was formed. As more of the salicylaldehyde complex was added, this precipitate was converted to the more familiar, dark green crystals of the desired product. This light green precipitate is possibly an octahedral nickel complex containing two methylamine molecules linked directly to the nickel atom. In the presence of larger amounts of bis-salicylaldehyde nickel(II), these two molecules are readily lost. The final dark green products were recrystallized from either chloroform or carbon

tetrachloride, and identities of the new compounds confirmed by determinations of the nickel content by precipitation with dimethylglyoxime.

Bis-N-methyl-5-chloro-salicylaldimine nickel(II): Found: Ni, 14.76. Calc. for Ni-$(C_8H_7ONCl)_2$ 14.84%.

Bis-N-methyl-5-bromo-salicylaldimine nickel(II): Found: Ni, 12.25. Calc. for Ni-$(C_8H_7ONBr)_2$ 12.11%.

All solvents used were carefully dried and purified by standard procedures. The spectral measurements were made with a Cary recording spectrophotometer, model 14, with 10-mm sample cells. These cells were contained in a thermostated tank which was controlled to ±0.5° at 15°, 25°, 35°, or 45° C. The following tables (I and II) give values of the molecular extinction coefficients at the above temperatures, in chloroform, benzene, carbon tetrachloride, cyclohexane, and ethyl alcohol.

The tables in many cases show a slight decrease in the extinction coefficient with

		378	8480	7580	6840	6100
		410	2440	2580	2910	3010
Bis-N-methyl-5-bromosalicylaldimine nickel(II)	8.00×10^{-5}	325	3630	4000	4570	4640
		378	8000	7300	6660	5970
		410	2290	2560	2690	2880

increasing temperature. This is attributed to the change in concentration that is due to the expansion of the solvent, and a suitable correction would show the extinction coefficient to remain constant.

DISCUSSION

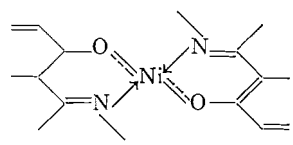
It should first be pointed out that these results differ from those of Sacconi *et al.* (6), who found a slight temperature variation in the intensities of the 325 mμ and 415 mμ bands of bis-N-methylsalicylaldimine nickel(II) in benzene solution. The present results are, however, in good agreement with others previously reported (5). Sacconi also reported that the "620 mμ" band is actually located at 615 mμ in chloroform, 630 mμ in dioxan, and 635 mμ in benzene. We could find no definite indication of such a shift.

The temperature dependent equilibrium observed both magnetically and spectrophotometrically in solutions of these complexes is unusual, and has otherwise been observed only in solutions of bis-formylcamphorethylenediimine nickel(II) (8). The addition to a planar nickel complex of an organic solvent may produce one of several effects: (*a*) the co-ordination of two solvent molecules to the nickel atom to form an octahedral, or more accurately, tetragonal paramagnetic complex; (*b*) conversion to a tetrahedral configuration; (*c*) a reduction in the splitting of the 3*d* energy levels by the ligand to produce a square planar, paramagnetic complex. Solvation of the resultant complex is possible in all cases and must be carefully distinguished from co-ordination occurring only in case (*a*). The first effect will be expected in basic solvents such as pyridine; thus bis-N-methyl-salicylaldimine nickel(II) forms a stable paramagnetic dipyridine adduct. Conversion to a tetrahedral configuration may possibly occur when the intermolecular forces of the crystalline solid are removed by the addition of a non-co-ordinating solvent such as cyclohexane, thus allowing the isolated molecule to assume the shape of lowest potential energy (9). The energy difference between the planar and tetrahedral configurations must be small allowing a thermal equilibrium; at low temperatures the more stable tetrahedral form will predominate, while at higher temperatures, where thermal distortion of the complex molecule becomes appreciable, the diamagnetic planar form will exist. Hence, in agreement with observation, the magnetic moment will decrease with increasing temperature. Alternatively, the removal of intermolecular crystalline forces may merely reduce the splitting of the 3*d* levels so that it is energetically preferable for the electrons to remain unpaired. However, it is less easy to determine the cause of this transition, as compared with the planar–tetrahedral change. That diamagnetism may be peculiar to the solid state, and that the change to paramagnetism

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

may occur in the absence of a solvent, is further shown by the observation that certain nickel–salicylaldimine complexes are paramagnetic in the molten state (10). In particular, the transition to paramagnetism of bis-N-methyl-salicylaldimine nickel(II) above 180° has been interpreted (11) as being due to the formation of a polymeric octahedral complex, but these results can with equal validity be interpreted as resulting from either effect (*b*) or effect (*c*) discussed above.

Previously (5) the relationships between the magnetic and spectral properties of nickel–salicylaldimine complexes in pyridine, alcohol, and dioxan solutions have been discussed. In these cases, octahedral paramagnetic adducts appear to be formed. This paper is concerned with the spectra of the benzene, methylbenzene, chloroform, carbon tetrachloride, and cyclohexane solutions. These spectra consist of four bands located at approximately 270 mμ, 325 mμ, 415 mμ, and 620 mμ, and in many cases a "shoulder" in the 360–370 mμ region is also apparent. The first of these bands at 270 mμ is produced by a transition in the benzenoid ring of the salicylaldehyde molecule (12). Similarly, the 325 mμ band must result from internal transitions within the conjugated system of the free ligand since it also occurs in the spectra of the free organic ligands. The band at 415 mμ is observed only in the spectra of the complexes, and from its high intensity must be considered a charge transfer band due to electron transfer in the new conjugated system present only in the complex.



The fourth band at 620 mμ (for which $\log \epsilon < 2$) is due to a so-called "forbidden" *d–d* transition of the nickel atom.

Bis-N-methylsalicylaldimine nickel(II) has been shown to exist in pyridine solution as the tetragonal dipyridine adduct, which shows absorption at 270 mμ and 378 mμ. After allowance is made for the shift of up to 20 mμ to longer wavelengths which is observed in all these pyridine solutions, the latter of these two bands may be considered the enhancement of the "shoulder" at 360–370 mμ. Certainly, high intensities of this band are characteristic of an octahedral configuration of these complexes. Also, in appropriate cases where an equilibrium between diamagnetic and paramagnetic forms occurs, its intensity is related in an inverse manner to the intensities of the 325 mμ and 415 mμ band. The relative intensities of these three bands may therefore allow conclusions to be drawn concerning the extent of solvent–solute interaction. The ethyl alcohol solution of this nickel complex absorbs at 325 mμ, 378 mμ, and 415 mμ, and the effect of increasing temperature is to increase the intensity of the first and last of these bands at the expense of the 378 mμ band. Hence, a temperature-dependent equilibrium exists in this solution between a diamagnetic planar form characterized by the 325 and 415 mμ bands, and a paramagnetic tetragonal species characterized by the 378 mμ band, since there is clearly sufficient interaction between the complex and the solvent to greatly enhance this last charge transfer band. It also may be noted that the spectra of the 5-chloro and 5-bromo derivatives show that the equilibrium has shifted in favor of the paramagnetic species. For the dioxan solution of this complex, the bands at 325 mμ and 410 mμ show only very small changes with temperature, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

only a slight shoulder is apparent at 360 mμ. Hence solute–solvent interaction is weak and any resultant tetragonal product must retain its fifth and sixth groups very weakly.

For solutions in benzene, the methylbenzenes, and chloroform, magnetic measurements again showed the occurrence of an equilibrium, but absorption bands are apparent only at 325 mμ and 415 mμ, and the intensities of these bands are temperature independent. Hence in these solvents, there can be no strong interaction between solvent and solute, since there is no enhancement of the 360–370 mμ charge transfer band. The paramagnetic form must therefore be either tetrahedral or square planar (paramagnetic). Basolo and Matoush (8) have previously concluded that the paramagnetic form of bis-formylcamphorethylenediimine nickel(II) in methyl benzene solutions is tetrahedral, since no direct correlation could be found between the magnetic susceptibilities of these solutions and the base strengths of the solvents. Whatever the configuration of the paramagnetic form, it is remarkable that there are no changes in the charge transfer bands, since the change from dia- to para-magnetism must result from changes in the splittings of the 3*d* levels and these levels are almost certainly involved in several of the charge transfer processes.

From the present results, similar conclusions regarding the configuration of the paramagnetic form may now be drawn for solutions in carbon tetrachloride and cyclohexane, for solutions of the 5-chloro derivative in benzene, chloroform, carbon tetrachloride, and cyclohexane, and of the 5-bromo derivative in carbon tetrachloride and cyclohexane. In all these solutions, the 325 mμ and 415 mμ bands are unaffected by temperature changes, so that solvent–solute interaction must be negligibly weak, and again the paramagnetic form can only be four-co-ordinated. A list of the solvents arranged in order of decreasing effect on these charge transfer bands further supports this deduction regarding the nature of the paramagnetic form, the order being pyridine > alcohol > dioxane > benzene > chloroform ~ methylbenzenes ~ carbon tetrachloride ~ cyclohexane. This order is that of decreasing basic strength, or decreasing co-ordinative ability of these solvents.

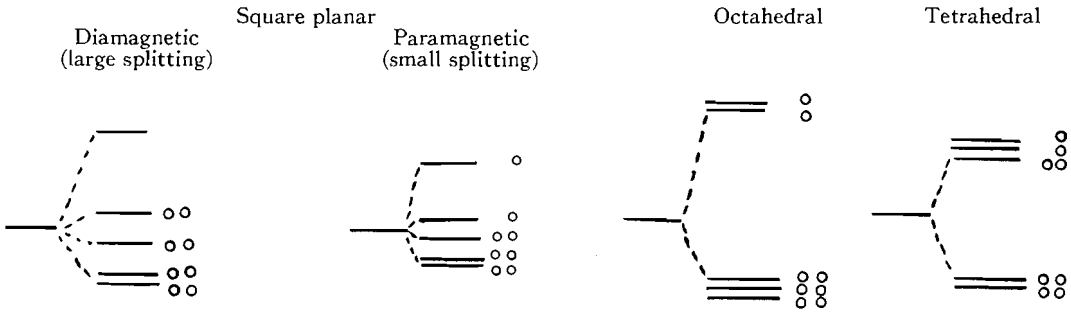
Since the 620 mμ band results from forbidden *d–d* transitions and is hence directly concerned with the configuration of the 3*d* electrons of the nickel atom, a direct relationship must exist between the intensity of this band and the concentration of the paramagnetic form. The above results show that without exception, the 620 mμ band increases in intensity with increasing temperature as compared with the observed decrease in magnetic moment. Unfortunately, the solubilities in cyclohexane were too low for accurate measurement of the optical densities in this region. It is noticeable that the intensity changes are much greater in certain cases than in others; thus the intensity of the 620 mμ band of the benzene solution of the 5-chloro compound shows much greater changes than that of the carbon tetrachloride solution. This is probably due to the fact that in this latter solvent the equilibrium lies very much more on the diamagnetic side, so that much smaller changes in the extinction coefficient can occur.

The effect of varying the solvents in the order of decreasing co-ordinative power is thus to change the configuration of the paramagnetic form from almost regularly octahedral for pyridine solutions, through more tetragonal configurations in alcohol and dioxan solutions, to either tetrahedral or planar paramagnetic configurations in chloroform, carbon tetrachloride, and cyclohexane. It is not reasonable to conclude that in these latter solvents, solvent interaction with the complex molecule is strong enough to produce paramagnetism (and hence a tetragonal configuration) and yet on the other hand, is so weak that the charge transfer bands are not affected. For such non-co-ordinating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

solvents as carbon tetrachloride and cyclohexane, the resultant paramagnetic product can contain no solvent molecules and hence can only be tetrahedral or square planar. The point in the above solvent series at which co-ordination of solvent molecules ceases is difficult to determine, and may depend on the balance between the co-ordinating power of the solvent, and the tendency of the complex molecule to attain a more energetically favorable configuration. Certainly in pyridine, ethyl alcohol, and probably in dioxan, these salicylaldimine complexes form tetragonal species, while in carbon tetrachloride and cyclohexane no co-ordination of solvent molecules occurs.

Assignment of the 620 mμ band is best made in terms of ligand field theory. The splittings of the 3*d* energy levels for different geometries of the ligand field are shown below together with the arrangement within these levels of the eight 3*d* electrons of the nickel(II) atom.



Hence, for the planar configurations, three "forbidden" *d–d* transitions are possible, which may be named ω_1, ω_2, and ω_3 according to the scheme of Belford, Calvin, and Belford (13). Only one transition is possible for the tetrahedral form, although the removal of the degeneracy of the upper triplet as a result of the Jahn–Teller effect will produce several transitions which differ only very slightly in energy content. For an octahedral form, only one transition is possible since the Jahn–Teller effect does not apply. Analysis of a typical 620 mμ band (Fig. 1) shows that after allowance is made

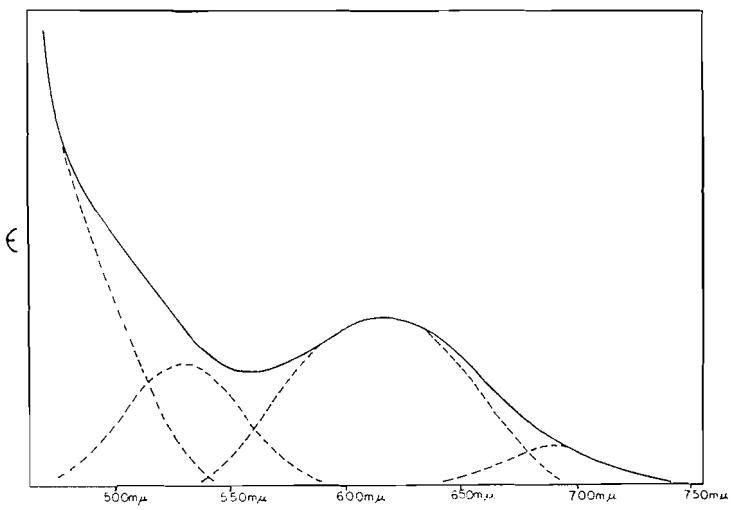


FIG. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

for the tail of the intense 415 mμ band, there remains a broad asymmetric peak which may be separated into three gaussian components. This closely resembles the spectra of planar copper complexes in the 650 mμ band region (13). Moreover, this 620 mμ band is also observed in ethyl alcohol solutions for which the paramagnetic form is tetragonal, while for pyridine solutions there is no absorption band in 600–650 mμ region. Hence this 620 mμ band must be produced by the diamagnetic complex, and as the proportion of this form increases with increasing temperature the intensity of this band will also increase in agreement with observation.

Sacconi, Paoletti, and Del Re (6) have previously suggested that the paramagnetic forms in these non-co-ordinating solvents are of the "outer" sp^3d type, this being the valence bond description of paramagnetic square planar complexes. This conclusion is based on the observation that bis-N-alkyl-salicylaldimine – nickel(II) complexes in benzene and dioxan solutions at 25° have a very low, almost zero, dipole moment; hence the paramagnetic form must still be planar. However, magnetic measurements (3) have shown that at this temperature and in these solvents, more than half of the complex is already in the diamagnetic planar form which has a zero moment. Thus, bis-N-methyl-salicylaldimine nickel(II) exists in benzene solution at 25° to the extent of 64% in the diamagnetic, trans-planar form. Hence, assuming a tetrahedral nickel(II) complex to have a moment of approximately 5 D, the observed value of 1 to 2 D is to be expected and may still be consistent with a tetrahedral configuration of the paramagnetic form. Moreover, if as suggested above, the paramagnetic form in dioxan is actually tetragonal, with two trans-solvent molecules, the dipole moment will in any case be zero. Only in solvents such as chloroform, carbon tetrachloride, and cyclohexane and at low temperatures, can an appreciable dipole moment be expected. Such measurements are now in progress, and it is hoped the results will make it possible to distinguish between tetrahedral and square planar paramagnetic forms.

These present results also show the effect on the equilibrium of differences in the solvent, and also differences in the complex itself. From a consideration of the intensity of the 620 mμ band at say 15°, it would appear that the proportion of diamagnetic form increases as the solvent is changed from chloroform to benzene to carbon tetrachloride, although this effect is less apparent at higher temperatures. The spectra of the alcohol solutions shows the effect of substitution on the aromatic ring. The halogen atom, substituted in the five position and acting through the conjugated system of the Schiff's base, will reduce the donor properties of the nitrogen atom. In other words, the ligand field strength will be reduced, thus facilitating the formation of a species in which the electrons remain unpaired. Thus the spectra of the alcohol solutions show that the intensity of the 378 mμ band which is characteristic of the tetragonal form is markedly greater for the 5-chloro and 5-bromo derivatives. The secondary effect of increased acidity of the phenolic group by this substitution is apparently of secondary importance to the reduced donor properties of the nitrogen atom in determining the strength of the ligand field.

Further substituted derivatives are being examined to determine more extensively the factors which control the equilibrium.

NOTE ADDED IN PROOF: Since this paper was submitted, Maki (J. Chem. Phys. **29**, 1129 (1958)) has made a more elegant assignment of the spectra of bis-N-methylsalicylaldimine nickel(II), as a solid and in pyridine and chloroform solutions. The conclusion is reached that for a complex with this *trans*-planar symmetry, only a small axial perturbation is sufficient to cause a change from dia- to para-magnetism. However, the charge transfer bands are not mentioned and from the above results it would seem more a matter of definition to determine whether the small axial perturbation produced by a solvent such as carbon tetrachloride can be termed "co-ordination", or whether it is sufficient to term the product a para-magnetic planar complex. Maki's work is certainly opposed to any possibility of tetrahedral configurations.

THE REACTIVITY OF CELLULOSE

III. THE NITRATION OF COTTON LINTERS ALTERNATELY WETTED WITH WATER AT VARIOUS TEMPERATURES AND DRIED, AND THE PROBABLE DISTRIBUTION OF THE NITRATE GROUPS[1,2]

T. P. YIN[3] AND R. K. BROWN

ABSTRACT

Cotton linters alternately wetted at 0° or 25° and dried show progressively greater ease of nitration paralleling the number of wetting–drying cycles. The reverse is found to be true for linters wetted at 50°, 75°, or 100°. Analysis of the data obtained from lead tetraacetate oxidation of the nitrates favors the depressive concept of nitration and indicates that the observed changes in reactivity occasioned by the wetting–drying treatments are largely due to greater alterations in the accessibility of the primary rather than the secondary hydroxyl groups.

INTRODUCTION

It is known that the physical treatment and moisture history of cellulose has a definite effect upon its reactivity (1, 2, 3). Highly swollen cotton linters nitrate to a significantly greater extent than do the same linters "collapsed" by drying from a water-soaked state (3). Furthermore, repeated experiments have shown that dewaxed cotton linters, alternately wetted with water at 25° and dried, exhibit a small increase in accessibility to thallous ethylate in ether, to a nitration mixture of sulphuric acid, nitric acid, and water, and to deuterium exchange with heavy water (4, 5). Thus the extent of reaction and doubtless the distribution of the reacted hydroxyl groups are determined to some extent by the treatment the cellulose has received prior to reaction.

The present work attempts to gain more information concerning the effects of the wetting–drying process on the reaction proclivities of the primary and secondary hyrodxyl groups of cellulose as well as to verify and extend the observation that linters wetted at 80° and dried become *less* rather than *more* reactive (5).

Accordingly, cotton linters were repeatedly subjected to alternate wetting and drying cycles, the wetting temperature ranging from 0° to 100°. The dried samples were nitrated and the nitrates examined by lead tetraacetate oxidation for glycol content. The data from the nitration and oxidation reactions were analyzed and certain conclusions made concerning the probable course of the nitration reaction.

EXPERIMENTAL

Preparation of the Cotton Linters

High grade cotton linters[4] were dewaxed (5) and air-dried. A quantity of the dried linters was divided into five 20- to 30-gram portions, each one of which was given 15 cycles of alternate wetting and drying, the wetting temperatures being, for the five portions respectively, 0° (a mixture of ice and water), 25°, 50°, 75°, and 100° (wet steam). Each wetting involved immersion of the linters in water at the specified temperature for a 3-hour period while the mixture was occasionally stirred. The 100° wetting was

accomplished by passing wet steam (at 100°) through a mass of loosely packed linters held in a wide tube with smaller openings at either end. The water was then separated from the linters by mild suction and the moist fibers spread out to dry in air. This preliminary drying was followed by one of greater intensity with phosphorus pentoxide as previously described (5). A sample (1.5–2 g) was retained while the bulk of the linters was again wetted and dried. In this way a number of samples of linters were obtained and all were kept in a large desiccator over phosphoric anhydride for 2 weeks before further treatment.

Nitration of the Dried Cotton Linters

Standard tables (6, 7) facilitated the preparation of a nitration mixture which would produce 10–11% nitrogen in the cellulose nitrate. A quantity of this reagent, sufficient for the whole series of experiments, was kept in a refrigerator and found to maintain its strength. The details of the nitration followed the published directions (3, 4) but with the modification that during the ½-hour nitration, the linters and mixed acid were constantly though gently stirred to facilitate diffusion of the liquid.

Nitrogen Estimation

Analysis for nitrogen by the Du Pont semimicronitrometer (8) followed the procedure adopted previously (5).

Lead Tetraacetate Oxidations

Glacial acetic acid was freed from aldehyde by heating for 3 hours under reflux with chromic anhydride (2.5 g per liter of acid) added in small quantities at suitable intervals to avoid violent reaction. The acid was then fractionated in an all-glass apparatus.

Acetic anhydride was purified by fractionation.

The nitrocellulose (0.5 g corrected for moisture absorption) was weighed to 4 figures in a capped weighing bottle and transferred to a 200-ml glass-stoppered volumetric flask. The sample was covered with 125 ml purified anhydrous ethyl acetate (9) and slowly dissolved by agitation in a mechanical shaker for 2–3 days. Fifty milliliters of 0.1 *N* lead tetraacetate (10) in glacial acetic acid was added followed by enough ethyl acetate to bring the total volume to the 200-ml mark. The flask was well shaken again and placed in a constant temperature bath at 25°±0.1°. Two blanks were prepared simultaneously and duplicate runs were made for each sample.

Consumption of lead tetraacetate by the cellulose nitrate was followed by amperometric titration (11) with 0.02 *N* sodium thiosulphate added from a microburette. The

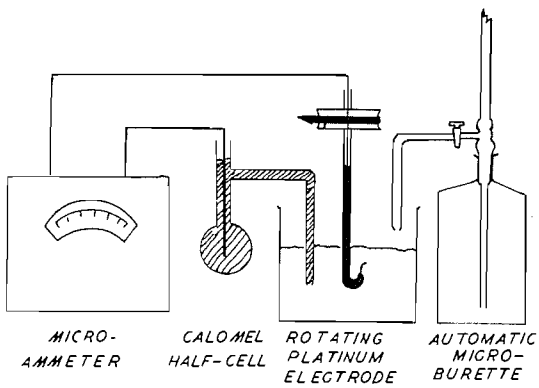

FIG. 1. Amperometric titration apparatus for the lead tetraacetate analyses.

apparatus is shown in Fig. 1 and consists of a rotating platinum electrode operating at 60 r.p.m., a saturated calomel half-cell, and a microammeter connected to the two electrodes. At suitable intervals the volumetric flasks were removed from the bath and briskly shaken. Suspended, undissolved material, if any, was allowed to settle and then a 10-ml aliquot was pipetted into 30 ml of potassium iodide – sodium acetate solution (12) in a 300-ml electrolysis beaker. The pipette was flushed with 10 ml of pure ethyl acetate and the washings added to the beaker. This is important, since the viscosity of the solutions of the cellulose nitrate in ethyl acetate varies with the nitrogen content of the nitrates producing variable delivery from the pipette. After the addition of 100 ml of distilled water the contents of the beaker was titrated with the two electrodes well-immersed in the liquid. The course of the titration was followed by the

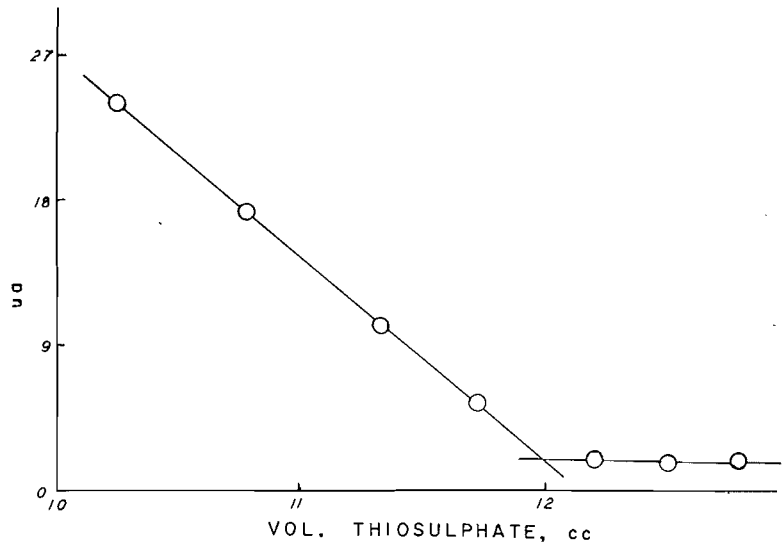

FIG. 2. Sample titration graph using the amperometric method.

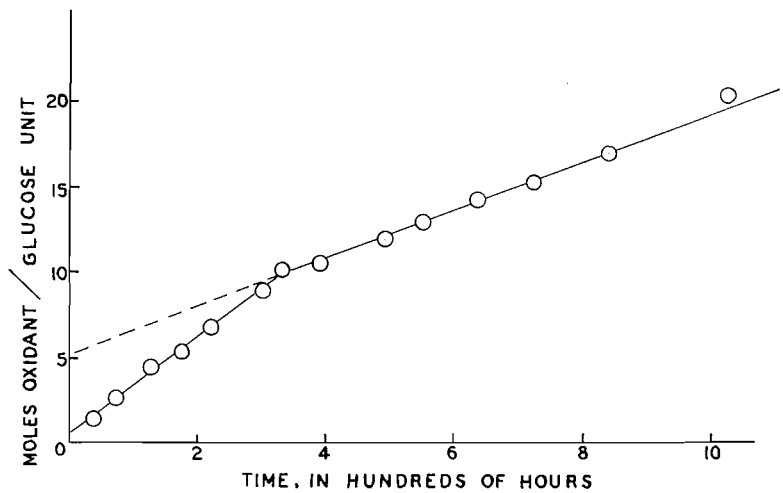

FIG. 3. Lead tetraacetate oxidation of the nitrate obtained from cotton linters which had received eleven cycles of immersion in water at 25° followed by drying.

scale readings of the microammeter. Usually 6–7 readings were recorded, three or four before and three after the equivalence point. This point was determined by plotting the volume of thiosulphate against the corresponding microammeter readings. A typical plot is shown in Fig. 2. Consumption of oxidant is expressed as the difference in titrations between blank and sample, and calculated as moles of oxidant consumed per glucose unit. One can add starch indicator to act as a visual check on the end point, but since the iodine is absorbed by the cellulose and the ethyl acetate layer, colorimetric end points are not reliable.

RESULTS AND DISCUSSION

Table I contains the data obtained from duplicate or triplicate nitrometer nitrogen analyses of the five series of nitrates. For convenience, the degree of substitution (D)[5] per glucose unit is listed along with the percentage of nitrogen. In addition the nitrogen analyses for the dewaxed but unwetted linters, nitrated by the same stock mixture, are noted in the same table. The decreased nitratability occasioned by one wetting at 0° or 25° (e.g. from 10.36% N to 10.20% N or 10.29% N) has been observed before (4, 5) and ascribed to a general collapse of the accessible cellulose from the partly swollen state which might have been attained during the dewaxing process. However, a similar single wetting–drying treatment at the higher temperatures (50°–100°) either maintains the same state or produces more reactive linters as in the case of the 75° series (an increase from 10.36% N to 10.63% N).

Examination of the data in Table I shows unmistakably that linters repeatedly wetted at 0° or 25° show enhanced nitration while those wetted at 50°, 75°, or 100° become less inclined to react as the number of wetting–drying cycles is increased. The differences are small, but several repetitions of this work show that the trend, though not the figures, is quite reproducible. The division between increasing and decreasing ease of nitration occurs somewhere in the region of 25° to 50°.

It should also be noted that the greatest over-all enhancement of reactivity caused by the wetting processes is found in the 0° series (0.41% N increase), while the most marked change in reactivity due to the first wetting is found in the 75° series (0.27% N increase). These observations *may* be significant.

Furthermore, of the five series of treated linters, only that exposed to steam at 100° gave a product which was non-uniform in physical appearance. It was somewhat more brittle and contained many small "nodules" which no doubt gave rise to the greater variability observed in the nitrogen analyses of the nitrates. At least three analyses were made on each nitrate of the 100° series in order to obtain a reasonable average value for the nitrogen content. These observations and the figures for the 100° series in Table I suggest that linters wetted by steam at 100° and dried, in addition to becoming less homogeneous, suffer a general reduction of accessibility to a technical nitration mixture.

The lead tetraacetate oxidations of the nitrates of these five series were carried out with the same stock solutions of the tetraacetate in acetic acid (normality, 0.0969). Although the nitrates in the ethyl acetate – acetic acid gave transparent, gel-like solutions, they were considered suitable for reaction and apparently presented no difficulties during the oxidations. Analyses were made by amperometric titration, since in several trials it was found that even though the blue-violet coloration of the starch–iodine complex disappeared, indicating complete reaction of the iodine with thiosulphate, the thin

[a]Moles of 2,3-glycol per glucose unit as measured by consumption of lead tetraacetate in moles per anhydroglucose unit.

[b]Total unnitrated hydroxyl content per anhydroglucose unit obtained from the degree of nitrate substitution D (Table I) subtracted from 3, the number of hydroxyl groups per anhydroglucose unit in cellulose.

organic layer of ethyl acetate still showed a faint yellow color of iodine. The starch was used, if at all, only as a visual aid for the determination of the approaching end point, and the exact equivalence point obtained amperometrically.

The consumption of lead tetraacetate by cellulose nitrate should reach a maximum when all free glycol groups in the anhydroglucose unit have reacted. However, in the present work, consumption continued to rise in all cases even after a period of 1200 hours. This phenomenon has been reported by other workers (12, 13). The glycol estimation, however, was obtained in the usual manner by extrapolation of the slower reaction curve to zero time. Figure 3 is typical of the results obtained in all cases and shows that a definite and unambiguous break occurs in the line. Duplicates were generally in very good agreement. The break in the oxidation curve usually occurred at about 300 hours. Confidence that the break did indicate completion of the glycol oxidation was obtained from the observation that cellulose trinitrate under similar conditions showed no evidence of oxidation (14).

Table II summarizes the oxidation data for the samples of nitrocelluloses from the five series of linters. It is unfortunate that for the series 50° and 75° only two sets of values are available. This was unavoidable at the time, since a choice was necessary because only a limited number of oxidations could be carried on simultaneously. Nevertheless, the information in Table II reveals that lead tetraacetate consumption (and therefore glycol content), *decreases* in the 0° series, but *increases* for the 50°, 75°, and 100° groups with the number of cycles. Since the capacity for reaction with the nitration mixture employed was found to follow the directly opposite trend in these four cases, one infers that the augmented ease of reaction for the 0° linters is at least partly due to *greater accessibility and reactivity* of the secondary hydroxyl units, whereas the lowered nitratability for the 50°–100° series is due, in part, to the *diminishing accessibility and reactivity* of the secondary hydroxyl groups developed by the repeated wetting and drying.

Cyclic treatment at 25°, however, yields linters whose accessibility to nitration, *and* glycol content of the resulting nitrate, increases with the number of wettings. One must infer, therefore, that the rising nitration is due to the greater availability of the primary hydroxyl groups, outweighing the fall in accessibility of those on carbons 2 and 3 of the glucose unit.

The region of 25° in wetting temperature appears to constitute a dividing line between high and low temperature wetting effects, the former increases while the latter decreases the accessibility of the secondary hydroxyl groups to technical nitration.

It is also to be noted that the glycol content of the unwetted but dewaxed and nitrated linters is lower than that of any of the singly wetted and dried samples, even though the nitrogen content exceeds that found for the 0° and 25° series.

In attempting to understand the causes of the changes in reactivity noted above and the resulting distribution of reacted hydroxyl groups, one must consider both the kinetics and the nature of the nitration reaction. Since the over-all rate of nitration is fairly rapid and the reaction is essentially complete within 10 minutes (15), the $\frac{1}{2}$-hour allowed for the nitration should give ample time for the equilibrium to be well established for both primary and secondary hydroxyl groups. Thus the differences in reaction rates between these two types of hydroxyls should not be a determining factor in the distribution of the reacted positions. It is true, however, that reaction at one hydroxyl of the glycol pair might somehow inhibit reaction at the second hydroxyl of the pair. What seems to be important is the position of equilibrium and the accessibility of the hydroxyl groups in determining the extent of reaction and the distribution of affected sites.

Because the nitration mixture is of constant composition, the equilibrium position

reached (16) at the completion of the reaction should be the same in all cases. Two factors might interfere with the attainment of this equilibrium. The first is the "bound water" content in the linters. Previous work (5) has shown that a series of linters wetted at 25° shows progressively greater water content, measured by Karl Fischer titration, as the number of cycles of wetting and drying increase. A stock nitration mixture should then, upon reaching equilibrium, have a slightly larger water content for the more frequently wetted and dried linters than is found in the case of the singly wetted and dried sample. The extent of nitration determined by the final composition of the nitration solution (16) should then be less. But, since the reverse was found true (5), small differences in the "bound water" content do not cause the regular variation in nitratability observed. The second factor, that of diffusion of the reagent to the reaction site, probably involving reaction with more resistant "hydrogen bonded" hydroxyls, appears to be important, since it has been shown that extension of the reaction time of nitration from 30 to 90 minutes obliterated the differences observed (5).

Some assistance in the clarification of this problem might be gained by a consideration of the three proposed concepts of the manner in which nitration occurs in the cellulose fiber. The most popular one, the *homogeneous* or *permutoid* method, considers that the fibrous structure of the cellulose is sufficiently swollen by the reaction environment that all portions of the macromolecule are uniformly exposed to the reagent and the hydroxyl groups are randomly substituted. This method is also referred to in this paper as the *random* method. The *heterogeneous* concept considers that the readily accessible regions of the fiber are extensively substituted and the hydrophobic shell so formed hinders the progress of the reagent to the interior of the micelles. There is thus produced a nitrate in which the glucose units are either completely substituted or entirely unsubstituted. The third concept of interest is termed the *depressive* method wherein a permutoid-like reaction occurs. The C_6 hydroxyl reacts without difficulty but substitution at either the C_2 or C_3 hydroxyl depresses the reactivity of the remaining member of the glycol pair (13, 17, 18).

Considerable evidence is available which discounts the heterogeneous viewpoint (18). The homogeneous or permutoid (random) theory agrees with a large mass of information available (18). However, the depressive mode of reaction has been postulated to account for the observation that in partly xanthated cellulose, the xanthate groups occupy the C_3 and C_6 but not the C_2 position (19), and the same concept may explain the presence of approximately half the nitrate groups in the primary position with the other half "distributed between" the two available secondary positions in cellulose nitrates containing from 2.5% to 7.5% nitrogen (20).

Expressions may be obtained for the coincidence of glycol groups for these three concepts of nitration and have been used in conjunction with data from tosylation, iodination, and oxidation experiments to estimate the probable distribution of substituents between the three available hydroxyl groups of cellulose (12, 13, 17, 21).

Setting H equal to the total molar value of the secondary hydroxyl groups unnitrated, and X as the concentration of the unreacted C_2 hydroxyl per anhydroglucose unit, the probability of glycol occurrence based on the assumption of random or homogeneous nitration is $(X)(H-X)$ whose value is maximum when $X = H-X = H/2$. Thus $H^2/4$ estimates the glycol occurrence. The depressive concept, permitting in the ideal case reaction at only one of either the C_2 or C_3 hydroxyls, would exhibit the presence of glycol only when the total degree of substitution in the secondary positions falls below one hydroxyl per glucose unit. The probability for glycol occurrence is then $[(H-X)+X]-1$

* + indicates increase; − indicates decrease in extent of nitration.

or H−1. Finally, the heterogeneous viewpoint allows either 100% glycol or 0% glycol per glucose unit and the estimate for glycol occurrence is obviously H/2 if it occurs at all.

Equating in turn these three expressions to the glycol content measured by lead tetraacetate oxidations, one obtains a figure for H representing the probable occurrence of *unreacted* secondary hydroxyl groups for each of the three modes of nitration. By subtracting this value from the total unnitrated hydroxyl content (F) per glucose unit (Table II), one arrives at probable values for unreacted primary hydroxyls (F−H). From this can be obtained the probable extent of nitration of the primary and secondary positions. For example, the equation for the sample isolated after one wetting–drying cycle at 0° is $0.057 = H^2/4$, or H/2 or H−1, according to the three assumptions, yielding values for the unnitrated secondary hydroxyl groups of H = 0.48, 1.06, and 0.11, respectively. Subtraction from the total amount of unnitrated hydroxyl groups (F in Table II) then gives values for the primary hydroxyl group as (1.24−0.48) = 0.76, etc. The probable extent of nitration in the two secondary positions is then (2−0.48) or 1.52, and that in the single primary position (1−0.76) or 0.24. All the nitrate substitutions calculated on the three assumptions are recorded in Table III.

The negative values for primary nitration shown in the lower section of Table III immediately eliminate heterogeneous nitration as a reasonable process. The figures for the probable reaction on the basis of random substitution suggest that the secondary positions react to a five- to seven-fold greater extent than do the primary positions. However, many examples can be quoted from the literature which clearly show that the primary hydroxyl in cellulose reacts more readily than do the secondary hydroxyl groups (22). In view of this, and the implication in the concept of random substitution that all hydroxyls are equally exposed to reaction and at equilibrium the extent of their reaction should be roughly the same, one would not expect this great preponderance of secondary over primary positions esterified. On the other hand, the depressive type of reaction, if permutoid-like, might be expected to yield after equilibrium is attained, a nitrate with the primary, and one of the two secondary positions more or less equally affected. This agrees with the analysis of the oxidation data on the basis of the depressive reaction theory. The observation by Murray and Purves (20) that half the nitrate groups in a nitrocellulose containing less than 8% nitrogen are found in the primary position lends support to the acceptance of the depressive permutoid-like reaction process as a reasonable mode for nitration. Although the homogeneous concept is favored for esterifications and etherifications in general, the suggestion has been made that nitration may not follow the course of most esterifications (23).

A further conclusion can be drawn from the data in Table III. The over-all change in primary and secondary nitrate substitution was obtained by subtracting the value after the first wetting–drying cycle from that obtained after the last, e.g. 1.57–1.52 or +0.05, in the case of the secondary nitrates in the 0° series assuming random substitution. The figures reveal that, except in the case of the 50° series, the differences in ease of nitration observed are largely due to the two- to three-fold greater change in reactivity of the primary over the secondary hydroxyl groups.

THE DETERMINATION OF ATOMIC RATIOS IN THE URANIUM–OXYGEN SYSTEM BY A THERMOGRAVIMETRIC METHOD[1]

L. G. STONHILL

ABSTRACT

A description is given of a thermogravimetric oxidation–reduction method for determining U–O ratios, especially suited to oxygen-sensitive materials of undetermined purity, and equally applicable to pure stoichiometric and non-stoichiometric oxides and their mixtures with each other and with uranium metal.

Provided that no uncombined base metals other than uranium, and no oxidizable or reducible matter other than its oxides, are present, it is not essential to know the detailed composition of the sample, since the assay is based on interconversion of the stoichiometric oxides UO_2 and U_3O_8 within that sample.

Incidental advantages of this method are: the avoidance of manipulation of the sample during the determination, precise reaction control, and immediate recording of the completion or otherwise of the required reaction.

INTRODUCTION

One of the chief characteristics of the uranium–oxygen system is the extent to which excess oxygen can be absorbed into the crystal lattice to form non-stoichiometric oxides. By far the most important of the oxides which has this ability is the dioxide, UO_2, often termed "brown oxide". In view of its function as an intermediate in the production of the metal, and being itself a potentially valuable reactor fuel, a knowledge of its exact U–O atomic ratio is often necessary. Current research into new methods of production has extended this need to materials, such as freshly precipitated oxide, which are extremely sensitive to oxidation by exposure to air and may contain inert impurities besides a large percentage of water.

It appeared likely that thermogravimetry offered a solution to the problems connected with this type of product, and would also provide a convenient general method for U–O ratios. A controlled-atmosphere apparatus (1) incorporating a Stanton milligram recording thermobalance was used in the investigation: the advantages of exact control over reaction conditions and a visible continuous record of the weight changes associated with a reaction make it possible to carry out a complete analytical operation within the assembly, thereby avoiding excessive manipulation of sensitive samples.

The standard chemical methods for determining atomic ratios, namely oxidation to U_3O_8 (2) or reduction to UO_2 (3), have been evaluated and refined by Bright *et al.* (4): these latter investigators point out the necessity of preparation and weighing in an oxygen-free atmosphere and recommend the use of an argon-filled dry box for these operations. Assumptions are usually made that the material under investigation contains only uranium oxide after a preliminary heat treatment to drive off water, etc. Though justifiable with familiar samples, such assumptions could not be made in the case of unusual products, and preliminary assays of material subject to aging should be avoided. The method to be described postulates only that oxidizable and reducible matter other than uranium and its oxides shall be absent, and uses interconversion of stoichiometric UO_2 and U_3O_8 as an internal standard on which to base the assay.

Composition of Oxides UO_x

The empirical formula UO_x may represent a homogeneous oxide species or, alternatively, a mixture of various oxidation states from UO_3 down to the uncombined metal.

[1]*Manuscript received September 30, 1958.*
Contribution from the Metallurgical Laboratories, Eldorado Mining and Refining Ltd., Ottawa, Canada.

Thus, UO may be the true monoxide, or mixed uranium metal and other oxides, and partial reduction of UO_3 with hydrogen results in a product $UO_{2.x}$ containing UO_3, U_3O_8, and the dioxide, as evinced by its behavior in the thermobalance and also by analysis (5). The importance of these alternative possibilities in the development of a general procedure for determining formulae will be considered below.

Thermogravimetric Behavior of Uranium Oxides

In view of the preceding observations it will be clear that a knowledge of the behavior of uranium in various oxidation states towards heat, and oxidizing and reducing atmospheres, is required. Figure 1 shows the effect of these factors on the pure oxides and also on the metal. Between UO_2 and U_3O_8 several phases have been detected by X-ray study: these tend to disproportionate on being heated (6), presumably without loss of oxygen from the system (7).

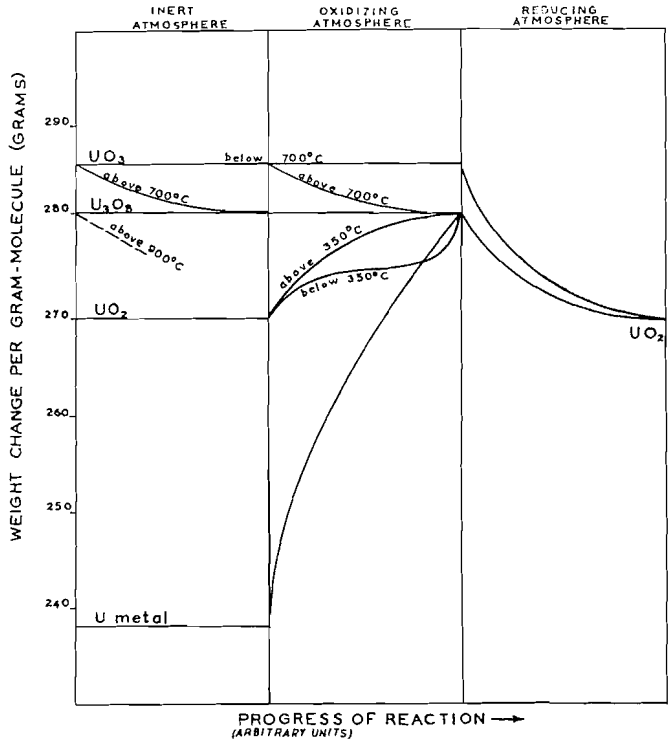

FIG. 1. Behavior of uranium and its principal oxides in various environments (temperatures approximate).

In the case of mixtures, the observed behavior depends on circumstances: in an inert atmosphere UO_3 will oxidize UO_2 with little or no evolution of oxygen until the rest of the uranium has been converted to U_3O_8; but if the material be oxidized by heating gradually in air from cold, the UO_3, which is unaffected by such treatment, will decompose on reaching a temperature of about 700° C, and the material will undergo a loss in weight.

The experimental observations on which Fig. 1 is based show (*a*) that for complete conversion of the uranium of any mixture to pure U_3O_8, it should be heated to 800° C to constant weight in air to ensure decomposition of UO_3, then cooled somewhat to compensate for a tendency of U_3O_8 to lose oxygen at that temperature; (*b*) that for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

similarly complete reduction to UO_2, temperature is not a critical factor but can be chosen so as to give a suitable reaction velocity; (*c*) that to ensure decomposition of hydrates, particularly of UO_3, and to volatilize traces of nitric acid, preliminary heating to at least 550° C is advisable.

Derivation of U–O *Molecular Formulae*

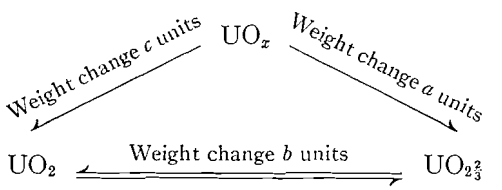
Suppose that a sample contains oxygen combined with uranium to an extent giving a general formula UO_x, and that the following reactions are made to occur in such a way that the whole of the uranium present is converted to the appropriate stoichiometric compound, either UO_2 or U_3O_8, thus

$$UO_x \rightarrow U_3O_8 \rightarrow UO_2,$$

or alternatively

$$UO_x \rightarrow UO_2 \rightarrow U_3O_8.$$

The weight changes accompanying these reactions can be obtained directly from the thermogravimetric record. For any given weight of uranium, let these weights be *a*, *b*, and *c* as shown diagrammatically:



The weight change in each reaction step will be proportional to the amount of uranium taking part (a constant, *k*) and the change in its level of oxidation: therefore, for the conversion UO_x to U_3O_8 to UO_2:

$$a = k(2\tfrac{2}{3}-x)$$

and

$$b = k(2\tfrac{2}{3}-2),$$

therefore

$$a/b = (2\tfrac{2}{3}-x)/\tfrac{2}{3} = 4-(3x/2).$$

Similarly for the alternative route UO_x to UO_2 to U_3O_8:

$$c = k(x-2)$$

therefore

$$c/b = (3x/2)-3.$$

Obviously the value of *x* is obtainable from either of these reaction cycles independently of the actual sample weight employed. In practice, however, several limiting possibilities should be distinguished.

Case *a*: $$2\tfrac{2}{3} < x \leqslant 3.$$

This arises when oxygen is present beyond the proportion required to give U_3O_8, and, therefore, presumably the material contains some UO_3. When the material is heated in air there will be a net *loss* in weight owing to the decomposition of this UO_3, but the general equations deduced above still apply.

Case *b*: $$x = 2\tfrac{2}{3}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Stoichiometric U_3O_8 is of course not further oxidizable by heating in air, but net weight changes associated with reduction followed by reoxidation will be equal.

Case *c*: $2 < x < 2\frac{2}{3}$.

This covers the range of oxides usually met. Either sequence of reactions may be employed.

Case *d*: $x = 2$.

The true dioxide is not often encountered, since, once it has been exposed to air, an excess of oxygen is always present (3), but it could be simulated by a mixture of metal with other oxides.

Case *e*: $0 \leqslant x < 2$.

In this case metal is most probably present in view of the uncertainties surrounding the monoxide UO (8, 9). Only the procedure involving a preliminary oxidation is applicable, as explained below.

Material Containing Uranium Metal

The presence of uncombined uranium metal invalidates the use of the equation derived above for reduction followed by oxidation, since the supposition that the whole of the uranium present takes part in the full cycle of reaction would not be true. However, the alternative preliminary oxidation procedure would be reliable, because the metal begins to oxidize at about 400° C (depending on its state of subdivision) and gives a final product of U_3O_8 in the same way as the oxides.

Samples containing uranium metal show a gain in weight during initial heating in nitrogen (see method, below) owing to nitride formation. On the admission of air, this nitride is converted to oxide.

ANALYTICAL PROCEDURE

Air is first displaced from the reaction chamber of the thermobalance by passing in oxygen-free nitrogen for about 10 minutes at a rate of 1 l. per minute. A sample of the material under test, weighing approximately 10 g (or, in the case of precipitated oxide, sufficient to contain that weight of UO_2), is then placed in the sample holder and the furnace lowered into position.

The material is thereby protected from oxidation, and may be subsequently balanced; the tare weight being known, this gives the weight of sample actually taken. Nitrogen is fed into the seal compartment at a rate of 0.75 l. per minute and the exhaust system, calibrated for an extraction rate of 1.5 l. per minute, set in operation.

The furnace is then heated to 600° C and held at this temperature until the sample has maintained a constant weight for about 5 minutes. If reduction is to be employed, the nitrogen flow rate is reduced to 0.25 l. per minute and 0.75 l. per minute hydrogen added to the gas stream; if oxidation, then the seal nitrogen flow is cut off and the gas input line disconnected to allow the entry of air. For faster oxidation a mixture of air and oxygen may be introduced. During this oxidation the furnace temperature is allowed to rise to 900° C, by which time the reaction should be complete (it is not essential to reach this temperature in the reduction stage—cooling can be commenced when reaction ceases) and the furnace is allowed to cool back to 600° C.

The reaction chamber is next purged with nitrogen under the same conditions used at the start of the operation; after 10 minutes the weight change accompanying the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

may be noted. The reverse operation, either reduction or oxidation, can then be carried out, and on its completion the standard conditions of nitrogen flush and temperature are restored so that each weight change is measured under as nearly as possible identical conditions, thereby avoiding spurious changes due to buoyancy, etc. The uranium–oxygen ratio is calculated from the formulae deduced above. Incidentally it is worth noting that the thermogravimetric record, by showing the actual weight change involved in the interconversion of UO_2 and U_3O_8, gives data from which the total uranium content of the sample may be calculated.

Certain special problems require a slight modification of the above procedure; thus, if a loss on ignition determination is to be carried out, the furnace temperature is initially raised to the necessary extent, then brought back to 600° C. Any weight loss commencing near 700° C would then require especial notice if the presence of UO_3 were possible. In the case of samples containing uranium metal, argon is used as the flushing gas in place of nitrogen.

RESULTS

A sample of U_3O_8 (99.9% pure) used as a reference standard in these laboratories was employed in the evaluation of the reduction–oxidation technique. In five consecutive runs the number of oxygen atoms per uranium atom was found to be 2.669, 2.672, 2.665, 2.665, and 2.668, giving an average value close to 2.668 compared with a theoretical 2.667 for 100% pure U_3O_8. It therefore appears that a good degree of accuracy is obtainable.

In order to test the procedure through both possible reaction cycles, and over a wide range of sample types, a number of materials which could be met in practice were taken. These are listed in Table I, together with the results obtained.

TABLE I

Atomic ratios obtained by the thermogravimetric procedure

Material	Atoms of oxygen per atom of uranium as determined by: Oxidation followed by reduction	Reduction followed by oxidation
UO_3 (technical)	3.003	3.005
UO_3 (partly reduced with hydrogen):		
Sample *a**	2.873	2.878
b	2.412	2.410
c	2.277	2.274
d	2.147	2.150
e	2.082	2.083
f	2.035	2.038
UO†	0.99	Not applicable
U (metal, 99.4% pure)	0.008	Not applicable

*Microscopic examination shows presence of UO_3.

†Prepared by oxidizing uranium metal in the thermobalance, followed by cooling in argon. Microscopic examination shows presence of uncombined metal.

The data recorded above indicate that the present method can be used over the full range U to UO_3 with an accuracy suitable for all practical purposes.

DISCUSSION

The need for caution in applying the method in the presence of uranium metal has already been noted, and the absence of oxidizable or reducible foreign matter presupposed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Apart from independent tests, these complications would normally manifest themselves in inconsistent results if both oxidation and reduction procedures were to be applied to the same material, and this might be used as a distinguishing criterion. Substantial quantities of free metals other than uranium, oxides of transitional metals, and certain compounds of uranium apart from the oxides would be expected to interfere.

From the point of view of accuracy this method compares favorably with earlier procedures with which, according to Bright (4), the number of oxygen atoms per atom of uranium can be determined to a precision of ± 0.005.

In conclusion, it is suggested that the general procedure is adaptable to the study of other metal–oxygen systems, as, for example, those involving molybdenum and tungsten, lead, etc., for which comparable reaction schemes might be devised.

ORBITAL CONSTRUCTIONS AND ELECTRON POPULATIONS IN THE TRANSITION ELEMENTS[1]

W. R. TROST

ABSTRACT

Orbital constructions and electron populations for the bands in the transition elements have been worked out. With the assumption of uniform density of states in delocalized bands among nearest neighbors, it is possible to predict correctly the lattice elected by the elements. Manganese and iron are exceptions. Numerical values for electron populations in the several *s*, *p*, *d*, and hybrid bands, including their bonding, antibonding, and non-bonding levels, are obtained.

INTRODUCTION

Though molecular orbitals were first proposed for metals by Bloch (1) in 1928, the orbital constructions and hence the electron populations for the bands in metals, particularly for the transition metals, are still lacking. In simple cases, such as the alkali metals, detailed calculations of the binding energy have been made and reasonable agreement with experimentally determined binding energies obtained (2). Even in the case of atoms with one valence electron, however, the definition in space of the atomic orbitals comprising the bands is missing. In the more complicated case of the transition metals, where up to 12 valence electrons and 9 atomic orbitals are to be counted for each atom, the binding energy calculations are more difficult, and the problem of locating the orbitals and electrons is also more complex. It is perhaps correct to say that as yet no general success has been met with here. Indeed in many cases, as a simplification, the *d* orbitals have been ignored. It is true that Pauling counted *d* electrons when he proposed metallic valences for the transition metals (3). However, the spatial constructions and the electron populations of the bands were not offered. Indeed, precisely because of a general lack of emphasis on the directive properties of the orbitals it has not been possible up till now to answer the simple structural question, "Why should a particular metal have one lattice rather than another?"

It would seem that a solution to the problem is implicit in the molecular orbital theory, particularly in view of recent developments in the ligand-field theory (4), and the work of Jaffe (5) and of Craig, Maccoll, Nyholm, Orgel, and Sutton (6, 7) on orbital pairs.

THE TRANSITION METALS

In the transition metals nine orbitals (one *ns*, three *np*, and five $(n-1)d$) are to be counted for each atom. To make a metal it is necessary to locate in space the nine orbitals of each of an infinite number of atoms in such a way that the orientations and the overlaps of every orbital become specified. The orbital constructions are to place the nuclei on lattice points. At the same time, through the overlap property, the orbital interactions that stabilize the lattice are established.

The number of valence electrons in the transition elements varies from 3 (s^2d^1) to 12 (s^2d^{10}). As bonding, antibonding, and non-bonding bands are, in general, to be expected from the orbital constructions, the net binding energy and hence the stability of the lattice will also be a reflection of the changing electron populations in these bands. It therefore becomes necessary to classify the energy levels of the several bonding, antibonding, and non-bonding bands, relative to each other, so that the valence electrons

[1]*Manuscript received July 31, 1958.*
Contribution from the Chemistry Department, Dalhousie University, Halifax, Nova Scotia.

can be placed and the populations in the bands calculated. That is, electron density and orbital overlap both become criteria for lattice stability.

THE ORBITAL CONSTRUCTIONS OF THE BANDS

The overlaps and symmetry relationships as between pairs of s, p, and d orbitals have been worked out in detail by several authors (5, 6, 7) and are summarized in Fig. 1. Removal of the restriction that the number of orbitals in overlap be limited to two permits more closely packed assemblies of these orbitals to be sought. When all orbitals have been so arranged, and consideration given to the numbers of electrons involved, lattice systems that reproduce the metallic lattices are obtained. The d, p, and hybrid orbitals become the orbitals that determine structure. The spherical s orbital, having no directional dependence, offers no choice between alternative close-packed structures. The results are summarized in Table I.

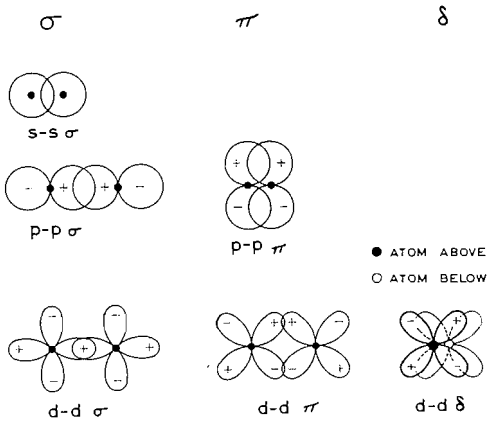

FIG. 1. Overlaps among orbital pairs.

TABLE I

Lattice systems and orbital assignments

Structure type	Orbital type	
	Bonding	Antibonding
1. *bcc*		
Nearest neighbors	s, p^3, $d\epsilon$	s'
Next to nearest	$d\gamma$	
2. *hcp*		
Nearest neighbors	s, d^5p, p^2 (or) sp^2, d^5p (or) sd^4p, p^2	
Next to nearest	d_z	d_z'
3. *ccp*		
Nearest neighbors	s, p^3, $d\epsilon$	$d\epsilon'$
Next to nearest	$d\gamma$	$d\gamma'$
4. Distorted *hcp*		
Nearest neighbors	sp^2, p	

1. *The p Orbitals*

The shape and the degeneracy of the orbitals provides a basis for choosing among alternative close-packed schemes. The p orbital construction shown in Fig. 2, in which each p orbital overlaps eight others, has three advantages. The arrangement can be

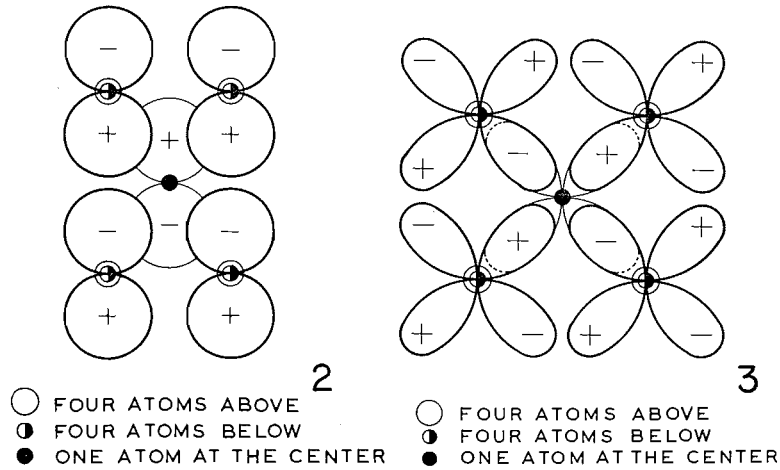

FIG. 2. The body-centered cubic p band.
FIG. 3. The body-centered cubic $d\epsilon$ band.

indefinitely and smoothly expanded, as more orbitals are added, to produce an indefinitely large and perfect body-centered cube. The arrangement has a threefold degeneracy, as the three mutually perpendicular directions are equivalent with $p_x(p_x)_8 = p_y(p_y)_8 = p_z(p_z)_8$. That is, the three p orbitals on each atom overlap the corresponding orbitals on the adjacent eight atoms in the same way. Finally, as an assurance that the overlap factor for the arrangement is favorable, the distance between the axes of the overlapping lobes is 0.81 the internuclear distance.

The result is that what will be called the *bcc* p band has cubic symmetry, is perfectly degenerate in the three p orbitals, is delocalized over all atoms in the lattice, and constitutes a close-packed assembly of p orbitals.

2. The d Orbitals

Turning to the d orbitals, it at once becomes evident that the degeneracy of the subshell cannot be retained in metallic bonding unless hybridization occurs, as all d orbitals cannot achieve the same overlap at the same time in any one lattice. The symmetry relationships for space-packing, however, separate the subshell into two groups of orbitals, the diagonal (d_{xy}, d_{xz}, d_{yz}) and the axial ($d_{x^2-y^2}$, d_{z^2}). Two different close-packed structures are possible for the diagonal orbitals. In the first of these, shown in Fig. 3, one orbital overlaps eight others. This configuration has the merit that each diagonal orbital becomes identically engaged, so that $d_{xy}(d_{xy})_8 = d_{xz}(d_{xz})_8 = d_{yz}(d_{yz})_8$, thereby preserving the degeneracy of the three orbitals and establishing a body-centered cubic lattice. In it the d band is delocalized over all atoms. The interlobar distance,[2] in this construction, is 0.58 the internuclear distance, a favorable feature for overlaps that is at least partly counterbalanced by the manner of approach of the orbitals. This is through the thickness of the lobes, much as in the d–$d\delta$ bonding of Fig. 1, which is not in the direction of maximum extension. The band will be called the *bcc* $d\epsilon$ band to conform with usage in the ligand-field theory (4). (The $d\epsilon$ level has also been called t_{2g} and γ^5.) The two remaining orbitals, $d_{x^2-y^2}$ and d_{z^2}, constitute the $d\gamma$ level.

A second way to close-pack d orbitals, shown in Fig. 4, places four orbitals around a central one. When the 3 diagonal orbitals on a central atom are so engaged, 12 atoms

[2]*The interlobar distance is the distance between the principal axes of the lobes.*

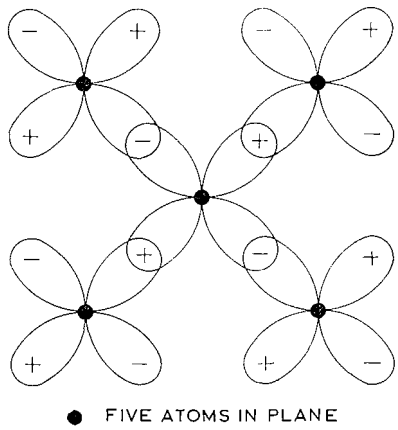

FIG. 4. The cubic close-packed $d\epsilon$ band.

surround the central one, in a cubic close-packed arrangement. That is, $d_{xy}(d_{xy})_4 = d_{xz}(d_{xz})_4 = d_{yz}(d_{yz})_4$, so the cubic close-packed $d\epsilon$ band, like the body-centered cubic $d\epsilon$ band, has cubic symmetry and is delocalized over all atoms. In each arrangement (i.e. *bcc* $d\epsilon$ and *ccp* $d\epsilon$) 2 *d* orbitals are still to be located. In both lattices, the direction of maximum extension of the $d\gamma$ orbitals ($d_{x^2-y^2}$, d_{z^2}) is identical with an octahedral arrangement of next nearest neighbors. The distance between the next nearest neighbors, as compared to the nearest neighbor distance, is 1.15 in *bcc* and 1.42 in *ccp*. In orbital constructions like that of Fig. 4 (for $d_{x^2-y^2}$, d_{z^2} has its maximum extension on the z-axis) these internuclear distances enable *bcc* $d\gamma$ to make a substantial minor contribution to the bonding,[3] whereas *ccp* $d\gamma$ is virtually non-bonding. The *bcc* $d\gamma$ will therefore support *bcc* $d\epsilon$ when fewer than five *d* electrons are present, but will weaken *bcc* $d\epsilon$ when more than five electrons are present. In the latter case, as antibonding levels in *bcc* $d\gamma$ become occupied, the cubic close-packed lattice with a *ccp* $d\epsilon$ band becomes preferred.

3. Hybrid Orbitals

Two hybrid orbital constructions lead to close-packed lattices. One of these applies to ground states between d^3 and d^7, which is just the gap left when orbital constructions based on the $d\epsilon$–$d\gamma$ split are employed. The second hybrid construction becomes relevant when the *d* subshell becomes non-bonding, as in s^2d^{10}.

The only hybrid sets that use four and five *d* orbitals and lead to close-packed structures are sd^4p and d^5p. In both of these 1×6 configurations, the bonding directions are towards the corners of a trigonal prism (8). When a set of identical atoms in this state are brought together a hexagonal close-packed lattice results, in which each atom is bonded to 6 neighbors through localized bonds, but is equidistant from 12, as shown in Fig. 5. The orbitals remaining after sd^4p or d^5p is chosen are accordingly to be placed with reference to the *hcp* system.

The last arrangement to be described is an sp^2 construction. The packing of sp^2 orbitals as in Fig. 6 sets up close-packed layers of atoms. The layers are bonded to each other

[3]*In view of the somewhat different shapes of the 2 orbitals it is possible that* $d\gamma$ *is not perfectly degenerate. A detailed analysis shows, however, that these orbitals also have small overlaps with nearest neighbors (the overlaps are small because of the orientations and shapes of the orbitals) that tend to make the two bonding functions equivalent. Therefore, although the band cannot be considered solely a next nearest neighbor band, it is possibly correct to describe it as a weakly bonding band with twofold degeneracy. It is also assumed in ligand-field theory (4) that* d_{z^2} *and* $d_{x^2-y^2}$ *remain degenerate in the* $d\gamma$ *level.*

through the p_z orbital, which provides a $p_z(p_z)_6$ band, and by a perpendicular delocalization in the three-center sp^2 molecular orbitals. A distorted hexagonal close-packed lattice appears, with six nearest neighbors in a layer, and three more distant ones above and three below. The electron cloud of the p_z band extends over the lattice but contains regularly spaced vacancies that have a definite shape. The superimposed sp^2 molecular orbitals through delocalization attain the shape of an endlessly repeated hour glass, with the thin part of the electron cloud between the layers and the thick part in the layer. The sp^2 band consists of an indefinite array of these, in parallel extension in a 1×6 packing, with each endless hour glass precisely occupying a vacancy in the electron cloud of the p_z band.

THE ATOMIC ORBITAL ENERGY LEVELS

An explanation of the properties of the transition metals should take account of both the spatial and the energy level properties of the orbitals. The foregoing consideration of the spatial problem gave rise to specific band systems with orbital constructions requiring one or another of four lattices, the body-centered cubic, the hexagonal close-packed, the cubic close-packed, and the distorted hexagonal close-packed. The energy level problem involves a consideration of both the atomic and molecular orbital energy levels. Complications arise here because of the likelihood that these levels change as the d subshell fills; as the principal quantum number varies; and in the molecular orbitals, as the band systems change. The atomic orbitals will be dealt with first.

An inspection of the ground states of the transition elements shows that the energy level of the $(n-1)d$ orbitals, which at first is above that of the ns orbital, as in s^2d^0, changes value until it is the stabler orbital, as in s^0d^9 and s^0d^{10}. This cannot be thought of as simply a regular increase in the stability of the d orbital as the d subshell fills, for energy is also contributed to the system in a non-linear way. Because of a lower electrostatic repulsive energy and a more favorable exchange energy among single electrons with parallel spins, states with the maximum number of singly filled orbitals are favored, as is well known from Hund's rule (4). As the magnitude of this energy term depends directly on the number of singly filled states, the d orbitals will be stabilized by increasing amounts as the number of valence electrons increases from one to six. Such a change is shown in the ground states of these atoms.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

Valence electrons	Ground states
1	s^1d^0
2	s^2d^0
3	s^2d^1
4	s^2d^2
5	s^2d^3, s^1d^4
6	s^2d^4, s^1d^5

The number of single electrons, and hence the magnitude of the exchange energy contribution, must necessarily diminish upon the addition of further electrons. This will make the d levels fall more slowly after the six-electron atom than before it. However, the linear factor, associated with the increasing positive charge on the nucleus, still persists. The d levels are stabilized more than s because the $(n-1)d$ electrons are on the average closer to the nucleus than the ns. The d levels are therefore more directly affected by the increasing electrostatic field of the nucleus. At the same time, the $(n-1)d$ electrons intervene between the nucleus and the spherical electron cloud of the ns orbital. A screening effect occurs that tends to make the s electrons somewhat unresponsive to an increase in the charge on the nucleus. Both affects foresay a steadily increasing relative stability in the d orbitals as the subshell fills. This can also be seen in the ground states of the elements.

Valence electrons	Ground states
7	s^2d^5, s^1d^6
8	s^2d^6, s^1d^7
9	s^2d^7, s^1d^8, s^0d^9
10	s^2d^8, s^1d^9, s^0d^{10}
11	s^1d^{10}
12	s^2d^{10}

It is to be noticed that the d levels are unambiguously below the s level for the first time in the ground state, s^0d^9.

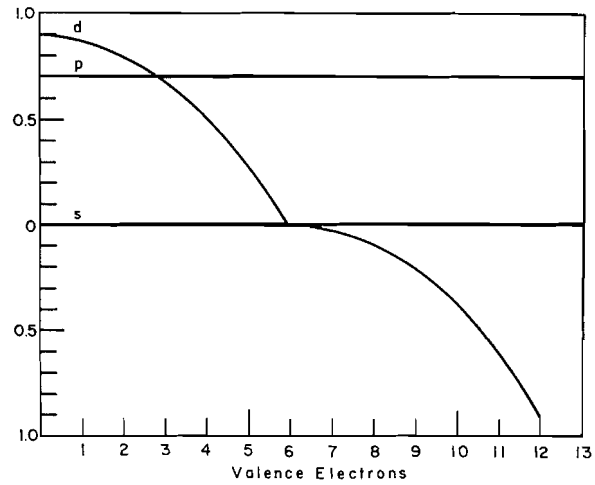

FIG. 7. Atomic orbital energy levels.

When the effects of filling the subshell are combined with the stabilizing property of single electrons in the subshell, a two-part curve as in Fig. 7 is forecast, which shows the change in the relative values of the energy levels as the number of valence electrons increases. When Fig. 7 was drawn, it was assumed that the d passes through the s level at six valence electrons (s^1d^5), and that d is just below p at three valence electrons (s^2d^1). As a simplification the two parts of the d curve were drawn to repeat each other.[4]

THE METALLIC BANDS

For an adequate description of the bands in a metal, in addition to the energy levels of the atomic orbitals and the orbital construction of the bands, it is necessary to know the binding energy and the density of states in the molecular orbitals that comprise the bands. Delocalized, localized, antibonding, and non-bonding bands are to be considered.

TABLE II

1. The Delocalized Bands

Bands in which electrons are delocalized over all atoms have been constructed from s, p, and d orbitals and, with a more limited delocalization, from sp^2 orbitals. These delocalized bands are specific cases satisfying the principal conditions for the classic Bloch molecular orbitals (1). The width of the bands, which is the separation between the lowest and the highest state in the band, and the level of the lowest lying state are to be obtained.

[4]*It is to be noted that Fig. 7 has been drawn independently of the principal quantum number. The assumption that the relative levels of the ns, np, and (n−1)d atomic orbitals are independent of n is certainly not correct. Figure 7 therefore becomes an average curve that need not be precisely correct for any element. The electron population values in Table II depend on Fig. 7 and therefore contain a substantial probable error. They are given to three significant figures, however, as this helps to keep the adding neat.*

It is convenient, though not entirely correct (see later for a rule of thumb), to assume that the density of states is uniform in delocalized bands made up of overlaps from among nearest neighbors. The phenomena of width in the band arises from the delocalization property. As the wave function for each electron extends over all nuclei incorporated in the delocalized wave function, and as no two electrons can be identical, successive electrons must lie in states that are distinguishable in the energy parameter. Consequently the density of states has a relation to the effectiveness of the delocalization property. In the multiple overlaps encountered in the prescribed orbital constructions, delocalization is measured by both the number of overlaps an orbital has, and by the magnitude of the overlap volume. The bands made up from orbitals in close-packed arrangements can be expected to be somewhat similar in both these regards. For the d orbitals it may be recalled that delocalized bands were found among both nearest neighbors (*bcc* $d\epsilon$ and *ccp* $d\epsilon$) and next nearest neighbors (*bcc* $d\gamma$ and *ccp* $d\gamma$). In these cases of nearest and next nearest neighbor bands, both the density of states and the binding energy must vary, with internuclear distance as the most direct parameter.

In detailed calculations (2) for the alkali metals it has been shown that both s and p states are populated in Li and Na. As there is only one valence electron in these metals it is necessary to conclude that upper states in the s band lie above lower states in the p band. Using the assumption of uniform density of states and remembering the threefold degeneracy of the *bcc* p band, an electron population chart as in Fig. 8 can at once be drawn. The separation between the s and p band heads, which is the only independent adjustment, has been arbitrarily chosen so that the s and p band populations become 0.775 and 0.225 electrons respectively.[5] Counting the degeneracy, this amounts to 0.775 and 0.075 electrons per orbital for the s and p orbitals respectively. This arbitrary decision is not unimportant. For it, along with the assumption of uniform density of states, at once defines the energy separation between s and p atomic orbitals in units of the width of a nearest neighbor delocalized band. This can be seen by comparing the ordinates of Figs. 7 and 8. Specific population figures did not appear in the calculations for the alkali metals referred to above. Pauling (9) has used the value 0.1 for the p orbital population in Li. A somewhat larger value was chosen here in the expectation that the energy separation between the atomic orbitals decreases as the principal quantum number increases. Such a trend would require a more important p orbital participation in the heavier alkali metals than in Li.

2. The Localized Bands

Band systems that retain more than a threefold degeneracy in the d orbitals set up an hexagonal close-packed lattice. In this lattice, both the d^4sp and d^5p hybrid configurations gave rise to orbital-pair overlaps between nearest neighbors, with the result that the bonding electrons became localized on pairs of nuclei. As in the ordinary convention for electron-pair covalent bonds, these spatially independent states are here assumed to be without appreciable effect on each other. That is, all such states exist at the same energy level. For purposes of definiteness, the discrete energy levels of the d^5p and of the sd^4p bands have been taken from the weighted average of the energy levels of the band heads of the delocalized s, p, and d bands. The decision, in so far as its correctness is concerned, could affect electron population calculations only in the case of one modification of the six-electron atom, Table II.

It should perhaps be mentioned that in another hybrid construction, that of the sp^2

[5]*See footnote 4.*

configuration in a distorted hexagonal close-packed lattice, a localization property also appears when the electron population is equal to or in excess of 0.66 electrons per orbital. Then bonding electron pairs can be associated with nuclear triads. The electron population was less than 0.66 per orbital in the 12 (or 2) valence electron atoms considered here.

3. The Antibonding and the Non-bonding Bands

The antibonding bands are identified with the corresponding bonding bands through the assumption of uniform density of states, and through the requirement that the binding energies of the bonding and antibonding states be equal and opposite. For electron population purposes, the bonding and antibonding bands then become a single

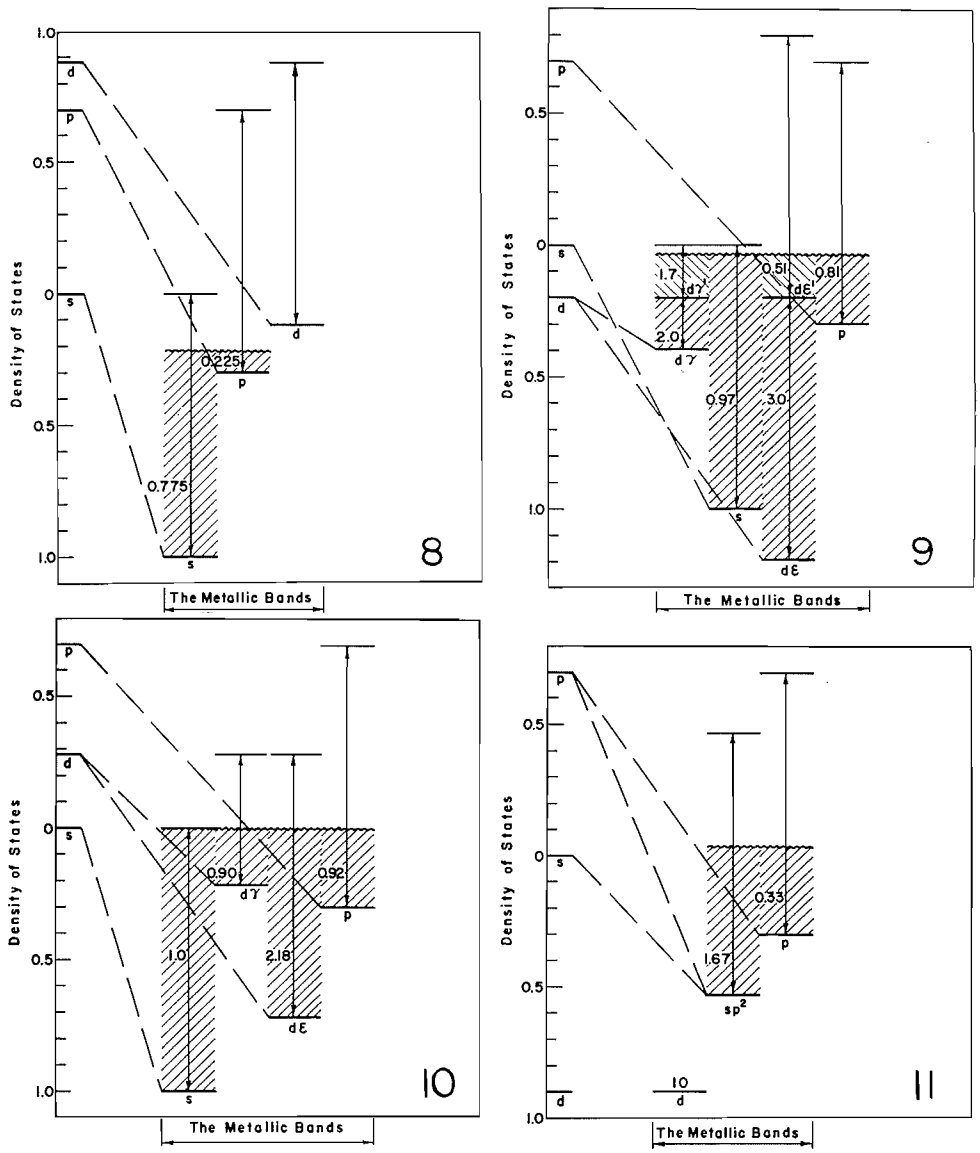

FIG. 8. Electron population chart for 1-electron atoms.

system of uniformly separated states, divided into equivalent bonding and antibonding portions by the energy level of the (non-bonding) atomic orbital. This can be seen in the electron population chart, Fig. 9, where bonding ($d\epsilon$, $d\gamma$) and antibonding ($d\epsilon'$, $d\gamma'$) bands are shown.

The symmetrical disposition of the bonding and antibonding states about the level of the non-bonding atomic orbital includes two variations that have a general significance. One points up the distinction to be made between nearest and next nearest neighbor bands; the other corresponds with a transition from localized to delocalized bands. Either the binding energy can decrease, which tends to compress the bonding and antibonding bands into a narrower region about the non-bonding level; or, if a decrease in delocalization occurs, both bonding and antibonding bands are compressed away from the non-bonding level towards their own lower and upper states, respectively. In each of these cases, the density of states is altered, though in the same way in both bonding and antibonding bands.

The next nearest neighbor bands, *bcc* $d\gamma$, *ccp* $d\gamma$, and *hcp* d_z, with internuclear distances of 1.15, 1.41, and 1.62 respectively, provide an example in which binding energies progressively decrease, compared to nearest neighbor bands like *bcc* $d\epsilon$ and *ccp* $d\epsilon$ where the internuclear distance is unity. In view of the proximity (overlap) there is a decrease in the resonance integral. The density of states must therefore necessarily increase as the internuclear distance increases conceivably until, when the internuclear distance is large enough, the atomic orbital is non-bonding and single states are achieved. By associating the levels of the band heads with the internuclear distance,[6] the density of states in *bcc* $d\gamma$ becomes twice, in *ccp* $d\gamma$ 5, and in *hcp* d_z 10 times that in nearest neighbor bands. As *bcc* $d\gamma'$ attains no antibonding population, for the lattice becomes unstable before antibonding electrons appear, the decision affects antibonding electron populations only in the eight and nine valence electron elements. The first antibonding electrons are absorbed by *hcp* d_z' and *ccp* $d\gamma'$. Once these bands are filled, creating in conjunction with *hcp* d_z or *ccp* $d\gamma$ the equivalent of one or two filled non-bonding d orbitals respectively, the question of the density of states in bands with different binding energies no longer affects the population figures.

A change in the delocalization factor may also occur more gradually than is implied in the assumption of the two extremes of delocalized and localized bonds. This is already indicated in the appearance of orbital constructions in which single orbitals overlap varying numbers of others (as for example eight in *bcc* $d\epsilon$, six in the distorted *hcp* p band, and four in *ccp* $d\epsilon$, compared with one in a localized bond) while still retaining the delocalized property. If delocalization were subject to such a continuous diminishment, its effect on the electron population figures would be real, though small, and found mostly in the 8-, 9-, and 10-electron atoms. If, for example, *ccp* $d\epsilon$ and *ccp* $d\epsilon'$ (because of the four co-ordination in their orbital constructions) were to some extent compressed away from the non-bonding level while *bcc* $d\epsilon$ and *bcc* $d\epsilon'$ (with eight co-ordination) were not, minor changes in the population of the antibonding *ccp* $d\epsilon'$ would result. The largest effect occurs when the *ccp* $d\epsilon'$ band is just beginning to be occupied, as in atoms with nine valence electrons, the correction tending to eliminate itself as more electrons are added.

The antibonding levels associated with the localized bonding orbitals achieve no significant population. It is therefore not necessary to specify them closely at this time.

THE FOUR LATTICES

The methods that have been outlined assume to predict both the lattice a transition

[6]*Approximately inversely proportional to the third power of the internuclear distance.*

element elects, and the electron population of the bands in that lattice. The predicted and the known lattices can be compared at once. Experimental values for electron populations are, however, not available, so the validity of the calculated populations cannot be properly assessed. In what follows a few words will be said about each metallic lattice.

1. The Body-centered Cubic Lattice

The band system for the body-centered cubic lattice consists of an s band, a p band (Fig. 1), and two d bands. The *bcc* $d\epsilon$ band has threefold degeneracy, and begins at a lower level than the *bcc* $d\gamma$ band which is a next nearest neighbor band, with twofold degeneracy.

In atoms with one valence electron, the electron population is confined to the s and p bands, Fig. 8. With an increase in the number of valence electrons, not only must more electrons be placed, but the energy level of the d orbitals falls relative to the s and p as shown in Fig. 7. In atoms with five valence electrons, the d orbitals may be fairly said to dominate the structure, holding 3.08 of the five electrons, Table II and Fig. 10. The important changes that occur in the band system as the valence electron count increases from three to six are the disappearance of a small antibonding population, a regular increase in the $d\epsilon$ population, and a relatively more rapid increase of the electron density in the $d\gamma$ band. These features combine to give the lattice its limited stability range.

It is evident that in any band system the upper levels make a smaller contribution to the binding energy than do the lower states. Moreover, in systems in which the band pattern changes because of changes in the symmetry of the orbital constructions, it follows that maximum binding energy and consequently a stable lattice corresponds with those constructions that provide a maximum population in the low-lying states. It is suggested as a rule of thumb for these multiple overlap systems that a stable lattice corresponds with an electron density of $2/m$ in the bonding orbitals. Here m is the number of lobes (not orbitals) in mutual overlap.

The rule of thumb may have some validity as a delocalization factor, though it is not in this sense that it will be applied. It is taken as a generalization of the delocalization observed in lone pairs and covalent bonds where m, the number of lobes that overlap, is 1 and 2 respectively, the electron density is 2 and 1 as is in each case required by the rule of thumb. In application to the multiple overlap systems, with m equal to 5 in the p band, 3 in the *bcc* $d\epsilon$ band, and 2 in the *ccp* $d\epsilon$ band, the rule of thumb electron densities become 0.4, 0.66, and 1.0 respectively. In so far as it has significance as a delocalization factor, the rule of thumb implies that the density of states in the respective bands differs in such a way as to make their lattice constructions stable, compared to alternate arrangements, at the prescribed electron density. If this is the case, the rule of thumb describes a limitation to the assumption of uniform density of states in the delocalized bands. It will actually be used, however, in a rather more rough and ready sense than this in what follows. In any event it should be noted that the rule of thumb does not apply, as an indicator of lattice stability, to the s orbitals, for this band does not determine structure.

Both the *bcc* $d\epsilon$ and the *ccp* $d\epsilon$ orbital constructions can be applied to atoms with three, four, five, or six valence electrons. The differences in the electron population charts for the two lattice systems, at any rate under the present assumptions, are entirely due to the difference, not in *bcc* $d\epsilon$ and *ccp* $d\epsilon$, but in *bcc* $d\gamma$ and *ccp* $d\gamma$. As *bcc* $d\gamma$ (at 1.15 the internuclear distance) provides more binding energy than *ccp* $d\gamma$ (at 1.41 the internuclear distance) the *bcc* $d\gamma$ band begins at a lower level. The effect of this is to increase the total number of d electrons lying at low and intermediate levels in the *bcc* bands, as compared with *ccp*, where the uppermost energy levels would have to be occupied as well. The concentration of electrons in the stabler states occurs whenever the *bcc* $d\gamma$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

band shows a population, which is in the four-, five-, and six-valence electron atoms, Table II. Consequently, the *bcc* lattice can be chosen over the *ccp* lattice unambiguously only for the four-, five-, and six-electron atoms. The over-all result is that the *bcc* $d\gamma$ band keeps the electron density of the *bcc* $d\epsilon$ band in the vicinity of 0.66, which is the rule of thumb density for *bcc d* (0.34, 0.56, 0.73, and 0.92 are the calculated values for the three-, four-, five-, and six-electron atoms respectively). The electron density in the *p* band is also close to the 'best' value, 0.4, except in the six-electron atom (0.32, 0.34, 0.31, and 0.22 in the three-, four-, five-, and six-electron atoms respectively).

There is no $d\gamma$ population in the three-electron atom. It is therefore not possible to make a choice between the *bcc* and *ccp* lattices for this element on the proffered grounds. Moreover, the antibonding population appearing when *bcc* is elected (Table II) and the relatively small *d* population, together indicate that the band system for the three-electron atom is apt to be different in detail from those of the other transitional elements. However, a close-packed metal can evidently be obtained.

A *d* band population of 4.54 electrons is calculated for the *bcc* system for the six-electron atom. Of this, 1.68 electrons are in the relatively weakly binding $d\gamma$ band. The result is that at this stage a concentration of electrons is beginning to build up in the less stable upper levels of the *d* band. This is to be expected as the principal *d* band has only threefold degeneracy, and at least four *d* electrons are available for bond formation. Instability features are also shown in the deviation of the *p* and *d* electron densities from the rule of thumb values. However, when the alternate band system for the six-electron atom, which employs a hexagonal close-packed lattice, is charted, an instability feature also appears in it. The d^5p band, a system of localized electrons, is incompletely occupied, Table II. It is therefore necessary to predict that an atom with six valence electrons will show two forms, one with a *bcc*, the other with an *hcp* lattice. The predictions therefore are that transition elements with four, five, and six valence electrons have a *bcc* lattice, as is in fact the case for βTi, βZr, V, Cb, Ta, αCr, Mo, and αW.

2. The Hexagonal Close-packed Lattice

The hexagonal close-packed lattice emerges as a consistent choice for elements with six, seven, or eight valence electrons, although the band systems that establish the lattice are subject to minor variations within this group. With both sd^4p and d^5p providing trigonal hybrids, either configuration will establish an *hcp* lattice. The difference between the two will therefore be small depending for the most part on whether an *s* band (with d^5p) or a d_z band (with sd^4p) is to be found in the lattice. The *p* band is doubly degenerate in either case, though a third alternative, that of a delocalized sp^2 band (in connection with d^5p), is also possible. These three alternatives correspond to rather slight changes in the over-all electron population picture, being confined to minor variations in the electron density and direction dependence property of the conductivity bands. In no case is the lattice affected, at any rate with respect to its classification as *hcp*. The electron population calculations, Table II, were made for d^5p in the case of the six-electron atoms, and for sd^4p for the seven- and eight-electron atoms.

In addition to the appearance of localized bonds, an important antibonding population also appears for the first time in this group of elements. The precise value of this population depends on the level selected for the d_z band which, like *bcc* $d\gamma$ and *ccp* $d\gamma$, is a next nearest neighbor band. The distance in d_z is 1.6 the nearest neighbor distance, so that the band would be expected to be less effective than either of the $d\gamma'$. The antibonding population is confined to the *d* orbitals and, under the assumptions used, is not quite equivalent to having an electron pair in a non-bonding d_{z^2} orbital in the eight-electron atom. In the latter case, the net-bonding electrons would be lowered from 7.0 to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

6.0. The prediction of an *hcp* lattice for the six-, seven-, and eight-electron atoms is borne out in the elements Mo, Tc, Re, Ru, and Os. Manganese and iron are exceptions and will be referred to again.

3. The Cubic Close-packed Lattice

Atoms with 9, 10, and 11 valence electrons satisfy the conditions for the *ccp* band system, Fig. 9. The transformation to the *ccp* lattice occurs when an extra electron is added to the *hcp* system. The ninth electron, going into the antibonding *d* levels of the *hcp* system would produce the near equivalent of two filled non-bonding *d* orbitals in that system. As a result, neither d^5p nor sd^4p can be constructed, and the *hcp* lattice is destroyed. At 9 electrons in the *ccp* system the $d\gamma$ band is nearly non-bonding, and becomes so at 10 electrons. The *ccp* $d\epsilon$ remains, and with an electron density of one electron per orbital provides the *d* orbital contribution to the binding energy and determines the structure.

The antibonding levels that are occupied as electrons are added to the *ccp* system are altogether in the *d* orbitals, with the increase for the most part to be found in the triply degenerate *ccp* $d\epsilon'$ band. That is to say, the bonding *s* and *p* and the antibonding *d* levels have approximately the same energy throughout this triad. The over-all result, going from 9 to 11 electrons in the *ccp* system, is to steadily diminish the net contribution of the *d* orbitals to the binding energy and the lattice. At 12 electrons the *d* orbitals have become altogether non-bonding, with 3 electrons in $d\epsilon'$ balancing 3 electrons in $d\epsilon$. Counting the non-bonding $d\gamma$, the non-bonding $d\epsilon$ now restore a fivefold degeneracy to the *d* orbitals. That is to say, at 12 electrons, the *d* subshell has become a part of the inner core. The prediction of a cubic close-packed lattice for 9-, 10-, and 11-electron atoms is observed without exception in these elements, namely Co, Rh, Ir, Ni, Pd, Pt, Cu, Ag, Au. The fact that αCo is *hcp* will be mentioned again.

4. The Distorted Hexagonal Close-packed Lattice

As described above, the 12-electron atom (speaking in valence terms) becomes a 2-electron atom, as the *d* levels are fully occupied and non-bonding. The band system projected for the 12-electron atom, Fig. 11, is therefore in principle also applicable to the 2-electron elements, Be and Mg. The only differences to be expected are those that can be associated with the principal quantum number. This band system is, however, incompatible with the two-electron elements, Ca, Ba, and Sr. These elements have vacant *d* levels, which by taking electrons away from the sp^2, *p* bands, permit quite different electron distributions and orbital constructions. It is therefore correct to predict a distorted hexagonal close-packed lattice for Be, Mg, Zn, and Cd, as is observed. It is also correct to predict that Ca, Ba, and Sr will not have the same distorted *hcp* lattice. (Ca, Sr, and Ba have cubic lattices.)

DISCUSSION

When the antibonding population is subtracted from the bonding population a figure giving the net number of bonding electrons is obtained, Table II. As this number sums up only the electron populations of the several bands, and as the properties and electron dependencies of the bands differ, the number of net-bonding electrons by no means shows all the significances of the band systems. For example, if the property of plasticity were to be judged from changes in overlap accompanying nuclear displacements that do not alter internuclear distances, the *s* band would be plastic, the *d* bands hard. Moreover, as the character of the overlaps are different in the different *d* bands, the band populations do not always correctly evaluate the relative magnitude of even so specific

For personal use only.

a property. As another example, the p band has consistently the lowest ionization potential and the lowest electron density (about 0.33 electrons per orbital) and may for these reasons be principally responsible for the properties of conductivity and paramagnetism in these metals. Nevertheless, other delocalized bands may on occasion also make important contributions to these two properties, as for example the d bands in the five-electron atoms.

In a more general way as well numbers for net-bonding electrons have less significance than the itemized list of their parts. This arises from the condition that in band systems electrons occupy successive levels and do not therefore all make the same contribution to the binding energy. This is possibly of most importance when the antibonding levels are just beginning to be occupied (the seven-, eight-, and nine-electron atoms). As the lowest levels of both bonding and antibonding bands are filled first, the net contribution to the binding energy of a bonding and antibonding band exactly cancel only when both bands are fully occupied. When the antibonding band is not completely full, it still cancels out a numerically equivalent population. To be correct from the binding energy point of view, however, the upper more weakly binding states in the bonding band are the ones to be selected. That is, the stablest states remain and give a binding energy contribution that is underemphasized in a number that by implication describes average electrons.

Whatever their deficiencies, it is nevertheless these numbers for net-bonding electrons that have the simplest correspondence with the concept of a numerical valence. They are therefore to be compared with the metallic valences proposed by Pauling (3) for the transition elements.

Valence electrons	1	2	3	4	5	6	7	8	9	10	11	12
Pauling's valence	1	2	3	4	5	6	6	6	6	6	5.5	4.5
Net-bonding electrons	1	2	3	3.9	5	6	7	7	4.6	3.8	3.0	2.0
Integral valence	1	2	3	4	5	6	7	6	5	4	3	2

It is evident that agreement is good until elements with an important antibonding population are encountered. In atoms with seven and eight valence electrons, the very weakly binding d_z band is being occupied. As it holds 0.6 and 1.0 binding electrons in the two elements respectively, the number 7 rather overestimates the effective situation. Also, in the atoms with 9 and 10 valence electrons, rather more than a justifiable weight is given to the antibonding population in $ccp\ d\epsilon'$, as has been mentioned. This cannot have a greater effect than to provide values for an 'average' valence of 5.0 and 4.0 for these elements respectively. In brief, that is, the concept of an integral valence can in fact be justified as a reasonable approximation to the net-bonding electron values, as shown above. Even with such adjustments to average values, a significant departure from the metallic valences proposed by Pauling for atoms with 9, 10, 11, and 12 valence electrons still remains. As additional support for the net-bonding electron values presented in this paper, their correspondence with conventional chemical valences for these elements may be pointed out. Moreover, the physical and chemical relationships that are evident in the series of elements, Be, Mg, Zn, and Cd strongly suggest divalent atoms throughout.

Lattice structures and band populations are the predictions made in this paper. Factual comparisons are possible for the lattices, but band populations have not yet been measured. Even in the comparison that is possible some ambiguity remains. For it is conceivable that a specific lattice and particularly a close-packed one can be set up from more than one set of orbital constructions, as was indicated in the case of the hexagonal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

close-packed lattice. Agreement with respect to the lattice does not, therefore, necessarily prove the correctness of the orbital constructions. The corollary is also ambiguous. If a lattice is incorrectly predicted for one member of a family, it does not necessarily follow that the orbital constructions are wrong for the other members, though they must of course be wrong in the specific case.

Of the 30 transition elements, the lattices of Mn and Fe (and Hg) were incorrectly forecast. This deviation from expectations corresponds with the appearance of the property of ferromagnetism in the transition elements and may therefore have a somewhat special significance. The assumption, implied by the application of the population figures to all elements in a subgroup, that the relative levels of the ns, np, and $(n-1)d$ atomic orbitals are independent of n is certainly not altogether correct. A general expectation is that the separations become smaller as n becomes larger. Secondly, the overlaps in the n type and $(n-1)$ type bands are apt to have different magnitudes, even among near neighbors. This has a direct bearing on the binding energies and also on the density of states if the bands are delocalized. It is known that the ratio of the radii of the $(n-1)$ to the n shell has its smallest values in the first transitional period, and in that period the minimum occurs at Fe. Taken together, these two factors, the decreasing separation between the atomic orbital energy levels and the increasing relative radius of the $(n-1)d$-orbitals as n increases, imply that the $(n-1)d$ orbitals become consistently more important to the binding energy with larger values of the principal quantum number. This accounts for the singular observation that the melting and boiling points of transition metals (with 4 to 10 valence electrons) invariably increase, while the melting and boiling points of non-transitional metals invariably decrease, with increases in n (atoms with 3 and 11 valence electrons are intermediate in this respect: Zn, Cd, and Hg fall into the non-transitional group with Be and Mg).

As it happens, the impact of what might be called these n-type variations have their maximum effect precisely at the elements Mn, Fe, and Co. Moreover, as the antibonding d bands are here just beginning to be occupied, the disposition of bonding and antibonding electrons will, at the same time, be most responsive to these changes. That is, both the cause and the response to the cause are maximal at Mn, Fe, and Co, among the transition elements. The problem becomes therefore to relocate the orbitals in these elements as specific cases (Fe has four lattices; Mn, three; and Co, two) and discover thereby, in the particular instances of αFe and αCo, the location and properties of the ferromagnetic orbitals, presumably resident in the $(n-1)d$ band.

ACKNOWLEDGMENTS

The author would like to thank the Department of Mines and the University of Toronto for their accommodations during a Sabbatical Year. Special thanks are due Professor Maurice Lister, who was kind enough to read the manuscript in draft form.

THE KINETICS OF THE EVOLUTION AND DISSOLUTION OF HYDROGEN AT ELECTRODES[1]

J. O'M. Bockris and H. Mauser

INTRODUCTION

The kinetics of the electrolytic evolution of hydrogen at electrodes have been treated previously only in an approximate way (Frumkin (1) and Bockris and Potter (2)); or upon the assumption that only one step influences the reaction rate (Parsons (3)); or without regard to H coverage (Vetter (4)). In the work reported here, a rigorous treatment of the kinetics of two probable paths for cathodic and anodic reactions of hydrogen at electrodes is developed, with attention to the evaluation of quantities which are open to experimentation and have values specific to certain reaction mechanisms.

GENERAL

The concept of a rate-determining step for a given path in electrode kinetics is regarded as follows. General equations are deduced for the velocity of the given reaction by way of a chosen path, and the current density at the electrode for a given overpotential can thence be expressed as a function of a number of electrochemical rate constants characteristic of steps within the path. Relations among these rate constants are then found which lead to a current density which depends, at constant overpotential, only upon *one* rate constant, k_p. The relations among the rate constants which give rise to this special case are then regarded as the condition for the over-all reaction to have a rate-determining step, p.

The conditions to provide a given rate-determining step can be deduced in terms of chemical (potential-independent) rate constants, or two types of electrochemical (potential-dependent) rate constants.

Thus,

$$\bar{k}_p = k_p \, e^{\pm \beta \Delta\phi \; zF/RT} \qquad [1]$$

where $\bar{k}_p$ is the electrochemical rate constant for a reaction involving the transfer of a charge z at a current density (c.d.) of i, $0 < \beta < 1$, $\Delta\phi$ is the Galvani p.d. between metal and solution; and k_p is the corresponding chemical rate constant. The reversible electrochemical rate constant is then

$$\bar{k}_{p,R} = k_p \, e^{\pm \beta \Delta\phi_R \; zF/RT} \qquad [2]$$

i.e., it is the value of $\bar{k}_p$ at the reversible potential.

Then,

$$\bar{k}_p = \bar{k}_{p,R} \, e^{\pm \beta \eta \; zF/RT} \qquad [3]$$

where η is the overpotential associated with the c.d., i.

A. Reaction Paths Considered

Likely paths for the hydrogen evolution reaction have been discussed (Bockris (5) and Breiter (6)). Here, the kinetics of only the two most probable paths will be considered; they differ only by the reaction in which hydrogen is desorbed.

[1]*Manuscript received September 6, 1958.*
Contribution from the John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A. This paper was prepared for presentation at the Symposium on Charge Transfer Processes held at the University of Toronto, Toronto, Ontario, September 4 and 5, 1958 (see Can. J. Chem. **37**, *120 (1959)).*

(*i*) *The Electrochemical Desorption Path* (*Kobosew and Nekrassow, 1930*)

Protons are discharged onto free sites* on the metal surface. The resulting chemisorbed hydrogen is desorbed to form a hydrogen molecule upon discharge onto it of a further proton. Conversely, hydrogen molecules adsorb on the electrode surface to form one adsorbed hydrogen atom and a proton in solution, the latter also being formed by the dissolution of chemisorbed hydrogen atoms.

(*ii*) *The Hydrogen Atom Combination Desorption Path* (*Tafel, 1903*)

Protons are discharged onto free sites. The resulting chemisorbed hydrogen atoms combine to form molecules. In dissolution, hydrogen molecules adsorb dissociatively on free sites on the electrode surface, each molecule forming two chemisorbed atoms. These dissolve, forming protons in solution.

The common step in both paths of the evolution reaction is the discharge of protons (Smits (7), Bowden and Rideal (8), Baars (9), and Erdey-Grúz and Volmer (10)). Proton discharge may occur either from hydroxonium ions or from water, the latter source of protons being probable only in alkaline solutions (Parsons and Bockris (11) and Poltorak (12)).

Each of the above-mentioned steps may become the rate-controlling step in either hydrogen evolution or dissolution. Because of the dependence of electrochemical rate constants upon potential, the rate-determining step may change with current density for a given electrode–solution system.

The following assumptions are made. (i) The systems considered have reached a stationary state. (ii) The symmetry factors (cf. Bockris (13)) involved in various charge-transfer partial reactions have the same value. (iii) H is chemisorbed on the electrode surface (and does not dissolve into the metal at an appreciable rate). (iv) There is no lack of supply of ions in solution to the electrode.

B. The Electrochemical Desorption Path

(*i*) *General Equations*

The reactions are

$$[4] \qquad H^+ + e_0^- \underset{-1}{\overset{1}{\rightleftharpoons}} MH$$

$$[5] \qquad H^+ + MH + e_0^- \underset{-2}{\overset{2}{\rightleftharpoons}} H_2$$

where MH represents hydrogen atoms, chemisorbed on the metal surface.

Assuming a Langmuir isotherm,†

$$[6] \qquad v_1 = k_1(1-k'c_H)c_{H^+}\, e^{-\beta\Delta\phi\, F/RT}$$

$$[7] \qquad v_{-1} = k_{-1}c_H\, e^{(1-\beta)\Delta\phi\, F/RT}$$

$$[8] \qquad v_2 = k_2c_Hc_{H^+}\, e^{-\beta\Delta\phi\, F/RT}$$

$$[9] \qquad v_{-2} = k_{-2}p_{H_2}(1-k'c_H)\, e^{(1-\beta)\Delta\phi\, F/RT}$$

where k' is a constant, such that $k'c_H$ is the fraction of surface covered with chemisorbed

**Free sites means here those not already occupied by hydrogen atoms.*

†If a logarithmic, and not a Langmuir, isotherm were used, a different general expression for the over-all current density would be obtained. However, the results at limitingly low, and limitingly high, degrees of surface coverage would be almost the same as those obtained here; and it is these limiting conditions which are most commonly needed in the use of relations between current density and, e.g., potential, as criteria of mechanisms.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

H at a given c.d., c_{H^+} is the hydroxonium ion concentration in the Helmholtz double layer; and other terms are as already defined.

In the steady state, the over-all velocity, v, is given by

[10] $$v = v_1 - v_{-1} = v_2 - v_{-2}.$$

Eliminating c_H and remembering that the current density is related to v by

[11] $$i = 2F\,v/\nu$$

where ν is the stoichiometric number,

[12] $$i = \frac{2F}{\nu}\,\frac{\bar{k}_{1,R}\bar{k}_{2,R}c^2_{H^+}\,e^{-2\beta\eta\,F/RT} - \bar{k}_{-1,R}k_{-2,R}p_{H_2}\,e^{2(1-\beta)\eta\,F/RT}}{c_{H^+}(\bar{k}_{2,R}+\bar{k}_{1,R}k')\,e^{-\beta\eta\,F/RT} + (\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})\,e^{(1-\beta)\eta\,F/RT}}.$$

Equation [12] shows that i is positive ("cathodic") if $\eta < 0$, negative ("anodic") if $\eta > 0$.

If $i = 0$, $\eta = 0$; then [11] yields

[13] $$e^{\Delta\phi_R\,F/RT} = \sqrt{K_1K_2(c^2_{H^+}/p_{H_2})}$$

where $K_1 = k_1/k_{-1}$ and $K_2 = k_2/k_{-2}$. Equation [13] is a form of the Nernst equation, i.e., confirms [12].

(ii) Cathodic Tafel Region

By the "Tafel region" is meant that region of the current density – potential relation for which $i = Ae^{B\eta}$ where A and B are constants. From [12] and for a net cathodic current density, two limiting cases give Tafel relations, i.e., if

[14] $$(\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+}\,e^{-\beta\eta\,F/RT} \gg (\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})\,e^{(1-\beta)\eta\,F/RT}$$

then,

[15] $$i = 2F\,\frac{\bar{k}_{1,R}\bar{k}_{2,R}c_{H^+}}{\bar{k}_{2,R}+\bar{k}_{1,R}k'}\,e^{-\beta\eta\,F/RT}.$$

But if

[16] $$(\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})\,e^{(1-\beta)\eta\,F/RT} \gg (\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+}\,e^{-\beta\eta\,F/RT}$$

then,

[17] $$i = 2F\,\frac{\bar{k}_{1,R}\bar{k}_{2,R}c^2_{H^+}}{\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2}}\,e^{-(1+\beta)\eta\,F/RT}.$$

By virtue of its form, [16] cannot be applicable at large negative overpotentials, when it must go over into [14]. Remembering that the cathodic Tafel region occurs only for $\beta\eta\,F/RT > 1$, the necessary relation among the rate constants for the occurrence of [17] is

[18] $$(\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2}) > (\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+}\,e^2.$$

(iii) Anodic Tafel Region

From [12], with condition [14]:

[19] $$i = -2F\,\frac{\bar{k}_{-1,R}\bar{k}_{-2,R}p_{H_2}}{(\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+}}\,e^{(2-\beta)\eta\,F/RT}$$

Or, with condition [16], [12] becomes:

[20] $$i = -2F\,\frac{\bar{k}_{-1,R}\bar{k}_{-2,R}p_{H_2}}{\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2}}\,e^{(1-\beta)\eta\,F/RT}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Equation [19], as a consequence of the form of [14], can be applicable only at lower positive values of the overpotential. The condition for it to occur at any potential in an anodic Tafel region,

$$[21] \qquad (\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+} > (\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})\, e^2.$$

(iv) "Reversible" Region

By the "reversible region" is meant the range of overpotentials for which the expansion of $e^{\pm\alpha\eta\, F/RT}$ can be written as $1\pm\alpha\eta\, F/RT$ to an accuracy not less than that corresponding to the experimental measurement of η.

Applying this condition to [12]:

$$[22] \qquad i = -4F\frac{\bar{k}_{1,R}\bar{k}_{2,R}c^2_{H^+}\,\eta F/RT}{(\bar{k}_{2,R}+\bar{k}_{1,R}k')c_{H^+}+(\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})}$$

and

$$[23] \qquad \bar{k}_{1,R}\bar{k}_{2,R}c^2_{H^+} = \bar{k}_{-1,R}\bar{k}_{-2,R}p_{H_2}.$$

(v) Coverage of Electrode with Adsorbed Atomic Hydrogen

The explicit expression for c_H follows from [10], utilizing [6]–[9], as

$$[24] \qquad c_H = \frac{\bar{k}_{1,R}c_{H^+}\, e^{-\beta\eta\, F/RT}+\bar{k}_{-2,R}p_{H_2}\, e^{(1-\beta)\eta\, F/RT}}{(\bar{k}_{1,R}k'+\bar{k}_{2,R})c_{H^+}\, e^{-\beta\eta\, F/RT}+(\bar{k}_{-1,R}+\bar{k}_{-2,R}k'p_{H_2})\, e^{(1-\beta)\eta\, F/RT}}.$$

Defining the degree of surface coverage at an overpotential η, θ_η, as

$$[25] \qquad \theta_\eta = k'c_H,$$

two limiting values for the Tafel regions follow from [24] and [25] as:

$$[26] \qquad (\theta_\eta)_c = \bar{k}_{1,R}k'/(\bar{k}_{1,R}k'+\bar{k}_2),$$

$$[27] \qquad (\theta_\eta)_a = \bar{k}_{-2,R}k'p_{H_2}/(\bar{k}_{-1,R}+\bar{k}_{-2,R}p_{H_2}k').$$

(vi) Influence of Concentration of Hydrogen Ions in Solution and Hydrogen Pressure in the Tafel Regions

The pH effects are known (Frumkin (15), Parsons (3), Bockris and Potter (5), and Bockris and Watson (14)).

The effect of hydrogen pressure on overpotential may be calculated in terms of the coefficient $\left(\frac{\partial\eta}{\partial \ln p_{H_2}}\right)_i$.

In the cathodic region, they follow from [15], for the condition [14]. Thence,

$$[28] \qquad \left(\frac{\partial\eta}{\partial \ln p_{H_2}}\right)_i = \frac{RT}{2F}.$$

If [16] applies, [17] gives:

$$[29] \qquad \left(\frac{\partial\eta}{\partial \ln p_{H_2}}\right)_i = \frac{RT}{2F}-\frac{RT}{(1+\beta)F}\left(\frac{k_{-2}k'p_{H_2}}{k_{-1}+k_{-2}k'p_{H_2}}\right).$$

In the anodic region, condition [14], resulting in [19], gives

$$[30] \qquad \left(\frac{\partial\eta}{\partial \ln p_{H_2}}\right)_i = -\frac{RT}{2F}\frac{\beta}{2-\beta}$$

whereas [16] and [20] give:

$$[31] \qquad \left(\frac{\partial\eta}{\partial \ln p_{H_2}}\right)_i = -\frac{RT}{(1-\beta)F}\left(\frac{1+\beta}{2}-\frac{k_{-2}k'p_{H_2}}{k_{-1}+k_{-2}p_{H_2}}\right).$$

(vii) Limiting Cases for the Electrochemical Path

The general equations for the electrochemical desorption path (cf. page 476) give rise to two general divisions, depending upon whether [14] or [16] is applicable. In the following tables, limiting values are given for the Tafel equation, degree of coverage with atomic hydrogen, and pressure coefficient of overpotential at constant current density, on the further assumption that the heights of the energy barriers in the successive reactions differ by an amount greater than about 3 kcal mole^{-1}.

C. The Atomic Hydrogen Desorption Mechanism

1. General Equations

The reactions are:

[32] $$H^+ + e_0^- \underset{-1}{\overset{1}{\rightleftharpoons}} MH,$$

[33] $$MH + MH \underset{-2}{\overset{2}{\rightleftharpoons}} H_2 + 2M.$$

Hence,

[6] $$v_1 = k_1(1-k'c_H)c_{H^+}\, e^{-\beta\Delta\phi\ F/RT}$$

[7] $$v_{-1} = k_{-1}c_H\, e^{(1-\beta)\Delta\phi\ F/RT}$$

[34] $$v_2 = k_2 c_H^2$$

[35] $$v_{-2} = k_{-2}(1-k'c_H)^2 p_{H_2}.$$

In the steady state:

[36] $$2(v_1-v_{-1}) = v_2-v_{-2} = v.$$

From [6], [7], [34], [35], and [36]

[37] $$\frac{1}{4}\left(\frac{k_2}{k'^2}-k_{-2}p_{H_2}\right)\left(\frac{i}{2F}\right)^2-\left(\bar{k}^2_{1,R}c^2_{H^+}\, e^{-2\beta\eta\ F/RT}+\frac{\bar{k}_{1,R}k_2}{k'^2}c_{H^+}\, e^{-\beta\eta\ F/RT}\right.$$
$$\left.+2\frac{\bar{k}_{1,R}\bar{k}_{-1,R}}{k'}c_{H^+}\, e^{(1-2\beta)\eta\ F/RT}\right.$$
$$\left.+k_{-2}p_{H_2}\frac{\bar{k}_{-1,R}}{k'}\, e^{(1-\beta)\eta\ F/RT}+\frac{\bar{k}^2_{-1,R}}{k'^2}\, e^{2(1-\beta)\eta\ F/RT}\right)\frac{i}{2F}$$
$$+\bar{k}^2_{1,R}\frac{k_2}{k'^2}c_{H^+}\, e^{-2\beta\eta\ F/RT}-\frac{\bar{k}^2_{1,R}}{k'^2}k_{-2}p_{H_2}\, e^{2(1-\beta)\eta\ F/RT} = 0.$$

From [37], with the condition $i = 0$ ($\eta = 0$), the first two terms vanish, whence, with [1] and [2],

[38] $$e^{\Delta\phi_R\ F/RT} = K_1K_2^{\frac{1}{2}}(c_{H^+}/\sqrt{p_{H_2}})$$

where $K_1 = k_1/k_{-1}$, $K_2 = k_2/k_{-2}$, the equilibrium constants of the partial reaction [32] and [33].

Also, from [37], with $\eta = 0$,

[39] $$\bar{k}^2_{1,R}k_2c^2_{H^+} = \bar{k}^2_{-1,R}k_{-2}p_{H_2}.$$

2. General Solution for Current Density (Cathodic and Anodic Currents)

From [37]:

$$\frac{i}{2F}=\frac{2}{(k_2/k'^2)-k_{-2}p_{H_2}}\left\{\left(\bar{k}^2_{1,R}c_{H^+}\,e^{-2\beta\eta\,F/RT}+\frac{\bar{k}_{1,R}k_2}{k'^2}c_{H^+}\,e^{-\beta\eta\,F/RT}\right.\right.$$
$$\left.+2\,\frac{\bar{k}_{-1,R}\bar{k}_{1,R}}{k'}c_{H^+}\,e^{(1-2\beta)\eta\,F/RT}+\frac{\bar{k}_{-1,R}k_2}{k'}p_{H_2}\,e^{(1-\beta)\eta\,F/RT}+\frac{\bar{k}^2_{-1,R}}{k'^2}\,e^{2(1-\beta)\eta\,F/RT}\right)(+)$$
$$\left(\bar{k}^4_{1,R}c^4_{H^+}\,e^{-4\beta\,F/RT}+2\,\frac{\bar{k}^3_{1,R}k_2}{k'^2}c^3_{H^+}\,e^{-3\beta\eta\,F/RT}+\frac{\bar{k}^2_{1,R}k_2k_{-2}}{k'^2}c^2_{H^+}p_{H_2}\,e^{-2\beta\eta\,F/RT}\right.$$
$$+4\frac{\bar{k}^3_{1,R}\bar{k}_{-1,R}}{k'}c_{H^+}\,e^{(1-4\beta)\eta\,F/RT}$$
[40] $$+2\,\frac{\bar{k}^2_{1,R}\bar{k}_{-1,R}}{k'}c^2_{H^+}\left(k_{-2}p_{H_2}+2\,\frac{k_2}{k'^2}\right)e^{(1-3\beta)\eta\,F/RT}+2\,\frac{\bar{k}_{1,R}\bar{k}_{-1,R}k_2k_{-2}}{k'^3}c_{H^+}p_{H_2}\,e^{(1-2\beta)\eta\,F/RT}$$
$$+6\,\frac{\bar{k}^2_{1,R}\bar{k}_{-1,R}}{k'^2}c^2_{H^+}\,e^{(2-4\beta)\eta\,F/RT}$$
$$+2\,\frac{\bar{k}^2_{-1,R}\bar{k}_{1,R}}{k'^2}c_{H^+}(k_2+k_{-2}p_{H_2})\,e^{(2-3\beta)\eta\,F/RT}+4\,\frac{k_{1,R}\bar{k}^3_{-1,R}}{k'^2}c_{H^+}\,e^{(3-4\beta)\eta\,F/RT}$$
$$+\frac{\bar{k}_{-1,R}k_2k_{-2}p_{H_2}}{k'^4}\,e^{2(1-\beta)\eta\,F/RT}$$
$$\left.\left.+2\,\frac{\bar{k}^3_{-1,R}}{k'^2}k_{-2}p_{H_2}\,e^{3(1-\beta)\eta\,F/RT}+\frac{\bar{k}^4_{-1,R}}{k'^4}\,e^{4(1-\beta)\eta\,F/RT}\right)^{\frac{1}{2}}\right\}.$$

In [40], the minus sign before the last bracket is taken; for, then, with $-\eta$, i is positive; and, if η is positive, i is negative, i.e., the signs of the i values change with the sign of η, in accordance with physical sense. If the plus sign is taken, i has the same sign, independently of the signs of η, i.e., the solution is unreal.

To obtain Tafel equations from [39], we rearrange the expression in such a way that a simple assumption regarding the predominance of one term over all others can result in expressions with only one potential dependent term.

3. Special Case of Equation [40] for $\bar{k}^4_{1,R}c^4_{H^+}e^{-4\beta\eta\,F/RT}$ Predominating in the Square Root Term (Cathodic and Anodic Case)

With this condition,

$$\frac{i}{2F}=\frac{2}{(k_2/k'^2)-k_{-2}p_{H_2}}\left\{\left(\bar{k}^2_{1,R}c^2_{H^+}\,e^{-2\beta\eta\,F/RT}+\frac{\bar{k}_{1,R}k_2}{k'^2}c_{H^+}\,e^{-\beta\eta\,F/RT}\right.\right.$$
$$\left.+2\,\frac{k_{-1,R}k_{1,R}}{k'}c_{H^+}\,e^{(1-2\beta)\eta\,F/RT}+\frac{\bar{k}_{-1,R}k_{-2}}{k'}p_{H_2}\,e^{(1-\beta)\eta\,F/RT}+\frac{\bar{k}^2_{-1}}{k'^2}\,e^{2(1-\beta)\eta\,F/RT}\right)$$
$$-\bar{k}^2_{1,R}c^2_{H^+}\,e^{-2\beta\eta\,F/RT}\left(1+\frac{2k_2}{k'^2\bar{k}_{1,R}c_{H^+}}\,e^{\beta\eta\,F/RT}+\frac{k_2}{k'^2}\,\frac{k_{-2}p_{H_2}}{\bar{k}^2_{1,R}c_{H^+}}\,e^{2\beta\eta\,F/RT}+4\,\frac{\bar{k}_{-1,R}}{k'\bar{k}_{1,R}c_{H^+}}\,e^{\eta\,F/RT}\right.$$
$$+\frac{2\bar{k}_{-1,R}(k_{-2}p_{H_2}+k_2/k'^2)}{k'\bar{k}_{1,R}c_{H^+}}\,e^{(1-\beta)\eta\,F/RT}+\frac{2\bar{k}_{-1,R}k_2k_{-2}p_{H_2}}{k'^3}\,e^{(1+2\beta)\eta\,F/RT}$$
[41] $$+6\,\frac{\bar{k}^2_{-1,R}}{k'^2\bar{k}^2_{1,R}c^2_{H^+}}\,e^{2\eta\,F/RT}$$
$$+\frac{2\bar{k}^2_{-1,R}(k_2/k'^2+2k_{-2}p_{H_2})}{k'^2\bar{k}^3_{1,R}c^3_{H^+}}\,e^{(2+\beta)\eta\,F/RT}+4\,\frac{\bar{k}^3_{-1,R}}{k'^3\bar{k}^3_{1,R}c^3_{H^+}}\,e^{3\eta\,F/RT}$$
$$\left.+\frac{\bar{k}^2_{-1,R}}{k'^4}\,\frac{k_2k_{-2}p_{H_2}}{\bar{k}^4_{1,R}c^4_{H^+}}\,e^{2(1+\beta)\eta\,F/RT}\right.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$$+\frac{2\bar{k}^3_{-1,R}}{k'^3}\frac{k_{-2}p_{H_2}}{\bar{k}^4_{1,R}c^4_{H^+}}e^{(3+\beta)\eta F/RT}+\frac{\bar{k}^4_{-1,R}}{\bar{k}^4_{1,R}}\frac{1}{k'^4c^4_{H^+}}e^{4\eta F/RT}\Bigg)^{\frac{1}{2}}\Bigg\}.$$

If the square root term of equation [41] is expanded, it is necessary to continue the expansion to the fourth term, otherwise the terms from the root term cancel with the terms before the square root. Utilizing the fact that all the terms in the square root after the first are $\ll 1$, then one obtains:

[42] $$\frac{k_2}{k'^2\bar{k}_{1,R}c_{H^+}} \ll e^{-\beta\eta F/RT}$$

[43] $$\frac{k_{-2}p_{H_2}}{\bar{k}_{1,R}c_{H^+}} \ll e^{-\beta\eta F/RT}$$

[44] $$\frac{\bar{k}_{-1,R}}{k'\bar{k}_{1,R}c_{H^+}} \ll e^{-\eta F/RT},$$

or, utilizing [39], [44] becomes:

$$k_2/k'^2\, k_{-2}\, p_{H2} \ll e^{-2\eta F/RT}.$$

These conditions, in [41], yield:

[45] $$i = 2F(k_2/k'^2)(1-e^{2\eta F/RT}).$$

Equation [45] expresses the net current under cathodic or anodic overpotential when the condition [42], [43], and [44] applies. Limiting conditions of this equation will be considered below.

4. Special Case of [40] for which $\bar{k}^2_{1,R}c^2_{H^+}(k_2k_{-2}/k'^2)p_{H_2}\ e^{-2\beta\eta F/RT}$ *Predominates in the Square Root Term*

Applying this condition to [40] one obtains:

[46] $$k'^2\bar{k}_{1,R}\,c_{H^+}/k_2 \ll e^{\beta\eta F/RT},$$

[47] $$\bar{k}_{1,R}c_{H^+}/(k_{-2}\,p_{H_2}) \ll e^{\beta\eta F/RT}.$$

Then, in [41]:

[48] $$i = 4F\,\bar{k}_{1,R}c_{H^+}\frac{1-[k'^2(k_{-2}p_{H_2}/k_2)]^{\frac{1}{2}}}{1-k'^2(k_{-2}p_{H_2}/k_2)}e^{-\beta\eta F/RT}.$$

5. Special Case of [40] for which $(\bar{k}^2_{-1,R}/k'^4)/k_2k_{-2}p_{H_2}\ e^{2(1-\beta)\eta F/RT}$ *Predominates in Square Root Term*

Applying this condition to [40] one obtains:

[49] $$k'\bar{k}_{-1,R}/k_2 \ll e^{-(1-\beta)\eta F/RT}$$

[50] $$\bar{k}_{-1,R}/(k'k_{-2}p_{H_2}) \ll e^{-(1-\beta)\eta F/RT}.$$

Then, from [41]:

[51] $$i = 4F\frac{\bar{k}_{-1,R}}{k'}\frac{1-(k_2/k'^2k_{-2}p_{H_2})^{\frac{1}{2}}}{1-(k_2/k'^2k_{-2}p_{H_2})}e^{(1-\beta)\eta F/RT}.$$

6. Special Case for which $(\bar{k}_{-1,R}/k'^4)\ e^{4(1-\beta)\eta F/RT}$ *Predominates in Square Root Term*

Application of this condition to equation [40] necessitates expansion of the square root term to four terms. The resulting conditions are:

[52] $$k'k_{-2}p_{H_2}/\bar{k}_{-1,R} \ll e^{(1-\beta)\eta F/RT},$$

[53] $$k_2/k'\bar{k}_{-1,R} \ll e^{(1-\beta)\eta F/RT},$$

[54] $$k'\bar{k}_{1,R}c_{H^+}/\bar{k}_{-1,R} \ll e^{\eta F/RT}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Or, utilizing [39], [54] becomes:

$$[55] \qquad k'^2 k_{-2} p_{H_2}/k_2 \ll e^{-2\eta\, F/RT}.$$

With these conditions in [40], one obtains:

$$[56] \qquad i = 2F\, k_{-2} p_{H_2}(e^{-2\eta\, F/RT} - 1).$$

7. Reversible Region

Near the reversible potential, i in [37] is limitingly small. This implies that the term in i^2 in [37] will be negligible compared with that in i. Correspondingly, η will be limitingly small. In this equation we expand the e function to the first term only in the i term (of [37]) and to the second term in the term independent of i (the first term vanishing). One obtains:

$$[57] \qquad i = -(4\eta\, F^2/RT) \Big/ \left(\frac{1}{\bar{k}_{1,R} c_{H^+}} + \frac{k'^2}{k_2} + \frac{2\bar{k}_{-1,R} k'}{\bar{k}_{1,R} k_2 c_{H^+}} + \frac{k'}{\bar{k}_{-1,R}} + \frac{1}{k_{-2} p_{H_2}}\right).$$

Then, with [39],

$$[58] \qquad i = -(4\eta\, F^2/RT) \Big/ \left[\frac{1}{\bar{k}_{1,R} c_{H^+}} + \left(\frac{k'}{\sqrt{k_2}} + \frac{1}{\sqrt{(k_{-2} p_{H_2})}}\right)^2 + \frac{k'}{\bar{k}_{-1,R}}\right].$$

Several limiting conditions can be derived for equation [58] by regarding Figs. 1, 2, 3, and 6 (cf. Tables). Thus, from Fig. 1, $\bar{k}_{1,R}$ is the smallest rate constant so that:

$$[59] \qquad i = -4\bar{k}_{1,R}\, c_{H^+}(F^2/RT)\eta.$$

From Fig. 2, $\bar{k}_{-1,R}$ is the smallest rate constant and thus gives

$$[60] \qquad i = -4(\bar{k}_{-1,R}/k')(F^2/RT)\eta.$$

From Fig. 3, k_{-2} is the smallest rate constant and therefore

$$[61] \qquad i = -4\, k_{-2}\, p_{H_2}\, (F^2/RT)\eta.$$

From Fig. 6, k_2 is the smallest rate constant and therefore

$$[62] \qquad i = -4\, \frac{k_2}{k'^2}\, \frac{F}{RT}\, \eta.$$

The pH and p_{H_2} dependence of these current densities in the reversible region may be noted as an aid to diagnostic evaluation of mechanism.

8. Coverage at the Equilibrium Potential

From [34] and [35],

$$[63] \qquad v_2 = v_{-2}.$$

Hence:

$$[64] \qquad \theta = \sqrt{\left(\frac{k_{-2} p_{H_2} k'^2}{k_2}\right)} \Big/ 1 + \sqrt{\left(\frac{k_{-2} p_{H_2} k'^2}{k_2}\right)}.$$

9. Coverage in the Tafel Region

From [6] and [7] and

$$[65] \qquad \tfrac{1}{2} v = v_1 - v_{-1}$$

$$[66] \qquad c_H = \frac{1}{k'}\, \frac{\bar{k}_{1,R} c_{H^+}\, e^{-\beta\eta\, F/RT} - (v/2)}{\bar{k}_{1,R} c_{H^+}\, e^{-\beta\eta\, F/RT} + (\bar{k}_{-1,R}/k')\, e^{(1-\beta)\eta\, F/RT}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

From [34] and [35], with: $v = v_2 - v_{-2}$

$$[67] \qquad c_H = \frac{1}{k'}\left[-\frac{k_{-2}p_{H_2}}{k_2/k'^2 - k_{-2}p_{H_2}} + \sqrt{\left(\frac{k_{-2}p_{H_2}k_2}{k'^2[(k_2/k') - k_{-2}p_{H_2}]^2} + \frac{v}{k_2/k'^2 - k_{-2}p_{H_2}}\right)}\right].$$

10. Limiting Cases for the Catalytic Desorption Mechanism

The equations derived in sections 5 and 6 are based upon certain mathematical restrictions, and, with these limitations, apply to both cathodic and anodic polarization. If further restrictions in regard to the relative values of the constants in equations [48] and [51] are taken into account, the simple limiting cases (equivalent to the existence of a predominant rate-determining step) shown in Tables V and VI arise.

DISCUSSION

The characteristic quantities given in Tables I, II, III, and IV allow a complete distinction to be made between (*a*) the electrochemical and catalytic desorption paths, and (*b*) the energy–distance profiles and thus the rate-determining step. The distinguishing criteria are summarized in Table V.

The use of these criteria is clearly restricted to the assumption that only either the electrochemical or catalytic desorption mechanisms occurs, and that the surface H atoms block part of the surface for the discharge of H^+ ions.

The Tafel equations deduced for various limiting conditions in Tables I–IV may be divided into two groups:

1. Those equations which have the form: current density = charge factors × equilibrium constant of reaction *before* the r.d.s. × rate constant of the r.d.s. × concentration factor × a potential factor.

In this type of equation there is agreement with the formulation of consecutive reactions proposed by Eyring (16) which implies that the free energy of activation of the over-all reaction is the difference in free energy between the initial state and the activated state of the rate-determining reaction.

2. Those equations which have the form: current density = charge factor × rate constant of r.d.s. and equilibrium constant of reaction *following* the r.d.s. × concentration factor* × potential factor.

In this latter type of relation, the only rate constant (apart from those which make up the equilibrium constants) is that for the step from the initial state of the over-all reaction to the state of highest energy in consecutive reactions, and, in this formal sense, the rate-determining step is consistent with the definition made by Eyring *et al.* (16) for the rate-determining step in consecutive reactions. However, consider, for example, (Table III) the expression

$$i = 4F\frac{\bar{k}_{1,R}}{k'}c_{H^+}\sqrt{\left(\frac{k_2}{k_{-2}p_{H_2}}\right)}\,e^{-\beta\eta F/RT}$$

with [39]:

$$i = 4F\frac{\bar{k}_{-1,R}}{k'}\,e^{-\beta\eta F/RT}.$$

Thus, in such expressions, the energy barrier which determines the over-all reaction rate is that between the energy of the surface-adsorbed H atom and the state of highest energy in the system. (In such cases, the surface of the electrode is highly covered.)

**Except in the case of equations containing k_{-1}, when no concentration factor occurs in the form of the relation given.*

For the above general kinetics of the h.e.r., it is possible to calculate an expression for the stoichiometric number, ν (Horiuti and Ikusima (17)), namely:

[68] $$\nu = \frac{2\, i_0 F}{RT}\left(\frac{\partial \eta}{\partial i}\right)_{\eta \to 0}.$$

In the limiting cases where a r.d.s. appears (except those leading to a limiting current density), as assumed in Tables I–IV, simple values of ν, namely, those of 1 or 2, are obtained. These values are shown in Table VI.

TABLE V

Distinguishing criteria in catalytic and electrochemical desorption paths

Energy profile (cf., Tables I–IV)	Tafel slope		Coverage (high region)		Pressure effect	
	Cathodic	Anodic	Cathodic	Anodic	Cathodic	Anodic
Electrochemical A	β	$2-\beta$	0	0	$\frac{RT}{2F}$	$-\frac{RT}{2F}\frac{\beta}{2-\beta}$
Catalytic A	β	$1-\beta$	0	0	$\frac{RT}{2F}$	$-\frac{RT}{2F}\frac{\beta}{1-\beta}$
Electrochemical B	$1+\beta$	$1-\beta$	$\frac{1}{k'}$	$\frac{1}{k'}$	$-\frac{RT}{2F}\frac{1-\beta}{1+\beta}$	$\frac{RT}{2F}$
Catalytic B	β	$1-\beta$	$\frac{1}{k'}$	$\frac{1}{k'}$	$-\frac{RT}{2F}\frac{1-\beta}{\beta}$	$\frac{RT}{2F}$
Electrochemical C	$1+\beta$	$1-\beta$	0	0	$\frac{RT}{2F}$	$-\frac{RT}{2F}\frac{1+\beta}{1-\beta}$

Catalytic D	1

Thus, the values of ν enable a distinction to be made between the catalytic desorption mechanism A or B with rate-determining discharge step and the corresponding electrochemical desorption step. This distinction is of particular use because these steps have the same Tafel slopes.

It may be noted that the appropriate value of i_0 which should be substituted into [68] is that measured very near to the reversible potential. In practice it is usual to substitute the value of i_0 obtained from an extrapolation of the Tafel line. If use of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

i_0 value gives simple values of ν, the existence of the same mechanism in the region of the reversible potential, as that which occurs in the Tafel region, is confirmed (for experimental values, see Pentland, Bockris, and Sheldon (18)).

Vetter (4) stated that it was not possible to apply a determination of ν to distinguish between a rate-determining discharge mechanism (catalytic path) and a rate-determining electrochemical desorption (electrochemical path), without independent knowledge of other kinetic characteristics of the reaction occurring in a given case. He purported to show that indefinite values of ν could arise from such an attempt. However, values of ν differing from the integral values of Table VI arise only in the absence of the simple limiting conditions given in Tables I–IV, whereupon no single rate-determining step awaits identification and ν (which concerns a rate-determining step) has no simple meaning. If a simple integral value of ν is obtained from an application of [68], its use in the evaluation of a rate-determining step is possible (Table VI).

INTERPRETATION OF LIGHT SCATTERING DATA OBTAINED FROM SOLUTIONS OF LARGE ROD-LIKE PARTICLES

M. E. REICHMANN

It has been shown that the number average molecular weight and particle size can be evaluated from the angular distribution of the intensity of scattered light in addition to the customary weight average molecular weight and z average particle size (1, 2, 3). An evaluation of two different averages is useful inasmuch as it provides an idea as to the width of the distribution function. It is the purpose of this note to show that although sound in theory, the evaluation of the number averages of rods is extremely inaccurate in practice.

Qualitative information concerning the width of the distribution can also be gained from an evaluation of both the z average and weight average particle size. It will be demonstrated that the latter can be determined in a more reliable way than the number average.

In all the derivations the assumption has been made of a one-to-one correspondence between polydispersity in molecular weight and length. As pointed out by Rice in the case of random coils, such a correspondence would not exist if the system was polydisperse in stiffness (4). An equivalent situation may arise in rigid rods if there was polydispersity in thickness. In this case it will be shown that the weight average length as determined from experimental data will be underestimated.

The correlation between the angular distribution of the intensity of scattered light and the molecular parameters is given by the following expression:

$$[1] \qquad Kc/R_\theta = (1/M_w P)+2Bc$$

(c = concentration in g/ml, R_θ = Rayleigh's ratio at angle θ, M_w = weight average molecular weight, B = second virial coefficient, and $K = 2\pi^2 n_0^2 (dn/dc)^2/N\lambda^4$, n_0 = refractive index of solvent, dn/dc = refractive index increment of solution, N = Avogadro's number, and λ = wave length in vacuum).

For rigid rods the function P is given by:

$$[2] \qquad P = \int_0^x \frac{\sin w}{w}\, dw - \left(\frac{\sin x}{x}\right)^2$$

$x = (2\pi/\lambda')\, L \sin \theta/2$ ($\lambda' = \lambda/n$, L = length of rod).

When x is small $1/P$ can be expressed by the first two terms of a power series (5):

$$[3] \qquad 1/P = 1+x_z^2/9$$

$$[4] \qquad (Kc/R_\theta)_{c=0} = \frac{1}{M_w}(1+x_z^2/9) \qquad (x_z = z \text{ average of } x).$$

Figure 1 demonstrates that this approximation represents the $1/P$ function in the range of $x^2 = 0$–3, and that the error in the evaluation of the limiting slope and intercept is not too large up to $x^2 = 15$. It requires therefore a distribution function with a negligible fraction of particles for which $x^2 > 15$.

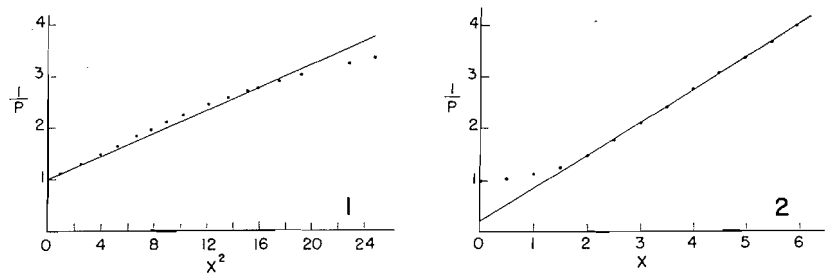

FIG. 1. Reciprocal of particle scattering function vs. x^2 (see text). Solid line was derived from approximation for small values of x.
FIG. 2. Reciprocal of particle scattering function vs. x (see text). Solid line was derived from approximation for large values of x.

When x is large P can be approximated by the following equation (1):

$$P = (\pi/2x_w)\ (1-1/\pi x_n) \qquad [5]$$

$$1/P = (2x_w/\pi)\ (1+1/\pi x_n+1/\pi^2 x_n^2+\ldots) \qquad [5a]$$

neglecting higher terms and introducing $x_w/x_n = M_w/M_n$

$$\frac{1}{P} = \frac{M_w}{M_n}\left(\frac{2}{\pi^2}+\frac{2x_n}{\pi}\right) \qquad [5b]$$

$$\frac{1}{PM_w} = \left(\frac{Kc}{R_\theta}\right)_{c=0} = \frac{1}{M_n}\left(\frac{2}{\pi^2}+\frac{2x_n}{\pi}\right). \qquad [5c]$$

In Fig. 2, $1/P$ for monodisperse rods ($M_w/M_n = 1$) is plotted as a function of x. The line is given by equation [5b]. As Fig. 2 indicates, equation [5b] is a good approximation provided $x > 2$.

Equation [5c] has been suggested as a basis for the evaluation of the number average molecular weight and length. Let us consider the expression in the brackets in [5c]. The value of the first term is 0.203. For $x > 2$ the second term will be larger than 1.30. Therefore the slope of $(Kc/R_\theta)_{c=0}$ versus $\sin\theta/2$ will be larger than an order of magnitude compared to the intercept. An average error of 3% in the slope will introduce an error of 30% or larger in the intercept, and since both M_n and L_n can only be evaluated with the aid of the intercept, this will also be the uncertainty in their determination.

Moreover, by neglecting the higher terms in [5a] the intercept is seriously affected. Remembering that it is the second term in the brackets that determines the intercept one can see that when $x = 2$ the third term will be 16% of the second, and with $x = 6$ the contribution of the third term will be 5% of the second term. Therefore, the intercept evaluated from experimental data will be too high, leading to too low values of the number average parameters.

Since the slope of $(Kc/R_\theta)_{c=0}$ vs. $\sin\theta/2$ can be evaluated with some precision, it would be useful to investigate whether independent information can be obtained from the slope alone. Introducing into [5c] $1/M_n = x_w/M_w x_n$ we obtain:

$$(Kc/R_\theta)_{c=0} = 2L_w/\pi^2 M_w L_n+(4L_w/M_w\lambda')\ \sin\theta/2. \qquad [6]$$

This is the equation derived by Casassa (6). M_w can be evaluated from the intercept of $(Kc/R_\theta)_{c=0}$ vs. $\sin^2\theta/2$ and thus the weight average length can be obtained from the slope of equation [6].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In the case of polydispersity in the thickness of the rod, the weight average molecular weight, as determined from the intercept of $(Kc/R_\theta)_{c=0}$ vs. $\sin^2 \theta/2$, will be given for a cylinder of radius r by:

$$M_w = \rho\pi N(r^2)_w L_w$$

whereas in the case of uniform thickness

$$M_w = \rho\pi N r^2 L_w' \qquad (\rho = \text{particle density}).$$

The slopes in equation [6] will be $4/\rho\pi N\lambda'(r^2)_w$ and $4/\rho\pi N\lambda' r^2$ respectively. Except in the case of a net side-to-side dissociation, $(r^2)_w > r^2$ resulting in the underestimation of the weight average length.

This can also be expressed in a different way. To preserve the one-to-one correspondence between molecular weight and length, we can formally replace the fluctuation in thickness by an equivalent fluctuation in length. A greater polydispersity in length than in the case of uniform thickness results. Rice has shown that any increase in polydispersity in length leads to a sharper downward curvature of $1/P$ vs. $\sin^2 \theta/2$ (4). The values of $1/P$ at high angles, and the particle length calculated from these values, would be consequently underestimated. Polydispersity in thickness can therefore be considered as the rod equivalent of polydispersity in stiffness in coils (4).

It is sometimes customary to examine polydispersity by comparing the particle length derived from the limiting slope of $1/P$ vs. $\sin^2 \theta/2$ (L_z), with the particle length derived from the best fit of the experimental data with a theoretical curve at high angles (7). It can be shown that the latter particle length will be very close to the weight average length, provided only that the distribution is not very wide. This follows from equation [5*a*]. Neglecting higher terms:

$$[7] \qquad 1/P = 2x_w/\pi^2 x_n + 2x_w/\pi$$

and the explicit $1/P$ function reduces when x is large to:

$$[7a] \qquad 1/P = 2/\pi^2 + 2x/\pi = 0.20 + 2x/\pi.$$

If x is large, $2x/\pi$ practically determines the value of $1/P$. The same applies to [7] provided x_w/x_n is not very large compared to one. Thus the x determined from the theoretical curve will be very close to x_w.

In a recent publication, light scattering data on tobacco mosaic virus have been reported (7). The particle size was determined from the limiting slope and from the best fit at high angles of the $1/P$ vs. $\sin^2 \theta/2$ curve. The small difference between these two values (10%), was taken as evidence in favor of a narrow distribution. What has been done in effect was a comparison between L_z and L_w. It is somewhat surprising that the length determined from high angle measurements (2900 Å) was lower than the length of the most frequent particle (3000 Å), as determined with the electron microscope. A similar discrepancy was obtained in our laboratory on potato X virus (see preceding article). These discrepancies resulted probably from polydispersity in thickness, as discussed above. The 10% difference would be a measure of the total polydispersity. In view of this it is not surprising that the distribution function of length in tobacco mosaic virus as obtained from electron microscope data was extremely sharp (8).

THE DIELECTRIC CONSTANT AND DIPOLE MOMENT OF 1,3-DIOXANE[1]

R. WALKER[2] AND D. W. DAVIDSON

In contrast to 1,4-dioxane, which has been extensively investigated, neither the dielectric constant nor the dipole moment of 1,3-dioxane has been previously measured, although the dipole moment has been recently calculated (1). The present note reports the static dielectric constants of liquid and solid 1,3-dioxane and the dipole moment as measured in cyclohexane and benzene solutions.

EXPERIMENTAL METHODS

1,3-Dioxane was prepared from 1,3-propanediol and paraformaldehyde by essentially the method of Clarke (2), followed by distillation in a Todd still over calcium oxide and a second distillation over calcium hydride. Boiling point (757 mm) 104.9–105.1° (corr.), n_D^{25} 1.4171. The water content, estimated by the Fischer method, was 0.013% and the absence of significant quantities of hydroxyl- and carbonyl-containing impurities was shown by the infrared spectrum. Gas chromatographic analyses showed only a trace (less than 0.3%) of volatile impurities, except for one sample.

Solvents were dried by refluxing over calcium hydride, followed by distillation. Benzene, after 84 hours of refluxing, had a water content of less than 0.001%.

Dielectric measurements on the liquid and solid were made by a method previously described (3). Dipole moment determinations were made at 25.0° C with a cell of 37 $\mu\mu$f capacitance using a substitution method which involved a number of reiterations to increase the total capacitance measured. For the most dilute solutions 20 reiterations were made.

Refractive indices were measured at 25.0° C with an Abbé Refractometer.

RESULTS AND DISCUSSION

The dielectric constant is shown as a function of temperature in Fig. 1. The melting point is indicated by the break in the curve at −44° C. In the liquid there is no dependence of dielectric constant (ϵ') on frequency up to at least 500 kc/sec. In the solid there is some dispersion of ϵ' over a temperature range extending a few degrees below the melting point where the points in the figure refer to measurements made at 10 kc/sec. At higher frequencies the curve shows less curvature before the melting point is reached.

Between the melting point and 25° C the static dielectric constant values for the liquid may be represented by

$$\epsilon_0 = -5.29_5 + 5.62_3 \times 10^3/T$$

with an average deviation of ±0.2%.

THE DIELECTRIC CONSTANT AND DIPOLE MOMENT OF 1,3-DIOXANE[1]

R. WALKER[2] AND D. W. DAVIDSON

In contrast to 1,4-dioxane, which has been extensively investigated, neither the dielectric constant nor the dipole moment of 1,3-dioxane has been previously measured, although the dipole moment has been recently calculated (1). The present note reports the static dielectric constants of liquid and solid 1,3-dioxane and the dipole moment as measured in cyclohexane and benzene solutions.

EXPERIMENTAL METHODS

1,3-Dioxane was prepared from 1,3-propanediol and paraformaldehyde by essentially the method of Clarke (2), followed by distillation in a Todd still over calcium oxide and a second distillation over calcium hydride. Boiling point (757 mm) 104.9–105.1° (corr.), n_D^{25} 1.4171. The water content, estimated by the Fischer method, was 0.013% and the absence of significant quantities of hydroxyl- and carbonyl-containing impurities was shown by the infrared spectrum. Gas chromatographic analyses showed only a trace (less than 0.3%) of volatile impurities, except for one sample.

Solvents were dried by refluxing over calcium hydride, followed by distillation. Benzene, after 84 hours of refluxing, had a water content of less than 0.001%.

Dielectric measurements on the liquid and solid were made by a method previously described (3). Dipole moment determinations were made at 25.0° C with a cell of 37 $\mu\mu$f capacitance using a substitution method which involved a number of reiterations to increase the total capacitance measured. For the most dilute solutions 20 reiterations were made.

Refractive indices were measured at 25.0° C with an Abbé Refractometer.

RESULTS AND DISCUSSION

The dielectric constant is shown as a function of temperature in Fig. 1. The melting point is indicated by the break in the curve at −44° C. In the liquid there is no dependence of dielectric constant (ϵ') on frequency up to at least 500 kc/sec. In the solid there is some dispersion of ϵ' over a temperature range extending a few degrees below the melting point where the points in the figure refer to measurements made at 10 kc/sec. At higher frequencies the curve shows less curvature before the melting point is reached.

Between the melting point and 25° C the static dielectric constant values for the liquid may be represented by

$$\epsilon_0 = -5.29_5 + 5.62_3 \times 10^3/T$$

with an average deviation of ±0.2%.

[1]*Issued as N.R.C. No. 5019.*
[2]*Present address: Department of Chemistry, The University, Hull, England.*

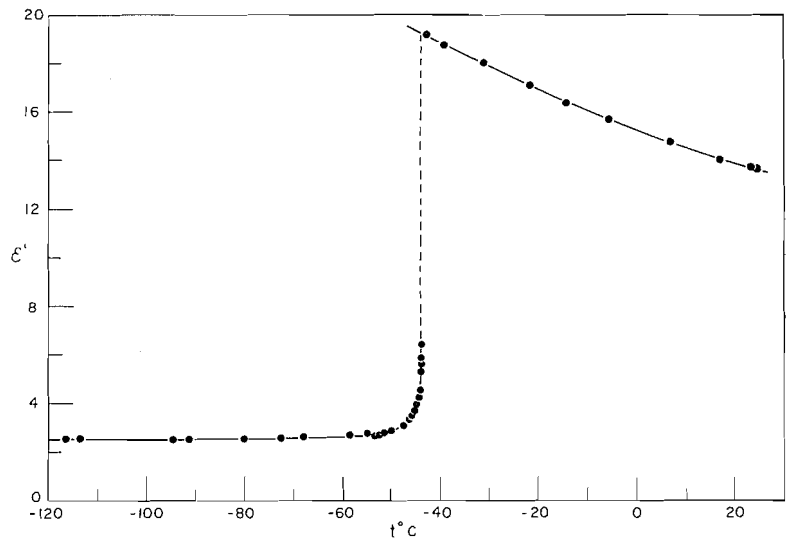

FIG. 1.

The dielectric results provide no evidence of the existence of more than one solid phase, although the possibility of a transition between two non-polar forms which do not differ greatly in density is not excluded. The value of ϵ_0 ($\sim$2.6) in the solid is about that to be expected for the square of the refractive index and shows the absence of any appreciable rotational polarization. 1,4-Dioxane exhibits a solid–solid transition some 11° below the melting point (4).

Figure 2 is a plot of Δ/w vs. w for the cyclohexane and benzene solutions. Here $\Delta = (\epsilon-\epsilon_1)-(n^2-n_1^2)$ and w is the weight fraction of dioxane. The dipole moment was calculated from

$$\mu^2 = \frac{27kT}{4\pi N_A}\frac{M}{(\epsilon_1+2)^2 d_1}\cdot\left(\frac{\Delta}{w}\right)_0$$

in which ϵ_1 and d_1 refer to the solvent and $(\Delta/w)_0$ to the value extrapolated to $w = 0$.

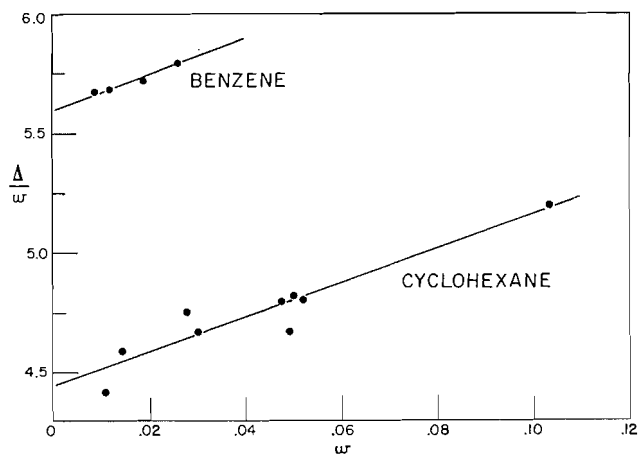

FIG. 2.

For personal use only.

As pointed out by Guggenheim (5), a least squares treatment of a quantity like Δ/w as a function of concentration weighs too heavily the less accurate data at low concentrations. Consequently we have fitted the data by least squares to the equations

$$\epsilon - \epsilon_1 = \alpha w + \beta w^2$$

$$n^2 - n_1^2 = \gamma w + \delta w^2$$

and obtained $(\Delta/w)_0$ as $(\alpha - \gamma)$. The straight lines in Fig. 2 result from this treatment.

The dipole moments obtained are 2.14_5 D from the solutions in cyclohexane and 2.13_4 D for those in benzene, with an over-all accuracy estimated at ± 0.03 D.

By the use of the Onsager equation (6) an "effective" dipole moment for the undiluted dioxane may be calculated from the dielectric constant of the liquid. At 25° C, μ (Onsager) = 2.55 D, a value which is practically independent of temperature. The difference between the Onsager moment and the dilute solution moments implies a considerable correlation between the moments of neighboring molecules in the liquid.

The value of the dipole moment calculated by Le Fèvre, Le Fèvre, and Smith (1), for the purpose of establishing the configuration of dimethylene pentaerythritol, was 1.86_5 D. Our measured values are sufficiently close to this figure not to change these workers' conclusion that the two 1,3-dioxane rings having ring atom 5 in common are most likely both in the chair configuration.

The difference between the moment of 1,3-dioxane and that of 2-methyl-1,3-dioxane (1.89 D in benzene (7)) is probably primarily due to the effect of the methyl group in making the ring flatter and the OCO angle larger. The calculation of the moment of 1,3-dioxane referred to above (1) made use of an assumed moment for the C–O–C group of 1.25 D, which is one experimental value of the dipole moment of dimethyl ether. However, in general the C–O–C group appears to have a higher moment in cyclic ethers, the dipole moment of pentamethylene oxide, for example, being 1.87 D (8). In addition, the presence of two C–O–C groups in the ring will change the charge distribution in such a way as to reduce the effective dipole moment associated with each.

To the extent that the contribution of C–H bond moments is negligible, there is no difference between the dipole moments of the chair and boat forms of 1,3-dioxane. Some indirect evidence, however, for the predominance of the chair form is afforded by the magnitude of the difference between μ (Onsager) and μ (solution), which is unusually large for a liquid in which hydrogen bonding is absent (6). Figure 3 illustrates what are perhaps the most favorable relative positions for neighboring molecules, along with the directions of their dipole moments. In each configuration the dipole moment lies in the plane of symmetry of the molecule and each molecule is represented by its projection on this plane. It is evident that complexes of the type shown for the chair configuration, in which neighboring molecules have their moments parallel to one another, will lead to an effective dipole moment considerably higher than that of an isolated molecule. For

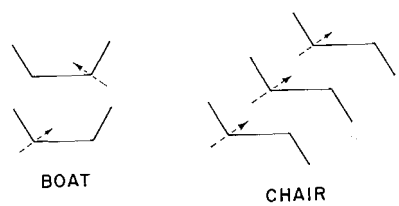

FIG. 3. "Favored" packing of molecules in 1,3-dioxane. Dipole moments are drawn through projections of O atoms on the planes of symmetry.

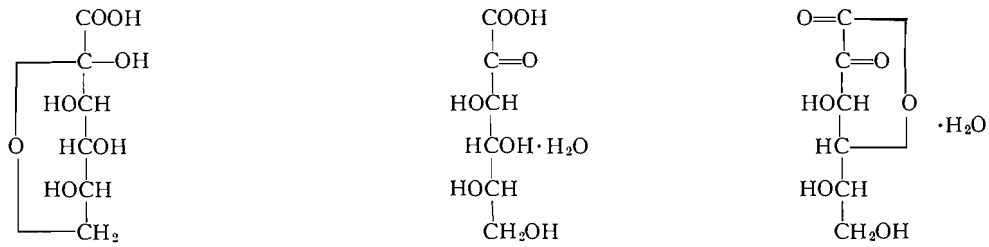
ON THE CONSTITUTION OF 2-KETO-L-GULONIC ACID

N. J. Gaspar* and J. M. Los

In the course of a polarographic investigation of 2-keto-L-gulonic acid (1) the following constitutional features were observed.

In aqueous solution the compound exists in the free acid lactol form as proposed by Reichstein and Grüssner (2), in equilibrium with an extremely small concentration of the free keto acid. The solid state can be either a free keto acid or the corresponding lactone. The latter crystallizes from a solution either of high viscosity or of high ionic strength. Sometimes mixtures of the two solid forms were obtained. Each form was invariably found to contain one molecule of water of crystallization.



free acid lactol in solution | free keto acid in solid state | lactone

The lactone is, of course, the keto tautomer of L-ascorbic acid.

The solid 2-keto-L-gulonic acid was made by the method of Reichstein and Grüssner (2): 20 g of diacetone-2-keto-L-gulonic acid were dissolved in 200 ml of distilled water. The solution was heated to boiling and was allowed to stand over a boiling water bath for 45 minutes. The water was then evaporated *in vacuo* till a sirup remained. We found

that crystallization from a low-viscosity solution yielded a different substance from that crystallizing at high viscosity. At intermediate viscosity, mixtures of these two would form.

This conclusion was drawn primarily from the results of alkalimetric titration: the product from low-viscosity solution was found to be 99.9% pure if its molecular weight was assumed to be 212, i.e. that of the free acid plus one molecule of water of crystallization. The substance obtained from the high-viscosity solution showed the same degree of purity if its molecular weight was put at 194. This could mean either that the water of crystallization does not appear in the latter case, or that the lactone ring has closed during crystallization.

Heating of the higher molecular weight compound at 50° *in vacuo* for a few hours also produced the compound of molecular weight 194, the loss of weight corresponding to exactly one molecule of water.

The decision as to the nature of the lower molecular weight compound could be made on the basis of the infrared spectra of both solid compounds (Fig. 1). The spectra were taken from KBr pellets (about 1.5 mg of solid in 400 mg of KBr) with a Perkin–Elmer Model 21 spectrophotometer. The product of molecular weight 212 has a strong adsorption peak at 5.75 μ, characteristic of the carbonyl stretching band and much like the corresponding peak of pyruvic acid at 5.73 μ. The product of molecular weight 194, however, shows a peak at 5.67 μ, which is typical of a lactone. Therefore it is concluded that the water is lost in the closing of the lactone ring and not by giving up water of crystallization (the slight adsorption around 6.10 μ seems characteristic of free water).

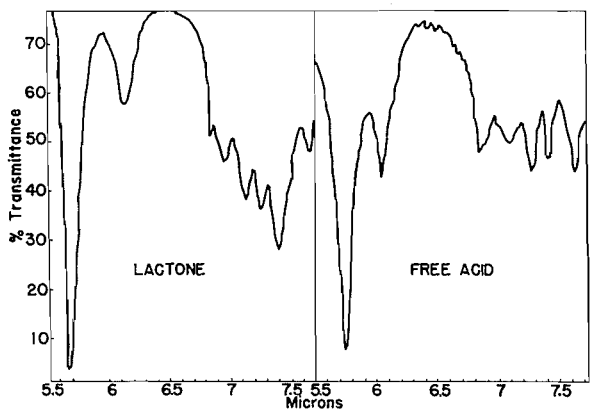

FIG. 1.

It is not likely that either of the two solid forms contains a lactol ring. Molecular models may show that the lactone cannot have a cyclohemiacetal ring as well. The most favorable case is a very strained double-ring structure obtained when the pyranose lactol has the boat conformation and the OH groups on C_2 and C_3 are *cis* to one another. Furthermore, it is not likely that a lactol ring exists in the solid free acid either: (*a*) the C=O adsorption peak at 5.75 μ is very large, (*b*) the above-mentioned transition of this free acid into the lactone form would probably require a total rearrangement within the crystal.

Both solid forms dissolve in water as the free acid, predominantly with a cyclohemiacetal ring. However, equilibrium with the free keto acid must exist, as borne out

by the completely rate-controlled current–voltage wave at the dropping mercury electrode (1). The ionization constant ($K = f\pm(c_{H^+}c_{A^-}/c_{HA})$) is 2.86×10^{-3} at 25° C and ionic strength 0.7 (1).

When KBr pellets were made not by mixing of the solid with KBr but by quickly freezing a solution of the free acid containing a high concentration of KBr, and then removing the water by freeze-drying, the lactone form was invariably produced.

In order to decide whether this is due to the high KBr concentration or to the lower temperature, the following experiment was carried out.

Two identical samples of the lactone (15 mg each) were dissolved in 10 ml of water. To one of these, 4 g of KBr was added. Each solution was then rapidly frozen in a dry ice – acetone mixture and the ice was sublimed *in vacuo*. The sample to which no KBr had been added was then mixed with 4 g of the latter. Identical pellets were made. The spectra showed clearly that the sample containing the KBr in solution had crystallized in the lactone form, the other as the free keto acid (in spite of the fact that it had its starting point in the solid lactone). We may therefore conclude that in the case of the first sample most of the water had been tied up as water of hydration of the K^+ and Br^- ions, lowering the activity of the water to such an extent that only the lactone could crystallize, just as if the crystallization had taken place from a very viscous solution.

Our thanks go to the National Research Council for financial assistance and to Merck and Company, Montreal, for providing the diacetone 2-keto-L-gulonic acid.

ISOLATION OF OLIGOSACCHARIDES IN IMPROVED YIELD BY THE ENZYMATIC DEGRADATION OF POLYSACCHARIDES

T. J. Painter[1]

Theoretical considerations originating with Kuhn (1) predict that, for random degradation of a uniform linear macromolecule, the yield of the n-membered fragment is given by $n\alpha^2(1-\alpha)^{n-1}$, where α is the degree of scission. The maximum possible yield of the fragment is then $n[2/(n+1)]^2[(n-1)/(n+1)]^{n-1}$, and occurs when $\alpha = 2/(n+1)$. Further calculation shows that the maximum possible yield of dimer plus trimer occurs when $\alpha = 0.59$, and amounts to 46%.

In the hydrolysis or acetolysis of polysaccharides, lack of randomness in the degradation usually results in considerably lower yields, and study of the literature shows that the combined yield of di- and tri-saccharides has seldom exceeded 35% by weight of the total hydrolyzate. Apart from the wastage of material, examination of the oligosaccharides obtained in these cases would reveal only the dominant structural features of the parent polysaccharide. In addition, misleading artifacts may arise from the recombination (reversion) of simple sugars, although in the case of acetolysis this effect appears to be minimized (2).

As Kuhn pointed out, these yields can be considerably increased if the oligosaccharides, once formed, are protected in some way from further degradation. Cellobiose octaacetate, for example, is partly protected by crystallization during the acetolysis of cellulose, and yields of over 40% are not uncommon (3). When completely protected, the maximum yield of n-mer in a random degradation would be $2/(n+1)$, and the maximum yield of dimer plus trimer, if both were protected, would be 83.3%.

This note suggests a possible method of protection in which the lower oligosaccharides are continuously removed from the system by dialysis. To achieve this, it is clear that neither the catalyst, nor any saccharides higher than those desired, should be dialyzable and that the former should not attack the membrane. These conditions were met quite closely by using some fungal hemicellulases and pectinases* in conjunction with a cellophane membrane (4).

Aqueous solutions of a series of polysaccharides, together with the enzyme preparation, were enclosed in cellophane dialysis bags which were large enough to permit a 100% increase in volume of the solution, such as would arise through osmosis. The bags were placed in beakers containing relatively large volumes of water, maintained at 37° C. At intervals, the dialyzates were replaced with fresh water until no further carbohydrate material was removed from the reaction mixture. The combined dialyzates in each case were concentrated to yield syrupy mixtures of sugars, which were shown by paper chromatography to contain large amounts of di-, tri-, tetra-, and higher saccharides, in addition to monosaccharides.

Quantitative experiments were carried out with the four polysaccharides listed in Table I. Each was used in conjunction with a purified hemicellulase preparation, which effected rapid and nearly complete (80–95%) conversion into dialyzable material, while having little effect on the cellophane membrane. The sugars obtained in each case were weighed and then adsorbed on small charcoal columns. The monosaccharide components were selectively eluted and weighed, and the weights of the oligosaccharides were assumed to be represented by the difference.

TABLE I

Recovery of oligosaccharides from polysaccharides

These figures provide merely an approximate indication of the possible general usefulness of the method. The yield of oligomers in a particular case will, of course, be greatly dependent upon the nature of the polymer and the enzyme preparation used, as well as conditions of temperature, pH, and concentration. It will also be dependent upon the

5-*O*-β-D-GALACTOFURANOSYL-D-GALACTOSE FROM GALACTOCARALOSE*

P. A. J. GORIN AND J. F. T. SPENCER

Galactocaralose, a polysaccharide formed by *Penicillium charlesii* G. Smith in Raulin-Thom medium has been shown to contain D-anhydrogalactofuranose units linked 1,5 linearly to a chain length of 9–10 units as indicated by the methylation (1, 2) technique. Its $[\alpha]_{5780}$ (−84°) suggested strongly that the galactose units have the β-configuration.

In the present work partial acid hydrolysis of galactocaralose, which contained smaller amounts of the more acid-stable mannocaralose, produced, as shown by paper chromatography, a homologous series of oligosaccharides. The mixture was fractionated on a cellulose column (3) and materials which appeared to be galactose (4.5%), galactobiose (1.8%), galactotriose (1.4%), galactotetraose (0.4%), and galactopentaose (0.8%) were obtained.

The galactobiose contained a furanose non-reducing end unit, since the sugar was rapidly hydrolyzed with 0.01 *N* sulphuric acid at 100° C (4). Only D-galactose was formed as shown by paper chromatographic examination and by preparation of the 1-methyl 1-phenylhydrazone derivative (5). Treatment of the disaccharide with excess lead tetraacetate in acetic acid resulted in nearly 2 moles of oxidant being consumed at a moderately rapid rate which ruled out 2-, 3-, and probably 4-substitution, and suggested that the glycosidic linkage was either 1,5 or 1,6 (6). A crystalline galactobiitol, obtained by sodium borohydride reduction (7) of the aldose, consumed in 2 minutes 4 molar equivalents of sodium periodate with concomitant release of 2 moles of formic acid; in a separate experiment 2 moles of formaldehyde were formed on sodium periodate oxidation. More prolonged treatment of the polyol resulted in overoxidation probably

5-*O*-β-D-GALACTOFURANOSYL-D-GALACTOSE FROM GALACTOCARALOSE*

P. A. J. GORIN AND J. F. T. SPENCER

Galactocaralose, a polysaccharide formed by *Penicillium charlesii* G. Smith in Raulin-Thom medium has been shown to contain D-anhydrogalactofuranose units linked 1,5 linearly to a chain length of 9–10 units as indicated by the methylation (1, 2) technique. Its $[\alpha]_{5780}$ (−84°) suggested strongly that the galactose units have the β-configuration.

In the present work partial acid hydrolysis of galactocaralose, which contained smaller amounts of the more acid-stable mannocaralose, produced, as shown by paper chromatography, a homologous series of oligosaccharides. The mixture was fractionated on a cellulose column (3) and materials which appeared to be galactose (4.5%), galactobiose (1.8%), galactotriose (1.4%), galactotetraose (0.4%), and galactopentaose (0.8%) were obtained.

The galactobiose contained a furanose non-reducing end unit, since the sugar was rapidly hydrolyzed with 0.01 *N* sulphuric acid at 100° C (4). Only D-galactose was formed as shown by paper chromatographic examination and by preparation of the 1-methyl 1-phenylhydrazone derivative (5). Treatment of the disaccharide with excess lead tetraacetate in acetic acid resulted in nearly 2 moles of oxidant being consumed at a moderately rapid rate which ruled out 2-, 3-, and probably 4-substitution, and suggested that the glycosidic linkage was either 1,5 or 1,6 (6). A crystalline galactobiitol, obtained by sodium borohydride reduction (7) of the aldose, consumed in 2 minutes 4 molar equivalents of sodium periodate with concomitant release of 2 moles of formic acid; in a separate experiment 2 moles of formaldehyde were formed on sodium periodate oxidation. More prolonged treatment of the polyol resulted in overoxidation probably

due to attack of the 2,3-*trans*-glycol of the anhydrogalactofuranose unit. Thus the only reasonable structure for the reducing disaccharide is the hitherto undescribed 5-*O*-D-galactofuranosyl-D-galactose, which complements the methylation data obtained from the original polysaccharide.

In agreement with the oxidation data, treatment of the galactobiitol with excess sodium periodate followed by sodium borohydride reduction gave a sirupy arabofuranosyl glycerol ($[\alpha]_D$ −129°). The latter, which gave an amorphous penta-*p*-nitrobenzoate, yielded arabinose and glycerol on acid hydrolysis and consumed 1 molar equivalent of sodium periodate which accords with the values expected from 2-*O*-L-arabofuranosyl glycerol. The configuration of the glycosidic linkage is deduced to be α by isorotational considerations mentioned later. It has been shown that in many glycopyranosyl-polyols the open-chain glycols are attacked preferentially by lead tetraacetate in acetic acid (8, 9). However, *trans* α-glycols in 5-membered ring systems may be oxidized relatively quickly with lead tetraacetate, and aqueous sodium periodate is a more specific oxidizing agent (10) for the required purpose. Based on Hudson's rules of isorotation (11), which have been used in the methyl glycopyranosyl and the glycopyranosyl glycerol series of sugars (8, 12), the specific rotation of 2-*O*-α-L-arabofuranosyl glycerol is calculated to be −108° using the following values: (*a*) 2-*O*-α-D-galactopyranosyl-glycerol, $[\alpha]_D$ +165° (13); (*b*) methyl-α-D-galactopyranoside·H_2O, $[\alpha]_D$ +179° (14); (*c*) methyl-α-D-arabofuranoside, $[\alpha]_D$ +123° (15).

EXPERIMENTAL

Optical rotations were measured at 27° C and evaporations done at 40° C. Solvents for paper chromatographic separations were ethyl acetate – acetic acid – water (9:2:2 v/v) for reducing oligosaccharides and butanol–ethanol–water (40:11:19 v/v) for other carbohydrates. *p*-Anisidine hydrochloride (16) was used as spray reagent for reducing and ammoniacal silver nitrate (17) for non-reducing sugars. R_{Gal} and R_{Rh} denote distances travelled by sugars on paper chromatograms compared to galactose and rhamnose, respectively.

Galactobiose from Galactocaralose

Trial hydrolyses of galactocaralose under a variety of pH's from 1 to 4 at 75° C for 18 hours (cf. the conditions of Andrews, Hough, and Powell (18) for partial hydrolysis of beet araban) showed that pH 2.2 gave the optimum yield of galactobiose (R_{Gal} 0.9), as judged from paper chromatograms. Therefore, galactocaralose (30.0 g), obtained by fermentation of Raulin-Thom medium by *Penicillium charlesii*, was dissolved in water (2 l.) and brought to pH 2.2 with sulphuric acid. After heating at 75° C for 18 hours the solution was neutralized ($BaCO_3$), filtered, and evaporated to a small volume which was added to excess methanol. The methanol-soluble material gave, on a paper chromatogram, a sugar corresponding to galactose and also four other slower moving yellow spots. The mixture of what appeared to be a homologous series of oligosaccharides was fractionated on a cellulose column. Ethyl acetate – acetic acid – water (9:2:2 v/v) eluted galactose (1.50 g); a 9:3:3 mixture gave galactobiose (0.55 g) then galactotriose (0.42 g) and a 9:4:4 mixture galactotetraose (0.12 g) and galactopentaose (0.24 g).

5-O-D-Galactofuranosyl-D-galactose

The sirupy material which appeared to be a galactobiose (19 mg), $[\alpha]_D$ −65° (*c*, 3.8 H_2O), was hydrolyzed as a 1% solution in 0.01 *N* sulphuric acid at 100° C. The specific rotation was −20° after 45 minutes, +5° (90 minutes), and +70° (16 hours; constant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

value). The product was neutralized ($BaCO_3$), filtered, and evaporated to a sirup (17 mg) which corresponded to galactose on a paper chromatogram and was converted to its 1-methyl 1-phenylhydrazone (13 mg), m.p. and mixed m.p. 179° C, which had an X-ray diffraction pattern identical with known material.

The above galactobiose (18.8 mg) was oxidized with 4 moles per mole of lead tetra-acetate in acetic acid (10 cc) containing water (0.5 cc). The oxidant uptake was 1.5, 1.6, 1.8, 1.9, and 2.2 moles after 2, 5, 15, 30, and 1260 minutes, respectively.

*5-O-*D*-Galactofuranosyl-*D*-galactitol*

The galactobiose (188 mg) was reduced by treatment with sodium borohydride (75 mg) in water (10 cc) for 3 hours. The solution was treated with excess acetic acid, followed by Amberlite IR120, and then evaporated to a crust which was repeatedly dissolved in methanol and evaporated. The product, which had R_{Gal} 0.6, crystallized and was recrystallized from methanol–ethanol. Yield 89 mg, m.p. 149–151° C, and $[\alpha]_D$ −65° (*c*, 0.9 H_2O). Calculated for $C_{12}H_{24}O_{11}$: C, 41.9%; H, 7.0%. Found: C, 41.8%; H, 7.2%. The polyol (15.0 mg in 10 cc water) was oxidized with 0.1 *M* sodium periodate (10 cc). After 2.5, 5, 7.5, and 10 minutes, 4.0, 4.3, 4.2, and 4.4 moles per mole of oxidant were consumed and 1.8 and 1.9 moles of formic acid produced after 2 and 7.5 minutes, respectively. About 0.5 moles of formic acid existed in each case as formate ester, as shown by titration with alkali. When a solution of the polyol (113γ) in 0.02 *M* sodium periodate (2.5 cc) was estimated for formaldehyde by the chromotropic acid method 2.1, 1.9, 2.0 moles per mole were produced after 2.5, 5, and 15 minutes, respectively.

*2-O-*L*-Arabofuranosyl-glycerol*

The galactobiitol (89 mg) was oxidized with aqueous sodium periodate (6 molar equivalents; 10 cc) for 1 minute and the solution then added to a suspension of Amberlite IR120 and Dowex-1 in water. The resin was filtered off and to the filtrate sodium borohydride (50 mg) was added. The solution was evaporated to a small volume and the mixture was worked up as in the previous sodium borohydride reduction. The sirupy derivative (41 mg) had R_{Rh} 0.95 and was purified on a cellulose column using *n*-butanol as solvent to give a material which had $[\alpha]_D$ −129° (*c*, 1.0 H_2O) and produced arabinose and glycerol on acid hydrolysis. The disaccharide consumed 0.96 moles per mole of sodium periodate after 1 hour, the specific rotation of the solution becoming constant after 30 minutes.

The purified glycerol derivative (19 mg) was heated for 30 minutes at 80° C in pyridine (2 cc) containing *p*-nitrobenzoyl chloride (0.20 g). The mixture was added to aqueous sodium bicarbonate and after this mixture was shaken for 30 minutes the precipitate was filtered off and reprecipitated twice from ethyl acetate with petroleum ether (b.p. 30–60° C). Yield, 62 mg. The powder had m.p. 88–92° and $[\alpha]_D$ 0° (*c*, 1.1 2,4-lutidine). Calculated for $C_{44}H_{31}O_{22}N_5$: C, 53.8%; H, 3.2%. Found: C, 53.2%; H, 3.5%.

The authors wish to thank Mr. J. A. Baignee and Mr. M. Mazurek for microanalytical determinations and Miss S. Lubin and Mr. N. Gardner for technical assistance.

THE CONDENSATION OF 1-PHENYL-2-PROPANONE WITH AROMATIC ALDEHYDES

R. A. ABRAMOVITCH AND A. OBACH

In connection with some other work it was necessary to determine whether, in the condensation of 1-phenyl-2-propanone (I) with aromatic aldehydes in the presence of piperidine, reaction took place at the methylene or at the ω-methyl group. If condensation took place at the methylene group the geometrical configuration would have to be determined, whereas the *trans*-isomer would be expected if reaction took place at the methyl group.

Previous work (1, 2, 3) had indicated that in the presence of aqueous alkali reaction took place at the methyl group

$$\underset{\text{(I)}}{C_6H_5{-}CH_2{-}CO{-}CH_3} + Ar{-}CHO \xrightarrow{OH^-} C_6H_5{-}CH_2{-}CO{-}CH{=}CHAr$$

whereas under acidic conditions reaction took place at the methylene group

$$C_6H_5{-}CH_2{-}CO{-}CH_3 + ArCHO \xrightarrow{H^+} C_6H_5{-}\underset{\underset{\underset{\text{(II)}}{Ar{-}C{-}H}}{\|}}{C}{-}CO{-}CH_3$$

Dickinson (4) reported that, with piperidine as a catalyst, salicylaldehyde reacted with 1-phenyl-2-propanone at the methyl group. In a reinvestigation of Dickinson's work Heilbron and Irving showed that condensation had actually taken place at the methylene group, but the geometry of the product was not established (5).

The condensation of 1-phenyl-2-propanone with benzaldehyde in the presence of piperidine and *n*-heptoic acid gave *cis*-1,2-diphenyl-1-butene-3-one (II; Ar=C_6H_5), whose structure and configuration were established by the fact that it reacted with sodium hypochlorite to give *cis*-α-phenylcinnamic acid (*cis*- with respect to the phenyl groups). The absence of a band for *trans*- CH=CH at 970 cm^{-1} in the infrared confirmed that condensation had not taken place at the terminal methyl group. The condensation with *m*-nitrobenzaldehyde similarly gave *cis*-1-*m*-nitrophenyl-2-phenyl-1-butene-3-one, which reacted with hypochlorite to give *cis*-1-*m*-nitrophenylcinnamic acid. The reaction of phenylpropanone with *o*-nitrobenzaldehyde, on the other hand, did not proceed as easily and only a 22% yield of *cis*-1-*o*-nitrophenyl-2-phenyl-1-butene-3-one was obtained

THE CONDENSATION OF 1-PHENYL-2-PROPANONE WITH AROMATIC ALDEHYDES

R. A. ABRAMOVITCH AND A. OBACH

In connection with some other work it was necessary to determine whether, in the condensation of 1-phenyl-2-propanone (I) with aromatic aldehydes in the presence of piperidine, reaction took place at the methylene or at the ω-methyl group. If condensation took place at the methylene group the geometrical configuration would have to be determined, whereas the *trans*-isomer would be expected if reaction took place at the methyl group.

Previous work (1, 2, 3) had indicated that in the presence of aqueous alkali reaction took place at the methyl group

$$\underset{\text{(I)}}{C_6H_5{-}CH_2{-}CO{-}CH_3} + Ar{-}CHO \xrightarrow{OH^-} C_6H_5{-}CH_2{-}CO{-}CH{=}CHAr$$

whereas under acidic conditions reaction took place at the methylene group

$$C_6H_5{-}CH_2{-}CO{-}CH_3 + ArCHO \xrightarrow{H^+} C_6H_5{-}\underset{\underset{\underset{\text{(II)}}{Ar{-}C{-}H}}{\|}}{C}{-}CO{-}CH_3$$

Dickinson (4) reported that, with piperidine as a catalyst, salicylaldehyde reacted with 1-phenyl-2-propanone at the methyl group. In a reinvestigation of Dickinson's work Heilbron and Irving showed that condensation had actually taken place at the methylene group, but the geometry of the product was not established (5).

The condensation of 1-phenyl-2-propanone with benzaldehyde in the presence of piperidine and *n*-heptoic acid gave *cis*-1,2-diphenyl-1-butene-3-one (II; Ar=C_6H_5), whose structure and configuration were established by the fact that it reacted with sodium hypochlorite to give *cis*-α-phenylcinnamic acid (*cis*- with respect to the phenyl groups). The absence of a band for *trans*- CH=CH at 970 cm^{-1} in the infrared confirmed that condensation had not taken place at the terminal methyl group. The condensation with *m*-nitrobenzaldehyde similarly gave *cis*-1-*m*-nitrophenyl-2-phenyl-1-butene-3-one, which reacted with hypochlorite to give *cis*-1-*m*-nitrophenylcinnamic acid. The reaction of phenylpropanone with *o*-nitrobenzaldehyde, on the other hand, did not proceed as easily and only a 22% yield of *cis*-1-*o*-nitrophenyl-2-phenyl-1-butene-3-one was obtained

under the conditions used in the previous condensations. This ketone was obtained as an oil and was best analyzed as its 2,4-dinitrophenylhydrazone. Its structure and configuration were established by the reaction with sodium hypochlorite which gave *cis*-1-*o*-nitrophenylcinnamic acid. Although the ketone gave a positive iodoform reaction no cinnamic acid could be isolated by this method.

EXPERIMENTAL

1,2-Diphenyl-1-butene-3-one

1-Phenyl-2-propanone (12.09 g) and benzaldehyde (5.76 g) were dissolved in benzene (70 ml), and piperidine (6 drops) and *n*-heptoic acid (3 drops) were added. The mixture was boiled under reflux for 24 hours using a Dean–Stark water separator to remove the water azeotropically. Most of the benzene was then evaporated and the residue steam-distilled. The residual oil solidified in the refrigerator overnight; the solid was filtered off and recrystallized from aqueous ethanol giving 1,2-diphenyl-1-butene-3-one (52.7% yield), m.p. 54–55°. Goldschmiedt and Knöpfer (1) give m.p. 53–54° for this compound. Infrared spectrum (Nujol mull) (main peaks only): 1655 (s) (α,β-unsaturated C=O), 1618 (m) (C=C), 1598 (w) (phenyl), 793 (w), 752 (m), 722 (m), 696 (s), and 685 cm^{-1} (s).

The product (0.108 g) was treated with sodium hypochlorite (2 ml) (prepared by dissolving sodium hydroxide (4 g) in water (10 ml) and passing chlorine gas (2 g) through this solution at 0°), heated to 90°, and the flask stoppered and shaken vigorously. Heating at 90° and shaking was continued for ½ hour, water being added after 15 minutes to dissolve the solid which separated on cooling. The solution was filtered and the cold filtrate acidified with gaseous sulphur dioxide. The acid which precipitated was filtered and recrystallized from aqueous ethanol to give *cis*-α-phenylcinnamic acid (54% yield), m.p. 169.5–170.5°. Stoermer and Voht give m.p. 172° for this compound (6).

1-m-Nitrophenyl-2-phenyl-1-butene-3-one

This was prepared similarly from *m*-nitrobenzaldehyde (7.04 g) and 1-phenyl-2-propanone (12.034 g). It crystallized from aqueous ethanol as yellow prisms (57.2% yield), m.p. 79–80°. Calc. for $C_{16}H_{13}O_3N$: C, 71.90; H, 4.90. Found: C, 72.15; H, 4.83. Infrared spectrum (Nujol mull) (main peaks only): 1660 (s), 1625 (w), 1602 (w), 1532 (s) ($-NO_2$), 826 (m), 819 (m), 728 (m), 703 cm^{-1} (s).

Oxidation of the ketone with sodium hypochlorite gave *cis*-α-*m*-nitrophenylcinnamic acid, m.p. 178–180°. Bakunin (7) gives m.p. 181–182° for this acid.

1-o-Nitrophenyl-2-phenyl-1-butene-3-one

The residue, after steam distillation of the product of condensation of *o*-nitrobenzaldehyde (7.0 g) and 1-phenyl-2-propanone (12.06 g), was extracted repeatedly with ether, the dried ($MgSO_4$) extract was evaporated, and the residual oil distilled under vacuum, the fraction b.p. 142–180° at 0.5 mm being collected (21.8% yield). This was redistilled (b.p. 180–186° at 0.6 mm) giving the nitroketone as an orange-red oil (12.8% based on *o*-nitrobenzaldehyde). Infrared spectrum (liquid film) (main peaks only): 1685 (s), 1618 (m), 1585 (m), 1535 (s), 1505 (w), 865 (m), 790 (w), 755 (m), 720 (s), 700 (s), and 675 cm^{-1} (w). The 2,4-dinitrophenylhydrazone crystallized from an ethyl acetate – ethanol mixture in red prisms, m.p. 188–189°. Calc. for $C_{22}H_{17}O_6N_5$: C, 59.06; H, 3.80. Found: C, 59.32; H, 3.75.

With sodium hypochlorite the ketone gave *cis*-*o*-nitrophenylcinnamic acid, m.p. 193–194°. With sodium hypoiodite, iodoform, m.p. 115–118°, was obtained but the cinnamic acid could not be isolated. The melting point of the acid as reported in the literature (8) is 193–195°.

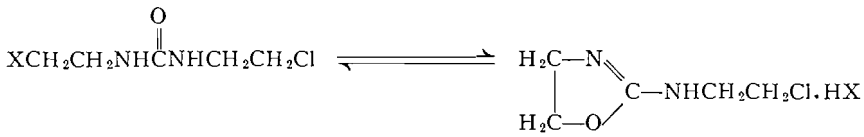
CYCLIZATION OF 1,3-BIS-(β-CHLOROETHYL)-UREA*

M.-E. KRELING AND A. F. MCKAY

It was found that the double melting point property of 2-(β-chloroethylamino)-2-oxazoline hydrochloride (II*a*) is associated with its conversion in the molten state into 1,3-bis-(β-chloroethyl)-urea (I*a*). Although 2-(β-chloroethylamino)-2-oxazoline hydrobromide (II*b*) does not exhibit a double melting point, it also rearranges in the molten state to the corresponding urea (I*b*).



I*a*, X = Cl
b, X = Br

II*a*, X = Cl
b, X = Br

1-(β-Bromoethyl)-3-(β-chloroethyl)-urea and 1,3-bis-(β-chloroethyl)-urea on heating in water cyclized respectively to the hydrobromide and hydrochloride salts of 2-(β-chloroethylamino)-2-oxazoline. The conversion of 1-(β-bromoethyl)-3-(β-chloroethyl)-urea into the hydrobromide salt II*b* rather than the hydrochloride salt of 2-(β-bromoethylamino)-2-oxazoline can be attributed to the lower bond energy of the C–Br linkage in comparison with the C–Cl linkage.

EXPERIMENTAL†

1,3-Bis-(β-chloroethyl)-urea

1,3-Bis-(β-chloroethyl)-urea (m.p. 126.5–128° C) was prepared in 61.2% yield by the method of Bestian (1). A mixture melting point determination with a known (2) sample of 1,3-bis-(β-chloroethyl)-urea gave no depression.

2-(β-Chloroethylamino)-2-oxazoline Hydrochloride

1,3-Bis-(β-chloroethyl)-urea (20 g, 0.1 mole) in water (50 ml) was heated under reflux for 1 hour. After the clear solution was evaporated to dryness *in vacuo*, crystals were obtained, yield 20 g (100%). These crystals melted at 103–104° C, resolidified and remelted at 121–123° C. Three crystallizations from absolute ethanol–ether (1 : 1) solution raised the melting points to 107–109° C and 125–127° C. Anal. Calc. for $C_5H_{10}Cl_2N_2O$:

**Issued as Report No. 22 from the L. G. Ryan Research Laboratories, Monsanto Canada Limited, Ville LaSalle, Quebec.*

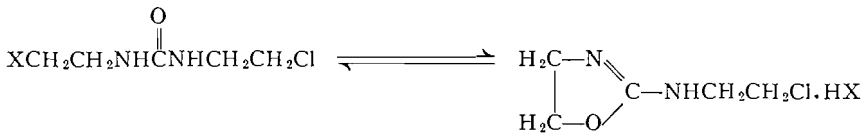
CYCLIZATION OF 1,3-BIS-(β-CHLOROETHYL)-UREA*

M.-E. KRELING AND A. F. MCKAY

It was found that the double melting point property of 2-(β-chloroethylamino)-2-oxazoline hydrochloride (II*a*) is associated with its conversion in the molten state into 1,3-bis-(β-chloroethyl)-urea (I*a*). Although 2-(β-chloroethylamino)-2-oxazoline hydrobromide (II*b*) does not exhibit a double melting point, it also rearranges in the molten state to the corresponding urea (I*b*).



I*a*, X = Cl
b, X = Br

II*a*, X = Cl
b, X = Br

1-(β-Bromoethyl)-3-(β-chloroethyl)-urea and 1,3-bis-(β-chloroethyl)-urea on heating in water cyclized respectively to the hydrobromide and hydrochloride salts of 2-(β-chloroethylamino)-2-oxazoline. The conversion of 1-(β-bromoethyl)-3-(β-chloroethyl)-urea into the hydrobromide salt II*b* rather than the hydrochloride salt of 2-(β-bromoethylamino)-2-oxazoline can be attributed to the lower bond energy of the C–Br linkage in comparison with the C–Cl linkage.

EXPERIMENTAL†

1,3-Bis-(β-chloroethyl)-urea

1,3-Bis-(β-chloroethyl)-urea (m.p. 126.5–128° C) was prepared in 61.2% yield by the method of Bestian (1). A mixture melting point determination with a known (2) sample of 1,3-bis-(β-chloroethyl)-urea gave no depression.

2-(β-Chloroethylamino)-2-oxazoline Hydrochloride

1,3-Bis-(β-chloroethyl)-urea (20 g, 0.1 mole) in water (50 ml) was heated under reflux for 1 hour. After the clear solution was evaporated to dryness *in vacuo*, crystals were obtained, yield 20 g (100%). These crystals melted at 103–104° C, resolidified and remelted at 121–123° C. Three crystallizations from absolute ethanol–ether (1 : 1) solution raised the melting points to 107–109° C and 125–127° C. Anal. Calc. for $C_5H_{10}Cl_2N_2O$:

**Issued as Report No. 22 from the L. G. Ryan Research Laboratories, Monsanto Canada Limited, Ville LaSalle, Quebec.*

†*All melting points are uncorrected. The microanalyses were determined by Micro-Tech Laboratories, Skokie, Ill., and Schwartzkopf Microanalytical Laboratory, Woodside, N. Y.*

C, 32.45; H, 5.45; Cl, 38.32; N, 15.14%. Found: C, 32.77; H, 5.37; Cl, 37.86; N, 14.96%.

A picrate (m.p. 192–194° C) was formed in the usual manner from water. The product was identified by a mixture melting point determination with a known (2) sample of 2-(β-chloroethylamino)-2-oxazoline picrate (m.p. 193–194° C).

A sample of 2-(β-chloroethylamino)-2-oxazoline hydrochloride (m.p. 107–109° C and 125–127° C) was held in the molten state for 1 minute. The molten mass crystallized immediately on cooling and the crystals melted sharply at 125–127° C. These crystals no longer gave a picrate and they did not depress the melting point of a known sample of 1,3-bis-(β-chloroethyl)-urea.

2-(β-Chloroethylamino)-2-oxazoline hydrochloride (9.25 g, 0.05 mole) in absolute methanol (180 ml) was passed through a column of Amberlite IRA-400 resin (150 ml in the hydroxyl form). The column was washed with the same volume of methanol and the eluate and washings were evaporated to dryness *in vacuo* under nitrogen. The residual crystalline mass melted at 81–84° C, yield 7.43 g (100%). These crystals of 2-(β-chloroethylamino)-2-oxazoline were very soluble in water, alcohol, and acetone. Three crystallizations from acetone–hexane solution raised the melting point to 84–86° C. Anal. Calc. for $C_5H_9ClN_2O$: C, 40.40; H, 6.10; Cl, 23.85; N, 18.85%. Found: C, 39.78; H, 6.35; Cl, 23.50; N, 18.52%.

2-(β-Chloroethylamino)-2-oxazoline Hydrobromide

Gaseous hydrogen bromide was passed into a solution of 2-(β-chloroethylamino)-2-oxazoline (841 mg, 0.005 mole) in water (10 ml) until a pH of 3 was obtained. The solution was evaporated *in vacuo* at 45° C and the resulting oil crystallized on standing in a vacuum desiccator overnight, yield 1.3 g (100%). Crystallization from ethanol–ether solution gave a constant melting point of 118.5–119.5° C. Anal. Calc. for $C_5H_{10}BrClN_2O$: C, 26.17; H, 4.39; halogen, 50.27; N, 12.21%. Found: C, 26.41; H, 4.26; halogen, 49.88; N, 11.77%.

A sample of 2-(β-chloroethylamino)-2-oxazoline hydrobromide in water was converted into its picrate (m.p. 193–194° C) in 95% yield in the usual manner.

1-(β-Bromoethyl)-3-(β-chloroethyl)-urea

1-(β-Chloroethylamino)-2-oxazoline hydrobromide (76 mg, 0.00033 mole) was heated for 15 minutes in dry *o*-xylene (3 ml) to 130–140° C (temperature of the oil bath). The mixture upon cooling deposited crystals, which were collected by filtration; yield, 42 mg (55.3%). Crystallization from warm (50° C) ethanol–ether solution raised the melting point from 108.5–110° C to 109–111° C. Anal. Calc. for $C_5H_{10}BrClN_2O$: C, 26.17; H, 4.39; halogen, 50.27; N, 12.21%. Found: C, 26.02; H, 4.35; halogen, 50.30; N, 12.01%.

Cyclization of 1-(β-Bromoethyl)-3-(β-chloroethyl)-urea

1-(β-Bromoethyl)-3-(β-chloroethyl)-urea (80 mg) in water (2 ml) was heated for approximately 1 hour at 70–80° C until a clear solution was obtained. The clear solution on treatment with aqueous picric acid solution gave a 93.5% yield of 2-(β-chloroethylamino)-2-oxazoline picrate (193–194° C) which was identified by a mixed melting point determination.

VOLUME 37 MARCH 1959 NUMBER 3

A PROPOSED STRUCTURE FOR CHLOROPHYLL *d*[1]

A. S. HOLT AND H. V. MORLEY[2]

ABSTRACT

Treatment of chlorophyll *a* or methyl chlorophyllide *a* with potassium permanganate effected oxidation of the 2-vinyl group without concomitant oxidation of the cyclopentanone ring. One of the products obtained was of especial interest because its visible absorption spectrum was identical with that of a previously known, but chemically uncharacterized, pigment—chlorophyll *d*. The preparation and identification of this oxidation product as 2-desvinyl-2-formyl-chlorophyll-*a* is given and its probable identity with chlorophyll *d* is discussed in detail.

Chlorophyll *d* is a pigment which has been reported to occur in a number of species of the Rhodophyceae, a group which contains chlorophyll *a* but, at most, only traces of chlorophyll *b* (1, 2). It was first isolated and described by Manning and Strain in 1943 (2). Recently Smith and Benitez (3) obtained chromatographically pure samples and calculated the specific absorption curve by determining the magnesium content and by assuming the molecular weight to be that of chlorophyll *a* (see Fig. 1). To date its chemical constitution has not been determined nor has any useful function been ascribed to it, although there have been speculations that it may be responsible for the anomalous action spectra of photosynthesis and chlorophyll fluorescence in red algae (1).

The present work arose from some observations made in connection with studies on the allomerization of chlorophyll *a*. When the phase test intermediate of chlorophyll *a*, in acetone containing base, was treated with dilute permanganate, it was oxidized immediately. Examination with a visual spectroscope showed a "red" absorption maximum at about 675 mμ, which was characteristic of Mg-purpurin-18 (4). However, when base was omitted a gradual but different spectral change occurred; two new "red" maxima appeared at about 650 and 685 mμ. When the mixture was chromatographed, there were, besides a minor zone of unchanged chlorophyll *a*, three new zones. The pigments were designated as fractions A, B, and C, in the relative order of their position on the column, fraction C being uppermost. Each fraction gave a positive phase test which indicated that allomerization had not occurred. Most interesting was fraction A which had visible absorption spectra in methanol and in ether which were identical with those published for chlorophyll *d* (2, 3). The present communication describes fraction A and evidence to indicate that it is similar to and probably identical with chlorophyll *d*. Fractions B and C will be discussed in a subsequent communication.

The change in spectrum obtained when fraction A in isopropanol was treated with methanolic magnesium methoxide (4) is given in Fig. 2. Enhanced absorption in the

"green" and decreased absorption in the "red" are characteristic of phase-test-positive pigment (5). When aqueous or methanolic KOH was added to a pyridine or dimethylformamide solution, the intermediate was more strikingly reddish to the eye than when magnesium methoxide was added, but was far less stable.

The positive phase test indicated that ring V of this product was intact. Thus, the remaining likely sites of oxidation were the vinyl group of ring I and the hydrogen atoms at positions 7 and 8 of ring IV. The appearance of an infrared absorption band at 1675 cm^{-1} in the spectrum of the magnesium-free derivative indicated that oxidation of the vinyl group had probably occurred (Fig. 3, curve 2). On comparing the infrared spectrum with that of pheophytin *b*, it seemed likely that the extra band was due to a conjugated aldehyde group (6). Treatment with small quantities of sodium borohydride (7) yielded a product whose spectrum no longer contained the band at 1675 cm^{-1} (Fig. 3, curve 4). This compound gave a positive phase test, and possessed a visible absorption spectrum which was, for all practical purposes, identical with that of meso-methyl pheophorbide *a* (8). Such a result was consistent only with the assumption that oxidation of the hydrogen atoms at positions 7 and 8 had not occurred, since replacement of these

in meso-methyl pyropheophorbide *a* by hydroxyl groups causes the "red" maximum to shift from 658 to 667 mμ (9).

Previously, Fischer and Walter (10) had carried out studies on the oxidation of the vinyl group of magnesium-free derivatives of chlorophyll *a* using permanganate in aqueous pyridine. These workers stated that owing to the activating influence of the 10-carbomethoxy group, oxidation yielded purpurins and left the vinyl group intact. To avoid this they chose chlorin-e_6-trimethyl ester and methyl pyropheophorbide *a* as starting materials. The 2-desvinyl-2-formyl derivatives were the only compounds isolated which possessed a conjugated carbonyl group. The 2-desvinyl-2-formyl structure of fraction A and its methyl derivative (prepared from methyl chlorophyllide *a*) was confirmed when their chlorin-e_6-trimethyl esters were shown to be identical with the known compound 2-desvinyl-2-formyl-chlorin-e_6-trimethyl ester (10). The absorption of this compound in the double bond stretching region is given in Fig. 3, curve 3, and clearly shows the ester (1725 cm^{-1}) and formyl (1673 cm^{-1}) bands. The oxime was also prepared and its spectrum was found to be identical with that reported earlier (10).

The formation of the 2-desvinyl-2-formyl derivative under the conditions described was in disagreement with the results of Fischer and Walter. These workers found only the 7,8-dihydroxy derivative when aqueous acetone was used as the solvent. Another disagreement was that while the spectrum of the magnesium-free derivative of fraction A agreed well with that given for 2-desvinyl-2-formyl-methyl pheophorbide *a* (prepared by ring closure of the 2-desvinyl-2-formyl-chlorin-e_6-trimethyl ester), that of the product obtained by introducing magnesium into the pheophorbide did not agree with the spectrum of fraction A. It was reported, however, that when magnesium was removed the resulting spectrum was shifted to the "blue" relative to that of the original pheophorbide. It was thought that this product may have resulted from a secondary reaction at the 2-position.

Having shown that fraction A was a 2-desvinyl-2-formyl derivative of chlorophyll *a*, it remained to show its relationship to chlorophyll *d*. Excellent agreement of the visible absorption spectra of fraction A and its magnesium-free derivative with those of chlorophyll *d* and pheophytin *d* in ether (3) are shown in Figs. 4 and 5. Fraction A

FIG. 4. Visible absorption spectrum of 2-desvinyl-2-formyl-chlorophyll-*a* in ether (solid line) compared with published spectrum of chlorophyll *d* (3) (indicated by crosses). The spectra were adjusted to make "blue" maxima equal.

FIG. 5. Visible absorption spectrum of 2-desvinyl-2-formyl-pheophytin-*a* in ether (solid line) compared with published spectrum for pheophytin *d* (3) (indicated by crosses). The spectra were adjusted to make the "blue" maxima equal.

appeared to be identical with chlorophyll *d* in all respects. The most significant similarity was the ready interconversion of the magnesium-free derivative and a product whose properties corresponded to those of a so-called isomer of pheophytin *d*, namely, isopheophytin *d*. This product has now been shown to be the dimethyl acetal derivative; it was formed readily in the presence of methanolic hydrogen chloride, the reagent used by Manning and Strain (2) to convert chlorophyll *d* into pheophytin *d*. Total conversion back to the 2-formyl compound is effected by extracting the acetal from ether into aqueous HCl, as shown in Fig. 6. Formation of the acetal of fraction A was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

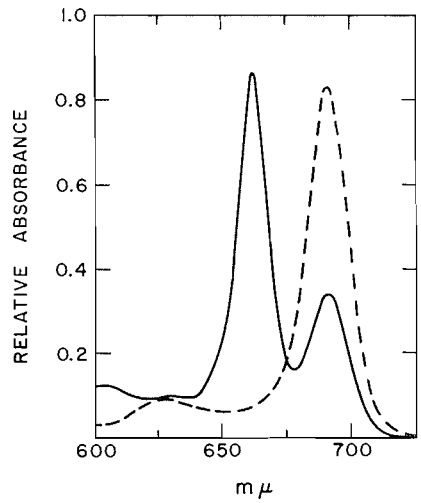

FIG. 6. Visible absorption curve of a mixture of 2-desvinyl-2-formyl-pheophorbide-*a* methyl ester in ether and its dimethyl acetal derivative. Solid line: after 1 minute exposure of the 2-formyl compound to 4.9% (w/w) methanolic HCl. Dashes: after extraction of the pigment into 20% (w/w) aqueous HCl and its transfer back into ether.

followed spectrophotometrically in methanol containing ammonium chloride (11) and resulted in an equilibrium mixture. Since the acetal of the 2-formyl-chlorin-e_6 derivative was always present in the mother liquor after crystallization, it would appear that it was formed in methanol, even in the absence of hydrochloric acid. From these findings it seems that absorption curves of 2-formyl derivatives of chlorophyll *a* should be measured in non-hydroxylic solvents, e.g. ether, to ensure that no contamination with the acetal occurs. Figure 3, curve 5, shows the double bond stretching region of the infrared absorption curve of the acetal. The carbonyl absorption band of the 2-formyl group is missing.

Although formation of the acetal of methyl pheophorbide *b* has been observed using orthoformic ester (12), it was not formed in detectable quantities in methanolic hydrogen chloride even after 24 hours. This difference in the behavior of the formyl groups at positions 2 and 3 is but one example of the non-equivalence of these positions in the phorbide nucleus. Other examples, still involving the formyl group, are as follows: (1) the carbonyl absorption band of the 2-formyl group of fraction A in chloroform absorbs at 1662 cm^{-1} (Fig. 3, curve 1), whereas that of chlorophyll *b* absorbs at 1655 cm^{-1} (6); and (2) introduction of a formyl group at position 2 of meso-methyl pheophorbide *a* causes a "red" shift and has little effect on the hydrochloric acid number, whereas its introduction at position 3 causes a "blue" shift and an increase of five in the acid number (8, 13). (The hydrochloric acid number is the percentage strength acid (w/w) which extracts about two-thirds of the pigment from an equal volume of ether solution (14).)

The probable effect of permanganate on the double bond of the phytol chain has not been mentioned. Oxidation at this point would not have affected the visible absorption spectrum but would have altered the chromatographic behavior. The product(s) formed would have been expected to be strongly adsorbed at the top of a sugar column. To test the effect of the presence of one hydroxyl group in the molecule the 2-hydroxymethyl derivative was prepared and co-chromatographed with a mixture of fraction A and chlorophylls *b* and *b'*, using the method described by Manning and Strain (2). Five zones were observed, the topmost being the firmly bound 2-hydroxy compound; further

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

down the column was the band of chlorophyll *b*, followed closely by fraction A and chlorophyll *b'*. The lowest band was well separated and was probably fraction A' (the "red" maximum in ether was at 687 mμ, as compared with 686 mμ for fraction A). The chromatographic properties of fraction A were identical with those described for chlorophyll *d* (2) making it likely that the phytol group was intact, and that fraction A and chlorophyll *d* are identical. Further support for this view is the fact that the specific absorption coefficient of the "red" absorption maximum was found to be in reasonable agreement with the value given by Smith and Benitez (3).

Unfortunately chlorophyll *d* was apparently absent from the three species of red algae which were made available to us. This was not unexpected, since conclusive demonstration of the occurrence of chlorophyll *d* in all 18 species tested by Manning and Strain (2) is lacking. *Chondrus crispus* and *Gigartina stellata* were collected fresh in the vicinity of Halifax, Nova Scotia, and were shipped immediately via air mail in iced containers. Upon their delivery, which was about eight to twelve hours later, the samples were extracted using published methods. *Rhodocorton rothii* was collected on the coast of Ireland and was delivered, in a moist condition, several days after its collection. No special storage conditions were maintained during transit. A further check upon the presence of chlorophyll *d* was the treatment of all chlorophyll pigment with aqueous hydrochloric acid to decompose any of the dimethyl acetal derivative which might have been formed from the use of methanol during extraction. It seems improbable that the condition of the first two species of red algae could have deteriorated during shipment to the extent that chlorophyll *d* was destroyed *in vivo* prior to their arrival. It is believed, however, that the successful re-isolation of chlorophyll *d*, perhaps from the original sources which were collected on the Pacific Coast of the United States of America (2, 3), will show this pigment to be a 2-desvinyl-2-formyl derivative of chlorophyll *a*.

EXPERIMENTAL

All solvents were reagent grade and were, with the exception of acetone, used without further purification. Acetone was refluxed with a slight excess of $KMnO_4$ and distilled over anhydrous K_2CO_3. Chlorophyll *a* and methyl chlorophyllide *a* were prepared as given previously (15, 16). Chlorin-e_6-trimethyl ester was prepared from chlorophyll *a* by mild hydrolysis in boiling 2% (w/v) methanolic KOH for 15 minutes, and subsequent isolation and treatment according to previous methods (17). Visible absorption spectra were measured on a Cary Recording Spectrophotometer, Model 11M; infrared absorption spectra were measured on a Perkin–Elmer Model 21, Double Beam Recording Infrared Spectrophotometer.

2-Desvinyl-2-formyl-chlorophyll-a

Chlorophyll *a* (1 g) dissolved in purified acetone (300 ml) was oxidized with freshly prepared aqueous potassium permanganate (3% w/v). About 18 ml were added in 3-ml portions with stirring during 1 hour. Samples were removed at 10-minute intervals and transferred into ether, and the course of the reaction followed spectrophotometrically. When the ratio of absorbance at 650 mμ to that at 687 mμ reached *ca.* 2.5, the mixture was poured into a large volume of ether and the manganese dioxide was removed by filtration. The filtrate was well washed with water and extracted three times with aqueous potassium hydroxide (0.5 *N*), which removed a small quantity of acidic products. After several washes with distilled water, the ether solution was evaporated to dryness under vacuum. The pigment was adsorbed on a powdered sucrose column from 1 l. of 50% (v/v) ether – petroleum ether (b.p. 30–60° C). Five hundred milliliters of 10% ether plus 5% isopropanol in petroleum ether removed unchanged chlorophyll *a* and fraction A

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

together, and left fractions B and C adhering to the column. Chlorophyll *a* and fraction A were separated later using 0.5% isopropanol in petroleum ether. Chlorophyll *a* passed into the suction flask ahead of fraction A. Fraction A was re-chromatographed and traces of impurities were removed by successive treatments with 50, 75, and 90% benzene in petroleum ether, followed by 0.5 and 1.0% isopropanol – petroleum ether mixtures. The yield was about 100 mg.

Prolonging the oxidation increased the yield of acidic products with concomitant decrease in the yields of fractions A, B, and C. No significant decrease in the ratio of absorbance at 687 to 650 mμ was noted, however.

2-Desvinyl-2-formyl-chlorophyllide-a Methyl Ester

Methyl chlorophyllide *a* (170 mg) was oxidized, and fractions corresponding to those designated above were isolated as follows: A and B were separated from C by passing the pigment dissolved in 60% $CHCl_3$ – petroleum ether mixture through a sugar column. A and B and a small amount of methyl chlorophyllide *a* passed into the suction flask. The mixture was dried and adsorbed on a fresh column from 25% $CHCl_3$ in petroleum ether and treated with 3.5% isopropanol in petroleum ether. Fraction A passed into the flask after methyl chlorophyllide *a*. It was then re-chromatographed and treated with 0.75% isopropanol plus 20% $CHCl_3$ in petroleum ether. The acid number of the magnesium-free derivative was 16.5.

2-Desvinyl-2-formyl-chlorin-e_6-trimethyl Ester

This was prepared as a reference compound by oxidation of chlorin-e_6-trimethyl ester using the method given for chlorophyll *a*. The product was isolated by the method of Fischer and Walter (10). It was also prepared by oxidation of chlorophyll *a* (0.7 g), and subsequent hydrolysis in methanolic KOH. After the transfer of the pigment mixture into ether, 15% HCl (w/v) was used to extract all pigment no longer containing phytol. This acid-extractable fraction was then esterified with diazomethane in ether. Extraction of the ether solution with 2% HCl removed the chlorin-e_6-trimethyl ester derivative of fraction C, while 5% HCl removed most of that of fraction B. The pigment remaining in the ether was evaporated to dryness and adsorbed on a powdered sugar column from 15% chloroform in petroleum ether, and treated with 10% $CHCl_3$ plus 0.7% isopropanol in petroleum ether. The sugar column was extruded and the main zone of pigment was isolated and extracted with ether. The ether solution was well washed with distilled water and evaporated to dryness. The product was crystallized from methanol containing a trace of acetone. The precipitate was removed and washed well with pentane. Two further crystallizations yielded long needles, m.p. 222–223° C. Found: C, 67.5; H, 6.15. Calculated for $C_{36}H_{40}O_7N_4$: C, 67.5; H, 6.25%.

The same compound was prepared by oxidation of methyl chlorophyllide *a* using appropriate variations of the above procedure. A mixed melting point of the products obtained from the three starting materials showed no depression. The visible absorption spectra were identical. Absorption maxima in ether: I, 691; II, 632; III, 575; IV, 545; V, 509; VI, *ca.* 480; VII, 414 mμ. Relative absorbancies: VII > I > V > IV > II > VI > III.

The oxime derivative was prepared as given by Fischer and Walter (10). Absorption maxima in ether: I, 671; II, 617; III, 564; IV, 534; V, 501; VI, 403 mμ. Relative absorbancies: VI > I > V > IV > II > III.

2-Desvinyl-2-formyl-pheophorbide-a Dimethyl Acetal Methyl Ester

The methyl ester of fraction A was dissolved in a small volume of 5% (w/w) methanolic

HCl. After 1 minute, the pigment was transferred into ether by dilution with distilled water. The pigment was evaporated to dryness after removal of acid, and adsorbed on a sucrose column from 1% pyridine in petroleum ether. The column was developed by 0.5% isopropanol in petroleum ether, and the main zone of pigment was removed after extrusion of the sugar. Absorption maxima in ether: I, 664; II, 634; III, 607; IV, 558; V, 534; VI, 505; VII, 471; VIII, 406 mμ. Relative absorbancies: VIII > I > VI = V > III > II > IV > VII.

2-Desvinyl-2-hydroxymethyl-pheophytin-a

2-Desvinyl-2-formyl-chlorophyll-*a* (5 mg) in methanol (20 ml) was treated with sodium borohydride (5 mg). After 2 minutes the "red" absorption maximum shifted from about 690 mμ to about 660 mμ. The mixture was poured into ether and was well shaken with aqueous 0.5% potassium acid phosphate, and with distilled water. The solution was evaporated to dryness and the pigment was adsorbed on sucrose from 100% benzene. The column was developed with 2% isopropanol in petroleum ether. Pigment in the main zone was isolated and magnesium was removed by dilute aqueous HCl in acetone. Absorption maxima in ether: I, 660; II, 630; III, 603; IV, 556; V, 533; VI, 503; VII, 490 mμ. Relative absorbancies: I > VI > V > III > VII > II > IV.

Determination of Magnesium Content of Fraction A

The magnesium content in 50 ml of an ether solution was determined by the method of Smith and Benitez (3). Absorbance per cm at 687 mμ: 6.60. Slope of the calibration curve at 540 mμ: 0.266 absorbance units per cm per 0.108 mg of magnesium. Absorbance of unknown at 540 mμ: 0.185, equivalent to 0.076 mg of magnesium. Weight of fraction A per 50 ml calculated using the specific absorption coefficient of Smith and Benitez: 2.99 mg. Weight calculated from magnesium determination assuming molecular weight of 895: 2.81 mg. Calculated extinction coefficient: 117.8; Smith and Benitez: 110.4 for chlorophyll *d*.

ACKNOWLEDGMENTS

The authors are very grateful to Miss C. I. MacFarlane of the Nova Scotia Research Foundation for having sent the samples of *Chondrus* and *Gigartina*, and to Dr. M. B. Allen of the Kaiser Foundation, Berkeley, California, for having sent the sample of *Rhodocorton*. Infrared absorption spectra were measured by Mr. F. Rollin. Technical assistance was provided by Mr. E. Versteeg.

A MASS SPECTROMETER WITH A LOW-TEMPERATURE IONIZATION CHAMBER

TO STUDY HETEROGENEOUS REACTIONS OF ATOMS AND FREE RADICALS: EXAMPLE, IODINE ATOMS[1]

L. P. BLANCHARD[2] AND P. LE GOFF

ABSTRACT

The main features of a mass spectrometer in which the ionization chamber can be cooled in a controlled way to the temperature of liquid nitrogen are given. Atoms or free radicals, formed in a heterogeneous quartz reactor that can be heated to 1000° C, effuse through a small hole in the wall of this reactor and enter directly into the ionization chamber. With this instrument it is possible to study the various ways in which unstable particles disappear during collisions on a metallic surface maintained at low and controlled temperatures.

The collision efficiency "*b*" of iodine atoms to form iodine molecules was found to vary between 1.7×10^{-3} and 4×10^{-3} on a surface at a temperature between +40° C and −25° C. Between −25° C and −60° C, the atoms are condensed at the same time as the iodine molecules; at lower temperatures, they are more "volatile" than iodine molecules, most of them colliding on the molecules of condensed iodine without reacting.

INTRODUCTION

In recent years an increasing number of workers have been focusing their attention on the study of atoms and free radicals trapped on surfaces maintained at liquid nitrogen or helium temperatures, but little attention has been paid to the trapping process itself.

A special mass spectrometer was designed and constructed in Nancy to study the primary process that takes place when a free radical collides with a surface at a controlled low temperature. Four possibilities must be considered in this process:

(1) that the radicals are adsorbed and trapped in the free state without undergoing any transformation;

(2) that the radicals are adsorbed on the surface but interreact to form stable molecules which immediately freeze to the surface;

(3) that the radicals are adsorbed and react as in (2) but form volatile products that leave the surface;

(4) that the radicals undergo elastic collisions with the cooled surface, while stable products are formed elsewhere by secondary reactions.

It has been reported that when the temperature of a surface on which radicals have been trapped is allowed to rise slowly, a point is reached where the radicals regain sufficient mobility to react and form stable molecules, giving off heat and sometimes light. The instrument mentioned above has been designed to study the mechanism of such reactions, since with it, it is possible to analyze directly the unstable as well as the stable products formed during the recombination–desorption process.

Operating Principle of the Instrument (See Fig. 1)

The ionization chamber of the mass spectrometer was machined out of a block of non-magnetic stainless steel that is mounted in such a way that its temperature can be lowered in a controlled manner to that of liquid nitrogen. The particles contained in a molecular jet coming from a nearby reactor are admitted to the ionization chamber through a slit "A_2" cut in one of the side walls. The present reactor is a quartz tube,

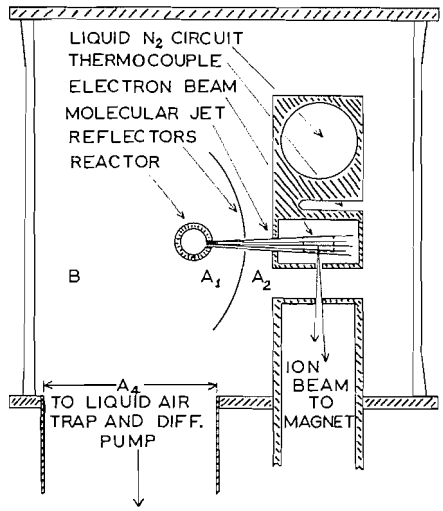

FIG. 1. Schematic diagram of the ion source. The ion source unit and the reactor are shown at a scale six times that of the bell jar enclosure.

3 mm i.d., that can be heated to 1000° C. This tube located 8 mm away from the ionization chamber contains a small orifice "A_1" through which effuse the gases of the molecular jet. The ion source and reactor assembly are located within a large bell jar, which is evacuated by a 600-liter-per-second mercury diffusion pump, and liquid-nitrogen trap.

The metallic block which contains the ionization chamber has no physical contact with the neighboring parts of the ion source: the filament (made of 0.258 mm carbon rod) is mounted on one of the pole pieces of the source magnet, while the other pole piece serves as the electron trap. Contrary to usual mass spectrometer technique, the ion source is grounded through the copper tubes of the liquid nitrogen circuit and the ion acceleration potential is applied to the magnet analyzer tube. Electrical insulation of the tube from the rest of the vacuum envelope is maintained by mineral-free synthetic rubber *o*-rings at the vacuum seals and teflon sheet elsewhere.

After deviation in the magnetic field the ion beam falls on the first copper–beryllium dynode of a 12-stage Allen-type ion–electron multiplier. The outcoming signal is fed to the vertical amplifier of a cathode ray oscilloscope. Fast scanning of the mass spectrum can be carried out by modulation of the magnet current (10 sweeps/second) or the ion acceleration potential (100 sweeps/second).

Flow and Pressure of Gases in the Ionization Chamber

A fraction of the molecular stream leaving the reactor enters directly into the ionization chamber while the complementary fraction diffuses into the bell jar.

Under usual operating conditions the following pressures are observed in the instrument: 1×10^{-2} mm Hg in the reactor, 1.1×10^{-4} mm Hg in the ionization chamber, and 1.6×10^{-5} mm Hg in the bell jar. Using the method previously described (2) for the statistical study of the fate of every molecule, an expression was found for the molecular concentration in that region of the chamber where the ionizing electron beam crosses the molecular stream. In the case of a condensable gas, with the reactor and the ion source both at room temperature, this expression is composed of two terms: one (amounting to 14% of the total concentration) which represents the "equivalent jet concentration", i.e. the molecules that have come directly from the reactor and have *not yet*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

collided with the chamber walls; the second (the remaining 86%) which corresponds to the molecules homogeneously distributed throughout the chamber and undergoing an average number of 102 collisions with the walls before leaving by a "collision" with one of the four slits.

If "b" is the probability that the particle will disappear at every collision with the walls, then the concentration C in the ionizing region is given by the following expression:

$$\frac{C}{C_0} = 0.14 + 0.86\left(\frac{T_r}{T_c}\right)^{\frac{1}{2}} \frac{(1-b)}{(1+101b)}$$

where T_r and T_c are respectively the temperatures of the reactor and of the ionization chamber and C_0 is the concentration in the case where $T_r = T_c$ and $b = 0$.

EXPERIMENTAL RESULTS

Experiments were carried out using mixtures of iodine vapor and argon, the argon serving as internal standard.

1. Spectrum of Iodine at Low Temperatures

When iodine vapor is introduced at a constant flow rate into the source through the reactor maintained at room temperature, i.e. +40° C, and the chamber is progressively cooled to lower temperatures, the following results are observed:

(*a*) *Between +40° C and −45° C* the reading of an ionization gauge located in the bell jar is constant; the I_2^+ peak decreases from 5.7 to 2.2 while the I^+ peak remains essentially constant at 1.4.* This is in fact the variation with temperature of the cracking pattern of iodine molecules.

(*b*) *Between −45° C and −70° C* the vapor pressure of iodine passes from 1×10^{-4} to approximately 1×10^{-6} mm Hg. Effectively the reading from the ionization gauge decreases and the I_2^+ and I^+ peaks fall to about 6% of their values at room temperature. It must be concluded that the condensation probability of iodine molecules on the walls varies gradually from zero to one in this temperature range.

(*c*) *Below −70° C* the condensation probability is equal to one. The remaining ionic intensities are constant and correspond to the molecules arriving in the jet directly from the reactor.

2. Dissociation of Iodine into Atoms

When the reactor is heated to 697° C, the ionization chamber being maintained at +40° C, the I_2^+ peak is observed to fall to 32% of its initial value, while the intensity of the I^+ peak remains constant. From thermodynamic data it can be assumed that the iodine molecules passing through the reactor are totally dissociated into atoms. Thus the iodine molecules observed would come solely from recombination reactions on the walls. The probability of recombination of an iodine atom at every collision has been calculated to be: 1.7×10^{-3}.

3. Freezing Experiments with Iodine Atoms and Molecules

When the ionization chamber is slowly cooled, the reactor being maintained at 697° C, the I_2^+ and I^+ peak intensities vary in a manner completely different from that observed when the reactor is at 40° C.

At first, the I_2^+ peak decreases slowly from 1.8 at +40° C to 1.6 at −40° C, then sharply to 0.3 at −70° C. The I^+ peak, on the other hand, increases from 1.2 to 1.5

*I_2^+ *and* I^+ *peak intensities are expressed as the ratio of the peak height to that of argon at each temperature.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

then decreases slowly to a value of 0.6. The fundamental difference from the first case resides in the fact that the I^+ peak maintains an appreciable intensity below $-70°$ C.

A detailed analysis of the various low temperature mass spectra has been given elsewhere (1), however the essential points of the method are as follows:

(1) The mass spectrometric sensitivity and cracking pattern of iodine having been obtained in the first experiment, the concentration of molecules at each temperature of the present case can be evaluated.

(2) By subtracting from the total I^+ peak measured that part due to the dissociative ionization of iodine molecules, the intensity of the I^+ peak due to iodine atoms is thus obtained at each temperature.

(3) By means of an iodine material balance in the ionization chamber and the assumption that the mass spectrometric sensitivity for I^+ coming from iodine atoms is constant, the concentration of these atoms in the ionization chamber at every temperature is obtained.

The experimental results are as follows (refer to Fig. 2):

(1) When the temperature drops from $+40°$ C to $-30°$ C, the iodine atom concentration decreases slowly, the collision efficiency for the recombination of iodine atoms increasing from 1.7×10^{-3} to about 4×10^{-3}.

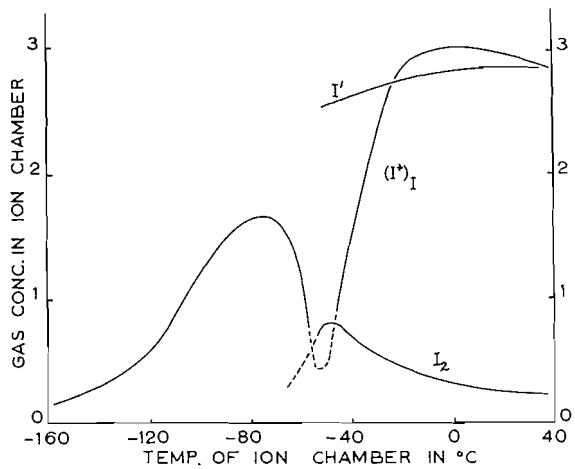

FIG. 2. Concentration variations of atomic and molecular iodine in the ionization chamber when this chamber is being cooled. Reactor at 697° C. The unit of concentration used on this graph corresponds to a pressure of 5×10^{-4} mm Hg at $+40°$ C.

(2) From $-30°$ C, the iodine atom concentration decreases sharply: iodine atoms disappear readily when they collide with the walls, *without* giving molecules which would desorb from the surface. However, it is not possible to distinguish whether the atoms are condensed in a free state within the matrix of the molecules condensing simultaneously, or whether the atoms recombine beforehand to form molecules that are immediately frozen out.

(3) When the temperature is lowered further, the iodine atom concentration presents a new maximum between $-70°$ C and $-80°$ C which would indicate that the majority of these atoms rebound from the layer of condensed iodine molecules without recombining or condensing.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

4. Defrosting Experiments

A film of iodine was condensed on the walls of the chamber:

(1) by cooling the chamber gradually, and later

(2) by introducing the vapor into a precooled source at −195° C.

Defrosting experiments showed no particular characteristics; iodine molecules alone were desorbed at the same rate and at the same temperature regardless of the reactor temperature during the freezing process.

The work described here was carried out in the laboratories of Professor M. Letort, to whom the authors are indebted for the facilities placed at their disposal. One of us (L.P.B.) wishes to thank the National Research Council of Canada for a Postdoctorate Overseas Fellowship.

THE DEHYDRATION OF UREA, BENZAMIDE, AND PHENYLUREA BY THIONYL CHLORIDE IN THE PRESENCE OF AMMONIA[1]

PAUL E. GAGNON, JEAN L. BOIVIN,[2] AND JOHN H. DICKSON[3]

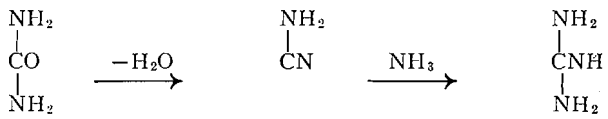
ABSTRACT

The decomposition of thionyl chloride in the presence of ammonia was found to give sulphur, ammonium sulphate, and ammonium sulphamate besides ammonium chloride. Heating urea and the reaction products of thionyl chloride and ammonia under pressure yielded guanidine hydrochloride and melamine, under different conditions of temperature, time, and pressure. Under similar conditions, benzamide was transformed into benzonitrile, and phenylurea into aniline or aniline black and diphenylurea, guanidine being absent.

INTRODUCTION

Guanidine has been synthesized from urea using various dehydrating agents, such as sulphur trioxide (1), sulphur dioxide (2), ammonium sulphamate (1), aluminum metal, or aluminum chloride (3) in the presence of ammonia or ammonium salts. In all cases, the highest yields of guanidine were obtained when the reaction was carried out under pressure (4). Since thionyl chloride is a good dehydrating agent, which reacts with water giving sulphur dioxide and hydrochloric acid, it is of interest to study its potentiality with respect to the dehydration of urea, benzamide, and phenylurea.

As the formation of guanidine is considered as an ammoniation of cyanamide, which in turn is produced by dehydration of urea:



there is an indication that guanidine would be unstable if thionyl chloride reacted alone with urea. It is known that ammonium salts or ammonia under pressure stabilize the molecule, and the effect of both will be necessary at high temperatures to prevent its decomposition into melamine (5).

Preliminary experiments carried out by heating, in a pressure vessel, urea, thionyl chloride, and ammonia which had been frozen separately in liquid air proved to be hazardous and unreliable. Therefore, to study the dehydrating properties of thionyl chloride with respect to urea and benzamide, a solution of thionyl chloride in anhydrous benzene was treated with an excess of ammonia. The yellow solid was collected and dried over calcium chloride and used without further purification. It will be called a thionyl chloride – ammonia complex since it is an ill-defined material (6, 7, 8, 9).

Thermal Stability of the Thionyl Chloride – Ammonia Complex

Since the synthesis of guanidine is best carried out under pressure, the thermal stability of the thionyl chloride – ammonia complex was studied under various conditions of temperature and pressure. It was observed that sulphur, ammonium sulphate, and ammonium sulphamate were the reaction products obtained, besides the normally

present ammonium chloride under different conditions. At atmospheric pressure over a range of temperature of 150–325° C, the yield of sulphur was nearly constant to 7.5% and there was an increase of ammonium sulphate from 0.9% at 150° C to 7.5% at 300° C and a decrease to 5.2% at 325° C, as shown in Table I. Ammonium sulphamate was obtained in maximum yield at 250° C, which decreased from 12.6 to 3.1% at 325° C.

Under an ammonia pressure of 100 and 300 p.s.i., the results were similar, but it was observed that ammonium sulphate was present in larger quantities from 275 until 350° C.

Guanidine from Urea and Thionyl Chloride – Ammonia Complex

As ammonium sulphamate is present in the decomposition products of the complex, it is expected that it could transform urea into guanidine (1). The reaction of the thionyl chloride – ammonia complex with urea was studied under various conditions of temperature, pressure, time, and ratio of reactants.

The method used consisted of mixing thoroughly urea with the dry thionyl chloride – ammonia complex and heating the mixture under normal pressure or under ammonia pressure in the autoclave. The reaction products were analyzed for sulphur, ammonium sulphate, ammonium sulphamate, guanidine, and melamine. Results are given in Table II for the reaction under 300 p.s.i. for a 30-minute period of heating.

TABLE II

Guanidine formation at 300 p.s.i. pressure for a 30-minute period of heating

325	5.7	23.5	2.1	31.2	4.5
350	5.6	7.5	1.3	17.5	3.7

At atmospheric pressure, urea was transformed into guanidine between 225° C and 250° C. The conversion of urea into guanidine reached a maximum at 275° C and then fell off sharply at higher temperatures so that no guanidine was found when the experiment was carried out above 325° C. The fact that melamine was found in place of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

guanidine at the higher temperatures indicates that the guanidine decomposed into cyanamide which trimerized into melamine. Ammonia pressure had a stabilizing effect, and the yield of guanidine was increased from 17 to 35% at 275–300° C when the pressure was either 100 or 300 p.s.i.

In the solid products, sulphur was present to a practically constant proportion of about 7.0% which, however, decreased with increasing temperatures to 5.6%. Ammonium sulphate increased proportionally with the amount of guanidine formed while the ammonium sulphamate content decreased.

With different ratios of urea at a temperature of 275° C and an ammonia pressure of 300 p.s.i., the yield of sulphur was practically constant and the production of ammonium sulphate varied directly with increasing quantity of urea used, whereas the yield of ammonium sulphamate varied inversely with the urea. When the reaction time was limited to 30 minutes, the yield of sulphur was about 7%. Between 60 and 150 minutes, it fell to 5%, but with longer periods of heating it decreased sharply and was less than 1% after 210 minutes. The proportion of ammonium sulphate in the reaction products remained constant for heating periods longer than 60 minutes. Although ammonium sulphate decomposed at temperatures above 300° C (10) during a reaction time of 30 minutes, it was quite stable at 275° C, even when heated for periods up to 3½ hours. Only traces of ammonium sulphamate were found in the reaction products under these conditions.

Guanidine and ammonium sulphate increased continuously with the reaction time up to a maximum yield of about 44%, and further heating had no apparent effect. The increase in the reaction time was unfavorable for the formation of melamine and the yield was reduced from 14.4% after 60 minutes to 10.5% after 210 minutes.

Benzonitrile from the Thionyl Chloride – Ammonia Complex and Benzamide

Since the thionyl chloride – ammonia complex was a dehydrating agent by way of the formation, on heating, of ammonium sulphamate, amides should be converted into the corresponding nitriles (11, 12). By heating the thionyl chloride – ammonia complex and benzamide under pressure, benzonitrile was obtained in only 5% yield at 175° C and more was formed as the temperature was increased until a maximum yield of 57.4% was reached at 325° C. The production of ammonium sulphate increased to a maximum of about 30% at 275° C and then decreased with increasing temperatures. A maximum yield of ammonium sulphamate was obtained at 150° C, but decreased continuously with the increase in temperature.

Products of the Reaction of Phenylurea with the Thionyl Chloride – Ammonia Complex

The reaction of the thionyl chloride – ammonia complex with phenylurea at different pressures led to a mixture of salts where aniline was present at the lower temperatures and aniline black at temperatures above 250° C. When the experiments were performed at atmospheric pressure, the highest yield of ammonium sulphate obtained was about 4% whereas the quantity of ammonium sulphamate for temperatures above 200° C was much lower. The yield of aniline, constant up to a temperature of 275° C, increased slightly at higher temperatures and was accompanied by an increase in the pressure.

An ammonia pressure of 100 p.s.i. gave rise to larger amounts of ammonium sulphamate at 150° C which decreased as the temperature was raised. Again fairly large amounts of aniline black were present up to 300° C. The ammonia pressure caused an increase in the yield of ammonium sulphate and a much higher yield of aniline which, however, decreased from 63.3% at 150° C to 22.0% at 325° C, while that of ammonium sulphate increased from 0.2% at 150° C to 7.9% at 325° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

A higher ammonia pressure of 300 p.s.i. favored the production of larger quantities of ammonium sulphate, the maximum yields being obtained at 200° and 275° C. Higher temperatures led to reduced yields. Ammonium sulphamate production was highest at the lower temperatures although the amount was a good deal lower. The maximum yield of aniline, 63.3%, was also obtained at the lower temperatures. Ammonia pressure stabilized aniline particularly at the higher temperatures where the minimum yield was found to be about 37%.

Also diphenylurea was obtained between 150 and 250° C at 300 p.s.i., in yields varying from 0.1 to 4.0%, depending on the temperature used. At pressure lower than 300 p.s.i., diphenylurea could not be isolated.

DISCUSSION OF RESULTS

The ill-defined thionyl chloride – ammonia complex was decomposed at ordinary pressure or under an ammonia pressure into sulphur, ammonium sulphate, and ammonium sulphamate. While it is difficult to account specifically for all these products, this behavior should be similar to that of sulphur dioxide and ammonia which give, by heating under pressure, ammonium sulphamate and sulphur and no ammonium sulphate (2). The fact that ammonium sulphate is present indicates that a similar oxidoreduction has taken place where ammonia reduced the chloro derivative of sulphur dioxide into sulphur giving water, which then hydrolyzed part of ammonium sulphamate into ammonium sulphate.

When urea is present, the mechanism of formation of the products sulphur, ammonium sulphate, ammonium sulphamate, guanidine, and melamine is easily explained by reactions similar to the synthesis of guanidine from urea, sulphur dioxide, and ammonia (2). In this case, urea is dehydrated into cyanamide and ammonolyzed into guanidine. Guanidine is present in the actual synthesis as the hydrochloride because of the greater solubility of this salt in liquid ammonia than the sulphamate salt, whereas guanidine sulphate is completely insoluble (5).

When monophenylurea was heated with ammonium sulphamate, aniline, guanidine, and cyanuric acid were produced (12). On heating thionyl chloride and ammonia with monophenylurea, ammonium chloride, sulphate, sulphamate, aniline, aniline black, and diphenylurea were formed. It was assumed that monophenylurea underwent ammonolysis to give urea and aniline, and also diphenylurea. It is well known that aniline, in the presence of an oxidizing agent, forms a polymer, or better a variety of polymers, grouped together under the generic name of aniline blacks, the exact constitution of which is still unknown; since free sulphur was absent, it was concluded that it had oxidized the aniline to form aniline black, sulphur being transformed into hydrogen sulphide.

The absence of urea or guanidine derivatives in the reaction products was explained by the inhibition of hydrogen sulphide to form ammonium sulphamate from the chloro derivative of sulphur dioxide.

EXPERIMENTAL

Thionyl Chloride – Ammonia Complex

Thionyl chloride (20.0 g) was added to a 1-l. flask containing anhydrous benzene (400 ml), and anhydrous ammonia was bubbled through the solution until there was no further evolution of heat. The light yellow solid which precipitated out was separated by filtration on a Büchner funnel, washed with anhydrous benzene, and dried in a vacuum desiccator over calcium chloride (yield, 30.4 g).

The dried yellow starting material (8.0 g) was added to the removable Pyrex glass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

liner of a pressure vessel which had a volume of 183 ml without the liner, and 108 ml with the liner in place. The liner was fitted with a glass wool plug, and air was displaced by the evaporation of several drops of liquid ammonia in the autoclave. The reaction vessel was then heated at the desired temperature for 30 minutes, removed from the heating jacket, and cooled rapidly.

The solid products were analyzed for sulphur, ammonium chloride, sulphate, and sulphamate (2). Ammonium sulphamate was extracted from the mixture by means of absolute alcohol in which it is slightly soluble and recrystallized to give a melting point of 131° C, which was not depressed by admixing an authentic sample.

Since it would be impracticable to give all the results obtained, the data were omitted.

Thionyl Chloride – Ammonia Complex and Urea

The yellow starting material (5.5 g), made from thionyl chloride and ammonia, and urea (3.0 g, 0.05 mole) were intimately mixed and heated as in the above method. The products were analyzed for sulphur, ammonium sulphate, ammonium sulphamate, guanidine hydrochloride, and melamine (2). Guanidine hydrochloride was isolated by absolute ethanol extraction of the dried products and recrystallized from a mixture of alcohol and acetone. It had a melting point of 184–185° C, which was not depressed by mixing with an authentic sample.

Reaction with Benzamide

The yellow starting material (5.5 g) was added to a glass liner containing benzamide (6.1 g, 0.06 mole, m.p. 130° C) which had been recrystallized. The two solid compounds were then thoroughly mixed and heated in the autoclave and cooled overnight. Caution was exercised in reducing the internal pressure to atmospheric pressure since benzonitrile could be entrained out.

Benzonitrile was determined by extraction with ether and weighing the residue. It boiled at 188–191° C and gave benzoic acid, m.p. 121° C, by hydrolysis with alcoholic sodium hydroxide. The residue which was insoluble in ether was analyzed for ammonium sulphate and sulphamate (2).

Reaction with Monophenylurea

The yellow starting material (5.5 g) and monophenylurea (6.8 g, 0.05 mole) were placed in a Pyrex liner, thoroughly mixed together, and heated in the autoclave. The solid products were analyzed for aniline, ammonium sulphate, ammonium sulphamate, and diphenylurea by extraction or precipitation with barium chloride (2).

DIALKYL PHOSPHOROISOTHIOCYANATIDATES[1]

MARSHALL KULKA

ABSTRACT

An improved method for the preparation of dialkyl phosphoroisothiocyanatidates (II) is given. These compounds (II) are labile and decompose under the influence of heat and catalysts to the corresponding alkyl thiocyanates (III). In the presence of water they hydrolyze to dialkyl hydrogenphosphates (VI) in high yield. A series of thiourea derivatives (VII) has been prepared from II and amines.

Some discrepancies have appeared in the literature regarding diethyl phosphoroisothiocyanatidate (1). The compound is referred to as a thiocyanate by some workers (2, 3, 4), and isothiocyanate by others (5, 6). There has also been a lack of harmony in regard to its properties and preparation. Saunders *et al.* (2) first reported that when diethyl phosphorochloridate (I) was heated under gentle reflux with potassium thiocyanate, diethyl phosphorothiocyanatidate boiling at 40° (13 mm) was obtained. Kosolapoff (7) pointed out that this boiling point was too low and when the English workers (3) re-examined the reaction, they found that it proceeded at room temperature to form diethyl phosphorothiocyanatidate in 50% yield boiling at 80–82° (1 mm). Other workers have employed acetone (5) and methyl ethyl ketone (4) as solvent but without improvement in yield.

Recently (5, 6) it was pointed out that the higher-boiling reaction product of I and potassium thiocyanate reacted readily with amines to form thiourea derivatives. This indicated that the product is diethyl phosphoroisothiocyanatidate (II) and not a thiocyanate. It can be assumed that II arises through a thiocyanate–isothiocyanate rearrangement which in phosphorus compounds would be expected to take place with ease.

Dialkyl phosphoroisothiocyanatidates (II) were required as intermediates in connection with a synthetic program of insecticides. For this reason a study of the preparation and properties of II was undertaken. It was found that the compound (II) could be readily prepared and in excellent yield by merely stirring a solution of I in dry benzene with ammonium thiocyanate at 20°, followed by washing with cold brine solution, drying, and cautiously distilling.

Diethyl phosphoroisothiocyanatidate (II) is a labile compound. Under the influence of heat it decomposed to a low-boiling material which appeared to be the same as that obtained by the original workers (2) and mistaken for II. The decomposition occurred very rapidly at 150°, more slowly in refluxing benzene or methyl ethyl ketone, and was catalyzed by traces of ammonium or potassium thiocyanate. The low-boiling phosphorus-free decomposition product did not react with amines but on heating with aqueous alcoholic alkali yielded diethyl disulphide and sodium cyanide, a reaction which is characteristic of alkyl thiocyanates. After an examination of the physical properties it was concluded that the decomposition product of II was ethyl thiocyanate (III, R = ethyl). In the same way di-*n*-butyl phosphoroisothiocyanatidate (II, R = *n*-butyl) on heating alone or in the presence of ammonium thiocyanate decomposed to butyl thiocyanate III, (R = *n*-butyl) and presumably butyl metaphosphate (IV).

It will be seen that II is both an anhydride and an isothiocyanate presenting at least two sites for attack. With warm water II did not react like a typical isothiocyanate. Instead hydrolysis occurred to form thiocyanic acid (V) and dialkyl hydrogenphosphate (VI) in high yield. This makes an excellent preparative method for VI. Primary amines attacked II at the isothiocyanate site to form dialkyl phosphorylthioureas shown in Tables I and II.

EXPERIMENTAL

Diethyl Phosphoroisothiocyanatidate (II, R = Ethyl)

To a stirred and cooled solution of diethyl phosphorochloridate (150 g) in dry benzene (100 ml) was added ammonium thiocyanate (75 g), and the reaction mixture was stirred at 15–20° for 5 hours. Then benzene (300 ml) was added and the reaction mixture quickly washed with cold dilute sodium chloride solution until the washings were no more acid to litmus. The benzene solution was dried over sodium sulphate, the solvent removed under slightly reduced pressure, and the colorless residual liquid distilled applying only steam heat, b.p. (1 mm) = 88°, $n_D^{23} = 1.4772$. The yield of the colorless liquid was 155 g or 91%. The pure product also distilled at 112–113° (12 mm). In a cool dark place it could be kept for several months.

Di-n-butyl Phosphoroisothiocyanatidate (II, R = Butyl)

This was prepared from di-*n*-butyl phosphorochloridate (I, R = butyl) and ammonium thiocyanate in 65% yield according to the procedure described above. The colorless liquid boiled at 104–105° (0.1 mm) and the pure product distilled at 153–155° (12 mm) with only slight decomposition, $n_D^{20} = 1.4728$. An attempt to analyze this compound for carbon and hydrogen gave erratic results as is usually the experience with phosphorus compounds.

n-Butyl Thiocyanate (III, R = Butyl)

(*a*) *From di-n-butyl phosphorochloridate.*—A reaction mixture of di-*n*-butyl phosphorochloridate (50 g), ammonium thiocyanate (30 g), and dry benzene (50 ml) was stirred and heated under reflux for 5 hours. The cooled reaction mixture was washed with water, the solvent removed, and the residue distilled, b.p. (12 mm) = 64°, $n_D^{20} = 1.4640$. The yield was 26 g. On redistillation this liquid boiled at 184–185°. These properties are identical with those of butyl thiocyanate reported in the literature (8). Anal. Calc. for C_5H_9NS: C, 52.17; H, 7.82. Found: C, 52.15; H, 7.95. The colorless odoriferous liquid contained nitrogen and sulphur but no phosphorus or chlorine, and when boiled with aqueous alcoholic potassium hydroxide yielded dibutyl disulphide and sodium cyanide.

(*b*) *Directly from di-n-butyl phosphoroisothiocyanatidate.*—A reaction mixture of di-*n*-butyl phosphoroisothiocyanatidate (14 g), dry benzene (50 ml), and ammonium thiocyanate (1 g) was heated under reflux for 3 hours, cooled, and filtered. The solvent was removed from the filtrate and the residue distilled. There was obtained two fractions, one consisting of butyl thiocyanate (5 g) and the other unchanged starting material (4 g).

Ethyl Thiocyanate

This compound boiling at 140–143° with $n_D^{25} = 1.4615$ was obtained in 85% yield as a colorless odoriferous liquid from diethyl phosphorochloridate in a manner similar to that described in section (*a*) for butyl thiocyanate and also directly from diethyl phosphoroisothiocyanatidate. The properties of this compound were identical with those of ethyl thiocyanate reported in the literature (9).

Diethyl Hydrogenphosphate (VI, R = Ethyl)

A mixture of diethyl phosphoroisothiocyanatidate (II, R = ethyl) (70 g) and water (350 ml) was heated on the steam bath with occasional swirling for 15 minutes. The aqueous thiocyanic acid was removed under slightly reduced pressure from the resulting clear solution and the residual liquid distilled, b.p. (0.2 mm) = 130–135°, $n_D^{24} = 1.4162$. These properties agree with those of diethyl hydrogenphosphate reported in the literature (10). The yield was 49 g or 89%.

A small portion of the diethyl hydrogenphosphate in alcohol solution when treated with a strong aqueous solution of lead acetate yielded white needles of the lead salt of VI (R = ethyl) which melted at 183–184°; lit. m.p. 180° (7).

Preparation of the N^1-Dialkylphosphoryl-N^2-substituted Thioureas

Method A.—Diethyl phosphoroisothiocyanatidate (II) (1 mole) was added dropwise with cooling and stirring to the amine (1 mole), the temperature being kept below 50°. The reaction product which solidified was crystallized from methanol or aqueous methanol.

Method B.—This method was essentially the same as method A except that dry benzene was used as solvent for the amine and the product usually crystallized from the benzene solution on cooling.

Method C.—This method was essentially the same as method A except that acetone was employed as solvent for the amine and the product usually crystallized from the acetone solution on cooling.

N^1-Di-n-butylphosphoryl-N^2-p-chlorophenylthiourea (VII, R = *n*-Butyl, R′ = *p*-Chlorophenyl)

This was prepared in 58% yield from di-*n*-butyl phosphoroisothiocyanatidate and *p*-chloroaniline by method B. It melted at 65–66° after crystallization from aqueous methanol. Anal. Calc. for $C_{15}H_{24}N_2O_3ClPS$: N, 7.39. Found: N, 6.94, 6.85.

$N^1,N^{1'}$-(1,4-Phenylene)-$N^2,N^{2'}$-bis(di-n-butylphosphorylthiourea)

This was prepared in 72% yield by method C from *p*-phenylenediamine and di-*n*-butyl phosphoroisothiocyanatidate. The white solid melted at 149–150°. Anal. Calc. for $C_{24}H_{44}N_4O_6P_2S_2$: N, 9.18. Found: N, 8.85.

N^1-Diethylphosphoryl-N^2,N^2-diethylthiourea

This was prepared in 65% yield by method A from diethyl phosphoroisothiocyanatidate and diethylamine. The white product when crystallized by dissolving in acetone and cooling in dry ice melted at 70–72°. When exposed to moist air it liquefied to an acidic product. Anal. Calc. for $C_9H_{21}N_2O_3PS$: N, 10.45. Found: N, 10.19, 10.56.

REACTIONS OF OXYGEN ACTIVATED BY ELECTRICAL DISCHARGE WITH BUTENE-1

J. M. S. Jarvie and R. J. Cvetanović

ABSTRACT

Reactions of oxygen activated by electrical discharge with butene-1 have been studied in a "spherical diffusion" reaction zone. When small concentrations of oxygen are passed through the discharge tube in helium as the carrier gas, and the concentration of butene-1 in the reaction zone is sufficiently high, the observed products are entirely explainable by an interaction of the ground-state oxygen atoms with butene-1. With large deviations from these conditions considerable complexities arise, and under some conditions α-butylene ozonide and its decomposition products become important and the products are then explainable without any significant participation of oxygen atoms in the process.

INTRODUCTION

The number of methods available for the production of oxygen atoms in the laboratory is limited. One of the earliest methods employed for the production of oxygen atoms was the gaseous electrical discharge in oxygen molecules (1). The other methods frequently used are the mercury-photosensitized decomposition of nitrous oxide and the photodecomposition of nitrogen dioxide, and both these methods have been used extensively in this laboratory to study reactions of oxygen atoms. With the use of the nitrous oxide technique the main features of the reactions of oxygen atoms with olefins have now been established (2). In the present work one of the olefin reactions with oxygen atoms produced by electrical discharge was studied in order to compare this method for producing oxygen atoms with the nitrous oxide and the nitrogen dioxide methods. The relatively simple reaction of oxygen atoms with butene-1 was chosen for this purpose. An experimental arrangement incorporating the usual features of a "diffusion flame technique" (3, 4) was adopted in order to minimize any tendency for the occurrence of surface reactions, and to find out at the same time whether the application of the Garvin–Kistiakowsky "Temperature Pattern Method" (5) for the determination of rate constants is suitable for this reaction.

In the reaction of oxygen atoms with butene-1, two principal products are formed, α-butylene oxide and *n*-butyraldehyde, together with smaller amounts of methyl ethyl ketone and traces of some other compounds (2). The addition products possess excess energy when formed because of the high heats of reaction and decompose if not deactivated collisionally. This fragmentation is essentially suppressed at a pressure of about 10 mm (6) and the course of the reaction is then relatively simple. In the present work, on the other hand, considerable complexities are observed, especially under certain conditions. At the same time the electrical discharge technique is widely used to generate oxygen atoms and study their reactions. It is therefore essential to emphasize its potentially complex character. The latter is due to several factors. The technique is restricted to relatively quite low pressures, and as a result the concentration of the primary reactant is also low so that secondary attacks by oxygen atoms on the products may and indeed very frequently do take place. Also, when "hot" products are formed in the primary step, as is the case in the addition of oxygen atoms to olefins, they will tend to decompose

[1]*Manuscript received September 29, 1958.*

[2]*National Research Council Postdoctorate Fellow 1956–57. Present address: Jackson Laboratory, Organic Chemicals Department, E. I. du Pont de Nemours and Company, Wilmington, Delaware, U.S.A.*

into free radicals at the low pressures, leading thus to further secondary reactions. An additional potential disadvantage of the low pressures is the difficulty of establishing whether any surface reactions occur. (In the present work any surface reactions in the reaction zone have been disregarded: it is likely that at least under some experimental conditions employed they are unimportant.) Another factor contributing to the observed complexities is the frequent presence, in addition to oxygen atoms, of other reactive or potentially reactive species, including here excess molecular oxygen when present. The object of the present work is to illustrate on the example of a reaction, the mechanism of which has been previously established by more convenient methods, some of the complexities which may be encountered in the application of the electrical discharge technique. The discussion of the obtained results is consequently more extensive than would be otherwise justifiable in view of its largely qualitative character.

EXPERIMENTAL

Apparatus

The apparatus used was an all-glass flow system. The gas flows were controlled by capillaries and needle valves (Edwards and Co.) with a constant pressure head. The pressure in the reactor was varied by means of internal capillaries of various dimensions. Helium and oxygen were passed through a liquid nitrogen trap before the discharge to remove any grease or mercury vapor in the gases, as these gave inconsistent results due to coating of the surface of the discharge tube (a quartz tube, 10 mm i.d.). An electrodeless discharge was used at microwave frequencies, supplied from a Raytheon Diatherm unit with the use of a 90% power output. The two probes were of copper wire, each a $\frac{1}{4}$ wavelength. These were placed at a distance of 22 cm from the nozzle through which the gases were discharged into a wide pyrex tube in which the reaction was carried out. The nozzle projected some distance into the reaction zone and had an orifice 0.5 mm in diameter. Butene-1 was introduced directly into the wide tube, but at a point below the nozzle to assure uniform distribution before the reaction zone was reached.

The products were frozen out in two liquid nitrogen traps and were transferred to a LeRoy still (7) at $-120°$ C and fractionated to obtain the products free of unreacted butene-1 and of any products of equal or greater volatility.

Attempts were made to measure the concentration of oxygen atoms at the nozzle by measuring the heat of recombination on a hot platinum wire, on a hot platinum wire coated with either silver or cobalt, and a silver-plated glass tip probe. It was found that all these methods gave inconsistent results so the direct measurement of the oxygen atom concentration was abandoned.

Materials

Research grade butene-1 (Phillips Petroleum Co.) was transferred to a storage volume at liquid nitrogen temperature and degassed at dry ice temperature. This was repeated several times until a pressure of 10^{-5} mm Hg was obtained.

Oxygen (People's Gas Co., Ottawa) was used without further purification. In some of the experiments extra-dry and pure oxygen (Matheson Co.) was used and it was found that the results obtained were identical with those obtained with the ordinary cylinder oxygen.

Helium (Air Reduction Co.) was passed through a liquid nitrogen trap to remove any water and was used without any further purification.

Analysis of Products

The products of the reaction after the removal of the unreacted butene-1 and of any products of equal or greater volatility in the low-temperature fractionation still

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

were passed through a gas–liquid chromotographic (GLC) column. The GLC apparatus used was modelled on that used by Callear and Cvetanović (8). The column consisted of 7.5-ft glass tubing (4 mm i.d.) packed with glass spheres passing 270 mesh with dinonyl phthalate as the liquid phase (4 g of dinonyl phthalate per 100 g of glass spheres). The column was maintained at room temperature. For some analyses a high resolution 50-ft column of $\frac{1}{4}$-in. copper tubing was used. It contained, as the stationary phase, 40 g of tricresyl phosphate per 100 g of firebrick (30–60 mesh). The products eluted from the column could be collected at liquid nitrogen temperature, and thus analyzed also by infrared and mass spectrometer.

The products of the reaction identified by these means were propionaldehyde, acetaldehyde, methyl alcohol, ethyl alcohol, *n*-butyraldehyde, α-butylene oxide, methyl ethyl ketone, and α-butylene ozonide. A sample of α-butylene ozonide was kindly prepared by Dr. T. Vrbaški using the method of Harries (9, 10).

RESULTS

The reaction of butene-1 with oxygen atoms produced by microwave discharge was found to be more complex than the corresponding reaction with oxygen atoms formed by mercury-photosensitized decomposition of nitrous oxide (2) or by photolysis of nitrogen dioxide (6). In the last two reactions *n*-butyraldehyde, α-butylene oxide, and small amounts of methyl ethyl ketone, acetaldehyde, and propionaldehyde are formed. In the present case, in addition to these compounds, ethanol and methanol and under certain conditions α-butylene ozonide and formaldehyde are also produced, and propionaldehyde is frequently formed in large amounts.

In order to obtain some insight into the mechanism of formation of these products, the pressure of butene-1, oxygen, and helium and the total pressure were varied.

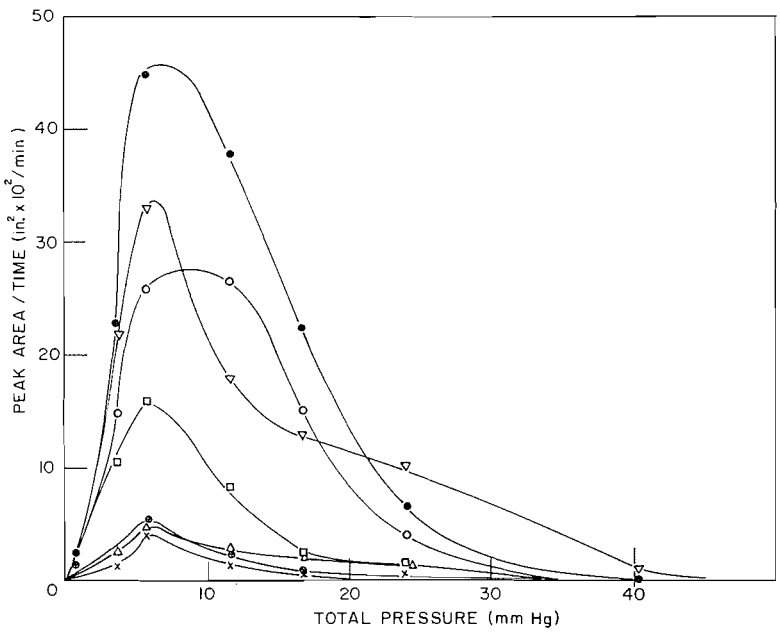

FIG. 1. Variation in the amounts of products formed per unit time with total pressure at low butene-1 flow. Oxygen flow 2.54 ml/min, helium flow 54.0 ml/min, butene-1 flow 0.75 ml/min: × methanol, △ methyl ethyl ketone, ⊕ acetaldehyde, □ ethanol, ○ *n*-butyraldehyde, ▽ propionaldehyde, ● α-butylene oxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Variation of Total Pressure

The total pressure was varied from 0 to 40 mm for both high and low butene-1 flows, using constant flows of the reactants in each case. In Fig. 1, the results obtained for the amounts of the products formed (measured as peak area per unit time from the GLC data) as a function of total pressure are shown for low butene-1 flow (0.75 ml/min). The main products are α–butylene oxide, propionaldehyde, ethanol, and *n*-butyraldehyde with smaller amounts of methyl ethyl ketone, acetaldehyde, and methanol. All the products show maxima at around 6.5 mm. It is understandable that there would be, at low pressure, a decrease in the amounts of the products formed due to recombination of the oxygen atoms on the walls of the discharge tube. However, at high pressure there was a gradual decrease in the amounts of products until at 40 mm there were essentially no products detectable on GLC. It was noted that during this gradual decrease the light intensity of the discharge appeared to decrease also. The light intensity of the discharge was therefore measured as a function of the pressure and it was found that the photocell readings showed a similar decrease to that observed above. Since the light intensity probably parallels in an approximate and qualitative manner the amount of dissociation of the molecules into atoms, it would appear that as the pressure is increased the energy available for dissociation of the molecules is reduced.

The experiments with high butene-1 flow (40 ml/min) showed the same general trends as found for low butene-1 flow and the maxima in the amounts of products were again at around 6 mm (Fig. 2). There was, however, an important difference: the amount of propanal formed remained in this case quite small, while it is one of the major products at low butene-1 flow.

Variation of Oxygen: Helium Ratio

The ratio of oxygen to helium was varied at constant pressure (3.5 mm) and constant butene-1 flow (0.75 ml/min). A plot of percentage oxygen against peak area of the products per unit time is shown in Fig. 3. The results obtained showed the same trends as before, with α-butylene oxide, propionaldehyde, *n*-butyraldehyde, and ethanol as the main products and smaller amounts of acetaldehyde, methyl ethyl ketone, and methanol. Up to about 7% oxygen there was an increase in the peak areas of each of the products, but as the percentage oxygen was still further increased (and at the same time the percentage of helium was correspondingly decreased) there was a general decrease in the amounts of the products. Since this is observed with all the products, it would appear that this effect is concerned with the initial formation of the oxygen atoms in the discharge. A possible explanation of this effect is that the efficiency of oxygen for the capture of electrons is less than that of helium, so that at high oxygen percentages the concentration of oxygen atoms is reduced.

Variation of Oxygen in the Absence of Helium

The flow of oxygen was varied from 0.80 ml/min to 25.6 ml/min in the absence of helium at a constant butene-1 flow (0.75 ml/min). The total pressure for this range of oxygen flows varied from 0.19 mm to 2.60 mm. Since the butene-1 flow was small compared to the oxygen flow, the total pressure was essentially the partial pressure of oxygen. Under these conditions it was found that the results were not reproducible. However, it was possible to note certain trends in the results. As the pressure of oxygen increased, there was an increase in the amounts of α-butylene oxide, propionaldehyde, and a small increase in the amount of acetaldehyde and methyl ethyl ketone, while amounts of ethanol and methanol decreased. Under these conditions, however, *n*-butyraldehyde was not found in the products.

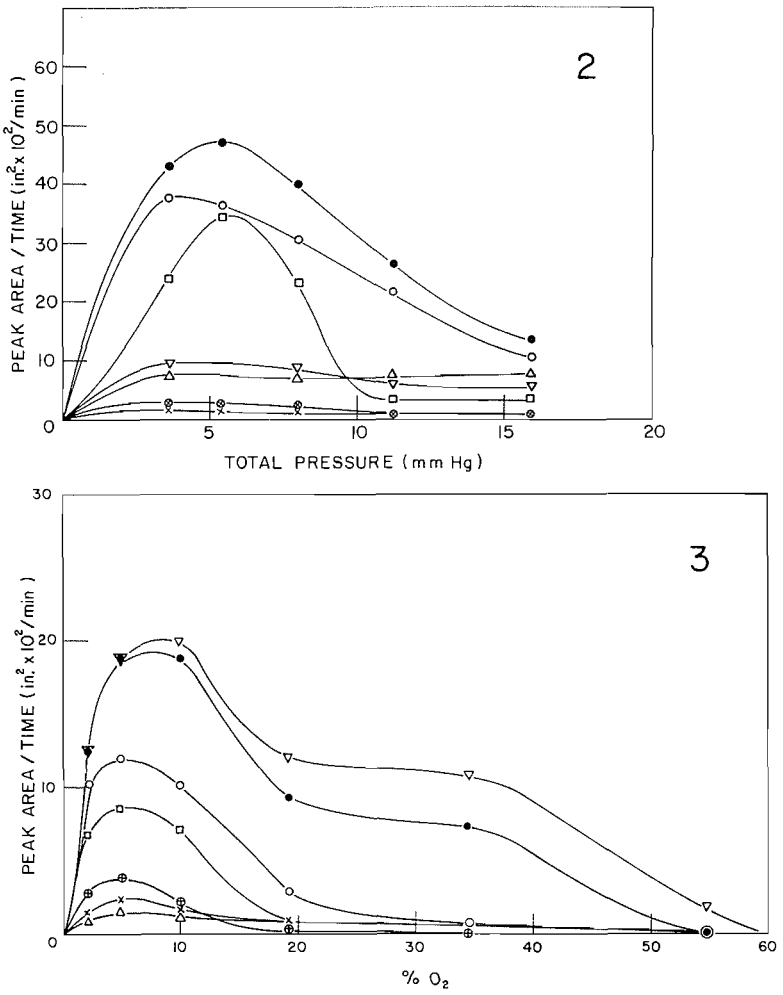

FIG. 2. Variation in the amounts of products formed per unit time with total pressure at high butene-1 flow. Oxygen flow 2.54 ml/min, helium flow 54.0 ml/min, butene-1 flow 40.1 ml/min: × methanol, △ methyl ethyl ketone, ⊗ acetaldehyde, □ ethanol, ○ *n*-butyraldehyde, ▽ propionaldehyde, ● α-butylene oxide.

FIG. 3. Plot of per cent oxygen in discharge gas against the amount of product formed per unit time. Total pressure 3.4 mm, butene flow 0.75 ml/min: × methanol, △ methyl ethyl ketone, ⊕ acetaldehyde, □ ethanol, ○ *n*-butyraldehyde, ▽ propionaldehyde, ● α-butylene oxide.

In all these experiments it was noted that a large diffuse GLC peak appeared at an elution time of about 200 minutes. This peak was collected and analyzed by infrared and mass spectra. It was found to be identical with a synthetic sample of α-butylene ozonide. Some observations on the stability and the manner of decomposition of a synthetic sample of α-butylene ozonide suggested that this compound was probably the main initial product in these experiments. It was probably formed directly from ozone and butene-1 while α-butylene oxide, acetaldehyde, and methyl ethyl ketone were formed in the course of the same reaction or together with propionaldehyde in the subsequent decomposition of the α-butylene ozonide. The absence of *n*-butyraldehyde suggested that a reaction of oxygen atoms with butene-1 was unimportant under these conditions.

Variation of Oxygen in the Presence of Helium

The partial pressure of oxygen was varied at constant total pressure (3.5 mm), constant helium flow (54.0 ml/min), and constant butene-1 flow (0.75 ml/min). The results obtained have been plotted in Fig. 4. Below 0.05 mm it was not possible to observe any products, perhaps because the small amounts of oxygen atoms formed recombined before they reached the nozzle. Above this pressure there was a steep increase in the amount of products to a maximum, and at higher partial pressures of oxygen there was a gradual decline in the amount of products formed. As was found above, propionaldehyde, α-butylene oxide, n-butyraldehyde, and ethanol were the main products with smaller amounts of acetaldehyde, methanol, and methyl ethyl ketone.

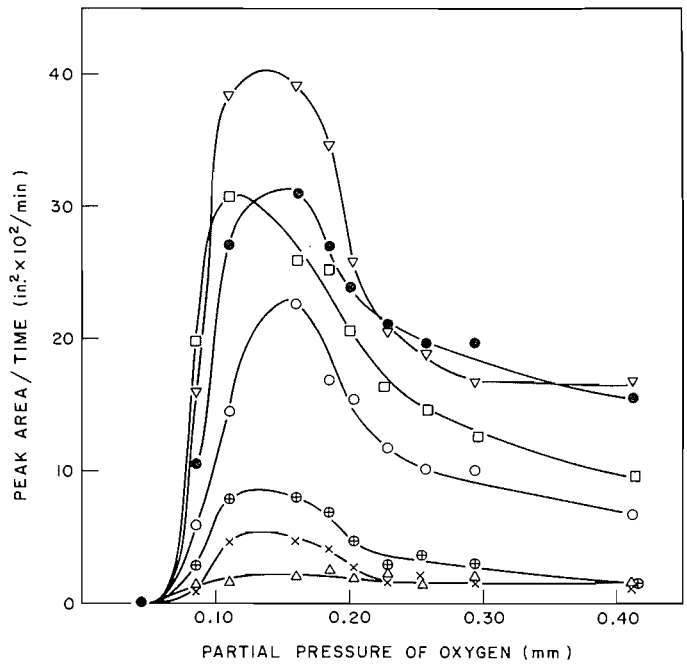

FIG. 4. Plot of oxygen pressure against the amount of products formed per unit time. Butene-1 flow 0.75 ml/min, helium flow 54.0 ml/min, total pressure 3.5 mm: × methanol, △ methyl ethyl ketone, ⊕ acetaldehyde, □ ethanol, ○ n-butyraldehyde, ▽ propionaldehyde, ● α-butylene oxide.

Variation of Butene-1

The flow rate of butene-1 was varied from 0.56 ml/min to 40 ml/min at constant flows of helium (54.0 ml/min) and oxygen (2.54 ml/min) and constant pressure (3.5 mm). A plot of the partial pressure of butene-1 against the GLC peak area per unit time is shown in Fig. 5. It is apparent from this graph that the compounds formed fall into two classes. The first class of compounds (α-butylene oxide, n-butyraldehyde, ethanol, and methyl ethyl ketone) show a steady rise in the amount formed at lower partial pressures of butene-1 and finally reach a constant value, while with the second class (propionaldehyde, acetaldehyde, and methanol) after an initial sharp increase in the amounts formed there is a gradual decrease to constant values. In order to determine whether these effects were due to a change in the discharge intensity, photocell readings were taken of the light intensities of the discharge and it was found that these remained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

constant. Thus, under these conditions the change in the amount of product formed is directly connected with the partial pressure of butene-1. At very low butene-1 flow (0.56 ml/min) a relatively large amount of water was formed, probably due to secondary attack on the compounds initially formed by excess oxygen atoms. This effect was not noted at higher concentrations of butene-1.

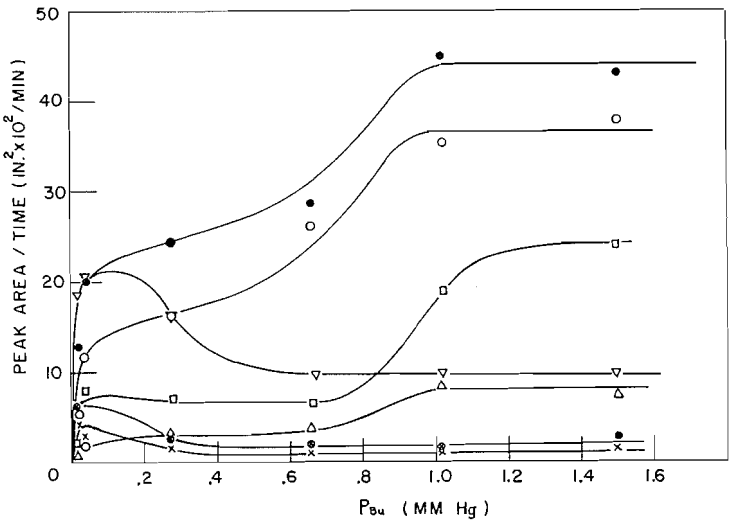

FIG. 5. Plot of butene-1 pressure against the amount of products formed per unit time. Total pressure 3.5 mm, oxygen flow 2.54 ml/min, helium flow 54 ml/min: × methanol, △ methyl ethyl ketone, ⊗ acetaldehyde, □ ethanol, ○ *n*-butyraldehyde, ▽ propionaldehyde, ● α-butylene oxide.

DISCUSSION

Since discharge is passed through oxygen and helium some distance from the nozzle, it is convenient to treat the reactions occurring in the discharge tube separately from those occurring at the nozzle, i.e. in the reaction zone where butene-1 is present as well.

The proposed reactions which are likely to occur in the discharge tube are the following:

$$\mathrm{He} + e \rightarrow \mathrm{He}^* \qquad [\phi_1]$$

$$\mathrm{O_2} + e \rightarrow 2\mathrm{O} \qquad [\phi_2]$$

$$\mathrm{O_2} + e \rightarrow \mathrm{O_2}^* \qquad [\phi_3]$$

$$\mathrm{He}^* + \mathrm{O_2} \rightarrow 2\mathrm{O} + \mathrm{He} \qquad [\mathrm{I}]$$

$$\mathrm{He}^* + \mathrm{O_2} \rightarrow \mathrm{O_2}^* + \mathrm{He} \qquad [\mathrm{II}]$$

$$\mathrm{He}^* + \mathrm{He} \rightarrow 2\mathrm{He} \qquad [\mathrm{III}a]$$

$$\mathrm{O_2}^* + \mathrm{He} \rightarrow \mathrm{O_2} + \mathrm{He} \qquad [\mathrm{III}b]$$

$$\mathrm{O} + \mathrm{O} + \mathrm{W} \rightarrow \mathrm{O_2} + \mathrm{W} \qquad [\mathrm{IV}]$$

$$\mathrm{O} + \mathrm{O} + \mathrm{M} \rightarrow \mathrm{O_2}^* + \mathrm{M} \qquad [\mathrm{V}]$$

$$\mathrm{O} + \mathrm{O_2}^* + \mathrm{M} \rightarrow \mathrm{O_3} + \mathrm{M} \qquad [\mathrm{VI}]$$

$$\mathrm{O} + \mathrm{O_2} + \mathrm{M} \rightarrow \mathrm{O_3} + \mathrm{M} \qquad [\mathrm{VII}]$$

$$\mathrm{O} + \mathrm{O_3} \rightarrow 2\mathrm{O_2}. \qquad [\mathrm{VIII}]$$

Reaction $[\phi_1]$ is probably the initiation reaction in the discharge since the efficiency for electron capture is greater in the case of helium than oxygen. When no helium is

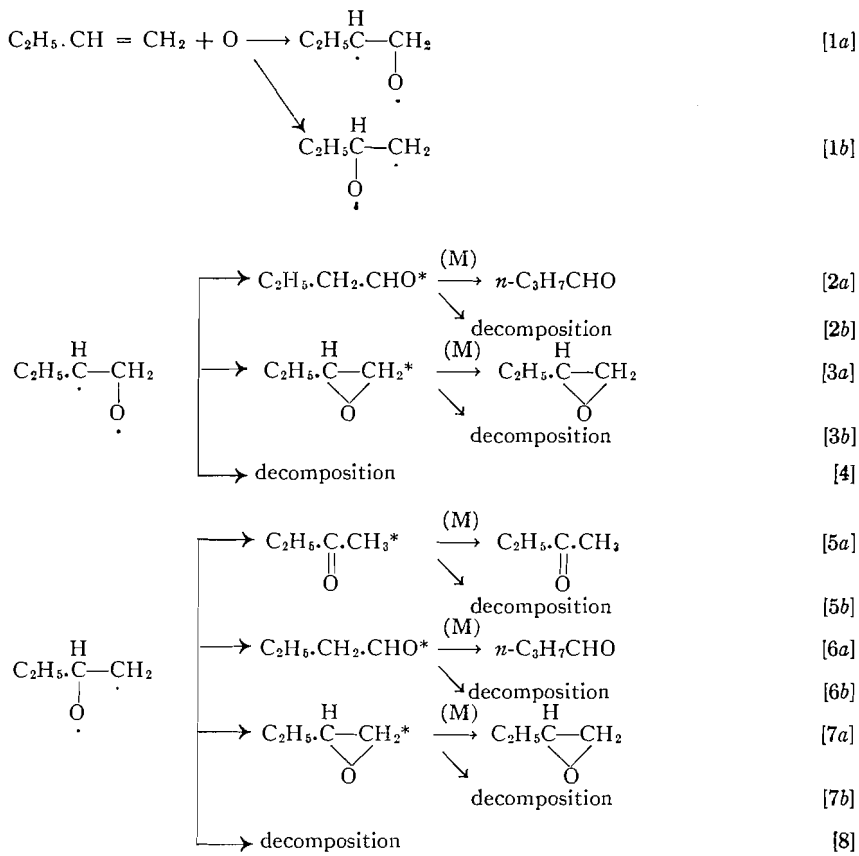
For personal use only.

present, reactions [ϕ_2] and [ϕ_3] take place giving oxygen atoms and excited oxygen molecules. Reactions [*I*] and [II] form oxygen atoms and excited oxygen molecules by transfer of energy from the excited helium. The quenching of the excited helium and excited oxygen are shown in reactions [III*a*] and [III*b*]. Reactions [IV] and [V] recombine oxygen molecules by third-body collision with the wall and other molecules, respectively. To account for the formation of ozone, reactions [VI] and [VII] are proposed. Reaction [VIII] re-forms oxygen molecules by the attack of oxygen atoms on ozone.

Of the products formed in the discharge tube the only ones which may reach the nozzle and eventually react with butene-1 in the reaction zone are: oxygen atoms, ozone, and excited oxygen molecules.

The general mechanism of reaction of oxygen atoms with butene-1 is as follows (2):



[1*a*] [1*b*] [2*a*] [2*b*] [3*a*] [3*b*] [4] [5*a*] [5*b*] [6*a*] [6*b*] [7*a*] [7*b*] [8]

where [1*a*], addition to the less substituted carbon atom of the double bond, largely predominates over [1*b*] so that considerably more n-C_3H_7CHO is formed than $C_2H_5.CO.CH_3$. There is reason to believe that pressure-independent decomposition processes, reactions [4] and [8], are not very important in this reaction (2). At pressures higher than about 10 to 30 mm the collisional deactivations in [2*a*], [3*a*], [5*a*], [6*a*], and [7*a*] are essentially complete, so that the main products are α-butene oxide, n-butyraldehyde, and a smaller amount of methyl ethyl ketone. In addition to these, even at the higher pressures, very small amounts of acetaldehyde and propionaldehyde are also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

formed (2, 6) and the mechanism of their formation is not yet known, although they may be due then to some pressure-independent fragmentation. At lower pressures the pressure-independent fragmentation processes begin to be of importance, especially so below about 10 mm. This leads to an increase in the amounts of acetaldehyde and propionaldehyde and to a decrease in the addition products (α-butene oxide, n-butyraldehyde, and methyl ethyl ketone) (6).

Disregarding for the moment methanol and ethanol, which are observed in the present work in addition to the above compounds, it is evident that under conditions of the experiments plotted in Fig. 5 (total pressure 3.5 mm, helium to oxygen ratio approximately 20) and when the partial pressure of butene-1 is sufficiently high the products formed are within the limits of experimental accuracy, quantitatively, such as would be expected to be formed in the reaction of the ground state oxygen atoms with butene-1 at the actual total pressure (3.5 mm). At such a low total pressure the pressure-dependent fragmentation is quite important and appreciable amounts of free C_2H_5 radicals and smaller amounts of free CH_3 radicals could be expected to be produced. The formation of ethanol and methanol is then explained by the interaction of these free radicals with the molecular oxygen present, as is frequently observed. Thus, in the reaction of butene-2 with oxygen atoms from the mercury-photosensitized decomposition of N_2O, the relatively large amounts of free CH_3 radicals form large amounts of methanol when some molecular oxygen is added (2). The same reaction with oxygen atoms from photolysis of NO_2 gives large amounts of CH_3NO_3 and CH_3NO_2 instead (11), because of the presence of excess NO_2. In the reaction of butene-1 with oxygen atoms from NO_2 photolysis some $C_2H_5NO_3$ has indeed been identified, suggesting the presence of free C_2H_5 radicals (the elution time of $C_2H_5NO_2$ is considerably larger than that of $C_2H_5NO_3$ and $C_2H_5NO_2$ would, therefore, not be observed in small amounts at the GLC column temperature used) (6). Similarly in the isobutene reaction very small amounts of CH_3NO_3 and CH_3NO_2 are found, suggesting formation of some free CH_3 radicals, as would be expected in this case. All this supports the proposed explanation for the formation of ethanol and methanol in the present work. The absence of these two compounds in the same reaction with oxygen atoms formed from N_2O, even when molecular oxygen is present (2), is explained by the much higher total pressures used and the consequent suppression of the pressure dependent fragmentation. In the NO_2 work, the excess NO_2 acted as free radical scavenger as already indicated, so that even at low pressures no alcohols were detected.

As the butene-1 pressure is decreased in Fig. 5, ethanol and the direct oxygen atom addition products, α-butene oxide, n-butyraldehyde, and methyl ethyl ketone, begin to decrease while propionaldehyde, acetaldehyde, and methanol increase. This suggests that under conditions of these experiments butene-1 pressure has to be relatively quite high before secondary processes are suppressed and that propionaldehyde, acetaldehyde, and methanol result at least to a large extent from secondary processes, especially so propionaldehyde. The trend in ethanol is consistent with the mechanism of its formation suggested in the preceding paragraph. It shows at the same time that the effect of decreasing butene pressure is not due (at least not predominantly so) to a decreasing efficiency of the gaseous mixture for collisional deactivation as butene concentration is lowered, since the trend in ethanol would be expected then to be the same as that of propionaldehyde, acetaldehyde, and methanol.

The foregoing explanations are supported by the difference in the composition of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

products at various pressures for a low and a high butene flow as shown in Figs. 1 and 2, respectively. In this case again, propionaldehyde, acetaldehyde, and methanol are much smaller, especially so propionaldehyde, at the high butene flow.

Relatively high butene-1 pressures necessary to suppress secondary processes even when the partial pressure of oxygen is small, as in Fig. 5, would seem to preclude quantitative use of the Garvin–Kistiakowsky's Temperature Pattern Method for this reaction, at least under conditions of the present experiments. At small butene-1 pressures, such as would be anticipated to be necessary in order not to confine the reaction to a very small region around the nozzle, considerable complexities arise. The results of the experiments at such low partial pressures of butene are shown in Figs. 1, 3, and 4. The observed complexities are difficult to explain in detail, but are likely to be of general occurrence under certain experimental conditions and may seriously affect both quantitative and qualitative studies of oxygen atom reactions. For this reason a discussion of these results may be in order.

The reasons for the general trend in the amounts of products formed with varying pressure, as shown in Fig. 1, have already been discussed. The gaseous mixture in these experiments consisted mainly of helium which is probably not too efficient as a collisional deactivator and there are no drastic changes in the character of the products formed. At higher pressure the relative increase in propionaldehyde is conspicuous. This is probably due to the simultaneous increase in the partial pressure of oxygen (the composition of the gases was kept constant while the pressure was varied). The effect of the increasing concentration of oxygen is shown better in Figs. 3 and 4. Here again the reasons for the general decline in the amounts of products formed as oxygen concentration is increased have already been discussed. Attention should now be focussed on the variation in the relative amounts of the products, and it is evident that at higher percentages of oxygen in the mixture propionaldehyde becomes relatively more important while *n*-butanal and ethanol tend to be suppressed. Roughly similar trend was observed when oxygen pressure was varied in the absence of helium. As the oxygen pressure was increased from 0.2 to 2.6 mm the amounts of α-butylene oxide and propionaldehyde increased, ethanol decreased, and *n*-butyraldehyde was not found in the products under these conditions. In these last experiments, however, the reproducibility was poor and also α-butylene ozonide was identified as an important product. This compound is unstable and the lack of reproducibility was almost certainly largely due to the varying extent of its decomposition.

The formation of α-butylene ozonide suggests an important participation of ozone in the process under these conditions. When ozone reacts at room temperature with butene-1 in the gas phase (in the presence of excess oxygen) propionaldehyde and formaldehyde appear to be the main products (12). The largely increased formation of propionaldehyde at low butene-1 and larger oxygen concentrations is probably due to this reaction. In agreement with this, under these conditions large amounts of polymerized formaldehyde were found in the liquid nitrogen trap for the collection of the products, from where samples of the polymer were directly withdrawn for qualitative identification.

The manner in which ozone is formed is uncertain. There are two general possibilities: it may be formed in and after the discharge but predominantly before the gases reach the nozzle, or it may result from the reactions which take place after the stream of gas containing oxygen atoms meets butene-1 in the reaction zone. The first possibility depends on the efficiency of reaction [VII] which competes with [VIII] and with the reverse

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of [VII]. Depending on the pressure of the gas and its efficiency as the "third body", a certain steady-state concentration of ozone should establish itself. It is not possible at present to predict with certainty whether this concentration should in a particular case be negligible compared with the concentration of oxygen atoms. The problem has been recently discussed by Herron and Schiff (13), who could not detect ozone mass spectrometrically in oxygen subjected to electrical discharge, although calculations based on literature values of rate constants of the above reactions (but for a different "third body") suggested detectable steady-state concentrations of ozone. Such calculated steady-state concentrations of ozone would be of the correct order of magnitude to be of importance under conditions of some of the present experiments.

The established formation of α-butylene ozonide cannot be regarded as a proof that ozone results directly from the discharge, since it may be, perhaps, equally well formed in the reaction zone. It is well known that under certain conditions in the atmosphere (and these conditions were simulated in the laboratory) ozone is formed in a chain reaction following an initial interaction of oxygen atoms with hydrocarbons (14). The detailed mechanism of this chain process is not known, although it appears reasonably certain that it involves initially an interaction of free radicals with molecular oxygen to form a hydroperoxy free radical. The latter, perhaps, reacts with another molecule of oxygen to give ozone. In agreement with these views it was possible to initiate ozone formation by generating free radicals in an oxygen atmosphere (14). Similar conditions can be readily envisaged in some of the experiments in the present work. Hydroperoxy radicals appear to be able also to react in some instances directly with olefins to form epoxides (15). It is evident then that explanations can be suggested for the results of some experiments in the present work, in particular to explain the formation of the ozonide, propanal, and the epoxide and the significant absence of *n*-butanal, as outlined before, without assuming any significant participation of oxygen atoms in the process (except, perhaps, in the initiation stage). Further substantial progress has to be made in this general field before a more reliable and quantitative discussion can be undertaken.

Substantial quantities of excited molecules of oxygen have been detected (13) mass spectrometrically in oxygen subjected to electrical discharge, the excited state being probably the $^1\Delta_g$ electronic state. What effect, if any, such molecules would have on butene-1 is not known. The increased formation of propanal at lower butene-1 concentrations, as shown in Fig. 5, cannot be due to excited molecules of oxygen since in this case no suppression with increasing butene-1 pressure would be expected. Under conditions of these experiments (low oxygen concentration in helium) no evidence was detected for any significant reaction of eventually present excited oxygen molecules with butene-1. Whether such molecules play a role in the experiments in which the concentration of oxygen in the discharge tube is large cannot be said at present because it is not possible to treat the results in a quantitative manner.

In conclusion, it ought to be stressed that the present work shows that under appropriate conditions oxygen atoms produced from molecular oxygen by electrical discharge lead to the same type of reaction as obtained with ground state oxygen atoms produced by mercury-photosensitized decomposition of nitrous oxide or by photolysis of nitrogen dioxide. The observed differences are understandable in view of the low over-all pressures and the excess molecular oxygen present. At the same time, considerable caution has to be exercised in the choice of the appropriate conditions when this technique is employed in order to avoid secondary processes which can sometimes completely mask the primary reactions of the oxygen atoms.

PREPARATION OF 1,5-DIPHENYLNAPHTHALENE[1]

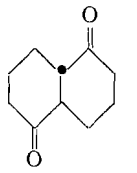
A. S. BAILEY[2]

ABSTRACT

The transformation of 1,5-dioxodecalin into 1,5-diphenylnaphthalene is described.

1-Phenylnaphthalene does not form solid complexes with the usual complexing agents (1) but has been found to form a complex with benzotrifuroxan (2). It was of interest, therefore, to prepare 1,5-diphenylnaphthalene and examine its complex-forming abilities. After this work was completed a synthesis of the hydrocarbon was reported in the literature (3).

It is stated (3) that treatment of 1,5-dioxodecalin (I, mixture of isomers) with phenylmagnesium bromide gives the glycol (III, m.p. 233–249°) in 33% yield. Under these conditions and using the pure *trans*-diketone (I) the only crystalline material isolated



I

VII

R.CH=CH.CH=CH.R

VIII

was the monoadduct (II, yield 45%), none of the glycol being formed. However, treatment of the diketone (I) with lithium phenyl gave an excellent yield of 1,5-dihydroxy-1,5-diphenyldecahydronaphthalene (III, m.p. 275–277°). The material appeared to be homogeneous and it most probably has structure (III) with the two phenyl groups equatorial. This is the most stable isomer, having the larger groups equatorial, and its formation is likely to be favored by "steric approach control" (4).

Buchta and co-workers dehydrated the glycol (m.p. 233–249°) with potassium hydrogen sulphate, affording an olefin (m.p. 117–119°, 22% yield) to which structure (IV, R = Ph) was assigned without any supporting evidence (3). By dehydrating the pure glycol (III) with formic acid, an olefin (m.p. 179–182°) has now been obtained which may have structure (IV, R = Ph), (V), or (VI); the ultraviolet spectrum of the olefin

[1]*Manuscript received October 7, 1958.*

[2]*Address during 1958–59, Royal Military College, Kingston, Ontario.*

showed λ_{max} 235 mμ (ϵ 19,300); λ_{inflex} 284 mμ (ϵ 6020); the absorption then steadily decreased (at 310 mμ, ϵ = 2400). Styrene has two absorption bands (λ_{max} 244 mμ, ϵ 12,000 and λ_{max} 282 mμ, ϵ 450) and the ultraviolet spectrum of 1-phenylcyclohexene contains only a single band (λ_{max} 247 mμ, ϵ 12,940) (5). Compounds having structures (V) or (VI) would be expected to show absorption of this type, the value of ϵ being smaller than 24,000 because of the non-coplanarity of the phenyl and reduced napththalene rings (6). This evidence suggests that the olefin obtained in this work is the conjugated diene (IV, R = Ph). The ultraviolet spectrum of (IV, R = Ph) indicates that the benzene and hexahydronaphthalene rings in this compound must be non-coplanar, since 1,4-diphenylbutadiene (VIII, R = Ph) has λ_{max} 328 mμ, ϵ 41,000 (5).

The corresponding diketone (IV, R = CO.CH_3) (7) has an absorption band at 295 mμ whose intensity (ϵ = 9020) is only one third of that of the open-chain analogue (VIII, R = $COCH_3$) which has λ_{max} 272 mμ (ϵ 31,000) and λ_{max} 279 mμ (ϵ 32,000) (8).

Dehydrogenation of the hexahydro compound using palladium–charcoal gave 1,5-diphenylnaphthalene (VII) in 80% yield as compared with the 20% obtained using sulphur (3). The ultraviolet spectra of 1-phenylnaphthalene and 1,5-diphenylnaphthalene are very similar, indicating non-coplanarity of the benzene and naphthalene rings.

EXPERIMENTAL

Ultraviolet spectra were determined in ethanol solution; infrared spectra measured in Nujol mulls unless otherwise indicated. All melting points are uncorrected.

1-Hydroxy-5-oxo-1-phenyldecahydronaphthalene (II)

To a solution of phenylmagnesium bromide (magnesium 3 g, bromobenzene 20 cc) in ether (50 cc) was added *trans*-1,5-dioxodecalin (5 g, m.p. 160°) (9) in benzene (100 cc) and the mixture refluxed and stirred for 5 hours. Next day water and saturated ammonium chloride solution were added, the aqueous layer extracted with benzene, the combined organic layers dried (magnesium sulphate), and the solvents removed. The semisolid residue was triturated with petroleum ether (10 cc, b.p. 60–80°) and then crystallized from benzene (25 cc) giving a solid (3.3 g, 45%) of m.p. 150–155°. Crystallization from benzene and then from methanol gave 1-hydroxy-5-oxo-1-phenyldecahydronaphthalene, colorless plates, m.p. 163–164° (mixed m.p. with starting material, 130–145°). Found: C, 78.4; H, 8.1%. Calc. for $C_{16}H_{20}O_2$: C, 78.7; H, 8.2%. Ultraviolet spectrum: λ_{max} 205 mμ (ϵ 9620); λ_{max} 251 mμ (ϵ 205); λ_{max} 257 mμ (ϵ 246); λ_{max} 263 mμ (ϵ 204); λ_{max} 266 mμ (ϵ 161). Infrared spectrum contained bands at 3390 cm^{-1} (OH); 1686 cm^{-1} (CO); 1600 cm^{-1} (ar. CC). The *2,4-dinitrophenylhydrazone* formed orange-colored needles (from acetic acid), m.p. 207–209°. Found: C, 62.2; H, 5.6; N, 13.4%. Calc. for $C_{22}H_{24}O_5N_4$: C, 62.3; H, 5.7; N, 13.2%. The *semicarbazone* crystallized from 2-methoxyethanol as colorless prisms, m.p. 253–255°. Found: C, 67.2; H, 7.9; N, 13.3%. Calc. for $C_{17}H_{23}N_3O_2$: C, 67.7; H, 7.7; N, 13.9%. A solution of the carbinol (1 g) in formic acid (10 cc) was refluxed for 30 minutes, the solution cooled, diluted with water, and the mixture extracted with ether. The ethereal extracts were washed with sodium carbonate solution, dried (magnesium sulphate), and the solvent removed, giving an oil whose ultraviolet absorption λ_{max} 240 mμ (ϵ 11,100) indicated that the double bond formed was conjugated with the benzene nucleus; but the infrared spectrum of the oil (natural film) contained two carbonyl bands (1710 and 1665 cm^{-1}) indicating the presence of some $\alpha\beta$-unsaturated ketone. The benzene mother liquors from the Grignard reaction were evaporated giving an oil which did not crystallize and whose infrared spectrum contained bands at 3370

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

cm^{-1}, 1692 cm^{-1}, and 1595 cm^{-1}. A portion of this oil was dehydrated with formic acid, the product isolated in the usual way and distilled up to 250° (oil bath) at 0.01 mm. The infrared spectrum of the resulting glass contained intense carbonyl bands (1715 and 1645 cm^{-1}) indicating absence of the glycol (III) in the original preparation. Ultraviolet spectrum of the glass: λ_{max} 237 mμ (ε 11,100).

1,5-Dihydroxy-1,5-diphenyldecahydronaphthalene (III)

Trans-1,5-dioxodecalin (5 g) in warm benzene (70 cc) was added dropwise to a solution of lithium phenyl prepared from lithium (1.7 g), bromobenzene (19 g), and ether (50 cc). The mixture was then stirred and boiled under nitrogen for 10 hours. Next day water and ammonium chloride solution were added, the suspension stirred for 2 hours, the solid collected, washed well with water, and dried (8.4 g, 87%), m.p. 250–255°. The glycol crystallized from 2-ethoxyethanol as colorless, hexagonal plates, m.p. 275–277°. Found: C, 81.7; H, 7.8%. Calc. for $C_{22}H_{26}O_2$: C, 82.0; H, 8.1%. Ultraviolet spectrum: λ_{max} 207 mμ (ε 21,080), λ_{max} 252 mμ (ε 417), λ_{max} 257 mμ (ε 487), λ_{max} 260 mμ (ε 417), λ_{max} 263 mμ (ε 368), λ_{max} 266 mμ (ε 278). The infrared spectrum contained bands at 3472 cm^{-1} (OH) and 1605 cm^{-1} (ar. CC).

1,5-Diphenylnaphthalene (VII)

The finely powdered glycol (2 g) was added to formic acid (25 cc) and the suspension heated under reflux (oil bath, 140°) for 30 minutes. Hot dimethylformamide (25 cc) was added, the solution boiled for 5 minutes, allowed to cool, the solid which separated collected, and washed with a little ethanol (1.3 g, 73%). After crystallization from acetic acid the product had m.p. 167–172°; crystallization from benzene gave a specimen of m.p. 179–182°. Found: C, 92.2; H, 7.3. Calc. for $C_{22}H_{22}$: C, 92.3; H, 7.7%. Ultraviolet spectrum: λ_{max} 235 mμ (ε 19,300), λ_{inflex} 284 mμ (ε 6020). Infrared spectrum 1597 cm^{-1} (ar. CC). The 1,5-diphenylhexahydronaphthalene (1.2 g) was mixed with 30% palladium–charcoal (0.2 g) (10) and heated (metal bath) at 240° for 30 minutes, the temperature of the bath was then raised to 300° (30 minutes), and finally to 330° (30 minutes), a slow stream of hydrogen being passed through the apparatus. The cold solid was extracted exhaustively with chloroform, the extracts evaporated, and the residue crystallized from benzene (0.94 g, 80%, m.p. 220–223°). 1,5-Diphenylnaphthalene formed colorless needles (from benzene) m.p. 223–224°, reported (3) m.p. 220–222°. Found: C, 94.2; H, 5.55. Calc. for $C_{22}H_{16}$: C, 94.3; H, 5.7%. Ultraviolet spectrum: λ_{max} 228 mμ (ε 48,200), λ_{max} 297 mμ (ε 14,200). The hydrocarbon did not give a solid complex with either 2,4,7-trinitrofluorenone or with benzotrifuroxan.

THE ADSORPTION OF HYDROGEN ON RUTHENIUM–ALUMINA[1]

M. J. D. Low and H. A. Taylor

ABSTRACT

The rate of adsorption of hydrogen on $Ru–Al_2O_3$ has been studied at four temperatures from 100 to 257° C at pressures from 15 to 80 cm DBP. The Elovich parameters α and a for these data have been calculated and their temperature and pressure dependencies found. It is shown that, regardless of temperature, the amount adsorbed at a given time and the parameters α and $\log a\alpha$ show a dependence on the initial pressure which is different above and below 25 cm DBP indicating different types of adsorption. The temperature dependencies yield an energy of activation for the initial rate of the high pressure chemisorption of 17.7 kcal $mole^{-1}$ which is independent of the pressure. Similar E values below 25 cm increase with a decrease in pressure. Four runs showed a very slow nitrogen adsorption on the same surface, raising the question of an enhancement of the adsorption of one gas by traces of another.

The elementary state of our knowledge of chemisorption and the lack of complete correlation with such physical factors as surface geometry or work function suggests that more attention be given to the chemical factors involved, such as the chemical reactions which may occur at surfaces contributing to chemisorption. It is obvious that, since the classical treatment of experimental data has not provided this information, new treatments and new techniques are necessary. The authors (1) have recently attempted this in a study of the chemisorption of hydrogen on nickel–kieselguhr. A variation, not hitherto observed, in the type of adsorption dependent on the initial gas pressure, independent of temperature, was discovered. That this effect is not peculiar to the nickel–hydrogen system is shown in the present study and in others which will be reported later. The accounting for the effect was given in the earlier paper. No repetition, here, is necessary, since the results presented speak for themselves.

EXPERIMENTAL

The adsorbent used was a commercial $Ru \cdot Al_2O_3$ hydrogenation catalyst weighing 15.82 g.[2] It consisted of 1.25 cm extruded Al_2O_3 pellets with 0.5% Ru on the surface and was placed in a Vycor tube in the constant-volume adsorption system described previously, in which the pressure changes during adsorption were read on a dibutyl phthalate (DBP) manometer. After 10 hours of evacuation at 500° C the pressure in the system was below 10^{-6} mm, the catalyst maintaining its original black color. Pure hydrogen was introduced and remained for 10 minutes at 500° C and 60 cm DBP pressure, followed by evacuation at the same temperature for 2 hours. This procedure was repeated six times. After the first treatment the catalyst turned grey and remained so until exposure to air occurred at the end of all the experiments, when it resumed its original color. A final treatment with hydrogen at 500° C and 30 cm Hg pressure was made for 2 hours. It was found that, after this treatment and after subsequent experiments, a pressure of less than 10^{-6} mm Hg could be attained by evacuating at 500° C for about 6 hours. A standard evacuation time of 10 hours at 500° C was adopted. The hydrogen was purified by diffusion through heated palladium thimbles. The catalyst was maintained at constant temperature by means of vapor baths.

The chemisorption rate data were treated using the Elovich equation (2),

$$dq/dt = a \exp(-\alpha q),$$

[1]*Manuscript received November 6, 1958.*
Contribution from the Nichols Laboratory, New York University, New York 53, New York, U.S.A.
[2]*Purchased from Baker and Co. Inc., Lot No. 1979. The support is* γ–Al_2O_3.

where q is the amount adsorbed in time t, a is the initial rate, and α, a constant. For large values of $a\alpha$ the integrated equation has the form (3),

$$q_{nt}-q_{mt} = (2.3/\alpha)\log(n/m),$$

where q_{nt} and q_{mt} are the volumes of gas at n.t.p. adsorbed at times nt and mt, n and m being integers. When, as in the present study, the values of $a\alpha$ are large, the closeness of approach to constancy of $(q_{nt}-q_{mt})$ for successive values of mt serves as a much more satisfactory test of the applicability of the Elovich equation than is ever possible by a linearity of a $q-\log t$ plot. Values of α are then readily obtained from the differences $(q_{nt}-q_{mt})$, and a can be calculated from the Elovich equation and the experimental points.

RESULTS

The experimental conditions of pressure and temperature and the calculated constant of the rate equations for the runs performed are summarized in Table I. The experiments were performed in the order shown in column 1. The temperature of the adsorbent T and the calculated initial pressure P_i are shown in columns 2 and 3. Column 4 lists the mean α value calculated as mentioned, and in column 5 are the average deviations in per cent of the α values found during the run. Column 6 lists the values of $\log a\alpha$ with their average deviation in per cent in column 7. Column 8 shows the initial rates, a, and column 9 the values of q_1, the calculated amount adsorbed at $t = 1$ minute.

Plots of q against $\log t$ were linear in all cases. The precision with which the Elovich constants can reproduce the experimental data is shown in Table II for two typical runs by a comparison of q_{obs} with q_{calc} calculated from the relation: $q = (2.3/\alpha)\log(1+a\alpha t)$.

Temperature and Pressure Dependencies of a and α

Inspection of Table I shows that a variety of initial pressures were used at each of four temperatures. Although these initial pressures were not identical at all temperatures they are close enough for comparative purposes. Each group of runs at nearly identical initial pressures could be used to determine the temperature dependence of a parameter, while from each group of runs at the same temperature a pressure dependence could be derived.

α–T, P Relations

Figure 1 shows plots of α values against $1/T$ for the five pressures approximating 15, 25, 30, 50, 65, and 80 cm DBP. The linearity of these plots suggested the representation of the α–T relation in the form $\alpha = u + w/T$. Since the slopes of the plots are not equivalent, the parameters u and w must be functions of the initial pressure. Plotting the values of u and w as a function of P_i as in Fig. 2, it becomes apparent that a change of slope occurs in the pressure range 25–27 cm DBP. This has been taken as a dividing mark and points at pressures above 25 cm have been taken in one group, points below 25 cm in another group, a linear dependence of u and w on P_i being assumed. In the high pressure range these dependencies are given numerically by the equations:

$$u = 33.26 - 0.0678\ P_i$$
$$w = -8710 + 10.02\ P_i$$

while at low pressures:

$$u = 90.40 - 2.322\ P_i$$
$$w = -29018 + 823.3\ P_i$$

using a least-squares method where justified by the number of points involved.

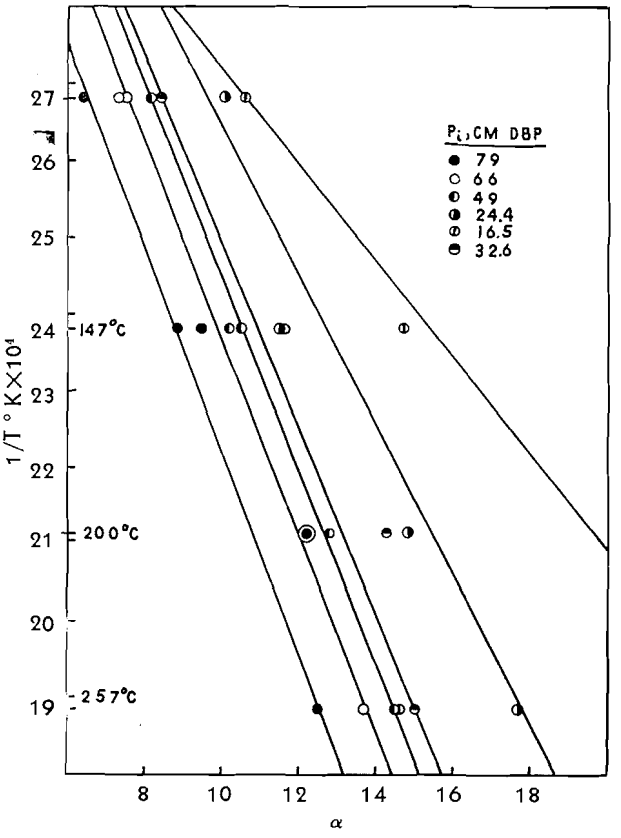

FIG. 1. Variation of α with temperature at different pressures.

log $a\alpha$–T, P Relation

In a similar manner $\log a\alpha$ is found to be linear in $1/T$ and is expressible by the equation:

$$\log a\alpha = r + s/T.$$

The terms r and s are found to be pressure dependent and show a similar linear dependence above and below 30 cm to that found for α. The following equations give the numerical dependencies:

high pressure: $r = 35.05 - 0.0456\ P_i$
$-s = 9513 - 10.52\ P_i$
low pressure: $r = 85.96 - 2.03\ P_i$
$-s = 28421 - 7585\ P_i$.

The change in the pressure dependence of both α and $\log a\alpha$ in the neighborhood of 25 cm is also reflected in the actual volumes of gas adsorbed at a given time q_t, when considered as a function of the initial pressure, P_i. Figure 3 illustrates this at 257° C where q_t values for 2, 10, and 100 minutes are plotted as a function of P_i. In each case there is an abrupt change of slope around 25 cm. Plots at the other temperatures show a similar effect at the same pressure irrespective of the temperature. Again, it was shown previously (1) that the energy of activation E as conventionally calculated may be related to the quantities represented here as w and s by the relation, $E = Rwq - sR$,

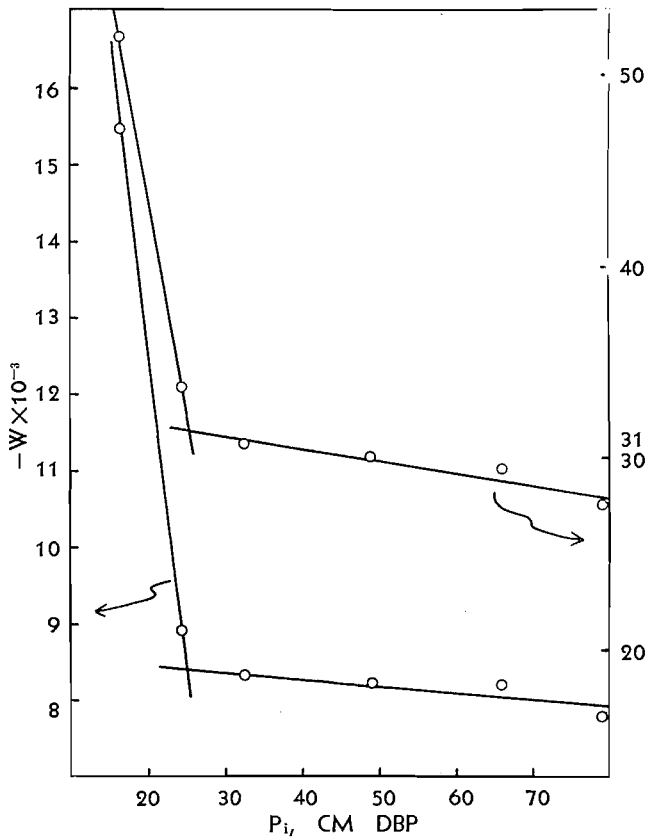

FIG. 2. Variation of w and u with initial pressure.

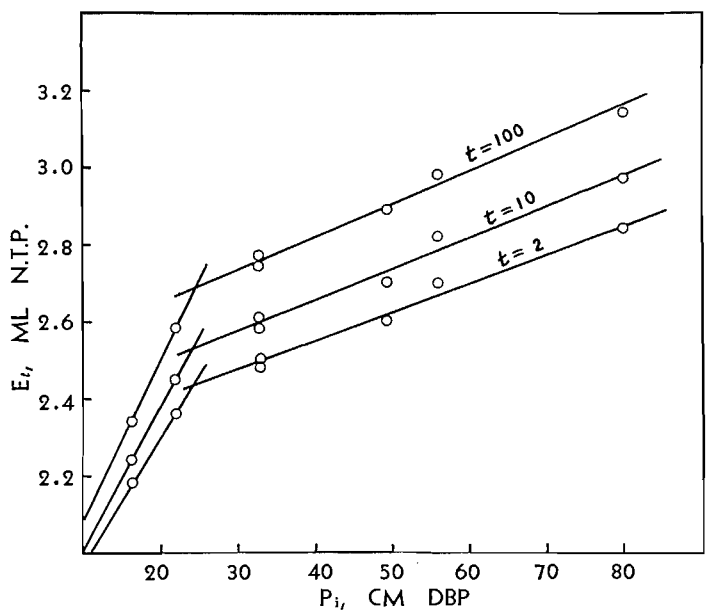

FIG. 3. Variation of q_t with initial pressure.

where R is the gas constant. Table III presents these various values in kcal/mole for the several initial pressures. Figure 4 shows the variation of $(-sR)$ as a function of the initial pressure. Although there is some scatter to the points there is distinct evidence of a change in pressure dependence around 25 cm. From the previous relation it is seen that $(-sR)$ is a measure of the energy of activation, E, at $q = 0$. It is essentially an extrapolated value for E at the beginning of the slow adsorption. In Fig. 5 are plotted values of J as a function of the initial pressure, derived by expressing the temperature dependence of the initial rates, a, by the relation, $\ln a = I + J/T$. If the initial rate of the slow adsorption, a, is Arrhenian, its energy of activation, E_a, should be given by $E_a = -JR$, where R is the gas constant. The similarity of Figs. 4 and 5 showing the change in slope at the same pressure, with an apparent independence of pressure above the break, becomes quantitative in the high pressure range. From Fig. 4 the high pressure value of $E_{q=0}$ is 17.7 kcal/mole. From Fig. 5 the high pressure value of J is -8800 yielding E_a as 17.6 kcal/mole. The agreement of these two values of E is, of course, necessary and only indicates consistency in the alternative treatments, on the one hand of a alone, on the other, of α and $a\alpha$. The agreement, nevertheless, provides some confirmation of the form of the temperature dependencies of α and $a\alpha$ used. The independence of initial pressure on the part of $E_{q=0}$ above 25 cm DBP contrasts with the marked dependence below 25 cm. This in itself is significant that two different adsorption processes are involved.

TABLE III

Data for activation energy

P_i	$-w$	$-s$	$-Rw$	$-sR$	$s/w = q_{E=0}$
79	7789	8836	15.48	17.56	1.13
66	8220	8880	16.33	17.64	1.08
49	8234	8432	16.36	16.75	1.02
32.6	8325	9518	16.54	18.91	1.14
24.4	8929	9914	17.74	19.70	1.11
16.5	15433	15906	30.67	31.61	1.03

Although E is positive for $q = 0$, it may be seen from Table III that as adsorption proceeds, E will rapidly become negative. As pointed out previously, therefore, E has no significance when calculated from values taken during the course of adsorption and its apparent variation during adsorption is no valid argument for "surface heterogeneity". It should be pointed out that in the present study, as in the earlier study on nickel, the temperature range covered corresponds to a decreasing total adsorption with increasing temperature. This may be seen from Fig. 6, which plots the amounts adsorbed after 100 minutes for the different temperatures and initial pressures. Although these are not strictly saturation values for the surface, so very little more gas is adsorbed after 100 minutes that they approximate saturation values. Thus in run 1134, 3.23 ml

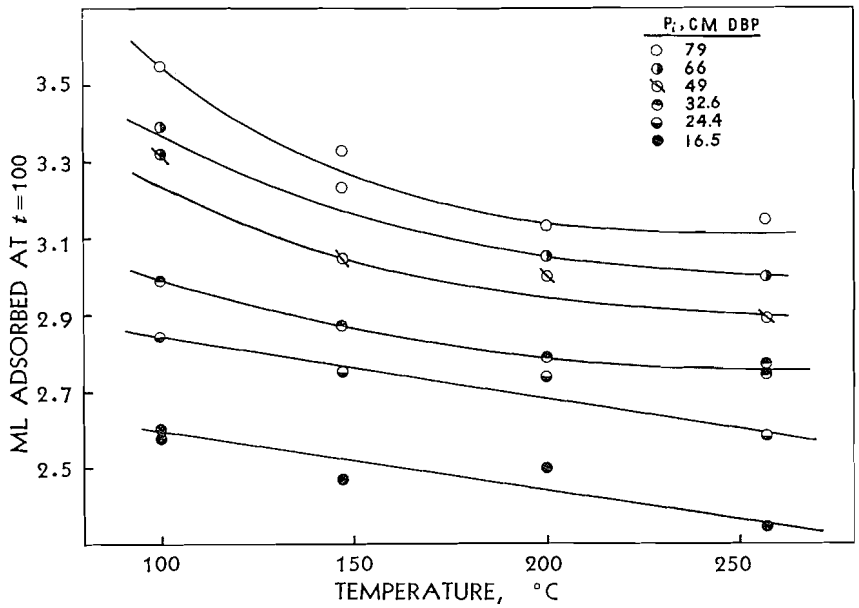

FIG. 6. Variation of the amounts adsorbed after 100 minutes with temperature at different initial pressures.

are adsorbed at 100 minutes, and 3.35 ml at 975 minutes. In run 1136 whereas 2.47 ml are adsorbed at 100 minutes only 2.60 ml are adsorbed at 1710 minutes. There is every indication at each pressure studied that the total adsorption is diminishing with increasing temperature. This contrasts with the classical studies of the variation of energy of activation of adsorption with coverage wherein the temperature range studied was restricted to regions in which the isobars increased with increasing temperature. It is not inconceivable that the well-known variation of the equilibrium amount adsorbed as a function of temperature, initially high at low temperature, decreasing to a minimum, rising to a maximum, and decreasing steadily thereafter as the temperature is increased, may simply reflect changes in the values of α associated with changes in the adsorption process.

Nitrogen Adsorption

At the conclusion of the experiments with hydrogen four exploratory runs were made using nitrogen. At 100° C and 257° C a definite but very slow adsorption of nitrogen was found to occur. The data are shown graphically in Fig. 7. Owing to the slow adsorption, the precision of the experiments was very poor and further investigation was abandoned. The results obtained, nevertheless, appear to confirm the views expressed by Amano and Taylor (4) that ruthenium should be included in group A of Trapnell's (5) classification as capable of adsorbing nitrogen. However, Trapnell's classification was intended for the pure metal films and may not apply to commercial catalyst preparations. Amano and Taylor found that in each initial run with each catalyst where there had been no previous contact with ammonia there was an anomaly in the rate of ammonia decomposition. Further, "between individual runs the catalyst was reduced for 2 hours at 450° C in hydrogen. After each such reduction the rate of decomposition rose gradually." The parallel situation in the present work with ruthenium after long use for hydrogen adsorption and possibly containing traces of unremoved hydrogen with

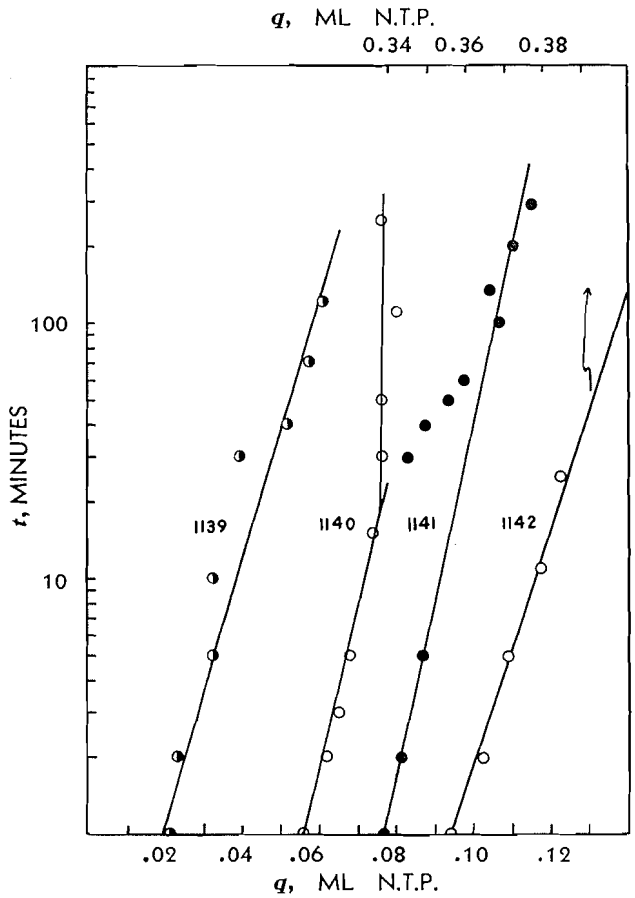

FIG. 7. Adsorption of nitrogen. 1139: P_i = 59.8 cm; 257° C; 1140: P_i = 73.1 cm; 257° C (displaced by +0.02 ml); 1141: P_i = 35.7 cm; 257° C (displaced by +0.04 ml); 1142: P_i = 59.4 cm; 100° C.

that of Amano and Taylor with a purposeful hydrogen treatment is obvious. It suggests that the small nitrogen adsorption may be facilitated by the presence of hydrogen. A similar effect was found by Gundry (6), who observed no nitrogen adsorption on clean nickel films but a small nitrogen adsorption in the presence of traces of hydrogen. The conclusion is obvious that the presence of hydrogen can create sites for nitrogen adsorption that are not already present on the clean metal or which nitrogen cannot make for itself. Considerable further study of the effects of traces of one gas on the adsorption of another, not alone from the point of view of poisoning but particularly for the possibility of enhancement of adsorption, is necessary for a complete understanding of the functions of the gas and the surface in chemisorption.

VIBRATIONAL SPECTRA OF NAPHTHALENE-d_0, -α-d_4, AND -d_8 MOLECULES[1]

S. S. MITRA[2] AND H. J. BERNSTEIN

ABSTRACT

The infrared and Raman spectra of the naphthalene-α-d_4 molecule have been obtained. The spectra of the d_0 molecule have also been repeated and for the most part previous measurements have been confirmed. Together with the literature data for the naphthalene-d_8 molecule, a complete assignment has been presented for all three molecules. It is recognized that the assignment is not definitive, although satisfactory agreement with the requirements of the band polarizations and contours, as well as product and sum rules, has been obtained. The calculated and observed values for the heat capacity and entropy are also in good agreement.

1. INTRODUCTION

A large amount of experimental work has been reported on the vibrational spectra of naphthalene and naphthalene-d_8 molecules. The present position has been summarized in three recent communications (1, 2, 3) (henceforth referred to as I, II, and III respectively), along with the presentation of three independent sets of assignments. Manneback (4) has given a theoretical discussion of the planar skeletal vibrations of the molecule. Calculations of vibrational frequencies using force constants transferred from benzene have been given by Brandmüller and Schmid (5) for the symmetrical A_g class, and by Scully and Whiffen (6) for the out-of-plane vibrations, A_u, B_{1u}, B_{2g}, and B_{3g}.

In the present investigation we have obtained the infrared[3] and Raman spectra of the intermediate α-d_4 compound, and along with the data on the d_0 and d_8 molecules, a complete assignment for all the three molecules has been attempted. Additional bands not used as fundamentals have been explained as combination tones.

2. EXPERIMENTAL

The photoelectrically recorded spectra of naphthalene and α-naphthalene-d_4[4] were obtained using a White Raman grating spectrometer (8). Mass spectrometric analysis of the d_4 sample gives its composition as 0.8, 10.6, 8.4, 70.4, 8.9, and 1.0%, respectively, for the $1D$, $2D$, $3D$, $4D$, $5D$, and $6D$ molecules. The Raman spectra are shown in Figs. 1 and 2.

The infrared spectra of the two compounds were measured on a Perkin–Elmer Model 12C double pass spectrometer equipped with CsBr, NaCl, and LiF optics. The infrared spectra were recorded for solutions in CS_2 and CCl_4 (about 1 M by volume). Comparison with a spectrum of a less pure sample of the α-d_4 compound enabled us to eliminate some of the bands not belonging to the d_4 molecule. The infrared spectra are shown in Figs. 3 and 4. The experimental data are tabulated in Table I.

The Raman and infrared data of Lippincott and O'Reilly (1) and Luther *et al.* (3) were used for the d_8 compound, except for the CsBr region where the spectrum has been carefully re-examined for reasons given in Section 4.

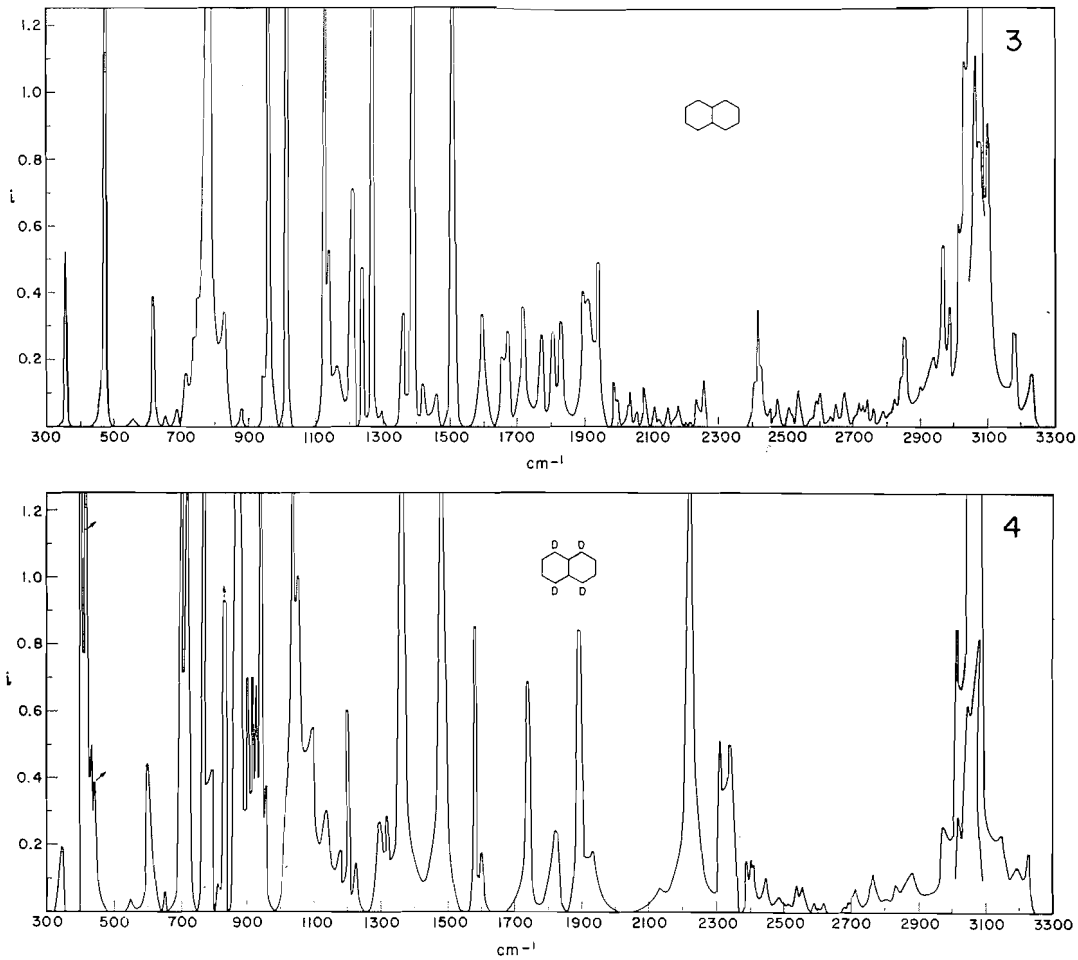

FIG. 3. Infrared spectrum of naphthalene in solution. 300 cm^{-1} to 700 cm^{-1}: solution in CCl_4 (CsBr prism); 700 cm^{-1} to 850 cm^{-1}: solution in CS_2 (NaCl prism); 850 cm^{-1} to 2000 cm^{-1}: solution in CCl_4 (NaCl prism); 2000 cm^{-1} to 3300 cm^{-1}: solution in CCl_4 (LiF prism). Intensities have been calculated for a 1 M solution and 1 mm path length except for the region 2000 cm^{-1} to 3300 cm^{-1} where the path length is 2.7 mm.

FIG. 4. Infrared spectrum of naphthalene-α-d_4 in solution. Conditions are the same as in Fig. 3. Intensities are calculated for a 1 M solution and 1 mm path length as usual, except for the region 2300 cm^{-1} to 3300 cm^{-1} where the path length is 2.7 mm. The arrows indicate bands due to the presence of other isotopically substituted species.

3. DISCUSSION

All three molecules belong to the D_{2h} point group. Each has 48 fundamental modes of vibration, of which 24 are Raman active, 20 infrared active, and 4 are completely inactive. Since the center of symmetry is a symmetry element of the D_{2h} point group, the mutual exclusion principle holds. In assigning the fundamentals the following points have been kept in mind.

(i) The frequencies of a particular mode in the three molecules should be in the order $d_0 > d_4 > d_8$.

(ii) The frequencies should lie in the spectral regions characteristic of the different types of vibrations, and should be consistent with the isotope ratio (R) associated with the type of vibration (1).

*p = polarized, d = depolarized.

†For rest of the infrared and Raman data on naphthalene-d_8 see ref. 1.

(iii) The Teller–Redlich product rule should be obeyed.

(iv) The frequency sum rules (9, 10) should be obeyed. In this particular case the application of these rules means for a particular symmetry class

$$\Sigma\nu(d_4) = (\Sigma\nu(d_0)+\Sigma\nu(d_8))/2$$

and

$$\Sigma\nu^2(d_4) = (\Sigma\nu^2(d_0)+\Sigma\nu^2(d_8))/2.$$

The assignment should be consistent with:

(v) the polarization of the Raman lines in the molten phase, and with the polarization of the infrared bands of single crystal samples (for this point see refs. 1, 2, 3; and also Person, Pimentel, and Schnepp (11); and Pimentel, McClellan, Person, and Schnepp (12));

(vi) the contours of the infrared bands in the gaseous phase (3, 11);

(vii) the intensity of the bands;

(viii) the calculations of Brandmüller and Schmid (5), and Scully and Whiffen (6);

(ix) the trends calculated by Manneback (4) for the skeletal modes; that is, the frequencies should be in the following increasing order:

$$A_gB_{3u}A_gB_{3u}\ldots.$$

$$B_{2u}B_{3u}B_{2u}B_{3u}\ldots$$

$$A_gB_{1g}A_gB_{1g}\ldots.$$

$$B_{2u}B_{1g}B_{2u}B_{1g}\ldots;$$

For personal use only.

(x) the experimental values of the heat capacity and entropy of gaseous naphthalene.

As we do not possess any single crystal or gas phase infrared spectra of the d_4 compound, for assigning the infrared modes of this molecule, criteria (v) in part and (vi) could not be used. Criterion (x) could be used only for the d_0 compound, since no experimental data on the thermodynamic properties of the d_4 and d_8 compounds exist.

4. INFRARED ASSIGNMENT

The band polarization measurements in the solids, and band contours in the gas phase spectra, decide unambiguously the species of many bands. The intensity and position aid in identifying the bands with particular vibrations. Our infrared assignments do not differ very much from those of McClellan and Pimentel (2). The bands for the intermediate d_4 molecule have been selected chiefly from intensity considerations and requirements of the product rule ratio and sum rules.

B_{1u} Class

McClellan and Pimentel's assignment of the four B_{1u} fundamentals for the d_0 and d_8 compounds is in complete agreement with Scully and Whiffen's predictions. We have accepted this assignment and have tried to choose four reasonable intermediate frequencies for the d_4 compound. From intensity considerations the band at 874 cm^{-1} is the only possibility for ν_{22}. In the case of ν_{23}, there are three strong bands of the d_4 molecule with frequencies intermediate between 782 cm^{-1} (d_0) and 626 cm^{-1} (d_8). A Fermi resonance has been assumed to occur between the pair at 729 cm^{-1} and 775 cm^{-1}, and the band at 710 cm^{-1} is considered to be a combination. A rough center-of-gravity calculation predicts the position of the unperturbed bands at 740 cm^{-1}. One of these is assigned as ν_{23} and the other a combination band of species B_{1u}. As the band at 407 cm^{-1} of the d_4 molecule is the strongest in that vicinity, it had to be selected as ν_{24}. However, if one accepts the reported (1) value of 408 cm^{-1} for the fundamental of the d_8 molecule, the criterion (i) of Section 3 is obviously violated. This suggested that a re-examination of the d_8 spectrum in this region would be worthwhile, and indeed, the position was measured at 404 cm^{-1} instead of 408 cm^{-1}. As no data below 300 cm^{-1} are available for the d_4 and d_8 compounds, values of 172 cm^{-1} and 163 cm^{-1} are estimated for the ν_{25} fundamental in these molecules.

B_{2u} Class

For the B_{2u} species our choice of ν_{31} (CC stretch) for the d_8 molecule is different from that in II. The chief criticism of the choice of the 1440 cm^{-1} band in II is that it is not observed in solution spectra of d_8, whereas the corresponding 1592 cm^{-1} band of the d_0 compound is a relatively strong band. Instead, we have chosen the fairly strong 1540 cm^{-1} band as ν_{31} in the d_8 compound. In I, the band at 1540 cm^{-1} has also been used instead of 1440 cm^{-1}. With reasonable choices for the CH and CD valence modes, the complete B_{2u} assignment is consistent with product and sum rules.

B_{3u} Class

Our assignment for the B_{3u} class differs from that of II only in two places, ν_{45} and ν_{47}. Instead of their 1143, 905 cm^{-1} pair for the ν_{45} mode in the d_0 and d_8 molecules we have preferred the 1210, 946 cm^{-1} pair. The chief reason is that the 1210 cm^{-1} band is stronger than the band in the 1140 cm^{-1} region of our spectrum of the d_0 compound in solution. For the ν_{47} mode we have chosen the 877, 756 cm^{-1} pair instead of the pair 742, 680 cm^{-1} adopted in II. Although both the 877 cm^{-1} and 742 cm^{-1} bands are observed in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

solution, only the former is observed in the gas phase. Moreover, according to Person, Pimental, and Schnepp (11) the best choice of symmetry class for the 877 cm^{-1} band is unambiguously B_{3u}, whereas that for the 742 cm^{-1} band is either B_{1u} or B_{3u}. Further the 680 cm^{-1} band is not observed in solution spectra of the d_8 compound but the band at 756 cm^{-1} is. This assignment thus coincides with I. Our assignments of the CH and CD valence modes are essentially similar to those of II.

5. ASSIGNMENT OF RAMAN FREQUENCIES

A_g Class

For assigning the Raman active A_g modes Brandmüller and Schmid's theoretical calculations are a good guide. All the intense and polarized bands observed in the Raman spectra are included in this class. Our assignment does not differ essentially from II. Corresponding strong and polarized bands of the d_4 compound could be identified and were assigned to the A_g species. Instead of the 1240, 1006 cm^{-1} pair we have preferred that at 1158, 929 cm^{-1} for one of the CH and CD bending modes in the d_0 and d_8 molecules. As neither of the bands (1240 or 1158 cm^{-1}) are polarized, one cannot have an unambiguous choice. Lippincott and O'Reilly's argument in favor of Fermi resonance between the two strong bands at 1379 cm^{-1} and 1460 cm^{-1} in the d_0 molecule has been accepted. Our estimated position for the unperturbed band, however, is 1405 cm^{-1} instead of their value of 1393 cm^{-1}, because the corresponding band of the d_4 compound is situated at 1397 cm^{-1}. Moreover, a rough center-of-gravity calculation with the observed intensities of the two bands in question also requires a higher value.

B_{1g} Class

Following II, the 1624, 1573 cm^{-1} pair has been assigned to the CC stretching frequency ν_{16}; but as we have not observed any corresponding line in the d_4 molecule, a value of 1610 cm^{-1} has been estimated for this mode in the intermediate compound. Since in our Raman spectrum of the d_0 compound no line has been observed at 1586 cm^{-1}, it has not been included in the present assignment. Instead, the 1483, 1451, 1408 cm^{-1} system has been chosen as the ν_{17} CC stretching mode in the d_0, d_4, and d_8 molecules respectively. Moreover, the 1451 cm^{-1} band of the d_4 compound clearly shows depolarization. Of the two CH in-plane deformation modes ν_{18} and ν_{20}, ν_{18} has been assigned as in II. A corresponding line at 1410 cm^{-1} was observed for the intermediate compound, which appears to be depolarized. In the case of ν_{20}, the 1145 cm^{-1} line of the d_0 molecule (being clearly a depolarized line) has been retained in the B_{1g} symmetry class as in II, but for its counterpart in the d_8 molecule we have used 829 cm^{-1} instead of 929 cm^{-1}, since the latter has already been included in our A_g symmetry class. The former choice has also been adopted in I. For the ν_{20} band of the intermediate compound, the 844 cm^{-1} band has been selected, which is depolarized and also has an isotope ratio value (R) of the right order. For the two in-plane distortion modes (ν_{19} and ν_{21}) there is no specific criterion for selection, excepting for Manneback's rule $A_g < B_{1g}$ for all skeletal modes. For the ν_{21} vibration, the 585 cm^{-1} line has been preferred to 611 cm^{-1} as chosen by II, because the latter was not observed in this work for the d_0 molecule; furthermore, the 585 cm^{-1} line is clearly depolarized. As we have not been able to detect any corresponding line in the d_4 molecule, an estimated value of 582 cm^{-1} has been used. The 569 cm^{-1} band seems to be the corresponding frequency in the d_8 molecule. Thus the assignment for the ν_{21} mode completely agrees with that of I. We have also adopted their selection of a rather high frequency for the ν_{19} mode. Thus for this mode the line at 1320 cm^{-1} has been chosen for the d_0 molecule, with its counterpart at 1295 cm^{-1} in d_8. As no line has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

been observed in the d_4 molecule in this region, a frequency of 1309 cm^{-1} has been estimated. After the selection of the CH and CD valence modes for the A_g class, the rest of the observed bands in these regions have been used in the B_{1g} class. As we do not have enough CD stretching lines in the d_8 molecule, an estimated frequency of 2220 cm^{-1} was used instead of using the 2257 cm^{-1} line twice (once in A_g and once in B_{1g}, as done in II).

Out-of-plane Modes (Raman)

For the out-of-plane deformation modes, calculations of vibration frequencies have been made by Scully and Whiffen (6). On the basis of their calculations for the d_0 and d_8 molecules it is not difficult to select the intermediate d_4 frequencies having proper intensity and obeying the sum and product rules. The major discrepancy of such an assignment is that the calculated thermodynamic functions for the d_0 compound show large deviations from the observed ones. On the other hand, McClellan and Pimentel's (11) assignment gives very good agreement between the calculated and experimental values of the thermodynamic properties, but is completely inconsistent with Scully and Whiffen's calculations. We have tried to present an assignment which gives reasonable agreement with the thermodynamic properties, and at the same time does not violate grossly Scully and Whiffen's predictions.

Agreement of calculated values of thermodynamic functions with the observed ones requires a low frequency line (preferably 195 cm^{-1}) to be included among the fundamentals. This has been done by II. In addition to this, a skeletal normal co-ordinate treatment requires that the lowest out-of-plane frequencies have the order $B_{1u} < B_{2g}$

$< B_{3g}$. Thus the present assignment of the non-planar deformation frequencies (B_{2g} and B_{3g}) has been chiefly based on the following facts: (1) inclusion of the 195 cm^{-1} band as a fundamental, (2) consistency with the trend indicated by Scully and Whiffen's calculations, (3) consistency with the inequality $B_{1u} < B_{2g} < B_{3g}$ for the lowest frequencies, and finally, (4) utilization of those few Raman bands left over, i.e. not used as A_g or B_{1g} modes. Final assignments given in Table II satisfy product and sum rule requirements also. One weak point of this assignment is that it has included two frequencies 874 cm^{-1} and 1099 cm^{-1} for the d_0 molecule, which we have not observed. As we are not left with any other bands to be used for this purpose we have used the data of Lippincott and O'Reilly (I) and Luther *et al.* (III). For the d_4 molecule all the lines have been recorded by us. And for the d_8 molecule, as usual, we have used the data of I.

6. A_u MODES

Finally we are left with the selection of four A_u fundamentals, which are inactive in both infrared and Raman. Very little basis exists for their selection. The bands which have been observed in the infrared spectra of the solid but not in gas or solution can be chosen for this species because, presumably, the selection rules for a free molecule could break down in the crystal field. In II, this procedure has also been followed, but as all frequencies chosen are greater than those calculated by Scully and Whiffen, we preferred to make a new choice, not inconsistent with the trends indicated by the calculations. Lines at 915 cm^{-1} and 730 cm^{-1} have been selected on the above basis (i.e., observed in solid phase only). The line at 698 cm^{-1} has been reported for solid naphthalene by Person, Pimentel, and Schnepp (11), and not in solution, but as it has also been observed by them in the gas phase, there is some doubt as to its assignment as an A_u mode. Luther *et al.*, however, have not observed this band in the gas phase. The last frequency selected at 400 cm^{-1} is just a guess, made by all the previous workers (I, II, and III) also. No attempt has been made to assign the A_u modes of the other two molecules.

The assignment of all the fundamentals is presented in Table II. The observed and calculated product rule ratios and $\Sigma\nu$ and $\Sigma\nu^2$ values are recorded in Table III.

7. THERMODYNAMIC PROPERTIES

The heat capacity and entropy of naphthalene-d_0 have been calculated at 451.0° K and 522.7° K using the above assignments. The formulas and physical constants published by the A.P.I. Research Project 44 (13) have been used in these calculations. The calculated values are compared with the experimental ones due to Barrow and

For personal use only.

McClellan (14) in Table IV. The agreement is not significant however, due to the uncertainty in the value of the lowest A_u frequency.

8. COMBINATION BANDS

Most of the infrared and Raman bands of the three compounds not used as fundamentals have been explained as combination bands. The assignment is consistent with the known symmetry established in some cases from the infrared solid data (11). The assignments are presented in Table V.

9. AN ALTERNATIVE ASSIGNMENT (B)

An alternative assignment of fundamentals is possible, which obeys all the necessary criteria mentioned above. This assignment differs from that given above (assignment A) only in a few respects. These are pointed out in Table VI. The essential difference is the inclusion of the 386, 350, 339 cm^{-1} system as an out-of-plane Raman mode and assigning the 195, 183, 180 cm^{-1} system to the A_u species. The calculated thermodynamic properties using this alternative assignment (B) are also included in Table IV.

TABLE VI
Alternative assignment (B) of some of the fundamentals

Species	Freq. No.	$C_{10}H_8$, cm^{-1}	$C_{10}H_4D_4$ (1-4-5-8), cm^{-1}	$C_{10}D_8$, cm^{-1}
A_g	ν_5	1239	1140	1006
A_u	ν_{10}	1094		
	ν_{11}	842		
	ν_{12}	730		
	ν_{13}	195		
B_{2g}	ν_{26}	1158	958	875
	ν_{28}	285	280	270
B_{3g}	ν_{37}	1099	1020	929
	ν_{40}	386	350	339

The chief drawbacks of this assignment are: firstly, the vibration frequency at 195 cm^{-1} has to be used as an A_u mode, although it is observed in the Raman spectrum. It is quite unlikely that an A_u mode will become Raman active in the molten state in violation of the selection rule, although Scully and Whiffen (6) in their assignment of the A_u class have assumed such violation. Secondly, two of the d_4 Raman bands at 1020 cm^{-1} and 1140 cm^{-1} used here, are very weak and rather doubtful. The only advantage of this assignment over the previous one (A) presented in this communication is that the numerical deviations from Scully and Whiffen's calculated frequencies for the out-of-plane modes are reduced.

ULTRAVIOLET ABSORPTION SPECTRA AND ACIDITIES OF ISOMERIC THIATRIAZOLE AND TETRAZOLE DERIVATIVES[1]

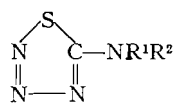
EUGENE LIEBER,[2] J. RAMACHANDRAN, C. N. R. RAO, AND C. N. PILLAI

ABSTRACT

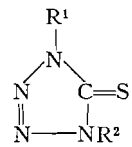
The ultraviolet absorption spectra of 5-(substituted)amino-1,2,3,4-thiatriazoles and the corresponding isomeric 1-substituted-tetrazoline-5-thiones have been studied. The spectra and the dipole moments of the 5-(substituted)amino-1,2,3,4-thiatriazoles eliminate the possibility of meso-ionic structures for these compounds. The dipole moments of 5-amino-, 5-methylamino-, and 5-dimethylamino-1,2,3,4-thiatriazole were all high but approximately of the same value (5.77 to 5.84 D). This suggests that the amino thiatriazoles are best represented by conventional covalent structures with significant ionic resonance contributions. The thiatriazole ring system exhibits a characteristic absorption maximum at 250–255 mμ and an electron-withdrawing effect approximately equal to the tetrazolyl ring system. The tetrazolinethionolyl ring system is similarly electron-withdrawing. The relative acidities of the 1-substituted-tetrazoline-5-thiones and the 5-alkylmercaptotetrazoles have also been studied and the results support the observations made on the basis of their ultraviolet absorption spectra.

INTRODUCTION

In recent communications, Lieber and co-workers (1, 2) reported upon the formation and chemistry of 5-(substituted)amino-1,2,3,4-thiatriazoles, I, and the corresponding isomeric 1-substituted-tetrazoline-5-thiones, II (R^2 = H). 5-Amino-1,2,3,4-thiatriazole[3]



I



II

(1, 3, 4) (I, R^1 = R^2 = H) has a high melting point (128–130°, decomp.), a well-defined crystalline character, and is easily soluble in water. In general, the crystalline character and relatively high melting points extend to the 5-(substituted)amino-1,2,3,4-thiatriazoles (I, R^1 = (substituted)aryl; R^2 = H) and the corresponding isomeric 1-substituted-tetrazoline-5-thiones (II, R^1 = (substituted)aryl; R^2 = H) (1). This behavior has been explained by the proposal (1) that compounds of structure I (R^2 = H) exist as a tautomeric mixture probably in zwitterion form, the latter being best expressed as a meso-ionic structure,[4] III (R^3 = H):

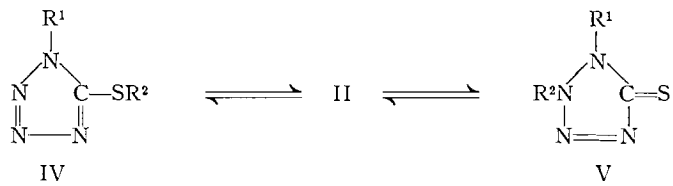
Contribution from the Department of Chemistry of De Paul University, Chicago, Illinois.
[2]*To whom all requests for reprints and additional information should be addressed.*
[3]*Nomenclature and ring number system from A. M. Patterson and L. T. Cappel, The ring index, Reinhold Publishing Corp., New York. 1940.*
[4]*A study of all the possible tautomeric structures, charged and uncharged, shows that the proton of 5-(substituted)-amino-1,2,3,4-thiatrazoles,* I (R^1 = *alkyl, aryl, or hydrogen,* R^2 = H), *could appear on all the nitrogen atoms present. It is represented on the nitrogen in position 3 in order to bring out its analogy to other meso-ionic structures.*

The 5-(substituted)arylamino-1,2,3,4-thiatriazoles (I, R^1 = substituted aryl; R^2 = H) undergo a facile isomerization in basic media to tetrazole derivatives which are found to be moderately strong acids (1). These latter compounds are also capable of tautomerism, of which structure IV (R^2 = H) is of principal interest due to the formation of the thiol-grouping. Recently, Lieber and co-workers (5) have demonstrated by a study of their infrared absorption spectra that the substances are thiones of structures II and V. The 5-(substituted)mercapto-tetrazoles (IV, R^1 = H; R^2 = alkyl, alkaryl, or aryl) are also of considerable interest in that they are isomeric with structures I and II. Two members of IV, namely, 5-methylmercaptotetrazole (IV, R^1 = H; R^2 = CH_3)



and 5-benzylmercaptotetrazole (IV, R^1 = H; R^2 = $C_6H_5CH_2$), are included in the present investigation. These derivatives are also acids. The present communication reports on the ultraviolet absorption spectra of the isomeric structures I, II, and IV and also the comparative acidities in order to gain an insight into the structural problems pointed out above.

EXPERIMENTAL

Compounds.—The 5-(substituted)amino-1,2,3,4-thiatriazoles (I, R^1 = H or CH_3; R^2 = substituent) and the 1-substituted-tetrazolinethiones (II, R^2 = H) were prepared by methods described elsewhere (1, 2, 3). 5-Methylmercaptotetrazole, IV (R^1 = H; R^2 = CH_3), m.p. 152° (uncorr.), was prepared by the method of Freund and Paradies (6). 5-Benzylmercaptotetrazole, IV (R^1 = H; R^2 = $C_6H_5CH_2$), m.p. 138–138.5° (uncorr.); anal. calc. for $C_8H_8N_4S$: S, 16.68; found: S, 16.75; this compound was prepared by essentially the same procedure by diazotization of S-benzyl isothiosemicarbazide hydrochloride and recrystallization from aqueous ethanol.

Spectroscopy.—A Beckman, Model DU, spectrophotometer and a Cary recording spectrophotometer were used for all the measurements. The wavelengths are recorded in mμ and the intensities in terms of logarithms of the molar extinction coefficients.

Comparative acidities.—The apparent dissociation constants of II (R^2 = H) and IV (R^2 = CH_3 and $C_6H_5CH_2$ respectively) were determined by potentiometric titration in 50% ethanol using a precalibrated photovolt pH meter. Standardization of the apparatus was accomplished with a series of substituted benzoic acids having reported pK_a's in the range encountered in the present investigation. It was found that differences in apparent dissociation constants as low as 0.1 pK_a units were reproducible.

Dielectric constant measurements.—The dielectric constant measurements were made in purified dioxan essentially as described in the literature (7).

RESULTS AND DISCUSSION

5-(Substituted)amino-1,2,3,4-thiatriazoles

The ultraviolet absorption data are summarized in Table I with a few typical absorption spectral curves shown in Fig. 1. 5-Amino-1,2,3,4-thiatriazole (I, R^1 = R^2 = H) shows

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

a strong absorption band at 267 mμ and the introduction of a saturated substituent causes a prominent bathochromic shift. Baker and co-workers (8, 9) during their investigation of cyclic meso-ionic compounds found that sydnones which contained no

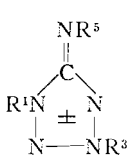
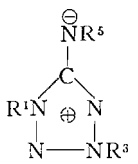
other conjugated system showed a well-defined absorption maximum around 292 mμ in the ultraviolet region. They explained this by the suggestion that the sydnone ring possessed aromatic character and was a hybrid of a large number of contributing forms. Henry, Finnegan, and Lieber (10) found that 1,3-dialkyl-5-aminotetrazoles, VI, have a characteristic absorption band between 254 and 258 mμ, whereas the usual substituted tetrazoles containing no other conjugated system have been reported to show only end absorption (11, 12). On this basis a structure of the type VI was proposed. Baker and Ollis (9) have suggested that meso-ionic structures be represented so that the sydnone ring becomes positively charged so as to emphasize its aromatic nature. This is shown by structure VII, which does not imply that a complete negative charge is resident



VI



VII

$R^5 = H$
$R^1 = R^3 = alkyl$

upon the exocyclic nitrogen atom. The difficulty of representing such structures is recognized (9), although the attempted exclusion of structures which can be represented satisfactorily[5] by any one covalent or polar structure might exclude compounds which

[5]*This was recognized by Baker and Ollis (9), who pointed out that "the inevitable ambiguity here is the word satisfactory".*

are, indeed, meso-ionic. Thus, Henry, Finnegan, and Lieber (10) found that, surprisingly, 2-methyl-5-alkylaminotetrazoles, VIII, which have been considered to possess the tetrazole ring system with normal covalent bonds, appear to exist principally in meso-ionic form, IX, since their ultraviolet absorption spectra are very similar to those for the 1,3-dialkyl-5-iminotetrazoles (structures VI or VII). The introduction of a methyl group

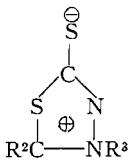
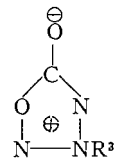
into the 5-amino position of either 1- or 2-methyl-5-aminotetrazole effects a bathochromic shift in the absorption maximum (10). The above ideas have been supported by the X-ray analysis of the hydrobromide of 1,3-dimethyl-5-iminotetrazole (13), and a modified 3-dimensional Fourier synthesis (14) has demonstrated unambiguously that the structures are cyclic meso-ionic. In their survey of known meso-ionic compounds Baker and Ollis (9) present structures which bear a close analogy to that of structure III proposed in this communication. Two such structures X and XI are shown below in comparison with structure III (*vide ut supra*).[6] Accordingly, the ultraviolet absorption data (Table I) and the analogies discussed above may appear to support a meso-ionic structure for the



X



XI

5-(substituted)amino-1,2,3,4-thiatriazoles (III).

Baker and Ollis (9) have defined a meso-ionic compound as a 5- or possibly 6-membered heterocyclic compound which cannot be satisfactorily represented by any one covalent or polar structure and possesses a sextet of electrons in association with all the atoms comprising the ring. The ring bears a fractional positive charge balanced by a corresponding negative charge located on a covalently attached atom or group of atoms. The 5-(substituted)amino-1,2,3,4-thiatriazoles can be represented as meso-ionic structures III (R^3 = H). However, a conclusive assignment of meso-ionic structure in these compounds is not possible on the basis of the ultraviolet spectra, since the dimethylamino derivative (I, $R^1 = R^2 = CH_3$) *in which no tautomerism is possible* also shows the same characteristic absorptions. For this reason the dipole moments of 5-amino- (I, $R^1 = R^2$ = H); 5-methylamino- (I, R^1 = H; $R^2 = CH_3$); and 5-dimethylamino-1,2,3,4-thiatriazole (I, $R^1 = R^2 = CH_3$), respectively, were determined. Although it has been demonstrated by Kaufman and co-workers (7) that this measurement does not provide a sound basis for the assignment of meso-ionic structures, it was felt that it could contribute to a clearer picture of the thiatriazole ring system. Further, if structures I (R^1 = H) are meso-ionic there would be a significant difference in the dipole moments of the 5-(monosubstituted)amino- and 5-(disubstituted)amino-1,2,3,4-thiatriazoles. The dipole moments obtained are summarized below:

Compound I		
R^1	R^2	μ (Debye units)
H	H	5.77
H	CH_3	5.72
CH_3	CH_3	5.84

While the dipole moments are large they are all approximately the same. It is therefore suggested that 5-amino-1,2,3,4-thiatriazole and its derivatives are best represented by

[6]*Recent investigations (15, 16) in progress in this laboratory have revealed that substances formerly considered to be derivatives of azidodithiocarbonic acid,* $N_3C(S)SH$, *are in reality derivatives of 1,2,3,4-thiatriazoline-5-thione, the simplest members of which has a relatively high decomposition point and is nicely crystalline. Its structure should be closely related to* XI (R^3 = H) *replacing the oxygens by sulphur.*

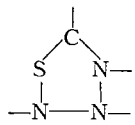
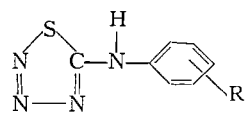
For personal use only.

conventional covalent structures and that the ultraviolet absorption spectral characteristics are due to the interaction of the thiatriazole nucleus with the substituent in the 5-position. Unfortunately, the dipole moment data do not provide the direction of the moment in these compounds.[7] The thiatriazole ring contains three nitrogen atoms (positions 2, 3, and 4) which are sp^2 hybridized and which should induce a large concentration of negative charge away from the ring and the substituent in the 5-position. The ultraviolet absorption data supports this suggestion.

From the data in Table I, it can be seen that all of the 5-alkyl substituted derivatives exhibit a shoulder at 255 mμ and an absorption band around 275 mμ. Since the unsubstituted compound (I, $R^1 = R^2 = H$) also exhibits a shoulder at 250 mμ, it is considered that this 250–255 mμ absorption is characteristic of the 1,2,3,4-thiatriazole ring system:

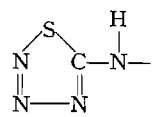


The major absorption bands at the longer wavelength are caused by the interaction of the amino or the substituted group with the heterocyclic nucleus. It will also be noted from Table I that there is very little change in the position of this maximum with different alkyl substituents including the benzyl group in the 5-amino position. Table I also shows that all of the 5-arylamino-1,2,3,4-thiatriazoles studied (I, $R^1 = H$; R^2 = aryl) show a distinct peak in the vicinity of 242 mμ, probably due to the thiatriazole nucleus. Also indicated are a shoulder and a peak at longer wavelengths probably due to the interaction of the aromatic ring with the heterocyclic nucleus. Analogies with the ultraviolet absorption spectra of 5-(substituted)amino tetrazoles (17) and substituted amino-1,2,3-triazoles (18) can be made. The 5-arylamino-1,2,3,4-thiatriazoles (I, $R^1 = H$; R^2 = aryl) may also be considered as substituted benzenes, XII. The position of the absorption maxima of the compounds represented by structure XII depends markedly



XII

on the nature of the substituent R on the aromatic ring, the λ_{max} increasing approximately in proportion to the electron-donating power of the substituent. This proportionality indicates that the grouping XIII is an electron-withdrawing group, capable of appreciable resonance interaction. Recently, Rao (19) has correlated the ultraviolet absorption spectra of meta- and para-disubstituted benzenes with reactivities and resonance parameters (20). The correlation of the wavelength displacements with the reactivities and



XIII

[7] *An investigation on an extended series of appropriate structures* I ($R^1 = H$; R^2 = *substituted aryl*) *to determine the direction of this moment is in progress and will be reported upon in a separate communication.*

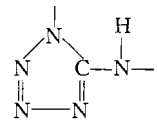
resonance parameters indicate that the electron-withdrawing ability of XIII by resonance interaction is of the same order of magnitude as that of the 5-aminotetrazolyl group:



This is surprising in view of the somewhat smaller electronegativity value for sulphur over that of nitrogen (21).

Accordingly, from the above discussion it is concluded that the ultraviolet absorption data and the dipole moments reported are due to hybridization effects (22) and the contribution of ionic resonance structures XIV and XV. The case here is similar to that reported by Kaufman and co-workers (7) for 1-ethyltetrazole, XVI, which has a higher moment (5.46 D) than the meso-ionic compound 1,3-dimethyl-5-iminotetrazole (4.02 D) (VI, $R^5 = H$; $R^1 = R^3 = CH_3$). In the case of XVI the moment is directed with the

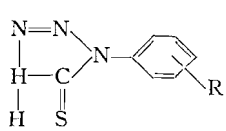
XIV XV

XVI XVII

negative pole away from the carbon atom in the ring, the high dipole moment probably due to the hybridization effects of the 2, 3, and 4 ring nitrogens and resonance contributions of ionic structures (7). In the case of 1,3-dimethyl-5-imino-tetrazole (VI, $R^5 = H$; $R^1 = R^3 = CH_3$; XVII), the moment is directed with the negative pole towards the exocyclic nitrogen at the 5-position, the lower value of the moment being the results of the hybridization effect of the nitrogen in position-2 in the ring of XVII, which results in a concentration of negative charge away from the exocyclic nitrogen atom and the ring.

1-Substituted Tetrazoline-5-thiones

The ultraviolet absorption spectral data obtained with the 1-(substituted)phenyl-tetrazoline-5-thiones (II, $R^2 = H$; $R^1 =$ aryl) are summarized in Table II. Considering these compounds as substituted benzene, represented by the structure XVIII, it will be noted (Table II) that the compounds display primary absorption bands in the region 217–254 mμ, which can be ascribed to the primary bands of the substituted benzene (19).



XVIII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

This primary absorption maximum varies in proportion to the electron-donating power of the substituents on the 1-phenyl group. Thus, a bathochromic shift in the absorption maximum is observed with substitution by groups capable of donating electrons by resonance interaction. This effect is appreciable in the case of the *p*-dimethylamino derivative (XVIII, R = 4-$(CH_3)_2N$) which exhibits the primary band at 254 mμ. From the

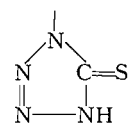
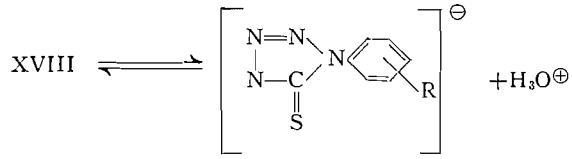
correlation of Rao (19), it is found that the 1-tetrazoline thionyl group, XIX, is electron withdrawing in nature of about the same order of magnitude as the 5-amino-tetrazolyl group and the 5-amino-1,2,3,4-thiatriazole group (XIII).



XIX

In addition to the primary band of the substituted benzene, the 1-aryl-tetrazoline-5-thiones (XVIII), in general, exhibit another absorption maximum between 252 and 295 mμ and a shoulder between 270 and 288 mμ (Table II). The absorption maximum is considered to be due to the acid XVIII and the shoulder as being due to the anion XX. No definite assignments seem to be possible in the case of the 1-(*p*-nitro)phenyl derivative (XVIII, R = 4-O_2N—C_6H_4), probably due to the absorption of the nitro group itself.



XX

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

In Fig. 2 are shown the absorption spectra of 1-phenyl-tetrazoline-5-thione (II, $R^2 = H$; $R^1 = C_6H_5$) in solvents of different pH. In 95% ethanol, the bands due to the undissociated acid and the anion are observed at 262 and 280 mμ respectively. In 0.1 *N* hydrochloric acid, however, the 262 mμ band appears as a strong peak and the shoulder at 280 mμ disappears. In 0.1 *N* sodium hydroxide solution, the shoulder at 280 mμ assigned to the anion becomes a peak and the 262 mμ band is absent. From Fig. 2 it can be seen that the compound is almost completely dissociated even in a buffer of pH 7.5. The absorption spectra further indicates that the anion is considerably resonance stabilized, since the anions absorb at higher wavelengths than the undissociated acids. Table II also lists the absorption maxima of some of the 1-substituted tetrazoline-5-thiones (II, $R^2 = H$) in 0.1 *N* sodium hydroxide in 95% ethanol. From the data in Table II it is seen that the 1-alkyl-derivatives exhibit only one absorption maximum at lower wavelengths than the 1-alkyl-derivatives. Further, the anion of 1-methyltetrazoline-5-thione (II, $R^2 = H$; $R^1 = CH_3$) absorbs at the same wavelength as the undissociated acid. This suggests that there is little or negligible extra resonance stabilization of the anion in the alkyl derivatives.

A study of the apparent dissociation constants of the 1-substituted tetrazoline-5-thiones (II, $R^2 = H$) summarized in Table III seems to support the observations based on the ultraviolet spectra regarding the electrical effects of the substituents in this system (R in XVIII). A plot of the pK_a values of the 1-substituted phenyltetrazoline-5-thiones

(XVIII) against the Hammett sigma (σ) values for groups (23) is reasonably linear as shown in Fig. 3. The slope of this line, the rho value (ρ), is smaller than the rho values for the 5-(substituted)phenylamino-4-phenyl-1,2,3-triazoles and the 5-(substituted)-phenylaminotetrazoles (24, 25). This indicates a smaller magnitude of the electrical effects of the substituents in the tetrazolinethione system (XIX). It is, however, interesting to note (Table III) that while the pK_a of the aryl derivatives varies between 3.36

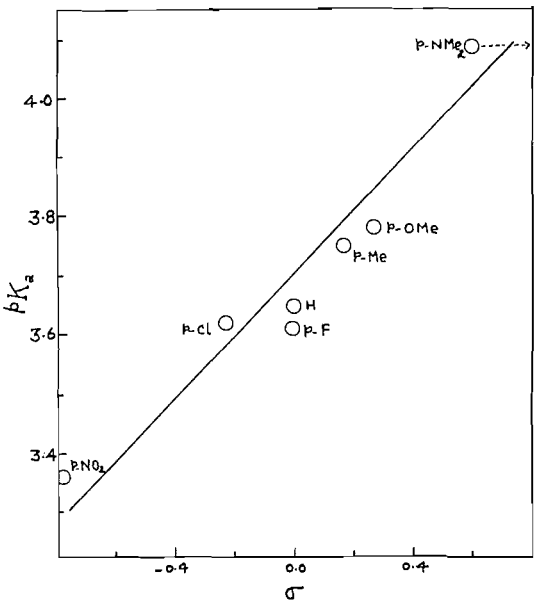

FIG. 3. pK_a of 1-substituted tetrazoline-5-thiones versus Hammet sigma (σ) values for groups.

and 4.09, the alkyl derivatives possess pK_a values between 3.80 and 3.91. In 1-(*p*-dimethylamino)phenyltetrazoline-5-thione (XVIII, R = 4-$(CH_3)_2N$) where there is strong complimentary substitution, the displacement of the primary benzene band in the ultraviolet spectrum is greatest as is also the effect on the acidity. The 2-methyl, 2-methoxy, and 2,4-dichlorophenyl derivatives exhibit the ultraviolet absorption bands (Table II) at wavelengths lower than the corresponding para isomers. The ortho derivatives also show slight increase in acidity from the para derivatives (Table III). Such behavior may be due to steric effects of the ortho substituents (26, 28). The possibility of intramolecular hydrogen bonding cannot be excluded in the case of the ortho-anisyl derivative (XVIII, R = 2-$CH_3OC_6H_4$). The band displacement exhibited by the *p*-fluorophenyl derivative (XVIII, R = 4-FC_6H_4) is too small to be accounted for on the basis of the proposed resonance parameter of -0.44 (20) for the *p*-fluoro group. A lower resonance parameter of the order of -0.10 seems more reasonable (26, 27).

The 5-alkyl mercaptotetrazoles (IV, $R^1 = H$; R^2 = alkyl)[8] are weaker acids (Table IV) compared to the corresponding 1-substituted tetrazoline-5-thiones (II, $R^2 = H$). The ultraviolet absorption of 5-alkyl mercaptotetrazoles (Table V) are similar to the derivatives of tetrazole (17) rather than those of the tetrazoline-5-thiones. Since there is no conjugating group in the 5-position, these mercapto derivatives absorb at lower wavelengths. Further, the ultraviolet absorption spectrum of the 5-methylmercapto derivative (IV, $R^1 = H$; $R^2 = CH_3$) in alkaline solution shows little extra resonance stabilization of the anion.

THE CHARACTERIZATION OF TRI-*O*-TOSYL SUCROSE[1]

P. D. Bragg and J. K. N. Jones

ABSTRACT

Tri-*O*-tosyl sucrose was synthesized by the action of *p*-tolylsulphonyl chloride upon sucrose in pyridine, and the tosyl groups were shown by methylation to be mainly (84%) located on the three primary hydroxyl groups.

INTRODUCTION

Hockett and Zief (1) prepared sulphonyl esters of sucrose by reaction with methane sulphonyl (mesyl) chloride or *p*-tolyl-sulphonyl (tosyl) chloride in pyridine solution. Although none of the products were isolated in crystalline form, analytical values were recorded for the tri-*O*- and octa-*O*-mesyl and tosyl sucrose derivatives. Tosyl and mesyl compounds undergo a large number of important reactions (2) so thorough characterization of the trisubstituted sucrose was considered to be desirable.

Tri-*O*-tosyl sucrose was prepared by Hockett and Zief's method (1). Complete methylation to tri-*O*-tosyl-penta-*O*-methyl sucrose was obtained by a single treatment with methyl iodide and silver oxide in dimethylformamide solution (3). Detosylation and subsequent hydrolysis gave a mixture of tri-*O*-methyl glucose, di-*O*-methyl fructose, and di-*O*-methyl glucose. A small amount (5%) of tri-*O*-methyl fructose was also present.

The methyl ethers of glucose were characterized by conversion to 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine and 2,4-di-*O*-methyl-*N*-*p*-nitrophenyl-D-glucosylamine respectively.

The di-*O*-methyl fructose was chromatographically identical with 3,4-di-*O*-methyl fructose. The measured rotation was lower than the quoted value (4) but this was probably due to the presence of an optically inactive impurity derived from the filter paper on which the sugar was fractionated. The identity of the fructose methyl ether was confirmed as 3,4-di-*O*-methyl-D-fructofuranose by periodic acid oxidation followed by bromine oxidation to dimethylsuccinic acid and the isolation of crystalline (−)-D-dimethoxysuccinamide formed by the action of ammonia on the methyl ester (5).

The isolation of 2,4-di-*O*-methyl-D-glucose from the hydrolysis mixture suggests that some undermethylation had occurred. In glucose the hydroxyl group at $C_{(3)}$ is less reactive than that at $C_{(2)}$, $C_{(4)}$, or $C_{(6)}$ (9), and 2,4-di-*O*-methyl glucose would result from undermethylation.

This sugar might arise through the formation of a 3,6-anhydro ring on the glucose residue of sucrose during methylation. But no 2,4-di-*O*-methyl-D-glucose was formed from methyl 2,4-di-*O*-methyl-3,6-anhydro α-D-glucoside when the latter was submitted to the conditions of hydrolysis used for the methylated sucrose derivative. The infrared spectrum of the methylated sucrose showed that hydroxyl groups were absent. However, it has been observed in these laboratories that incompletely methylated polysaccharides which had been submitted to the Kuhn methylation procedure in dimethylformamide (3) gave an infrared spectrum without hydroxyl peaks, and yet gave amounts of sugars which indicated that methylation was incomplete. This phenomenon is as yet unexplained.

The tri-*O*-tosyl sucrose consisted mainly therefore of 6,1[1],6[1]-tri-*O*-tosyl sucrose. This

[1]*Manuscript received November 10, 1958.*

result is in agreement with the results of Lemieux and Barrette (6), who found that the trianhydro sucrose derived from the above compound was different from that obtained from 4,1^1,6^1-tri-*O*-tosyl sucrose, which had been prepared from 2,3,6,3^1,4^1-penta-*O*-acetyl sucrose (7). This structure is also supported by the isolation of a sirupy di-iodo-di-deoxy-mono-*O*-tosyl sucrose pentaacetate from the action of sodium iodide (8) on tri-*O*-tosyl sucrose pentaacetate. The iodine atoms are probably located on the $C_{(6)}$ of both fructose and glucose moieties, the tosyl group on fructose-$C_{(1)}$ remaining unsubstituted. In agreement with this, Lemieux and Barrette (6) obtained only a mono-iodo derivative from 4,1^1,6^1-tri-*O*-tosyl sucrose.

It is probable that the tri-*O*-tosyl sucrose is not pure. However the high yield (89%) of di-iodo-di-deoxy-mono-*O*-tosyl sucrose pentaacetate (analysis indicates 94% purity) that was prepared from it shows that at least 84% of the preparation must have tosyl groups on $C_{(6)}$ and $C_{(6^1)}$. Since no other tri-*O*-methyl glucoses were found, which would be the case if other tri-*O*-tosyl sucroses were present, the preparation is probably purer than the above figure. The chromatography solvent used (*n*-butanol : ethanol : water, 3 : 1 : 1) resolved 2,3,4-tri-*O*-methyl-D-glucose (R_f 0.62) from 2,3,6-tri-*O*-methyl- (R_f 0.59) and 3,4,6-tri-*O*-methyl-D-glucose (R_f 0.58). Complete separation from 2,4,6-tri-*O*-methyl-D-glucose (R_f 0.61) was not obtained but since tosylation at $C_{(3)}$ of sucrose is unlikely (9) it is probable that this methylated sugar was not present.

Reduction of 6,1^1,6^1-tri-*O*-tosyl sucrose with lithium aluminum hydride gave 6,6^1-dideoxy sucrose (cf. 6), which was cleaved by invertase to 6-deoxy-D-glucose and D-rhamnoketose.

EXPERIMENTAL

Paper chromatograms were developed in the solvent system: *n*-butanol : ethanol : water (3 : 1 : 1). Reducing sugars were detected by *p*-anisidine hydrochloride and a resorcinol spray reagent was used for the specific detection of ketoses (10). Melting points are uncorrected and were determined on a Kofler microheating stage.

Tri-O-tosyl Sucrose

This was prepared by Hockett and Zief's method (1) and had $[\alpha]_D^{17}$ +41.3° (*c*, 2.06 in chloroform). Anal. Calc. for $C_{33}H_{40}O_{17}S_3$: S, 11.9%. Found: S, 11.5%.

Methylation of Tri-O-tosyl Sucrose

Tri-*O*-tosyl sucrose (7.3 g), dried over phosphoric oxide, was dissolved in dimethylformamide (120 ml), which had been distilled from barium oxide, and methyl iodide (45 ml). Silver oxide (45 g) was added portionwise with vigorous stirring, the temperature was not permitted to rise above 35°. After 7 hours, the mixture was filtered, the precipitate was washed with dimethylformamide (2×50 ml), and then chloroform (50 ml), and the combined liquids were poured into 1% aqueous sodium cyanide (500 ml). The aqueous layer was shaken with chloroform, which was then added to the chloroform layer and the combined solutions were washed well with water, dried (sodium carbonate), and concentrated to a sirup (5.33 g) $[\alpha]_D^{24}$ +49.5° (*c*, 4.05 in chloroform). The product showed no hydroxyl peaks in its infrared spectrum. Anal. Calc. for $C_{38}H_{50}O_{17}S_3$: OMe, 17.8%. Found: OMe, 20.7%. The high value for methoxyl suggests contamination of the product with dimethylformamide.

Detosylation of the Methylated Sucrose

The sirup (5.2 g) in 85% aqueous methanol (200 ml) was stirred with 4% sodium amalgam (125 g) for 18 hours. After filtration and neutralization with solid carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

dioxide, the solution was concentrated to a solid which was extracted with boiling chloroform (3×150 ml). The extract afforded a sirup (2.6 g) which on concentration did not give a solution in water or 50% aqueous ethanol sufficiently clear for optical rotation measurements.

Hydrolysis and Separation of the Methyl Sugars

The methylated sucrose (2.6 g) was hydrolyzed with 0.01 *N* sulphuric acid (150 ml) at 100° for 1½ hours. After neutralization the resulting mixture (2.4 g) was examined on paper chromatograms. With *p*-anisidine, tri-*O*-methyl glucose (R_f 0.62), di-*O*-methyl fructose (R_f 0.52), and di-*O*-methyl glucose (R_f 0.48) were detected. The resorcinol spray showed the presence of a small amount of a further component, tri-*O*-methyl fructose, having an identical R_f value to the tri-*O*-methyl glucose which previously masked it.

The mixture of sugars was fractionated on a cellulose column (30×3 cm) using methyl ethyl ketone : water azeotrope as solvent (7). A complete separation of the component sugars was not obtained so the fractions were combined to give a tri-*O*-methyl hexose fraction (0.75 g) and a di-*O*-methyl hexose fraction (1.2 g).

The tri-*O*-methyl hexose fraction was dissolved in 0.35% methanolic hydrogen chloride (25 ml) and the rotation was followed until equilibrium was reached (22 hours). After neutralization with silver oxide and removal of the silver ions with hydrogen sulphide, tri-*O*-methyl glucose (R_f 0.65) was separated on sheet paper chromatograms from a small amount of tri-*O*-methyl methyl fructofuranoside. The di-*O*-methyl hexose fraction was similarly fractionated into di-*O*-methyl glucose (R_f 0.49) and di-*O*-methyl methyl fructofuranoside (R_f 0.66).

Characterization of the Methyl Sugars

Tri-*O*-methyl hexose (280 mg) was refluxed with redistilled aniline (110 mg) in ethanol (10 ml). Removal of the ethanol under reduced pressure initiated crystallization. After recrystallization from ether – light petroleum (60–80°), the colorless needles had m.p. and mixed m.p. 144°–146° with authentic 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine. Anal. Calc. for $C_{15}H_{23}O_5N$: OMe, 31.3%. Found: OMe, 30.9%.

The di-*O*-methyl hexose (202 mg), having $[\alpha]_D$ +54° (*c*, 2.0 in water), was refluxed for 3 hours with *p*-nitroaniline (164 mg) in ethanol (5.5 ml) and acetic acid (5 drops). The reaction mixture was concentrated to a smaller volume and cooled to 5°. The light-brown precipitate was washed with ethanol and recrystallized as pale yellow crystals from ethyl acetate, m.p. 251°, $[\alpha]_D^{24}$ −250° (*c*, 0.38 in pyridine). Anal. Calc. for $C_{14}H_{20}O_7N_2$: OMe, 18.9%. Found: OMe, 19.9%. 2,4-Di-*O*-methyl-*N*-*p*-nitrophenyl-D-glucosylamine has m.p. 250°–251° $[\alpha]_D$ −252° (pyridine) (11).

The di-*O*-methyl methyl fructofuranoside was hydrolyzed (0.05 *N* H_2SO_4; 2 hours; 100°) to yield di-*O*-methyl-D-fructose (0.57 g), $[\alpha]_D$ −45° (*c*, 2.64 in water). Anal. Calc. for $C_8H_{16}O_6$: OMe, 29.7%. Found: OMe, 28.3%. Di-*O*-methyl fructose (160 mg) in 1.15 *M* periodic acid (5 ml) was kept at 25° for 3 days. The solution was freed from iodine by extraction with carbon tetrachloride. Barium chloride (0.5 g) and excess barium carbonate were added, and after filtration, enough bromine was added to give a saturated solution. After 2 days, excess bromine was removed by aeration, hydrobromic acid by lead carbonate, and lead ions with hydrogen sulphide. The solution was filtered and the filtrate was concentrated to a solid which was then refluxed overnight with 4% methanolic hydrogen chloride. Excess hydrogen chloride was removed with lead carbonate, as above, and the filtrate was concentrated to a solid. Chloroform extraction of the solid and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

subsequent evaporation of the solvent yielded a sirup (40 mg) which was dissolved in methanolic ammonia (3 ml) and kept at 0°. After 6 days, white crystals (15 mg) of (−)-D-di-methoxysuccinamide were deposited, $[\alpha]_D$ −94° (*c*, 0.60 in water), m.p. and mixed m.p. 275° (capillary tube) with authentic (−)-D-dimethoxysuccinamide. The compound showed maxima in the infrared at 3330 (s), 3150 (s), 2910 (w), 1637 (s), 1425 (s), 1341 (m), 1314 (w), 1210 (m), 1193 (m), 1139 (m), 1100 (s), 1023 (m), 881 (m), 825 (w), 805 (m), 705 (m) cm^{-1} and gave an identical infrared spectrum to authentic (−)-D-dimethoxysuccinamide.

Reaction of Sodium Iodide with Tri-O-tosyl Sucrose

Tri-*O*-tosyl sucrose pentaacetate (2.0 g) was heated at 110° for 2 hours with sodium iodide (5 g) in acetone (5 ml). The reaction mixture was poured into chloroform and after filtration was washed well with water containing sodium thiosulphate (5%) and sodium hydrogen carbonate (5%). After drying ($CaCl_2$), concentration of the chloroform extract gave sirupy mono-*O*-tosyl-di-iodo-di-deoxy sucrose pentaacetate (1.7 g) $[\alpha]_D^{19}$ +40° (*c*, 3.8 in chloroform). Anal. Calc. for $C_{39}H_{36}O_{16}I_2S$: I, 26.5%. Found: I, 24.9%.

Reduction of Tri-O-tosyl Sucrose

Tri-*O*-tosyl sucrose was reduced (10 hours) with $LiAlH_4$ at the boiling point of tetrahydrofuran. Following destruction of excess hydride with moist ethyl acetate and deionization of the solution with ion-exchange resin, 6,6^1-dideoxy sucrose was isolated as a chromatographically homogeneous, crisp solid (R_f 0.32), $[\alpha]_D^{19}$ +49.7° (*c*, 1.27 in water). Anal. Calc. for $C_{12}H_{22}O_9$: CMe, 9.7%. Found: CMe, 9.2%.

Dideoxy sucrose was completely hydrolyzed by invertase (48 hours) to give two compounds which cochromatographed with authentic rhamnoketose and 6-deoxy glucose.

MASS SPECTROMETRIC STUDY OF THE REACTIONS OF SOME HYDROCARBONS WITH ACTIVE NITROGEN[1]

JOHN T. HERRON, J. L. FRANKLIN,[2] AND PAUL BRADT

ABSTRACT

The reactions of active nitrogen with acetylene, ethylene, and propylene have been studied in a flow system using a mass spectrometer to analyze the products continuously. Certain features of the mass spectra of the products can be explained on the basis of cyano radical replacement reactions.

Winkler and his co-workers have studied the reactions of active nitrogen with acetylene (1), ethylene (2), and propylene (3), in addition to a large number of other compounds (4). The major product containing nitrogen, aside from small amounts of cyanogen, was HCN. In the case of the acetylene reaction an additional product was found in the form of a polymer, containing about 32% nitrogen.

We have made a mass spectrometric study of these reactions, using a flow system. The nitrogen atoms were produced by passing a stream of nitrogen gas at from 1 to 5 mm pressure through a 2450 Mc electrodeless discharge. The atom concentration as measured by gas titration with NO (5) was of the order of 2 mole %. The reactor was made of 10-mm i.d. glass tubing. Hydrocarbons were added to the system through an inlet located about 20 cm ahead of a small glass leak through which the gas stream was continuously sampled and analyzed by a mass spectrometer. With linear flow rates of the order of 1 meter/second, the time for the gas to pass from the hydrocarbon gas inlet to the sampling leak was about 0.02 second.

This type of experimental arrangement does not permit observation of any but very long-lived free radicals. Since the reaction flames themselves extended only a few centimeters from the reactant inlet, it seems reasonably certain that our analytical results refer only to stable products.

In general our results are very similar to those of Winkler and co-workers. However, several new features were observed. For acetylene we found the major product to be HCN, along with smaller amounts of $(CN)_2$, as indicated by their peaks at m/e 27 and

TABLE I

Observed mass spectra

Reactant, m/e	C_2H_2	C_3H_4	C_2H_4	C_3H_6
50	22	100	30	100
51	100	380	100	270

52 respectively. In addition, however, there were peaks at m/e 50 and 51, but no peaks at higher masses. Similarly, for methyl acetylene, there were peaks at m/e 50, 51, and m/e 63, 64, 65, but again none at higher masses. The relative magnitudes of the ion currents are shown in Table I. The m/e 52 peak has been omitted.

In the case of the acetylene reaction, the absence of peaks at masses greater than m/e 52 (C_2N_2) makes it difficult to conceive of the m/e 51 peak being due to anything other than C_3HN which we feel certain is cyanoacetylene. The mass 50 peak is probably C_2CN^+ from C_2HCN. It is not diacetylene, since other peaks from the mass spectrum of diacetylene were absent.

Similarly the mass 65 peak probably corresponds to the methyl cyanoacetylene ion, $CH_3C_2CN^+$, the ions of mass 64 and 63 would represent the loss of one and two hydrogens from the parent molecule. Of course, the peaks at 63, 64, 65 could also be attributed to propargyl cyanide, though we think this less likely.

It is difficult to account for these products other than through direct replacement of a hydrogen by a cyano radical. Since diacetylene is not found in either reaction, it seems certain that the C_2H radical does not play an important part. Hence we cannot account for the cyanoacetylene as resulting from the reaction

$$CN + C_2H \rightarrow C_2HCN.$$

Furthermore, the methylacetylene reaction leads to the formation of considerably more cyanoacetylene than methyl cyanoacetylene as is shown in Table II. The absence of a peak at m/e 78 in the products of reaction with methylacetylene shows that the C_3H_3 radical probably plays very little part in the reaction and thus suggests that recombination of this radical with CN is not responsible for the C_3H_3CN observed.

TABLE II

Per cent of N in products for typical experiments

Product reactant	NH_3	HCN	C_3HN	C_2N_2	C_3H_3N	C_4H_3N	C_4H_5N
C_2H_2	13	62	7	18			
C_3H_4	6	75	6	12	?	1	
C_2H_4	<1	97	<1	2	<1		
C_3H_6	?	>78	<4	12	5		1

We consider the most plausible set of reactions to be:

$$CN + C_2H_2 \rightarrow C_2HCN + H \qquad \Delta H^* = -12$$
$$CN + CH_3C_2H \rightarrow C_2HCN + CH_3 \qquad \Delta H = -22$$
$$\rightarrow CH_3C_2CN + H \qquad \Delta H = -12$$
$$\rightarrow CH_2CNC_2H + H \qquad \Delta H = -7$$

Table II gives the per cent of the total nitrogen in each product. The actual numerical values are necessarily somewhat crude, inasmuch as we had no way of determining the relative sensitivities of the various products. In addition the formation of brown deposits on the walls of the reactor largely negates any attempt at exact analyses.

Nevertheless, it can be seen that the proportion of products containing the cyano radical is quite high, i.e. of the order of 25%. This would seem to argue that the cyano radical plays a rather important part in these reactions. It is interesting to note that

*Kcal/mole, estimated from group equivalent values (ref. 6).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in the case of the acetylene reaction, as the flow rate of acetylene is increased, the amount of cyanogen increases quite steeply, and then falls off again as conditions approach complete consumption of the active nitrogen (1). The cyanogen is presumably produced by the recombination of CN radicals.

With the olefins studied, the major product containing nitrogen was again HCN, which accounted for 97% of the nitrogen in the ethylene reaction, and more than 78% in the propylene reaction. The later reaction also yielded appreciable amounts of cyanogen.

Although the mass spectra over the range of masses 50–70 show several interesting features, it would be unwise to draw overly firm conclusions from them, since the peaks are quite small. The spectra are shown in Table I.

With ethylene the largest peaks were at masses 51, 52, and 53 with a series of smaller peaks extending to mass 56. The peak at mass 52 can be attributed at least in part to cyanogen, while that at mass 53 can be attributed to C_3H_3N, which could be cyanoethylene. The peaks at 50, 51 may be due in part to cyanoacetylene, since acetylene is a product of this reaction (2). As can be seen from Table II the proportion of nitrogen in products other than HCN is very small.

In the case of propylene, however, this may not be the case. Propylene gave a series of peaks from masses 50 to 58, and from 63 to 67, the two largest being at 52 and 53. The series at 63 to 67 is probably due to C_4H_5N, which may be either propenyl cyanide, isopropenyl cyanide, allyl cyanide, or a mixture of them. The peak at mass 53 may be cyanoethylene.

By analogy with the corresponding acetylene reactions, the following reactions can be written to describe the olefin reactions:

$$\begin{aligned}
CN + C_2H_4 &\rightarrow C_2H_3CN + H && \Delta H \text{ (ref. 6)} = -10\\
CN + CH_3C_2H_3 &\rightarrow C_2H_3CN + CH_3 && \Delta H = -22\\
&\rightarrow CH_3C(CN)CH_2 + H && \Delta H = -11\\
&\rightarrow CH_3C_2H_2CN + H && \Delta H = -8\\
&\rightarrow CH_2(CN)CHCH_2 + H && \Delta H = -7
\end{aligned}$$

Unfortunately, we were unable to obtain samples of pure cyanoacetylene or methyl cyanoacetylene in order to compare mass spectra. We have obtained the mass spectra of the three possible C_4H_5N products. They are very similar, and have approximately the spectra m/e 67:66:65:64:63; 100:35:6:20:7. In view of the presence of a large m/e 53 peak, the discrepancy in the spectra from m/e 65 to 63 may be due to the presence of a C_3H_4 component.

It is of interest that ammonia was produced in the reactions with both acetylenes and with ethylene,* although it was not detected in the propylene reaction (Table II). Very approximately, the amount of ammonia produced increased with the proportion of cyano containing products. We are unable to propose a mechanism for this formation of ammonia. It might come about by successive recombination of N atoms, which are relatively abundant, with H atoms, but this is purely speculative.

The complete mechanism for the reaction of N atoms with the lower acetylenes and olefins is certainly very complex and we have made no effort to determine it. We do think that the evidence points to the importance of the CN radical in the reaction and strongly suggests that it forms several important products by displacement reactions at one of the carbons of the double or triple bond.

**In agreement with an earlier observation on the ethylene reaction by J. T. Herron and H. I. Schiff (1955, unpublished).*

THE METAL-CATALYZED DECOMPOSITION OF NITROUS OXIDE (I). DECOMPOSITION ON PURE SILVER, SILVER–GOLD, AND SILVER–CALCIUM ALLOYS[1]

KENNETH E. HAYES[2]

ABSTRACT

The decomposition of nitrous oxide on silver, a silver – 1.14% gold alloy, and a series of silver–calcium alloys has been studied. On all of these catalysts the *initial rate* of decomposition is proportional to the nitrous oxide pressure. The activation energy for pure metals, including platinum and gold, is proportional to the work function. For the silver–calcium alloys the activation energy falls rapidly with increasing calcium content, suggesting that the work function of these alloys falls with increasing calcium content.

INTRODUCTION

This investigation was undertaken as part of a larger program concerned with the silver-catalyzed oxidation of ethylene. For many years this laboratory has been interested in the direct oxidation of ethylene to ethylene oxide using silver–calcium alloys as catalysts (1, 2). However, although a great amount of work has been reported in this field, certain ambiguities remain. It was hoped that the investigation of a comparatively simple reaction, such as the decomposition of nitrous oxide, would prove fruitful in establishing an unequivocal mechanism of the silver-catalyzed oxidation of ethylene.

Although the catalytic decomposition of nitrous oxide by semiconductors has claimed the attention of many workers, comparatively little has been done with metallic catalysts. To date the only metals to have been investigated are platinum (3), gold (4), silver (5), and nickel (6), and even for these, activation energies have been reported only for the first two.

The investigation of Suhrmann (7) on the effect of nitrous oxide on the resistance of transparent nickel films (8) and on the photoelectric emission of platinum surfaces (9) shows that nitrous oxide is probably chemisorbed on metals as N_2O^-, the rate determining step in the decomposition then being the adsorption of nitrous oxide, followed by a fast thermal dissociation of nitrogen from the adsorption complex. If this is correct, then the activation energy for the decomposition should be proportional to the work function of the catalyst.

EXPERIMENTAL

Apparatus

The apparatus used was a conventional high-vacuum system. The reactor was a wire wound Pyrex glass tube, 35 mm O.D. and approximately 30 cm long. At one end of this tube was a 29/42 female standard taper joint, for ease in changing catalysts; the matching male joint had a 6-mm thermocouple well running through the center, this tube ending in the center of the reactor, and bent at such an angle so as to be within the catalyst mass when the catalyst was installed. An all-glass centrifugal circulating pump, a 1-liter ballast flask, and a mercury manometer completed the reactor circuit. U-tubes filled with silver turnings were inserted between the reactor and the manometer, and also

between the reactor and inlet to the vacuum system, to prevent contamination of the catalysts by mercury. The temperature of the reactor was held to within ±2° C by a Bristol controller. Catalyst powders were contained in a Pyrex glass boat placed in the center of the reactor. When foils were used as catalysts these were wrapped around the center thermocouple well.

Nitrous Oxide

The nitrous oxide was supplied by the Matheson Company and had a nominal purity of 98%. It was purified in the conventional manner by a triple sublimation/distillation, always discarding the first and last fractions.

The Catalyst

1. The pure silver catalyst was prepared as a foil (10 feet×0.625 in.×0.002 in.) from a vacuum melted, chill cast ingot, the silver had been purified by a triple-electrolysis of Mint-Grade silver, and had a purity of 99.998% as found by spectrographic analysis. This catalyst weighed 37.000 g.

2. The silver–gold alloy foil was prepared in a similar manner to the pure silver foil, i.e. the metals were melted together in a small induction furnace, chill cast under vacuum, and rolled. The gold, which again had been purified by repeated electrolysis, analyzed as 99.9995% Au. The foil contained 1.14% Au. The catalyst was of the same thickness and width as for No. 1, two lengths were used in the experiments to give weights of 28.500 and 40.000 g.

3. The silver–calcium alloys were prepared from an 8.5% calcium in silver master alloy. Some 50–60 g of 60–200 mesh alloy were held in steam at from 200–350° C for from 1–8 hours. After cooling, the alloy was then subjected to the following leaching schedule: (*a*) soak in cold 20% acetic acid for 10 minutes, (*b*) wash well in distilled water, (*c*) repeat (*a*), (*d*) repeat (*b*), (*e*) boil in 20% acetic acid for 30 minutes, (*f*) repeat (*b*), (*g*) boil in 20% acetic acid for 60 minutes, (*h*) repeat (*b*), (*i*) boil in distilled water for 30 minutes, (*j*) drain and dry, resieve the catalyst, retaining only the 60–200 mesh size, and send sample to analysis. By varying the temperature of the steam, and/or the steaming time, a series of catalysts was prepared with residual calcium contents varying from 0.11% to 1.70%.

Experimental Technique

A sample of the catalyst powder was weighed out accurately and put into the reactor as described, the reactor was closed, using a sulphur-free mass-spectrometer wax[3] to seal the 29/42 joint together, the necessary glass blowing was then done, and the catalyst evacuated, by mercury pump, at 500° C for 19–20 hours. This treatment was sufficient to remove any adsorbed gases, such as water, oxygen, or carbon dioxide that had been picked up during storage. Experiments were always performed to check on the reaction kinetics before the activation energy runs, by making observations at constant temperature and different initial pressures. Activation energy runs were always made using the bracketing technique.

RESULTS AND DISCUSSION

For all of the catalysts studied, the *initial rate* law is given by:

$$[1] \qquad \frac{-dP_{N_2O}}{dt} = kP_{N_2O}.$$

[3]*Manufactured by Robert R. Austin, Box 374E, Pasadena 8, California, U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

This is illustrated in Fig. 1, which gives typical results for a plot of initial rate (cm/min) against initial nitrous oxide pressure. Steacie and Folkins (5) have shown that, on silver catalysts, the over-all rate of the decomposition is given by:

$$[2] \qquad \frac{-dP_{N_2O}}{dt} = \frac{kP_{N_2O}}{1+bP_{O_2}},$$

the integrated form of [2] is:

$$[3] \qquad k = \frac{(1+ab)}{t} \ln [a/(a-x)] - \frac{bx}{t},$$

where a is the initial nitrous oxide pressure and x is the amount of nitrous oxide that has reacted after time t. Following Steacie and Folkins we may write

$$\frac{1}{t} \ln \frac{a}{(a-x)} = K_m,$$

and $x/t = V$. A plot of K_m against V will then give a straight line if equation [2] is correct. Although this investigation deals in the main with initial rates, an indication that equation [2] is correct is illustrated in Figs. 2 and 3, which give the raw data for the decomposition on pure silver foil at 793° K and the K_m–V plot for the same data. The fall from linearity of the last points for the low pressure experiment is probably due to the reaction becoming diffusion controlled, the extent of reaction having taken place exceeding 95%.

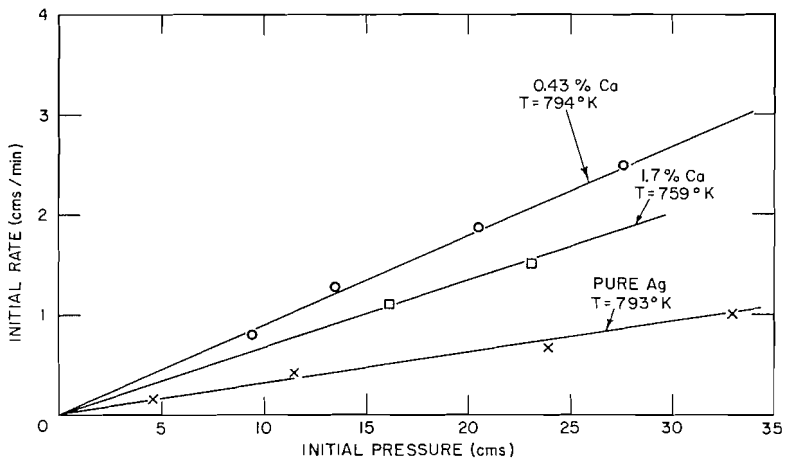

FIG. 1. Dependence of initial rate on N_2O pressure.

In Fig. 4 a plot of $-\log k$ against $1/T$ is given (where k is the initial rate constant per gram of catalyst) for most of the catalysts that were used. Not all of the results are shown for the sake of clarity. The values of the activation energies were obtained by the method of Least Mean Squares, which gave at the same time the values of the logarithm of the pre-exponential factor, A.

In Fig. 5, a composite plot of activation energy against work function, and activation energy against calcium content in silver, is shown. The activation energies obtained by Hinschelwood and Pritchard for platinum and gold are included for completeness. The point for Ag – 1.14% Au is placed on the E–ϕ line quite arbitrarily, being defined solely by the value of E.

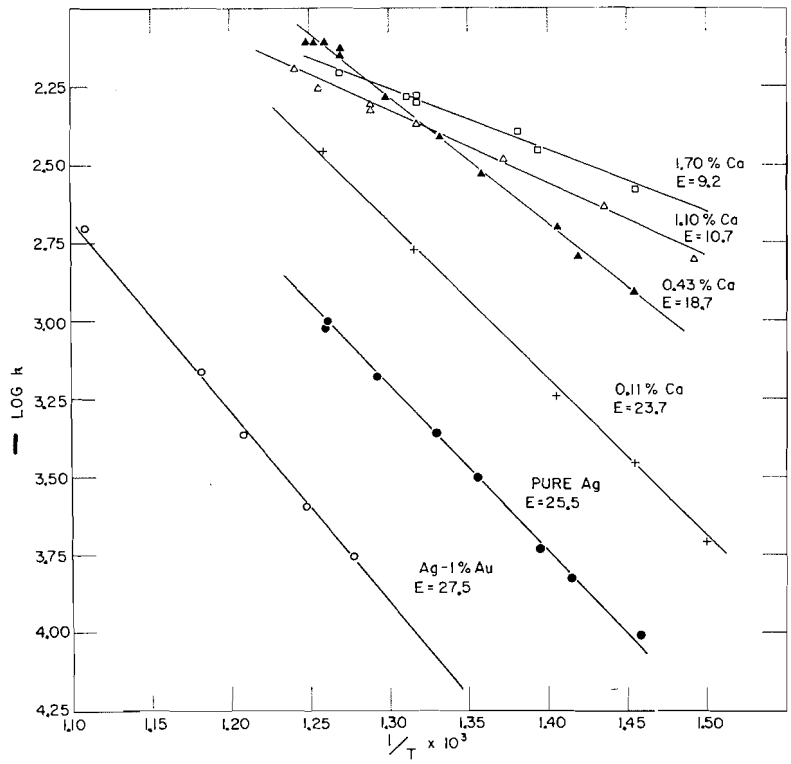

FIG. 4. Arrhenius plot for the various catalysts.

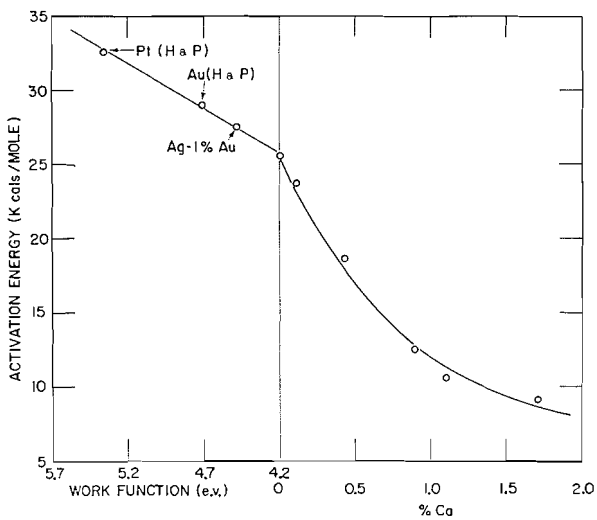

FIG. 5. The relationship between activation energy and work function for pure metals, and between activation energy and calcium content for Ca–Ag alloys.

From the linear relationship between E and ϕ it may be concluded that the rate determining step in the decomposition involves an electron transfer from the catalyst to the adsorbed gas. In this case, there are two possible mechanisms: (1) that the rate determining step is the adsorption of N_2O as N_2O^-,

$$N_2O + e \overset{\text{r.d.s.}}{\rightleftharpoons} N_2O^- \qquad [4a]$$

$$N_2O^- \underset{\text{fast}}{\longrightarrow} N_2 + O^- \qquad [4b]$$

or (2) that the r.d.s. is the dissociative chemisorption of nitrous oxide

$$e + N_2O \overset{\text{r.d.s.}}{\longrightarrow} N_2 + O^-. \qquad [5]$$

Although the present work is unable to distinguish between these two mechanisms, it is clear that the removal of adsorbed oxygen, either by the reaction between two adsorbed O^- ions, or between O^- and gaseous N_2O, cannot be the rate determining step, as either of these two reactions involves the donation of electrons back to the catalyst. Such a requirement would lead to the expectation of finding that the activation energy decreased with increasing work function, in opposition to the observed facts. It is hoped that a projected study of the adsorption characteristics of nitrous oxide on these catalysts, together with a detailed examination of the over-all reaction rate will be able to settle the mechanism of the reaction more definitely.

From Fig. 4 and the right-hand side of Fig. 5, it is seen that residual calcium has a marked effect both on the specific activity of the catalysts and on the activation energy. On the basic postulate that the activation energy is proportional to the work function, it is apparent from Fig. 5 that the role of calcium in the Ca–Ag alloys is to lower the work function, and hence enhance the N_2O decomposition. In view of the well-known role of alkaline earths in governing emission from oxide covered cathodes (10), this result is not surprising.

Figure 6 shows the compensation effect that was obtained with the Ag–Ca alloys. A possible explanation for this effect is that these alloys are truly heterogeneous, even on the macroscale. The values of Ca % of Fig. 5 refer to catalyst samples of 60–200 mesh, and for several samples of the same catalyst the Ca analysis was reproducible to 1% or better. However, an analysis of various mesh sizes for the same catalyst showed that the calcium content was strongly dependent on the degree of subdivision of the catalyst.

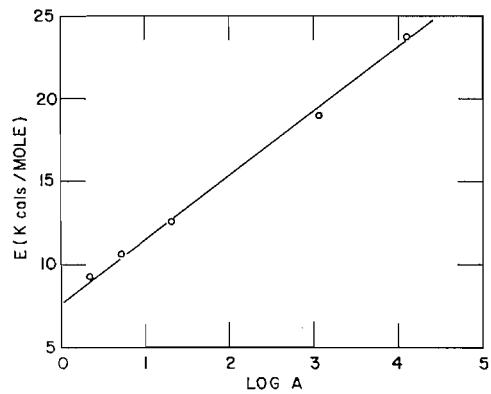

FIG. 6. The compensation effect for Ca–Ag alloys.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12

Three samples of one catalyst gave the following result: (1) average mesh size 80, Ca % = 0.69; (2) A.M.S. 100, Ca % = 0.53; (3) A.M.S. 150, Ca % = 0.22. It therefore follows that the activation energies found for the Ag–Ca alloys are probably only approximations, good over only a small temperature range; more detailed and accurate values of k extending over a much larger temperature range might be expected to produce log $k - 1/T$ plots with definite curvatures.

THE BROMINATION OF URACIL AND THYMINE DERIVATIVES[1]

A. M. MOORE[2] AND SHENA M. ANDERSON[2]

ABSTRACT

The bromination of 1,3-dimethyluracil, uracil, and thymine and of the nucleosides and nucleotides of the latter two compounds has been followed potentiometrically and spectrophotometrically. The results indicate that all the compounds except uracil react initially with 1 mole of bromine to form 5-bromo-6-hydroxy-hydropyrimidine derivatives. If the resulting compound still has a hydrogen at position 5 it may undergo dehydration on heating or with acid catalysis to form the corresponding 5-bromopyrimidine, which is then capable of further reaction with bromine. Uracil itself appears first to undergo substitution to 5-bromouracil, and then both the uracil and 5-bromouracil are brominated together to yield ultimately 5,5-dibromo-6-hydroxyhydrouracil.

INTRODUCTION

The study of the chemical changes induced by ultraviolet light in the uracil and cytosine components of nucleic acids has led to the recognition that the initial products of reaction in aqueous systems belong to the class of 6-hydroxy-hydropyrimidines (8, 9, 10, 12). This finding has led, in turn, to new interest in the 5-bromo-6-hydroxyhydrouracils and related compounds both as intermediates in the synthesis of the irradiation products and as chemical analogues of such products.

A recent report by Wang (11) has shed a good deal of light on the bromination reactions of uracil and 1,3-dimethyluracil. Our own studies reported here have included these compounds but have also been extended to the nucleosides and nucleotides of uracil and thymine.

EXPERIMENTAL

The spectrophotometric measurements were made with a Beckman Model DK2 Recording Spectrophotometer. Except where otherwise noted the spectroscopic changes during bromination were determined by adding 10^{-2} M bromine water a few microliters at a time to 10^{-4} M pyrimidine solutions. The small dilution involved has been neglected.

For the potentiometric titrations a platinum and a saturated calomel electrode were used in conjunction with a Leeds and Northrup Student Potentiometer in the earlier experiments, and with a Radiometer Titrator in the later ones. A small beaker equipped with a magnetic stirrer and held at room temperature (22–24° C) was charged with a measured volume of 10^{-2} M solution of the pyrimidine compound in acetate buffer and, with continuous rapid stirring, the potential was measured after successive additions of standard bromine water (approximately 10^{-2} M). The bromine was dispensed from a small automatic burette with blackened reservoir. To minimize the effect of a rather rapid initial drift in potential the measurements were all made 1 minute after each addition of bromine. Corresponding measurements using the same volume of buffer in place of the pyrimidine solution were used to determine a blank correction.

The uracil, uridine, uridylic acid, and thymine were obtained from Nutritional Biochemicals Corp., the thymidine from California Biochemical Research Corp. The uracil was recrystallized twice from water and dried at room temperature *in vacuo*. 1,3-Dimethyluracil was prepared from it by the method of Davidson and Baudisch (2) and was

recrystallized from 95% ethanol (m.p. 122° C; ϵ = 8600 at 266 mμ). The rest of the compounds were used as received after checking that the molecular extinctions and other characteristics of their absorption spectra were in satisfactory agreement with published values (1).

RESULTS

1,3-Dimethyluracil

Potentiometric titration (Fig. 1) indicated that any excess bromine beyond 1 mole per mole of dimethyluracil remained in solution as free bromine. This finding was supported by the spectrophotometric measurements (Fig. 2) which demonstrated that 1 mole of bromine was sufficient to eliminate completely the absorption band at 266 mμ. The absorption curves throughout the reaction exhibited isosbestic points at 215 and 245 mμ, thus pointing to a quantitative conversion of 1,3-dimethyluracil to 5-bromo-6-hydroxy-1,3-dimethyluracil. If, after the addition of 1 mole of bromine, the solution was heated at 100° C or if it was acidified to pH 1 (HCl) the spectrum underwent further progressive change, with a new isosbestic point at 254 mμ, to yield finally and quantitatively 5-bromo-1,3-dimethyluracil (ϵ_{max} = 8000 at 283 mμ; ϵ_{min} = 1290 at 245 mμ; m.p. 181° C) (cf. curve 5, Fig. 2).

Uridine and Uridylic Acid

These behaved similarly and will be considered together. Both compounds lost their 262 mμ absorption band on addition of 1 molecular equivalent of bromine, the transformation exhibiting isosbestic points at 234 and 291 mμ in both cases. An experiment with uridylic acid is illustrated in Fig. 3.

To follow the titration of these compounds with bromine two procedures were employed. At a concentration of 10^{-4} *M* the optical density at 260 mμ was found to decrease linearly with the amount of added bromine to a limiting value corresponding to the absorbance of the product; thereafter the density remained constant. The limiting density was reached in the case of uridine at 0.97 and in the case of uridylic acid at 0.99 moles of bromine per mole of pyrimidine.

In the second procedure, by using concentrations of the order of 10^{-3} *M* for both the bromine and the pyrimidines it was possible to observe the appearance of the absorption band at 390 mμ due to free bromine when the end point was reached. At this wavelength the optical density was constant (nearly zero) up to the end point and then rose rapidly as extra bromine was added. The end point occurred for uridine at 1.01 and for uridylic acid at 0.95 moles bromine per mole of pyrimidine.

In the case of uridylic acid an argentimetric titration (potentiometric) of the free bromide ion at the end point verified that 1 mole of bromine while eliminating the absorption band at 262 mμ yielded 1 equivalent of bromine.

When the brominated solution of uridylic acid was heated at 100° C the spectrum developed a new maximum at 278 mμ and minimum at 242 mμ as dehydration gave rise to 5-bromouridylic acid. (Compare ϵ_{max} 279 mμ, ϵ_{min} 244 mμ for the deoxyribonucleotide of 5-bromouracil in 0.1 *N* HCl (3).)

Uracil

The spectral changes accompanying the reaction of bromine with uracil in 0.1 molar acetate buffer (pH 4.7) are illustrated in Fig. 4. Two moles of bromine were required to eliminate the absorption maximum at 259 mμ. Although, at that wavelength the absorbance decreased progressively as bromine was added, the situation was quite

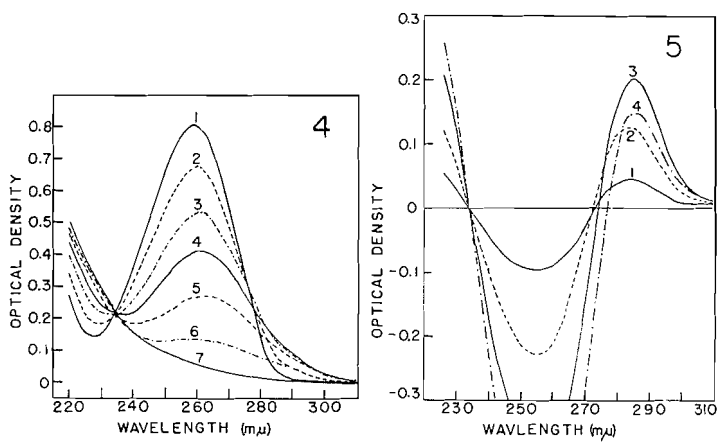

FIG. 4. Bromination of uracil (10^{-4} *M*; in 0.1 *M* acetate buffer, pH 4.7). Curves 1–7 respectively show the spectra obtained upon adding zero, 0.32, 0.64, 0.96, 1.28, 1.60, and 1.92 moles of Br_2 per mole of uracil.

FIG. 5. Differential spectra obtained by placing 10^{-4} *M* uracil in both the sample and reference cuvettes of the spectrophotometer and then recording the spectrum after successive additions of Br_2 to the sample cuvette. Curves 1–4 respectively represent 0.41, 0.84, 1.44, and 1.85 moles of Br_2 per mole of uracil.

different at 280 mμ. Here the absorbance first increased to a maximum and then decreased again as more bromine was added. The changes during the first part of the reaction can be more clearly understood by examining the differential spectra (Fig. 5).

The form of the absorption curves suggested that 5-bromouracil (λ_{max} = 276 mμ) was being produced as an intermediate and that it reacted eventually with more bromine to yield 5,5-dibromo-6-hydroxyhydrouracil. In such an event presumably the 5-bromouracil would increase in amount initially to the point at which it would be reacting with bromine at the same rate as the residual uracil and then, as the uracil was used up, the reaction of the 5-bromouracil would predominate. If this were true one might expect that if one added 5-bromouracil to the uracil initially, in sufficient quantity, the absorption curves during the bromination would not exhibit the preliminary increase in the region of 280 mμ. A series of mixtures of the two compounds was studied in this way and this was indeed the finding. Figure 6 gives one example in which 5-bromouracil was added initially to the sample to a concentration of 0.55×10^{-4} *M*. The same amount of 5-bromouracil was added to the reference cell so that its contribution to the absorption curve was cancelled out. The changes during bromination thus appeared as the simple removal of uracil and its conversion to 5,5-dibromo-6-hydroxyhydrouracil, the known final product.

The results of the potentiometric titration with bromine, included in Fig. 2, were in agreement with the spectrophotometric measurements in indicating no end point until 2 moles of bromine had been added per mole of uracil.

Thymine

The family of absorption curves obtained for the bromination of thymine exhibited 2 isosbestic points (at 223 and 233.5 mμ) corresponding to a mole for mole conversion of thymine to 5-bromo-6-hydroxyhydrothymine. The elimination of the absorption band required approximately 1 mole of bromine. As the thymine was found chromatographically to contain several per cent of uracil as impurity quantitative study was not pursued further in this case.

Thymidine

The spectral changes during the bromination of thymidine resembled those for thymine but with isosbestic points at 225.5 and 236 mμ (Fig. 8). The absorption band at 265 mμ was eliminated by 1.07 moles of bromine per mole of thymidine. The rate of reaction was lower than in the case of the uracil derivatives so that some minutes were required for it to go to completion. A 10-minute reaction time was employed in the experiments reported here. The effect of heating the brominated thymidine solution is shown in the final curve of Fig. 8.

Reaction of Uracil with 5,5-Dibromo-6-hydroxyhydrouracil

As an aid in interpreting the results of the uracil bromination experiments the following reaction has been investigated: 0.112 g uracil (0.001 mole) and 0.288 g of 5,5-dibromo-6-hydroxyhydrouracil (0.001 mole) were dissolved in 10 ml of 1 *N* HCl at 100° C and the solution was kept in the steam bath at 100° C. Samples were withdrawn from time to time and the absorption spectra recorded after diluting 1:1000 with water. The results are illustrated in Fig. 7. It should be pointed out that, after about 30 minutes, 5-bromouracil began to crystallize from the solution, so that its concentration remained constant from then on. At the times the samples were taken aliquots were also removed for chromatography on paper along with markers of uracil, 5-bromouracil, and 5,5-dibromo-6-hydroxyhydrouracil. The paper chromatogram was developed with *n*-butanol saturated

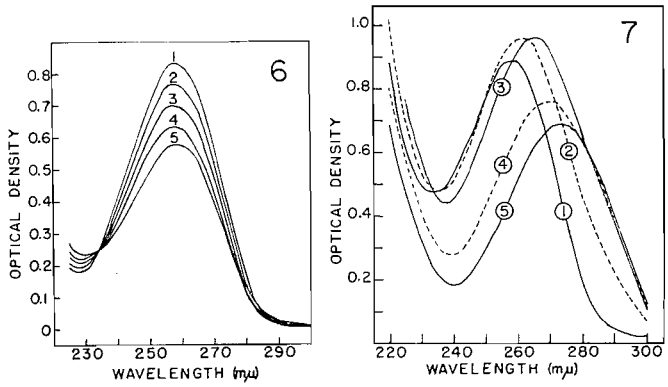

FIG. 6. Bromination of a mixture of uracil (10^{-4} M) and 5-bromouracil (0.55×10^{-4} M). Curves 1–4 correspond respectively to zero, 0.125, 0.25, 0.375, and 0.50 moles of Br_2 per mole of pyrimidine. A solution of 5-bromouracil (0.55×10^{-4} M) was used as a reference in the spectrophotometer.

FIG. 7. Bromination of uracil by means of 5,5-dibromo-6-hydroxyhydrouracil. Curves 1–5 show the spectra obtained for samples withdrawn at 3 minutes, 1 hour, 2 hours, 4 hours, and 24 hours respectively.

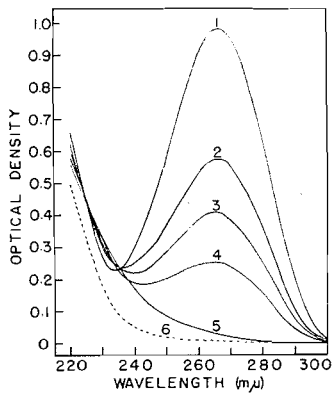

FIG. 8. Bromination of thymidine (10^{-4} M). Curves 1–5 respectively correspond to addition of zero 0.47, 0.65, 0.84, and 1.21 moles of Br_2 per mole of thymidine. Curve 6 shows the effect of heating at 100° C for 10 minutes after adding 1.21 molecular equivalents of Br_2.

with water and the spots located by the ultraviolet print method. The formation of 5-bromouracil (R_f 0.48) and the disappearance of both uracil (R_f 0.31) and 5,5-dibromo-6-hydroxyhydrouracil (R_f 0.62) during the reaction was clearly evident (Fig. 9).

DISCUSSION

The results of these studies lead to the conclusion that the reaction of dilute solutions ($\leqslant10^{-2}$ M) of uridine, uridylic acid, and 1,3-dimethyluracil with bromine water may be summarized:

[1]

[2] 
(Dehydration)

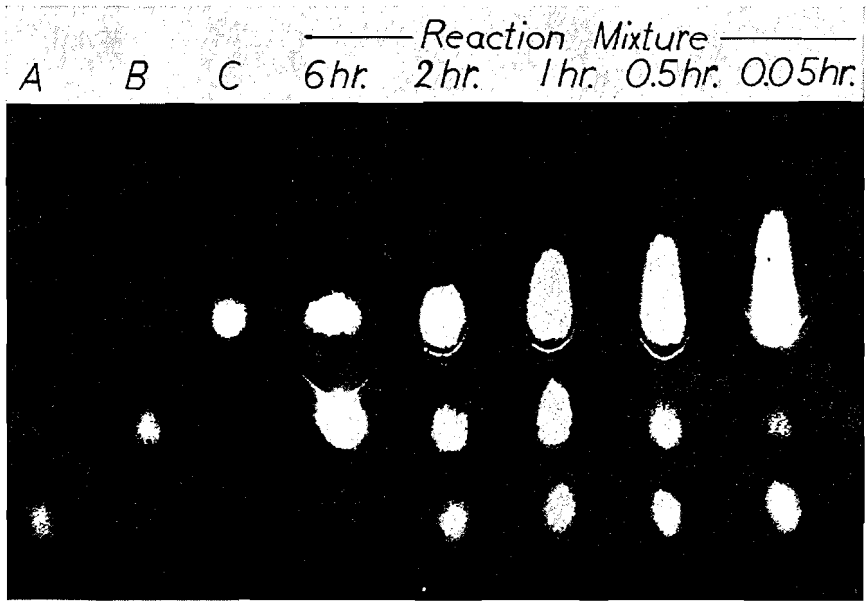

FIG. 9. Paper chromatogram showing reaction of uracil with 5,5-dibromo-6-hydroxyhydrouracil. Origin at top. Lanes A, B, and C represent markers (0.01 ml) of 5,5-dibromo-6-hydroxyhydrouracil (0.1 *M*), 5-bromouracil (10^{-2} *M*), and uracil (10^{-2} *M*) respectively. Solvent: *n*-butanol saturated with water. The narrow arc preceding some of the uracil spots is due to the presence of HCl in the reaction mixture.

The products of reaction [1], all 5-monobromo-6-hydroxyhydrouracil derivatives, are moderately stable compounds which, however, lose water on heating or, with acid catalysis, at room temperature to yield nearly quantitatively the corresponding 5-bromouracil derivative. Both reactions are readily observed spectrophotometrically, the first leading to elimination of the original absorption band in the 260–265 mμ region, the second producing a new band in the vicinity of 280 mμ. Unless reaction [2] is promoted the uptake of bromine stops when 1 mole has reacted. In the case of uridylic acid it was shown that 1 equivalent of bromide ion was produced at this stage.

Thymine and thymidine undergo the first of the foregoing reactions but the products, lacking any hydrogen on position 5, are not capable of the subsequent dehydration. Instead, on heating in weakly acid solution they react in a manner that leads to a marked decrease in ultraviolet absorption at all wavelengths <280 mμ. This change is probably attributable to opening of the pyrimidine ring but we have made no attempt to isolate the products.

The foregoing interpretation is in general agreement with the conclusions of Wang (11) based on his study of the bromination of 1,3-dimethyluracil.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

The case of uracil itself we have found to be rather more complicated than Wang's interpretation would indicate. The potentiometric titration gave no end point until 2 moles of bromine had been added per mole of uracil (Fig. 1) and 2 moles of bromine were required to eliminate the absorption band at 259 mμ (Fig. 4). The picture is further complicated by the transient appearance of what appears to be 5-bromouracil during the bromination.

This is the behavior that one would expect of a reaction proceeding as follows:

[3] 
[4] 
If we represent the instantaneous concentrations of bromine, uracil, 5-bromouracil, and 5,5-dibromo-6-hydroxyhydrouracil at time t by s, x, y, and z respectively then we may write for these reactions the following equations in which the subscript zero implies initial concentration:

$$-dx/dt = k_1xs, \quad [5]$$

$$dy/dt = k_1xs - k_2ys, \quad [6]$$

$$dz/dt = k_2ys, \quad [7]$$

$$-ds/dt = k_1xs + k_2ys, \quad [8]$$

$$x_0 = x+y+z, \quad [9]$$

$$s_0 = s+y+2z. \quad [10]$$

An analytical solution of these equations does not yield the values of y and z in a convenient explicit form, but it has been possible, with the aid of a Datatron electronic digital computer, to calculate the final concentrations of x, y, and z for values of s_0 from zero to $2x_0$ and for values of $\kappa = k_2/k_1$ ranging from 0.5 to 2.0. Using these concentrations together with the known molecular extinctions of the three organic compounds the corresponding absorption spectra have been calculated for $\kappa = 2$ and are plotted in Fig. 10 for comparison with the experimental curves (Fig. 4). The general agreement is very good. The variation of the curves is not sufficiently sensitive to κ to make this a good way of estimating this constant, but an estimate may be obtained from the experimental results. From equation [6] it is evident that when uracil and 5-bromouracil are both reacting with bromine in such a way that $dy/dt = 0$, $k_1xs = k_2ys$ and $\kappa = k_2/k_1 = x/y$. Thus by brominating various initial mixtures of uracil and 5-bromouracil and determining the ratio at which $dy/dt = 0$ one may estimate κ. This is easily done, since,

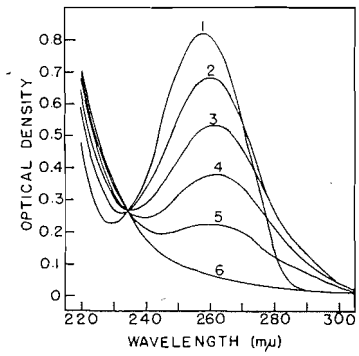

FIG. 10. Calculated curves for the bromination of uracil (10^{-4} M) by mechanism proposed in text, assuming $\kappa = 2$, and amounts of Br_2 ranging from zero to 2 molecular equivalents in 5 equal steps.

of the various components of the reaction mixture, only the 5-bromouracil contributes appreciably to the optical density at 282 mμ. The initial density change, ΔD_{282}, for a fixed amount of added bromine (0.1 mole) is nearly a linear function of the initial uracil:bromouracil ratio, and interpolation to $\Delta D_{282} = 0$ yields $\kappa = 1.7$. The reactions [3] and [4] are so rapid that direct estimation of k_1 and k_2 was not feasible.

The foregoing is not the only possible mechanism for the bromination of uracil that might be considered. An alternative would be the route suggested by reactions [1] and [2] followed by reaction of the 5-bromouracil thus formed with a second mole of bromine. Qualitatively this would explain the formation of 5-bromouracil and the over-all consumption of 2 moles of bromine.

Unfortunately for this hypothesis the dehydration of the 5-bromo-6-hydroxyhydrouracils is quite a slow reaction at room temperature and near neutral pH's, whereas the over-all bromination (2 moles) as observed during the present experiments is very rapid—too fast to measure by our technique. For all the uracil derivatives which we have investigated, the dehydration of the 5-bromo-6-hydroxyhydrouracil derivative is markedly slower than the dehydration of the corresponding 6-hydroxyhydrouracil derivative. Now the dehydration of 6-hydroxyhydrouracil itself at pH 5 and 20° C has a half life of about 19 hours (7) so that one would expect 5-bromo-6-hydroxyhydrouracil to have a half life of at least this magnitude under these conditions.

We must conclude that this can not be the mechanism by which the 5-bromouracil is formed and that, in contrast with the 1-substituted uracils which react by the mechanism cited in reactions [1] and [2], uracil itself first undergoes substitution at position 5 and only then enters into reactions [1] and [2].

One further point deserves comment here. It has been stated in the literature that uracil solutions treated with 1 molecular equivalent of bromine and subsequently heated give quantitative yields of 5-bromouracil (11). Our findings indicate that, before heating, such solutions contain 5,5-dibromo-6-hydroxyhydrouracil, 5-bromouracil, and uracil in roughly comparable amounts. How then can one explain the reported high yield of 5-bromouracil?

We suggest that the explanation lies in the fact that one of the two bromine atoms of 5,5-dibromo-6-hydroxyhydrouracil is capable of acting as a brominating agent. Hilbert and Jansen (4) observed that warm aqueous solutions of the compound liberated iodine from potassium iodide, and Johnson *et al.* (5, 6) showed that under similar conditions it oxidized thiourea and brominated malonic acid. In each case the dibromo-compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

itself was reduced to 5-bromouracil. In the present instance the residual uracil is presumably brominated on heating, at the expense of the 5,5-dibromo-6-hydroxyhydrouracil so that 5-bromouracil is the sole product.

In the usual preparation of 5-bromouracil, one evaporates to dryness a brominated solution of uracil which is strongly acid (HBr). Our study of the reaction between uracil and 5,5-dibromo-6-hydroxyhydrouracil under similar conditions of acidity and temperature showed that 5-bromouracil is formed in good yield at the expense of both reagents. With an initial concentration of 10^{-4} M for each compound the reaction was too slow to follow conveniently but at 0.1 M concentration, as reported here, the reaction proceeded at an easily measurable rate. Evaporation of a reaction mixture would provide ideal conditions for complete reaction. We believe that this mechanism provides the solution of the apparent discrepancy between our findings and those of Wang (11). On the other hand, this reaction is evidently much too slow to necessitate its inclusion along with reactions [3] and [4] in describing the kinetics of bromination of dilute (10^{-4} M) solutions of uracil at room temperature.

ACKNOWLEDGMENT

The authors gratefully acknowledge their indebtedness to Dr. J. M. Kennedy of the Theoretical Physics Branch, Atomic Energy of Canada Limited, for programming and carrying out the computations, the results of which are reported in the foregoing pages.

PRESSURE AND TEMPERATURE EFFECTS ON THE KINETICS OF THE ALKALINE FADING OF ORGANIC DYES IN AQUEOUS SOLUTION[1]

DAVID T. Y. CHEN AND KEITH J. LAIDLER

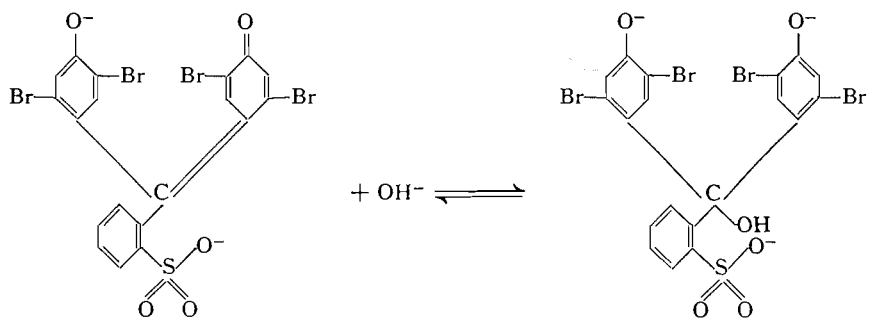
ABSTRACT

The rates of the alkaline fading of bromphenol blue, phenolphthalein, crystal violet, and malachite green have been studied from atmospheric pressure to 16,000 pounds per square inch. The rates for phenolphthalein and malachite green were also measured over a range of temperatures in order to determine the activation energies and entropies. The reactions went essentially to completion with the exception of the fading of phenolphthalein, for which the effects of temperature and pressure on the back reaction and equilibrium constant were also studied. No effect of pressure was found for the fading of crystal violet, but the reactions of the other three dyes were accelerated by pressure, so that there are negative volumes of activation. These are correlated with the entropies of activation and are interpreted in terms of the reaction mechanisms.

INTRODUCTION

Previous work (1, 2, 3, 4) has shown that for a number of reactions in aqueous solution the effects of pressure may be interpreted in terms of the electrostriction of the solvent around ions and dipoles. The present investigation consists of a study of reactions involving the attack by a hydroxide ion on large organic dye molecules. These reactions are of such a nature that electrostriction effects are not as powerful as in many of the previous reactions studied, so that structural effects are expected to play a part in determining the influence of pressure. Since the reactions chosen are structurally similar to one another, but are quite different electrically, they provide a useful means of separating the two effects. The dyes used were bromphenol blue, phenolphthalein, crystal violet, and malachite green, and of these the first two are negatively charged and the second two positively charged.

The kinetics of the alkaline fading of bromphenol blue were first studied under atmospheric pressure by Panepinto and Kilpatrick (5) and by Amis and La Mer (6). The results of these workers led to the following proposed mechanism, which was suggested by Amis and La Mer:



Quinoid form (blue) Carbinol form (colorless)

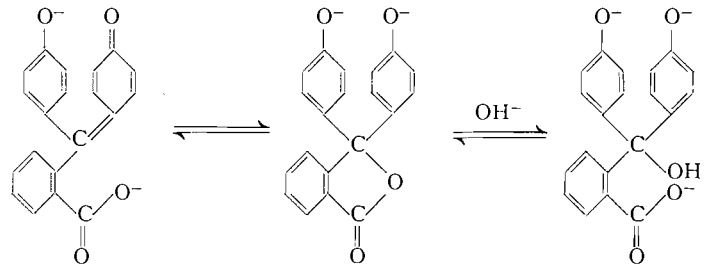
The reaction went to completion.

The alkaline fading of phenolphthalein was studied by Kober and Marshall (7), Biddle

[1]*Manuscript received November 20, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.

Can. J. Chem. Vol. 37 (1959)

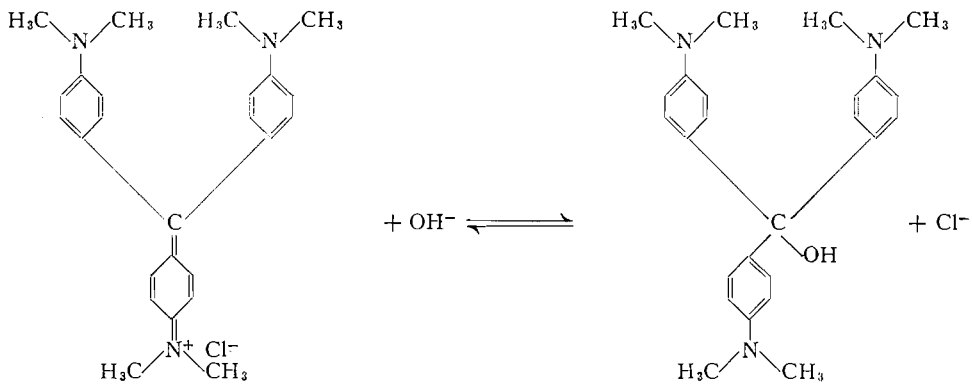
and Porter (8), Lund (9), Wygaerts and Eeckhout (10), and by Barnes and La Mer (11). The mechanism of the reaction can be represented by the following equations:



Quinoid form (red) Lactone form Carbinol form (colorless)

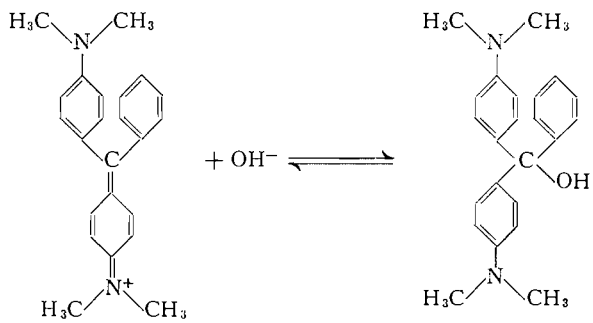
The reaction does not go to completion, and in our investigation the kinetics have been investigated in both directions over a range of temperatures and pressures.

The kinetics at atmospheric pressure of the fading of crystal violet in alkaline solution was studied by Biddle and Porter (8), Hockberg and La Mer (12), Goldacre and Phillips (13), and in great detail by Turgeon and La Mer (14). The reaction goes essentially to completion, and again involves the formation of a carbinol, as indicated below:



Quinoid form (violet) Carbinol form (colorless)

Very little work has previously been done on the fading of malachite green, which proceeds according to the equation:



Quinoid form (green) Carbinol form (colorless)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

In 1909 Sidgwick and Moore (15) made a few rate measurements, and Goldacre and Phillips (13) later made some studies in buffered solutions of pH 7.9.

It is to be seen that the four reactions may be represented schematically by the following equations:

$$(\text{B.P.B.})^- + \text{OH}^- \leftrightarrows (\text{B.P.B.})^{=}\text{OH}$$
$$(\text{P.P.})^- + \text{OH}^- \leftrightarrows (\text{P.P.})^{=}\text{OH}$$
$$(\text{C.V.})^+ + \text{OH}^- \leftrightarrows (\text{C.V.})\text{OH}$$
$$(\text{M.G.})^+ + \text{OH}^- \rightleftarrows (\text{M.G.})\text{OH}$$

The first two are reactions between ions of the same sign, the last two between ions of opposite sign. If electrostatic effects alone were important the first two reactions would therefore be expected to involve a decrease in volume during the activation process, and to be accelerated by pressure. The last two reactions, on the other hand, should involve an increase in volume and should be retarded by pressure. The results below show that these anticipations are realized in the first two cases, but that the third reaction is unaffected by pressure. The fourth reaction is accelerated by pressure. These results may be due to the fact that the charges do not approach very closely in the formation of the activated complex, and that structural effects are important.

EXPERIMENTAL PROCEDURE

Materials

The bromphenol blue used in the investigation was an Eastman Organics product. A stock solution was prepared by dissolving the dye in absolute ethanol, adding 0.01 *M* sodium hydroxide to convert it to the monosodium salt, evaporating the resulting solution in vacuum to dryness, and diluting with water to 1 liter. The phenolphthalein used was a C.P. grade Fisher product, and it was recrystallized three times from absolute methanol. The crystal violet used was an Anachemia Chemicals Ltd. product, and was purified by precipitating it as the carbinol, dissolving in hydrochloric acid, and recrystallizing the chloride twice; the crystals were dried in a vacuum desiccator. The malachite green used was a Fisher Scientific Company product (M-73), and was found by analysis to have the composition $2[C_{23}H_{25}N_2]C_2H_2O_4 + C_2H_2O_4$ (mol. wt. 926.90). It was purified by recrystallizing it twice from water.

High-pressure Technique

The high-pressure technique used has been described in detail in a previous paper (4) in which a diagram of the apparatus is shown. In brief, the pressure vessel is designed so that the solutions are separated by mercury from the oil used in the rest of the apparatus, and so that samples can be introduced and withdrawn within a short period of time.

Kinetic Procedure

Since the sodium hydroxide was in all cases in excess of the dye, the reactions in the case of bromphenol blue, crystal violet, and malachite green were simple first-order reactions. The phenolphthalein reaction, on the other hand, had to be treated as consisting of opposing first-order reactions.

The first-order rate constants for the bromphenol blue reaction were obtained by plotting the logarithm of the photometric density L against the time and determining the slopes. The kinetic runs were carried out using a mixture that was 2×10^{-5} *M* in bromphenol blue and 0.2 *M* in sodium hydroxide. Five-milliliter samples were taken at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

intervals of about 1500 seconds and delivered into a colorimeter tube containing 5 ml of water. The photometric densities of the solution were determined in an Evelyn photoelectric colorimeter using filter 565; the Lambert–Beer law was found to be obeyed by the dye solutions.

Since the phenolphthalein fading is reversible the mechanism must be represented as

$$(\text{P.P.})^{=} + \text{OH}^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (\text{P.P.})^{\equiv}\text{OH}.$$

The rate of disappearance of the dye is therefore given by

$$[1] \qquad -\frac{d[(\text{P.P.})^{=}]}{dt} = k_1[(\text{P.P.})^{=}][\text{OH}^-] - k_{-1}[(\text{P.P.})^{\equiv}\text{OH}],$$

where k_1 is the second-order rate constant for the forward reaction and k_{-1} is the first-order rate constant for the reverse reaction. Since $[\text{OH}^-]$ is practically constant we can combine it with k_1 to form a pseudo-first-order constant k_1', the resulting equation being

$$[2] \qquad -\frac{d[(\text{P.P.})^{=}]}{dt} = k_1'[(\text{P.P.})^{=}] - k_{-1}[(\text{P.P.})^{\equiv}\text{OH}].$$

The behavior is therefore that of reversible first-order reactions, which obey the kinetic law

$$[3] \qquad k_1' + k_{-1} = \frac{2.303}{t} \log \frac{c_e}{c_e - c}.$$

Here c_e is the equilibrium concentration of the carbinol form of phenolphthalein, and c is the concentration of the carbinol form at any time t. Let c_r be the total concentration of phenolphthalein, c_e' the equilibrium concentration of the pink form of phenolphthalein, and c' the concentration of the pink form at any time t. Then since

$$[4] \qquad c_e = c_r - c_e'$$

and

$$[5] \qquad c = c_r - c',$$

equation [3] becomes

$$[6] \qquad k_1' + k_{-1} = \frac{2.303}{t} \log \frac{c_r - c_e'}{c' - c_e'}.$$

The absorption of light by the substance was found to obey the Lambert–Beer law, and the concentration of the colored substance is therefore directly proportional to the photometric density L according to the expression

$$[7] \qquad c' = L/K_1.$$

Here K_1 is the calibration constant whose value depends on the nature of the colored substance and the characteristics of the filter used. L is the photometric density, equal to $\log (I_0/I)$, where I_0 is the intensity of the incident light and I that of the transmitted light. Equation [6] therefore becomes

$$[8] \qquad k_1' + k_{-1} = \frac{2.303}{t} \log \frac{L_r - L_e}{L - L_e},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

where L_e is the photometric density of the solution at equilibrium, L_τ is the photometric density of the solution when all its phenolphthalein is in the pink form, and L that at any time t. L_τ and L_e are constants. From equation [8] it can be seen that a plot of $\log (L-L_e)$ against the time should result in a straight line with a slope equal to

$$-\frac{k_1'+k_{-1}}{2.303},$$

so that the value of the combined rate constant $(k_1'+k_{-1})$ can be calculated. The individual rate constants k_1 and k_{-1} can be found from the equilibrium constant K, which is equal to k_1/k_{-1}. If $(k_1'+k_{-1})$ is called k_c then

$$[9] \qquad k_1 = \frac{k_1'}{[OH^-]} = \frac{k_c-k_{-1}}{[OH^-]} = \frac{k_c-k_1/K}{[OH^-]}.$$

From this

$$[10] \qquad k_1 = \frac{k_c}{[OH^-]+(1/K)}$$

so that

$$[11] \qquad k_{-1} = k_c-k_1'.$$

The kinetic runs with phenolphthalein were carried out using a solution that was 1.00×10^{-5} M in phenolphthalein and 0.01 M in sodium hydroxide. Ten-milliliter samples were taken at about 2000-second intervals and the photometric densities of the samples were determined in the Evelyn photoelectric colorimeter using filter 540 (the absorption maximum is at 550 μ). The photometric density at equilibrium was determined in each case by allowing the reaction mixture to remain under the experimental conditions for at least 24 hours. The value of the combined rate constant k_c was determined by plotting $\log (L-L_e)$ against the time.

The procedure with crystal violet was similar to that with bromphenol blue. The dye shows an adsorption maximum at 590 μ and the best filter was No. 565. The Lambert–Beer law was again obeyed. The kinetic runs were carried out in a mixture that was 5.0×10^{-6} M in dye and 2.0×10^{-3} M in sodium hydroxide. Samples were withdrawn at intervals of about 900 seconds and the photometric densities L determined using the colorimeter. The values of $\log L$ were plotted against the time, and straight lines obtained in each case. The apparent first-order rate constants were calculated from the slopes of the lines.

The kinetic procedure with malachite green was similar to that with crystal violet. The solutions used were 0.0004 N in NaOH and 0.00002 M in malachite green. Owing to the much lower concentration of NaOH used the solutions were protected from CO_2 with a soda-lime tube. For runs under pressure, 40 ml each of the reacting solution were mixed and introduced into the pressure vessel. Ten-milliliter samples were taken at about 1000-second intervals and the photometric density measured as before using filter No. 565. In each case the logarithms of the photometric densities were plotted against the time.

EXPERIMENTAL RESULTS

Bromphenol Blue

Rate constants for the bromphenol blue reaction were determined at a temperature of 25.0° C and at pressures varying from atmospheric to 16,000 pounds per square inch. Typical plots of $\log L$ against time are shown in Fig. 1, and the rate constants,

slope of the line corresponds to a volume of activation of -14.9 cc per mole. The energy of activation for the reaction was determined by Amis and La Mer (6), and the results at zero ionic strength are

$$\Delta S^* = -13.34 \text{ calories per degree per mole},$$
$$E = 12.2 \text{ kcal per mole},$$
$$A = 2.04 \times 10^{10} \text{ liters per mole per second}.$$

$\Delta V^* = -14.90$ cc/mole.

Phenolphthalein

Since an activation energy for the phenolphthalein reaction had not previously been determined, the rates of the reaction in both directions were measured over a range of temperatures. From the slopes of plots of log $(L-L_e)$ against time, the values of $k_1'+k_{-1}$ can be calculated, and the results are included in Table II. By allowing the mixtures to

DISCUSSION

Comparison with Previous Work

It is difficult to compare the rate constants obtained in the present investigation with those obtained by previous workers, owing to the different conditions employed. The following comparisons may, however, be of interest.

For bromphenol blue the value of the rate constant obtained at 25.0° C and 1 atm pressure was 0.000932 $M^{-1}\,\text{sec}^{-1}$. Extrapolation of Amis and La Mer's (6) results to the same ionic strength (0.2 M) gives 0.000854 $M^{-1}\,\text{sec}^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

For the fading of phenolphthalein the present values of K, k_1, and k_{-1} at 25° C and 1 atm pressure are as shown below:

$$K = 65.25\ M^{-1},$$
$$k_1 = 0.00572\ M^{-1}\ \text{sec}^{-1},$$
$$k_{-1} = 0.0000858\ \text{sec}^{-1}.$$

The values obtained by Barnes and La Mer (11) under the same conditions are:

$$K = 66.70\ M^{-1},$$
$$k_1 = 0.00634\ M^{-1}\ \text{sec}^{-1},$$
$$k_{-1} = 0.0000972\ \text{sec}^{-1}.$$

For crystal violet the value of k_1 obtained in the present work was 0.260 M^{-1} sec^{-1} at 25.0° C. The value of Turgeon and La Mer (14), corrected to the same ionic strength, was 0.256 M^{-1} sec^{-1}. It was found that for this reaction there was some catalysis by the mercury in contact with the solution in the case of the work done in the high pressure vessel; the rate constant in the absence of mercury was 0.207 M^{-1} sec^{-1}.

On the whole the agreement between the results of the present work and those of the previous workers is quite satisfactory.

Significance of the ΔV^* Values

The ΔV^* values obtained in the present investigation are listed in the last column of Table VII, which also gives the values of E, A, and ΔS^*. Also included in this table are the data for a number of other reactions; the last four are in solvents other than pure water.

TABLE VII

Summary of data for reactions in aqueous solution

Reaction	E (kcal)	A	ΔS^* (e.u.)	ΔV^* (cc per mole)	Ref.
Bromphenol blue + OH^-	12.2	2.0×10^{10}	−13.3	−14.9	Present work
Phenolphthalein + OH^- (k_1)	8.6	1.1×10^{4}	−41.9	−19.7	Present work

$C_5H_5N + C_2H_5I \rightarrow C_5H_5N^+(C_2H_5)I^-$	14.4	3.6×10^{5}	−35.4	−15.8	18, 19

Figure 8 shows a plot of ΔV^* against ΔS^* for all of the reactions listed in Table VII. As previously shown (4), there is a fairly good correlation between the values, although the reactions studied in the present work show greater deviations than do the other reactions. This is presumably due to the fact that structural factors are playing a more important role. When electrostatic interactions are predominant a correlation is expected, for reasons discussed in a previous paper (3), but structural effects may introduce deviations.

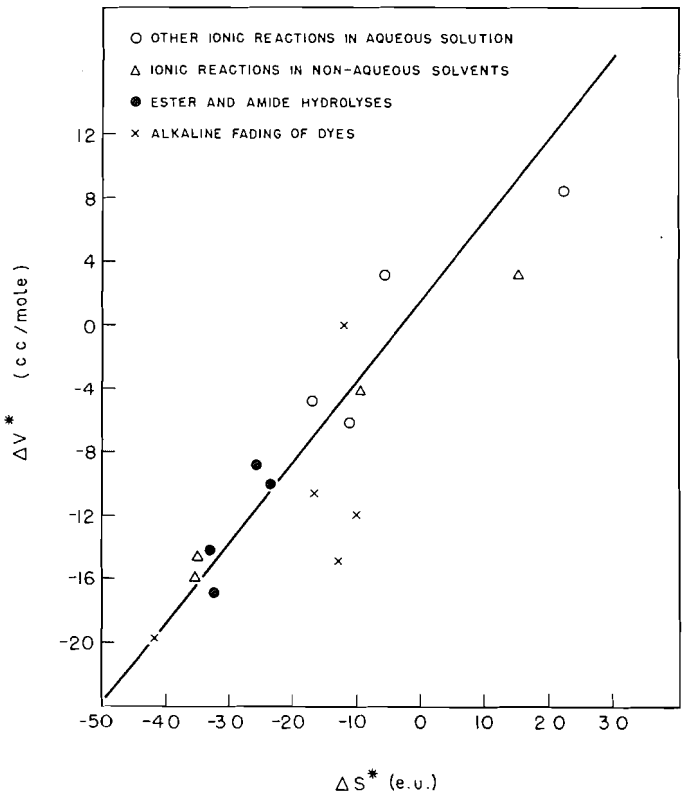

FIG. 8. Plot of ΔV^* against ΔS^* for a number of reactions.

The values of ΔV^* obtained in the present investigation will now be discussed with reference to the mechanisms. The negative volumes of activation obtained for the fading of bromphenol blue and of phenolphthalein are consistent with the fact that there is an approach of charges of the same sign. However, since the hydroxide ion approaches the uncharged central carbon atom, a strong electrostatic effect is not to be expected. It therefore seems likely that structural effects contribute, and some evidence with regard to this is referred to below.

With crystal violet there is no volume of activation in spite of the approach of ions of opposite sign. The hydroxide ion, however, attacks the central carbon atom which is separated by several Ångstroms from the three nitrogen atoms which share the positive charge. Electrostriction effects are therefore unimportant, and the zero value of ΔV^* suggests that there is no volume change due to structural effects.

This conclusion gives the clue to the negative volumes of activation found with the other three fading reactions. The crystal violet ion is the only one of the four investigated in which the three benzene rings lie in a plane. This arises because the resonance involving the quinoid forms of the rings can occur with all three rings.* In the case of bromphenol blue, phenolphthalein, and malachite green only two of the three rings can be involved

**Spectroscopic results (20) have in fact indicated that, owing to repulsion between hydrogen atoms on neighboring rings, the crystal violet ion is not quite planar but that the three rings are twisted slightly out of the plane. This is not found with malachite green and other molecules in which one ring does not enter into the resonance and is therefore out of the plane of the other two rings.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in such resonance. The third ring may therefore be twisted out of the plane of the rest of the molecule, and the molecule may occupy a somewhat greater volume relative to the carbinol form.

The suggestion is therefore that in the bromphenol blue, phenolphthalein, and malachite green reactions the quinoid forms of the dyes may structurally be somewhat larger (relative to the carbinol forms) than in crystal violet, so that the fading reaction involves a decrease in volume. In the bromphenol blue and phenolphthalein reactions there may also be small contributions from electrostriction effects; these, however, will be unimportant for malachite green for the same reason as for crystal violet.

SOME OBSERVATIONS ON THE THEORY OF DIELECTRIC RELAXATION IN ASSOCIATED LIQUIDS[1]

B. E. CONWAY

ABSTRACT

The theory of absolute reaction rates is examined for the case of relaxation in associated polar liquids where the activation process is probably an excitation of a librational motion to one of complete rotation over a rotational potential energy barrier. The rotational barriers in water are calculated using the point-charge model of the water quadrupole and the effect of thermal bond bending is examined. The experimental heats of activation for dielectric relaxation in water and deuterium oxide are discussed and their temperature dependence examined; the heat capacity change for rotational activation is derived. Isotopic effects in the heats of activation, the relaxation times, and frequency factors are discussed. A qualitative explanation is sought for the homogeneity of relaxation times in water; rotation of water molecules in the fields of the hydroxonium and hydroxide ions present in water may account for the narrow distribution of relaxation times observed experimentally. This mechanism is shown to be consistent with other theoretically derived quantities and with the mechanism of proton mobility in water. A different mechanism is indicated in ice, where the proton concentration is lower, but in ice containing extra protons, the mechanism probably reverts to that existing in water.

INTRODUCTION

Although it appears that a number of substances, e.g. H_2S, hydrogen halides, N_2, O_2, CH_4, and certain ammonium salts exhibit rotation–libration transitions (1) as indicated by changes of the specific heat (2, 3) and dielectric constant (4, 5) over a relatively narrow range of temperatures, a free rotation model for treatment of dielectric relaxation behavior is in general inapplicable to more polar associated condensed phases, e.g. water and the alcohols. In such systems the molecules execute librational oscillations rather than rotational motion except upon activation when a temporary libration–rotation transition is indicated, the frequency of which is inversely related to the relaxation time as determined from dielectric dispersion or absorption conductance studies. In the theory of absolute reaction rates as applied to ordinary chemical reactions, the passage of the reacting particle over the potential-energy barrier has been regarded as a transition of one vibrational mode into a linear translational one along the reaction co-ordinate. Extraction of the partition function for this motion from the total partition function for the activated state, followed by multiplication by the classical average linear velocity of the particle along the reaction co-ordinate, leads to the familiar rate expression for the rate constant of the process. It has usually been assumed (6, 7) without proof that the same expression holds for a libration–rotation activation in dielectric relaxation. It is of interest to show that a formal treatment of rotational instead of the translational activation leads to the same absolute rate equation.

For an activation of, for example, a diatomic molecule A from librational to complete rotational motion we may write the equilibrium constant $K^{\ddagger}$ for the quasi-equilibrium between activated and initial states as

$$K^{\ddagger} = (F_A{}^{\ddagger}/F_A)\, e^{-E_0/RT}.$$

Extracting the partition function for the rotational motion arising from the activation gives

$$K^{\ddagger} = (F_A{}^{\ddagger\prime}/F_A)(1/\sigma)(8\pi^3 IkT/h^2)^{\frac{1}{2}}\, e^{-E_0/RT}, \qquad [1]$$

[1]*Manuscript received June 4, 1958.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.

where $F^{\pm}$ is the total partition function for the activated state and F_A that for the initial state; E_0 is the energy of activation at 0° K and $F^{\pm\prime}$ differs from $F_A{}^{\pm}$ since one librational mode has been converted to one of free rotation in the activated state; σ is the Ehrenfest symmetry factor. If the molecule has a moment of inertia I, its classical rotational kinetic energy in one degree of freedom is $\frac{1}{2}I\omega^2$ if ω is the angular velocity. The average angular velocity $\bar{\omega}$ is hence $(kT/2\pi I)^{\frac{1}{2}}$, whence the corresponding average effective circular frequency $\bar{\nu}$ for σ-fold symmetry is

$$\bar{\nu} = \sigma\bar{\omega}/2\pi = \sigma(kT/8\pi^3 I)^{\frac{1}{2}}. \qquad [2]$$

By analogy with the procedure for activation in a linear vibrating bond, we now multiply $K^{\pm}$ by $\bar{\nu}$ to obtain the rate constant $\mathbf{k}$. Then from [1] and [2]

$$\mathbf{k} = 1/\tau = (kT/h)(F_A{}^{\pm\prime}/F_A)\, e^{-E_0/RT} \qquad [3]$$

where τ is the relaxation time. The expression is thus of the same form as for bond-stretching activation in ordinary chemical reactions.

HEAT OF ACTIVATION AND ITS TEMPERATURE DEPENDENCE

Heats of activation for dielectric relaxation processes may be obtained by determination of the temperature dependence of the critical wavelength at which dispersion of the dielectric constant occurs. In water and deuterium oxide, the heat of activation determined in this way shows a marked apparent dependence upon temperature. The plot of the logarithm of the experimental relaxation times (τ)* against $1/T$ is non-linear and apparent heats of activation, $\Delta H^{\circ\pm}$, derived by taking tangents at various temperatures on this plot, decrease with increasing temperature. Arrhenius plots based on the data for water collected by Smyth (8) and on the measurements of Collie, Hasted, and Ritson (9) for water and heavy water are shown in Fig. 1. The temperature dependence of the heat of activation found in the dielectric relaxation measurements parallels that

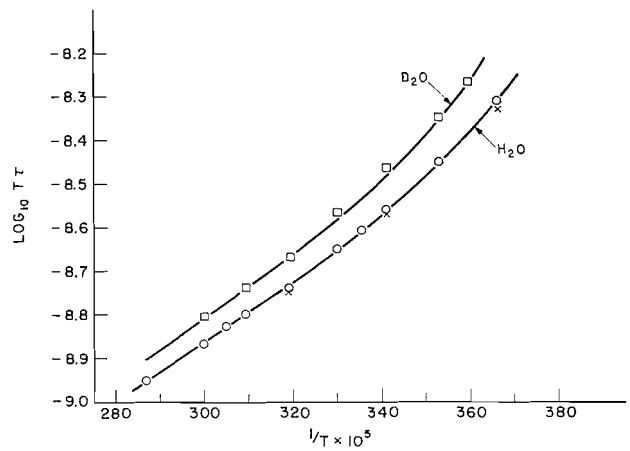

FIG. 1. Arrhenius plots for dielectric relaxation times for water and deuterium oxide.

□ Data for D_2O based on values of Collie, Hasted, and Ritson (9).

From the form of the rate equation, it is clear that it is the log of $T\tau$ which should be plotted in order to obtain the heat of activation. Although log τ itself is often plotted (11, 12), the data for water appear to be of sufficient accuracy to justify plotting log $T\tau$. This has been done in Fig. 1.

found for the viscosity of water and for proton mobility in aqueous acid solutions, which process has a rate controlled by the frequency of rotation of water molecules (10). The non-linearity of the Arrhenius plots could arise from a temperature dependence of $\Delta H^{\circ\ddagger}$ and of the entropy of activation, $\Delta S^{\circ\ddagger}$, usually regarded as constant. If $\Delta H^{\circ\ddagger}$ varies with temperature, it is because there is a finite difference of heat capacity, $\Delta C_p^{\ddagger}$, between molecules in the activated state and those in the initial state of the relaxation process. $\Delta C_p^{\ddagger}$ can be evaluated as follows and hence the true dependence of $\Delta H^{\circ\ddagger}$ and $\Delta S^{\circ\ddagger}$ upon temperature, calculated. We may write [3] in the form

$$\mathbf{k} = 1/\tau = (kT/h)\, e^{-\Delta G^{\circ\ddagger}/RT}, \qquad [4]$$

where $\Delta G^{\circ\ddagger}$ is the standard free energy of activation corresponding to $\Delta H^{\circ\ddagger}$ and $\Delta S^{\circ\ddagger}$. With $K^{\ddagger}$ as defined above, it follows from equation [4] that

$$K^{\ddagger} = (1/\tau)(h/kT).$$

Following the treatment of Everett and Wynne-Jones (13), we may obtain $\Delta C_p^{\ddagger}$ from knowledge of pairs of $K^{\ddagger}$ values at various pairs of temperatures, since by applying the treatment of Everett and Wynne-Jones to the activation equilibrium constant $K^{\ddagger}$, it may be shown in general that for pairs of results 1,2 at different temperatures

$$\frac{\Delta_{1,2}(T \ln K^{\ddagger})}{\Delta_{1,2}T} = \frac{\Delta C_p^{\ddagger}}{R}\cdot\frac{\Delta_{1,2}(T \ln T)}{\Delta_{1,2}T} + B, \qquad [5]$$

where $B = (\Delta S_0^{\circ\ddagger} - \Delta C_p^{\ddagger})/R$. The slope of the line obtained by plotting $\Delta_{1,2}(T \ln K^{\ddagger})/\Delta_{1,2}(T)$ versus $\Delta_{1,2}(T \ln T)/\Delta_{1,2}(T)$ then gives $\Delta C_p^{\ddagger}/R$. $K^{\ddagger}$ values are calculated from the data given by Smyth (8) and Collie, Hasted, and Ritson (9), and terms in the equation [5] are plotted in Fig. 2 from which $\Delta C_p^{\ddagger}$ for water and deuterium oxide may be calculated as -33.2 cal $^{\circ}$ C^{-1} mole^{-1}. Isotopic differences in $\Delta C_p^{\ddagger}$ cannot be detected within the accuracy of the derivation of $\Delta C_p^{\ddagger}$, since the calculation requires high accuracy in the initial data, because a second derivative of the relaxation times with respect to temperature is, in effect, being calculated. The results shown in Figs. 2 and 3 speak well for the accuracy of the data on the relaxation times, since satisfactory lines are obtained in the $\Delta C_p^{\ddagger}$ plot (Fig. 2) and there is very little spread amongst the points through which the lines in Fig. 3 have been drawn.

If $\Delta C_p^{\ddagger}$ is independent of temperature,

$$\ln K^{\ddagger} = \frac{A}{T} + \frac{\Delta C_p^{\ddagger}}{R} \ln T + B, \qquad [6]$$

where A $= \Delta H_0^{\circ\ddagger}/R$ and B is another constant. $\Delta H_0^{\circ\ddagger}$, the heat of activation at the absolute zero (if water remained a liquid down to this temperature), can be derived from Fig. 3 using equation [6]. The values of $\Delta H_0^{\circ\ddagger}$ calculated from slopes of the two lines in Fig. 3 are significantly different, viz. 13.7 kcal g mole^{-1} for water and 14.0 kcal g mole^{-1} for deuterium oxide. Values of $\Delta H^{\circ\ddagger}$ at other temperatures can be derived together with $\Delta G^{\circ\ddagger}$ and $\Delta S^{\circ\ddagger}$ using equation [4] and the data for the relaxation times (8, 9). The thermodynamic data for the activation process are summarized in Table I for one temperature and several results of interest may be pointed out. Firstly the value of $\Delta C_p^{\ddagger}$ is surprising as it is large and negative and similar to that found, for example, in the ionization of acids. $\Delta S^{\circ\ddagger}$ on the other hand is positive but it follows from the data given that it becomes less positive as the temperature is raised. Qualitatively, this is as

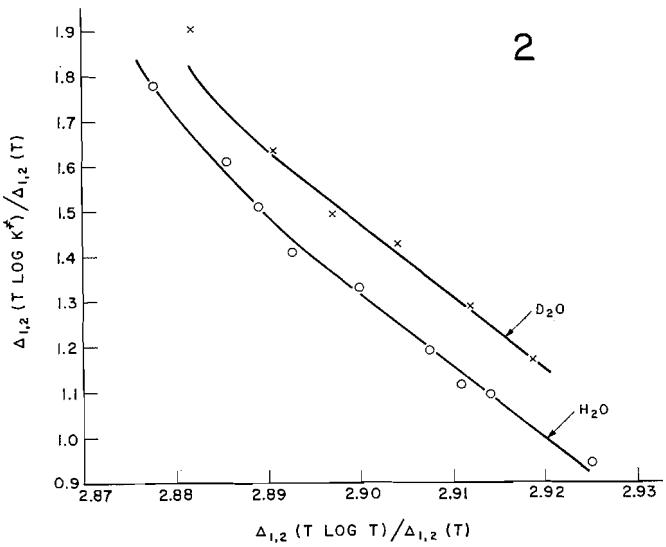

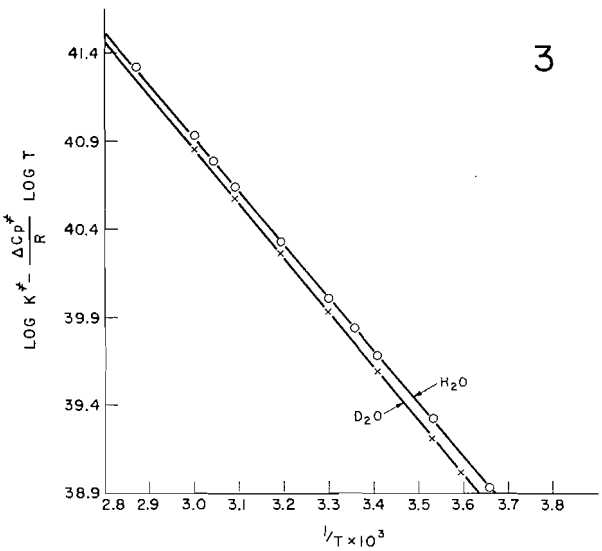

FIG. 2. Wynne-Jones plots for $\Delta C_p^{\neq}$ for H_2O and D_2O.
FIG. 3. Wynne-Jones plots for $\Delta H_0^{\circ\neq}$ for H_2O and D_2O.

expected, for reasons which are discussed below. However, the difference of sign between $\Delta C_p^{\neq}$ and $\Delta S^{\circ\neq}$ is difficult to account for but may be connected with long-range structure breaking (29) in the water. Similar anomalous differences between the signs of ΔC_p and ΔS° values for ionization of bases in water are known (13) and are connected with structure breaking (32).

$\Delta H^{\circ\neq}$ diminishes with increasing temperature since $\Delta C_p^{\neq}$ is negative. It has been considered (14, 15) that increase of temperature causes increasing breakage of H bonds in water. If this were so, the decrease of $\Delta H^{\circ\neq}$ with increase of temperature would be readily accounted for, since with increasing breakage of H bonds, fewer would have to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

be broken in the activation step. However, thermodynamic considerations (cf. 16) preclude the possibility that any significant proportion of H bonds are broken even near the boiling point. This is confirmed by the fact that the latent heat of vaporization of water at the boiling point is still close to the energy required to break four half-hydrogen bonds per molecule, each having the usually accepted (16, 17) dissociation energy of about 5–6 kcal mole^{-1}. The structural change in water which occurs through the melting point and at higher temperatures is best regarded as resulting from the "bending" (16) of the O—H---O bonds rather than from their dissociation; on the basis of such a model the temperature dependence of the dielectric constant has been quantitatively deduced (16) and the change of radial distribution function with temperature accounted for. It is of interest to apply this model in order to examine the effect of bond-bending upon the activation energy for rotation of a water molecule in water.

THE ROTATIONAL POTENTIAL ENERGY BARRIER

The H bond in water can be regarded (16) to a satisfactory approximation as arising from the sum of a number of electrostatic interactions between point charges in each OH bond dipole and the two partially hybridized unshared pairs of electrons on the oxygen atoms of neighboring water molecules. Due to hybridization, these unshared pairs have a strong directional character (16, 18) and act as localized centers of negative charge. The electrostatic model for the hydrogen bond has been shown to be adequate (19) except for extreme vibrational excursions of the H atom or for very short bonds where covalent canonical forms become important. For water, the electrostatic model provides a satisfactory basis for calculation of bulk dielectric properties of the substance (16, 20). It will therefore be applied here in order to examine the features of the potential energy barrier for a water molecule rotating in the field of its nearest neighbors whose orientations have been thermally perturbed from the average orientations existing in ice. As a basis for the calculation, an idealized 4-co-ordinated structure is assumed such as exists to a first approximation in ice and to an important extent (21) in liquid water near the melting point. The rotational potential barriers for motions about the bond XY and the dipole axis of the water molecule shown in Fig. 4 in a thermally unperturbed structure have already been calculated by Conway *et al.* (10). The method used may be adapted for calculation of the rotational barrier when one or more bonds are bent and there is thermal perturbation of the ideal structure. Reference is made to Fig. 5 where XYZ is the water molecule undergoing rotation, for example about the axis XY. The choice of the mode of rotation is somewhat arbitrary but the one assumed here and in the previous calculations, (10), involves least breakage of hydrogen bonds and may therefore be the preferred motion; other modes, e.g., the axial spin mode previously examined in connection with proton mobility (10), cannot lead to a change of dielectric polarization of the water upon application of a field and is hence not considered here.

In the hydrogen bond YZW, point charges are assumed to be localized as in the model

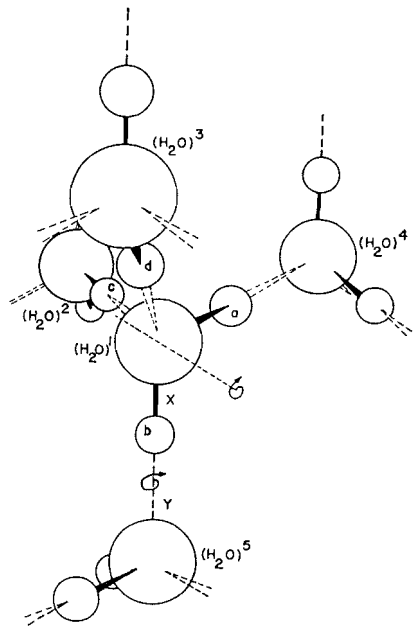

FIG. 4. The situation of a water molecule H_2O^1 amongst tetrahedrally co-ordinated neighbors showing the possible modes of rotation about H bond XY through H atom b, or axially; the latter mode involves breaking of all four bonds through H atoms a, b, c, and d.

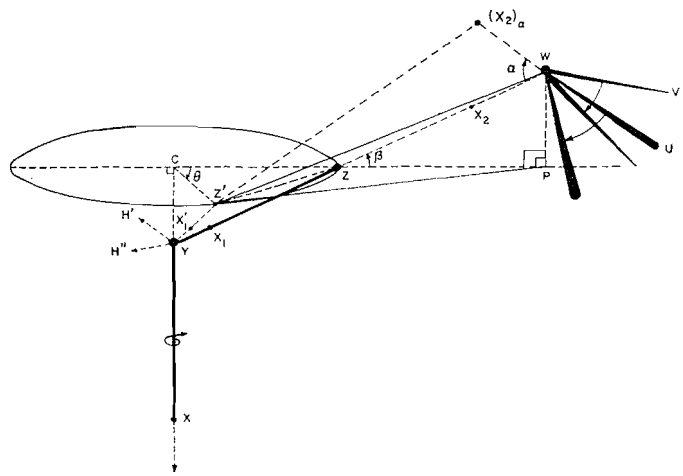

FIG. 5. Model for calculation (cf. 10) of the rotational potential energy barrier for a water molecule in water as a function of the angle of rotation, θ, and the angle α, of disorientation or bond bending of bonds with nearest neighbors.

given by Lennard-Jones and Pople (16). The energy of the hydrogen bond YZW is then calculated as a function of the angle, θ, of rotation of the bond YZ from its equilibrium position, as previously carried out (10) but now for various degrees of bond-bending determined, for example, by the degree of disorientation, α, of the directed lone pair of electrons X_2 in the hydrogen bond YZW, or of the OH bond. For any position of Z (e.g. at Z'), the distance WZ' or X_2Z' may be computed and the energy of electrostatic

For personal use only.

interaction between the two electronic charges at W and X_2, and the one at the proton at Z' (16), can be calculated (16). The other four electrostatic interactions (16) leading to the total interaction energy in the bond are calculated similarly for various values of θ. It can be shown (10) that

$$(WZ')^2 = 4(CZ')\ (\sin^2\theta/2)\ [CZ'+ZW\cos\beta]+(ZW)^2 \qquad [7]$$

and similar expressions may be obtained for the other distances required, e.g., WX_1', X_2Z', X_2X_1'. As the molecule XYZ is rotated, lone-pair electrons directed towards other hydrogen atoms H′ and H″ (not shown in Fig. 5) also suffer rotation. The energy of the two hydrogen bonds involving these orbitals are calculated as a function of θ by equations similar in form to that of [7].

When the orbital directed from W to X_2 is oriented by an angle, α, from the colinear configuration YX_1ZX_2W, X_2Z' and other similar distances may be calculated trigonometrically, since it may be shown that

$$(X_2Z')^2 = (ZW)^2+(WX_2)^2-2(ZW).(WX_2)\cos\alpha+4(CZ')\sin^2\theta/2.[CZ'+ZW\cos\beta]. \qquad [8]$$

The form of this equation is general, so that other distances may be calculated, e.g. X_2X_1' as a function of θ and α; alternatively the molecule XYZ in Fig. 5, and hence the bond YZ may be considered oriented and the barrier for rotation of the molecule UVW about UW or VW calculated.

In order to examine the *form* of the dependence of the height of the rotational barrier for a given water molecule upon the angle α, calculations have been carried out for four values of α from 0° to 90° and for six values of θ from 0° to 100°. It must be emphasized that only a very small fraction of molecules will be thermally disoriented to angles as large as 90°. A greater number will be thermally disoriented at lower values of α. However, a rotation of a given molecule will involve bending or temporary breaking of bonds with neighbors and this will also facilitate the rotation of the neighbors themselves. Thus, those molecules which do rotate, would preferentially tend to do so at regions of the liquid where there is already a transient thermal disorientation. The process of activation is therefore probably best regarded as a somewhat co-operative one involving the participation of other molecules as well as the one which actually "rotates".

Each H bond has six component coulombic interactions and the resulting 144 interactions for the range of angles considered enables the electrostatic potential energy of the representative water molecule to be calculated as a function of θ and α for various assumed conformations of the structure; for example one, two, three, or four bonds to nearest neighbors may be considered to be disoriented. The total energy of the representative water molecule is calculated by summing the relevant individual partial coulombic interactions as described previously (10). Examples of the effect of bond bending on the rotational barrier are shown in Figs. 6 and 7. As a given molecule rotates in an ideal ice-like structure the molecule successively passes through the configurations shown as projections in Fig. 8. Unless the structure is perturbed, it is clear that any rotation must always lead to states of higher energy, since repulsive interactions will occur either between pairs of OH bonds or between the unshared-pair orbitals as they come into opposition as shown in Fig. 8. This leads to maxima at 120° and 240° in the rotational barrier as shown in Fig. 6. The energy of repulsion which arises when two OH bonds are in opposition is diminished if there is some bending of the H bonds, as shown by the result in Fig. 6; one of the most important qualitative effects of thermal bending is seen to be the diminution of the energy of this repulsive interaction. That such an

H^1 and H^2 are H atoms in the representative H_2O molecule undergoing rotation.

interaction may be of importance in the experimental relaxation behavior in ice is indicated by the fact that the heat of activation for relaxation in ice is 13.2 kcal $mole^{-1}$, i.e., significantly larger than the energy necessary (viz. the heat of sublimation) completely to break all four "half"-hydrogen bonds per water molecule in ice. In liquid water, where $\Delta H^{\circ\ddagger}$ is between 2 and 5 kcal $mole^{-1}$ over the temperature range 0–75° C, this effect must be almost absent, Figs. 6 and 7 show that if the degree of bending is sufficient, the repulsive interaction, for example at 120° of rotation, is eliminated and in fact replaced by one of attraction. Under these conditions a new potential energy minimum occurs other than that at the initial state (0°) and at the intermediate state (180°) of the rotation. We may identify minima of this kind with the transient "thermal wells" postulated by Garton (22) to explain the dielectric behavior of polar liquids. We have, of course, only considered some special cases where one bond to a nearest neighbor water molecule is bent or disoriented. Qualitatively similar effects arise if two or more bonds are simultaneously bent; however, such a situation will be statistically less probable than that in which fewer bonds to a given water molecule are bent.

From Figs. 6 and 7, it is clear that the barrier for rotation of a given water molecule can be considerably lowered by thermal bending of bonds or "disorientation" of neighboring molecules and hence the dependence of $\Delta H^{\ddagger}$ upon temperature qualitatively explained. In so far as disorientation of molecules other than the given one is involved, the rotation process is a co-operative one.

An alternative explanation for the temperature dependence of the thermodynamic parameters for dielectric relaxation in water may be sought in terms of the hole-theory of liquids (23); thus Schellman (24) has suggested that defects (missing bonds) in the ice structure are propagated in the rotational process, and a similar effect could occur in water. Rotation at defect sites will certainly require less energy of activation and this may be demonstrated by calculating the rotational barrier for such sites, as shown in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Fig. 9. This approach is equivalent to assuming that a significant number of hydrogen bonds are completely dissociated in water and ice; whilst this is thermodynamically unlikely (16), metastable crystal imperfections in ice may, however, provide the necessary sites for rotation in that case (33).

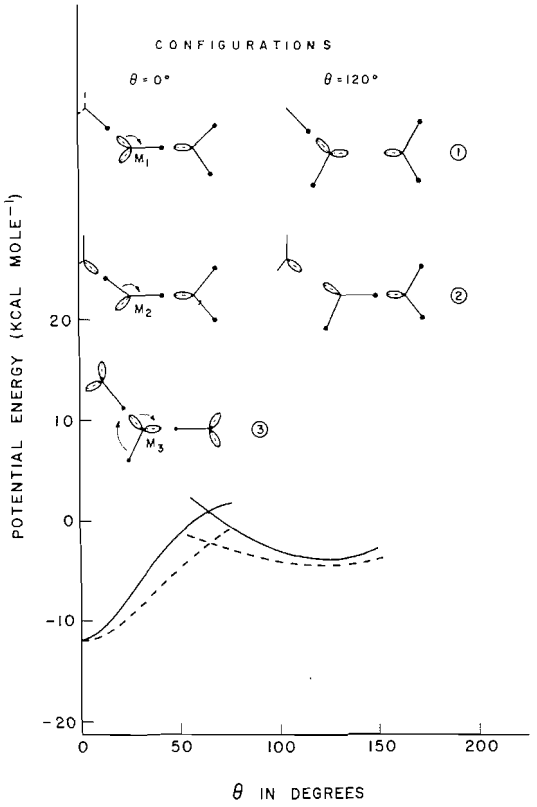

FIG. 9. The rotational potential energy barrier from 0 to 120° for a water molecule M in ice at a bond vacancy site where there are only three H bonds to the representative molecule. Projections of three situations are shown: (1) rotation about the OH. . . . O bond (dotted line); (2) rotation about the O. . . . HO bond (solid line). The configurations at $\theta = 0°$ (initial state) and $\theta = 120°$ (final state) are indicated; (3) rotation in this configuration can only lead to OH bonds in opposition with a resultant increase of potential energy with no minimum as in Fig. 6 for $\alpha = 0$.

FREQUENCY FACTORS

Since $\Delta H_0^{\circ\ddagger}$ has been evaluated for relaxation in water and deuterium oxide, we can use equation [3] as a basis for comparison of experimental and theoretical frequency factors.

If the potential energy function for libration is of the form $V = V_0 \cos\theta$, and three modes of restricted rotation are possible in the initial state, F_A in equation [3] may be written (27)

$$F_A = \frac{8\pi^2(8\pi^3 I_1 I_2 I_3 k^3 T^3)^{\frac{1}{2}}}{h^3} \frac{\sinh(V_0/kT)}{V_0/kT} F_v \cdot F_t, \qquad [9]$$

where F_v is the product of partition functions for the internal vibrations in the bonds of the molecule and F_t the total translational partition function. The cosine potential function will only be applicable if the internal field is uniform. This, however, is unlikely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

for the short range interactions considered above. Inspection of the minima near $\theta = 0$ in the rotational potential energy diagrams indicates (Fig. 6) that the potential function near the minima is more accurately represented by $V = \frac{1}{2}K\theta^2$, where K is the force constant for the restricted rotation, so that (cf. 28) F_A is then given by

$$F_A = \left[1-\exp\left(\frac{-h\nu_1}{kT}\right)\right]^{-1}\cdot\left[1-\exp\left(\frac{-h\nu_2}{kT}\right)\right]^{-1}\cdot\left[1-\exp\left(\frac{-h\nu_3}{kT}\right)\right]^{-1}\cdot F_v\cdot F_t, \qquad [10]$$

where ν_1, ν_2, and ν_3 are the three frequencies of restricted rotation corresponding to the normal modes of rotation of an unhindered non-linear triatomic molecule. In equation [1], $F_A^{\ddagger\prime}$ differs from F_A only on account of the conversion of one mode of libration to one of (temporary) free rotation.

Hence*

$$\mathbf{k} = \frac{kT}{h}\cdot\frac{1}{\left[1-\exp\left(\frac{-h\nu_3}{kT}\right)\right]^{-1}}\cdot e^{-E_0/RT} \qquad [11]$$

if the librational mode designated as 3 is the one which becomes a free rotational motion in the activation step. The frequency ν_3 may be estimated from the rotational potential energy function. Figure 10 shows the dependence of the energy of a water molecule in water (in the thermally unperturbed structure) upon θ^2 in degrees. The slope of the line in Fig. 10 calculated in terms of erg molecule^{-1} and radians gives $K = 2.1\times10^{-12}$. Now for the simple harmonic libration of type 3,

$$\nu_3 = 1/2\pi(K_3/I_3)^{\frac{1}{2}} \qquad [12]$$

and taking I_3 as 1.9×10^{-40} g cm^2 (37), gives $\bar{\nu}_3 = 550$ cm^{-1}. This is in satisfactory agreement with the value of the frequency of hindered rotation ($\bar{\nu} = 570$ cm^{-1}) calculated by a different method from Morse functions by Cross *et al.* (14). The value falls in the

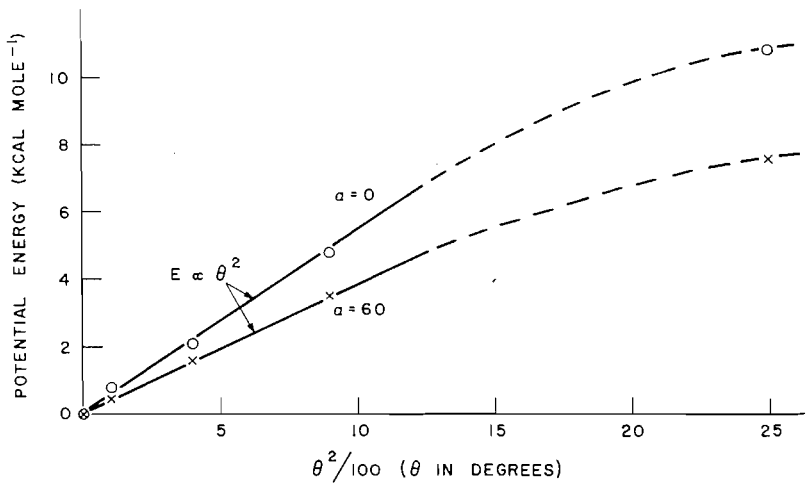

FIG. 10. Plot of potential energy vs. square of angle, θ, of rotation for low values of θ, and two values of α, showing the effect of bond bending on the force constant K.

**This involves the assumption that the other two librational modes maintain the same frequencies during the rotational motion. Whilst this is probably true only as a first approximation, the results which follow for the ratio of frequency factors for relaxation in H_2O and D_2O ice confirm the general correctness of the assumption, at least in the case of ice.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

middle of the infrared band in water ascribed to "hindered rotation" (14). The above calculation is based on the rotational potential energy function for the unperturbed structure, i.e., with no bond-bending; this is justified by the fact that the majority of the molecules observed spectroscopically will be in states corresponding to a relatively unperturbed structure, since perturbed molecules will be distributed as $e^{-E/RT}$, where E is the energy involved in causing a perturbation. Lower values of $\bar{\nu}_3$ result when perturbed structures (i.e. α in Fig. 5 differs from zero) are considered, since then K_3 is less, as shown for example in Fig. 10. We may now evaluate the apparent frequency factor in equation [11], whereupon

$$\mathbf{k} = (kT/h)\ (0.93)\ e^{-E_0/RT} = 5.8\times10^{12}\ e^{-E_0/RT}. \qquad [13]$$

Direct comparison of this frequency factor with those obtained experimentally near room temperature is complicated by the large temperature dependence of the experimental heat of activation found at room temperature for relaxation in water.

In a condensed phase, E_0 and $\Delta H_0^{\circ\ddagger}$ are almost identical (35) but differ from the experimentally measured activation energy, $E^{\ddagger}$, according to

$$E^{\ddagger} = E_0+\Delta C_p{}^{\ddagger}T+RT. \qquad [14]$$

The experimental behavior is represented by

$$1/\tau = Ae^{-E^{\ddagger}/RT} = [(ekT/h)\ e^{\Delta S_0{}^{\ddagger}/R}]\ e^{-E^{\ddagger}/RT}. \qquad [15]$$

In order to compare the experimental frequency factor in [15] with that arising theoretically in [13], we convert [13] into a form comparable with [15] by eliminating E_0 in [13] using equation [14], so that both equations involve $E^{\ddagger}$. Hence

$$k = 5.8\times10^{12}e.\ e^{\Delta C_p{}^{\ddagger}/R}\ e^{-E^{\ddagger}/RT} \qquad [16]$$

and the frequency factor A is then $5.8\times10^{12}\ e.\ e^{\Delta C_p{}^{\ddagger}/R}$. At 20° C, A is 3×10^{14} sec^{-1}, whilst the apparent frequency factor from [16], to be compared with the experimental value, is 6×10^{5} sec^{-1} using the value of $\Delta C_p{}^{\ddagger}$ derived above. It is clear that the simple model in which a loose libration becomes a complete rotation does not account adequately for the experimental frequency factor which is much higher than that deduced theoretically with the above model; accordingly an alternative mechanism must be sought (see below). Further insight into the molecular processes occurring in the activation step may be obtained by considering isotopic effects in water and ice.

ISOTOPIC EFFECTS

In ice, the ratio of frequency factors for the relaxation rates, $1/\tau$, in H_2O and D_2O is (29) 1.45. The libration frequencies for any pair of corresponding modes of libration in ordinary and heavy ice will be in the ratio (see equation 12)

$$\nu_{H_2O}/\nu_{D_2O} = (2)^{\frac{1}{2}},$$

since the force constants for the libration of the isotopic molecules are approximately the same. The $\sqrt{2}$ factor is also confirmed by the experimental infrared data for water (14). Equation [11] then gives the ratio of frequency factors for the relaxation in ice and D_2O ice as 1.1 if the libration frequencies are such that $h\nu_3 > kT$. The experimental ratio is close to $\sqrt{2}$. This suggests that the libration which becomes a rotation in the relaxation process is a looser one than those predominating in the normal ice structure, since then, if $h\nu_3 < kT$, equation [11] indicates that the isotopic ratio of frequency factors becomes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

$\sqrt{2}$. This value could be accounted for if the relaxation process in ice only occurs at sites where there is a considerable perturbation of the structure, e.g. at crystal defects or imperfections (33) or holes, where one or more of the normal four hydrogen bonds is absent or where two H atoms are in opposition in a given bond. The librational potential energy well for a molecule at a bond-vacancy site will then be less deep (Fig. 9) and the librational frequency of the molecule would be correspondingly less. Sufficiently loose librations ($\nu_3 < kT/h$) to account for the isotopic factor of $\sqrt{2}$ must have frequencies less than about 210 cm^{-1}. Such a mode of motion is, in fact, known in ice (14) near this frequency.

In liquid water the situation is different. From the data in Table I, the entropy of activation, e.g., at 30° C for D_2O is 5.1 and that for H_2O at the same temperature is 4.4 cal ° C^{-1} $mole^{-1}$. The ratio of experimental frequency factors for H_2O and D_2O at 30° C is hence $\exp[-0.7/R] \doteqdot 1/\sqrt{2}$, i.e. in the *opposite direction* to that found with ice. Qualitatively the higher positive entropy of activation found for the relaxation rate in D_2O than in H_2O follows from the greater degree of order which exists in liquid D_2O (14) than in water owing to the greater apparent* strength of "deuterium-bonds" than that of hydrogen bonds. In the rotation of the D_2O molecule from its initial state of libration more entropy is gained than in water, since the initial state is more regular in D_2O. The apparent strength of the "deuterium bond" in D_2O is some 0.23 kcal $mole^{-1}$ greater than that of the hydrogen bond in water, as may be deduced from the heats of sublimation of D_2O and H_2O (12,631 and 12,170 cal $mole^{-1}$ respectively (30)); hence in D_2O there will be less thermal perturbation of the structure by bond-bending than in H_2O. The origin of this isotopic difference in the heats of sublimation has been explained by Eucken (31). The greater interaction energy between D_2O molecules in heavy water than between H_2O molecules in ordinary water also accounts for the consistently higher value (about 0.3 kcal) of $\Delta H^{\circ\ddagger}$ (Table I) for the relaxation rate in D_2O than in H_2O, since more energy is required rotationally to displace a D_2O molecule than an H_2O molecule. The higher value of $\Delta H^{\circ\ddagger}$ leads to an isotopic effect on the relaxation rate opposite in direction to that arising from the difference in frequency factors. Thus at 30° C, the ratio of the terms containing the heats of activation for rotation of H_2O and D_2O is $(e^{-3650/RT})/(e^{-3970/RT})$, i.e. 1.71. The ratio of the relaxation rates is hence

$$(1/\tau_{H_2O})/(1/\tau_{D_2O}) = 0.7 \times 1.71, \text{ i.e. } 1.20.$$

At 30° C, comparison of the actual values of τ (8) for D_2O and H_2O gives $\tau_{D_2O}/\tau_{H_2O} = 1.22$.

Positive values of $\Delta S^{\circ\ddagger}$ which are found (Table I) for the relaxation process in water may be contrasted with the negative ones found for more complex molecules, e.g., permitol (36). However, it is not difficult to see that the rotation of large and complex molecules such as the chlorinated diphenyls may well require more co-operative (and hence less probable) reorientation by neighboring molecules than is the case for rotation of a water molecule in water. Furthermore, an important qualitative difference between these cases is that the water is already a relatively highly ordered structure (21), whilst there is no evidence that a similar structure exists in permitol. Any thermal perturbations, such as those involved in the reorientation of a molecule, may not unreasonably be supposed to lead locally to more disordered configurations in the quasi-crystalline water structure. That this is likely is indicated by the positive values of $\Delta S^{\ddagger}$ which become more positive with decreasing temperature (see the data in Table I). Such a

*This effect arises (34) from the lower zero-point librational energies of the deuterium analogue than those of water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

trend of the $\Delta S^{\ddagger}$ values would not be unexpected in the case of water, since the degree of quasi-crystalline structure in the liquid increases with decrease of temperature so that the initial state of the relaxation process can become relatively more ordered, i.e., have a lower entropy. A more quantitative evaluation of the frequency factors for the rotation process in liquid water and deuterium oxide must await a more detailed knowledge of the structure of water and how it depends on temperature.

PROTON MOBILITY IN WATER AND ICE, AND THE ROTATION MECHANISM

We have shown previously (10, 26) in calculations of the proton mobility in aqueous solutions, that above a certain critical concentration of about 10^{-6} M in H_3O^+ ions, there is a sufficient flux of protons that virtually all rotations of solvent molecules which occur do so in the fields of each newly produced H_3O^+ ion as the latter is formed from an antecedent H_3O^+ ion by rapid proton tunneling (10) to an adjacent water molecule already reoriented in the immediately preceding proton jump event. Whilst the actual concentration of H_3O^+ and OH^- ions is small (10^{-7} g ion $l.^{-1}$ at 25° C, of each ion), they can indirectly affect a large number of water molecules.

The rotation rate, which is observed in dielectric dispersion experiments, may therefore correspond to rotation of water molecules in the fields of the H_3O^+ (and/or OH^-) ions, as the protons arrive at various sites during their motion throughout the liquid. Such a mechanism is consistent with a number of aspects of the relaxation behavior.

Rotation of water molecules adjacent to the H_3O^+ ions may account for the apparent lack of any significant distribution of relaxation times in water; thus, it has consistently been observed that the dispersion behavior can be treated in terms of a single* relaxation time, which suggests that the rotations occur in a relatively reproducible environment, e.g. adjacent to and in the strong orienting fields of the ions. On the other hand, random thermal bond bending in "non-ionic" environments in the bulk water structure might be expected to lead to a distribution of heats of activation for rotation, and hence of the corresponding relaxation times.

In support of these views, it may be noted that the heat of activation for rotation in water (3–5 kcal $mole^{-1}$) is considerably less than that required to break four hydrogen bonds even in a partially thermally perturbed structure of water. The rotation process in the field of the new H_3O^+ ion upon arrival of a proton at a given water molecule will have a lower heat of activation (cf. 10) than that for rotation in the bulk of the solvent, since the energy of interaction (*ca.* 15 kcal $mole^{-1}$) of the water dipole with the ion assists the rotation process. When molecules are rotated near the ion out of their normal average orientations in the 4-co-ordinated water structure, a multiplicative effect can originate, since rotation of one molecule causes temporary opposition of OH bonds between nearest neighbors (i.e., there are "bonds" doubly occupied by H atoms as shown in Fig. 8); this facilitates rotation of a neighboring molecule by repulsion in the doubly occupied "bonds". This effect will enhance the probability of rotation and could account for the experimentally observed greater probability of rotation than that calculated for simple thermal reorientation on the basis of librational partition functions as from equations [13] and [16].

In ice, the different isotopic effects from those in water and the much greater heat of activation suggest a different mechanism for the rotational process. We have shown previously (26) that on account of the lower proton concentration in ice, the proton

**Some heterogeneity may still be present but not apparent in the Cole and Cole plot. This, for example, is shown with mixtures (36) in certain ranges of concentration.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

mobility in ice is no longer limited in its rate (as it is in water) by the rotation of water molecules in the fields of H_3O^+ ions, the rotation process occurring predominantly amongst neighboring water molecules in the absence of ionic fields. The observed heat of activation for the relaxation is then about 13 kcal mole^{-1} (29, 33) as expected (see Figs. 6, 9) for thermal reorientation.

The self-consistency of the proposed change of mechanism may be checked by calculating the relative probabilities of relaxation by the field-induced mechanism, (I), and the thermal reorientation mechanism, (II). Process I can be regarded as a pseudo-unimolecular reaction involving H_3O^+ and H_2O while II is to be regarded as unimolecular involving only H_2O. $\Delta H^{\circ\ddagger}$ for I is 3.9 kcal mole^{-1} at 25° C (see Table I) and $\Delta H^{\circ\ddagger}$ for II is 13.3 kcal mole^{-1} (29). The relative probability R that rotations will occur in unit volume and time by process I or by II is given approximately by

$$R = 3\times10^{14}\, a_{H_3O^+}\times 4\, \exp[-3900/RT]/1.8\times10^{-15}\times55.5\, \exp[-13300/RT] \quad [17]$$

and is unity when $a_{H_3O^+}$ is about 10^{-5} g ion l.$^{-1}$. In equation [17], the figures 3×10^{14} and 1.8×10^{15} are the experimental frequency factors for rotation in water and ice, respectively, and the factor 4 allows for the fact that each H_3O^+ ion influences the orientation of four nearest neighbor water molecules. The mechanism of rotation would hence tend to become predominantly II as C_{H^+} is decreased much below about 10^{-5} g ion l.$^{-1}$ (as in ice) and mainly I in more acidic solutions ($a_{H_3O^+} > 10^{-5}$ g ion l.$^{-1}$). Comparable contributions from both mechanisms would occur at proton concentrations of the order of magnitude of 10^{-5} g ion l.$^{-1}$. This concentration, at which a change of mechanism for rotation is predicted, is of a similar order of magnitude as that for which the change of mechanism for proton mobility is indicated (26).

Upon addition of extra protons to the ice by the formation of solid solutions with an acid we should expect a change of mechanism of proton mobility back to that (viz. rate-determining rotation of water molecules in the field of H_3O^+ ions) which occurs in water (10), and a corresponding drop of the heat of activation for rotation of the water molecule as discussed above. In ice containing traces of HF this is actually found (33) and the experimentally observed heat of activation for relaxation drops from 13 kcal mole^{-1} in pure ice to about 5 kcal mole^{-1} in HF–ice, a value very close to that for liquid water at 0° C (Table I). It therefore appears that the mechanisms for relaxation in pure ice and water differ on account of the different orders of concentration of ions in these phases, the critical concentration of H_3O^+ or OH^- ions for the change of mechanisms both of proton mobility (26) and dielectric relaxation, being about 10^{-6} to 10^{-7} mole l.$^{-1}$. Although protons are present in ice, it appears that they do not participate significantly in the relaxation process unless they are present above the critical concentration (10, 26). Below this concentration the rotation of the molecules can occur at non-ionic defect sites. This conclusion is supported by the work of Gränicher *et al.* (33). The proton polarization mechanism of Latimer (25) appears to be applicable only when the ice contains extra protons (33).

In pure liquid methanol where the proton concentration is very much lower than in ice or water, it is experimentally found (12, 36) that the frequency factor for relaxation is about 2.5×10^{12} (36) and $\Delta C_p^{\ddagger}$ is very small or zero within the experimental accuracy of the results (12). Theoretically, using [13], a value of the order 10^{13} is expected if the mechanism is one of rotation amongst other methanol molecules and not in the fields of ions. These values are in much better agreement than in the case of water considered above and give a further indication that in liquid water a simple rotation process amongst

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

other water molecules is unlikely to be the mechanism of relaxation. The isotopic ratio of relaxation frequencies in MeOH and MeOD appears to be about $(2)^{\frac{1}{2}}$ (12), within the experimental uncertainties, as expected from [13] if the librational mode becoming a rotation upon activation, is a loose one, and is consistent with a non-ionic mechanism. This is also the ratio found for ice, for which the non-ionic mechanism is indicated.

ACKNOWLEDGMENT

The author is indebted to Dr. D. W. Davidson for making available some results on the relaxation behavior of MeOH and MeOD prior to their publication.

NOTES

PREPARATION AND CHEMISTRY OF TRANS 1-CYANO-4-CHLORO-2-BUTENE

CL. DAESSLE, E. J. TARLTON, AND A. F. MCKAY

Trans 1-cyano-4-chloro-2-butene (III) and 1-cyano-2-chloro-3-butene (II) were prepared by the addition of butadiene to a complex of aluminum chloride and cyanogen chloride in nitromethane. Cowen (1) previously used this complex to add cyanogen

$$\underset{\text{I}}{CH_2{=}CH{-}CH{=}CH_2} + CNCl \xrightarrow{AlCl_3} \underset{\text{II}}{CH_2{=}CH{-}CHClCH_2CN} + \underset{\text{III}}{CH_2ClCH{=}CHCH_2CN}$$

chloride to monoolefins. Both 1-cyano-4-chloro-2-butene (III) and 1-cyano-2-chloro-3-butene (II) were converted in liquid ammonia into 1-cyano-1,3-butadiene. The former compound also gave 1-cyano-1,3-butadiene on treatment with hexamethylenetetramine. The known 1,4-dicyano-2-butene (2, 3, 4) was prepared by the reaction of sodium cyanide with 1-cyano-4-chloro-2-butene in the presence of cuprous chloride.

3-Carbethoxy-7-cyano-5-hepten-2-one was prepared by condensation of ethyl acetoacetate with 1-cyano-4-chloro-2-butene in the presence of sodium ethylate. Similar reaction with diethyl malonate gave ethyl 2-carbethoxy-6-cyano-4-hexenoate (12.6% yield), identified by its conversion to pimelic acid through subsequent hydrogenation, hydrolysis, and decarboxylation (5).

The main bands of the infrared absorption spectra of these nitrile derivatives are listed in Table I. The assignments agree with those reported by Bellamy (6). 1-Cyano-4-chloro-2-butene, 1,4-dicyano-2-butene, and 3-carbethoxy-7-cyano-5-hepten-2-one display a strong absorption band at 968–972 cm^{-1} characteristic of CH out-of-plane

TABLE I

Infrared absorption bands of nitrile derivatives

	C—H stretching	C≡N stretching	C—H in-plane deformations	C—H out-of-plane deformations	Other bands
$CNCH_2CH{=}CHCH_2Cl$	3040, 2960, 2930, 2850	2270 (m)	1412, 1441	968 (s), 936 (w), 909 (w)	688
$CNCH_2CH{=}CH{-}CH_2CN$		2265 (m) 2230 (sh)	1416 (s)	972 (s), 912 (m)	
$CN{-}CH{=}CH{-}CH{=}CH_2$	3120, 3080, 3000, 2950, 2925, 2860	2235 (s)		1004 (m), 966 (sh), 958 (sh), 933 (m)	1623 (C=C) (m) 1593 (m), 1530
$CNCH_2CHClCH{=}CH_2$	3080, 2965, 2930, 2875	2270 (m)	1414	986 (s), 955 (sh), 938 (s), 909 (sh)	700 (s), 1530

s, Strong; m, medium; w, weak; and vw, very weak absorption bands; sh, shoulder on stronger absorption bands.

deformation for a trans —CH=CH— group. 1-Cyano-1,3-butadiene and 1-cyano-2-chloro-2-butene have absorption bands at 1004 cm^{-1} and 986 cm^{-1}, respectively, which are associated with the CH out-of-plane deformations of the vinyl group. 1-Cyano-1,3-butadiene also has an absorption band at 966 cm^{-1}, since it also contains the —CH=CH— grouping. The absorption spectrum of 1,4-dicyano-2-butene was determined in Nujol mull so the C—H stretching vibrations are not recorded in Table I.

EXPERIMENTAL[1]

Cyanogen Chloride

Cyanogen chloride was prepared as a clear, colorless liquid in 70% yield by the method of Barnett *et al.* (7).

Addition of Cyanogen Chloride to Butadiene

Cyanogen chloride (52 ml, 1.0 mole) was vaporized into a mixture of anhydrous aluminum chloride (133.5 g, 1.0 mole) in nitromethane (100 ml) cooled to −5° C. Butadiene (27 l., 1.1 mole) was led in under the surface of this reaction mixture over a period of 3 hours. Strong cooling was required to maintain the temperature between 0 and 5° C. After the addition of the butadiene, the reaction mixture was poured into ice and water, and acidified with dilute hydrochloric acid solution. This acidified mixture was extracted with ether, the ether was removed by evaporation, and the residue was distilled *in vacuo*. The following fractions were obtained: (1) liquid b.p. 90–95° C at 15 mm, yield 25 g; (2) yellow liquid b.p. 100–105° C at 15 mm, yield 12.5 g; and (3) liquid b.p. 100–150° C at 2–3 mm, yield 3.5 g. Redistillation *in vacuo* using a Vigreux column gave 16.5 g (14.3%) of 1-cyano-2-chloro-3-butene (b.p. 74–76° C at 13 mm, n_D^{25} 1.45837) and 19 g (16.4%) of 1-cyano-4-chloro-2-butene (b.p. 105–107° C at 13 mm, 67–68° C at 1.5 mm, n_D^{25} 1.47330, d_4^{25} 1.087, M_R calc. 29.44, found 29.85). 1-Cyano-2-chloro-3-butene, anal. calc. for C_5H_6ClN: C, 52.05; H, 5.23; Cl, 30.70; N, 12.12%. Found: C, 51.94; H, 5.27; Cl, 30.02; N, 12.54%. 1-Cyano-4-chloro-2-butene, anal. calc. for C_5H_6ClN: C, 52.05; H, 5.23; Cl, 30.70; N, 12.12%. Found: C, 51.86; H, 5.41; Cl, 30.34; N, 12.41%. The physical constants reported by Prichard and Whitman (8) for 1-cyano-4-chloro-2-butene are b.p. 44–46° C at 0.3 mm and n_D^{25} 1.4735.

In other experiments where the amount of aluminum chloride was reduced to 0.1 mole or replaced by antimony pentachloride, only resinous products were obtained. In the presence of zinc chloride (ethereal solution), cyanogen chloride and butadiene failed to react.

1-Cyano-1,3-butadiene

Method A.—1-Cyano-4-chloro-2-butene (4.8 g, 0.042 mole) was dissolved in liquid ammonia (80 ml) and the solution was allowed to stand for 3 hours. After the ammonia had evaporated from the reaction mixture, the residue was extracted with ether. The liquid residue from the ether extract was fractionally distilled *in vacuo*. The main fraction (b.p. 56–58° C at 42 mm; n_D^{25} 1.4892) was 1-cyano-1,3-butadiene, yield 2.4 g (75%). Anal. Calc. for C_5H_5N: C, 75.91; H, 6.37; N, 17.70%. Found: C, 75.61; H, 6.37; N, 18.18%. The physical constants of 1-cyano-1,3-butadiene are reported by Snyder and Poos (9) to be b.p. 49.5–53° C at 31 mm, n_D^{20} 1.4852–1.4895.

Method B.—1-Cyano-2-chloro-3-butene (4.8 g, 0.042 mole) on treatment with liquid

[1]*All melting points and boiling points are uncorrected. Microanalyses by Micro-Tech Laboratories, Skokie, Ill.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

ammonia under the conditions described in method A gave a 72% yield of 1-cyano-1,3-butadiene (b.p. 56–58° C at 43 mm). This product was identified by its infrared spectrum and analysis.

Method C.—1-Cyano-4-chloro-2-butene (5.6 g, 0.05 mole) was added to hexamethylenetetramine (7 g, 0.05 mole) in chloroform (50 ml) and the reaction mixture was heated under reflux for 18 hours. After the reaction mixture cooled to room temperature, the precipitated hexamethylenetetramine hydrochloride was removed by filtration. The filtrate was evaporated to remove chloroform and the residue was filtered free from solid. Fractional distillation of the filtrate gave 1.5 g (45%) of 1-cyano-1,3-butadiene (b.p. 75° C at 70 mm). This product was identified by a comparison of its infrared spectrum and physical properties with 1-cyano-1,3-butadiene prepared by method B.

1,4-Dicyano-2-butene

1-Cyano-4-chloro-2-butene (3.42 g, 0.03 mole) was added over a period of 1 hour to a refluxing suspension of sodium cyanide (1.5 g, 0.03 mole) and cuprous chloride (0.12 g) in acetonitrile (8.4 g) under an atmosphere of nitrogen. The reaction mixture was refluxed for a further period of 48 hours after which the hot mixture was filtered and the filter cake was washed with hot acetonitrile. The combined filtrate and washings were evaporated and the crystalline residue was dissolved in methanol. This methanol solution on cooling deposited crystals (m.p. 74–76° C), yield 1.2 g (35%). The reported melting points of 1,4-dicyano-2-butene are 75–77° C (4) and 74° C (2).

3-Carbethoxy-7-cyano-5-hepten-2-one

A solution of ethyl acetoacetate (6.3 g, 0.045 mole) and sodium metal (1.05 g, 0.045 mole) in ethanol (23 ml) was treated dropwise (cooling) with 1-cyano-4-chloro-2-butene (5.2 g, 0.045 mole), and the reaction was allowed to proceed at room temperature overnight. The precipitated sodium chloride was removed by filtration and the filtrate was evaporated *in vacuo*. Dilution of the residue with water (20 ml) followed by ether extraction gave a crude oil, which was distilled *in vacuo* to give 2.5 g (26.6%) of 3-carbethoxy-7-cyano-5-hepten-2-one (b.p. 134–136° C at 0.6 mm, n_D^{25} 1.4592, d_4^{25} 1.078). Anal. Calc. for $C_{11}H_{15}NO_3$: C, 63.11; H, 7.22; N, 6.69%. Found: C, 63.27; H, 7.12; N, 7.06%.

ACKNOWLEDGMENT

The infrared absorption spectra were determined by Dr. C. Sandorfy of the Department of Chemistry, University of Montreal, Montreal, Quebec.

INFRARED SPECTRUM OF CRYSTALLINE H_2S_2

NUMAN ZENGIN[1] AND PAUL A. GIGUÈRE

Wilson and Badger (1) have measured the infrared spectrum of gaseous hydrogen persulphide, H_2S_2, while Fehér and his co-workers (2, 3) have studied the Raman spectrum of the liquid. However, no structural investigation of the crystal, either by X-ray diffraction or spectroscopy, has been reported yet. The infrared spectrum of that solid is of some interest in view of the close analogy of the molecule with hydrogen peroxide, on the one hand, and the absence of hydrogen bonding, on the other hand.

The sample of H_2S_2 used for the present work was prepared after the method of Butler and Maass (4). Three successive fractional distillations were sufficient to yield a clear, colorless liquid, free from higher polysulphides. All traces of water were removed by collecting the distillate over P_2O_5. The final product seemed very stable when kept at dry-ice temperature in a Pyrex flask previously treated with gaseous HCl. No analyses were carried out since the purity of the persulphide was confirmed by the absence from its spectra of any absorption due to H_2S. As a further precaution the measurements were always made on freshly distilled samples. Clear, transparent films of the solid were easily obtained by deposition of the vapor on disks of NaCl or CsI cooled to liquid-air temperature in a conventional absorption cell. From the amount of liquid used and the surface of the salt disk and its metal support, the thickness of the crystalline films was estimated of the order of 10 microns. The infrared absorption was measured over the range 290 to 5000 cm^{-1} with a Perkin–Elmer, Model 12-C spectrometer using prisms of NaCl, KBr, and CsBr.

The various bands observed are shown in Fig. 1 and the frequency of the maxima are listed in Table I along with those of the gas and the Raman shifts of the liquid. As could be expected from the weakness of the intermolecular forces, the vibrational frequencies of the free molecule change very little in the condensed phases. For the same

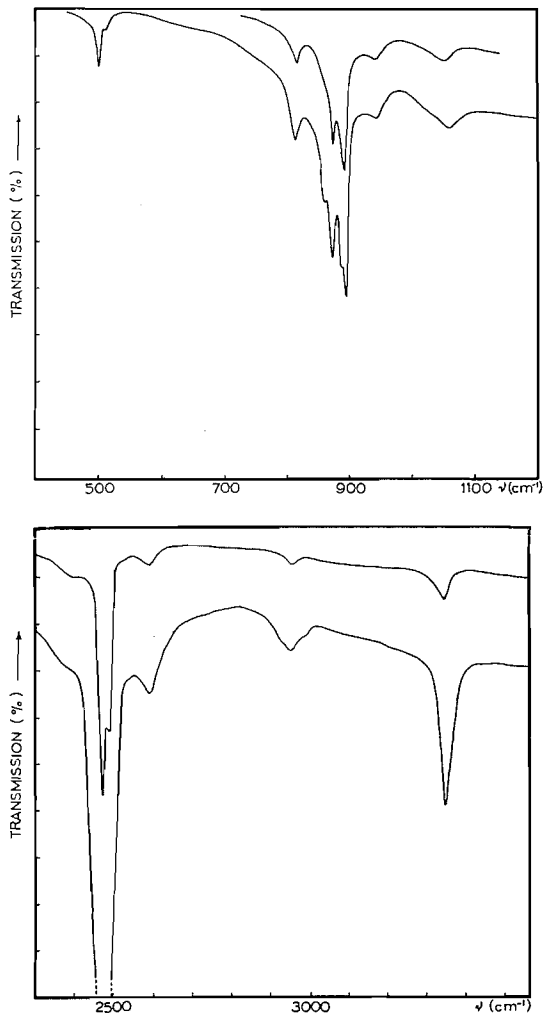

FIG. 1. Infrared absorption spectra of crystalline H_2S_2, for two films of different thickness.

reason the H_2S_2 bands are much sharper than those of its oxygen analogue, H_2O_2 (5). Apart from ν_3, the S–S stretching vibration at 501 cm^{-1}, the S–H stretching and bending fundamentals give rise to regions of strong absorption near 2500 and 880 cm^{-1} respectively. Because the crystal structure of H_2S_2 is unknown the various peaks in these two bands cannot be assigned unambiguously. Tentatively the pair of strong lines at 890 and 868 cm^{-1} may be ascribed to the asymmetric (ν_6) and the symmetric (ν_2) bending modes although they could also be two components of the former mode. The very weak shoulders at 10 cm^{-1} on the low-frequency side of the two main peaks, visible only in the thickest samples, might conceivably belong to the isotopic molecules $HS^{32}S^{34}H$ (natural abundance about 4%). They show roughly the same relative intensity as some of the isotopic bands of SO_2 (6). Sum–difference combinations of the bending frequencies with a lattice vibration of some 65–70 cm^{-1} give rise to the weak satellites at 814 and 940 cm^{-1}. Another combination band at 1070 cm^{-1} involves, no doubt, ν_6 and a frequency of the order of 200 cm^{-1}. This is of the right magnitude for ν_4, the torsional frequency,

which has not been detected yet. It must be added, however, that it could also fit one of the libration frequencies of the H_2S_2 molecule, namely that about the S–S axis. As in the case of H_2O_2 (7) these two frequencies are expected to lie fairly close together. Naturally the corresponding frequencies are very much higher in solid H_2O_2 (about 650 cm^{-1}) on account of the strong hydrogen bonds. The strongest lines at 2480 and 2495 cm^{-1} also show sum–difference combinations with a lattice frequency of about 110–120 cm^{-1}. Finally the overtone bands at 2960, 3345, and 4840 cm^{-1} are assigned after the corresponding vapor bands (1).

ELECTRON SPIN RESONANCE ABSORPTION SPECTRUM OF PUMMERER'S OXYGEN RADICAL

J. B. FARMER, Y. MATSUNAGA,* AND C. A. MCDOWELL

Though dehydro-hydroxy-binaphthylene-oxide (I) was prepared as early as 1914 by Pummerer and Frankfurter and reported to dissociate nearly completely into free radicals in dilute benzene solution (1), no magnetic measurements have been done on this compound.

The electron spin resonance absorption spectra of dehydro-oxy-binaphthylene-oxide (I), and binaphthyl-bis-peroxy-binaphthylene-oxide (II) in benzene and pyridine solutions, were examined at room temperature at a frequency of 9 k Mc/s, in a high-resolution high-sensitivity electron spin resonance spectrometer constructed in this department (7). The resonance spectrum shown in Fig. 1 was found in both cases and attributed to the existence of the free radical (III). The reddish-violet solution of this free radical is somewhat sensitive toward oxygen, but for these measurements it was unnecessary to handle it in vacuum or in an inert atmosphere.

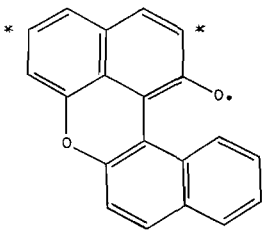
(II)



(III)

Dehydro-hydroxy-binaphthylene-oxide (I) and binaphthyl-bis-peroxy-binaphthylene-oxide (II) were prepared by the methods given in refs. 1 and 2, respectively.

The spectra of the two compounds in benzene or pyridine consist of three equally-spaced lines with a separation of 2.5 oersteds. The center of spectrum of Pummerer's radical is located 0.50 oersted lower in field than that of diphenyl-picryl-hydrazyl. If we take the g-value of the latter as 2.0036 (3), the value for Pummerer's radical is approximately 2.0039.

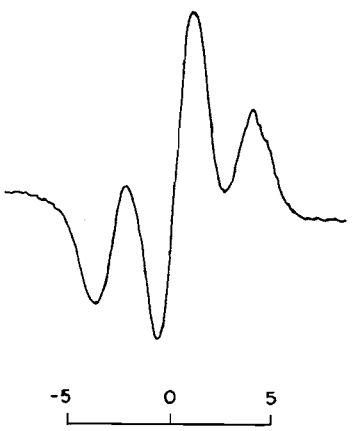


FIG. 1. Electron spin resonance absorption spectrum of Pummerer's oxygen radical.

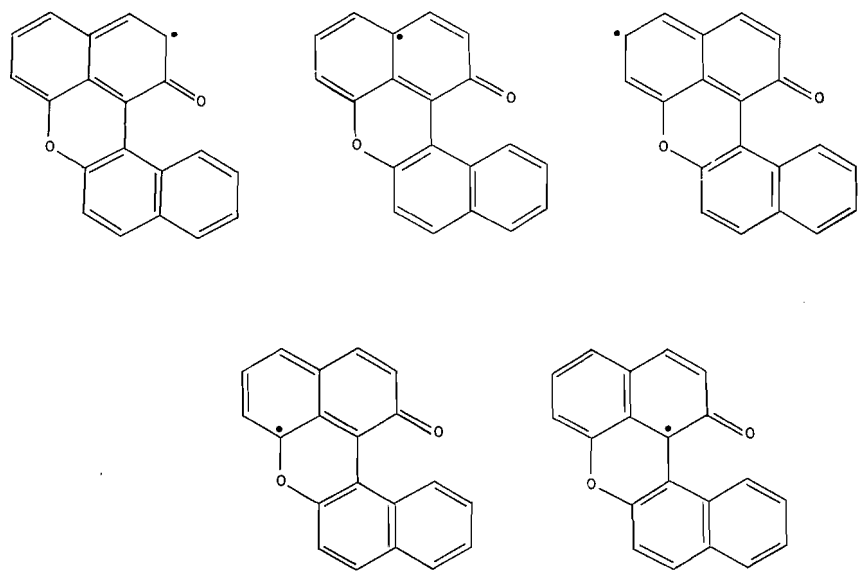
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

As the compounds (I) and (II) give the same resonance spectrum, it appears that the middle part of the compound (II) does not form a biradical in the process of dissociation, or the lifetime of the radical formed is too short to be detected.

The number of lines in Fig. 1 shows that only two protons among eleven in Pummerer's radical can interact with the unpaired electron. It is suggested that the radical is highly distorted by steric hindrance and the distribution of the unpaired electron is restricted to the naphthalene nucleus to which the peroxide oxygen atom is attached. By the simple LCAO-MO method, the density of the frontier electrons, i.e., the electrons in the highest occupied energy level, in β-substituted naphthalene was calculated by Fukui *et al.* (4). Based on their result, the protons which contribute to the hyperfine splitting can be assigned to those attached to the starred carbon atoms in (III). The same conclusion can be obtained by consideration of the following resonance structures:



If we assume that the unpaired electron density on each carbon atom in Pummerer's radical is given by one half of the frontier-electron density in β-substituted naphthalene, the constant Q in the relation $a_j = Q \cdot \rho_j$ (5) is about 42 in the present case. This value seems to be of the correct order.

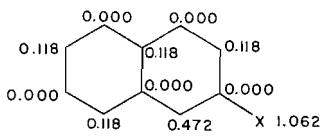


FIG. 2. Density of frontier electrons after Fukui *et al.* (Assumed $\alpha_x = \alpha_c$, $\beta_{cx} = \beta_{ar}$.)

The anomalous stability of Pummerer's radical may be due, in part, to conjugation between the naphthalene nucleus and the attached oxygen atom. However, the main reason is probably that the bulky substituent protects the oxygen atom from any reaction, as in the case of 2,4,6-tri-tert-butyl-1-phenoxyl (6).

We wish to thank the National Research Council and the Defence Research Board for grants in aid of this work.

THE ADSORPTION OF SULPHUR DIOXIDE BY GRAPHITE*

H. L. MCDERMOT AND B. E. LAWTON

INTRODUCTION

The adsorption of sulphur dioxide by a number of carbon blacks and graphite has been studied by Beebe and Dell (1). The carbon blacks used were Spheron 6 and a number of samples of Spheron 6 which had been deoxygenated at successively higher temperatures. A very pure graphite whose properties have already been described (4) was used. It was found that the untreated Spheron 6 with about 4% of oxygen on its surface adsorbed about seven times more sulphur dioxide than the samples from which virtually all the oxygen had been removed. It was also found that Spheron 6 which had been deoxygenated and graphitized at 2700° C displayed a similar isotherm to that of pure graphite. Thus it was concluded that the adsorption of sulphur dioxide provided a sensitive method for the detection of chemisorbed oxygen. It is likely that this conclusion can be extended to all polar groups on the surface. In the work reported here the adsorption of sulphur dioxide by artificial graphites was undertaken as a part of the program to study these carbons. Isotherms were measured to test for the presence of chemisorbed oxygen and to ascertain whether the hysteresis effects reported with non-polar gases on these graphites also existed for sulphur dioxide. Finally, isotherms were measured at a number of temperatures to study the temperature dependence of the branches of the hysteresis loop.

EXPERIMENTAL AND RESULTS

The graphites used in these experiments were two Acheson graphites designated by us as GF-3 and GF-5. Their properties have been given before (3, 5).

The sulphur dioxide was obtained from the Matheson Company and used without further purification.

Isotherms were measured at four temperatures for each graphite: at 236.6°, 244.5°, 256.8°, and 273.2° K for GF-3; and at 244.3°, 253.8°, 261.5°, and 273.2° K for GF-5. Adsorption was measured by means of a simple volumetric adsorption apparatus. A Dewar flask full of cracked ice and water was used for the isotherms at 273.2° K. For the lower temperatures, the bath was cooled by pumping liquid nitrogen through a copper coil. Two bath fluids were used: a 50 : 50 mixture of water and ethylene glycol, and a 65 : 35 mixture of chloroform and carbon tetrachloride. The bath was agitated by an electric stirrer and regulated by a sulphur dioxide vapor pressure thermometer. Before each isotherm, the sample was evacuated for at least 12 hours at 200° C.

THE ADSORPTION OF SULPHUR DIOXIDE BY GRAPHITE*

H. L. MCDERMOT AND B. E. LAWTON

INTRODUCTION

The adsorption of sulphur dioxide by a number of carbon blacks and graphite has been studied by Beebe and Dell (1). The carbon blacks used were Spheron 6 and a number of samples of Spheron 6 which had been deoxygenated at successively higher temperatures. A very pure graphite whose properties have already been described (4) was used. It was found that the untreated Spheron 6 with about 4% of oxygen on its surface adsorbed about seven times more sulphur dioxide than the samples from which virtually all the oxygen had been removed. It was also found that Spheron 6 which had been deoxygenated and graphitized at 2700° C displayed a similar isotherm to that of pure graphite. Thus it was concluded that the adsorption of sulphur dioxide provided a sensitive method for the detection of chemisorbed oxygen. It is likely that this conclusion can be extended to all polar groups on the surface. In the work reported here the adsorption of sulphur dioxide by artificial graphites was undertaken as a part of the program to study these carbons. Isotherms were measured to test for the presence of chemisorbed oxygen and to ascertain whether the hysteresis effects reported with non-polar gases on these graphites also existed for sulphur dioxide. Finally, isotherms were measured at a number of temperatures to study the temperature dependence of the branches of the hysteresis loop.

EXPERIMENTAL AND RESULTS

The graphites used in these experiments were two Acheson graphites designated by us as GF-3 and GF-5. Their properties have been given before (3, 5).

The sulphur dioxide was obtained from the Matheson Company and used without further purification.

Isotherms were measured at four temperatures for each graphite: at 236.6°, 244.5°, 256.8°, and 273.2° K for GF-3; and at 244.3°, 253.8°, 261.5°, and 273.2° K for GF-5. Adsorption was measured by means of a simple volumetric adsorption apparatus. A Dewar flask full of cracked ice and water was used for the isotherms at 273.2° K. For the lower temperatures, the bath was cooled by pumping liquid nitrogen through a copper coil. Two bath fluids were used: a 50 : 50 mixture of water and ethylene glycol, and a 65 : 35 mixture of chloroform and carbon tetrachloride. The bath was agitated by an electric stirrer and regulated by a sulphur dioxide vapor pressure thermometer. Before each isotherm, the sample was evacuated for at least 12 hours at 200° C.

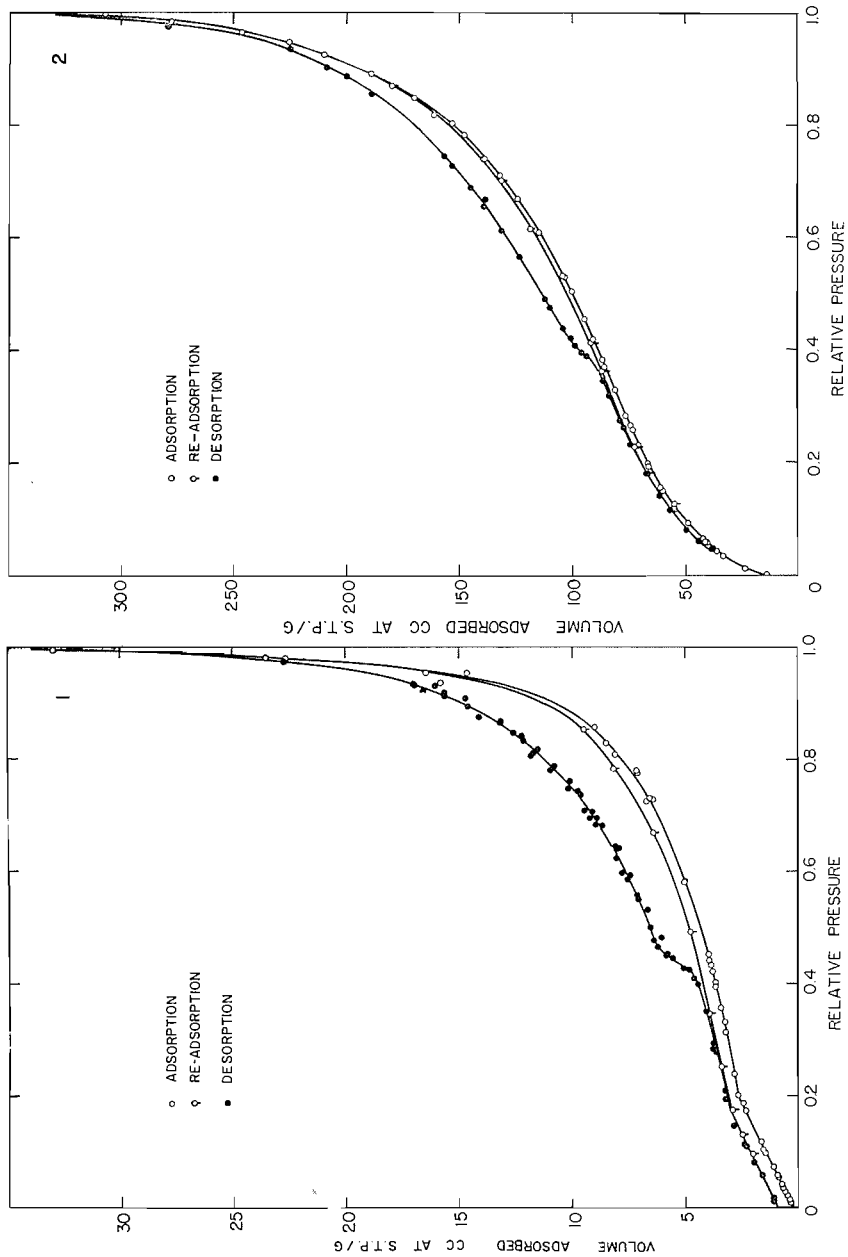

FIG. 1. The adsorption of sulphur dioxide by GF-3 at 256.8° K.
FIG. 2. The adsorption of sulphur dioxide by GF-5 at 253.8° K.

Two typical isotherms are presented in Figs. 1 and 2. Figure 1 shows the isotherm of sulphur dioxide adsorbed on GF-3 at 256.8° K. Figure 2 depicts the isotherm for GF-5 at 253.8° K. It is interesting to note that the isotherm in Fig. 1 shows a sharp break at a relative pressure of about 0.2. This break, which was characteristic of the isotherms measured with GF-3, was absent in those measured with GF-5.

DISCUSSION

The low adsorption of sulphur dioxide by these graphites is indicative of their lack of chemisorbed oxygen. This point is illustrated by Fig. 3, which compares the adsorption of sulphur dioxide by GF-3 and GF-5 with the data of Beebe and Dell (1) for a deoxygenated carbon black and a very pure graphite. All four carbons adsorb sulphur dioxide to about the same degree. It has been demonstrated that smooth isotherms such as have been observed with these graphites for the adsorption of nitrogen and argon are indicative of heterogeneous surfaces (2). The graphites contain little ash and the data given here show the absence of chemisorbed oxygen, hence the heterogeneity must be of the topographic type.

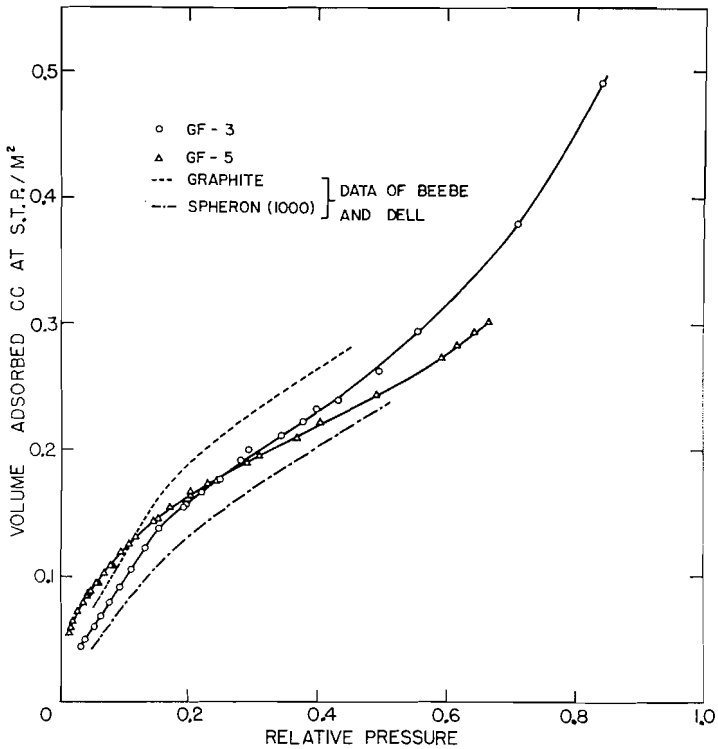

FIG. 3. A comparison of the adsorption of sulphur dioxide by three graphites and a deoxygenated carbon black.

Figures 1 and 2 show that isotherms of both of these graphites give evidence of what we have called "swelling" type hysteresis as well as the normal hysteresis caused by the presence of pores. The "swelling" type hysteresis manifests itself as a second curve just above the initial adsorption curve extending from low to high relative pressures. Isosteric heats have been calculated from both of these curves using data from all four

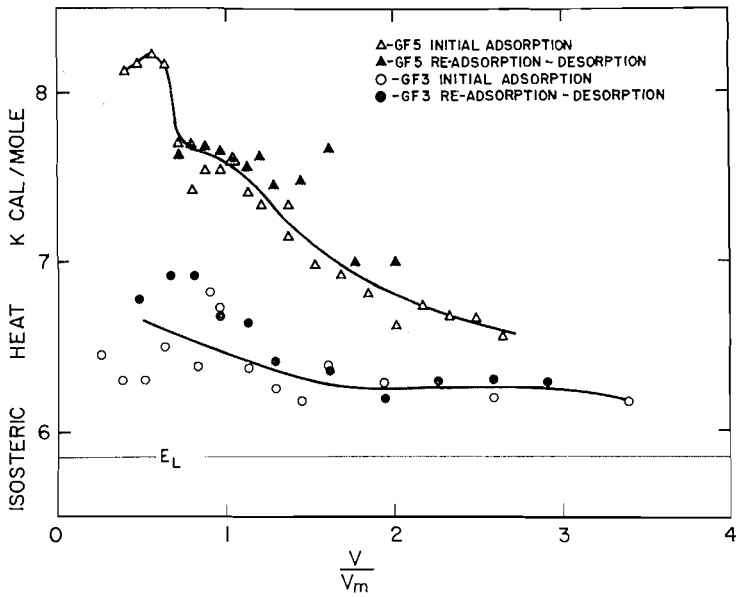

FIG. 4. Isosteric heats for the adsorption of sulphur dioxide by GF-3 and GF-5.

temperatures. These heats presented in Fig. 4 show values well above the heat of liquefaction of sulphur dioxide. Within the experimental error, no difference could be discerned between heats calculated from the initial adsorption curves and those calculated from the desorption and readsorption curves. Thus no heat effect can be detected in this way which could be attributed to swelling of the graphite crystallites. Possibly the method is too rough to measure the heats involved.

THE REACTION OF ACTIVE NITROGEN WITH HYDROGEN BROMIDE[1]

H. B. DUNFORD AND BERNADINE E. MELANSON

ABSTRACT

The reaction of active nitrogen with hydrogen bromide was found to produce bromine and ammonium bromide as the main products, along with traces of compounds tentatively identified as bromamine, NH_2Br, and bromimine, $NHBr_2$. Hydrogen abstraction from hydrogen bromide by nitrogen atoms, imine and amine radicals can account for ammonia formation. Considerable catalysis of nitrogen atom recombination by hydrogen bromide appears to occur. A resonance transfer of the electronic energy responsible for the nitrogen afterglow to bromine with a resultant bromine emission spectrum is proposed to account for the orange reaction flame.

INTRODUCTION

In an early study Willey and Rideal (1) attributed the reactivity of active nitrogen in its reaction with hydrogen bromide to excited nitrogen molecules. However, Ewart and Rodebush (2) believed that the reactivity was due entirely to atomic nitrogen. The present paper reports the results of a more extensive investigation of the reaction.

EXPERIMENTAL

Hydrogen bromide was produced by burning the mixture obtained by bubbling cylinder hydrogen through Baker's C. P. bromine (3) which was kept at room temperature. The resultant hydrogen bromide and excess hydrogen were passed through a trap cooled with a dry ice – acetone mixture to remove moisture, and the hydrogen bromide was retained in a second trap cooled with liquid air. It was stored for use after a single bulb-to-bulb distillation.

The nitrogen was activated by a condensed discharge and was reacted with the hydrogen bromide in a fast flow system. Details of the type of apparatus have been described elsewhere (4, 5). In the present system the flow rate of molecular nitrogen was 3.64×10^{-5} mole per second at a pressure of 0.8 mm of mercury. Reaction time was 0.2 second. Condensable gases obtained as reaction products were retained in traps cooled with liquid air and analyzed after fractionation in a LeRoy still (6). The rate of salt deposition from the reaction of active nitrogen with hydrogen bromide was determined in a special series of experiments in which the salt was washed from the system with distilled water and titrated for bromide ion. The washing process eventually removed some of the metaphosphoric acid used to poison the flow system, so that when products condensable in liquid air were being analyzed, the salt was removed from the system by

reaction with active nitrogen. In a few experiments, products of the reaction of active nitrogen with salt were retained for analysis by placing liquid air around the second trap in the flow system.

Bromine and various mixtures of bromine – hydrogen bromide and hydrogen – hydrogen bromide were also reacted with active nitrogen. Flow rates of hydrogen and hydrogen bromide were each determined by conventional pressure–volume–time measurements. Liquid bromine was stored in a cylindrical container which was immersed in an ice–water mixture. Bromine vapor from the container was pumped through various sizes of calibrated flowmeters.

The maximum yield of hydrogen cyanide obtained from the reaction of active nitrogen with ethylene was also determined at room temperature and at 340° in order to determine the flow rate of atomic nitrogen (4). In two experiments ethylene was fed into a reaction vessel which had previously been coated with ammonium bromide.

RESULTS

The Reaction of Active Nitrogen with Hydrogen Bromide

At 80° C the reaction of active nitrogen with hydrogen bromide produced an orange flame and effectively quenched the nitrogen afterglow. As was observed earlier (2), the flame consisted of bands in the 590–600 mμ region. At 380°, the typical active nitrogen afterglow could be observed emerging from the reaction vessel at all but the highest rates of hydrogen bromide input; about two inches below the reaction vessel the afterglow was replaced by the orange flame.

A salt deposit formed on the walls of the reaction vessel in experiments conducted at 80° C. At higher temperatures, it formed only on the walls of the tubing connecting the reaction vessel to the first liquid air trap. Kjeldahl determinations and Volhard titrations indicated a 1.01:1.00 ratio (±0.01) of ammonium to bromide ions. Tests for hydrazine hydrobromide (7) were negative as were tests for oxidizing agents with potassium iodide. It was therefore concluded, in agreement with the findings of Ewart and Rodebush, that the salt was pure ammonium bromide.

The volatile products of the reaction of active nitrogen with hydrogen bromide, which were separated on the LeRoy still, were as follows. Hydrogen bromide was removed by distillation at −135° C. The rate of its recovery was determined by pressure–volume measurements and by titration with standard alkali solution. A small amount of product (A) was recovered at −90° C. Crude measurements indicated that its vapor pressure obeyed the equation $\log p_{mm} = -1.7\times10^3/T+9.0$ over the pressure range 0.01 to 0.4 mm. The material was white in the solid state, gave a negative Nessler test, and liberated iodine when warmed with frozen potassium iodide solution. Its rate of formation was of the order of 10^{-8} mole per second. Bromine was distilled at 50° C and trapped on frozen potassium iodide solution. The iodine liberated upon warming was titrated with standard thiosulphate solution. A trace of material (B) was removed after the distillation of bromine. It was white when frozen and had a vapor pressure, measured over the range 0.01 to 0.05 mm, comparable to that of hydrazine (8). However, it gave a negative test with salicylaldehyde (7). Furthermore, any hydrazine which might have been formed might be expected to react with excess hydrogen bromide to form hydrazine hydrobromide. It is proposed tentatively that A and B are bromamine, NH_2Br, and bromimine, $NHBr_2$, respectively. Neither compound has been isolated before, although the preparation of ether solutions of NH_2Br and $NHBr_2$ has been reported (9).

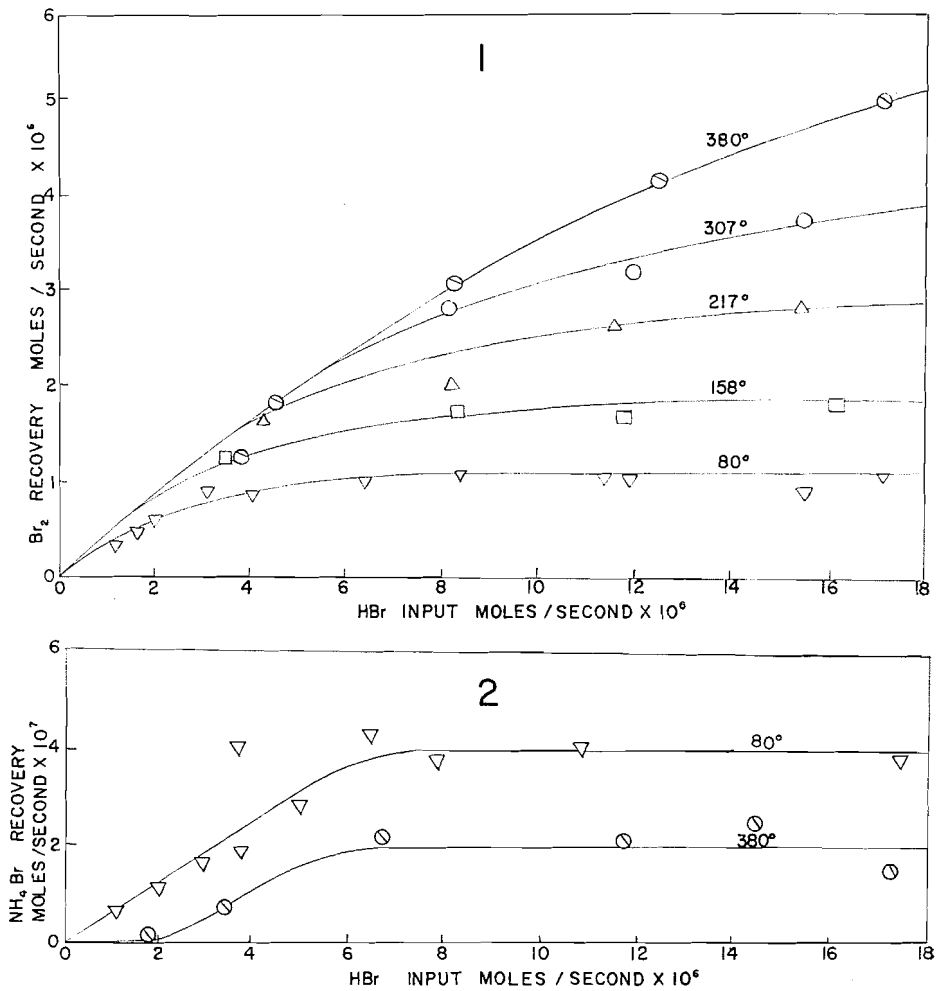
The rates of formation of bromine and ammonium bromide at various flow rates of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

hydrogen bromide are shown in Figs. 1 and 2, respectively. The maximum rate of recovery of hydrogen cyanide from the reaction of active nitrogen with ethylene at 80° C was 8.0×10^{-6} mole per second, and this was unaffected by the presence of ammonium bromide in the reaction vessel; at 340° it was 9.0×10^{-6} mole per second.[2] Since the rate of hydrogen cyanide recovery from the reaction of active nitrogen with ethylene becomes constant above 250°, the latter figure is used as an indication of the atomic nitrogen flow rate at all temperatures.

The Reaction of Active Nitrogen with Ammonium Bromide

The flame of the reaction of active nitrogen with ammonium bromide, as observed with a pocket spectroscope, was the same as that obtained in the corresponding hydrogen bromide flame. As the salt with its orange flame was slowly swept along the flow system



FIGS. 1 and 2.

[2]*Larger temperature coefficients from room temperature to 250° for the rate of hydrogen cyanide production from the reaction of active nitrogen with ethylene have been observed in faster flow systems (10).*

a blue glow gradually developed between the nitrogen afterglow and the orange emission. The blue glow, as observed spectroscopically, appeared as a continuum with its long wave length edge at approximately 510 mμ. In a typical experiment active nitrogen was reacted for 1 hour with 1.5×10^{-4} mole of ammonium bromide which had previously been deposited in the reaction vessel. All but a trace of the salt was destroyed and 4.2×10^{-5} mole of hydrogen bromide, 5.5×10^{-5} mole of bromine, and a trace of compound B were recovered.

The Reactions of Active Nitrogen with Bromine and Hydrogen – Hydrogen Bromide and Bromine – Hydrogen Bromide Mixtures

When bromine was fed into the active nitrogen stream no product was recovered except molecular bromine (1). However, the same orange band as that observed in the flame of active nitrogen reactions with hydrogen bromide and ammonium bromide was observed in the flame produced by the interaction of active nitrogen and bromine. Furthermore, when the input of bromine was stopped, but the flow of active nitrogen was continued, the same blue continuum, as observed in the reaction of active nitrogen with ammonium bromide was produced as the orange flame retreated rapidly.

The results of the combined additions of bromine – hydrogen bromide and hydrogen – hydrogen bromide mixtures are summarized in Fig. 3.

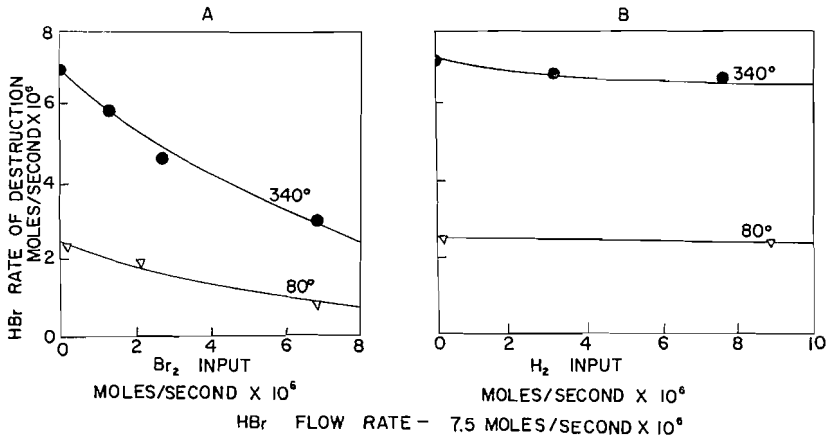

FIG. 3.

DISCUSSION

The mechanism of ammonium bromide formation proposed by Ewart and Rodebush, with added thermochemical data,[3] is as follows:

$$N + HBr \rightarrow NH + Br + 1 \text{ kcal}, \quad [1]$$

$$NH + HBr \rightarrow NH_2 + Br + 1 \text{ kcal}, \quad [2]$$

$$NH_2 + HBr \rightarrow NH_3 + Br + 17 \text{ kcal}, \quad [3]$$

[3] *All heats of reaction are calculated from the following data:*
D_{H-Br} = *87 kcal*, D_{H-H} = *104 kcal*, D_{Br-Br} = *46 kcal—Selected values of chemical thermodynamic properties. National Bureau of Standards, Washington, D.C. 1950.*
D_{N-H} = *88 kcal—Pannetier, G. and Gaydon, A. G. J. chim. phys.* **48**, *221 (1951).*
D_{NH_2-H} = *104 kcal—Swarcz, M. Chem. Revs.* **47**, *75 (1950).*
D_{N_2} = *225 kcal—Hendrie, J. M. J. Chem. Phys.* **22**, *1503 (1954).*
ΔH_f NH_3 = *11 kcal—Handbook of chemistry and physics.*
ΔH_{sublt} NH_4Br = *44 kcal—Smits, A. and deLange, W. J. Chem. Soc. 2936 (1928).*

For personal use only.

$$NH_3 + HBr \rightarrow NH_4Br + 44 \text{ kcal}, \quad [4]$$

$$2Br + M \rightarrow Br_2 + M + 46 \text{ kcal}. \quad [5]$$

There is ample evidence that atomic nitrogen is present in active nitrogen and that it is chemically reactive (11). However, if reactions [1–5] were the only ones occurring then the optimum rate of recovery of ammonium bromide would be equal to the flow rate of atomic nitrogen, and the rate of molecular bromine formation would be 1.5 times as great. Actually, the maximum recovery rates of ammonium bromide and bromine obtained at 80° C are, respectively, only 1/22 and 1/9 as great as the available supply of atomic nitrogen, as indicated by the maximum recovery of hydrogen cyanide from ethylene. At 380° the yield of ammonium bromide is still lower and the bromine recovery has climbed to 5/9 the amount of atomic nitrogen available.

Reactions of the type:

$$2NH \rightarrow N_2 + H_2 + 153 \text{ kcal}, \quad [6]$$

$$2NH_2 \rightarrow N_2 + 2H_2 + 81 \text{ kcal}, \quad [7]$$

$$N + NH \rightarrow N_2 + H + 137 \text{ kcal}, \quad [8]$$

$$N + NH_2 \rightarrow N_2 + 2H + 49 \text{ kcal}, \quad [9]$$

would have the effect of a reduction in the yields of bromine and ammonium bromide. Reaction [9], which is spin allowed for three out of every eight collisions, would be favored over the more exothermic reaction

$$N + NH_2 \rightarrow N_2 + H_2 + 153 \text{ kcal},$$

which is spin disallowed. Reactions [6–9] inclusive presumably would have very low activation energies and might occur more rapidly on the wall, since they are all free radical or atomic reactions.

However, even if every imine radical were destroyed in [8], the yield of bromine would still be too large, namely one-quarter of the available supply of atomic nitrogen. Only the possible fate of atomic hydrogen formed in [8] and [9] might reconcile the above mechanism with the experimental observations.

Atomic hydrogen, if formed, might be expected to recombine

$$2H + M \rightarrow H_2 + M + 104 \text{ kcal} \quad [10]$$

or to undergo one of the following reactions:

$$H + HBr \rightarrow H_2 + Br + 17 \text{ kcal}, \quad [11]$$

$$H + Br_2 \rightarrow HBr + Br + 41 \text{ kcal}, \quad [12]$$

$$H + Br + M \rightarrow HBr + M + 87 \text{ kcal}. \quad [13]$$

Both reactions [12] and [13] would decrease the yield of bromine. The ratio k_{12}/k_{11} is known to be about 10 over a considerable temperature range (12). Since both [11] and [12] are extremely rapid, they might be expected to consume most of the available atomic hydrogen before it could reach the reaction vessel wall.

Two rather serious objections can be raised to the mechanism outlined in [1–13]. First, an increase in the flow rate of hydrogen bromide should increase the rate of bromine formation through [1–3] and [11], yet plateaus in bromine production are observed at the two lowest temperatures at which the reaction was studied.

Second, if the above mechanism is to account for the low rate of recovery of bromine at 80°, then [8–9] followed by [12] must be remarkably efficient processes. The slope of the curve in Fig. 3A would indicate that if [12] is extensive in the present system, its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

effect is largely offset by [11]; cf. the effect of added chlorine on the rate of destruction of hydrogen chloride observed by Wiles and Winkler (10). Furthermore the existence of excess active nitrogen at high flow rates of hydrogen bromide at high temperatures is not compatible with the postulate of extensive occurrence of [8–9] in the present system.

In the reaction of active nitrogen with hydrogen chloride, where hydrogen abstraction by atomic nitrogen is prohibitive energetically at lower temperatures, the initiation steps were assumed to be

$$N + HCl \rightarrow [H\text{–}Cl\text{–}N],$$
$$N + [H\text{–}Cl\text{–}N] \rightarrow N_2 + H + Cl.$$

If the corresponding initial steps occurred in the present system, then ammonia formation would proceed through the reactions

$$N + H + M \rightarrow NH + M, \qquad [14]$$
$$NH + H_2 \rightarrow NH_3, \qquad [15]$$

as first proposed by Steiner (13).

A qualitative comparison of other reactions involving atomic hydrogen in the reaction of active nitrogen with hydrogen chloride and in the present system may be of interest. In the former system considerable quantities of atomic hydrogen are liberated and largely removed through the reactions

$$H + HCl \rightarrow H_2 + Cl,$$
$$H + Cl_2 \rightarrow HCl + Cl,$$

which have activation energies of 5 and 3 kcal, respectively. In the present system, the corresponding reactions [11] and [12] both have activation energies of 2 kcal or less, and so removal of hydrogen atoms is even more rapid. Since no ammonia is formed through [14–15] in the reaction of active nitrogen with hydrogen chloride, it might appear even less likely in the present system, where the steady state concentration of atomic hydrogen is even lower. A more convincing argument perhaps is the fact that if the reactions

$$N + HBr \rightarrow [H\text{–}Br\text{–}N], \qquad [1a]$$
$$N + [H\text{–}Br\text{–}N] \rightarrow N_2 + H + Br, \qquad [16a]$$

which would be the principle source of atomic hydrogen, were predominant at 80°, then the yield of molecular bromine would be one-quarter of the available supply of atomic nitrogen, provided, as appears to be the case, that the net regeneration of hydrogen bromide from atomic hydrogen reactions is not of prime significance at 80°.

A mechanism which would appear to account for most features of the reaction satisfactorily is [1*a*] followed by

$$[H\text{–}Br\text{–}N] \rightarrow NH + Br, \qquad [1b]$$
$$N + [H\text{–}Br\text{–}N] \rightarrow N_2 + HBr. \qquad [16b]$$

Ammonia formation could proceed through [2–3].

If [16*b*] is predominant at 80°, an increase in the flow rate of hydrogen bromide would mainly increase the rate of nitrogen atom recombination. Hence the plateau in the rate of bromine production can be explained. At higher temperatures, if [1*b*] becomes increasingly important, then the temperature coefficient for bromine production, and its increased sensitivity to hydrogen bromide flow rate with increased temperature, can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

explained. It is thus not necessary to attach prime importance to reactions [6–13] in the present system.

Whether the substance which catalyzes the recombination of atomic nitrogen will be decomposed is dependent on the fraction of the recombination energy which is transmitted to the remainder of the complex. For a hydrogen bromide complex, it would appear that this fraction is less than the ratio of the bond dissociation energies of hydrogen bromide and nitrogen, namely 87/225, or 0.39, provided that the hydrogen bromide remains in its electronic ground state. For a hydrogen chloride complex, the fraction must have a minimum value of 0.46. The difference might be attributed to the relative sizes of the p orbitals of chlorine and bromine, the latter being too large to facilitate formation of a strongly bonded complex with atomic nitrogen.

There remains the problem of why the yield of ammonium bromide decreases with increasing temperature. Because of the appreciable sublimation pressure of ammonium bromide at higher temperatures (one atmosphere at 396° C), the occurrence of [4] is prevented in a hot reaction vessel. Ammonia, which at 80° would be removed rapidly from the flow system by [4], could, to a large measure, be destroyed by reaction with active nitrogen at higher temperatures. The rapid rate of reaction of active nitrogen with ammonia, even in competition with the reaction of active nitrogen with ethylene, introduced as a second reactant, has been demonstrated previously (14).

Because the bands in the 590–600 mμ region are produced as a result of the interaction of active nitrogen and pure bromine, it would appear that bromine, produced in the reactions of active nitrogen with hydrogen bromide and ammonium bromide, respectively, is responsible for the emission of the same orange band in the latter two reactions.

Ewart and Rodebush originally proposed that the transfer of two vibrational quanta from the $B\ ^3\Pi_g$ state of nitrogen to a ground state molecule of hydrogen bromide, followed by a modified $B\ ^3\Pi_g \rightarrow A\ ^3\Sigma_u^+$ transition in the active nitrogen as the cause of the orange flame. This appeared plausible as the appropriate vibrational energy spacings of the B state of nitrogen are roughly double those of the ground state of hydrogen bromide, and the selection rule for the transfer of vibrational quanta states that $v = \pm 1$ or ± 2. However, if the interaction of active nitrogen and bromine is responsible for the orange band, then an explanation in terms of a modified nitrogen afterglow is not possible, since the vibrational energy spacings of the ground state of bromine differ by a factor of approximately nine from those of the B state of nitrogen (15).

Transitions between the ground state of bromine, $X\ ^1\Sigma_g^+$, and the state $B\ ^3\Pi_{0u}^+$ are known in both emission and absorption. A careful plot of the potential functions of both states shows that the energy corresponding to the transition from the first vibrational level of the X state of bromine to the 15th, 16th, and 17th levels of the B state matches exactly the energy emitted in the first positive bands of active nitrogen. The transition does not violate the Franck–Condon principle; furthermore, an appreciable fraction of ground state bromine molecules have $v = 1$ at 80° C. Such a resonance transfer is much more likely to occur when the energy matching is exact (16). The return transitions $15' \rightarrow 2''$, $16' \rightarrow 2''$, and $17' \rightarrow 2''$ could account for the orange emission. Transitions to the zero vibrational level of the ground state would violate the Franck–Condon principle.[4] That the emission occurs in such a selective wave length region might indicate that

[4]*The referee has pointed out the apparent violation of spin conservation in the energy transfer process proposed above. However, the* $^3\Pi$–$^1\Sigma$ *transition in the halogens appears identical with a* $^1\Sigma$–$^1\Sigma$ *transition (17). No real significance can be attached to the S and* Λ *quantum numbers, but only to* Ω *for the excited state of bromine.*

quenching of the B state bromine molecules occurs in the present system more rapidly than the exchange of vibrational quanta among B state molecules of bromine. The quenching of the B state of iodine and bromine by various gases by an induced predissociation mechanism has been observed by various authors (15).

The blue emission continuum corresponds to that observed for the two-body recombination of $^2P_{3/2}$ and $^2P_{1/2}$ bromine atoms followed by a $B \rightarrow X$ transition. The source of excited bromine atoms is not clear. Furthermore the probability of the two-body atom recombination occurring is very slight, but it appears to provide the only readily available explanation of the blue glow. The two-body recombination of atoms has been observed spectroscopically for the halogens at high temperatures (18) and for tellurium vapor in an intense discharge (19).

MEASUREMENT OF Ni^{63} WITH A 2π PROPORTIONAL COUNTER[1]

J. R. MacEwan,[2] J. U. MacEwan, and L. Yaffe

ABSTRACT

Measurement of Ni^{63}, a β^- emitter with very low maximum energy, is described. External absorption curves were determined in aluminum and a range 8.5 ± 0.5 mg/cm^2 was found. This corresponds to a maximum energy of the β radiation of 72.7 ± 2.5 kev, in reasonably good agreement with values obtained by other methods. Self-absorption curves of electrolytically deposited samples were obtained and attempts made to compare these with the theoretical predictions of Gora and Hickey.

A. INTRODUCTION

An investigation of the counting characteristics of Ni^{63}, a nuclide emitting 67-kev beta rays, was undertaken, since few precise 2π counting studies have been made in this energy range. Self-absorption measurements with Ni^{63} are particularly interesting because Gora and Hickey's (1) theoretical expressions for self-absorption in wide-angle geometries have yet to be verified for use with nuclides emitting soft beta radiation. Their general expression for self-absorption is an integrated form of equation [1], which corrects for the extra distance a particle emitted at an angle θ to a normal on the source mount surface must travel before reaching the surface.

$$[1] \qquad A(x, \theta) = \frac{a_0 \cos\theta}{k}\left(1 - e^{-\frac{kx}{\cos\theta}}\right)$$

where $A(x, \theta)$ is the detected activity of particles emitted at an angle θ from a source of thickness x, consisting of material of specific activity a_0, and k is the absorption coefficient. They have refined this treatment further to include the case where a fraction, p, of the particles incident on the source mount are scattered back towards the active volume of the counter, but were unable to include the effects of self- and back-scattering in the source. This relationship was very successfully applied by them to their results for self-absorption of C^{14} in narrow- and wide-angle geometries.

In addition, a measurement of the range of Ni^{63} beta particles in aluminum was made because it provides a check on this method for determination of maximum energies in this range as compared with beta spectrometer and other proportional counter studies.

B. EXPERIMENTAL TECHNIQUES AND RESULTS

Tracer Purification and Source Preparation

The active material used in this investigation was prepared by the irradiation of spectrographically pure nickel in the Brookhaven reactor in a position where the flux was predominantly thermal. A gamma-emitting impurity, identified as Co^{58} by scintillation spectrometry, was found. This was presumably produced by the reaction $Ni^{58}(n,p)$-Co^{58}. The cobalt was removed by dissolving the nickel in 9 *M* HCl and eluting the resulting solution through an anion exchange column (2). One passage through the column was sufficient to effect a complete separation, with the cobalt being retained on the resin.

The resulting solution was evaporated to dryness and the nickel chloride was dissolved in an ammonia – ammonium sulphate electrolysis solution. The resulting electrolyte had a nickel concentration of 0.03 moles per liter. All sources used for measurement in this investigation were prepared by electroplating nickel from aliquots of this stock solution onto copper planchets 1 in. in diameter, to give deposits 0.70 in. in diameter. Plating was carried out in rotating anode plating cells at a current density of 20 ma/cm^2. The rotational speed and anode shape were adjusted until extremely uniform deposits were obtained.

The sources were counted on an internal source proportional counter (AEP CFIS 2) with a 2π geometry. An AEP 1448 amplifier-discriminator unit, a Marconi AEP scale of 1000, and a Dynatron power supply P200A comprised the associated electronic equipment. The counter gas was C.P. methane, dried over silica gel. The long, flat plateaux (approximately 400 v long and with slopes of 0.5% per 100 v) and general stability of this equipment ensured that any small observed variations in counting rate were due solely to counting statistics. Coincidence loss corrections were made for all sources wherever necessary. The calibration curve for this correction was obtained using a multiple source technique (3).

External Absorption Curve

When an aluminum foil is placed over the source in an internal source counter, the chamber is effectively converted into an end window counter. Unless the foil is in intimate contact with the source, besides the reduction in counting rate caused by absorption in the absorber, further reductions are caused by absorption in the methane trapped between the foil and source and also by scattering of beta particles at the foil surface. It was found that these latter effects could be eliminated by laminating the aluminum absorbers onto the source with a thin layer of plastic adhesive, in this case a solution of VYNS resin in cyclohexanone. For the thinnest foils employed, the weight of aluminum was 0.23 mg/cm^2 and that of plastic about 0.06 mg/cm^2. With thicker aluminum foils the ratio of aluminum to plastic increased accordingly, and in this investigation the absorbers were considered to consist solely of aluminum. Aluminum foils with mass thicknesses of 0.23, 0.66, and 1.90 mg/cm^2 were laminated singly and in various combinations onto the source to cover the range of absorbers used, 0 to 13.5 mg/cm^2. In most cases sufficient counts were obtained at each absorber thickness to give satisfactory statistics, but in those instances where a small number of counts were obtained the accuracy of the plotted values is indicated in the usual manner.

Self-absorption Curve

To investigate the phenomenon of self-absorption of Ni^{63}, a series of active sources was prepared by electrodeposition. All sources were prepared from material of the same specific activity. The range of source thicknesses investigated varied from 0.05 to 4.50 mg/cm^2. Weights of the deposits were determined on a five-place balance sensitive to 0.005 mg. The deposits were checked for circular symmetry by measuring across several diameters and the mass thickness of the source calculated using the mean of these diameters. All observed counting rates were corrected to correspond to the same area of active surface—a correction $\leqslant 1.5\%$. Sufficient counts were obtained in all cases so that the statistical variation was negligible.

C. RESULTS AND DISCUSSION

External Absorption Curve

Results for the absorption of radiation in aluminum are plotted in Fig. 1. The measured

counting rates are a composite of the detected radiation from Ni^{59} ($\sim 0.02\%$) which decays by K-electron capture with the emission of a Co $K\alpha$ X-ray (4), and of Ni^{63}, which decays by emission of a 70-kev beta particle (4, 9). The low activity component has a half-thickness of 9.0 mg/cm^2. This value is in agreement with that given in X-ray tables for the absorption of Co $K\alpha$ X-rays of 9.4 mg/cm^2 and serves to identify this component as Ni^{59}. The absence of a gamma-ray background indicates that the anion exchange separation completely removed the radioactive impurity, Co^{58}. The absorption curve for the soft component, the Ni^{63} radiation, was obtained in the usual manner by deducting the Ni^{59} background from the total activity, as shown in Fig. 1. The value for the range of Ni^{63} in these experiments is estimated to be 8.5 ± 0.5 mg/cm^2. A 'visual method' of estimating the range from the absorption curve was employed, since a suitable standard is as yet not available in this energy range for a Feather analysis (5). Values of 0.52_3 mg/cm^2 and 1.33 cm^2/mg were found respectively for the half-thickness and absorption coefficient of Ni^{63} beta radiation. (Since the curve is very close to a true exponential, these values can be used over most of the range.)

The value of the range found in this work for Ni^{63} is greater than that given by Wilson and Curran (6) of 6.0 mg/cm^2 and by Brosi *et al.* (4) of 6.6 mg/cm^2. However, as the individual measurements made to determine the external absorption curve can be accurately reproduced, there is no reason to suspect this new value. It is difficult to assess the accuracy of Wilson and Curran's result, as they failed to publish an absorption

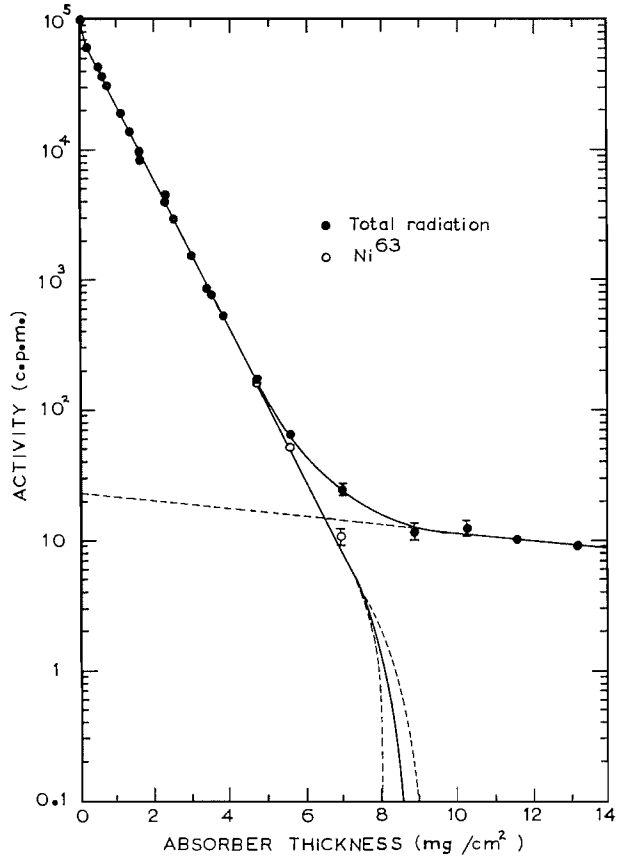

FIG. 1. Absorption curve for Ni^{63} in aluminum.

For personal use only.

curve. Brosi *et al.* determined their range value using a Feather plot. Unfortunately they do not state which nuclide was used as a standard in the range determination. As they followed the absorption of Ni^{63} over only three decades of activity, the use of a standard having an energy spectrum different from Ni^{63} could result in an appreciable error in the estimated range. Furthermore, examination of their absorption curve shows that they did not completely eliminate the scattering phenomenon which occurs when the first absorber is placed over the source. This could also account for their low value for the range.

There are many empirical and semiempirical expressions for relating the maximum energy of a beta-ray spectrum to the observed range of these particles in aluminum. However, only Glendenin's range–energy curve (7) and Libby's range–energy relation (8) are recommended for use below 100 kev. The maximum energy of Ni^{63} beta particles obtained from these relations, using the range value found in this work, are 72.5 ± 2.5 and 72.9 ± 2.5 kev respectively.

This value is slightly higher than a recent value of 67.0 ± 0.5 kev by Preiss, Fink, and Robinson (9) but is considered to be reasonably good agreement, bearing in mind the method used. This presents additional justification for this fairly rapid, seemingly rough method and further verification of the range–energy formulae quoted above.

Self-absorption Curve

The results of the self-absorption measurements are summarized in the data plotted in Fig. 2. For convenience, the apparent specific activity, rather than the actual specific activity, of each source was plotted against the mass thickness of deposit. The apparent specific activity of the active material was arbitrarily taken as unity to simplify the comparison of these results with Gora and Hickey's theoretical expression. The experimental results are nearly identical with those obtained in a 2π geometry by Schweitzer, Stein, and Nehls (10).

In Fig. 3, three separate curves are drawn representing Gora and Hickey's theoretical self-absorption expression corresponding to values of the back-scattering factor, p, of

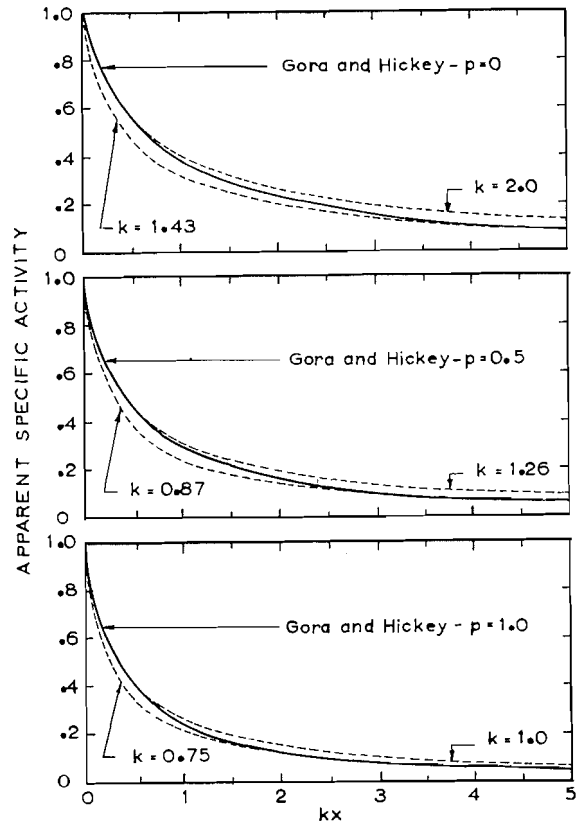

FIG. 3. A comparison of self-absorption of Ni^{63} with the theoretical curves by Gora and Hickey. Experimental data for Ni^{63} taken from Fig. 2 and shown as dotted lines for various values of R.

0.0, 0.5, and 1.0. These correspond to the respective cases where either none, half, or all the emitted particles incident on the source mount are scattered back towards the active volume of the counter. If Gora and Hickey's expression is an adequate description of the processes occurring in a source and mount, then it should be possible to make the experimental results coincide with the theoretical curve by proper selection of the back-scattering factor, p, and the absorption coefficient, k. By selecting various values of k, consistent with various parts of the experimentally determined absorption curve, it was attempted to correlate the self-absorption results shown in Fig. 2 with the theoretical curves in Fig. 3. It is apparent that the experimental results for Ni^{63} self-absorption are not consistent with the theoretical expressions. As can be observed, the correlation is improved when a correction is made for source mount back-scattering, with better correlation for the hypothetical case $p = 1.0$ than for $p = 0.5$. From this it may be concluded that for low energy beta-emitters the effects arising from self-scattering and back-scattering are important enough to invalidate any description of self-absorption in a 2π system which ignores these processes. Similar results have been obtained in conditions where 4π 'geometry' prevails (11).

When a value of the mass absorption coefficient, k, is selected to make the theoretical and experimental curves coincide for large source thicknesses, it is observed that the experimentally determined apparent specific activity decreases more rapidly than that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

predicted theoretically. This suggests that the back-scattering processes in the source degrades the energy of the scattered particle, so that it is more easily absorbed in the overlying layers of atoms in the source. This is in agreement with the experimental work of Pate and Yaffe (11), who also suggest that the effect is more marked for wide-angle geometries. In addition, their results show that the back-scattering factor, p, for an infinitely thick source mount increases with decreasing energy of the beta emitter. This probably accounts for the fact that Gora and Hickey could successfully interpret their results for self-absorption of C^{14} (β^-, 0.154 Mev), while the results for Ni^{63} are inconsistent with their equations.

THE REACTIONS OF ACTIVE NITROGEN WITH ACETYLENE, METHYLACETYLENE, AND DIMETHYLACETYLENE[1]

A. SCHAVO[2] AND C. A. WINKLER

ABSTRACT

Hydrogen cyanide was the main nitrogen-containing product of all three reactions, but whereas only about one-half the available active nitrogen was converted to product in the acetylene reaction, the conversion by methyl- and dimethyl-acetylene was substantially complete. A faster-than-linear increase of HCN production with acetylene flow rate was observed at low flow rates. Similar behavior was just perceptible in the corresponding curve for methylacetylene, while no observable inflection was present with dimethylacetylene. Polymer formation was pronounced with acetylene, less so with methylacetylene, and practically absent with dimethylacetylene. Small amounts of cyanogen resulted from all three reactions, while condensable hydrocarbons were obtained in significant yields from the methyl- and dimethyl-acetylene reactions only at higher flow rates of the alkynes.

In a previous investigation (1) of the reaction of active nitrogen with acetylene, the products were found to be HCN, C_2N_2, CH_4, and H_2, together with a nitrogen-containing polymer. The conversion of active nitrogen to HCN appeared to be only about one-half that observed under optimal conditions in similar reactions with saturated and olefinic hydrocarbons. Since it was of interest to determine whether the relatively low extent of HCN formation from acetylene was characteristic of the acetylene structure, the reactions of active nitrogen with methyl- and dimethyl-acetylene have now been investigated. At the same time, some additional information was obtained about the reaction of acetylene itself.

EXPERIMENTAL

The apparatus, purification of reactants, experimental procedures, and analytical methods were similar in all essential respects to those used in previous investigations (for references, see (2)). Hydrogen cyanide and cyanogen were analyzed by titration methods, other condensable products by low temperature distillation, and non-condensable products with a mass spectrometer. A solution of ammonium hydroxide (2 *M*) was found to be effective for removing polymer from the wall of the reaction vessel, presumably because it attacked the metaphosphoric acid with which the wall was poisoned.

The flow rate of active nitrogen was estimated from the rate of production of hydrogen cyanide from ethylene at 300° C to be approximately 12 micromoles/second (3, 4).

RESULTS AND DISCUSSION

There were some rather interesting differences for the three reactions. Figure 1 shows the yields of HCN, and Fig. 2A those of C_2N_2, at different flow rates of the reactants. The relative rates of HCN production at lower flow rates, particularly from 0 to about 5 micromoles per second, were in the order acetylene < methylacetylene < dimethylacetylene. On the other hand, in the same flow rate range, the rate of production of HCN from acetylene showed a rather pronounced "induction" effect, i.e. it increased

[1]*Manuscript received November 12, 1958.*

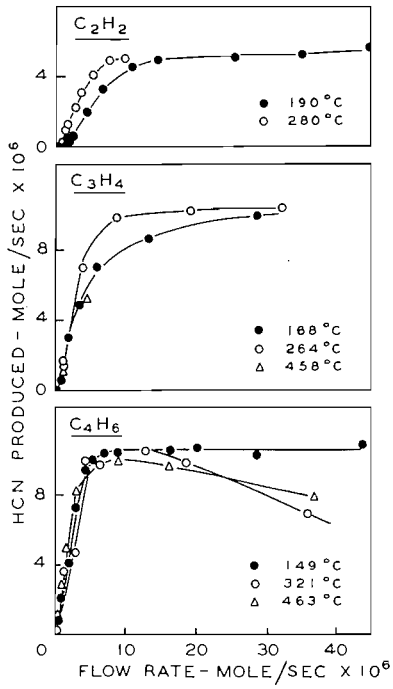

FIG. 1. Dependence of hydrogen cyanide production on the flow rates of the hydrocarbons in the reactions of active nitrogen with acetylene, methylacetylene, and dimethylacetylene.

rather markedly with flow rate, whereas similar behavior was much less evident for methylacetylene and not apparent at all in the results for dimethylacetylene. When the ratio of the rate of HCN production to flow rate of reactant is plotted against flow rate, as in Fig. 2B, the linear increase in this ratio for acetylene and possibly also for methylacetylene at the lower flow rate indicates quadratic dependence of HCN production on flow rate of hydrocarbon in this region. A similar conclusion is not possible for dimethylacetylene, although it is conceivable that it might hold for flow rates below those experimentally accessible in the present study.

Marked differences were observed also in the maximum extents to which active nitrogen could be converted to HCN in the three reactions. With acetylene, this conversion never exceeded about one-half the available active nitrogen,[3] while maximum production of HCN from methyl- and dimethyl-acetylene appeared to correspond roughly to the flow rate of active nitrogen in the system.

The yield of cyanogen was observed previously to pass through a maximum with increased flow rate of acetylene itself (1), but the same did not appear to be true with the other two acetylenes (Fig. 2A). Further, although small but significant yields of hydrogen and methane were obtained from the reaction of acetylene with active nitrogen, mass spectrometric examination showed not more than traces of these products in the non-condensables from the reaction with methylacetylene. In the reaction of dimethylacetylene, small amounts of methane (2×10^{-7} mole/second) were found only at high flow rates.

[3]*Independent experiments with acetylene in this laboratory by Mr. George have confirmed this observation for temperatures up to 400° C.*

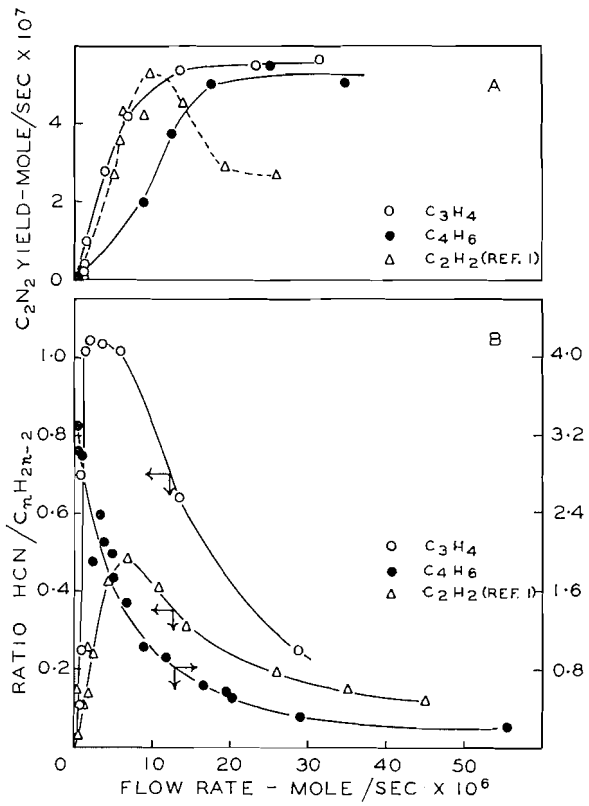

FIG. 2. A. Dependence of cyanogen production on the flow rates of the hydrocarbons in the reactions of active nitrogen with acetylene, methylacetylene, and dimethylacetylene.
B. Relation between ratio HCN/hydrocarbon and the flow rates of the hydrocarbons in the reactions of active nitrogen with acetylene, methylacetylene, and dimethylacetylene.

Other hydrocarbons were not found in more than trace amounts in the condensable products from the methyl- and dimethyl-acetylene reactions at lower flow rates. However, when the flow rates had been increased to about 10 to 20 micromoles/second, the methylacetylene reaction yielded C_2H_2 (1.7×10^{-7} mole/second), C_3H_6 (3×10^{-7} mole/second), and C_4H_8 (8×10^{-6} mole/second), while the dimethylacetylene reaction yielded C_2H_2 (1.8×10^{-7} mole/second), C_2H_6 (8×10^{-8} mole/second), C_3H_6 (2×10^{-6} mole/second), and a C_5 fraction (8×10^{-6} mole/second).

Polymer yields from the acetylene and methylacetylene reactions are shown in Table I. The amount of polymer from the reaction of dimethylacetylene was too small for quantitative estimation. Analyses of the polymers[4] showed their composition to be somewhat similar from the two reactions, with roughly 65% carbon, 27% nitrogen, and 7% hydrogen. However, the composition of the polymer probably has limited significance, since it seems likely that it would be subject to considerable variability as a result of attack by free radicals, active nitrogen, hydrogen atoms, and the parent hydrocarbon. They were all insoluble in the common solvents and were attacked only slowly by a mixture (equal volumes) of concentrated nitric and sulphuric acids.

[4]*We are indebted for these analyses to Dr. Léo Marion, Director, Division of Pure Chemistry, National Research Council, Ottawa.*

TABLE I

Yields of polymer from the reactions of acetylene and methylacetylene with active nitrogen

Acetylene		Methylacetylene	
Flow rate (mole/sec×10⁶)	Polymer yield (g/sec×10⁶)	Flow rate (mole/sec×10⁶)	Polymer yield (g/sec×10⁶)
7.6	128	1.4	22
11.0	98	6.7	65
		16.1	50

In the previous paper (1) it was suggested that HCN was produced in the acetylene – atomic nitrogen reaction by

$$C_2H_2 + N \rightarrow C_2H_2N \rightarrow HCN + CH. \quad [1]$$

However, this reaction would be endothermic and correspondingly doubtful if, as now seems likely (2), the heat of sublimation of graphite must be taken to be at least 170 kcal/mole. An alternative, which suffers no similar difficulty, would be to assume a relatively long-lived complex such that HCN might be formed by further reactions of the type

$$C_2H_2N + N \rightarrow 2HCN \quad [2]$$

$$\rightarrow 2CN + H_2 \quad [3]$$

$$2C_2H_2N \rightarrow HCN + CH \equiv C - CN + H_2 \quad [4][5]$$

$$\rightarrow HCN + H + CN + C_2H_2. \quad [5]$$

Such bimolecular processes would explain the observed greater-than-linear dependence of HCN yield on C_2H_2 flow rate at low flow rates of acetylene.

Reaction [4] is an interesting possibility, since it seems reasonable that the unsaturated nitrile should polymerize rapidly, hence account not only for formation of polymer with about the composition observed, but perhaps also for the reaction of not more than about one-half the available active nitrogen to form HCN.

The higher conversions of active nitrogen to HCN by methyl- and dimethyl-acetylene may be explained if the corresponding complexes were comparatively unstable and predominantly suffered decomposition similar to reaction [1], i.e. reactions such as:

methylacetylene:

$$C_3H_4 + N \rightarrow C_3H_4N \rightarrow HCN + C_2H_3 \quad [6]$$

$$\rightarrow HCN + C_2H_2 + H \quad [7]$$

$$\rightarrow CN + C_2H_2 + H_2, \quad [8]$$

dimethylacetylene:

$$C_4H_6 + N \rightarrow C_4H_6N \rightarrow HCN + C_3H_5 \quad [9]$$

$$\rightarrow HCN + C_3H_4 + H \quad [10]$$

$$\rightarrow HCN + C_2H_2 + CH_3 \quad [11]$$

$$\rightarrow CN + C_3H_6. \quad [12]$$

[5] *A product of mass 51, thought to be cyanoacetylene, has been observed in a mass spectrometric study of the reaction between active nitrogen and acetylene. (Private communication from Dr. J. L. Franklin, Humble Oil and Refining Company, while working at the National Bureau of Standards, Washington.)*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.233.112.2 on 09/04/12
For personal use only.

It is possible that polymer is formed in the methylacetylene reaction mainly by polymerization of $CH_3C \equiv C-CN$, which may be produced in a reaction similar to reaction [4]. The absence of polymer in the dimethylacetylene reaction may be ascribed to greater instability of the dimethylacetylene – nitrogen atom complex, which would not favor such a reaction.

Any radicals resulting from the foregoing reactions (e.g. C_2H_3, C_3H_5) would be expected to react rapidly with active nitrogen.

$$C_2H_3 + N \rightarrow HCN + CH_2 \quad [13]$$

$$\rightarrow CN + CH_3, \text{ etc.} \quad [14]$$

$$C_3H_5 + N \rightarrow HCN + C_2H_3 + H, \text{ etc.} \quad [15]$$

The amount of HCN formed from acetylene – nitrogen atom complexes by reactions such as [2], [4], and [5] would almost certainly be limited by interaction of the complexes or their reaction with nitrogen atoms to regenerate molecular nitrogen and the parent hydrocarbon or CH radicals. Reaction of the complex with acetylene to form polymer would also decrease the extent to which HCN may be produced. An upper limit of about one-half the active nitrogen converted to HCN is therefore not surprising, even if reaction [4] does not occur.

The absence of methane in the products from methyl- and dimethyl-acetylene is readily explained if the single carbon free radicals produced in these reactions, e.g. CH_3 and CH_2, are rapidly consumed by active nitrogen. The production of methane during the acetylene reaction suggests, therefore, that the single carbon free radical from this reaction, presumably the CH radical, is not rapidly attacked by active nitrogen. This might mean that the reaction

$$CH + N \rightarrow HCN$$

requires a three-body collision, while the corresponding reaction to form CN + H is not favored.

Cyanogen production in all three reactions is probably by recombination of CN radicals. Since the cyanogen yield from acetylene passes through a maximum, while that from the other two reactions increases steadily with flow rate of hydrocarbon, the CN radicals are probably produced directly by decomposition of the methyl- and dimethyl-acetylene complexes (e.g. reactions [8] and [12]), but indirectly from acetylene complexes by further nitrogen atom attack or interaction of complexes as in reactions [3] or [5].

The presence, in the products, of small amounts of hydrocarbons, such as C_2H_6 and C_3H_6, and the larger amounts of C_4H_8 and C_5 fraction at higher flow rates of methyl- and dimethyl-acetylene, indicate that H atom and free radical reactions occurred under these conditions. However, there would seem to be little point in attempting to detail these, since they probably bear little relation to the nitrogen reactions which are of principal concern.

It might be noted that the production of as much as 3.3 moles HCN per mole dimethyl-acetylene requires hydrogen rearrangement in the complex. Similar behavior has been indicated by the results for some other reactions of active nitrogen with hydrocarbons (2).

SOME YIELDS IN THERMAL NEUTRON FISSION OF U^{233} AND Pu^{239} [1]

ROSALIE M. BARTHOLOMEW, J. S. MARTIN,[2] AND A. P. BAERG

ABSTRACT

Relative yields of Sr^{89}, Sr^{91}, Ba^{139}, Ba^{140}, and La^{141} have been measured for U^{233} and Pu^{239} thermal neutron fission. Ion exchange separations and 4π beta-counting methods were used. The following relative values were obtained for the nuclides as listed: 1.05, 1.00, 1.00, 1, and 1.10 in U^{233} fission and 0.301, 0.431, 1.07, 1, and 1.01 in Pu^{239} fission.

INTRODUCTION

Although the mass distribution of the products of U^{235} fission has been well studied and yields accurately determined for most masses, relatively few accurate measurements have been made for the fission of the nuclides U^{233} and Pu^{239}. Radiochemical studies of the fission of U^{233} have been reported by Grummitt and Wilkinson (9) in 1948 and by Steinberg *et al.* (16) in the same year. Papers reporting earlier radiochemical studies of Pu^{239} fission have been summarized by Steinberg and Freedman (13). All of the radiochemical data, with revised values for U^{233} fission yields, together with some more recent relative mass spectrometric measurements have been summarized by Steinberg and Glendenin in 1955 (14).

Mass spectrometric relative yield measurements in U^{233} fission have been reported for the isotopes of xenon, cesium, and krypton (6) and the isotopes of zirconium, molybdenum, and ruthenium (15). Similar relative values for Pu^{239} fission have been obtained for the isotopes of xenon by Fleming and Thode (5) and for the isotopes of cerium, neodymium, and cesium by Krizhansky *et al.* (11).

Absolute mass spectrometric yields for some nuclides have been obtained by the isotope dilution technique. In Pu^{239} fission preliminary values have been reported for cesium, cerium, neodymium, and samarium isotopes by Wiles *et al.* (17). Absolute values for the isotopes of neodymium and cerium are reported for U^{233} fission by Kukavadze *et al.* (12).

All of the data, both radiochemical and mass spectrometric, reported to 1958 have recently been evaluated and summarized by Katcoff (10). The radiochemical data were obtained using end-window Geiger counters and the values have an accuracy of 10–20% (14). The mass spectrometric yields have a relative accuracy, in most cases, of 1–2% and absolute values are usually accurate to 3–5% (14).

During the 1958 International Conference on the Peaceful Uses of Atomic Energy, further data have become available. These include radiochemical measurements of the heavy rare earths in Pu^{239} fission (4), absolute mass spectrometric yields for Cs^{133}, Xe^{135}, Nd^{143}, Sm^{149}, and Sm^{151} for both U^{233} and Pu^{239} fission (3), and for the isotopes of Xe and Kr in Pu^{239} fission (7). Anikina *et al.* (1) have reported absolute yields for isotopes of Sr, Cs, Ba, Ce, Nd, and Sm for U^{233} and Pu^{239} fission. They have also obtained yields of La^{139} and Eu^{153} for U^{233} fission and of Pr^{141} for fission of U^{233} and Pu^{239} using mass spectrometric methods requiring the comparison of integrated ion currents.

We have recently used improved radiochemical methods (2) to measure relative yields of Sr^{89}, Sr^{91}, Ba^{139}, Ba^{140}, and La^{141} in U^{235} fission with a reliability believed comparable

with that achieved by mass spectrometric techniques. Except for the mass 91 chain the cumulative yields of these masses can better be obtained by radiochemical determination of the nuclides listed and the purpose of this work was to extend the measurements already made for U^{235} fission to fission of U^{233} and Pu^{239}.

EXPERIMENTAL

Except for several minor modifications, the procedure used for the relative yield measurements here was the same as that reported earlier (2). In the work with U^{235} relatively large samples (10 to 50 mg) of natural uranium were irradiated as the oxides in the Chalk River NRX reactor. In the present experiments with U^{233} and Pu^{239}, however, samples of about 100 μg only were sealed in quartz for the irradiations. Under these conditions it was found that up to 50% of the fission fragments were embedded in the quartz and not recovered in the subsequent dissolution. As a consequence of partial segregation of the products arising from differences in fragment ranges, very significant errors in the relative yield values were observed, even for adjacent masses. To avoid these errors from the loss of fission fragments, the fissile material was deposited as the nitrate solution on a pure iron oxide matrix (50 mg) to serve as a fragment catcher in the quartz tube. The samples were dried and heated to the oxide before sealing.

Following irradiation, the samples were crushed and dissolved in aqua regia containing small quantities (about 50 μg each) of suitable carriers, then dried, and taken up in 9 N hydrochloric acid. This solution was passed through an anion column to remove the Pu^{239} or U^{233} and iron together with various anionic fission products. The cations in the effluent, predominantly the alkali metals, alkaline earths and rare earths, were subsequently adsorbed on a cation column and the various species separated by elution with ammonium α-hydroxyisobutyrate. Details of the separation procedures and 4π beta-counting methods have been given in ref. 2. All yield calculations were based on half-lives as quoted in the same reference.

In the absolute beta counting of Sr^{89} and Y^{91} small corrections (usually less than 1%) were made for the presence of 27.7-year Sr^{90} and its 64.8-hour Y^{90} daughter. To make these corrections it was assumed that the ratio of yields Sr^{90}/Sr^{89} is 1 for U^{233} fission and 1.5 for Pu^{239} fission, while the Sr^{91}/Sr^{90} yield ratio was assumed to be 1 for U^{233} and 0.9 for Pu^{239} fission.

RESULTS AND DISCUSSION

The relative yield values obtained are listed in Table I, each set of experiments being divided into two groups: one for the Ba^{139}/Ba^{140} ratios and the other for the ratios of Sr^{89}, Sr^{91}, and La^{141} to Ba^{140}. In Table II the values of Table I have been combined and converted to absolute values on the basis of selected yields for mass 140 as given by Katcoff (10). The errors quoted reflect only the precision of the values given in Table I. Included for comparison in Table II are the relevant yields quoted in refs. 10 and 14.

U^{233}

In U^{233} fission the value of 5.60% for the yield of Ba^{140} corresponds to that of Ce^{140} determined mass spectrometrically by Kukavadze *et al.* (12). We make the reasonable assumption that the yields of Ce^{140} and Ba^{140} are equivalent. With this assumption our results for Sr^{89} and Sr^{91} are somewhat lower than those reported for these masses in ref. 14. The Zr^{91} yield of ref. 14 is based on relative mass spectrometric data fitted together with the aid of earlier radiochemical yields for Sr^{89}, Zr^{95}, Mo^{99}, and Ru^{103} to give a yield curve for the light mass group (15). The discrepancies with the present

	6	1		0.99_3	0.30_6	0.43_3
	7	1		1.02_3	0.31_0	0.43_8
	8	1		1.03_2	0.29_7	0.43_8

TABLE II

Yields normalized to selected values for Ba^{140}

	Ba^{140}	Ba^{139}	La^{141}	Sr^{89}	Sr^{91}
U^{233}	5.60	5.59	6.17	5.87	5.61
Standard deviation		0.02	0.05	0.12	0.06
Data of ref. 14*	5.6 Ce^{140}			6.1	6.09 Zr^{91}
Pu^{239}	5.68	6.07	5.75	1.71	2.45
Standard deviation		0.04	0.09	0.04	0.05
Data of ref. 10	5.68	5.7	5.2 Ce^{141}	1.9	2.4 Y^{91} 3.0%

*The original data, based on 6.0% for Ba^{140} (16), are renormalized to 5.6% for this nuclide.

results are, however, probably within the associated errors.

Anikina *et al.* (1) have reported values of 5.91 and 5.57% respectively for La^{139} and Pr^{141}. These values are based on mass spectrometer integrated ion currents and are to be compared with 5.59 and 6.17% respectively for Ba^{139} and La^{141} relative to 5.6% for Ba^{140}. The differences are greater than the quoted errors allow and no explanation for the discrepancies is obvious.

Pu^{239}

In Pu^{239} fission the yield of Ba^{140} given by Steinberg and Glendenin (14) was 5.36%. This value was increased to 5.68% by Katcoff (10) to make the total yields 100% each for the light and heavy groups. The preliminary mass spectrometric values of Wiles *et al.* (17) indicate a yield of 7.36% for Ce^{140}. On the other hand, Krizhansky *et al.* (11) have made relative measurements of the cerium isotopes which agree well with those of Wiles *et al.* except at mass 140. Accepting the absolute values of Wiles *et al.* for masses other than Ce^{140} and combining these with the relative values of Krizhansky *et al.*, the Ce^{140} absolute yield becomes 5.63%, which agrees well with that selected by Katcoff for Ba^{140}.

The yields of Ba^{139}, Ce^{141}, Sr^{89}, and Sr^{91} quoted in ref. 10 are from the data of Steinberg *et al.* (13, 14) normalized to a value of 5.68% for Ba^{140}. Comparison of these yields with those obtained here shows agreement within the experimental errors. The integral mass spectrographic value of 6.02% for Pr^{141} given by Anikina *et al.* (1) is greater than the value (5.75%) we obtained for La^{141}. The difference is larger than the quoted errors

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.233.112.2 on 09/04/12
For personal use only.

and also larger than could reasonably be attributed to independent formation of Ce^{141}. The value for Sr^{91} found here is in good agreement with that of ref. 10. There is, however, a large difference between it and the values for Y^{91} (10, 14) implying a high independent yield for the latter. The difference seems excessive but may possibly arise from a short-lived isomeric state in Sr^{91} which feeds Y^{91}. Evidence for such chain branching has already been given by Grummitt and Milton (8) for U^{235} fission.

PROTONATION OF THE CARBONYL GROUP

II. THE BASICITIES OF SUBSTITUTED BENZALDEHYDES[1]

K. YATES[2] AND ROSS STEWART

ABSTRACT

The basicities of seven meta- and para-substituted benzaldehydes have been determined by a spectrophotometric method in sulphuric acid media. The simple Hammett relation does not hold for these bases but a good correlation exists between pK_{BH^+} and σ^+. The effects of substitution on the wavelengths of maximal ultraviolet absorption in benzaldehyde are compared with those in acetophenone.

The basicity of *o*-tolualdehyde was determined in an attempt to estimate the steric effects of ortho substitution. The effects of symmetrical trisubstitution on the basicity of benzaldehyde and acetophenone are compared and discussed.

INTRODUCTION

In connection with studies of the protonation of ketones reported previously (1) and of carboxylic acids to be reported soon, we have determined the effects of ring substitution on the basicity of benzaldehydes. In determining the strengths of these very weak bases we have again followed the approach used by Hammett in his classical investigations (2) utilizing the concept of the H_0 acidity function. This has the advantage of yielding basicity values which are absolute in so far as they are based on dilute aqueous solution as the standard state. Pratt and Matsuda (3) determined relative basicities of some oxygen-containing organic bases in benzene solution by their effect on acid catalyzed reactions. Gordy and Stanford (4) have also determined relative basicities of similar compounds by a spectroscopic method. Wepster (5) has used a number of physical and chemical properties to determine base strengths of substituted nitrobenzenes.

EXPERIMENTAL

Commercially available benzaldehydes were purified either by vacuum distillation under a small positive pressure of nitrogen or by several recrystallizations. *o*-Tolualdehyde was prepared from *o*-bromotoluene by the method of Smith and Nichols (6). (B.p. 89°/22 mm, $n_D^{24} = 1.5410$. Lit. b.p. 72°/6 mm, and $n_D^{25} = 1.5430$ (7).) Stock solutions of these compounds in the range 10^{-2}–10^{-3} molar were titrated against standard alkali immediately after use and found to be free of the corresponding benzoic acids.

Sulphuric acids of various concentrations were prepared by dilution of Fisher C.P. reagent grade sulphuric acid (95.0% min.). Further solutions up to 99.9% were prepared by mixing the above with 30% fuming sulphuric acid (Baker & Adamson Reagent). Determination of the H_0 values of these acids and the preparation of suitably absorbing solutions of the aldehydes in them is described in Part I of this series.

The extinction coefficients of these solutions at various concentrations of sulphuric acid were determined at two wavelengths with quartz cells of 1 cm path length using a Beckman Model DU Spectrophotometer, whose cell compartment was maintained at 25±0.1° by means of thermospacers. The sulphuric acids were tested for optical clarity in the regions used and a solvent blank of the same concentration as that containing the aldehyde was used. Ultraviolet absorption spectra of the aldehydes in 44.0% and

[1]*Manuscript received November 12, 1958.*

[2]*Holder of N.R.C. studentships, 1957–59.*

95.5% acids measured with a Cary Model 14 Recording Spectrophotometer were used to locate the wavelengths of maximal absorption of the unprotonated (λ_u) and protonated (λ_i) forms. These are listed in Table I.

TABLE I

Absorption spectra of substituted benzaldehydes

	In 44.0% H_2SO_4			In 95.5% H_2SO_4		
Substituent	λ_{max} (mμ)	log ϵ_{max}	$\Delta\lambda_u$ (mμ)	λ_{max} (mμ)	log ϵ_{max}	$\Delta\lambda_i$ (mμ)
m-Chloro	250	3.89	−1	297	4.16	1
p-Chloro	263	4.18	12	316	4.37	20
p-Nitro	270	4.13	19	282	4.25	−14
p-Methoxy	290	3.87	39	344	4.23	48
Hydrogen	251	4.08	0	296	4.36	0
o-Methyl	260	4.26	9	302	4.48	6
m-Methyl	258	4.03	7	301	4.27	5
p-Methyl	264	4.14	13	313	4.43	17

The pK_{BH^+} values were determined by the method of Davis and Geissman (8) as follows: The extinction coefficients $\epsilon(\lambda_u)$ and $\epsilon(\lambda_i)$ of the two species were measured in at least 12 different concentrations of acid. The function $[\epsilon(\lambda_i)-\epsilon(\lambda_u)]$ which is linearly related to the fraction ionized was plotted against H_0. At the inflection point of this curve it can be shown that the fraction ionized equals the fraction un-ionized, hence $\log (c_{BH^+}/c_B) = 0$ and $H_0 = pK_{BH^+}$. In all cases a sigmoid titration type curve was obtained and the inflection point taken as the mid-point of the "straight" portion. The results of a typical determination are shown in Fig. 1. The advantages and limitations of the method are discussed by the above authors. In cases where λ_i is very close to λ_u or where $\epsilon(\lambda_i) \gg \epsilon(\lambda_u)$ we have found that smooth curves cannot be obtained. The method fails for *m*-nitrobenzaldehyde and the second decimal in the pK_{BH^+} value of the *p*-nitro isomer is of doubtful significance.

Because of the possibility of chemical change other than protonation occurring in the strongly acid solutions the absorption spectra of the aldehydes in 95.5% acid were repeated after 1 hour's standing. They were found to undergo no appreciable change and on subsequent dilution the spectra reproduced closely those of control solutions in dilute acid. The possibility of sulphonation in very high concentrations is not serious, since this region is not in a critical part of the curve. However, to minimize any such effects all measurements used in determining pK_{BH^+} were taken as rapidly as possible after the addition of the acids.

RESULTS AND DISCUSSION

Effects of Meta and Para Substitution on Basicity

The values of pK_{BH^+} for the substituted benzaldehydes are listed in Table I and are plotted as a function of σ (9), the Hammett substituent constant in Fig. 2. It can be seen that the correlation is rather poor even if only meta and para substituents are considered (open circles). The 2,4,6-substituted compounds (closed circles) will be discussed in a later section. The four points through which the dotted line is drawn represent those substituents which are not able to supply electrons to the positively charged conjugate acid by direct resonance with the group and hence are expected to obey the Hammett equation (10),

$$\log (K/K_H) = \rho\sigma.$$

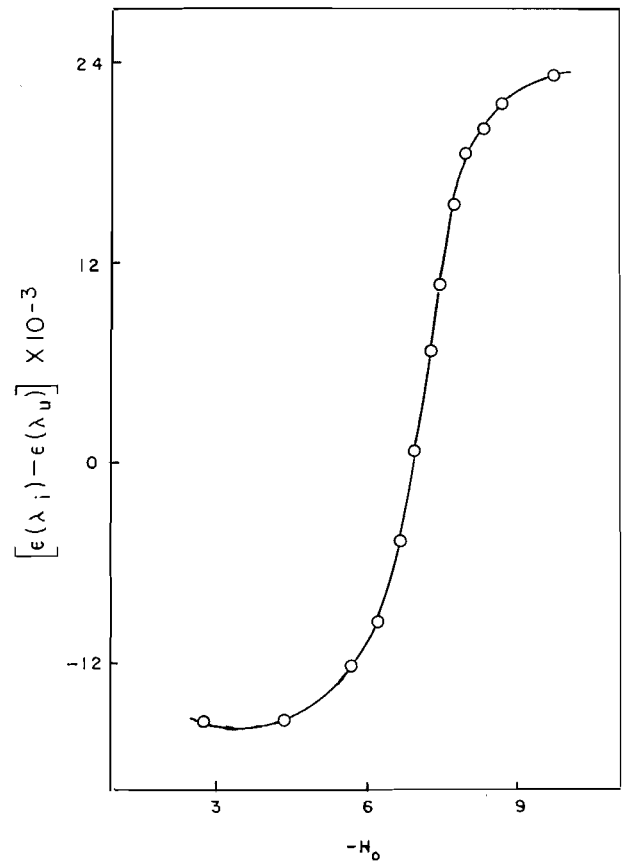

FIG. 1. The function $[\epsilon(\lambda_i)-\epsilon(\lambda_u)]\times10^{-3}$ plotted against $-H_0$ for *p*-chlorobenzaldehyde.

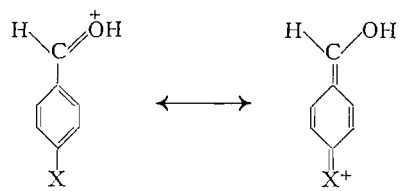
The other three points represent para substituents which are able to do this owing to contributions from structures like II.



I II

The latter substituents thus give higher basicities than their σ values predict owing to increased stabilization of the conjugate acid.

Several investigators (11) have noted that substituents such as *p*-methoxy are able to stabilize carbonium ions to a much greater extent than is indicated by their σ values, and σ^+ values have been derived (12) for groups which are able to supply electrons for use in reactions where a positive charge is developed in conjugation with the group. Figure 3 shows a plot of pK_{BH^+} of the same seven compounds against σ^+. A good linear correlation ($r = 0.994$) now exists for both meta and para points.
