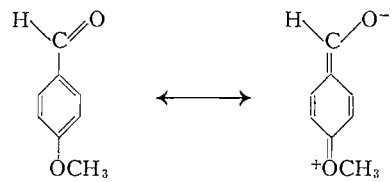
As might be expected these results are very similar to those obtained with substituted acetophenones (1) in which similar resonance effects are possible. However, two points of difference arise. In the case of the ketones the basicity of the *p*-methoxy group was found to be lower than that predicted by the σ^+ value. Similar deviations for alkoxy groups have been noted by other workers (13). The above deviation was explained on the basis that solvent–solute hydrogen-bonding for such groups should be particularly strong in sulphuric acid with a consequent increase in σ^+, thus lowering the basicity. The point for the analogous *p*-methoxybenzaldehyde, however, falls on a good straight line through all the other points. This is surprising, since the solvent effects discussed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

previously (1) should be at least as strong for benzaldehydes. The possibility of protonation occurring at the methoxy rather than the formyl group was considered but rejected for two reasons:

1. The spectral changes of *p*-methoxybenzaldehyde in sulphuric acid parallel those of other benzaldehydes and acetophenones, i.e. a pronounced red shift on protonation. If protonation occurred preferentially at the methoxy group the change would be expected to be in the opposite direction as in the case of anilines which undergo a blue shift on protonation (14).

2. The evidence of other workers (3, 4) indicates that alkyl aryl ethers are considerably less basic than aromatic aldehydes and ketones. This difference should be even more pronounced where there is an electron-withdrawing formyl group para to the alkoxyl group as shown below:



III IV

The second point of difference between the two series is the magnitude of the reaction constant. The ρ value obtained from the meta and para points in Fig. 3 is 1.85 (least squares calculations used throughout), whereas the value for acetophenones is 2.17 (neglecting the point for *p*-methoxy). The larger ρ for the acetophenone series compared to the benzaldehyde series suggests that the charge is more localized on the ketone carbon atom of the former than on the aldehyde carbon of the latter (15). A similar effect occurs in the solvolysis of α-phenylethyl chloride compared to the benzyl compound (16).[3] The greater localization of charge in the cases of the ketone conjugate acid and the α-phenylethyl carbonium ion can be rationalized in terms of steric hindrance of the methyl group to solvation in the cations.

Effects of Substitution on the Ultraviolet Spectra

Forbes *et al.* (17) have shown in a recent series of papers that para substitution of benzaldehydes produces displacements of the wavelength of maximum absorption (π–π^* transitions) relative to that of the parent compound. These displacements are directly related to those produced by similar substitution in nitrobenzenes and acetophenones and it was suggested that this proportionality is primarily due to the similarity of resonance effects on the transition energies in all three types of compounds. In Figs. 4*a* and 4*b* the wavelength displacements produced by the introduction of substituents in benzaldehyde ($\Delta\lambda_u$) and its conjugate acid ($\Delta\lambda_l$) are taken from Table I and plotted against the corresponding values for acetophenones. Since most of Forbes' measurements were taken in neutral solvents, it is interesting to see that a good correlation ($r = 0.981$) still exists for the unprotonated forms (Fig. 4*a*). Despite the large change in medium the slope of the line (0.88) is close to that observed by Forbes, although the wavelength shifts appear to be more pronounced in 44.0% sulphuric acid. This indicates that, although medium effects on the spectra are rather large, they are similar for both types of carbonyl compound.

An equally good correlation ($r = 0.984$) is found for the conjugate acids (Fig. 4*b*,

[3]*We are grateful to the referee for drawing this to our attention.*

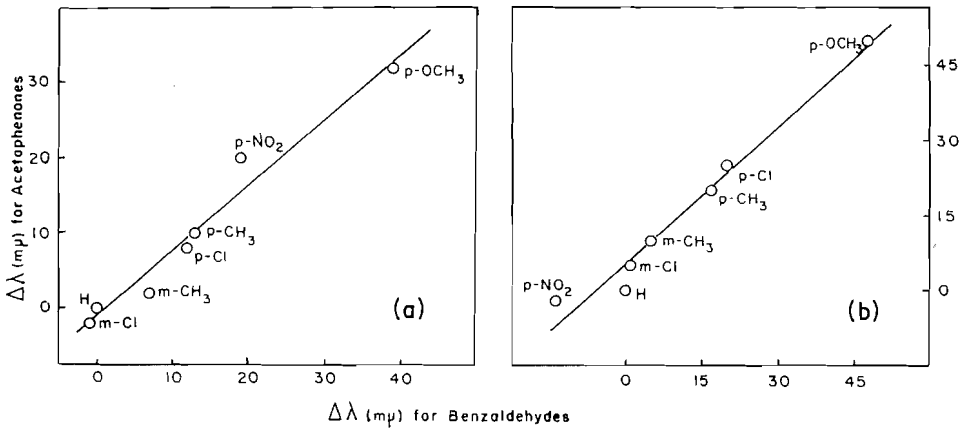

FIG. 4. Wavelength displacements of the principal ultraviolet band obtained on introducing substituents (*a*) into acetophenone and benzaldehyde and (*b*) in the conjugate acids of acetophenone and benzaldehyde.

slope = 0.90) and the displacements are now in the approximate order of the ability of the groups to donate electrons by resonance. The fact that the slopes of the lines in Figs. 4*a* and 4*b* are approximately unity indicates that resonance is of comparable importance in the acetophenone and benzaldehyde series being possibly slightly more important in the latter case. A further indication of this is the fact that those groups which can donate electrons by resonance (*p*-methoxy, *p*-methyl, *p*-chloro) produce *a slightly larger* increase in basicity when substituted in benzaldehyde than when substituted in acetophenone. This is despite the greater over-all ρ for the acetophenones.

Steric Effects of Alkyl Groups

It is interesting to compare the effect of methyl substitution in different positions on the basicities of benzaldehydes as shown in Table II and Figs. 2 and 3. It is apparent that ortho methyl substitution produces an increase in basicity roughly comparable to para substitution. Symmetrical trimethyl substitution as in 2,4,6-trimethylbenzaldehyde results in a greatly enhanced basicity as shown in Fig. 3, where we have assumed the sigma value for 2,4,6-trialkyl substitution to be $\Sigma\sigma^+$ para (21). The extent of deviation of the three alkyl groups ($CH_3 > C_2H_5 > i\text{-}C_3H_7$) is in the order of decreasing size possibly reflecting decreasing extents of steric hindrance to solvation of the cations. If the latter effect was unimportant the three points would all presumably deviate even farther from the straight line.

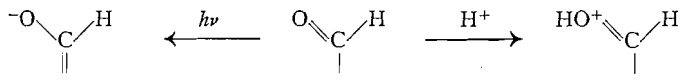
Braude and Sondheimer (18) among others (19) have used changes in electronic spectra and dipole moments to estimate the steric effects of two ortho methyl groups on the coplanarity of the carbonyl group and the benzene ring for both benzaldehydes and acetophenones. Their results as shown in Table III indicated a mean rotation of about 15–20° for 2,4,6-trimethylbenzaldehyde. (The amount of π orbital overlap is reduced by an amount which varies as $\cos^2 \theta$ (20).) The process studied by Braude and Sondheimer in evaluating the extent of steric interference was the absorption of a photon to give the excited state crudely represented by VI. The oxygen atom as a result of bearing an increased negative charge should be larger than the oxygen atom in V.



VI V VII

The protonation reaction on the other hand results in a positively charged oxygen atom as in VII which should be smaller than the oxygen in V, smaller at least in the direction at right angles to the O—H bond axis. The greater degree of coplanarity thus allowed the conjugate acid compared to the neutral aldehyde and the consequent increased resonance with the ring may explain the enhanced basicity of 2,4,6-trimethylbenzaldehyde.

TABLE III

Steric effects of 2,4,6-trimethyl substitution in benzaldehyde and acetophenone (18)

Compound	θ_ϵ*	θ_μ†	μ_{obs} (D)	μ_{calc} (D)	pK_{BH^+}

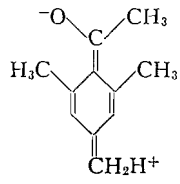
2,4,6-Trimethylacetophenone	63°	62°	2.81	3.03	−7.9	(22)

*Mean interplanar angle calculated from ratio of observed ϵ of K band to that expected in a uniplanar system (Braude and Sondheimer (18)).

†Mean interplanar angle calculated from observed dipole moment data (18).

It is interesting to compare the effects of similar substitution on the basicity of acetophenone. Table III shows that the observed dipole moment of 2,4,6-trimethylacetophenone is much lower than the calculated value and approaches the value for saturated ketones (μ = 2.75 D for acetone (18)) unlike mesitaldehyde whose observed dipole moment is close to the calculated value. This indicates that the contribution of dipolar resonance structures such as VIII is greatly reduced by steric inhibition. This is due to the bulky acetyl methyl which overlaps the ortho groups much more than does the



VIII

carbonyl oxygen. In support of this the mean interplanar angle θ calculated from ultra-

For personal use only.

violet spectra is 63°. This should result in drastic reduction of π-orbital overlap involving the carbonyl group and the ring. In agreement with this the basicity of 2,4,6-trimethylacetophenone (22) is found to be 1.75 log units less than the parent compound, whereas the inductive effects alone of three methyl groups would normally be expected to increase the basicity. The shrinking of the carbonyl group as a result of protonation, which we discussed above as an explanation for the enhanced basicity of 2,4,6-trimethylbenzaldehyde, is not an important factor in the case of the ketones. Here it is the ketone methyl which is largely responsible for the steric repulsions rather than the carbonyl group as for the aldehydes.

THE REACTION OF METHYL RADICALS WITH FORMALDEHYDE[1]

S. TOBY[2] AND K. O. KUTSCHKE

ABSTRACT

Azomethane was photolyzed in the presence of up to 30 mole per cent formaldehyde and formaldehyde-d_2 at temperatures from 80° C to 180° C. The value of the activation energy for the abstraction reaction with methyl radicals was found to be 6.2 kcal mole^{-1} for CH_2O and 7.9 kcal mole^{-1} for CD_2O. The results indicated that the formyl radical was stable over the temperature range studied.

INTRODUCTION

This work was undertaken to provide data on a reaction which is of considerable interest in mechanisms of oxidation. Kodama and Takezaki (1) have reacted methyl radicals, produced by the thermal decomposition of azomethane at 310° C, with formaldehyde. They cite a value of 5.63 kcal per mole for the activation energy of the abstraction reaction; however, very little experimental data was given. It seemed desirable to investigate this reaction more fully.

EXPERIMENTAL

The methyl radicals were produced by photolysis of azomethane (2) using standard photochemical procedures. The optical system consisted of a Hanovia S-500 medium pressure mercury arc, two quartz lenses which produced an approximately parallel beam of light, and a Corning 5860 filter used with two filters of clear Pyrex glass. This combination gave radiation at approximately 3660 Å with an intensity of about 10^{14} quanta cm^{-3} sec^{-1} (using azomethane as an actinometer). A photocell was used to measure relative absorption.

The reaction cell was a cylindrical quartz vessel of volume 189 cm^3 connected to a magnetic stirrer, two Wood's alloy cutoffs (3), and a quartz spiral manometer. The whole was situated in an insulated box, the temperature of which could be kept constant within 1° C up to 200° C. Experiments were done at temperatures from 80° C (below which formaldehyde readily polymerizes) to 180° C (above which azomethane decomposes thermally).

The thermostatted section of the apparatus was connected to a conventional gas analysis system. After an experiment the non-condensable products were passed through a solid nitrogen trap into a gas burette via a small mercury diffusion pump backed by a Toepler pump. Carbon monoxide was oxidized over cupric oxide at 260° C and measured as carbon dioxide. The remaining mixture of nitrogen and methane was analyzed mass spectrometrically. Ethane was distilled through a Ward still at −180° C and its purity checked by the mass spectrometer.

Azomethane, supplied by Dr. L. C. Leitch of these laboratories, was distilled *in vacuo*, the center fraction being retained. Mass spectrometric analysis detected no impurity. Formaldehyde monomer was prepared by repeated distillation of α-polyoxymethylene (4), the only impurity being a trace of CO_2. The formaldehyde was stored at liquid nitrogen temperature. Illumination of pure formaldehyde produced less than 0.01% photodecomposition in a time comparable to the normal experiment. There was no detectable dark reaction between formaldehyde and azomethane.

Formaldehyde-d_2, supplied by Dr. L. C. Leitch (5), contained 99.4% atom per cent deuterium. In the case of runs using formaldehyde-d_2, methanes-d_0 and -d_1 were formed. It was confirmed that there was no deuterium exchange when the non-condensables were left in the CuO furnace for an hour.

Up to 5% of the azomethane was decomposed, and up to 2% of the formaldehyde was allowed to react. The azomethane concentration was kept at approximately two millimoles per liter corresponding to pressures of about 50 mm. The light intensity was not intentionally varied, but two arcs which had a difference of 20% in their output were used.

RESULTS AND DISCUSSION

The results of experiments with CH_2O are given in Table I and with CD_2O in Table II. They are consistent with the following reaction scheme:

$$CH_3N_2CH_3 \xrightarrow{h\nu} 2CH_3 + N_2, \quad [0]$$

$$2CH_3 \rightarrow C_2H_6, \quad [1]$$

$$CH_3 + CH_3N_2CH_3 \rightarrow CH_4 + CH_2N_2CH_3, \quad [2]$$

$$CH_3 + CH_2O \rightarrow CH_4 + CHO, \quad [3]$$

$$CH_3 + CHO \rightarrow CH_4 + CO. \quad [4]$$

Some experiments were performed in which azomethane was photolyzed alone. In this case

$$\frac{k_2}{k_1^{\frac{1}{2}}} = \frac{R_{CH_4}}{R^{\frac{1}{2}}_{C_2H_6}[Azo]}.$$

This same rate expression holds when CD_2O was present, since all methane formed in reaction [2] is undeuterated. A plot of log $k_2/k_1^{\frac{1}{2}}$ against the reciprocal of the absolute temperature is shown in Fig. 1. The presence of up to 30 mole % CD_2O is seen to have no effect on the value of log $k_2/k_1^{\frac{1}{2}}$. The slope of the best straight line through the points leads to a value of 8.4 ± 0.3 kcal mole^{-1} for E_2, assuming E_1 is zero. This differs from the value of 7.6 obtained by Jones and Steacie (2) and 7.3 by Ausloos and Steacie (6) but agrees with the value obtained by Wenger (7).

A conventional treatment of the results gives

$$\frac{k_3}{k_1^{\frac{1}{2}}} = \left(\frac{R_{CH_4}-R_{CO}}{R^{\frac{1}{2}}_{C_2H_6}} - \frac{k_2}{k_1^{\frac{1}{2}}}[Azo]\right)\frac{1}{[CH_2O]}.$$

The results obtained were not sufficiently accurate to use this expression, since it involves the difference between two quantities which, in this case, are of similar magnitude. The CH_2O results may be treated by assuming a steady state of formyl radical concentration. In this case

$$\frac{k_3}{k_1^{\frac{1}{2}}} = \frac{R_{CO}}{R^{\frac{1}{2}}_{C_2H_6}[CH_2O]}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

This rate expression is approximately constant at constant temperature with up to 30-fold changes in CH_2O concentration, as shown in Table I. A plot of log $k_3/k_1^{\frac{1}{2}}$ against $1/T$ is given in Fig. 2 and the least mean square line is given by

$$k_3/k_1^{\frac{1}{2}} = 780 \exp[-(6200 \pm 300)/RT] \text{ (mole liter}^{-1})^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}.$$

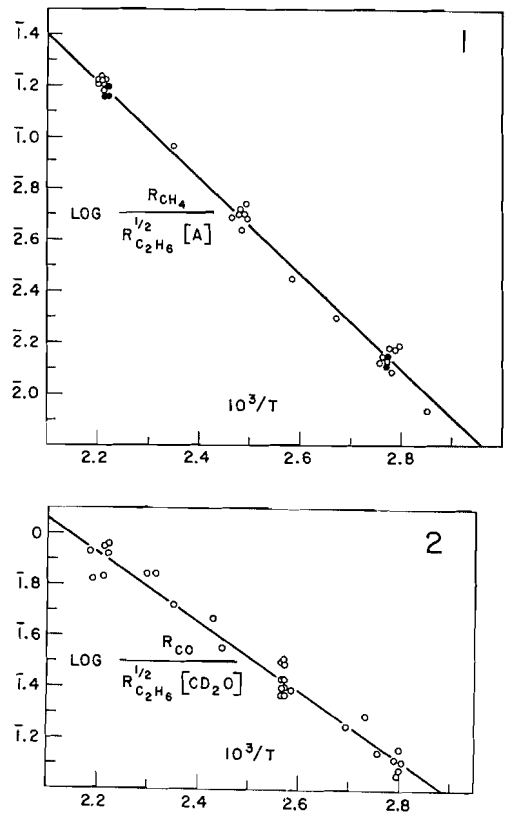

FIG. 1. Arrhenius plot for the reaction $CH_3 + CH_3N_2CH_3$: ● azomethane alone, ○ variable amounts CD_2O present; see text.
FIG. 2. Abstraction of hydrogen from CH_3O by methyl radicals.

The only published result with which this may be compared is the value of 5.63 kcal mole^{-1} for E_3 given by Kodama and Takezaki (1).

In the case of the CD_2O experiments the rate equations give directly

$$\frac{k_3'}{k_1^{\frac{1}{2}}} = \frac{R_{CH_3D} - R_{CO}}{R^{\frac{1}{2}}_{C_2H_6}[CD_2O]}$$

and

$$\frac{k_3'}{k_2} = \frac{R_{CH_3D} - R_{CO}}{R_{CH_4}} \frac{[Azo]}{[CD_2O]}.$$

These expressions are plotted in Fig. 3 and give

$$k_3'/k_1^{\frac{1}{2}} = 960 \exp[-(7900 \pm 300)/RT] \text{ (mole/liter)}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}$$

and

$$k_3'/k_2 = 0.48 \exp(590 \pm 300/RT) \text{ (mole/liter)}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

respectively. From Fig. 1

$$k_2/k_1^{\frac{1}{2}} = 1700 \exp[-(8400\pm300)/RT] \text{ (mole/liter)}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}},$$

hence

$$k_3'/k_1^{\frac{1}{2}} = 810 \exp[-(7800\pm400)/RT] \text{ (mole/liter)}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}},$$

in satisfactory agreement with the former value. The values $E_3 = 6.2$, $E_3' = 7.9$ kcal mole^{-1} may be compared with the corresponding activation energies for the abstraction reaction with acetaldehyde and acetaldehyde-*d* as found by Ausloos and Steacie (8). They obtained $E = 6.8$, $E' = 7.9$ kcal mole^{-1} for the corresponding reactions.

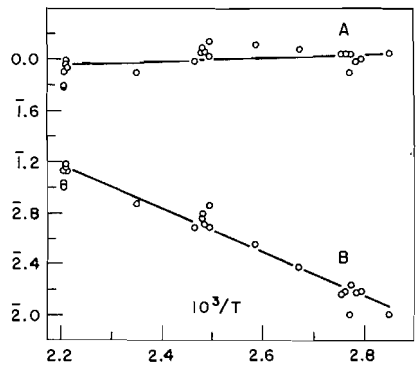

FIG. 3. Abstraction of deuterium from CD_2O by methyl radicals: A: $\log\{(R_{CH_3D}-R_{CO})/R_{CH_4}[CD_2O]\}$ vs. $10^3/T$; B: $\log\{(R_{CH_3D}-R_{CO})/R^{\frac{1}{2}}_{C_2H_6}[CD_2O]\}$ vs. $10^3/T$.

In Fig. 4 the amounts of the products of the CD_2O experiments are plotted as a function of CD_2O concentration. It can be seen that the amount of CH_3D and CO formed increases linearly with CD_2O concentration. There is, however, no corresponding decrease

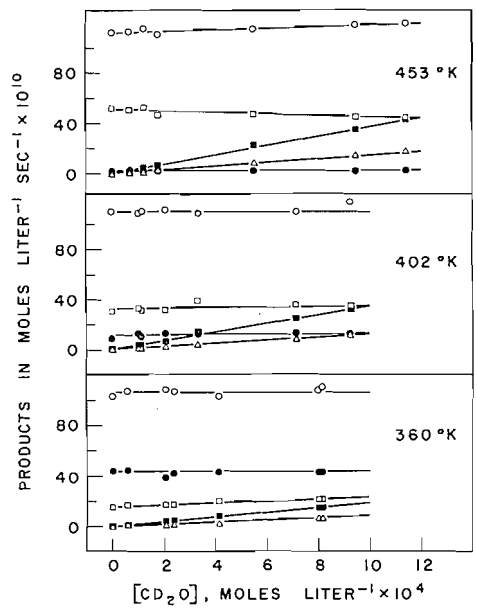

FIG. 4. Products of CD_2O experiments as functions of formaldehyde-d_2 concentration: ○ N_2, ● C_2H_6, □ CH_4, ■ CH_3D, △ CO.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

in the amounts of CH_4 and C_2H_6 formed. Since the amount of azomethane photolyzed shows no appreciable increase with CD_2O (as shown by the N_2 formed), the source of the extra methyl radicals is not apparent. It is possible that fewer addition products of CH_3 + azomethane were formed in the presence of CD_2O but this could not be verified. The corresponding graph for the CH_2O runs is not given, since the light intensity was not constant. However, it may be seen from Table I that the increase in CH_4 and CO production at constant temperature has no corresponding decrease in C_2H_6 production.

Other Fates for the Formyl Radical

The addition reaction corresponding to the disproportionation reaction [4] is

$$CH_3 + CHO \rightarrow CH_3CHO. \qquad [5]$$

No acetaldehyde was found by mass spectrometric analysis of the products, however. If any acetaldehyde were formed it seemed likely that it would copolymerize with the excess CH_2O. The residues from several runs were therefore collected and tested with Leys reagent, which will detect 0.1% acetaldehyde in CH_2O solution (9). The tests were negative and from this it can be inferred that reaction [4] occurs at least four times as fast as reaction [5] under the conditions studied.

For the CD_2O experiments $k_5'/k_4' = R_{CH_3D}/R_{CO} - 2$. The value of R_{CH_3D}/R_{CO} is reasonably constant with CD_2O concentration and with temperature as shown in Table II. The results give $k_5'/k_4' \simeq 0.4$. These findings agree with those of Lossing (10), who found that reaction [4] was much faster than reaction [5] at 55° C.

No hydrogen was found in the products. This does not rule out the occurrence of

$$CHO \rightarrow CO + H \qquad [6]$$

because any H formed would probably undergo addition rather than abstraction reactions with azomethane, since CH_3 adds to azomethane approximately five times as fast as it abstracts from it in the temperature range employed (2). Reaction [6] is thought not to have occurred, however, for the following reasons.

In the CD_2O experiments it was found that the CH_3D/CO ratio was approximately 2.4 regardless of temperature or CD_2O concentration. E_6 is at least 12 kcal mole^{-1} (11), which is undoubtedly much higher than E_3 or E_4. If an appreciable fraction of the carbon monoxide were formed by reaction [6] then it would be expected that the CH_3D/CO ratio would decrease as the temperature increased, and this is not in accordance with the results obtained. Hence reaction [6] is slow up to at least 180° C.

Other possible fates for the formyl radical were

$$2CHO \rightarrow (CHO)_2, \qquad [7]$$

$$2CHO \rightarrow CO + CH_2O. \qquad [8]$$

The residues of several experiments were collected and analyzed mass spectrometrically for glyoxal with negative results, ruling out the appreciable occurrence of reaction [7] in the system studied. Reaction [8] could not be directly checked, however; its occurrence would not be in accordance with the rate law found.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for his interest in this work and Miss Bernice Thornton and Mrs. K. O. Kutschke for the mass spectrometer analyses.

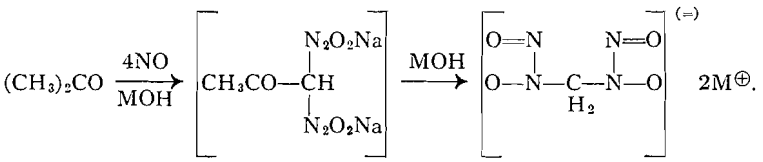
THE STABLE ALKYLATION PRODUCTS OF ORGANONITROSOHYDROXYLAMINES[1]

M. V. George, R. W. Kierstead, and George F Wright

ABSTRACT

The stable alkylation products of alkyl and aryl nitrosohydroxylamines seem to exist in a hitherto unknown structure, the diimide dioxide linkage. The alternative possibility is the alkyl diazotate monoxide structure, but the latter cannot account for the pure methane evolved when the substances are treated with methyl halide Grignard reagent. The principal products of this reaction with Grignard reagents are diimide monoxides formed subsequently by addition of an equivalent of reagent with elimination of the original alkoxy group as its magnesium salt. Nitration of N-methyl-N′-phenyldiimide dioxide shows that in salt-forming media (nitric–sulphuric) the N_2O_2R group is electrically negative, but dipole moment studies show that it is highly degenerate. This resonance stabilization is not unexpected in view of the high stability of the diimide dioxides in acidic media.

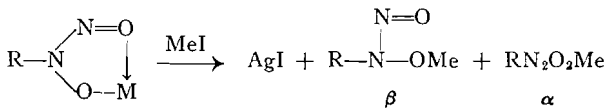
The first nitrosohydroxylamines were prepared (1) by reaction of nitric oxide with substances containing an active methylene group in presence of ethanolic sodium hydroxide. Typical is the reaction with acetone which may be postulated as follows:



I

The second, more orthodox, method of preparation involved the nitrosation of an arylhydroxylamine (2), and led to the preparation of salts such as ammonium phenylnitrosohydroxylaminate (cupferron). The free acids are rather unstable.

When the silver salts of these nitrosohydroxylamines (II, M = Ag) are treated with alkyl iodides two products, designated α and β, are formed. The β isomers may be desig-



II

nated as the nitroso derivatives of hydroxylamine O-ethers, since they give a positive Liebermann test and some may be synthesized by nitrosation of the O-alkylhydroxylamines (3, 4).

The structure of the α derivative was not proved. Hantzsch (5) suggested structures III or IV while Bamberger and Ekecrantz (6) suggested either IV or V. To this list may be added VI, although it is in conflict with one structure proposed for nitroso dimers (7, 8, 9, 10, 11).

There are two claims that nitroso dimers are best represented by structure VI or charge-distorted modification of it. An X-ray diffraction study (8) of tribromonitroso-

[1]*Manuscript received October 14, 1958.*

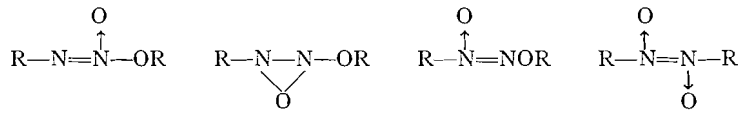
Can. J. Chem. Vol. 37 (1959)

benzene has been interpreted in terms of a central plane containing two nitrogen and two oxygen atoms, but it is doubtful whether this definition is justified when six bromine atoms are present. A more specific claim (10) that the *cis* and *trans* isomers of VI (R = Me) have been isolated may be interpreted in terms of polymorphism. Moreover, there is no convincing reason to expect that substances having structure VI would show the instability characteristic of nitroso, carboxylic, or peroxidic dimers. For these reasons we prefer to exclude VI for consideration as a nitroso dimer, and to include it among the possible structures of the α-alkylated nitrosohydroxylamines.



III IV V VI

In view of present knowledge structure III is inadmissable because it may clearly be assigned to isonitramines (12). The postulation of structures IV or V is justified by the observation (13) that basic hydrolysis of the methyl derivative of phenylnitrosohydroxylamine regenerates the salt (II, M = Na or K). We have extended this observation by hydrolysis of the dimethyl α derivative of the salt I using hydrazine as the basic reagent. Subsequent precipitation by use of sodium or barium hydroxide yields the appropriate salt of I rather than of methylene dinitramine (14).

Thus hydrolytic evidence favors IV or V rather than III, but it should be noted that VI is not excluded by this criterion since the alkylazoxy linkage is known to react with alkalis (15). The principal evidence favoring IV and V in contrast to VI has been presented by Bamberger (6, 13), who reduced methyl phenylnitrosohydroxylaminate and its *p*-bromo analogue. Reduction with zinc and acetic acid was said to give diazonium salts, while neutral reduction with aluminum amalgam gave the methyl ester of benzenediazotic acid. However, identification seems to have been accomplished only by odor and color tests. Only when the reduction was alkaline (4% sodium amalgam) was phenylhydrazine or its *p*-bromo analogue characterized in favor of structures IV and V rather than VI. But alkaline conditions also would yield sodium phenylnitrosohydroxylaminate by hydrolysis. Since this salt is easily reduced to phenylhydrazine, Bamberger's argument is not entirely convincing.

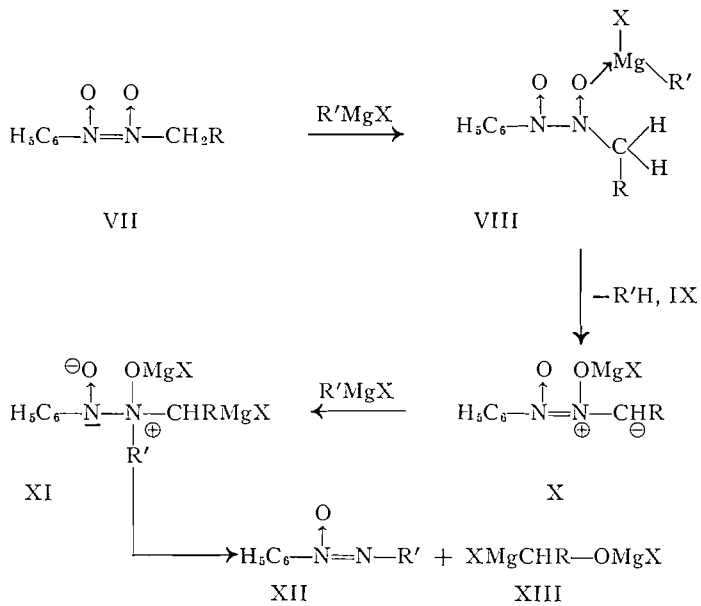
In order to evaluate further the criterion of reduction for a choice between structures IV, V, and VI we have applied alternative reducing agents to the methyl derivative of phenylnitrosohydroxylamine. We have found, like Bamberger, that the substance is fairly resistant. It is practically unchanged by reagents like titanous chloride in acetic anhydride, aqueous sodium bisulphite, aqueous sodium arsenite, and aqueous (47%) hydriodic acid, although a 4% yield of aniline was obtained from the latter reaction. A 24% yield of aniline was obtained, together with unchanged reagent and unidentifiable material, by catalytic reduction with platinum. But also, the alkaline reagent, sodium hydrosulphite, gave a 4% yield of phenylhydrazine together with a 65% recovery of the original substance. In fact the only reduction which might support Bamberger's contention for IV and V is that with lithium aluminum hydride which gives a 40% yield of phenylhydrazine. However, the latter reductant must be considered together with Grignard reagents which it resembles in its behavior.

Treatment of the methyl α derivative from phenylnitrosohydroxylamine with methyl halide Grignard reagent by the Kohler modification of the Zerewitinoff analysis (16)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

shows that one equivalent of pure methane is liberated easily. Enough may be collected at room temperature for demonstration of an uncontaminated infrared spectrum. The analysis shows also that 1.5 equivalents of Grignard reagent are added during the process. Since it has been shown that the isolable reaction product is fixed as its magnesium salt (and therefore cannot easily undergo further reaction), the evidence for active hydrogen would seem to exclude IV or V as possible structures, but not VI with its methylene group adjacent to an azoxy linkage. Accordingly VI (R = C_6H_5, R′ = Me) is now designated for the α derivative of phenylnitrosohydroxylamine, and it is named N-phenyl-N′-methyldiimide dioxide.*

When methylphenyldiimide dioxide (VII, R = H) is treated with an excess of bromotoluene Grignard reagent in ethyl ether the significant product is N-4-tolyl-N′-phenyldiimide N′-oxide (17) (XII, R′ is *p*-tolyl). When an excess of VII is used to ensure complete consumption of the Grignard reagent both methanol and toluene (IX, R′ = tolyl) can be isolated. On the basis of this information the reaction may be formulated as follows:



Although either of the oxide linkages might be expected to co-ordinate with the Grignard reagent only the co-ordination shown in VIII would seem to be propitious for elimination of R′H, IX. The remaining dipolar fragment, X, should then co-ordinate and add Grignard reagent to give XI, from which XIII (R = H) (finally leading to methanol) and XII would be produced. It is noteworthy that none of the isomeric N′-4-tolyl-N-phenyldiimide N′-oxide (the structure of which was proved (17) by facile bromination in the phenyl substituent) was found among the reaction products.

**It has become evident that the nomenclature of azo and azoxy compounds is inadequate for communication among chemists. A revision has been suggested (15), but this in turn cannot be used to describe structures such as VI. Consequently we suggest that azo compounds be designated by the Chemical Abstracts classification, N,N′-diimide* (R—N=N—R′), *that azoxy compounds be called diimide oxides (or monoxides), and that substances with structures corresponding to VI be called diimide dioxides. For example the α- and β-4-chlorophenylazoxybenzenes would be renamed N-phenyl-N′-[4-chlorophenyl]diimide N-oxide and N′-oxide respectively. From this adaptation of amine oxide nomenclature it becomes simple to describe the unsymmetrical azo and azoxy compounds as well as our diimide dioxides.*

For personal use only.

When an otherwise comparable experiment is carried out by use of methyl chloride Grignard reagent the isolable product, besides unchanged VII, would then be designated as N-methyl-N′-phenyldiimide N′-oxide. This oily product (XII, R′ = Me) has been characterized by analysis and by reaction with lithium aluminum hydride which converts it to the previously known N-methyl-N′-phenyldiimide. The structure of XII (R′ = Me) is assigned principally by analogy with XII (R′ = tolyl), but also it might be expected that the structure isomeric with XII (in which the amine oxide group is vicinal to the methylene group) would liberate methane from methyl halide Grignard reagent. Actually the product (XII, R′ = Me) was very sluggish in this respect and only 0.3 equivalent could be discovered under the forced conditions of pyridine solvent at 100° C.

The yield of XII is always low (when R′ = Me, 14%) and this circumstance is not unexpected in view of the known reactivity of N-oxides toward Grignard reagents. For example the free N-oxide group in VIII would be expected to oxidize Grignard reagent, leading to reduction products. Presumably such reactions would be slower than the series shown as VII → XIII. In order, then, to rationalize the low yields of diimide monoxides from the dioxides in terms of side reactions with the Grignard reagent we have chosen an especially difficult example. The addition of N-methyl-N′-phenyldiimide dioxide to an equivalent of benzyl chloride Grignard reagent in diethyl ether gives a yield not exceeding 7% of the monoxide. About 40% of the diimide dioxide is recovered indicating that much of VIII or X does not react further, and that some of the Grignard reagent is consumed in reactions not included in the formulation VII → XIII. The recovery of at least 7% of a derivative of benzaldehyde from the remaining complex mixture indicates that reduction of the monoxide has occurred subsequent to its formation.

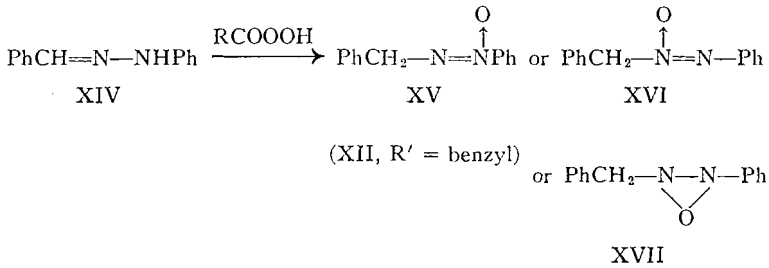
$$C_6H_5N_2OCH_2C_6H_5 \xrightarrow{RMgX} ROMgX$$

$$+$$

$$H_5C_6{-}\overset{H}{\overset{|}{C}}{=}N{-}N{-}C_6H_5 \xleftarrow{\text{rearr.}} H_5C_6{-}N_2{-}CH_2{-}C_6H_5$$

This latter reaction seems to be a significant one because reversal of addition (Grignard reagent into diimide dioxide) only raises the monoxide yield to 10%. However, threefold dilution under the latter conditions raises this yield to 14%. Moreover, equivalent addition into a tube containing a downward-pitched screw which conveys its contents into a dry-ice bath within 1 minute, Fig. 1, raises the final yield of diimide monoxide to 20%. It would appear from these experiments that low yield of diimide monoxide is partly due to reaction of XI (or some XII formed in the system before hydrolysis) with Grignard reagent. This conclusion is not vitiated by the 25% yield to be obtained when benzyl chloride Grignard reagent in diethyl ether is added slowly to the whole of N-methyl-N′-phenyldiimide in dioxane. It may be expected that the dibenzylmagnesium which remains in solution after precipitation of magnesium halides is less reactive toward XI or XII than is the whole Grignard reagent.

There are contradictions in the literature with respect to the structure that we have assigned to XII (R′ = benzyl). The diimide monoxide produced by this reaction has also been obtained by the peracid oxidation of benzaldehyde phenylhydrazone, XIV (18). Of the three possible structures which may be written, Bergmann *et al.* favored the epoxy arrangement XVII; but later two independent groups of workers favored the



structure N-benzyl-N′-phenyldiimide N-oxide, XVI. One group (19) based its contention on bromination to N-benzyl-N′-*p*-bromophenyldiimide N-oxide, but a repetition (20) of this bromination was unsuccessful. The other group (21) approved XVI because a reaction of XIV with ethyl chloride Grignard reagent yielded diphenylamidine, XIX, but their argument is unconvincing. Indeed the formation of XIX may be explained at least as well on the basis of XV.

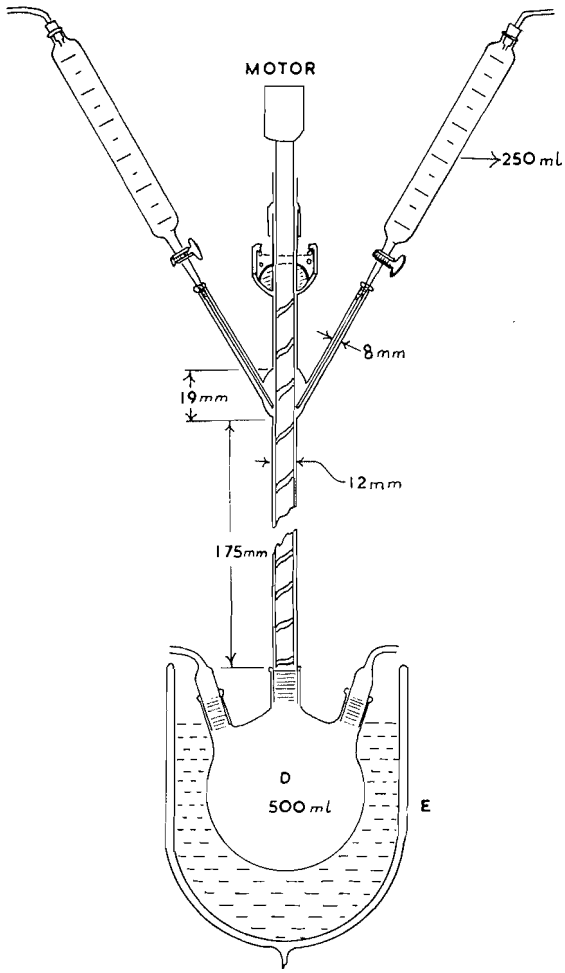


FIG. 1.

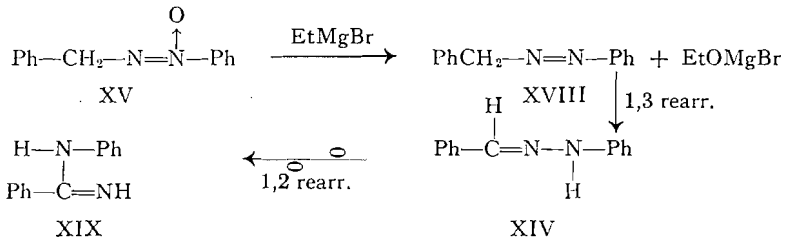
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.



As may be seen by this formulation the reduction of XV → XIX is accomplished by the oxidation of Grignard reagent. By contrast the mechanism of Witkop and Kissman does not include the necessary oxidation step. On the other hand their mechanism does include reactions involving active hydrogen, although Witkop and Kissman searched for and could not find ethane. Lack of evidence for active hydrogen under normal conditions of Grignard treatment is confirmed by our results, although we did observe the formation of gas indicative of active hydrogen under forcing conditions (i.e. with prolonged reaction at 100° C when N-methylmorpholine was used as the reaction medium). This behavior is not unexpected when substances like XVIII, XIV, and XIX are present. For example acetone anil can be made to show the presence of active hydrogen (22). In summary it may be said that neither Pausacker nor Witkop and their co-workers have any real evidence for designation of XVI as the structure for the peroxidation product of benzaldehyde phenylhydrazone.

Actually this conclusion was drawn some years ago (19) by Lythgoe and his co-workers after preparation of both 4-chlorobenzylphenyldiimide monoxides by peroxidation of 4-chlorobenzylphenyldiimide. The product corresponding to XV was geoisomerized to the peroxidation product of 4-chlorobenzaldehyde. Also this chloro analogue of XV was brominated to give the 3-bromo-4-chlorobenzyl analogue, whereas the peroxidation product corresponding with XVI was brominated to give N-4-chlorobenzyl-N′-4-bromophenyldiimide N′-oxide.

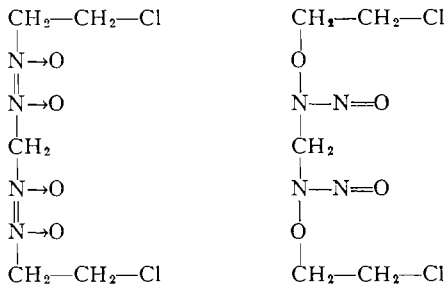
Thus by the standard proof (17) Lythgoe and his co-workers have demonstrated the structure (XV) as the product that we obtain from phenylmethyldiimide dioxide and benzyl chloride Grignard reagent. This demonstration is not vitiated by the possibility that a modernized version of structure XVII may also explain part of the experiments of Lythgoe and his co-workers.

The behavior of Grignard reagents with N-methyl-N′-phenyldiimide dioxides provides an explanation for the action of lithium aluminum hydride in terms of the reaction sequence VII → XII inclusive, where the metal hydride replaces Grignard reagent. Moreover the heterogeneous reductants mentioned by Bamberger should behave as metal hydrides and also give N-phenyldiimide N-oxide (XII, R′ = H) initially, which ultimately would be reduced to the phenylhydrazine that eventually is obtained.

It should be noted that the nomenclature devised for diimide dioxides does not imply that characteristic properties may be specified for this group alone. In all instances at least one alkyl group must be attached to a nitrogen and no diimide dioxide has been prepared in which both organic groups attached to nitrogen are aromatic. For example an attempt to oxidize 4,4′-dichlorodiphenyldiimide to the dioxide with boiling 40% nitric acid leads only to 4,4-dichloronitrodiphenyldiimide oxide (23). On the other hand both organic groups attached to nitrogens may be aliphatic. Traube (1) prepared N,N′-methylene-bis-[N-methyldiimide]tetroxide and the ethyl homologue by treatment of the silver salt of methylene-bis-nitrosohydroxylamine (I) with the alkyl iodides. We have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

prepared the 2-chloroethyl analogue (XX) by the same method taking advantage of the unusual stability of these substances toward prolonged boiling with 70% nitric acid in order to destroy the unstable isomer, di-2-chloroethyl methylene-bis-nitrosohydroxylaminate (XXI). We have also prepared methylene-bis-[methyldiimide]tetroxide and its



XX XXI

ethyl analogue by treatment of the sodium or ammonium salt of I with dialkyl sulphate but in this event the nitroso isomers corresponding with XXI evidently are destroyed *in situ*, since the tetroxides corresponding with XX are isolated in a pure state.

The chemical reactions of these aliphatic diimides have been examined by use of methylene-bis-[methyldiimide]tetroxide but they are not very informative. Pyrolysis gives methanol, nitrous oxide, and carbon, while alkaline hydrolysis gives formic acid, methanol, and nitrous acid. Treatment with bromobenzene Grignard reagent gives a small yield of benzophenone phenylhydrazone. On the other hand treatment with methyl iodide Grignard reagent under analytical conditions (Soltys machine) shows that reaction in isoamyl ether is limited to evolution of gas indicative of two equivalents of active hydrogen. A precipitate is formed immediately, which accounts for the fact that only 0.1 equivalent of Grignard reagent is found additionally to be consumed in the system.

The infrared spectra through the 1600–600 cm^{-1} range have been determined for a series of diimide dioxides, the monoxides derived from them, some oxime methyl ethers, and some methyl isonitramines (III). These spectra are shown in Table I. Among this limited number of examples two bands may be assigned tentatively to the motion of the diimide dioxide linkage. The first of these is a weak to medium absorption at 1194–1210 cm^{-1}, while the other is a consistently strong band at 995–1018 cm^{-1}. These bands are not observed among the other candidates of Table I. On the other hand the spectra of diimide dioxides are noticeably transparent in the 1000–700 cm^{-1} range whereas the O-ethers and the isonitramines show considerable absorption in this region. Although such spectral evidence cannot of itself be considered to be definitive, it does seem to confirm the chemical evidence that structure VI, and not III, IV, or V, is correct for α methylation derivatives of nitrosohydroxylamines.

The behavior of the alkyldiimide dioxide linkage as an aromatic substituent is of interest. Despite the inertness of this diimide dioxide linkage it may be displaced by forced bromination, and 4-bromonitrobenzene is obtained when N-methyl-N′-4-nitrophenyldiimide dioxide is treated in this manner. The oxidizing action of the alkyldiimide dioxide linkage may be involved, since N-methyl-N′-4-nitrophenyldiimide dioxide may be converted in part to nitrobenzene by prolonged reflux in ethanol. This reduction finds its counterpart in the oxidation of the ethanol to acetaldehyde.

[a]Prepared according to Semper, L. and Lechertadt, L. Ber. 51, 928 (1918).
[b]Prepared according to Aurvens, K. V. and Otters, B. Ber. B, 57, 446 (1924).

The dissimilarity of the diimide dioxide linkage with that of the monoxides may be observed by nitration of N-methyl-N′-phenyldiimide dioxide. It is well known (24) that aromatic diimide monoxides are slowly nitrated, and almost not at all in the aromatic ring adjacent to the N → O linkage. However when substitution in this NO-adjacent ring does occur the group enters in the meta position (25). By contrast N-methyl-N′-phenyldiimide dioxide is nitrated rapidly in nitric – sulphuric acid mixture. As would be expected from this rapidity the 58% yield of this rapid nitration is predominantly (81%) the para isomer. Only 7% is found as the meta isomer and 12% as the ortho isomer.

The meta isomer could not be hydrogenolized satisfactorily to metanitroaniline but its positional isomerism seems to be proved by the tin – hydrochloric acid reductions of the ortho and para isomers to ortho- and para-nitroaniline respectively. Moreover the para isomer may be reduced to the amine which can be diazotized and then converted to N-methyl-N′-4-chlorophenyldiimide dioxide. This compound has been synthesized (2) from 4-chlorophenylnitrosohydroxylamine.

The crystallography of this 4-chloro analogue has been examined carefully in connection with a single crystal study now in progress. Incidental to this study it has been found that this typical diimide dioxide is monomeric. It has also been found that, unlike nitramines (26), the "atom polarization" of N-methyl-N′-4-chlorophenyldiimide dioxide is normal in the sense that it amounts to only a few per cent of the total (P_{E+A}) distortion polarization in a weak electric field. However the orientation polarization seems to present an anomaly.

From the formal structural representation of the diimide dioxide linkage one may draw an analogy with the nitro group. The dipole moment studies (Table II) might at

TABLE II

Electrical polarizations of some diimide dioxides in benzene at 20±0.05° C

Diimide dioxide	Polarization values				Solid dielectric			
	α	β (neg.)	P_T, cc	R_D, cc	d_4^{20}	ϵ	P_{E+A}, cc	μ, Debyes

[a]Extrapolated n_0^{20} of solutions. [b]Calc. for $n_\alpha+n_\beta+n_\gamma/3$ of solid. [c]Air displacement. [d]Flotation in zinc chloride. [e]Dioxane used instead of benzene as solvent.

first inspection seem to confirm this analogy. This $N_2O_2CH_3$ group might then be assigned the group moment 3.26 D, negative with respect to hydrogen, just as the nitro group moment is 4.0 D, negative according to the orientation polarization of nitrobenzene. Actually the observed moment (3.74 D) of N-methyl-N′-3-nitrophenyldiimide dioxide is approximate to the value calculated from $\mu_{resultant} = (m_1^2+m_2^2+2m_1m_2 \cos\theta)^{\frac{1}{2}} = 3.69$ D, where m_1 and m_2 are the group moments of $N_2O_2CH_3$ and NO_2, and θ is 120° C. However the calculated value for N-methyl-N′-4-nitrophenyl diimide dioxide (0.74 D) is widely divergent from the observed moment of 3.50 D. Likewise, a calculation

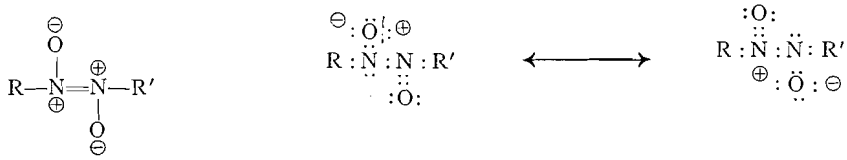
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of moment for N-methyl-N′-2-nitrophenyldiimide dioxide (θ = 60° C) gives μ = 6.29 D which is considerably higher than the observed value (5.19 D). A comparable discrepancy is found for N-methyl-N′-4-chlorophenyldiimide dioxide which shows a moment of 2.64 D, about one Debye greater than that expected by calculation.

If one reconsiders the $N_2O_2CH_3$ group in respect of these discrepancies it is apparent that a simple analogy with the nitro group is not valid, and this distinction may be seen in the geometry of the group. One may depict *cis* and *trans* forms and would expect distinct physical and chemical differences. However, the variation in structure probably is more subtle than can be expressed by this simple geometry.

cis *trans*

It would appear from the results of Table II that the group moment of the diimide dioxide group is subject to wide variation depending on the substituents that may be attached to it. This variation is best explained in terms of N–N bond rotation, in which the anharmonicity is a function of the group substituent to the diimide dioxide linkage. Of course this concept conflicts with the orthodox doubly bonded diimide structure, but it is doubtful that the diimide dioxides should assume such a structure. Indeed, it would appear that the adjacent positive charge of a diimide dioxide structure such as XXII is somewhat anomalous and is better explained as a resonance hybrid of XXIII*a* and *b*.



XXII XXIII*a* XXIII*b*

The resonance formulation is not intended to depict *trans* planarity; indeed the rotameric conformation of XXIII is thought to account for the apparent anomalies among the nitro and chloro derivatives described above. Certainly the conformation is not *trans* as shown in XXIII because in this event the electric moment of N,N′-dibenzyldiimide dioxide would be zero instead of 3.05 D (Table II).

The authors are grateful to Messrs. Myers and Bedard, Canadian Armament Research and Development Establishment, for the determinations of infrared absorption. They acknowledge extensive financial aid from the Defence Research Board of Canada.

EXPERIMENTAL*

N-Methyl-N′-phenyldiimide Dioxide

To a mixture of cupferron (160 g, 0.6 mole) and sodium bicarbonate (140 g, 1 mole) in 1160 ml of water was added 210 g (1 mole) of dimethyl sulphate during 7 hours with stirring. Cooling with a water bath was necessary. After 15 subsequent hours of stirring

Melting points have been corrected against appropriate standards (Can. J. Technol. **34, 89 (1956)). X-Ray diffraction patterns are recorded, using* CuK_α (Ni *filtered) radiation, in Ångstroms at relative intensities* $[I/I_1]$.

at 20° C the deep-red system was extracted with a total of 1500 ml of diethyl ether. This extract, dried with calcium chloride, was distilled finally at 0.5 mm to yield 119 g of oil, b.p. 98–100° C, which partially solidified. This product was diluted by addition with $\frac{1}{2}$ volume of petroleum ether, b.p. 40–60° C, then cooled, and finally filtered. The solid was crystallized from 3.5 l. of petroleum ether (b.p. 40–60° C) and cooled to give 94 g, m.p. 37.5–39° C (60%). A similar recrystallization raised the melting point to 39.5–40.5° C. Absorption in the ultraviolet region showed λ_{max} at 262 mμ; E_{max} 10,690. The X-ray diffraction pattern was [10] 3.48; [9] 4.78; [7] 4.14; [6] 7.16; [5] 4.17; [4] 6.58; [3] 3.13; [2] 2.89, 3.38; [1] 5.19, 3.17, 3.09, 2.85, 2.61.

When this substance was heated to 100° C with 85% sulphuric acid or chlorosulphonic acid it was recovered unchanged. Likewise it was unaffected by 6 hours' treatment with acetic anhydride at 200° C.

Hydrazine Phenylnitrosohydroxylaminate

A mixture of 4.56 g (0.03 mole) of N-methyl-N′-phenyldiimide dioxide and 3.0 g (0.06 mole) of 100% hydrazine hydrate was refluxed for 17 hours, then cooled, and diluted with 15 ml of absolute ethanol. Several crystal crops totalling 3.40 g (66%, m.p. 127–128° C) were combined and crystallized from 90 ml of absolute ethanol, 2.61 g (51%) of the salt, m.p. 127–128° C (decomp.); recrystallized, m.p. 128.5–129° C. Calc. for $C_6H_{10}O_2N_4$: C, 42.3; H, 5.92; N, 32.9. Found: C, 42.3; H, 6.02; N, 33.8. Acidification of 0.25 g in 3 ml of water by 3 ml of 12% hydrochloric acid gave 1.6 g (77%), m.p. 56.5–58° C, of phenylnitrosohydroxylamine. After crystallization from 5 ml of petroleum ether (b.p. 40–60° C) the product, m.p. 58–59° C, was characterized by mixture melting point. The presence of hydrazine was demonstrated by treatment of the salt with aqueous picric acid. The hydrazine picrate melted at 182–183° C.

Reduction of N-Methyl-N′-phenyldiimide Dioxide

(*a*) *Catalytic reduction.*—A solution of 3.8 g (0.025 mole) in 50 ml of absolute ethanol with Adams catalyst absorbed 2 moles of hydrogen and then yielded aniline, b.p. 180–184° C (756 mm), which was characterized as acetanilide, 0.43 g, 24%, m.p. 112–114° C. Also 12% of the original dioxide was recovered unchanged.

(*b*) *By hydriodic acid.*—After 2 days' reflux of 1.0 g (0.0066 mole) in 3 ml of 47% hydriodic acid, 0.76 g (76%) of the original dioxide was recovered unchanged. An ether extract of the remainder was treated with oxalic acid in ether to give 4.6 mg (0.25%) of aniline oxalate, m.p. and m.m.p. 153.5–155.5° C.

(*c*) *By sodium hydrosulphite.*—A mixture of 0.99 g (0.0065 mole) in 8 ml of ethanol and 6.8 g (0.039 mole) of sodium hydrosulphite in 20 ml of water was heated with stirring at 80° C for 45 minutes. Extraction with diethyl ether yielded 65% of the unchanged starting material. The aqueous–alcoholic solution was concentrated under reduced pressure and the residue was extracted by ether to give 90 mg of oil. Treatment with picric acid yielded 104 mg (4.7%) of crude phenylhydrazine picrate, m.p. 135–137° C, which was crystallized from benzene, m.p. and m.m.p. 145.5° C.

(*d*) *By lithium aluminum hydride.*—A solution of 0.99 g (0.0065 mole) in 25 ml of dry ether was added to a solution of 0.813 g (0.0215 mole) of lithium aluminum hydride in 25 ml of the same diethyl ether with stirring during 20 minutes at 20° C. After a subsequent 30-minute stirring time the system was treated with 5 ml of 10% aqueous sodium hydroxide and then extracted with ether to yield 0.4 g of an oil. Distillation at 125–130° C (18 mm) gave 0.23 g (40%) of phenylhydrazine, characterized by conversion to *p*-chlorobenzaldehyde phenylhydrazone, m.p. and m.m.p. 125–126° C.

Bromination of N-Methyl-N′-phenyldiimide Dioxide

A mixture of N-methyl-N′-phenyldiimide dioxide (3.04 g, 0.02 mole) with 8 g (0.05 mole) of bromine in 10 ml of carbon disulphide was refluxed with 150 mg of iron filings for 15 hours. Subsequent steam distillation (4 l.) yielded 1.06 g, m.p. 68.5–71.5° C, which was crystallized from 7 ml of ethanol, and 0.48 g (6.1%, m.p. 89.8–90.8° C) of crude 1,2,3,5-tetrabromobenzene, crystallized further from ethyl acetate, m.p. 99–99.7° C. Calc. for $C_6H_2Br_4$: C, 18.3; H, 0.51. Found: C, 18.3; H, 0.73. Chloroform extraction of the steam distillation residue gave 0.51 g, m.p. 219–220° C, crystallized from dioxane, m.p. 221.6–221.9° C. This substance was not identified. Calc. for $C_7H_3Br_4$: C, 21.7; H, 0.75. Found: C, 21.1; H, 0.75.

N-Methyl-N′-4-nitrophenyldiimide Dioxide

To a chilled solution of 10.6 ml (0.26 mole) of 99% nitric acid and 45.3 ml (0.846 mole) of 100% sulphuric acid was added 19.8 g (0.13 mole) of N-methyl-N′-phenyldiimide dioxide during 15 minutes with constant stirring at 0° C. After a short time of warming to room temperature the system was poured into 400 g of crushed ice. Filtration removed 25.5 g which was twice crystallized from carbon tetrachloride to yield 12 g (47%) of the para–nitro derivative, m.p. 152–153° C. Calc. for $C_7H_7N_3O_4$: C, 42.6; H, 3.58; N, 21.3. Found: C, 42.7; H, 3.33; N, 20.8. The X-ray diffraction pattern was [10] 3.18; [8] 7.76, 7.49; [6] 4.69; [5] 5.04; [3] 3.68, 3.52; [2] 11.1; [1] 2.31; [0.5] 2.16. The ultraviolet absorption in ethanol gave λ_{max} at 243 mμ, 330 mμ with E_{max} 10,970 and 567 respectively. The substance was recovered unchanged after 12 hours at 200° C with acetic anhydride.

An unsuccessful attempt was made to prepare this compound by peroxidation of methyl 4-nitrobenzenediazotate (27). This ester was prepared via the silver salt from 4-nitrobenzenediazonium sulphate by Bamberger's method but the 2 g obtained from 6.9 g of *p*-nitroaniline was used without characterization because of its tendency toward decomposition. The orange-yellow solid (0.011 mole) was mixed with 15 ml of acetic acid and 9 ml of 30% hydrogen peroxide and kept at 0° C for 12 hours, then at 25° C for 2 days. Upon treatment with 150 ml of water and extraction with ether 1.11 g of red-brown solid was obtained upon evaporation. This solid was developed on a chromatoplate (28) (prepared from 80% silica gel and 20% plaster of Paris at 120° C) together with *p*-nitrophenol and also N-methyl-N′-4-nitrophenyldiimide dioxide. The developer was 18:1 benzene–acetone. By means of a sulphuric – nitric acid spray (95:5) only *p*-nitrophenol and not the diimide dioxide could be detected.

A mixture of 2.51 g (0.013 mole) of N-methyl-N′-4-nitrophenyldiimide dioxide and 9.2 g (0.078 atom) of granulated tin was treated with 18.8 ml (0.188 mole) of concentrated hydrochloric acid during 25 minutes. After 40 minutes of reflux the system was cooled and treated with 20 g of sodium hydroxide in 40 ml of water and then steam-distilled. From the distillate was obtained 0.89 g, m.p. 135–140° C, of *p*-phenylenediamine which was crystallized from benzene, m.p. and m.m.p. 139–140° C, 0.3 g (22%).

N-Methyl-N′-4-aminophenyldiimide Dioxide

A mixture of the para–nitro derivative (0.97 g, 0.0049 mole) and 15 ml of hydroiodic acid (sp. gr. 1.5) was heated under reflux for 15 minutes. After 12 hours at 20° C the system was diluted with 20 ml of water to precipitate 0.25 g (26%) of unchanged starting material, m.p. 152–153° C, after crystallization from carbon tetrachloride.

The amine (0.19 g, m.p. 171–172.5° C, 23%) was precipitated by addition of alkali to pH 8. It was crystallized from ethanol (95%), m.p. 176.5–176.8° C. The X-ray diffraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

pattern was [10] 4.81; [9] 3.51; [7] 4.25; [5] 3.47; [4] 7.56, 3.03; [2] 6.58, 5.86, 5.26, 2.05; [1] 2.93, 2.61. Calc. for $C_7H_9N_3O_2$: C, 50.3; H, 5.43; N, 25.1. Found: C, 50.7; H, 5.35; N, 25.5.

4-Chlorophenylhydroxylamine (2)

To a refluxing system comprised of 180 g (1.14 mole) of 4-chloronitrobenzene in 1200 ml of ethanol and 24 g (0.45 mole) of ammonium chloride in 300 ml of water was added 300 g (4.6 atom) of zinc dust in 10-g lots. One-minute periods of addition and stirring were alternated with 1-minute periods of reflux until the color of the reaction mixture passed its lightest stage of brown and began once more to darken. The residual zinc dust was quickly filtered hot. Steam distillation of the filtrate gave 50 g (30.5%), m.p. 83–83.5° C.

N-Methyl-N′-4-chlorophenyldiimide Dioxide

(*a*) *From N-Methyl-N′-4-aminophenyldiimide dioxide.*—To a suspension of N-methyl-N′-4-aminophenyldiimide dioxide (100 mg, 0.006 mole) in 0.8 ml of concentrated hydrochloric acid plus 0.5 ml of water at 0° C was slowly added a solution of 50 mg of sodium nitrite in 0.3 ml of water. To the orange-yellow reaction mixture at 0° C was then added 90 mg of cupric chloride in 0.75 ml of concentrated hydrochloric acid during 20 minutes. The system was then slowly warmed to 20° C and subsequently heated at 60° C for 10 minutes. When the mixture was cooled 60 mg (54%) of N-methyl-N′-4-chlorophenyldiimide dioxide separated, m.p. 70–71° C. After crystallization from petroleum ether (b.p. 40–60° C) a mixture melting point (71–72° C) with an authentic specimen (2) was not depressed. The X-ray diffraction pattern was [10] 5.34; [9] 3.52; [8] 3.36; [6] 3.71; [5] 4.36; [4] 4.92; [3] 6.28; [2] 2.19, 1.91; [1] 6.51, 2.94, 2.59, 2.51, 2.44, 2.22.

(*b*) *From 4-chlorophenylhydroxylamine.*—A solution of 50 g (0.348 mole) of 4-chlorophenylhydroxylamine in 335 ml of ethanol was acidified (2) with 135 ml of 2 *N* hydrochloric acid and the stirred system was held at 5° C. Then 24.6 g (0.356 mole) of sodium nitrite in saturated aqueous solution was added during 30 minutes. The precipitate was filtered off, washed with water, and, partially dried, was suspended in a solution of 80.5 g (0.761 mole) of sodium bicarbonate in 935 ml of water. The stirred suspension was treated with 45 ml (0.475 mole) of methyl sulphate. After 40 minutes the system was chilled and filtered. The crude product (54 g) was dissolved in a minimum of boiling ethanol. The hot filtrate was chilled to remove 4-chlorophenyl-bis-diimide (9.4 g, 23.9%). The filtrate was steam-distilled and 17.5 g (m.p. 69–70° C, 27%) of N-methyl-N′-4-chlorophenyldiimide dioxide was obtained from the ether extract of the distillate. After crystallization from petroleum ether (b.p. 40–60° C) it melted at 73.1–74.6° C. Rod-shaped crystals suitable for X-ray diffraction studies were obtained from *p*-cymene; they cleaved well along (100), (001), and (102).

The refractive indices were measured by the crushed crystal immersion method (29) as α, 1.49, about 10° C from (010), while β is 1.67 along (001), and γ is 1.78 about 20° C from (100). The density by flotation in aqueous zinc chloride at 29° C is 1.476, while by the air-displacement method (30) it is 1.470. Calculations of the polarization (from $\alpha+\beta+\gamma$ divided by 3) gave 46.2 cc in contrast to 50.9 cc obtained from $\epsilon = 3.020$ by dielectric constant measurement of the pelleted solid (31).

Zero level Weissenberg photographs of crystals mounted on the *b*-axis (in capsules because of sublimation) were carried out with CuK_α radiation giving constants: $a = 17.20 \pm 0.04$ Å, $b = 3.91 \pm 0.01$ Å, and $c = 13.11 \pm 0.04$ Å of a monoclinic cell with $\beta = 108.0 \pm 0.2°$ C. Since this corresponds with a cell volume of $(838$ Å$)^3$ and the molecular volume

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

is calculated as (210 Å)^3 there are four molecules per unit cell. Molecular weight by the Rast method was determined at 190 (calc., 186.6).

Examination of Weissenberg photographs showed no extinctions on (*hkl*), but (*oko*) reflections were found only when $k = 2n$ and (*hol*) reflections only when $l = 2n$. The space group is therefore assigned at $P2_{1/c}$. Structure factors have been determined (32).

p-Chloroaniline

Although N-methyl-N′-4-chlorophenyldiimide dioxide was unaffected by hydriodic acid at 100° C for 30 minutes, reduction was effected in a mixture of 0.56 g (0.003 mole) of the substance with 2.14 g (0.018 atom) of granulated tin to which 3.7 ml (0.095 mole) of concentrated hydrochloric acid was added during 3 minutes. Subsequently the system was maintained at 90–100° C for 30 minutes and at 20° C for 12 hours. After treatment with 6 g of sodium hydroxide in 6 ml of water the system was ether-extracted. Evaporation of the extract left 105 mg, m.p. 60–68° C, which was crystallized from petroleum ether (b.p. 40–60° C), 50 mg (13%) of *p*-chloroaniline characterized by m.p. and m.m.p. of 68.5–70° C.

4-Nitrobromobenzene

A system comprised of 0.98 g (0.005 mole) of N-methyl-N′-4-nitrophenyldiimide dioxide, 1.6 g (0.01 mole) of bromine, 100 mg of iron filings, and 5 ml of carbon disulphide was refluxed for 3 hours and then steam-distilled. The cooled distillate (220 ml) yielded 0.14 g, m.p. 67.6–69.5° C, of crude 4-nitrobromobenzene which was crystallized from ethanol, m.p. 113–115° C, 90 mg (9%), and then from commercial hexane, m.p. and m.m.p. 122.7–123.3° C.

Nitrobenzene

When a solution of N-methyl-N′-4-nitrophenyldiimide dioxide (2.56 g, 0.013 mole) in 50 ml of 95% ethanol was refluxed for 41 hours the cooled system precipitated 1.31 g (51%) of starting material, m.p. 152–153.5° C. Distillation of the filtrate gave 0.26 g of an oil, b.p. 78° C (10 mm), which on redistillation was shown to be nitrobenzene (0.23 g, 14%, b.p. 208–212° C at 756 mm, n_D^{20} 1.55256, m.p. and m.m.p. 6–7° C).

In an experiment, identical except for the addition of 0.1 g of concentrated sulphuric acid and for a 120-hour reflux, only 13% of starting material was recovered and 48% of nitrobenzene was obtained. Additionally a precipitate was formed in a trap containing acid – alcoholic 2,4-dinitrophenylhydrazine solution which surmounted the reflux condenser. This was proved by mixture melting point to be acetaldehyde 2,4-dinitrophenylhydrazone, m.p. 162–164° C.

N-Methyl-N′-3-nitrophenyldiimide Dioxide

The mother liquor (1100 ml) from which the N-methyl-N′-4-nitrophenyldiimide dioxide was removed (see above) was concentrated to a volume of 250 ml and then cooled to give 5.2 g, m.p. 103–111° C. A second crop (1.18 g, m.p. 108–113° C) was obtained by concentrating the filtrate and then eluting it on a Doucil column (1 in. × 14 in.) by means of 450 ml of 1:1 Commercial hexane – carbon tetrachloride. The combined eluates gave 6.38 g which was crystallized from 400 ml of benzene, 1.04 g (4%) of N-methyl-N′-3-nitrophenyldiimide dioxide, m.p. 128–132° C. Recrystallization from methanol raised this melting point to 133–134° C. Calc. for $C_7H_7N_3O_4$: C, 42.6; H, 3.58; N, 21.3. Found: C, 42.3; H, 3.50; N, 21.4. The X-ray diffraction pattern was [10] 3.23; [3] 7.86; [2] 4.65; [1] 4.25, 3.94, 3.70; [0.5] 6.10, 5.27. The ultraviolet absorption in ethanol at 23° C showed λ_{max} at 254 Å with E_{max} 15,350.

N-Methyl-N′-2-nitrophenyldiimide Dioxide

The eluted Doucil column (see above) was further eluted, now with carbon tetrachloride (450 ml) and then with chloroform (400 ml). These eluates gave 2.22 g, m.p. 52–60° C, and 0.55 g, m.p. 62–66° C, respectively. The combination was crystallized from a 1:1 mixture of benzene and petroleum ether (b.p. 40–60° C), 1.9 g 7.4%, m.p. 60–64° C. A similar recrystallization raised this melting point to 66.5–67.3° C. Calc. for $C_7H_7N_3O_4$: C, 42.6; H, 3.58; N, 21.3. Found: C, 42.3; H, 3.67; N, 20.9. The X-ray diffraction pattern was [10] 4.13, 3.52; [9] 7.79; [8] 5.81, 4.87, 3.87, 3.39; [6] 5.21, 2.54; [5] 4.64; [4] 3.05; [1] 7.08, 6.44. The ultraviolet absorption in ethanol at 23° C was λ_{max} 258, 289 Å with E_{max} 10,830 and 9,415 respectively.

A system comprised of 100 mg (0.0005 mole) of this isomer with 0.37 g (0.0031 atom) of granulated tin and 0.75 ml of concentrated hydrochloric acid was refluxed for 40 minutes. The cooled system, treated with 1.2 g of sodium hydroxide in 8 ml of water was ether extracted. The extract contained 35 mg, m.p. 93–97° C. This was crystallized from benzene, m.p. 100–101° C (14 mg, 26%), and then was characterized by m.p. and m.m.p. (100–102° C) as orthophenylenediamine.

N,N′-Dibenzyldiimide Dioxide

This substance was prepared in 38% yield, m.p. 58–59° C, from N-benzylhydroxylamine (33) by the previously reported procedure (3). The X-ray diffraction pattern was [10] 4.53; [8] 4.10; [7] 3.16; [6] 5.38, 4.71; [5] 3.96, 3.10; [4] 2.36; [3] 2.60; [2] 7.0; [1] 2.24, 2.91, 3.29, 3.58.

A 4% solution in benzene showed bands with the following per cent transmission (% *T*) at the recorded frequency in cm^{-1}: (89) 494, (90) 555, (86) 601, (51) 710, (66) 741, (91) 835.

N-Benzyl-N′-phenyldiimide Dioxide

To a solution of sodium ethoxide (1.38 g Na in 50 ml of absolute ethanol, 0.06 mole) was slowly added 9.3 g (0.06 mole) of cupferron. After further addition of 7.59 g (0.06 mole) of freshly distilled benzyl chloride the system was refluxed for 210 minutes. Removal of the solvent under reduced pressure left a brown residue which was extracted by diethyl ether. The evaporated extract was crystallized from a hexane–ether mixture, 2.28 g (16.7%), m.p. 80–81° C. Calc. for $C_{13}H_{12}N_2O_2$: C, 68.4; H, 5.31; N, 12.3. Found: C, 68.6; H, 5.42; N, 12.2. The X-ray diffraction pattern was [10] 4.25; [9] 5.75; [8] 3.90; [7] 4.60, 4.73; [6] 4.10; [5] 3.55, 3.17; [4] 5.06; [3] 3.26, 2.36; [2] 3.38, 3.44, 3.03; [1] 2.93.

Action of Grignard Reagents on Diimide Dioxides

(*a*) *In the Soltys apparatus.*—N-Methyl-N′-phenyldiimide dioxide was studied by the reported procedure (34) in isoamyl ether with methyl iodide Grignard reagent in the same solvent which was distilled from sodium and then from methyl iodide Grignard reagent under nitrogen. The system evolved gas at 25° C but in order to complete the reaction it was heated by boiling water bath for 10 minutes prior to and 10 minutes after the addition of aniline. The active hydrogen was found to be 0.88 and 1.01 equivalent for two determinations in which "addition" of reagent was 1.66 and 1.59 equivalent. In a separate determination the gas was collected before the addition of aniline and was shown to be methane, free from ethane, by infrared absorption in a gas cell with potassium bromide windows: 3205 (W), 2916 (M), 2814 (S), 2786 (S), 1341 (M), 1328 (M), 1290 (S), 1258 (M), 1023 (M) cm^{-1}. Under comparable conditions the gas from N-methyl-N′-phenyldiimide N′-monoxide did not appear to be evolved at 25° C, and at 100° C it did not exceed 0.3 equivalent, although pyridine was the solvent. N,N′-Dibenzyldiimide

For personal use only.

dioxide (9) in isoamyl ether medium showed 0.7 active hydrogen and 0.3 equivalent of Grignard addition. In the better solubilizing medium, N-methylmorpholine, the active hydrogen was 1.5 and the equivalent of Grignard addition was 1.9. The gas evolved was proved by infrared absorption to be only methane. A simple Zerewitinoff determination in pyridine (finally at 100° C) gave 0.4 active hydrogen. N-Benzyl-N′-phenyldiimide dioxide in isoamyl ether medium showed 0.5 active hydrogen and 0.7 equivalent of Grignard addition, whereas the determination in N-methylmorpholine showed 1.9 equivalent each of hydrogen and Grignard addition. The gas evolved was entirely methane (infrared). A Zerewitinoff determination in pyridine at 100° C showed 0.2 equivalent of active hydrogen.

(*b*) *N,N′-Diphenyldiimide monoxide.*—An ether solution (265 ml, 0.1 *N*, 0.027 mole) of bromobenzene Grignard reagent was added slowly to a solution of N-methyl-N′-phenyldiimide dioxide (2.6 g, 0.0172 mole) in 50 ml of diethyl ether during 150 minutes with constant stirring. Subsequently the system was treated with 100 ml of saturated ammonium sulphate. The ether phase was steam-distilled (0.93 g of unidentified oil in the distillate) and the residue was extracted by diethyl ether. Distillation of this red extract gave a 0.69-g fraction, b.p. 80–120° C (0.6 mm), and a 1.18-g fraction, b.p. 115–130° C (0.6 mm). The latter fraction, crystallized from 4 ml of petroleum ether (b.p. 40–60° C) gave 0.58 g, m.p. 34.5–35.5° C (17%), of diphenyldiimide monoxide identified by mixture melting point (35–36° C) after recrystallization from 4 ml of methanol.

(*c*) *N-Methyl-N′-phenyldiimide N′-oxide.*—Methyl chloride Grignard reagent (185 ml, 0.21 *N*, 0.0389 mole) was added slowly to a stirred solution of 4.2 g (0.0276 mole) of N-methyl-N′-phenyldiimide dioxide in 50 ml of diethyl ether during 3 hours at 20° C. After subsequent decomposition by means of 100 ml of saturated ammonium sulphate a deep-red solid (37 mg, m.p. 126–127° C decomp.) separated from the ether layer. This unidentified solid melted at 140.5° C after crystallization from benzene (60.8% C, 3.70% H). The ether layer was steam-distilled. Ether extraction of the steam distillate removed 2 g of a yellow oil, the higher boiling fraction of which (b.p. 106° C at 1 mm) was 14% of unchanged starting material, m.p. 37–39° C, while the lower boiling fraction gave 0.90 g (b.p. 90–106° C at 16 mm). Crystallization from petroleum ether, b.p. 40–60° C, gave 0.54 g (14%) of N-methyl-N′-phenyldiimide N′-monoxide, m.p. −3 to 0° C. Two similar crystallizations raised this melting point to 6.5–8.5° C, n_D^{20} 1.556. Calc. for $C_7H_8N_2O$: C, 61.7; H, 5.85; N, 20.6. Found: C, 61.9; H, 6.18; N, 20.7. The brown viscous residue from steam distillation (1.27 g) was not identified.

(*d*) *N-Methyl-N′-phenyldiimide.*—To a stirred solution of 180 mg (0.0047 mole) of lithium aluminum hydride in 10 ml of absolute diethyl ether was added 180 mg (0.0013 mole) of N-methyl-N′-phenyldiimide N′-monoxide during 10 minutes. After 35 minutes of subsequent stirring 1 ml of water was added and the system was filtered. The ether extract of the filtrate, dried over magnesium sulphate, was mixed with 3 ml of ether containing 180 mg of anhydrous oxalic acid to give 95 mg, m.p. 138–139° C, of crude methylphenyldiimide oxalate. Two crystallizations from absolute ethanol gave 36 mg (13%), m.p. 145–146° C, which did not depress the melting point of an authentic specimen (35, 36).

(*e*) *N-4-Tolyl-N′-phenyldiimide N′-monoxide.*—To a solution of 3.8 g (0.025 mole) of N-methyl-N′-phenyldiimide dioxide in 50 ml of dry diethyl ether was slowly added during 4 hours at 25° C 200 ml of 0.185 *N* *p*-bromotoluene Grignard reagent (0.037 mole). Then 100 ml of saturated aqueous ammonium chloride solution was added. Evaporation of the separated non-aqueous layer left a red liquid which was steam-distilled. Ether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

extraction of the distillate (250 ml) gave 60 mg of *p,p'*-bitolyl. Ether extraction of the steam distillation residue gave 4.75 g of oil which was distilled, the first fraction (b.p. 100–120° C, 0.5 mm) of which was more bitolyl (total 0.21 g, 6%) identified after methanol crystallization by m.p. and m.m.p., 118–119° C. The higher boiling fraction (2.85 g, b.p. 120–150° C at 0.5 mm) was crystallized from methanol, 2.23 g, m.p. 42–48° C. Two further crystallizations raised the melting point to 50–51° C (1.67 g, 31.5%), and a mixture melting point with an authentic specimen (17) was not depressed. The X-ray powder diagram was [10] 4.35; [9] 3.72; [8] 4.62; [7] 7.49; [6] 3.05; [5] 6.52; [4] 3.15; [3] 5.27; entirely identical with that of the authentic sample but appreciably different from that of N-4-tolyl-N'-phenyldiimide N-monoxide, also prepared by Bigiavi and Sabatelli, [10] 4.67; [9] 3.95; [8] 3.34; [7] 9.34; [6] 3.65; [5] 4.17; [4] 5.34; [3] 5.65; [2] 4.98; [1] 3.49. In a separate experiment the mixture of 0.048 mole of *p*-bromotoluene Grignard reagent and 0.032 mole of the diimide dioxide reacted for 2 hours at 20° C. A Gilman test 1 (37) for excess Grignard reagent was then negative. The red oil obtained after hydrolysis was dried and distilled through a 10-plate column to give 2.04 g, b.p. 40–70° C (756 mm), and 1.65 g, b.p. 70–115° C (756 mm), as well as 5.34 g, b.p. 100–140° C at 10 mm. The first fraction was redistilled, 0.44 g (43%), b.p. 50–60° C, and identified as methanol by its *p*-nitrobenzoate, m.p. and m.m.p. 95–96° C. The second fraction was redistilled, b.p. 100–110° C (756 mm), 0.43 g (12% as toluene) which was converted to 2,4,6-trinitrotoluene, m.p. and m.m.p. 80–81° C for characterization.

(*f*) *N-Benzyl-N'-phenyldiimide N'-oxide.*—The best preparation involved the addition of 100 ml of 0.2 *N* benzyl chloride Grignard reagent in diethyl ether (0.02 mole) to a dioxane solution of N-methyl-N'-phenyldiimide dioxide (1.53 g, 0.01 mole in 50 ml) during 90 minutes. Then 25 ml of saturated aqueous ammonium chloride was added. The white solid which separated was filtered off and its quantity was augmented by chilling the non-aqueous layer at 0° C for 12 hours, 0.54 g (25%) as N-benzyl-N'-phenyldiimide N'-monoxide, m.p. 198–199° C decomp. This melting point was not depressed by admixture with a sample prepared according to Lynch and Pausacker (19). Moreover the X-ray diffraction patterns were identical: [10] 3.90; [9] 5.60; [8] 4.40; [7] 8.98; [6] 4.20; [5] 4.82; [4] 5.40; [3] 3.44; [2] 10.3; [1] 3.66. Calc. for $C_{13}H_{12}N_2O$: C, 73.6; H, 5.70; N, 13.2. Found: C, 73.8; H, 5.34; N, 13.2.

Preparations in diethyl ether alone were less successful. The yield by adding Grignard reagent to an equimolar amount of the diimide dioxide in 65 ml of ether was 10%, which was lowered to 7% by reversing the order of addition, while threefold dilution with consequent longer addition time gave 14% yield. The best yield in diethyl ether (20%) was obtained by adding equivalent amounts at equivalent concentrations of the reagents from two burettes into a tube in which a downward pitched screw conveyed the mixture to a dry-ice-cooled trap within 1 minute of the time of introduction.

The other products of these reactions are of interest. The red oil remaining after evaporation of the filtered non-aqueous part of the hydrolyzate showed at least 6 constituents when examined on a chromatoplate (28). Column chromatography of the red oil on alumina (100–150 mesh activated at 150° C for 10 hours) eluted by benzene gave 3.18 g which was rechromatographed similarly to give 2.74 g that yielded 0.51 g (19%) of bibenzyl (m.p. and m.m.p. 51–52° C) by crystallization from methanol. The methanolic filtrate on treatment with 2,4-dinitrophenylhydrazine reagent gave 0.58 g (m.p. 227–228° C, 7%) of crude benzaldehyde 2,4-dinitrophenylhydrazone, identified by m.p. and m.m.p. (234–236° C) after crystallization from benzene.

Elution of the alumina columns by chloroform gave a liquid (1.99 g) which was crystal-

lized from petroleum ether (b.p. 40–60° C) to give unchanged starting material, m.p. 38–39° C, 1.85 g, 40%, characterized by mixture melting point.

A modification of the preparation of N-benzyl-N′-phenyldiimide N′-oxide was made by filtration of the reaction system. To a stirred solution of 6.1 g (0.04 mole) of N-methyl-N′-phenyldiimide dioxide in 50 ml of absolute diethyl ether was added 0.06 mole of benzyl chloride Grignard reagent (300 ml, 0.2 *N*) during 2 hours. The system was filtered under nitrogen to remove the white precipitate from the ultimately red solution. Hydrolysis of this filtrate by addition of 50 ml of saturated aqueous ammonium chloride gave 3.6 g of viscous oil after drying and evaporation of the ether. Treatment of this oil with 15 ml of hexane precipitated 0.1 g (1.2%) of N-benzyl-N′-phenyldiimide N′-oxide, m.p. 198–199° C after crystallization from toluene, authenticated like the main bulk of this product by mixture melting point and infrared spectra.

The hexane-soluble portion of the oil was chromatographed on alumina to yield by hexane elution 0.6 g (10%) of unchanged methylphenyldiimide dioxide (m.p. 38–39° C) and then by carbon tetrachloride elution 0.1 g (1.3%, m.p. 154–155° C after crystallization from cyclohexane) of benzaldehyde phenylhydrazone, authenticated by mixture melting point and infrared spectra.

The white precipitate from the reaction system was hydrolyzed by treatment with 75 ml of saturated aqueous ammonium chloride. The ether extract of the hydrolyzate, evaporated and then dissolved in hot toluene, yielded 1.2 g (14%) of N-benzyl-N′-phenyldiimide N′-oxide, m.p. 198–199° C. Evaporation of the mother liquors left 4.5 g of unidentified red oil.

Solvolysis of N-Benzyl-N′-phenyldiimide N′-Monoxide

A mixture of 0.5 g (0.00236 mole) of the monoxide and 5 ml of glacial acetic acid (13) was gently refluxed for 15 minutes and then poured into 25 g of crushed ice. The system, neutralized by addition of sodium bicarbonate, was ether-extracted. Evaporation left an oil (0.76 g) from which 0.28 g (42%) of benzaldehyde 2,4-dinitrophenylhydrazone (m.p. and m.m.p. 235–236° C) was isolated by treatment with 2,4-dinitrophenylhydrazine reagent.

Analysis of N-Benzyl-N′-phenyldiimide N′-Monoxide in the Soltys Machine

By the technique used for analysis of methylphenyldiimide dioxide the N-benzyl-N′-phenyldiimide N′-monoxide did not react at all at room temperature; at 100° C it yielded only 0.5 active hydrogen and 0.7 equivalent of addition. Consequently the isoamyl ether was replaced by N-methylmorpholine (dried over solid potassium hydroxide, then barium oxide, and distilled under nitrogen, b.p. 136–136.5° C). In this reaction medium 1.9 equivalent of active hydrogen and 1.9 equivalent of addition were observed, after 20 minutes at 100° C. No gas was evolved at 25° C. A Zerewitinoff determination at 100° C in pyridine showed 0.3 equivalent of active hydrogen.

N′,N′-Methylene-bis-[N-ethyldiimide]tetroxide

A solution of 45 g (0.294 mole) of monoammonium methylene-bis-nitrosohydroxylaminate (1) in 140 ml of 8% aqua ammonia was stirred during 24 hours while 88.5 ml (0.675 mole) of diethyl sulphate was added gradually, the pH being maintained at 8 by addition of more ammonia. The precipitate which was filtered off weighed 8.2 g, m.p. 145° C, after it was dried and washed with chloroform. This 15% molar yield of ammonium N-ethyl-N′-diimidomethylnitrosohydroxylaminate dioxide could be purified by rapid solution in 40 ml of water at 70° C, followed by quick cooling to avoid decom-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

position with evolution of colorless gas. The recovery was 41% of that added, m.p. 150.1–150.6° C decomp., but a second crop, m.p. 149° C, could be obtained by dilution of the liquors with ethanol. Calc. for $C_3H_{11}N_5O_4$: C, 19.8; H, 6.13; N, 38.6. Found: C, 19.9; H, 6.40; N, 38.1.

The reaction liquor from which the ammonium salt precipitated was treated during 7 hours with 50 ml of diethyl sulphate and sufficient ammonia to maintain the pH at 8. The clear solution was then extracted three times with chloroform and these extracts were vacuum evaporated to leave 10 g of gummy solid which was treated with 10 ml of 68% nitric acid. After the strenuous evolution of nitrogen oxides had ceased the hot solution was cooled and neutralized by strong alkali. The crystals (4.4 g, m.p. 75.8–76.3° C) were N′,N′-methylene-bis-[N-ethyldiimide]tetroxide.

This compound also was obtained when 2.96 g (0.014 mole) of the ammonium salt described above was dissolved in 10 ml of water with 12 ml of 10% aqueous sodium hydroxide (0.03 mole) and was treated during 24 hours with 3.9 ml (0.03 mole) of diethyl sulphate. The product (1.3 g) was crystallized from 95% ethanol (1.5 ml per g) 0.68 g, m.p. 78.9° C. More of the same compound was obtained (0.4 g) by concentration of the mother liquors followed by fume-off with hot nitric acid. Calc. for $C_5H_{12}N_4O_4$: N, 29.2. Found: N, 29.6.

The methyl analogue was prepared in the same manner but with less complication because the ammonium salt did not precipitate. Consequently a 33% yield, m.p. 136° C, could be obtained within one day. The X-ray diffraction diagram was [10] 5.88; [9] 3.87; [8] 3.80; [7] 3.12; [6] 3.58; [5] 5.21; [4] 2.60; [3] 3.23; [2] 3.96, 3.35; [1] 2.40, 2.32, 2.36.

N,N′-Methylene-bis-methyldiimide tetroxide, m.p. 136° C, may be crystallized from 70% nitric acid in which it is quite stable, even during several hours at the boiling point of this medium. The density at 20° C of the solid substance is 1.368 (flotation) in comparison with 1.378 calculated from the following X-ray data. The crystal is orthorhombic pyramidal with $a = 14.38 \pm 0.04$ Å, $b = 15.16 \pm 0.04$ Å, $c = 7.16 \pm 0.02$ Å when crystallized from benzene. Reflections (Weissenberg) are found in (*hkl*) only when $h+k$, $k+l$, and $l+h$ are even; in (*hol*) only when $h = 2n$, $l = 2n$, and $h+l = 4n$; in (*okl*) only when $k = 2n$, $l = 2n$, and $k+l = 4n$. Hence the space group is $C_{2\gamma}^{19}(F_{ddm})$. There will be eight molecules per unit cell with a twofold molecular symmetry axis. Since the volume of the unit cell is 1561 Å^3, the total number of electrons is 688. The absorption coefficient for CuK_α radiation is thus 12.6 cm^{-1}.

The crystals are twinned parallel to the *b*-axis and are strongly piezoelectric, indicating lack of centrosymmetry. The refractive indices measured by the crushed crystal technique are $\alpha = 1.38$, $\beta = 1.445$, $\gamma = 1.48$, so $\alpha+\beta+\gamma/3 = 1.44$. A tentative orientation was chosen and structure factors were determined (38).

N,N′-Methylene-bis-[N-β-chloroethyldiimide]tetroxide

A suspension of 2.23 g (0.0146 mole) of monoammonium methylene-bis-nitrosohydroxylaminate in 50 ml of water was treated with water until solution was complete. To this solution was added 4.96 g (0.0202 mole) of silver nitrate in 25 ml of water. The silver salt was filtered off, washed twice with water, and thrice with absolute ethanol. It was then suspended in 30 ml of absolute ethanol and 5.55 g (0.029 mole) of 1-chloro-2-iodoethane was added. After 5 days the silver iodide was filtered off and washed with absolute ethanol. Evaporation of the filtrate left 2.16 g which was treated with 2 ml of 68% nitric acid to destroy the nitroso compounds. After the strenuous reaction had subsided the system was diluted with water and the crystals were filtered off, 1.20 g

For personal use only.

(37%), m.p. 87.8–89.5° C, not raised by crystallization from ethanol (5 ml per g). Calc. for $C_5H_{10}N_4O_4Cl_2$: N, 21.4. Found: N, 21.8.

Bromobenzene Grignard Reagent with Methylene-bis-[methyldiimide]tetroxide

Into 75 ml (0.1375 mole) of bromobenzene Grignard reagent under nitrogen at 0° C was added 3.28 g (0.02 mole) of the powdered tetroxide during 30 minutes with strong gas evolution. The brownish-red system was filtered to remove a gummy mass from which, after hydrolysis, 0.50 g (15%) of the tetroxide was recovered by decomposition of the remainder with 70% nitric acid, m.m.p. 134° C. The filtered reaction mixture was hydrolyzed by 12% hydrochloric acid and the dried non-aqueous layer was distilled, finally at 130° C (20 mm) to remove 2.02 g of biphenyl. Continuation gave a distillate, b.p. 140–240° C (9 mm), which was dissolved in 4 ml of ethanol, 0.71 g, m.p. 126–130° C. This 13% yield of benzophenone phenylhydrazone was twice crystallized from ethanol, m.p. 133–133.5° C, not depressed by admixture with the authentic compound.

Pyrolysis of Methylene-bis-[methyldiimide]tetroxide

The substance decomposed smoothly when 4.92 g (0.03 mole) was heated during 2 hours at 210–220° C. After 15 minutes at 245° C the distillate was converted by means of *p*-nitrobenzoyl chloride to 1.68 g (89%) of the methyl ester. The pyrolysis residue (0.32 g, 93%) was carbon. Analysis of the evolved gas showed that 86% was nitrous oxide.

Qualitative and Quantitative Tests with Methylene-bis-[methyldiimide]tetroxide

A Barger–Rast molecular weight determination in camphor was 163, calc. 164. The substance was unaltered by treatment with acid hydrogen peroxide during 7 hours, and it did not react after 12 hours in methanol with sodium borohydride, but a vigorous reaction occurred with lithium aluminum hydride. However, no products could be isolated from the latter reaction. No reaction occurred with benzaldehyde, *p*-nitrobenzaldehyde, cyclohexanone, urea, but a vigorous reaction occurred with hot phenylhydrazine. No recognizable product was obtained. The alkaline hydrolysis of the tetroxide yielded methanol, formic acid, nitrous acid, and perhaps some hydrogen cyanide either with 30% aqueous sodium hydroxide or with sodium ethoxide.

The active hydrogen determination was carried out in the Soltys machine by the prescribed procedure (34) in isoamyl ether for 20 minutes at 100° C, but it was observed that a precipitate formed immediately upon addition of the reagent and a red solution was formed which faded upon heating. The active hydrogen was found to be 1.9 equivalent. The amount of Grignard reagent which underwent an addition reaction was only 0.1 equivalent, undoubtedly due to the insolubility of the original precipitate from which methane was evolved.

Electrical Polarization Studies

Dielectric constants and specific volumes of either benzene or (in one instance) dioxane solution were carried out as described previously (39, 40) and calculations were made by the method of Halverstadt and Kumler (41). The distortion polarization was determined either from refractive index, additive refractions, or by direct determination with the solid substance (31). Densities were determined by an air-displacement method (30) or by flotation. The results are shown in Table II.

Infrared Spectra

The spectra have been obtained with a Perkin–Elmer 21 spectrometer by Messrs. Bedard and Myers of Canadian Armament Research and Development Establishment,

THE ELECTRONIC STATES OF *CIS*- AND *TRANS*-ACETYLENE[1]

H. HOWARD AND G. W. KING

ABSTRACT

The electronic energy levels of *cis*- and *trans*-bent planar centrosymmetric acetylene molecules, with $\angle CCH = 120°$ and $r_{CC} = 1.383$ Å, have been calculated by the LCAO/-ASMO/CI procedure. The lowest energy state that can spectroscopically combine with the linear ground state is found to be of symmetry class A_u belonging to the *trans*-bent molecule and to lie at 4.58 ev above the ground state. This compares favorably with the experimentally observed electronic transition of lowest energy which is of type $(^1A_u - ^1\Sigma_g^+)$ and at 5.24 ev. The lowest-energy allowed transition to a *cis*-bent state of these dimensions is at 9.39 ev, and hence this may not form part of the unanalyzed system of bands in the 2000–1500 Å region, as has been suggested. However, a transition to a *trans*-bent state of type $(^1B_u - ^1\Sigma_g^+)$ is predicted to fall in this region. The energies of other electronic states are discussed in relation to the observed absorption systems of acetylene.

INTRODUCTION

The molecular orbitals method has been successful in predicting the geometry and energy of electronic states of simple and highly symmetric molecules. Such orbitals are commonly constructed by linear combination of appropriate atomic orbitals (LCAO/MO method). Qualitative, empirical extensions to more complex systems have been made in which the stereochemistries of electronically excited molecular states are also considered; in papers on this subject by Walsh (1) and Mulliken (2) the acetylene molecule is considered in some detail as an example. It is known experimentally (3, 4) that the absorption bands of acetylene in the 2400–2000 Å region are due to a transition from a linear ground state of $^1\Sigma_g^+$ symmetry, with $r_{CC} = 1.202$ Å, to a *trans*-bent planar excited state of A_u electronic symmetry (point group C_{2h}) with $r_{CC} = 1.383$ Å and $\angle CCH = 120°$. Thus the excited molecule resembles an ethylene molecule with two *trans* hydrogen atoms missing.

We report, in this paper, the results of calculations of the electronic energy levels of *cis*- and *trans*-bent planar acetylene molecules, belonging to symmetry point groups C_{2v} and C_{2h} respectively, both with the same carbon–carbon bond length as in the A_u state above and with 120° carbon–hydrogen bond angles. Insofar as the approximations which it has been necessary to make are valid, the calculations reveal patterns of energy levels that are helpful in identifying further optical transitions involving bent excited states and which enable comparisons to be made with the predictions of Walsh and Mulliken. Ross (5) has already calculated the energy levels of the linear molecule by a similar method, and by using his values a comparison can be made between the experimental and theoretical energy of the $(^1A_u - ^1\Sigma_g^+)$ transition. This is of especial interest, since the latter quantity is a difference in energies obtained from independent calculations on two models of quite different geometry and electronic structure, and hence this provides a stringent test of the accuracy of these methods of calculation.

THEORY

The basic LCAO/MO procedure is well known (see 6, 7) and is presented in outline here to illustrate its application to this problem.

We consider specifically N of the electrons in a molecule; these may be all the electrons

[1]*Manuscript received December 22, 1958.*
Contribution from the Burke Chemical Laboratories, Hamilton College, McMaster University, Hamilton, Ontario.

or a certain fraction of these, called "valence electrons" which are significantly disturbed by light absorption or change in geometry. An orthonormal set of single-electron molecular wave functions $\phi_\nu(\mathbf{r}_\nu)$ are constructed, $\mathbf{r}_\nu$ being the position vector of the νth electron. 2^N possible determinantal antisymmetrized product (ASMO) wave functions, each satisfying the Pauli principle, can be constructed for the N-electron system. These have the normalized form.

$$\Phi_p = (N!)^{-\frac{1}{2}} |\phi_0(q_0)\ \phi_1(q_1) \ldots\ldots \phi_N(q_N)| \quad [1]$$

where only terms in the leading diagonal are written between bars. q_ν is a scalar product of $\mathbf{r}_\nu$ with basic spin vectors α or β.

Suitable linear combinations of the functions [1] can be classed as eigenfunctions of the squared spin angular momentum operator S^2;

$$\Omega^S = \sum_{q,p} a_{q,p}\, \Phi_p^S \quad [2]$$

where the a's are coefficients.

The total Hamiltonian operator H for the N-electron system may be written

$$H = H^\circ + \sum_{\nu \neq \mu}^{N} e^2/r_{\nu\mu} \quad [3]$$

where

$$H^\circ = \sum_{\nu=1}^{N} H^\circ_\nu(\mathbf{r}_\nu),$$

$H^\circ_\nu(\mathbf{r}_\nu)$ being the single-electron operator for the νth electron in a potential field due to the nuclei plus non-valence electrons, and the second term in [3] represents the inter-electronic repulsion between the valence electrons. We seek the best approximations to the eigenvalues E_k of H in the variational form

$$\int \Psi_k^{S*} H\, \Psi_k^S\, d\tau \quad [4]$$

for the lowest energy state and states orthogonal to this, where in general the Ψ_k are combinations of the linearly independent AP Ω^S; in practice a finite number m of these are taken in each combination.

$$\Psi_k^S = \sum_m b_{km}\, \Omega_m^S. \quad [5]$$

The MOs ϕ_i are each generally formed by linear combination of some n AOs,

$$\phi_i = \sum_n c_{in}\chi_n. \quad [6]$$

The LCAO/SCF method (8) is an iterative process for evaluating [4]; the coefficients c_{in} in [6] and an effective Hamiltonian H^* in [4] are varied to minimize the energy, subject to retaining orthonormality of the MOs. This method is most readily applied when Ψ_k consists of a single AP Φ_p, such as in ground-state closed-shell molecular configurations; it gives a good approximation to the best MOs for such states.

In the alternative LCAO/MO/CI procedure used here, approximate MOs are constructed from analytic AOs in equation [6], and the best Ψ_k of type [5] determined variationally. Large determinantal secular equations are obtained, which can generally be factored into blocks along the leading diagonal if the molecule has symmetry and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

ϕ_t are constructed so as to transform like irreducible representations of the appropriate symmetry point group.

The single-electron form of H° in [3] and the orthogonality of the ASMO Φ_p in [1] lead to elements of type

$$E_l' = \int \Omega_l^{S*} H \, \Omega_l^S \, d\tau \qquad [7]$$

along the principal diagonals of the secular determinants; these are first approximations to the eigenvalues of H, and the simple LCAO/MO treatment consists in evaluating these. The E_l' are necessarily approximate because the ASMO functions employed are, in general, only approximations to exact wave functions. This is corrected by introducing Configuration Interaction (CI), this term being applied when the off-diagonal elements of the secular determinants, of form

$$\int \Omega_l^{S*} \left| \sum_{\nu \neq \mu}^{N} e^2/r_{\nu\mu} \right| \Omega_m^S \, d\tau, \qquad [8]$$

are evaluated and the eigenvalues of H are obtained by solution of the full secular determinants.

The integrals [7] and [8] can all be evaluated by standard methods (9).

APPLICATION TO ACETYLENE

In linear acetylene, six electrons constitute the carbon–carbon bond; excitations of either one or two of these give rise to the energetically low excited states (5). In the approximation used here, the corresponding set of six electrons in the *cis*- and *trans*-bent molecules were taken as valence electrons. Of the remaining eight, the carbon 1*s*-electrons were taken merely to screen their respective nuclei, reducing the net charge to $+4e$; the hydrogen atoms and their electrons were neglected (see (5) for comments on the validity of this approximation; a similar justification should apply here). Exchange and repulsion effects between the valence electrons and those contributed by each carbon atom to a carbon–hydrogen bond were included in the calculation.

Apart even from non-planar states of acetylene, there are an infinite possible number of geometrical configurations for planar states, with different combinations of bond lengths and angles. The only geometric data available for a bent state are those for the *trans*-bent A_u state (3, 4) and were used as a basis for our calculations. In both the *cis*- and *trans*-bent models, the carbon–carbon bond length was taken as 1.383 Å, and sp^2-hybridized carbon atomic orbitals were used in forming the molecular orbitals, the hydrogen atoms being formally attached at C–C–H angles of 120°. The use of these specific dimensions does not restrict the applicability of the results as much as would appear at first sight, since what is essentially a 3-electron carbon–carbon bond in the A_u state, similar to that found in benzene, recurs in other excited configurations. In any case, for other electronic states with different actual dimensions, these calculations give excitation energies to such vibronic energy levels as have approximately the dimensions used here, in accordance with the Franck–Condon principle.

Real, normalized Slater AOs were used for the carbon $n = 2$ atomic orbitals, of form:

$$\begin{aligned} a_s &= (\delta^5/3\pi)^{\frac{1}{2}} r_a \exp(-\delta r_a) \\ \left.\begin{aligned} a_x &= \\ a_y &= \\ a_z &= \end{aligned}\right\} & (\delta^5/\pi)^{\frac{1}{2}} r_a \exp(-\delta r_a) \left\{\begin{aligned} x_a \\ y_a \\ z_a \end{aligned}\right. \end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

centered on each of the carbon atoms a and b. The z-axes on each atom projected towards each other, and the x-axes were perpendicular to the molecular plane. δ was assigned the value 1.59.

The a_s Slater function is nodeless; a better form for the $2s$ orbital is one that is orthogonal to the corresponding $1s$ orbital;

$$a_s^\circ = (a_s - 0.21284\, a_{1s})/0.9771.$$

This form was used in evaluating all mononuclear integrals in which the $2s$ orbital occurred, for which it gives significantly improved values. The sp^2-hybridized AOs were:

$$\chi_1 = (3)^{-\frac{1}{2}}(a_s + 2^{\frac{1}{2}}a_z) \qquad \chi_2 = (3)^{-\frac{1}{2}}(b_s + 2^{\frac{1}{2}}b_z)$$
$$\chi_3 = a_x \qquad \chi_4 = b_x$$
$$\chi_5 = 3^{-\frac{1}{2}}a_s - 6^{-\frac{1}{2}}a_z - 2^{-\frac{1}{2}}a_y \qquad \chi_6 = 3^{-\frac{1}{2}}b_s - 6^{-\frac{1}{2}}b_z \mp 2^{-\frac{1}{2}}b_y$$
$$\chi_7 = 3^{-\frac{1}{2}}a_s - 6^{-\frac{1}{2}}a_z - 2^{-\frac{1}{2}}a_y \qquad \chi_8 = 3^{-\frac{1}{2}}b_s - 6^{-\frac{1}{2}}b_z \pm 2^{-\frac{1}{2}}b_y$$

where the orbitals χ_7 and χ_8 were taken as pointing towards the hydrogen atoms, the upper and lower signs referring to *trans-* and *cis*-states respectively. The sets of LCAO/MOs constructed from these AOs which span the irreducible representations of point groups C_{2h} and C_{2v} are shown in Table I, together with their appropriate symmetry representations.† The N_i are normalizing factors.

TABLE I

LCAO/MOs for *cis-* and *trans*-bent acetylene

MO	Description	Symmetry classification C_{2v}	Symmetry classification C_{2h}
$\phi_0 = (2N_0)^{-\frac{1}{2}}(\chi_1+\chi_2)$	$(\sigma_g.2sp^2)$	a_1	a_g
$\phi_1 = (2N_1)^{-\frac{1}{2}}(\chi_3+\chi_4)$	$(\pi_u.2p)$	b_2	a_u
$\phi_2 = (2N_2)^{-\frac{1}{2}}(\chi_5-\chi_6)$	$(2sp^2)$	b_1	b_u
$\phi_3 = (2N_3)^{-\frac{1}{2}}(\chi_5+\chi_6)$	$(2sp^2)$	a_1	a_g
$\phi_4 = (2N_4)^{-\frac{1}{2}}(\chi_3-\chi_4)$	$(\pi_g.2p)$	a_2	b_g
$\phi_5 = (2N_5)^{-\frac{1}{2}}(\chi_1-\chi_2)$	$(\sigma_u.2sp^2)$	b_1	b_u

ϕ_3^* (*cis*) $= 1.0005(\phi_3 - 0.09602\,\phi_0)$.
ϕ_3^* (*trans*) $= 1.0061(\phi_3 - 0.10972\,\phi_0)$.
ϕ_5^* (*cis*) $= 1.0481(\phi_5 + 0.29939\,\phi_2)$.
ϕ_5^* (*trans*) $= 1.03628(\phi_5 + 0.26228\,\phi_2)$.

The MOs ϕ_0 and ϕ_3, also ϕ_2 and ϕ_5, belong to the same symmetry species in both *cis-* and *trans*-models and are not orthogonal to each other. Properly orthogonal forms of ϕ_3 and ϕ_5 are shown starred at the bottom of Table I. The lack of orthogonality between ϕ_0 and ϕ_3 is small, and could be ignored in many parts of the calculation; but the orthogonalized forms of ϕ_3 were used, for example, in calculating the orbital energies ϵ_3 described below. The orthogonalized ϕ_5^* orbitals were used throughout in evaluating integrals. The description in the table indicates the AOs from which the MOs are formed, and also the corresponding MOs of the linear molecule. This description will be retained for convenience in discussing ϕ_3^* and ϕ_5^* orbitals.

AP wave functions were constructed in determinantal form [1] from these MOs by the principles outlined in the previous section: these could be classified according to the

†*Detailed character tables, tables of direct products, and correlations between representations of these groups for acetylene are given in reference (3), p. 2711. Walsh (1) makes a slightly different classification of the C_{2v} species: as a result his symmetry species b_1 and b_2 are interchanged with respect to these used here. Where Walsh's conclusions are mentioned (see discussion, later) his symbols are changed to accord with the definitions used here, which appear more generally accepted in the literature: see (10).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

symmetry of the occupied MOs under the appropriate point groups. Only combinations corresponding to singlet states were used as Ω functions [2]. Then the integrals [4] break down into sums of integrals over electrons in MOs, of form

$$\text{"Orbital Energy"} \quad \epsilon_a = \int \phi_a^*(\nu)[H^\circ_\nu(\mathbf{r}_\nu)]\phi_a(\nu)\, d\tau_\nu$$

$$\zeta_{bd}^{ac} = \iint \phi_a^*(\nu)\,\phi_b^*(\mu)[e^2/r_{\nu\mu}]\phi_c(\nu)\,\phi_d(\mu)\, d\tau_\nu\, d\tau_\mu.$$

The former type of integral only arises in evaluation of the diagonal elements of the determinants. The latter type can be expanded into sums of integrals over AOs. These were evaluated independently from the tables of Kotani (11) and Kopineck (12) by five-point Lagrangian interpolation, the separate values being in excellent agreement. Certain mononuclear integrals were obtained from formulae given by Barnett and Coulson (13) and Roothan (14).

The orbital energy integrals ϵ_a require special mention. Their evaluation is discussed in detail by Ross (5) in an appendix to his paper. The operator involved can be split into two parts,

$$H^\circ_\nu = T^\circ_\nu + U^\circ_\nu.$$

U°_ν is the potential energy operator for the νth electron and contains terms representing nuclear attraction and exchange and repulsion with the carbon–hydrogen bond electrons. The evaluation of integrals over this operator is straightforward, since each integral splits up into a sum of integrals over AOs, and these are all to be found in the tables referred to above. However, as Ross shows, it is not easy to get satisfactory values for integrals involving the kinetic energy operator T°_ν when analytic Slater atomic orbitals are used, even when these are in properly orthogonalized form. Here we did not explicitly evaluate the kinetic energy integrals, but took the kinetic energies of 2*s*- and 2*p*-electrons to be equal in Slater AOs. Such an assumption is merely the most reasonable one to make in the circumstances; it is admitted that a different choice of kinetic energies could alter the final energy levels by some 2- or 3-electron volts. However, it enabled immediate comparison to be made with the results of Ross for the linear molecule; and since in this comparison only differences in energies are involved, there is some cancellation of such errors in the same direction as may be introduced by our assumption.

For each of the four symmetry classes of both *cis*- and *trans*-acetylene the necessary matrix elements were calculated between the ground state and between all excited states which differed in configuration from the ground state in the assignment of either one or two electrons, and which had energies lying, in first approximation, within approximately 50 ev of the ground state. The calculations were pursued in duplicate, by each author, to minimize error. Eight large determinantal equations were obtained, of orders ranging between 10 and 14. The lower roots of these were obtained using a Bendix D-15G digital computer, for which a subroutine for evaluating matrices by diagonalization was available. The computer was programmed to substitute series of possible values for the roots in the equations and evaluate the resultant matrices. Graphical interpolation gave the roots as values where the matrix equalled zero. While mathematically inelegant, this method can be recommended for speed and simplicity.

RESULTS

The calculated energies of the lower electronic states of *cis*- and *trans*-bent acetylene are given in Tables II and III. All values are relative to the energy of the ground $^1\Sigma_g^+$

state of the linear molecule, obtained by recalculation from the figures of Ross.* The energies "no CI" and "CI" are relative to Ross' corresponding 6-electron calculation results. Allowance has been made for the change in nuclear repulsion energy in going from the linear to the bent carbon–carbon nuclear separation.

TABLE II

Calculated energy levels for *trans*-bent acetylene

Symmetry	Configuration	Energy levels

B_1	$(a_1\sigma_g 2sp^2)(b_2\pi_u 2p)^2(b_1 2sp^2)(a_1 2sp^2)^2$	20.87	22.23

In general, the off-diagonal elements in the secular determinants are small compared to the E_i'; consequently, single configurations [2] dominate in most excited states after applying CI, and the simple MO description in the tables for the electronic states can be retained. Extensive configurational mixing does occur in the lowest electronic states of B_1 and B_u symmetry, leading to considerable depression of energy after CI. Here the MO description is not accurate but is retained for convenience.

The treatment only gives approximate energies for higher electronic states of a given symmetry class, but these could be readily calculated from the secular determinants, and some are included in the tables. The results are shown graphically in Fig. 1, which also shows the lower linear state energy levels calculated by Ross. The left-hand side shows the levels before, and the right-hand side after, CI is applied.

Experimentally, the lowest energy transition observed in absorption for gaseous acetylene is that mentioned in the Introduction, a $(^1A_u - {}^1\Sigma_g^+)$ transition at 5.24 ev (3, 4). The calculated energy of 4.58 ev compares favorably with this; furthermore, these calculations agree that a ^1A_u *trans*-bent state is the lowest to which transition is allowed from the ground state. The MO description for this ^1A_u state agrees with that predicted by

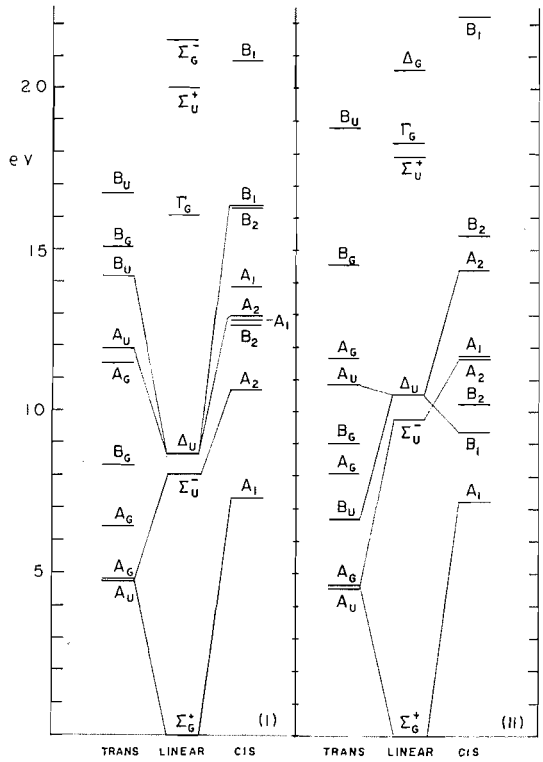

FIG. 1. Energy levels for bent and linear acetylene (i) before CI, (ii) after CI. Correlations are shown here between the lower energy states.

Ingold and King (3) from general valency arguments, by Walsh (1) from MO correlation diagrams, and by Mulliken (2) from analogy with the electronically similar nitrogen and carbon monoxide molecules. However, Walsh correlates this state with a linear Δ_u state; Fig. 1 shows correlation with a linear Σ_u^- state, which is lower in energy than Δ_u according to Ross; this order is preferred by Mulliken.

Acetylene exhibits complex absorption in the 2000–1550 Å region, which is especially intense and of different appearance below 1725 Å (15), indicating the presence of an additional electronic transition here. The bands in this region have not been analyzed: however, Wilkinson (16) has found that discrete absorption bands in the 1520–1280 Å region can be assigned to two Rydberg transitions and two transitions to excited states called *B* and *C*, both of the latter lying some 9.2 ev above the ground state and being *trans*-bent, their band structure being similar to that for the $(^1A_u{-}^1\Sigma_g^+)$ transition mentioned above. There is also some evidence that state *C* is planar and state *B* nonplanar.

Electronic transitions from the ground state to planar, *trans*-bent A_u and B_u states are allowed; the former being a perpendicular-type transition, the latter possessing both perpendicular and parallel components. The calculated $(^1B_u{-}^1\Sigma_g^+)$ transition energy is 6.70 ev; this would correspond to absorption in the 2000–1550 Å region. Wilkinson, following Mulliken's predictions of a ^1B_u state at 8.6 ev, discusses its identification with his '*B*' state, but finds an insufficiency of parallel bands in the spectrum to justify this assignment. We suggest that the $(^1B_u{-}^1\Sigma_g^+)$ transition is responsible for the strong

For personal use only.

absorption around 1725 Å, and that much of the absorption around 2000–1800 Å is due to the tail of the lowest (^1A_u–$^1\Sigma_g^+$) transition, which, on Franck–Condon grounds, has an intensity maximum in this region. It is possible that Wilkinson's state *B* may correlate with some planar state which cannot formally combine with the ground state, such as the A_g state at 8.1 ev; when this is bent out of plane (coming under symmetry class '*A*' of the C_2 point group) it can combine with the ground state in a perpendicular-type transition. However, the observed high absorption coefficient does mitigate this possibility. The lowest allowed transition to a *cis*-state is calculated to be ($^1B_1$–$^1\Sigma_g^+$)* at 9.4 ev, and although it must be remembered that this figure does not necessarily correspond to the electronic origin of a transition, it is rather high to be used to explain the 2000–1550 Å absorption as due to transition to a *cis*-state.

QUANTITATIVE GAS CHROMATOGRAPHY OF REACTION PRODUCTS FROM THE CATALYTIC OXIDATION OF ETHYLENE[1]

C. H. AMBERG, E. ECHIGOYA,[2] AND D. KULAWIC

ABSTRACT

A simple two-stage gas chromatograph is described which employs only one detector for both effluent streams. It was designed specifically for the routine quantitative analysis of mixtures of ethylene oxide, carbon dioxide, and ethylene in the presence of water vapor and a large excess of air, and for concentrations down to 0.2% by volume of individual components.

INTRODUCTION

The routine quantitative analysis of products from the catalytic oxidation of ethylene is of considerable interest in this laboratory for operations both on the bench and pilot plant scale. It was desirable, in particular, to evolve a method by which both the selectivity of the catalyst and the total conversion of ethylene could be computed exclusively from the analytical data furnished by one gas sample. The indirect titration methods frequently employed for the analysis of ethylene oxide and carbon dioxide (following absorption in Lubatti's reagent and sodium hydroxide, respectively) have disadvantages in that they are not suitable for low gas concentrations and in that two separate gas samples have to be collected. Moreover, information about two components only is thus obtained.

A two-stage gas chromatographic apparatus has been constructed which is able to analyze quantitatively the amounts of ethylene oxide, carbon dioxide, and ethylene in a 10-cc sample of moist air. Analysis on a single column and at invariant temperatures has not proved feasible, chiefly because of the generally high retention time of ethylene oxide and water relative to that of air, carbon dioxide, and ethylene.

EXPERIMENTAL

Apparatus

The apparatus was modelled on that of Simmons and Snyder (1) in which two chromatographic columns could be run alternately in series and in parallel. The flow scheme in the present instance was rearranged so as to enable the effluent from both columns to be detected by one thermal conductivity cell only (see Fig. 1). Column lengths and flow rates were adjusted so that peaks passing through opposite sides of the cell K would not interfere with each other. By reversing the polarity of the bridge output at appropriate times, all recorded peaks were made to point in the same direction.

The columns were made of $\frac{1}{4}$-in. coiled copper tubing. Column 1 was 15 ft long and packed with 32.8 g of *n*-octadecane supported on Celite 545 in the ratio 40:100 w/w. The Celite had been size-graded by flotation as described by James and Martin (2). Celite is to be preferred to firebrick, because it was found to cause less tailing of the ethylene oxide bands. Column 2, 7.5 ft in length, was packed with 27.1 g of 35- to 80-mesh silica gel (Davison No. 12).

Helium was used as the carrier gas at an inlet pressure of 31 p.s.i.g.; it was first led through a silica gel drying column. Both streams were vented to the atmosphere at the rate of 90 cc/min as measured by the soap film method. The accuracy of these measure-

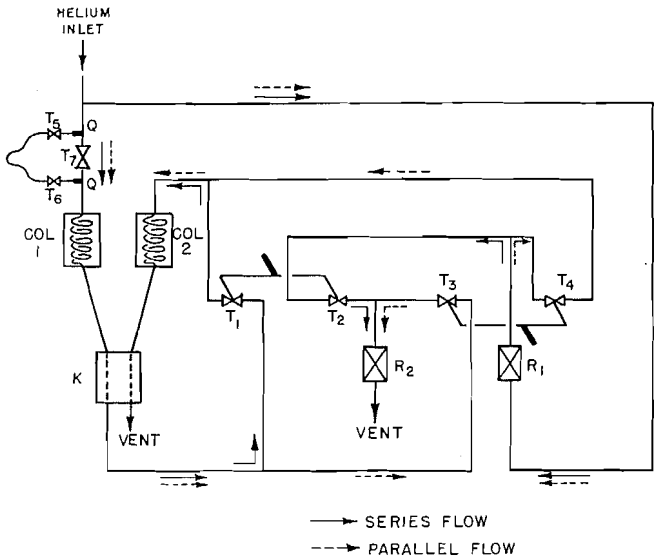

FIG. 1. Schematic flow diagram.

ments was ±0.5%. However, to adjust the dummy flow resistances, needle valves R_1 and R_2 (1), it was found more expedient to employ a Fisher and Porter Flowrator. This resulted in possible 1–2% differences in flow rate between the two streams, still sufficient to give a base line change of no more than 10 μv on changing the flow pattern from series to parallel flow.

A thermal conductivity cell (Gow-Mac Co., Model 9285) served as the detector, K, in conjunction with a recording potentiometer that could be attenuated from 20 mv to 1 mv full scale deflection. A bridge current of 200±0.2 ma was maintained with a 6-v lead storage battery.

The assembly also included Hoke toggle valves T_1 to T_4, which were joined by handles as indicated by the "double pole switches" in Fig. 1. This facilitated the instantaneous change of flow pattern.

Samples were introduced by means of a calibrated 10-cc doser. This consisted of a ¼-in. copper U-tube furnished with toggle valves T_5 and T_6, and a pair of bayonet fittings (Crawford Co., Swagelok), which enabled the doser to be inserted into the gas stream across bypass valve T_7.

The whole unit with the exception of the doser was constructed to fit into a water bath, 1 ft deep by 1 ft in diameter; this was thermoregulated at 30±0.05° C. Figure 2 gives a general view of the apparatus. Temperature and pressure regulating devices are not shown. Additional needle valves, not included in Fig. 1, simply serve to isolate the unit during shutdown. The two glass fittings at the vents on the left can be connected to flowmeters; a Flowrator is shown in position in one of them.

Procedure

To analyze a sample, the doser is evacuated and then flushed with reactor gas. Before insertion, the open ends at T_5 and T_6 must be pumped free of sample, since the calibrated volume is contained between T_5 and T_6. The introduction of an additional volume of air is of no consequence, but the volume of atmospheric carbon dioxide contained therein appears as a positive intercept on the peak height axis of the calibration curve (*v.i.*).

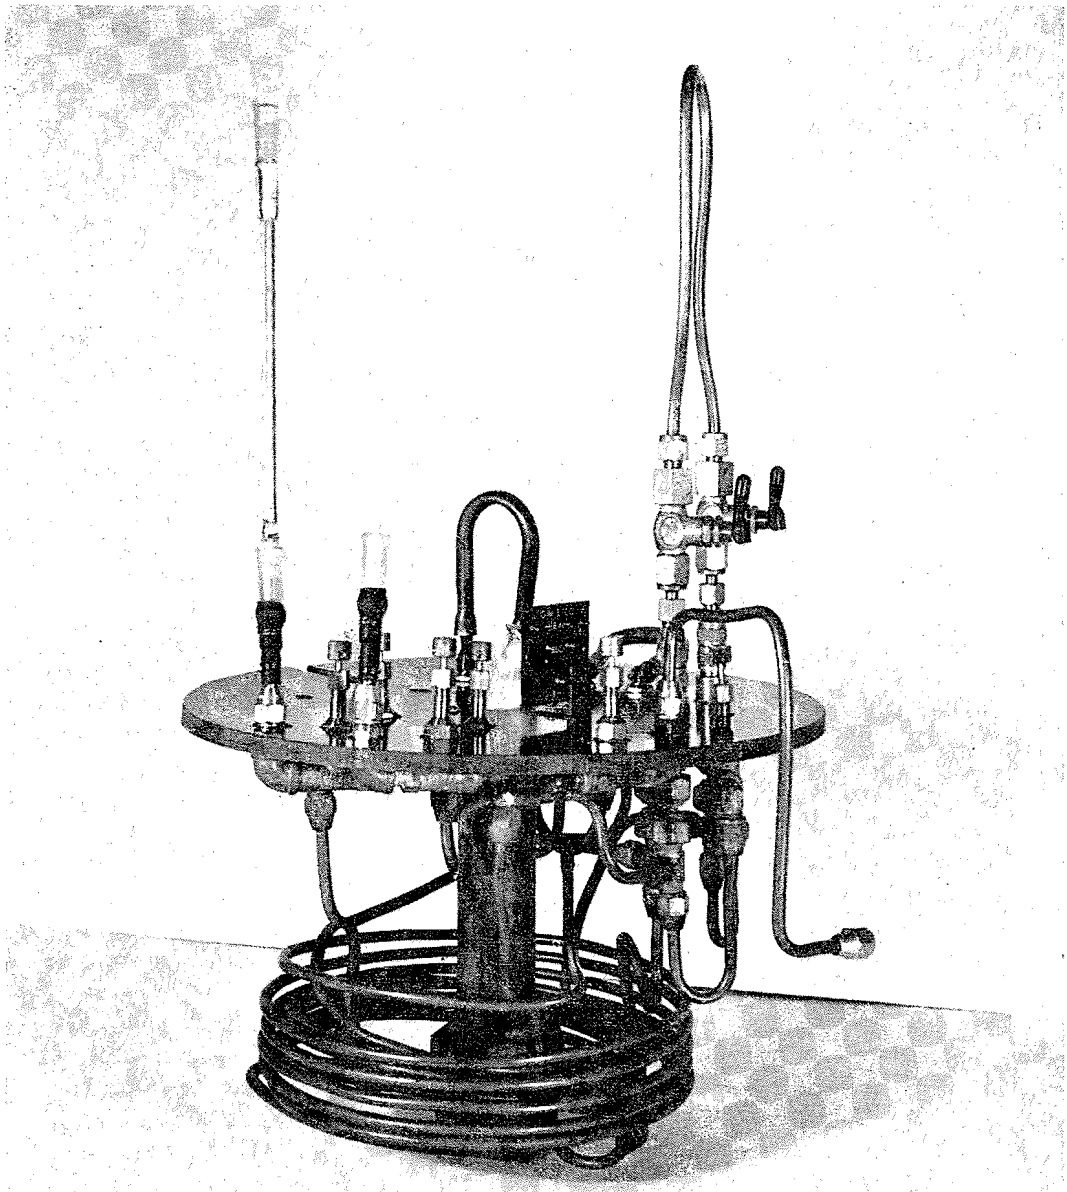

FIG. 2. View of the apparatus.

The sample is introduced with the instrument set for series flow. After 5.5 minutes the flow pattern is switched to parallel flow. At this point ethylene oxide and water are still partitioning in column 1, while carbon dioxide and ethylene are partitioning in column 2, the air having already passed through both columns and out to atmosphere.

Ethylene oxide is now recorded. It is followed by a clearly delineated water front. No

For personal use only.

attempt was made to evaluate water quantitatively because of poor and irreproducible peak formation. Both vapors are vented without entering the silica gel column; this is an essential step, since they would otherwise contaminate the gel.

After reversal of the polarity of the bridge output, carbon dioxide and ethylene elute from column 2 and are recorded. Under the conditions indicated it takes 25 minutes to complete a run.

Calibrations

Calibrations were performed with the separate gases by means of four open-ended pipettes ranging from 0.078 to 0.72 cc in volume. These consisted of different lengths of 2-mm steel tubing soldered onto hypodermic syringe needles. They were flushed with the gas to be calibrated, closed at one end with a finger, and inserted into the evacuated doser through a rubber serum cap. Finally, air was allowed to flush the remaining gas into the doser. Corrections to normal pressure and a convenient standard temperature had to be applied.

This relatively simple method has not been used before to our knowledge; we feel, therefore, that its reliability merits discussion in some detail. Table I shows the results of calculating the best straight line by the method of least squares. The precision of the slopes and intercepts was calculated at the 95% confidence level.

TABLE I

Linear calibrations (peak height vs. gas volume)

Gas	Approx. sensitivity, moles/mv $\times 10^6$	Confidence limit,* ±%	Intercept, cc	Confidence limit,* ±cc
C_2H_4O	4	0.4	0.0038	0.0018
CO_2	8	0.8	−0.014	0.0037
C_2H_4	11	0.6	0.0012	0.0027

*At the 95% level.

The two main sources of error during calibration are probably loss by diffusion from the needle during transfer and loss through incomplete transfer into the calibrated part of the doser. The first of these was calculated to be about 0.001 cc/sec, 1 second being the approximate maximum time of transfer. The other factor was of the same order of magnitude or less, as established by separate experiments.

Loss errors of this type to some extent invalidate the use of the method of least squares which is based on random distribution of errors. For this reason the calibration line for ethylene oxide was recalculated using highest values only. This changed the value of the slope by less than one part in 10^4 and reduced the intercept by 0.001 cc, neither change being significant.

It is possible that all calibration lines were slightly curved (3), the degree of curvature being reflected in part by the confidence limits in Table I. For ethylene oxide and ethylene satisfactory results were obtained by assuming linear relationships and by drawing a parallel line through the origin, i.e. assuming the intercepts to be due to calibration losses only. For ethylene, at any rate, a zero intercept fell within the calculated limits.

The curvature of the carbon dioxide line was somewhat more marked. Also, the negative intercept was too large to be accounted for by atmospheric carbon dioxide alone. Hence, a calibration curve was obtained graphically and fitted by a quadratic equation. The resulting intercept of −0.0036 cc agreed closely with blank determinations using atmospheric air. The final curve had to be corrected for the atmospheric carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

dioxide contained in the calibrated volume of the doser.

Calibrations were frequently checked using one pipette only. After a shutdown, 3–5% drifts in the slopes towards equilibrium values were found over as much as a 2-day period, after which sensitivities remained steady within 1%.

The instrument has been in use for approximately seven months with its original columns, during which time over 1000 runs have been carried out. It was found beneficial to purge the columns every 6–8 weeks at 50–60° C for several hours. Although there is some uncertainty regarding the initial period, no significant deterioration has been observed over the past 5 months. Variations in the final sensitivity value, once stability had been reached after a new start, were found to be about ±3%.

Performance

The best way to evaluate the accuracy of the apparatus was to analyze synthetic mixtures of ethylene oxide, carbon dioxide, and ethylene. A conventional B.E.T. apparatus was used to measure out the gas volumes into a 1-l. calibrated bulb. Air was admitted at atmospheric pressure and the mixture displaced from the bulb by mercury.

Table II shows a series of such tests in the order in which they were carried out. It is believed that deviations here were due to experimental errors in measuring out the gas mixtures at least as much as they were due to fluctuations in the analyzer. This is borne out by the following observations.

(1) Agreement was excellent where only one gas was handled. With increasing experience this was equally true for two gases, but some deviations occurred when three gases were involved.

(2) To exclude any possibility of mutual interference, separate tests were made during calibrations with a pipette. No sign of interference was discovered. Therefore, although no unambiguous standard was available with an accuracy known to be substantially higher than that expected of the analyzer, we estimate an approximate accuracy of ±5%, where the gas concentrations are in the 0.2 to 0.3% region. This will improve to at least ±2% for concentrations of 1% and higher.

TABLE II

Analysis of synthetic mixtures

Finally, inspection of Table III will give some indication of the precision of the apparatus in the analysis of reactor gas. To make this as unbiased a selection as possible, *all* the results of an arbitrary, continuous 30-day period are given for those cases where more than one analysis had been carried out for a given set of reaction parameters. Each of the nine runs shown was done on the same bench reactor under different conditions. It should be noted that most of the ethylene oxide concentrations in the table are near the lower limit considered practicable for our instrument in its present form.

TABLE III

Analysis of the products from a bench reactor

Run	Interval between samples, hours	% Composition		
		C_2H_4O	CO_2	C_2H_4
A	0	0.26	0.36	4.32
	1	0.26	0.37	4.38

	2	0.22	0.34	2.46
	1	0.23	0.33	2.49
D	0	0.17	0.29	2.73
	19	0.16	0.26	2.72
E	0	0.27	0.40	4.42
	2.5	0.26	0.41	4.49
F	0	0.26	0.36	5.60
	1	0.24	0.35	5.56
G	0	0.26	0.46	5.94
	1	0.26	0.44	6.00
	17	0.25	0.39	6.01
H	0	0.25	0.41	4.41
	18	0.24	0.42	4.38
I	0	0.28	0.52	2.50
	18	0.31	0.52	2.56

Again, it is difficult to assign responsibility for the fluctuations in the results. Undoubtedly some are due to variations in reactor conditions, as is suspected, for instance, in run G. At any rate, they allow approximate outside limits of repeatability to be estimated. These limits are at least equal to, and probably somewhat better than, the expected limits of accuracy specified above.

ACKNOWLEDGMENT

The authors wish to thank Mr. W. Thayer for valuable help in the construction of the apparatus and, in particular, for suggesting the use of bayonet fittings for sample introduction.

THE SURFACE ENERGY OF TOBERMORITE[1]

STEPHEN BRUNAUER, D. L. KANTRO, AND C. H. WEISE

ABSTRACT

The total surface energy (or surface enthalpy) of a calcium silicate hydrate, tobermorite, having the composition of $Ca_3Si_2O_7 \cdot 2H_2O$, was determined at 23.5° C. The tobermorite was obtained from the room-temperature hydration of tricalcium silicate, Ca_3SiO_5, or β-dicalcium silicate, β-Ca_2SiO_4, two of the most important constituents of portland cements. The hydration reactions were carried out in three different ways, and 14 preparations were obtained. For each preparation the heats of solution in a mixture of nitric acid and hydrofluoric acid were measured at 23.5° C, and the surface areas were determined by the B.E.T. method, using water vapor at 25° C as the adsorbate. The cross-sectional area of the adsorbed water molecule was taken to be 11.4 Å^2. The surface energy of tobermorite at 23.5° C was found to be 386 ± 20 ergs/cm^2. It is close to the geometric mean of the surface energies of calcium hydroxide and hydrous amorphous silica, previously reported.

Nitrogen adsorption did not measure the true surface area of most tobermorite preparations. This was indicated by negative surface energy values in a number of instances.

INTRODUCTION

Tricalcium silicate and β-dicalcium silicate are two of the most important constituents of portland cement, together making up about three-fourths of a portland cement by weight. In experiments reported earlier (4, 5, 8) the two silicates were hydrated at room temperature by three methods: (*a*) in a small steel ball mill, (*b*) in paste form, and (*c*) in a polyethylene bottle rotated on a wheel. The stoichiometry of the hydration of β-dicalcium silicate by all three methods was represented by the equation

$$2\beta\text{-}Ca_2SiO_4 + 4H_2O = Ca_3Si_2O_7 \cdot 3H_2O + Ca(OH)_2 \quad [1]$$

and the stoichiometry of the hydration of tricalcium silicate by methods (*b*) and (*c*) was represented by the equation

$$2Ca_3SiO_5 + 6H_2O = Ca_3Si_2O_7 \cdot 3H_2O + 3Ca(OH)_2. \quad [2]$$

The same calcium silicate hydrate, tobermorite, was produced in all five cases. Only the ball-mill hydration of tricalcium silicate produced a different calcium silicate hydrate, afwillite (4), which is not discussed in the present paper but will be discussed in a future publication.

Among the three methods of hydration, method (*b*) is of especial importance, because it attempts to simulate the hydration of portland cement in concrete and mortar. In paste hydration, both tricalcium silicate and dicalcium silicate produce tobermorite, and there is ample evidence that in the hydration of portland cements both silicates produce tobermorite. In all probability, the properties of concrete and mortar are determined to a greater extent by the properties of tobermorite than by the properties of any of their other constituents.

Although in the above reactions the calcium silicates were mixed with distilled water, lime saturation was established at an early stage of hydration, after which the reaction proceeded in a saturated calcium hydroxide solution. Under these conditions, the calcium silicate hydrate obtained was the high-lime end member of a series of hydrates designated by Taylor (13) as calcium silicate hydrate (I) or CSH (I). Because of the similarity of this hydrate to the natural mineral tobermorite (12), in the earlier papers (4, 5, 8) it was called tobermorite and, in the absence of general agreement on nomenclature, that

Contribution from the Research and Development Laboratories, Portland Cement Association, Skokie, Illinois.

name will be retained here. Bernal (3) proposed the structural formula $Ca_2[SiO_2(OH)_2]_2$-$[Ca(OH)_2]$ for this compound.

The natural mineral tobermorite and some of its synthetic varieties are well crystallized substances, but the tobermorite obtained in the room-temperature hydration of tricalcium silicate or β-dicalcium silicate was poorly crystallized, exhibiting only three X-ray diffraction lines (8). The tobermorite was also very finely divided; its specific surface area in the 14 preparations used in the present experiments ranged from 244 to 376 meters^2/g. Because of the colloidal nature of the hydrate, its equilibrium water vapor pressure varied with water content in a continuous rather than stepwise manner. At a vapor pressure of 8×10^{-3} mm of mercury the water content was about 2.8 moles, at 5×10^{-4} mm it was about 2.1 moles per mole of tobermorite.

The method used for the determination of surface energy (or, more strictly, surface enthalpy) was similar to that used for the determination of the surface enthalpies of amorphous silica and hydrous amorphous silica (10); namely, the heat-of-solution method. Heats of solution at three different concentrations, water content, and surface area were measured for each preparation, and the composition was determined by chemical and X-ray analysis. From these data, the heat of solution, water content, and surface area of the tobermorite were calculated. The results were then subjected to a least squares analysis to evaluate the surface energy and other parameters.

EXPERIMENTAL

Materials

The preparation of tricalcium silicate was described in an earlier paper (7), and that of β-dicalcium silicate in another (11). The analyses of the two silicates were given in the latter paper.

Details of the three methods of hydration were also given in earlier papers; one described ball-mill hydration (4), another paste hydration (5), and a third one hydration in the polyethylene bottle (8). All hydrations were carried out in a constant-temperature room, kept at 23.5±0.5° C. The hydration products were dried either at a vapor pressure of 5×10^{-4} mm of mercury (the vapor pressure of ice at −78° C) or at 8×10^{-3} mm of mercury (the equilibrium pressure of $Mg(ClO_4)_2\cdot2H_2O$ and $Mg(ClO_4)_2\cdot4H_2O$). The methods of drying were described in previous papers (4, 7).

Fourteen preparations (batches) were made, as shown in Table I. C-17 and C-18

TABLE I

Hydration of calcium silicates

Batch designation	Calcium silicate	Method of hydration	Time of hydration	Vapor pressure of drying
C-17	Ca_3SiO_5	Paste	17 months	5×10^{-4}
C-18	Ca_3SiO_5	Paste	17 months	8×10^{-3}
C-23	β-Ca_2SiO_4	Paste	17 months	5×10^{-4}
C-24	β-Ca_2SiO_4	Paste	17 months	8×10^{-3}
D-28	β-Ca_2SiO_4	Ball-mill	46 days	5×10^{-4}
D-35	Ca_3SiO_5	Bottle	47 days	5×10^{-4}
D-40	β-Ca_2SiO_4	Bottle	162 days	5×10^{-4}
D-42	Ca_3SiO_5	Bottle	49 days	5×10^{-4}
D-43	Ca_3SiO_5	Bottle	49 days	8×10^{-3}
D-47	β-Ca_2SiO_4	Ball-mill	63 days	5×10^{-4}
D-49	Ca_3SiO_5	Bottle	49 days	5×10^{-4}
D-50	Ca_3SiO_5	Bottle	49 days	5×10^{-4}
D-51	β-Ca_2SiO_4	Ball-mill	47 days	5×10^{-4}
D-52	β-Ca_2SiO_4	Ball-mill	64 days	5×10^{-4}

were the same paste divided into two parts, one part dried at 5×10^{-4}, the other at 8×10^{-3} mm pressure. The same was true of C-23 and C-24. D-42 and D-43 were also the same preparation; however, when the slurry was divided into two parts, a slight separation of the constituents occurred, as evidenced by chemical analysis.

Each batch was analyzed for calcium oxide, silicon dioxide, aluminum oxide, carbon dioxide, and loss on ignition, with results shown in Table II, columns 2 to 6. The magnesium oxide, sodium oxide, sulphur trioxide, and boric oxide contents were assumed to be the same as in the unhydrated calcium silicates. The methods of analysis used were reported before (7).

D-47	62.43	33.41	0.11	17.48	0.59	1.93% Fe, 0.05% FeO, 0.03% Fe_2O_3
D-49	71.15	28.11	0.12	18.92	0.26	3.42% Ca_3SiO_5
D-50	72.79	26.02	0.14	19.76	0.14	3.99% Ca_3SiO_5
D-51	62.75	33.36	0.11	16.78	0.37	1.72% Fe, 0.34% FeO, 0.14% Fe_2O_3
D-52	63.22	33.51	0.11	18.10	0.38	1.31% Fe, 0.16% FeO, 0.12% Fe_2O_3

*All Ca_3SiO_5 preparations contained 0.23% MgO and 0.08% Na_2SO_4, and all β-Ca_2SiO_4 preparations 0.22% MgO, 0.06% Na_2SO_4, and 0.53% B_2O_3.

Because in the ball-mill hydration of dicalcium silicate some iron was rubbed off the steel balls, the ball-mill batches were analyzed for free, ferrous, and ferric iron. The method used was a modification of that proposed by Wesly (14). The results are shown in Table II, column 7.

Eight of the batches contained some unhydrated tricalcium silicate or dicalcium silicate. The amounts of these were determined by X-ray quantitative analysis, using magnesium hydroxide as an internal standard, as described before (8). The results are shown in Table II, column 7.

All the analytical results in Table II are given on ignited weight basis; i.e., the sum of the component oxides of the *ignited* batch is taken as 100%. The composition of each batch was calculated, with the results shown in Table III. The excess water, given in column 6, is the water in the tobermorite in excess of two molecules per molecule. Thus, the composition of the tobermorite in C-17 was $Ca_3Si_2O_7.2.08H_2O$, in C-18 it was $Ca_3Si_2O_7.2.79H_2O$.

Measurements

The method of determination of the heats of solution was described before (10, 11). Three sample weights were used: approximately 0.7, 1.0, and 1.3 g. The calorimeter acid was a mixture of 8 ml of 49.4% hydrofluoric acid with sufficient 2 *N* nitric acid added to make the total weight 420 g.

The surface areas were measured by the B.E.T. method (6), using water vapor and

*The composition of each batch also includes the data of Table II, column 7, which were not repeated in this table. However, Fe_2O_3 is in the form of $Fe_2O_3 \cdot H_2O$ under the drying conditions employed. In addition, all Ca_3SiO_5 preparations contained 0.33% $Mg(OH)_2$ and 0.08% Na_2SO_4, and all β-Ca_2SiO_4 preparations 0.32% $Mg(OH)_2$, 0.06% Na_2SO_4, and 0.94% H_3BO_3.

nitrogen as adsorbates. Water vapor adsorption was measured gravimetrically at 25° C and nitrogen adsorption volumetrically at −195.8° C.

RESULTS

The heats of solution of the seven batches of hydrated tricalcium silicate are given in Table IV, and those of the seven batches of hydrated β-dicalcium silicate in Table V. From each heat value, the heat of solution of tobermorite was calculated by correcting for the heats of solution of the other substances present in the batch. The heats of solution of tricalcium aluminate hexahydrate, calcium carbonate, magnesium hydroxide, and boric acid were given in an earlier paper (7), and those of tricalcium silicate, β-dicalcium silicate, and sodium sulphate in another (11). The heats of solution of free iron, ferrous oxide, and ferric oxide monohydrate in the nitric acid – hydrofluoric acid mixture were found to be 1450, 360, and 255 cal/g, respectively. The 1.0- and 1.3-g samples of ball-mill hydrated β-dicalcium silicate usually contained some undissolved ferric oxide at the end of the calorimetric runs. Appropriate corrections were made for this in the calculations.

The heats of solution of 0.2, 0.3, 0.4, 0.5, 0.7, and 0.9 g of calcium hydroxide in the acid mixture were found to be 439.1, 437.3, 435.6, 435.6, 441.3, and 447.3 cal/g, respectively. Each value is the average of four to seven determinations. The results can be represented by two intersecting straight lines. The increase in heat of solution at higher concentrations is caused by the precipitation of calcium fluoride (11).

In the calculation of the heat of solution of tobermorite, it was assumed that the heats of solution of the constituents of the hydration products were additive. The correction for the deviation from additivity will be discussed later.

The specific surface areas of the 14 batches of hydration products are shown in Table VI. The adsorption area of a nitrogen molecule was taken to be 16.2 Å^2, and that of a water molecule 11.4 Å^2. The reasons for adopting the latter value were given in an earlier paper (8). Only the areas obtained by water vapor adsorption were used, for reasons to be discussed later.

In the calculation of the specific surface area of tobermorite from the specific surface area of the hydration products, it was assumed that all of the surface resided in tobermorite. The error introduced by this approximation was negligible except possibly for the ball-mill hydrated dicalcium silicate batches. Because of the prolonged grinding, in these batches about 2% of the total surface area was contributed by calcium hydroxide. Nevertheless, no attempt was made to correct the area, for two reasons. In the first place, a reliable determination of the surface area of the calcium hydroxide could not be made (8). In the second place, the slight error introduced by overestimating the tobermorite surface was partly compensated by a simultaneous overestimation of the heat of solution of tobermorite. This was because not only the surface area but also the surface energy of calcium hydroxide was neglected. As will be seen later, the results obtained for the four ball-mill hydrated batches agreed very well with those obtained for the 10 other batches.

DISCUSSION

Analysis of Data

After the heat of solution, the specific surface area, and the water content of the tobermorite in each sample of each batch were calculated, the data were subjected to a least squares analysis, similar to that described in an earlier paper (10). The main

difference was that an additional parameter was used in the present treatment, to correct for the non-additivity of the heats of solution.

In an investigation of the heat of decomposition of tricalcium silicate into β-dicalcium silicate and calcium oxide (11), it was found that the heat of solution of an equimolar mixture of β-dicalcium silicate and calcium oxide in the acid mixture was not equal to the sum of the heats of solution of the two components dissolved individually. A similar non-additivity was expected and found for the heats of solution of tobermorite

and calcium hydroxide. Since a separate determination of this effect would have been extremely laborious, it was evaluated from the data of the present experiments as a parameter in the least squares calculations.

The parameters were evaluated from the experimental data in three different ways. The heats of solution were determined at three sample weights, 0.7, 1.0, and 1.3 g; and in the first evaluation, the data obtained for each weight were treated separately. The three equations employed were of the form

$$[3] \qquad H_{ijk}+w_jh-A_j\epsilon_s-c_jX_k = H_k$$

where H_{ijk} is the heat of solution, in cal/g of $Ca_3Si_2O_7\cdot 2H_2O$, of the ith sample of the jth batch, having weight k;

w_j is the "excess water" content of the jth batch (Table III, column 6) in g/g of $Ca_3Si_2O_7\cdot 2H_2O$;

h is the average heat evolved, in cal/g of water, when $Ca_3Si_2O_7\cdot 2H_2O$ reacts with water to form a tobermorite of higher water content;

A_j is the average specific surface area of the jth batch in meters^2/g of $Ca_3Si_2O_7\cdot 2H_2O$;

ϵ_s is the average surface energy (or surface enthalpy) of $Ca_3Si_2O_7\cdot 2H_2O$ in cal/-meters^2;

c_j is the total calcium oxide in the hydration products in the jth batch, in g/g of $Ca_3Si_2O_7\cdot 2H_2O$;

X_k is the non-additivity correction factor for a sample having weight k, expressed in cal/g of calcium oxide; and

H_k is the heat of solution, in cal/g of $Ca_3Si_2O_7\cdot 2H_2O$, of a sample of weight k, having zero surface and zero excess water.

The term c_jX_k is the correction to the heat of solution of tobermorite, caused by non-additivity of the heats of solution of the hydration products. The value of c_j is approximately 1 for all hydrated tricalcium silicate batches and approximately 2/3 for all hydrated dicalcium silicate batches.

A least squares analysis of the data led to the results shown in Table VII, columns 2 and 3. Actually, three values were obtained for each of the parameters h, ϵ_s, and X (one for each sample weight), and the values given in column 2 are the weighted means of the three values.

TABLE VII

Results of least squares analyses

1	2	3	4	5	6	7
	Individual weight		Five-parameter		Six-parameter	
Parameter	Weighted mean	Standard error	Weighted mean	Standard error	Weighted mean	Standard error
$H_{0.7}$ (cal/g of $Ca_3Si_2O_7\cdot 2H_2O$)	455.5	4.0	453.7	1.2	450.9	1.1
$H_{1.0}$ (cal/g of $Ca_3Si_2O_7\cdot 2H_2O$)	448.7	3.1	446.9	1.1	450.3	1.1
$H_{1.3}$ (cal/g of $Ca_3Si_2O_7\cdot 2H_2O$)	451.0	2.0	452.1	1.2	451.5	1.1
X (cal/g of CaO)	10.6	1.8			11.1	1.2
h (cal/g of H_2O)	420.4	14.9	419.0	9.7	422.2	9.9
ϵ_s (cal/meters^2)	0.0927	0.0072	0.0929	0.0036	0.0914	0.0048
ϵ_s (ergs/cm^2)	388	30	389	15	383	20

The values of X for the 0.7-, 1.0-, and 1.3-g samples were found to be 7.2 ± 4.6, 14.6 ± 3.6, and 9.8 ± 2.4 cal/g of calcium oxide, respectively. In the second evaluation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of the parameters, the heat of solution of tobermorite was recalculated for each sample, using the appropriate values of c and X for correction. The equation then was of the form

[4] $$H'_{ijk}+w_j h - A_j \epsilon_s = H_k$$

where $H'_{ijk} = H_{ijk} - c_j X_k$. All terms in eq. [4] have the same meaning as in eq. [3]. In the second evaluation, the data for all weights were used together. The results for the five parameters are given in Table VII, columns 4 and 5.

As the data in the previous paragraph show, the errors in $X_{0.7}$, $X_{1.0}$, and $X_{1.3}$ are so large that, actually, the three parameters may be equal. In the third evaluation it was assumed that the parameter X was the same for all three weights. The equation used was of the form of eq. [3]; the data for all weights were used together, and six parameters were calculated. The results are shown in Table VII, columns 6 and 7.

The values of the parameters, and even of the standard errors, obtained in the five- and six-parameter calculations are very close to each other. There is little to choose between them; consequently, the mean value estimates are probably as good as any that can be obtained from the present data.

The Surface Energy of Tobermorite

1. The surface energy of tobermorite obtained in the room temperature hydration of tricalcium silicate or β-dicalcium silicate and having a composition of $Ca_3Si_2O_7 \cdot 2H_2O$ is 386 ± 20 ergs/cm^2 at 23.5° C. The qualification in this statement as to the source of tobermorite is probably essential. It was stated in the Introduction that the tobermorite obtained in the room-temperature hydration of the two calcium silicates was a poorly crystallized substance exhibiting only three X-ray diffraction lines. Better crystallized tobermorites of the same composition can be prepared in a variety of ways, and their surface energies may be different from the value reported here.

The surface energy value of 386 ergs/cm^2 is intermediate between the surface energies of calcium hydroxide and hydrous amorphous silica (silanol), 1180 and 129 ergs/cm^2, respectively (9, 10). This was expected, for two reasons: the calcium silicate hydrate is chemically intermediate between calcium hydroxide and hydrous silica, and it is also intermediate structurally. The calcium hydroxide consisted of nearly perfect crystals (9), the hydrous silica was completely amorphous (10), and the tobermorite was very poorly crystallized. Actually, the surface energy of tobermorite is very close to the geometric mean of the surface energies of calcium hydroxide and hydrous amorphous silica.

The standard error of 20 ergs/cm^2 is an estimate of the precision of the experimental measurements and not of the accuracy of the surface energy value. The least squares analysis evaluates the random errors but not the systematic errors. For example, if the area of an adsorbed water molecule, 11.4 Å^2, is in error by 5%, the surface energy value is also in error by 5%, from this factor alone.

2. To present a clearer picture of the consistency of the results, in Fig. 1 the variation of the heat of solution of $Ca_3Si_2O_7 \cdot 2H_2O$ with specific surface area is shown for the 1.0-g samples. The average heat of solution of the tobermorite in each preparation was calculated, and the results were corrected (1) for the excess water by using $h = 420$ cal/g of water, and (2) for non-additivity by using $X = 11.1$ cal/g of calcium oxide (Table VII). C-17 and C-18 had the same specific surface area; the arrows in the figure indicate which point belongs to which preparation. The same is true of C-23 and C-24, and D-42 and D-43.

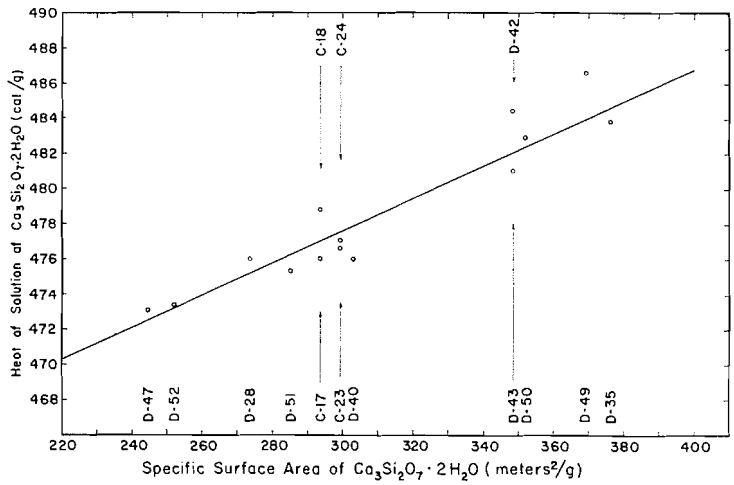

FIG. 1. Variation of the heat of solution of $Ca_3Si_2O_7 \cdot 2H_2O$ with specific surface area for 1.0-g samples.

The straight line drawn in Fig. 1 is a theoretical curve, based on $H_{1.0} = 450$ cal/g of $Ca_3Si_2O_7 \cdot 2H_2O$, and $\epsilon_s = 0.092$ cal/meters². Although the points are scattered, the line appears to be a good representation of the results. Similar data for the 0.7-g samples show somewhat more scatter and those for the 1.3-g samples somewhat less. The point that falls farthest from the straight line is 2.6 cal/g too high (D-49). Such deviations may come about by slight differences in the body structure or somewhat greater differences in surface structure. (The 2.6 cal/g is 0.58% of the heat of solution of the body of tobermorite, and 7.6% of the energy of the surface of the tobermorite in D-49.) However, probably, the real reason is random variation caused by accumulation of the errors in all measurements. This is seen from the results for the pairs C-17 and C-18, and D-42 and D-43. Each of these pairs was a single preparation divided into two parts and dried at different vapor pressures (Table I). As Fig. 1 shows, the difference between the heats of solutions is 2.8 cal/g for the first pair and 3.4 cal/g for the second, the drier preparation giving the lower value for the first pair, and the higher value for the second.

As Fig. 1 shows, only 4 of the 14 preparations had heats of solution deviating from the theoretical value by more than 1.0 cal/g. The average of the absolute values of the deviations is 1.1 cal/g. This corresponds to 0.24% of the heat of solution of the body of tobermorite or to 3.8% of the surface energy. Thus, even if all variation in the heat of solution is ascribed to variation in body structure, or in surface structure, the conclusion is that *both the body structure and the surface structure of tobermorite are highly reproducible.* The different starting materials (tricalcium silicate and β-dicalcium silicate) and the different methods of hydration (ball-mill, paste, bottle) produced a tobermorite of the same body structure and the same surface structure. The method of preparation, however, appears to have an effect on the specific surface area. Tobermorite obtained in ball-mill hydration seems to have the smallest specific surface, and that produced in bottle hydration, the largest.

There is no variation of ϵ_s with specific surface area within the experimental error. Similar result was obtained by Benson and co-workers (1, 2) for sodium chloride. The areas of their samples varied from 1 to 50 meters²/g.

3. The tobermorite formed in the room-temperature hydration of tricalcium silicate

or β-dicalcium silicate has probably three molecules of water of hydration per molecule, rather than two (5, 8). It would be of considerable interest to know the surface energy of $Ca_3Si_2O_7 \cdot 3H_2O$, but the difficulties in its experimental determination would be very great. This is because the binding energies of combined water and adsorbed water overlap. At a water vapor pressure of 8×10^{-3} mm of mercury, tobermorite contains 2.8 moles of water per mole, of which 2.54 moles are combined water and 0.26 moles adsorbed water (8). At a higher vapor pressure, tobermorite would contain more combined water and more adsorbed water.

A rough estimate of the surface energy of $Ca_3Si_2O_7 \cdot 3H_2O$ can be made on the basis of the following considerations. Tobermorite is a layer crystal, like the clay minerals. At a vapor pressure of 5×10^{-4} mm of mercury, it contains two moles of combined water per mole, and the distance between the layers is 9.3 Å. At a vapor pressure of 8×10^{-3} mm the distance between the layers is 10.4 Å, indicating that the third mole of combined water, or at least a part of it, is between the layers. On the other hand, in the surface area determinations water vapor does not penetrate between the layers; it measures the external surface areas of the tobermorite crystallites (8). If *all* of the third mole of combined water were between the layers, the surface energy of $Ca_3Si_2O_7 \cdot 3H_2O$ would be only slightly different from that of $Ca_3Si_2O_7 \cdot 2H_2O$.

The opposite extreme would be if all of the third mole of combined water were on the surface. In earlier work, it was found that the surface energy of calcium hydroxide was 130 ergs/cm^2 lower than that of calcium oxide (9), and the energy of the surface of hydrous amorphous silica (silanol) was 130 ergs/cm^2 lower than that of amorphous silica (siloxane) (10). It seems, therefore, reasonable to assume that a mole of combined water on the surface of $Ca_3Si_2O_7 \cdot 2H_2O$ would lower the surface energy by about 130 ergs/cm^2.

It follows from the above considerations that *the surface energy of tobermorite having a composition of* $Ca_3Si_2O_7 \cdot 3H_2O$ *falls in the range 320±70 ergs/cm^2, and probably it is not far from the upper limit of the range.*

4. The tobermorite crystallites are very thin sheets. The dimensions of the sheets are of the order of several thousand Angstrom units, the thickness is only two or three unit cells (20 to 30 Å). It was shown in an earlier work (8) that the specific surface area can be calculated from crystal structure and density data. If the sheets are all two unit cells thick, the area should be 377 meters^2/g, and if they are all three unit cells thick, it should be 251 meters^2/g.

On the basis of water vapor adsorption, the specific surface area of the tobermorite in D-47 is 244 and that in D-35 is 376 meters^2/g (Fig. 1). All other area values fall between these limits. Thus, the indication from the water adsorption results is that all tobermorite crystallites are two or three unit cells thick; and the indication from the crystallographic data is that water adsorption measures the true surface of tobermorite.

In contrast with this, with one exception (D-28), nitrogen adsorption indicates smaller specific surface areas (Table VI), ranging down to 21% of the area measured by water (C-23). That nitrogen does not measure the true surface of tobermorite can be seen from the following considerations. As Fig. 1 shows, the heat of solution of the tobermorite in D-35 is about 8 cal/g larger than that of the tobermorite in D-28, but the surface area of the former is only about half as large, as measured by nitrogen adsorption (Table VI). This would indicate a *negative* surface energy, an absurdity. Several other pairs of preparations would, likewise, lead to negative surface energy values.

The probable explanation for the low nitrogen areas is that aggregation of the tober-

morite crystallites, or rolling of the sheets, or both together prevent nitrogen molecules from reaching some parts of the surface that are accessible to water molecules.

The Heat of Hydration, h

1. The heat evolved when $Ca_3Si_2O_7 \cdot 2H_2O$ reacts with liquid water at 23.5° C to form a hydrate of higher water content was evaluated from data on preparations ranging in water content from 2.0 to 2.8 moles per mole of tobermorite. It was stated before that of the 2.8 moles, 2.54 moles were chemically combined and 0.26 moles were adsorbed water. The latter value corresponds to a surface coverage of about 18%. The fact that at 8×10^{-3} mm vapor pressure this adsorbed water remains on the surface indicates that the free energy of binding of the 0.26 moles of adsorbed and 0.54 moles of combined water to $Ca_3Si_2O_7 \cdot 2H_2O$ is the same. It seems a fair approximation to assume that the heat of binding is, likewise, the same. Thus, the value of $h = 420$ cal/g of water is probably a good value for the heat of hydration, especially since 11 of the 14 preparations were dried at 5×10^{-4} mm pressure, at which the amount of adsorbed water is negligible.

If it is assumed that the heat of hydration of $Ca_3Si_2O_7 \cdot 2H_2O$ is the same for the uptake of the entire additional mole of water, it follows that

$$Ca_3Si_2O_7 \cdot 2H_2O(c) + H_2O(1) = Ca_3Si_2O_7 \cdot 3H_2O(c), \quad \Delta H_{296.6} = -7600 \text{ cal.} \qquad [5]$$

The value of ΔH was rounded off to the nearest 100 cal. The heat evolved is intermediate between the heat of hydration of calcium oxide to calcium hydroxide, 15,620 cal (9), and the heat of hydration of siloxane to silanol, 4660 cal (10).

2. The heat of solution of $Ca_3Si_2O_7 \cdot 3H_2O$ having zero surface can be calculated from the data of Table VII. For 0.7-, 1.0-, and 1.3-g samples it is 406.4, 402.9, and 405.9 cal/g of $Ca_3Si_2O_7 \cdot 3H_2O$, respectively.

ACKNOWLEDGMENTS

The authors are greatly indebted to Dr. Paul Seligmann for deriving the complicated statistical equations, to Dr. Fred Ordway for valuable discussion of the paper, to Messrs. E. E. Pressler and E. LaBonde for most of the analytical data, and to Miss Edith Turtle for most of the X-ray data.

THE OXIDATION OF SOME TERMINAL-SUBSTITUTED POLYHYDRIC ALCOHOLS BY ACETOBACTER SUBOXYDANS[1]

L. HOUGH,[2] J. K. N. JONES, AND D. L. MITCHELL

ABSTRACT

Various terminal-substituted pentitols and hexitols, which possessed either the L-*lyxo*- or the D-*ribo*-configuration at the three contiguous carbon atoms adjacent to the terminal carbon atom, were oxidized to ketoses by *Acetobacter suboxydans*. The terminal hydroxyl group of the polyol was replaced by -H, -*O*Me, -*S*Et, and -*O*Ac groups; several 1,1-dithioacetal derivatives of aldoses were also tested. The preparation of 1-*O*-acetyl-DL-galactitol, 1-deoxy-1-*S*-ethyl-D-arabitol, and 6-deoxy-6-*S*-ethyl-L-sorbose are described. 6-Deoxy-6-*S*-ethyl-L-sorbose was prepared by the microbiological oxidation of 1-deoxy-1-*S*-ethyl-D-glucitol.

INTRODUCTION

The oxidation of unsubstituted sugar alcohols by proliferating cells of *Acetobacter suboxydans* has resulted in the formulation of the Bertrand–Hudson rule for oxidations occurring within the pH range of 5–6.5 (1, 2). Thus a polyol with the D-*erythro* configuration (I) is oxidized mainly at the secondary alcohol group adjacent to the terminal primary alcohol to give a ketose (II). Many examples of this reaction have been reported (3, 4, 5, 6, 7, 8). More recently, cell-free extracts have been used for the oxidation of some polyols in an alkaline environment (optimum pH 7.8), although the reaction is less specific since polyols possessing either the L-*threo*- (III) or D-*erythro*- (I) configurations were utilized (9).

Investigation of the microbiological oxidation of various ω-deoxy-sugar alcohols at pH 5–6.5 has shown that ω(*n*)-deoxy-polyols with the D-*erythro* configuration at the carbon atoms (*n*-2) and (*n*-3) (where *n* equals the number of carbons in the chain) (e.g. VI and VII) gave copper reducing products even when the favorable D-*erythro* configuration was absent at the other end of the chain (10, 11). This configuration is present in L-fucitol (6-deoxy-L-galactitol) (IV), which has been shown to be oxidized at carbon 4 to give 1-deoxy-D-*xylo*-3-hexulose (L-fuco-4-ketose) (V). Hudson, Stewart, and Richtmyer reconciled this evidence with the known specificity of the organism by suggesting that the secondary alcohol at carbon 5 of 6-deoxy-L-galactitol (IV), which can be considered as a *C*-methyl derivative of a pentitol, serves at the enzyme surface in a capacity similar to the primary alcohol of an unsubstituted acyclic polyol. We have investigated the specificity of this microbiological oxidation with a view to the preparation of 3-hexuloses and 3-pentuloses.

A limited number of polyols which possess the favorable D-*ribo*- (VI) or L-*lyxo*- (VII) configuration adjacent to a substituent other than hydroxyl at the terminal carbon atom have been tested as substrates for *A. suboxydans* and some gave reducing products. The substituents included a hydrogen atom (ω-deoxy), ω-*O*-methyl, ω-deoxy-ω-*S*-ethyl, and an ω-*O*-acetyl group. All of the unbranched polyols except 1-deoxy-1-*S*-ethyl-L-arabitol were oxidized to reducing products, which unlike the polyols gave bright yellow or orange spots with *p*-anisidine hydrochloride on paper chromatograms. Similar color reactions were reported for 2-*O*-methyl-3-hexuloses (12) and more commonly for 2-hexuloses (13). Although 1-deoxy-L-arabitol (5-deoxy-L-lyxitol) was oxidized by *A. suboxydans*

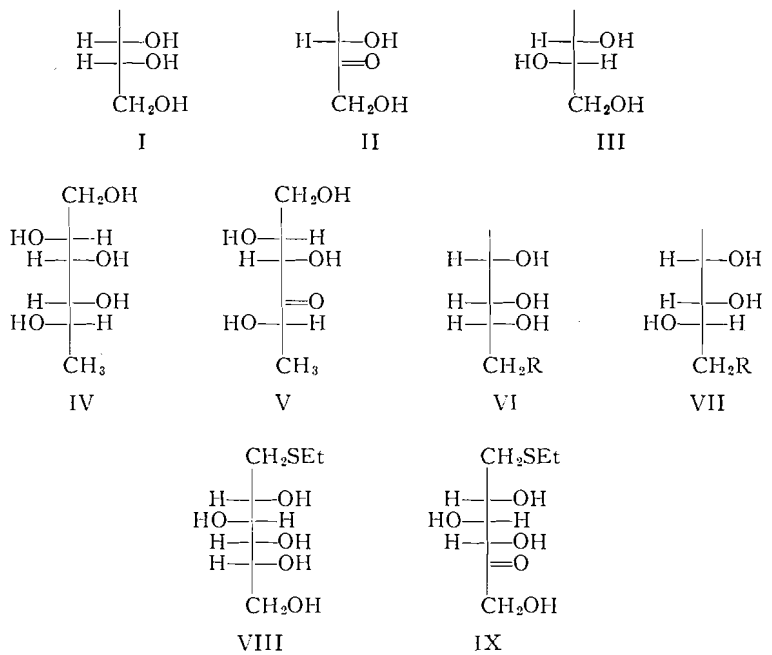
[1]*Manuscript received December 9, 1958.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario, and the Department of Organic Chemistry, The University, Bristol 8, England.
[2]*Present address: Department of Organic Chemistry, The University, Bristol 8, England.*

(11) to give a reducing product that resulted in a typical ketose reaction with *p*-anisidine hydrochloride, the substitution of a thioethyl group for a hydrogen atom at carbon-1 in this molecule completely inhibited the oxidation. However, in the cases of 6-deoxy-L-galactitol and 6-deoxy-6-*S*-ethyl-L-galactitol, both substrates yielded reducing compounds in moderate yields. Terminal-branched polyols like diethyldithioacetals (aldose mercaptals) were also tested but they did not appear to be oxidized by *A. suboxydans*, thus supporting the observations of Hudson (1) and Iselin (14).

Estimates of the amounts of reducing sugars formed from the oxidation of various substrates by *A. suboxydans* were made by copper-reduction measurements on aliquots taken from the culture medium at various times during incubation. However, this determination was found to be unsatisfactory when the substrate contained sulphur and unexpectedly high reducing values were obtained; ω-deoxy-ω-thioethyl polyols and dithioacetals reduced the copper reagent when tested in control solutions. An approximate reducing value was obtained by subtracting a 'control reducing value' from the reducing value of the medium which was being tested for biochemical oxidation. The reducing values reported by Bollenback and Underkofler for sugar dithioacetals, when they were used as substrates for *A. suboxydans*, were most likely due to the oxidation of the sulphur atom(s) by the copper reagent (11).

The finding that 6-substituted derivatives of L-galactitol, such as 6-deoxy-L-galactitol (L-fucitol), 1,6-dideoxy-L-galactitol (1,6-dideoxy dulcitol (10)), and 6-deoxy-6-*S*-ethyl-L-galactitol were oxidized by *A. suboxydans* prompted an investigation of the preparation and oxidation of similar derivatives. Two possible synthetic routes to 3-hexuloses might use either L-galactose or DL-galactitol (dulcitol) as starting compounds.

Preferential esterification of the primary alcohol group at carbon 6 of D-galactose and D-glucose has been accomplished by Duff (15, 16) using 50% acetic acid at 100° C. Acetylation of DL-galactitol under slightly modified conditions followed by chromatography on charcoal (25) yielded a crystalline monoacetate as the major product. Periodate



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.233.112.2 on 09/04/12
For personal use only.

oxidation experiments revealed that esterification had taken place at one of the primary alcohol groups, and the compound was therefore identified as 1-*O*-acetyl-DL-galactitol (6-*O*-acetyl-DL-galactitol). Since only one-half of the DL-galactitol derivative, the D-isomer (i.e. 6-*O*-acetyl-L-galactitol), can be utilized by *A. suboxydans*, a lower copper reducing value would be anticipated from this substrate than from an L-isomer, such as 6-deoxy-L-galactitol, and this has been verified experimentally.

The oxidation product of 1-deoxy-1-*S*-ethyl-D-glucitol (VIII) has been identified conclusively as 6-deoxy-6-*S*-ethyl-L-sorbose (IX), since after conversion to the 2,3-*O*-isopropylidene derivative, reductive desulphurization gave 6-deoxy-L-sorbose which was characterized as the derived phenylosazone.

At the present time, structural studies are in progress on the products formed by oxidation with *A. suboxydans* of 6-deoxy-6-*S*-ethyl-L-galactitol and 1-*O*-acetyl-DL-galactitol. From the known specificity of the microorganism, these products are probably derivatives of 3-hexuloses.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (*ca.* 15 mm). Optical rotations were determined in water at 23°±3° C unless otherwise stated. Paper chromatography was carried out by the descending method (17) on Whatman No. 1 filter paper using the following solvent systems (v:v): (*a*) ethyl acetate – acetic acid – water (9:2:2); (*b*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*c*) butan-1-ol–ethanol–water (40:11:19); and (*d*) butan-1-ol–pyridine–water (10:3:3). Paper electrophoresis was carried out on Whatman No. 3 filter paper impregnated with 0.05 *M* borate buffer (pH 9.2 at 1800 volts for 1.5 hours). Reducing compounds were detected on paper chromatograms and paper electrophoretograms by the *p*-anisidine hydrochloride reagent (13). Non-reducing compounds were detected on paper chromatograms with an alkaline silver nitrate reagent (18) and on paper electrophoretograms by 3% (w:v) lead tetra-acetate in absolute benzene (19). The rate of movement on paper chromatograms is quoted relative to that of rhamnose (R_{Rh} value). On paper electrophoretograms the mobilities are quoted relative to that of D-glucose (M_G value), and are corrected for endosmosis from the rate of movement of tetra-*O*-methyl-D-glucose relative to the D-glucose standard.

Acetobacter suboxydans (A.T.C.C. No. 621) was kindly supplied by Dr. N. K. Richtmyer. The stock culture was grown on agar slopes on a medium consisting of sorbitol (5%, w:v), yeast extract (0.5% w:v),* and potassium dihydrogen phosphate (0.05% w:v) (10). The substituted polyols under examination (Table II) were made up as a broth containing the polyol (1–3%, accurately weighed), yeast extract (0.5% w:v), potassium dihydrogen phosphate (0.05% w:v), and were fortified with sorbitol (0.1% w:v). Control solutions, made up in duplicate, contained the above constituents except the substituted polyol. The solutions (10 ml) in 75-ml conical flasks were autoclaved (15 p.s.i., 20 minutes), cooled to room temperature, and inoculated with a 72 hours' culture of *A. suboxydans* grown on sorbitol (1 drop). The flasks were stored without agitation at 27° C.

At intervals, an aliquot sample (*ca.* 2 ml) was removed from the medium with a sterile pipette and a little examined directly on paper chromatograms and paper electrophoretograms. The remainder (1 ml) was deproteinized and the reducing power estimated using Somogyi's microcopper reagent (20). Solutions of the sulphur-containing polyols

were made up to identical concentration for copper-reduction estimation. The reducing values of the two control solutions were then subtracted from the reducing value of the medium containing the sulphur-containing polyols under biochemical test. The reducing values are quoted in moles of reducing sugar (calculated as L-sorbose)/100 moles of polyol.

The results are shown in Table II. The 1,1-diethyldithioacetals of D-arabinose, D-glucose, D-galactose, and the 1,1-dibenzyldithioacetal of D-arabinose were not oxidized by *A. suboxydans* as revealed by the copper-reducing power of the culture medium and the absence of any products on paper chromatograms.

Preparation of Substrates

2-Amino-2-deoxy-D-glucitol and 2-acetamido-2-deoxy-D-glucitol were prepared by borohydride-reduction of the respective aldoses according to the method of Bragg and Hough (21). 5-Deoxy-D-ribitol and 5-*O*-methyl-D-ribitol were prepared from D-ribono-1→4-lactone (22). 1-Deoxy-1-*S*-ethyl-polyols were prepared from the corresponding aldose diethyldithioacetals by partial desulphurization with aged Raney nickel (23).

1-Deoxy-1-S-ethyl-D-arabitol

D-Arabinose diethyldithioacetal (3.0 g) was partially desulphurized (23) to yield 57% of product melting at 124–125° C, and with $|\alpha|_D^{28}$ 13°±1° (*c*, 1.1). Anal. Calc. for $C_7H_{16}O_4S$: C, 42.8; H, 8.2; S, 16.3. Found: C, 43.1; H, 8.2; S, 16.7.

1-Deoxy-1-S-ethyl-D-arabitol Tetraacetate

1-Deoxy-1-*S*-ethyl-D-arabitol was acetylated with acetic anhydride in pyridine. The product crystallized when it was poured into a slurry of chipped ice and water, and it was collected by filtration. Recrystallization from aqueous ethanol yielded flakes that melted at 58° C, and with a $|\alpha|_D$ 38°±4° (*c*, 1.3, chloroform). Anal. Calc. for $C_{15}H_{24}O_8S$: C, 49.4; H, 6.6; S, 8.8. Found: C, 49.8; H, 6.8; S, 8.2.

1-O-Acetyl-DL-galactitol (6-O-Acetyl-DL-galactitol, 1-O-Acetyl-dulcitol)

Dulcitol (100 g) was heated under reflux with 50% acetic acid (100 ml) for 36 hours at 80° C (15, 16). Upon cooling, most of the unreacted dulcitol was recovered by filtration and the soluble acetates were obtained as a white residue upon removal of the solvent. Paper chromatographic examination of the residue indicated at least four constituents which had R_{Rh} values of 0.96, 1.23 (major constituent), 1.90, and 2.22 (solvent *a*). The mixture (55 g) was fractionated on a short charcoal column (10×12 cm) of Ultrasorb S.C.* 120–240 (24, 25). Elution was then carried out stepwise with successive fractions (3 liters) of water, and 1.5, 3, 5, 8, 12.5, and 25% ethanol; the major constituent was found in the 8% ethanol fraction. This fraction was filtered, deionized with Amberlite resins (IR-120 (H) and IR-400 (carbonate)) at 5° C, and concentrated to dryness. The product (18 g—low yield due to an accident) after recrystallization from ethanol melted at 131–133° C and possessed a strong adsorption peak in the infrared at ν_{max} 1745 cm^{-1} (nujol). Sorbitol hexaacetate gave an absorption peak at ν_{max} 1748 cm^{-1} and D-glucose diethyldithioacetal possessed a double-peaked adsorption at ν_{max} 1730 and ν_{max} 1750 cm^{-1}. Anal. Calc. for $C_8H_{16}O_7$: C, 42.9; H, 7.2; OAc, 19.2. Found: C, 43.0; H, 7.1; OAc, 19.7.

Structural Determination by Periodate Oxidation Experiments

Oxidations were carried out in the dark at 18° C.

**British Carbo Norit Union Ltd., West Thurrock, Gray's, Essex, England.*

The sample (23 mg) was dissolved in water (21 ml) containing 0.3 *M* sodium metaperiodate solution (4 ml). At intervals, aliquots (2 ml) were withdrawn for either the determination of periodate consumption or the estimation of formic acid liberated (26). Formaldehyde was estimated on aliquots that were diluted 10-fold prior to the estimation (27).

TABLE I

The periodate oxidation of 1-*O*-acetyl-DL-galactitol

*Moles/mole of 1-*O*-acetyl-DL-galactitol.

*6-Deoxy-6-S-ethyl-*L*-sorbose Phenylosazone*

A culture medium containing 1-deoxy-1-*S*-ethyl-D-glucitol was oxidized for 10 days with *A. suboxydans*. A portion of the solution was deproteinized, deionized with Amberlite resins (IR-120 (H) and IR-4B (OH)), and concentrated to a syrup. The components were separated by paper chromatography (Whatman 3MM) in the usual way (solvent *c*). Some of the syrupy ketose (18 mg) was dissolved in a mixture of phenylhydrazine (0.1 ml), acetic acid (0.1 ml), and water (0.5 ml), and heated in a water bath at 70° C for 3 hours. The phenylosazone (18 mg) was washed first with water, followed by benzene, and was finally recrystallized from aqueous ethanol to give a product melting at 185–190° C. Anal. Calc. for $C_{20}H_{26}N_4O_3S$: C, 59.7; H, 6.5; N, 13.9. Found: C, 59.6; H, 6.5; N, 13.7.

*Reductive Desulphurization to 6-Deoxy-*L*-sorbose (via the O-Isopropylidene Derivative)*

A solution of 6-deoxy-6-*S*-ethyl-L-sorbose (0.20 g) in acetone (20 ml) containing concentrated hydrochloric acid (0.2 ml) was shaken at room temperature for 2.5 hours

followed by neutralization with silver carbonate. The filtrate was concentrated to a syrup which was non-reducing and moved on paper chromatograms at a rate considerably faster than the original ketose. The *O*-isopropylidene derivative (0.12 g) was dissolved in ethanol containing freshly prepared Raney nickel W-2 catalyst (6 ml settled volume) (28) and was heated under reflux for 4 hours. After cooling and filtering free of nickel, a syrup (97 mg) was obtained which had $|\alpha|_D$ 18°±2° (*c*, 1.2, ethanol). (Lit. for 2,3-*O*-isopropylidene-L-sorbose $|\alpha|_D$ 17.9° (29).)

A solution of the syrupy *O*-isopropylidene compound (61 mg) was dissolved in a mixture of phenylhydrazine (0.1 ml), acetic acid (0.1 ml), and water (2 ml), and heated in a water bath at 70° C for 3 hours. The phenylosazone which crystallized from the solution during heating was collected by filtration and washed with cold water followed by ether. Its melting point (175–180° C) was not depressed when admixed with an authentic specimen prepared from 6-deoxy-L-sorbose (30). (Lit. melting point 183–185° C (29) and 168–172° C (9).) The infrared adsorption spectra of the derived and authentic specimens were identical over the frequency range of 600–4000 cm^{-1}.

ACKNOWLEDGMENTS

The authors wish to thank Dr. N. K. Richtmyer of the National Institute of Arthritis and Metabolic Diseases, National Institute of Health, Bethesda, Maryland, for cultures, and Mr. D. J. Anderson for a specimen of sorbitol hexaacetate. One of us (D.L.M.) thanks the Ontario Research Foundation for a scholarship.

MYCOCHRYSONE

I. ISOLATION, PROPERTIES, AND PRELIMINARY CHARACTERIZATION[1]

G. READ,[2] P. SHU,[3] L. C. VINING, AND R. H. HASKINS

ABSTRACT

Mycochrysone, an orange-red crystalline pigment, has been isolated from in vitro cultures of an inoperculate discomycetous fungus. It possesses quinonoid properties and forms a monoquinoxaline derivative. At least two phenolic or enolic groups are present, one of which is in the *peri* position to a quinone carbonyl. Reduction of the pigment with a zinc dust – zinc chloride mixture gives perylene, together with some hydroperylenes. The pigment shows limited antibiotic activity.

An inoperculate discomycete, designated PRL 1252, which was isolated from a diseased *Pinus sylvestris* seedling, produces an orange-red pigment when grown in vitro on an agar-solidified nutrient medium. The mold probably cannot be identified accurately until its sexual stage is discovered in nature and the organism, for the present, remains unnamed (9). For this reason it is not possible to follow the customary practice of naming the pigment after the species designation and the name "mycochrysone" has therefore been chosen. Cultures grown on a Difco potato dextrose agar were found to give the best yields of pigment, which appeared as sheaves of bright orange needles in the mycelial exudate and in the surrounding medium.

When pigment yield appeared optimal by visual inspection, the cultures were harvested, freeze-dried, and defatted with petroleum ether. The extract yielded a pale yellow thermolabile oil with an infrared spectrum characteristic of a triglyceride ester. The pigment was extracted from the residue by repeated leaching with chloroform at room temperature in the dark, since in solution it is thermolabile and photosensitive. The extracts, upon careful concentration, gave an orange-red microcrystalline solid in a yield of 4% of the total dry weight of mycelium and agar. Paper chromatographic examination suggested that the pigment contained only a single component. Recrystallization from hot solvents usually resulted in gel formation but analytically pure samples, which decomposed slowly when heated above 180° C, were obtained by concentrating cold chloroform solutions as in the initial extraction. Recrystallization by concentrating cold ethereal solutions frequently gave a dimorphic form as short orange-brown rods which decomposed slowly above 200° C and which could be converted to the orange-red modification by recrystallization from chloroform.

Mycochrysone was found to inhibit the two Gram-positive bacteria *Bacillus subtilis* and *Staphylococcus aureus* but showed no activity against a typical Gram-negative bacterium (*Escherichia coli*), a yeast (*Candida albicans*), or a filamentous fungus (*Penicillium roqueforti*).

Determinations of molecular weight by the Rast method were unsatisfactory owing to decomposition of the pigment, but a value of 370 was obtained by isothermal distillation (4). This was in good agreement with values of 358 and 367 for the reduction equivalent obtained by measuring hydrogen uptake over palladized asbestos. Tests for

nitrogen, halogens, and sulphur were negative, and elemental analyses best fitted a formula of $C_{20}H_{14}O_7$. No C- or O-methyl groups were detected; a Zerewitinoff determination corresponded to 2.66 active hydrogens per mole.

In concentrated sulphuric acid, a deep blue solution was formed. Dilution with water precipitated an amorphous dark red solid, distinct from the original pigment, which could not be crystallized and appeared heterogeneous when chromatographed on paper. A similar product was deposited after a few minutes from the orange-red solution given by the pigment in cold concentrated hydrochloric acid, or on warming an alcoholic solution with dilute mineral acid. Since no reducing sugars could be detected after the latter treatment, the pigment is not a simple glycoside. Mycochrysone dissolved readily in aqueous alkali to form a purple solution. It could be recovered unchanged when precipitated with acetic acid after a short interval in sodium bicarbonate but above pH 9 degradation was rapid. Prolonged exposure in solution to even slightly alkaline conditions (pH 7.2) caused extensive decomposition. The product formed was heterogeneous and has not been investigated further.

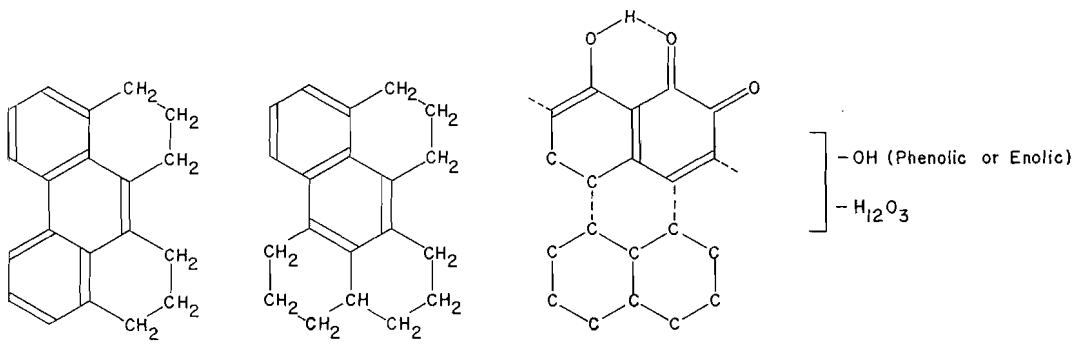
Solutions of mycochrysone were reduced by sodium hydrosulphite or zinc and dilute acid. The uptake of 1 mole of hydrogen over palladium catalyst was rapid and when the leuco compound so formed was reoxidized by exposure to air, the original pigment was regenerated. The recovery was not quantitative. This readily reversible reduction, together with positive ethylenediamine and indole tests (11), indicates that a quinone group is present. With titanium trichloride a methanolic solution of mycochrysone gave a violet color which faded to a violet-brown; in methanol containing pyridine a red-brown color was obtained after shaking and subsequently a brown precipitate formed. Such reactions are shown by 1,2-quinones and by 1,4-quinones with a hydroxyl group in either the 2-position or *peri* to one of the quinone carbonyls (17). An inconclusive Craven test (7) was obtained, but the purple and brown color with boroacetic anhydride and ferric chloride, respectively, provide evidence for a *peri*-hydroxyl group in the chromophore. The boroacetate derivative could not be isolated, and it appeared to be degraded when allowed to stand in the reaction medium. With methanolic lead acetate the pigment formed a purple precipitate, suggesting that a second, more acidic group is also present. This is supported by the solubility in bicarbonate, a property not associated with chelated *peri*-hydroxyl groups. Although an accurate pK value for this group could not be obtained because of the instability of the pigment in alkali, the pH of a solution in 80% methanol after rapid neutralization with 0.5 moles of alkali was 7.75. Since this would represent a minimum value for the pK_1 of the most acidic hydroxyl, the group is too weakly ionized to be a 2-hydroxy-1,4-quinone but must be activated to some extent. Brockmann and Muxfeldt (3) report a pK of 4.65 and 4.8 for lawsone and despeptidoactinomycin, respectively, in 50% dimethylformamide, while Schwarzenbach and Suter (13) give pK's of 2.73 and 5.18 for 2,5-dihydroxybenzoquinone in water. Under very mild conditions the pigment gave a yellow-brown quinoxaline, $C_{26}H_{18}O_5N_2$, decomposing above 229° C. Considered with the absence of a strongly dissociated acidic group in the molecule the ease with which this reaction occurred suggested that an *o*-quinone, and not a 2-hydroxy group adjacent to a quinonoid carbonyl, was present.

Zinc dust reduction gave only traces of volatile material. Better yields were achieved by fusion with zinc dust in a zinc chloride – sodium chloride eutectic mixture (6). The products were partially separated by chromatography on alumina and the major fraction found to be perylene, obtained in a yield of 13%. A second component with a typical phenanthrene absorption spectrum was shown to be identical with an authentic sample

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of hexahydroperylene. This ultraviolet evidence has been used previously by Hua-chih and Conrad-Billroth (10) to show that the hydroperylene has structure I but the fact appears to have been overlooked in more recent publications (5, 19). The remaining component was a volatile oil with an ultraviolet spectrum characteristic of a highly substituted naphthalene. During the preparation of authentic hexahydroperylene considerable amounts of a volatile by-product with very similar spectral properties were obtained. Analyses indicate a formula $C_{20}H_{22}$, and considering its origin there is little doubt that this is a hitherto unreported decahydroperylene. Since the bathochromic displacement of the absorption spectrum is considerably greater than that of a 1,8-disubstituted naphthalene, the compound is assigned the structure II, and it is clear that, contrary to the report of Zinke and Benndorf (18), products intermediate between octa- and tetradeca-hydroperylene are formed. Since these hydroperylenes are readily obtained from perylene by reduction, no significance is attached to their presence in the product from zinc dust fusion of the pigment. Moreover, the formation of perylene by this treatment does not restrict the carbon skeleton of the pigment to that of perylene, for under these conditions derivatives of 1,1′-dinaphthyl would also be expected to give a fully condensed ring hydrocarbon (12, 14). The possibility of naphthalene derivatives dimerizing is more remote, although, under the experimental conditions used, β-naphthoquinone did give a trace of perylene. The absence of an aromatic central ring in a perylene skeleton is suggested by the failure to obtain mellitic acid upon oxidation of the pigment with concentrated nitric acid (8).

On the basis of the above facts, the partial structure III is proposed for mycochrysone. This accommodates all of the carbon atoms and suggests a close structural relationship between the pigment and 4,9-dihydroxyperylene-3,10-quinone, isolated by Anderson and Murray from the fruiting bodies of the fungus *Daldinia concentrica* (1).



(I) (II) (III)

EXPERIMENTAL

Production

Petri dishes (9 cm diameter) containing potato dextrose agar (Difco) were inoculated at 5 to 8 well-separated points with blocks (*ca.* 0.5 cm cube) of agar and mycelium from 7-day-old cultures. Incubation was carried out for 7 days at 28° C, followed by 14 days at room temperature (20–25° C). Crystals of the pigment appeared among the dark mycelium after 7 to 10 days. On suitable liquid media, in shaken flasks, growth of the organism was more rapid and profuse, but under these conditions no mycochrysone could be detected.

Isolation

The freeze-dried mycelium and agar (143 g) from 160 plates were macerated in a Waring blendor with petroleum ether (1 liter) and the mixture kept for 12 hours at room temperature before filtering. The solvent was then evaporated to give a pale yellow oil (1.7 g) which decomposed on attempted distillation at 90° C at 0.05 mm.

Analar chloroform (3 liters) was added to the residue and the suspension was kept in the dark for 3 days at room temperature. The orange solution was filtered and concentrated to about 700 ml on a rotary evaporator to precipitate the pigment as orange microcrystalline needles. The extraction was repeated and the filtrate was added to the initial concentrate and again evaporated to about 700 ml. After the mixture had been left to stand at 4° C overnight the product (4.27 g) was filtered off and dried (100° C, high vacuum). On treatment of the residual mycelium and agar with a further 6 liters of chloroform in two extractions, as above, an additional 1.48 g of pigment was obtained.

Prepared in this way the pigment gave a single zone (R_f 0.60) when examined by circular chromatography on formamide-treated paper with chloroform as mobile phase. It was considered sufficiently pure for most experiments. After two crystallizations from chloroform by the same technique used in the initial isolation, the pigment decomposed slowly above 180° C. Found: C, 65.31, 65.67, 65.74; H, 3.82, 4.08, 3.68; active hydrogen (Zerewitinoff) 0.72%; no nitrogen, halogen, methoxy, or terminal methyl. Calculated for $C_{20}H_{14}O_7$: C, 65.57; H, 3.85; 3 active hydrogens, 0.82%. Ultraviolet absorption in ethanol λ_{max} 236, 307, and 438 mμ; log ϵ 4.50, 3.62, and 3.78, respectively.

The purified pigment was soluble in methanol, ethanol, and acetone, fairly soluble in benzene, chloroform, ether, and water, but insoluble in petroleum ether or carbon disulphide.

Quinoxaline

o-Phenylenediamine (200 mg) in ethanol (15 ml) was added to a solution of the pigment (100 mg) in hot ethanol (25 ml) and the reactants refluxed for 15 minutes. The quinoxaline separated after a few minutes as brown prisms, decomposing slowly above 223° C. Two recrystallizations from ether gave the product as yellow-brown prisms decomposing slowly above 229° C. Found: C, 71.11; H, 3.87; N, 6.05%. Calculated for $C_{26}H_{18}O_5N_2$: C, 71.22; H, 4.14; N, 6.39%.

Attempts to prepare analytical samples of this derivative from methanolic solutions invariably gave a product with a lower decomposition point (from 210° C). Such samples gave lower values on analysis for C, H, and N, and it is concluded that under these conditions a small amount of oxidative degradation takes place.

When a methanolic solution containing mycochrysone and an excess of *o*-phenylenediamine, or an ethereal solution of the reactants together with anhydrous sodium sulphate, was kept for 12 hours at room temperature (2), it was shown by paper chromatography using formamide-treated paper and benzene as mobile phase that mycochrysone (R_f 0.05) had been completely converted to the quinoxaline (R_f 0.50).

Molecular Weight Determinations

Isothermal distillation in acetone solution at 45° C using cholesterol as a standard gave a value of 370 for the molecular weight. The experiment was carried out in the dark. Microhydrogenations using 5% palladium–asbestos catalyst in ethanol at room temperature and atmospheric pressure showed a rapid uptake of hydrogen corresponding to reduction equivalents of 358 and 367. Under these conditions a further slow reduction took place.

Antibiotic Properties

Activity against bacteria and fungi was tested using the streak-dilution assay (15) on Waksman's glucose-broth supplemented agar (16). A stock solution containing 1 mg/ml of mycochrysone was prepared in 50% aqueous ethanol. Subsequent dilutions were made in sterile distilled water and aliquots of the suspension were mixed immediately with the cooled but still molten agar to give a range of final concentrations. Suspensions of the test organisms were streaked over the surface of the agar plates. *Staphylococcus aureus* v. *pyogenes* (PRL M2), *Bacillus subtilis* (PRL R2), *Escherichia coli* (PRL B44), and *Candida albicans* (ATCC 10231) were incubated at 37° C. Complete suppression of growth was obtained with the *Staphylococcus* at 5 μg/ml and with the *Bacillus* at 15 μg/ml. The remainder of the organisms and *Penicillium roqueforti* (PRL 1763), which was incubated at 28° C, were not inhibited at the highest concentrations tested (100 μg/ml). Controls included in the assay demonstrated that inhibition was not due to solvent toxicity.

Zinc Chloride – Zinc Dust Fusion (Typical Run)

A stirred solution of mycochrysone (49 mg) in acetone (5 ml) and zinc dust (1 g) was evaporated to dryness by an air stream so that a fine precipitate of the pigment adhering to the zinc was obtained.

Zinc dust (3.5 g) was stirred into a melt of zinc chloride (4.0 g) and sodium chloride (0.8 g). On cooling, the mass was broken up, ground into a fine powder, and divided into two equal portions. One was intimately mixed with the pigment-coated zinc and added in equal portions to five small test tubes. The second half of the melt was divided similarly, placed on top of the first layer, and tamped firmly down.

The reactants were heated at 210° C for 4 minutes and subsequently at 310° C for 5 minutes. The froth formed on top of the melts during the heating was dispersed with glass rods. On cooling, the zinc and zinc chloride were dissolved in hot, dilute hydrochloric acid. The aqueous suspension was extracted with benzene (4×100 ml) and the extract evaporated to dryness, redissolved in petroleum ether – benzene (95:5), and chromatographed on a column (7×1.5 cm) of alkaline alumina (Brockmann Grade I). Two fluorescent fractions were collected, the first eluted with petroleum ether – benzene (95:5), and the second with petroleum ether – benzene (50:50). The second fraction was evaporated to dryness and sublimed in high vacuum to give perylene (4.4 mg, 13%), m.p. 272–274° C, undepressed on admixture with an authentic sample. Found: C, 95.44; H, 4.85%. Calc. for $C_{20}H_{12}$: C, 95.21; H, 4.79%.

The first fraction was found to contain a mixture of an oil and a solid. The products from several fusions were combined and sublimed. The solid fraction was separated from the oil by trituration with petroleum ether and purified by a further sublimation (110° C at 0.01 mm). The compound, m.p. 176–182° C (softening at 168° C), gave ultraviolet and infrared spectra indistinguishable from an authentic sample of hexahydroperylene (m.p. 178–184° C), and the melting point on admixing the two compounds showed no depression.

β-Naphthoquinone (50 mg) under the same conditions gave perylene (0.14 mg, 0.35%).

Decahydroperylene

Perylene (100 mg) was reduced in a benzene and alcohol solution with sodium (1 g). The conditions differed from those employed by Zinke and Benndorf (19) only in that the reaction was completed in 45 minutes. Chromatography of the product on a column (8×1.4 cm) of cationotropic alumina (Brockmann Grade I) gave the following fractions:

THEORY OF THE TRANSIENT PHASE IN AN ENZYME SYSTEM INVOLVING TWO ENZYME–SUBSTRATE COMPLEXES

THE CASE OF THE FORMATION OF PRODUCTS FROM THE FIRST COMPLEX[1]

LUDOVIC OUELLET[2] AND JAMES A. STEWART[3]

ABSTRACT

A theoretical treatment is worked out for the kinetic scheme

$$\begin{matrix} E + S \rightleftarrows ES_1 \rightarrow ES_2 + P_1 \\ ES_2 \rightarrow E + P_2 \end{matrix}$$

in which the concentration of P_1 is followed. The steady-state and transient phase equations are obtained subject to the condition that the substrate concentration is greatly in excess of the enzyme concentration. The conditions under which evidence in favor of this mechanism can be obtained from experimental data are discussed. Under certain conditions, the weight of the enzyme corresponding to one active site can be determined. Methods for the evaluation of the different constants are described.

INTRODUCTION

The description of the transient phase of an enzyme–substrate system in cases involving one enzyme–substrate complex or two consecutive enzyme–substrate complexes with products appearing as a result of the decomposition of the last complex has been given previously (1, 2). In certain cases, such as the hydrolysis of esters by chymotrypsin (3) or by trypsin (4), there are indications that the release of products involves two steps, one for the release of the alcohol and one for the release of the acid. Following the rate of appearance of the first-appearing product is often possible (if the alcohol is a phenol, for example, and can be determined colorimetrically), and could provide additional useful information on the mechanism of the reaction. The purpose of this paper will be to discuss such a case in more detail than has been done previously (5).

THEORY

Let us consider the system

$$\underset{e_0-y_1-y_2}{E} + \underset{s_0}{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{y_1}{ES_1} \xrightarrow{k_2} \underset{y_2}{ES_2} + \underset{p_1}{P_1}$$

$$\underset{y_2}{ES_2} \xrightarrow{k_3} E + \underset{p_2}{P_2}.$$

In most cases the concentration of the substrate s_0 is much larger than the concentration of the enzyme e_0, so that s_0 can be considered constant during the transient phase. The following differential equations describe the system:

$$[1] \qquad \dot{y}_1 = k_1 s_0 (e_0 - y_1 - y_2) - (k_{-1} + k_2) y_1,$$

$$[2] \qquad \dot{y}_2 = k_2 y_1 - k_3 y_2,$$

[1]*Manuscript received August 22, 1958.*
Contribution from the Chemistry Department, the University of Ottawa, Ottawa, Canada.
[2]*Present address: Université Laval, Quebec, Canada.*
[3]*Present address: Laboratories of the Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada.*

[3] $$\dot{p}_1 = k_2 y_1,$$

[4] $$\dot{p}_2 = k_3 y_2.$$

Steady State

The steady state equations are obtained by setting $\dot{y}_1$ and $\dot{y}_2$ equal to zero. This leads to

[5] $$\dot{p}_1 = \dot{p}_2 = \frac{k_1 k_2 k_3 e_0 s_0}{k_1 s_0 (k_2 + k_3) + k_3 (k_{-1} + k_2)}$$

which can be reduced to the following classical form of Michaelis and Menten (6)

[6] $$\dot{p}_1 = \frac{V s_0}{K'_m + s_0}$$

where V, the maximum rate is given by

[7] $$V = \frac{k_2 k_3 e_0}{k_2 + k_3}$$

and K'_m, the experimental Michaelis constant is

[8] $$K'_m = \frac{k_3}{k_2 + k_3} \frac{k_{-1} + k_2}{k_1}.$$

It should be noticed that if $k_3 \gg k_2$, the complex ES_2 exists only in very small amounts and the steady state description of the system is given by

[9] $$V = k_2 e_0$$

[10] $$K'_m = (k_{-1} + k_2)/k_1 = K_m$$

corresponding to the case of a single complex.

Transient Phase

Eliminating y_2 between equations [1] and [2] leads to

[11] $$\ddot{y}_1 + (k_1 s_0 + k_{-1} + k_2 + k_3)\dot{y}_1 + [k_1 s_0 (k_2 + k_3) + k_3 (k_{-1} + k_2)] y_1 - k_1 k_3 e_0 s_0 = 0,$$

which can be written as

[12] $$\ddot{y}_1 + P\dot{y}_1 + Q y_1 - R = 0.$$

It has been shown previously (2) that the case $P^2 - 4Q < 0$, leading to periodic solutions, is not particularly interesting because the period is longer than the transient phase. In the cases where $P^2 - 4Q > 0$, the solution of equation [12] is

[13] $$y_1 = (R/Q) + M e^{Ft} + N e^{Gt}$$

where

[14] $$F = \tfrac{1}{2}[-P + \sqrt{(P^2 - 4Q)}]$$

[15] $$G = \tfrac{1}{2}[-P - \sqrt{(P^2 - 4Q)}]$$

and M and N are constants to be determined from the boundary conditions that at time zero, $y_1 = 0$ and $\dot{y}_1 = k_1 e_0 s_0$.

This leads to the following values for M and N

[16] $$M = -(R/Q) \frac{k_3 G + Q}{k_3 (G - F)},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[17] $$N = (R/Q)\frac{k_3F+Q}{k_3(G-F)}.$$

Inserting the value of y_1 into equation [3] and integrating one obtains for the value of p_1 as a function of time

[18] $$p_1 = \frac{k_2Rt}{Q}+\frac{k_2M}{F}(e^{Ft}-1)+\frac{k_2N}{G}(e^{Gt}-1).$$

When t is sufficiently large, so that the terms e^{Ft} and e^{Gt} become negligible (F and G are always negative),

[19] $$p_1 = \frac{k_2Rt}{Q}-\frac{k_2M}{F}-\frac{k_2N}{G}.$$

It is evident that equation [19] is the proper integrated form of equation [5] for an open system in which s_0 is maintained constant.

A qualitative plot of the function represented by equation [18] is shown in Fig. 1. The initial exponential rise is due to the term $(k_2N/G)(e^{Gt}-1)$ of the expression. The approach to steady state, with decreasing rate is due to $(k_2M/F)(e^{Ft}-1)$. The relative magnitudes of these two terms depend on the relative magnitudes of F and G. As all the quantities involved are positive, G will usually be larger than F, and e^{Gt} will approach 0 more rapidly than e^{Ft}, whilst the coefficient of e^{Gt} containing F/G will be smaller than the coefficient of e^{Ft} containing G/F. This condition suggests that the e^{Ft} term will be easier to detect, experimentally, than the e^{Gt} term.

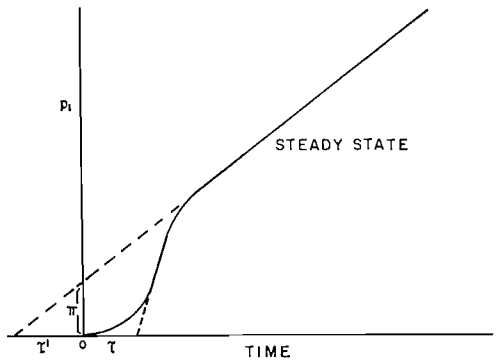

FIG. 1. Schematic plot of amount of product 1 (p_1) against time, in the general case.

The straight line obtained after steady state conditions have prevailed introduces, when extrapolated to the axes, two quantities that can be measured: τ', the intercept on the time axis, and π, the intercept of the p_1 axis.

From equation [19], which describes the steady state condition of the system, τ' can be obtained by making $p_1 = 0$, and solving for t. After substitution of the proper quantities for R, Q, M, N, and F, τ' becomes

[20] $$\tau' = \frac{k_3^2-k_1k_2s_0}{k_1k_3(k_2+k_3)(s_0+K'_m)}.$$

Two extreme cases regarding the relative magnitudes of k_2 and k_3 will be considered. In the first case, if $k_3 \gg k_2$, corresponding to only a fleeting existence of the complex ES_2, equation [20] reduces to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

[21] $$\tau' = 1/k_1(s_0+K_m) - k_2 s_0/k_3^2(s_0+K_m).$$

The first part of this expression is identical with that obtained in the case where only one complex is formed (1). The second part could be considered a correction term the magnitude of which depends on the relative magnitudes of $k_1 s_0$, k_2, and k_3.

In the second extreme case where $k_2 \gg k_3$, τ' becomes

[22] $$\tau' = -s_0/k_3(s_0+K'_m) + k_3/k_1 k_2(s_0+K'_m).$$

In the second term of equation [22], k_3/k_2 is small by hypothesis. On the other hand, $1/k_1(s_0+K'_m)$ is usually very small (3). At any rate, it could be measured from the true induction period, τ, if it is not small (see Fig. 1, and equation [37]). In the cases where an induction period cannot be detected, the influence of the second term of equation [22] on τ' is negligible, as it is k_3/k_2 times an undetectably small quantity. Under those conditions, τ' becomes

[23] $$\tau' = -s_0/k_3(s_0+K'_m).$$

If enough data are available to plot $1/\tau'$ against $1/s_0$, the intercept on the $1/\tau'$ axis of the straight line obtained would give $-k_3$. The slope of the straight line obtained is K'_m, the experimental Michaelis constant obtained under steady state conditions. Since a value for $k_3 e_0$ can readily be obtained from the steady state rate of the reaction, under the condition that $k_2 \gg k_3$ (see equation [7]), a value for the concentration of the enzyme e_0 can be calculated, in moles per liter, the units of p_1. In the case of pure enzymes, e_0 can be measured directly in grams per unit volume, and one can calculate the number of grams of enzyme reacting with 1 mole of substrate to form the complex ES_2. This would give the number of active sites per molecule of enzyme if the molecular weight of the enzyme was known from other methods.

Similar information could, of course, be obtained from the intercept on the p_1 axis. According to equation [19] the extrapolated value of p_1 at $t = 0$ is

[24] $$\pi = [k_2^2 e_0 s_0^2/(k_2+k_3)^2(s_0+K'_m)^2] - k_2 k_3^2 e_0 s_0/[k_1(k_2+k_3)^2(s_0+K'_m)^2].$$

In the case $k_3 \gg k_2$, π could become negative, depending on the relative magnitudes of k_2 and $k_1 s_0$. At best it is small compared to e_0.

In the case, $k_2 \gg k_3$, π becomes

[25] $$\pi = e_0 s_0^2/(s_0+K'_m)^2 - k_3^2 e_0 s_0/k_1 k_2(s_0+K'_m)^2.$$

The second term of this expression becomes negligible unless $k_1 s_0 \ll k_3$, a somewhat improbable situation, as k_1 is usually unmeasurably large. With the condition that $k_2 \gg k_3$, π then reduces to

[26] $$\pi = e_0 s_0^2/(s_0+K'_m)^2.$$

At high concentrations of substrate, compared to K'_m, the ratio $s_0^2/(s_0+K'_m)^2$ becomes practically equal to 1 and

[27] $$\pi = e_0.$$

Hartley and Kilby (7) have reported that the extrapolation of the concentration of *p*-nitrophenol produced during the hydrolysis of *p*-nitrophenol acetate by chymotrypsin to zero time gives the molar concentration of the enzyme. Such an observation could be interpreted as evidence that chymotrypsin has but one active site.

At low concentrations of substrate compared to K'_m, similar considerations lead to somewhat more complex results that will not be discussed.

Equations [24] and [25] indicate that the intercept on the p_1 axis is very small unless k_3 is much smaller than k_2 and $k_1 s_0$. Unless these conditions are fulfilled, equation [18] is hardly of any use as the steady state is approached very rapidly and the influence of the exponential part is very small. For these reasons, a discussion of equation [18] will be limited to the cases where k_2 and $k_1 s_0$ are larger than k_3. Under these conditions

[28] $$P = k_1(s_0+K_m)$$

[29] $$Q = k_1 k_2(s_0+K'_m)$$

where K_m and K'_m are described as

[30] $$K_m = (k_1+k_2)/k_1$$

[31] $$K'_m = k_3 K_m/k_2.$$

The series development of $\sqrt{(P^2-4Q)}$ leads to

[32] $$F = -\frac{k_2(s_0+K'_m)}{s_0+K_m} - \cdots$$

[33] $$G = -k_1(s_0+K_m)+k_2(s_0+K'_m)/(s_0+K_m) - \cdots$$

A further simplification can be obtained in F and G if experimental conditions are so chosen that s_0 is much larger than K'_m. The conditions $k_2 \gg k_3$ and equation [31] imply that such conditions could be realized and still have s_0 of a magnitude comparable to K_m. This leaves

[34] $$F = -\frac{k_2 s_0}{s_0+K_m} - \cdots$$

[35] $$G = -k_1(s_0+K_m)+k_2 s_0/(s_0+K_m) - \cdots$$

Under these conditions equation [18] becomes

[36] $$p_1 = \pi+k_3 e_0 t+k_2(M/F)\exp[-k_2 s_0/(s_0+K_m)]t + k_2(N/G)\exp[-k_1(s_0+K_m)+k_2 s_0/(s_0+K_m)]t.$$

At the very beginning of the reaction, the second exponential will have a retarding effect on the appearance of the product P_1. Figure 2 is a theoretical plot of p_1 as a function of time according to equation [18]. It is obtained by assuming that $s_0 \gg K_m$ and assigning values of 100, 10, and 1 to $k_1 s_0$, k_2, and k_3 respectively. Under these conditions $F = -11.3$ and $G = -99.8$, which justifies, in part, the assumption that under the present conditions F and G can be approximated to the values given by equations [34] and [35].

The short induction period indicated in Fig. 2 can be calculated by expanding $\exp[(-k_2 s_0/(s_0+K_m)]t$ in series and taking the first two terms only, since t is small at the beginning of the reaction. The extrapolation to $p_1 = 0$ of the curve obtained when $\exp[-k_1(s_0+K_m)]t$ is negligibly small gives

[37] $$\tau = 1/k_1(s_0+K_m).$$

In cases where both a measurable π, interpreted according to equation [25], and a measurable τ, interpreted according to equation [37] appear, values for both k_1 and k_2 can be obtained. Such cases are unknown, as far as we know. In the known cases where the mechanism described here could apply, the induction period is unmeasurably small (3). Such behavior implies that $\exp(Gt)$ is unmeasurably small even at the beginning of the reaction. Under such conditions, equation [35] becomes, assuming $k_2 \gg k_3$,

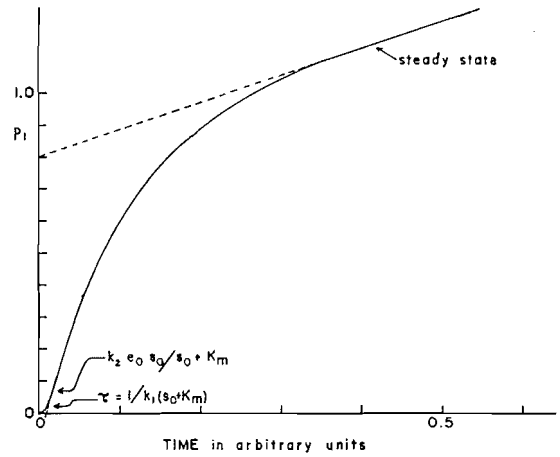

FIG. 2. Theoretical plot of p_1 as a function of time assuming $s_0 \gg K_m$ and $k_1 s_0 = 100$, $k_2 = 10$, $k_3 = 1$ $k_{-1} = 0.1$. The ordinate p_1 is in enzyme concentration units.

$$[38] \qquad p_1 = e_0 + k_3 e_0 t - e_0 \exp[-k_2 s_0/(s_0 + K_m)]t.$$

If a physical property proportional to p_1 can be measured, k_2 and K_m can be evaluated from the values of $k_2 s_0/(s_0 - K_m)$ at different concentrations of substrate, using the Guggenheim technique (8).

At the beginning of the reaction, the series development of the exponential part of equation [38] would give a good approximation of the function. From equation [38], one can then describe the initial rate of production of the first appearing product, P_1, by,

$$[39] \qquad p_1 = [k_3 + k_2 s_0/(s_0 + K_m)]e_0 t.$$

The smaller k_3 becomes, compared to k_2, the better the approximation. Values for k_2 and K_m can be obtained from initial rate data using the ordinary techniques of enzyme kinetics (9). In so doing, one assumes that the concentration ES_1 is in a steady state right at the beginning of the reaction while the concentration of ES_2 reaches a steady state sometime later.

RÉSUMÉ

Une discussion théorique de la cinétique, dans le cas de réactions enzymatiques, d'une réaction du type

$$E + S \rightleftharpoons ES_1 \rightarrow ES_2 + P_1$$
$$ES_2 \rightarrow E + P_2$$

est présentée. Différentes situations expérimentales sont analysées en termes des simplifications qu'elles apportent et des renseignements qu'elles donnent sur le système. L'analyse du système permet de justifier la détermination des constantes cinétiques et en certains cas de donner une approximation de la masse de l'enzyme par site actif, si le mécanisme proposé ci-haut est appuyé par des données expérimentales suffisantes.

A STOPPED-FLOW MIXING DEVICE FOR THE SPECTROPHOTOMETRIC STUDY OF RAPID REACTIONS[1]

JAMES A. STEWART[2] AND LUDOVIC OUELLET[3]

ABSTRACT

A simplified stopped-flow mixing device, which has been adapted to a Beckman DU spectrophotometer, is described. Removable storage syringes are used to inject the required solutions into the apparatus, while the operations of filling the reaction syringes, mixing the reactants, or standardization are achieved with T-bore stopcocks. Provision has been made in the design for interchangeable mixing chambers and observation cells. The temperature is controlled by circulating water through a suitable enclosure surrounding the reaction syringes. A zero-suppression method has been devised to record the extent of reaction.

The transient phase kinetics of several enzyme systems has been described from the experimental and theoretical point of view by Chance (1, 2, 3, 4, 5, 6, 7, 8), Beers (9, 10, 11), Gutfreund (12, 13, 14, 15, 16), and Laidler (16, 17). This type of investigation, which provides useful information not obtainable from steady state kinetics, has not been fully utilized probably because of the complex experimental technique. Therefore, this paper will attempt to develop a simplified technique for the study of transient phase kinetics employing the stopped-flow apparatus along the lines of other workers (1, 4, 5, 6, 11, 18, 19, 20, 21).

APPARATUS

A block diagram of the apparatus is shown in Fig. 1. A Beckman Model DU spectro-

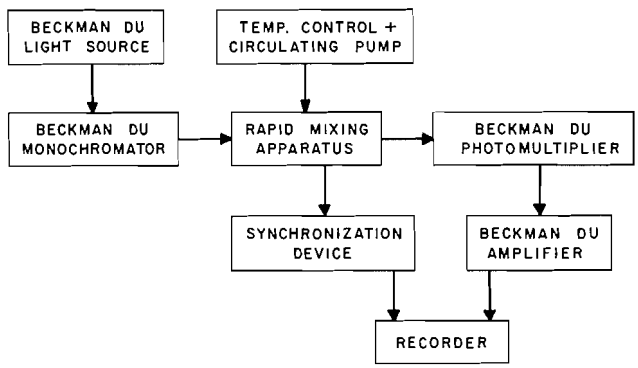

FIG. 1. Block diagram of the apparatus.

photometer equipped with a photomultiplier attachment and recording adapter (#5800) was used. The time constant of the circuit was decreased by altering the load resistance on the photomultiplier cell from 22 meg and 0.01 μf to 0.68 meg and 0.002 μf. The 510-ohm output resistor of the Beckman recording adapter was replaced with a 750-ohm potentiometer, so that the output impedance or sensitivity could be varied.

Stopped-flow Mixing Apparatus

The stopped-flow method was originally conceived by Chance (1) for the rapid mixing of enzyme and substrate. The apparatus to be described is in principle the same, but such features as a plunger-release mechanism, standardization, temperature control, magnetic stopcock at the outlet, the use of rubber "O" ring seals, removable storage syringes, and interchangeable observation tubes and mixing chambers have been added for greater ease in operation and construction.

The details of the apparatus, which is illustrated in Fig. 2, are as follows. The 1-ml

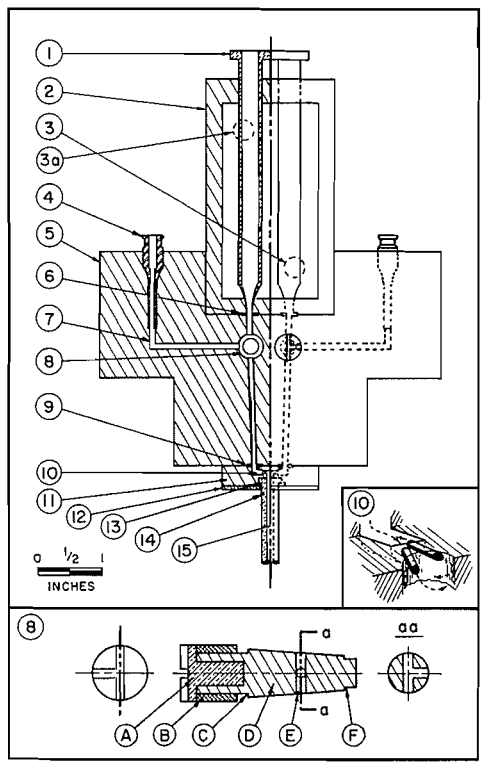

FIG. 2. The stopped-flow mixing apparatus.

reaction syringes "1" are held in the plexiglass enclosure "2" which acts as a constant-temperature bath, fitted with water inlet "3" and outlet "3*A*". The reaction syringes are filled from removable storage syringes located on hypodermic needles "4" embedded in the plexiglass section "5". The lower insert in Fig. 2 gives the details of the T-bore plug of the stopcock "8", which connects the veins "7" from storage syringe to reaction syringe, reaction syringe to mixing chamber, or storage syringe to mixing chamber. The T-slotted head of brass core "*A*" is positioned to coincide with T-bore "*E*" to aid in the alignment of the bore with the veins. An aluminum sleeve "*B*" secures the plexiglass plug "*D*" to brass core "*A*". External leakage of liquid is prevented by rubber "O" ring seals located at "*C*" and "*F*", which are held in position by pressure plates (not illustrated).

A three-dimensional sketch of the mixing chamber "10" is shown in the right-hand insert of Fig. 2. Here, each reactant enters through a pair of 0.5-mm jets that are located

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

between the tangent and diameter of the chamber and diagonal to each other (19). The mixed reactants pass into the observation cell "15" where the change in absorbance is measured photoelectrically. The present 2-mm observation cell is constructed of plexiglass, but provision has been made in the design for the use of quartz or pyrex observation tubes. These will be sealed in the plexiglass block "11" by a rubber O ring and pressure plate "12".

The plexiglass sections "2", "5", and "11" are fastened together with vertical screws,

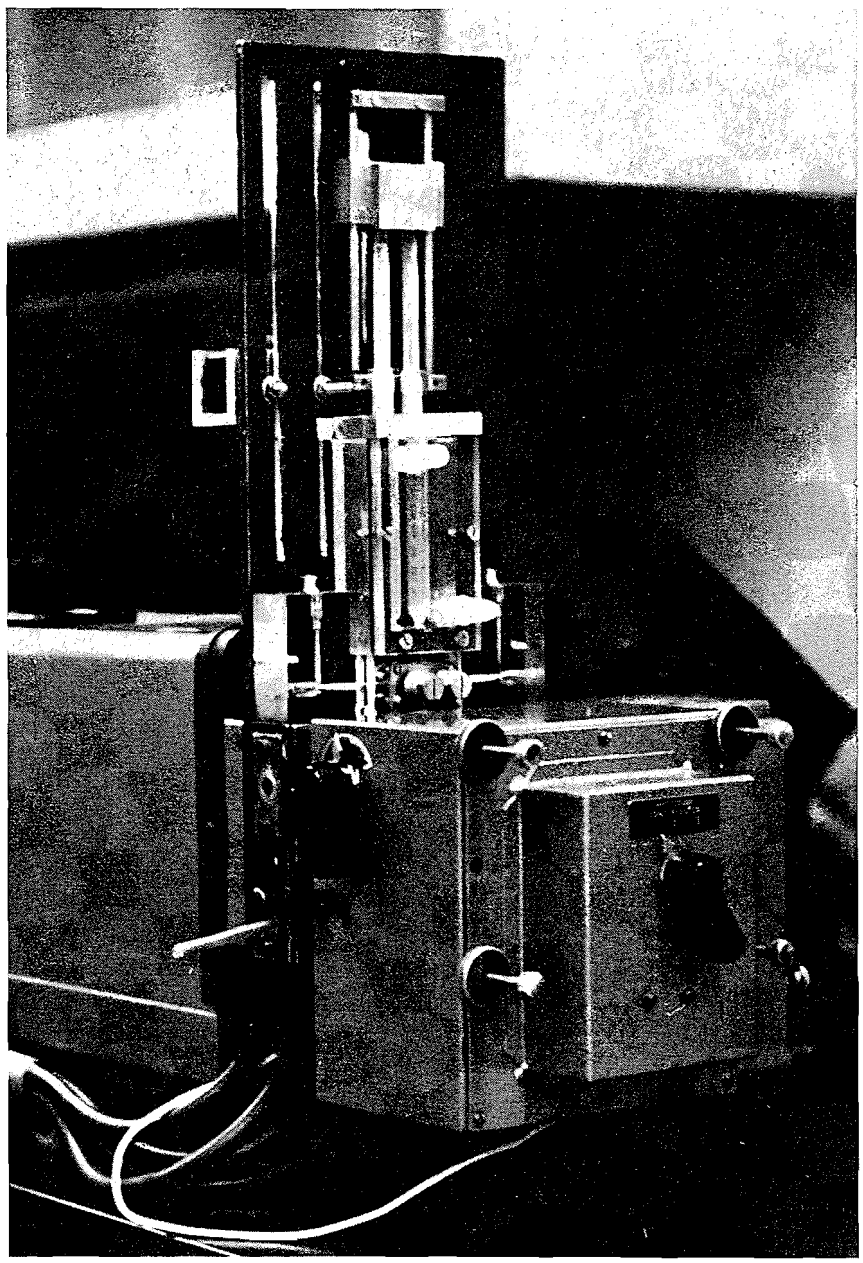

FIG. 3. The stopped-flow apparatus mounted in the Beckman DU.

and external leakage at the joins is prevented by rubber "O" ring seals at "6" and "9". The apparatus is attached to an aluminum plate which replaces the cell compartment of a Beckman DU spectrophotometer as illustrated in Fig. 3. This aluminum plate also supports the plunger and synchronization mechanism.

Plunger Holder and Release Mechanism

Equal portions of two reactants are driven manually from the reaction syringes into the observation cell by the mechanism shown in Fig. 4. A track consisting of two vertical rods carries a brass block that drives the plungers. A plunger-release plate restrains the

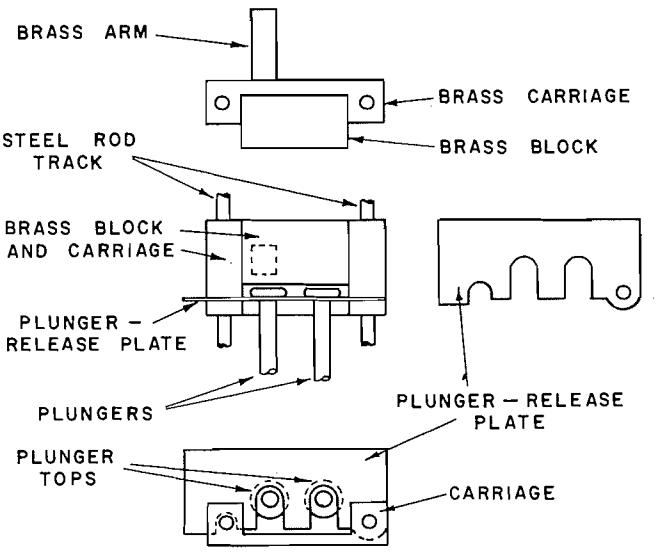

FIG. 4. The plunger holder and release mechanism.

downward motion of the plungers, and is hinged to one side of the track so that the plungers may be freed. This allows the reaction syringes to be filled by pressure from the storage syringes, or the plungers to be removed for the elimination of residual air by completely filling the syringes.

Synchronization Mechanism

The synchronization mechanism in Fig. 5 is used to synchronize the events of stopped

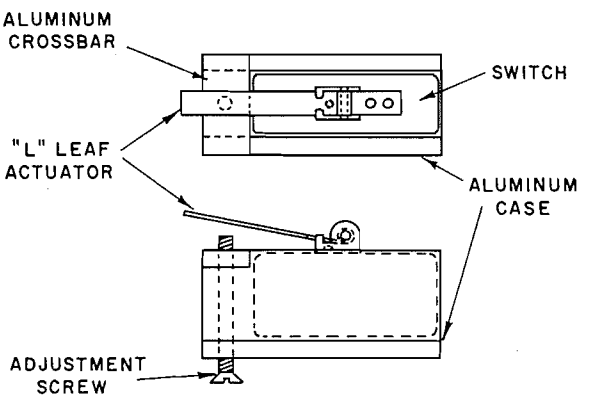

FIG. 5. The synchronization mechanism.

For personal use only.

flow and the beginning of recording. This is accomplished by a brass arm on the carriage of the plunger mechanism (Fig. 4), which actuates the "L" leaf of a snap-action switch when it reaches the crossbar of the case surrounding the switch (Fig. 5). Synchronization is adjusted by a screw located in this cross bar.

In the "on" position the switch applies an electrical potential to initiate the sweep circuit of a cathode-ray oscillograph, the chart drive of a pen recorder, or the operation of a time-marker device. In the case where more than one potential is to be synchronized a fast acting four-pole-double-throw relay is incorporated in the circuit.

Temperature Control

Water from a thermostated bath capable of control to $\pm 0.1°$ C is circulated through the enclosure around the reaction syringes, Beckman thermospacers, and the lamp housing of the spectrophotometer.

Recorders

The cathode-ray oscillograph, the pen oscillograph, and the high-speed strip-chart recorder are all suitable for studying rapid reactions, each having its own particular advantage. The cathode-ray oscillograph is useful when a response of <0.01 second is required, while the pen oscillograph could be recommended above this range because of the direct-writing feature. In the case of certain reactions, which have been studied in this laboratory, the high-speed strip-chart recorder with a response of 0.25 second for a 10-inch deflection was found to be sufficient.

MODE OF OPERATION

Reactants kept in a constant temperature bath are transferred to the reaction syringes by means of suitable storage syringes. The reaction is recorded by manually driving the plunger mechanism, which forces the reactants into the mixing chamber and the observation cell. When the flow stops, a synchronized recorder produces the reaction trace.

The following zero suppression method was found to achieve the sensitivity required by the stopped-flow technique (5). With the phototube shutter closed (0% transmittance) the output voltage of the recording adapter is given an arbitrary value (300 mv available) using the suppression and dark current adjustments. The phototube shutter is then opened, and the slit of the monochromator varied until this output is zero. The latter may be chosen to correspond to 100% transmittance or a convenient percentage reaction with an appropriate standard solution in the observation cell. The first procedure is used when the reactants are colorless but the products colored, while the second is adapted to follow the disappearance of colored reactants.

APPLICATION

The apparatus described has been employed in a kinetic study of the enzymatic hydrolysis of *p*-nitrophenyl acetate with trypsin and is the subject of a subsequent paper (22). The stopped-flow method, however, has been used in a similar instance for the study of *p*-nitrophenyl acetate hydrolysis with chymotrypsin (15). Therefore, it was convenient to repeat part of this work as a check on technique.

Hydrolysis of p-Nitrophenyl Acetate with Chymotrypsin

Theoretical.—Measurements of the rate of appearance of *p*-nitrophenol at small values of t have been employed for this chymotrypsin system to evaluate F given in the relationship,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

[1] $$P_1 = k'_3\, e_{0t} + e_0\,(1-\exp Ft) \qquad \text{(ref. 23)}$$

where P_1 is the concentration of *p*-nitrophenol, k'_3 is the apparent rate constant for deacetylation of enzyme, e_0 is the initial concentration of enzyme, t is the time, and $-F$ is the quantity to be determined. If equation [1] is treated as suggested by Guggenheim (24) the result is

[2] $$\log|r_1+r_3-2r_2| = \log \text{constant} + (Ft_1/2.303) \qquad \text{(ref. 15)}$$

where r_1, r_2, and r_3 are readings directly proportional to P_1 taken at the times t_1, $t_1+\Delta t$, and $t_1+2\Delta t$, respectively. Therefore, F can be determined from the slope of a plot of $\log|r_1+r_3-2r_2|$ against t_1.

EXPERIMENTAL

Enzyme.—Twice crystallized chymotrypsin (salt-free) was purchased from the Mann Research Laboratories, Inc., New York.

Substrate.—*p*-Nitrophenyl acetate was synthesized according to the method of Chattaway (25), and recrystallized from an ethanol–water solution m.p. 78–79°.

Buffers.—The appropriate buffered solutions were prepared from monosodium and disodium phosphate so that the reaction solutions contained 0.05 *M* phosphate.

Solvent.—To improve the solubility of the substrate 20% (v/v) isopropyl alcohol was used.

RESULTS

Figure 6 gives the Guggenheim plot for the reaction trace in Fig. 7 that was recorded

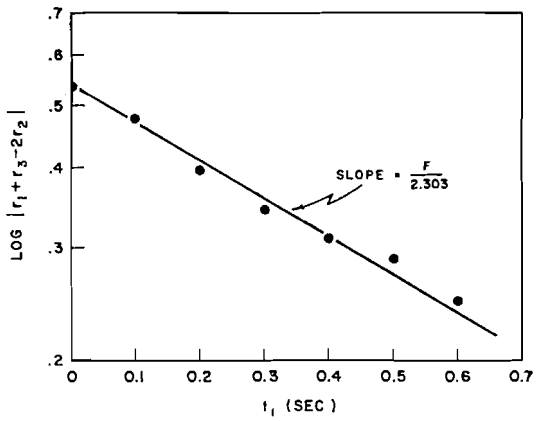

FIG. 6. A Guggenheim plot of the reaction trace for the chymotrypsin–NPA system.

THE TRYPSIN CATALYZED HYDROLYSIS OF *p*-NITROPHENYL ACETATE[1, 2]

JAMES A. STEWART[3] AND LUDOVIC OUELLET[4]

ABSTRACT

The hydrolysis of *p*-nitrophenyl acetate (NPA) by trypsin has been investigated in the early stage of the reaction using stopped-flow techniques. The influence of pH on the initial rate suggests competitive inhibition of the active site of the enzyme by hydrogen ions. The dissociation constant of the enzyme obtained from the kinetics of this reaction ($pK = 6.9$) indicates possible catalysis by an amino group or an imidazole group of the enzyme. Lysine methyl ester as an analogue of the enzyme catalyzes the hydrolysis of NPA under similar experimental conditions. The results are described in terms of an assumed mechanism and the nature of the catalytic site is discussed.

Hartley and Kilby (1, 2) first reported that the enzyme chymotrypsin was capable of catalyzing the hydrolysis of *p*-nitrophenyl acetate (NPA). From their results they concluded that the mechanism consisted of three distinct stages. The first stage is extremely rapid and concerns the combination of enzyme with substrate, the second stage is moderately rapid and involves the liberation of phenol and the acetylation of the enzyme, while the last stage, which is slow, liberates acetate with the consequent regeneration of enzyme.

Gutfreund and Sturtevant (3), employing stopped-flow techniques, showed that the rate constant for acetylation (second stage) of chymotrypsin with NPA was pH independent. This is contrary to their results for dinitrophenyl acetate (4) and the results of other workers (5) who report pH dependence.

The purpose of our investigation into the mechanism of trypsin catalyzed hydrolysis of NPA is mainly to clarify the problem as to whether or not the rate constant related to acetylation is pH independent, and compare the suggested mechanism with a mechanism recently proposed by Cunningham (6). His scheme, which emphasizes the hydroxyl group of a serine residue as primary site rather than the imidazolyl group of histidine, satisfies the available experimental evidence (7). However, when trypsin (8) or chymotrypsin (9) are treated with DFP^{32} (diisopropyl fluorophosphate) no histidine residue occurs in the vicinity of the phosphorylated serine, so that we would like to present some evidence that an amino group other than the imidazolyl might function as part of the catalytic site.

EXPERIMENTAL

Twice crystallized trypsin (salt-free) was obtained from the Mann Research Laboratories Inc., New York. The substrate *p*-nitrophenyl acetate was synthesized as described by Chattaway (10). All reactions were carried out in 20% (v/v) isopropyl alcohol at 25° C with 0.025 *M* phosphate as buffer. The pH values quoted refer to the buffer and were measured in the absence of alcohol, but in the presence of enzyme, using a Beckman Model G pH meter.

The rapid acetylation reaction was studied employing the stopped-flow apparatus

described previously (11), while the slow deacetylation reaction was followed with a Cary Model 11 spectrophotometer using the differential technique. The data were treated according to the suggested mechanism by the theoretical method outlined in a preceding paper (12).

RESULTS AND DISCUSSION

Effect of pH on Acetylation

The initial rapid production of *p*-nitrophenol, corresponding to the formation of acetyl-trypsin was recorded at several substrate and hydrogen-ion concentrations. The constant F (12) was then calculated from the reaction trace using the Guggenheim technique (13). A typical Lineweaver–Burk plot (14) of some of the results is given in Fig. 1, where the extrapolation of $1/F$ at infinite substrate concentration yields the same value for $1/k_2$ at two widely separated pH values. The fact that seven such plots between pH 6.2 and 7.8 produced the same result for $1/k_2$ strongly suggests competitive inhibition by hydrogen-ions. The same result, though not elucidated as competitive inhibition, was obtained with chymotrypsin (3). Similar to the usual Michaelis–Menten treatment, the slopes obtained from the Lineweaver–Burk plot in Fig. 1 involve K_m/k_2. According to Laidler (15), the variation of K_m/k_2 with pH provides the dissociation constants of the groups which comprise the active site of the enzyme. It should also be pointed out, as has been done previously (3), that should the three-step mechanism be general for other enzyme systems, then the standard Michaelis constant may consist of a rather large number of constants.

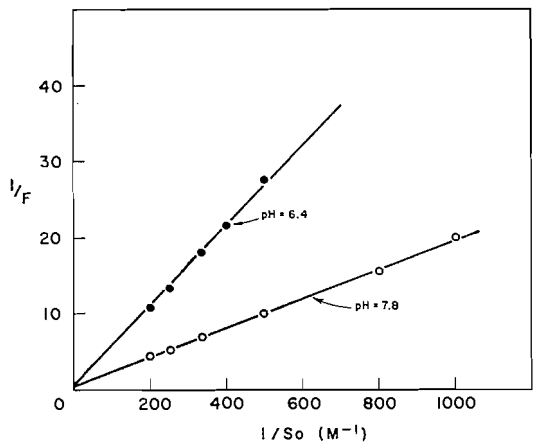

FIG. 1. A Lineweaver–Burk plot of the hydrolysis of NPA by trypsin (1 mg/ml) at pH 6.4 and 7.8.

The results given in Fig. 1 can be explained if we assume that hydrogen-ion competitively inhibits the initial combination of enzyme and substrate. With this in mind, the scheme for acetylation becomes,

$$(a) \qquad E + H^+ \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} EH^+$$

$$(b) \qquad E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES_1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

(*c*) $$ES_1 \xrightarrow{k_2} ES_2 + P_1$$

where E is the active form and EH^+ the inactive form of the enzyme, S is the substrate, ES_1 is the Michaelis complex, ES_2 is the acetylated enzyme, P_1 is the phenol, and k_1, k_{-1}, k_2, k_4, and k_{-4} are the appropriate rate constants. When this scheme is treated theoretically (12) and the effect of hydrogen-ion taken into account (15, 16, 17) $-F$, the quantity to be determined, formulates to

[1] $$F = -\frac{(k_2+k'_3)\,s_0+k'_3K'_m}{s_0+[(k'_3+k_2+k_{-1})/k_1](Ka+[H])/Ka}$$

when $k_2 \gg k'_3$

[2] $$F = -\frac{k_2 s_0}{s_0+K'_m}$$

where

[3] $$K'_m = K_m\left(\frac{Ka+[H]}{Ka}\right)$$

[4] $$K_m = \frac{k_2+k_{-1}}{k_1}$$

and

[5] $$Ka = k_{-4}/k_4.$$

Equation [2] may be also written as,

[6] $$-\frac{1}{F} = \frac{1}{k_2}+\frac{1}{s_0}\left(\frac{K_m}{k_2}+[H]\frac{K_m}{Ka\,k_2}\right).$$

Figure 2 was obtained by plotting the slopes of equation [6] against [H]. The resultant dissociation constant $Ka = 1.4\times10^{-7}$, which is related to the active site of the enzyme, was calculated from the intercept K_m/k_2 and the slope $K_m/k_2\,Ka$.

Equation [2] may be rearranged in still another fashion,

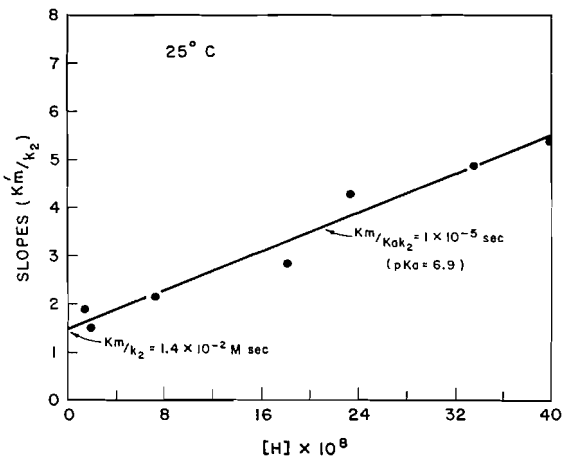

FIG. 2. The determination of K_m/k_2 and $K_m/Ka\,k_2$ for the trypsin–NPA system, from a plot of slopes against $[H^+]$.

[7] $$-\frac{1}{F}=\left(\frac{1}{k_2}+\frac{1}{s_0}\frac{K_m}{k_2}\right)+[\mathrm{H}]\frac{K_m}{s_0 Ka\, k_2}.$$

The constants k_2 and K_m were evaluated by plotting the intercepts of equation [7] against $1/s_0$, as illustrated in Fig. 3. The rate constant of acetylation $k_2 = 1.5\ \mathrm{sec}^{-1}$ was estimated from the intercept $1/k_2$, which allowed a Michaelis constant $K_m = 2.1 \times 10^{-2}\ M$ to be determined from K_m/k_2, the slope of the line.

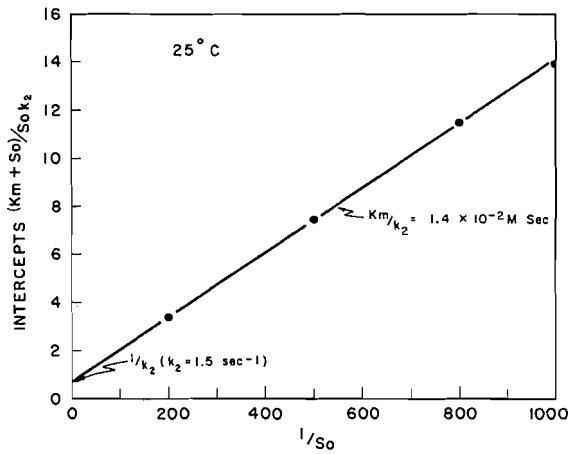

FIG. 3. The estimation of $1/k_2$ and K_m/k_2 by means of a plot of intercepts versus s_0, for trypsin catalyzed hydrolysis of NPA.

The results for k_2, Ka, and K_m are included in Table I, where the constants for trypsin and chymotrypsin are compared.

TABLE I

Kinetic constants for the enzymatic hydrolysis of *p*-nitrophenyl acetate

Constant	Trypsin	Chymotrypsin*
k_2 (sec^{-1})	1.5	3.1
K_m (M)	2.1×10^{-2}	6.8×10^{-3}

Effect of pH on Deacetylation

The reactions which represent deacetylation are:

(*d*) $$\mathrm{ES_2} \xrightarrow{k_3} \mathrm{E}+\mathrm{P_2}$$

(*e*) $$\mathrm{ES_2}+\mathrm{H^+} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} \mathrm{ES_2H^+}$$

where ES_2 is the unstable form and ES_2H^+ the stable form of the acetylated enzyme, P_2 is acetate, and k_3, k_5, and k_{-5} the appropriate rate constants. When t is large the rate is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

[8] $$\dot{p}_1 = \dot{p}_2 = k'_3\, e_0 \text{ (refs. 3, 10)},$$

where

[9] $$k'_3 = k_3\left(\frac{Ka'}{Ka'+[\mathrm{H}]}\right)$$

and

[10] $$Ka' = k_{-5}/k_5.$$

The slow deacetylation reaction was studied spectrophotometrically by following the phenol produced after the rapid acetylation reaction had subsided. The results were conveniently corrected for the spontaneous hydrolysis of NPA by placing the reaction solution in the sample cell and the same solution less enzyme in the reference cell of a double beam spectrophotometer, and recording the difference in absorbance. The reaction was started by introducing equal portions of NPA simultaneously into both cells with hypodermic syringes. The necessary corrections were then applied to the records to take into account that the fraction of colored species of *p*-nitrophenol, i.e. $pK_a = 7.15$ (18), varies with pH.

In the above manner the rates at different hydrogen-ion concentrations, which are plotted as the reciprocal rate against [H] in Fig. 4, were obtained. This plot gives a dissociation constant $Ka' = 1\times10^{-7}$ for acetylated trypsin and compares favorably with the constant Ka, concerned with the active site. The rate constant for deacetylation, $k_3 = 1.3\times10^{-2}$ sec^{-1}, was determined from the intercept of Fig. 4; the extinction coefficient of *p*-nitrophenol was taken as 1.8×10^4 (19), and the molecular weight of trypsin as 21,000 (20).

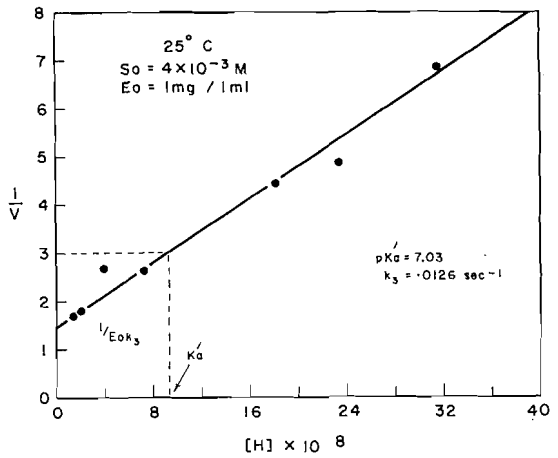

FIG. 4. A plot of the reciprocal rate of liberation of *p*-nitrophenol against $[H^+]$, for the determination of k_3e_0 and Ka' in the catalyzed hydrolysis of NPA by trypsin.

Mechanism of Hydrolysis

When the effect of proton inhibition is introduced, the result suggests a mechanism similar to that proposed by Cunningham (6). Quite different from former mechanisms his scheme advocates the hydroxyl group as primary site, rather than the imidazolyl which is now thought to be secondary. To facilitate a comparison of the two mechanisms those stages which correspond to reactions (*a*) to (*e*) are represented in the scheme outlined in Fig. 5. As our present experimental method does not detect the acyl-transfer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

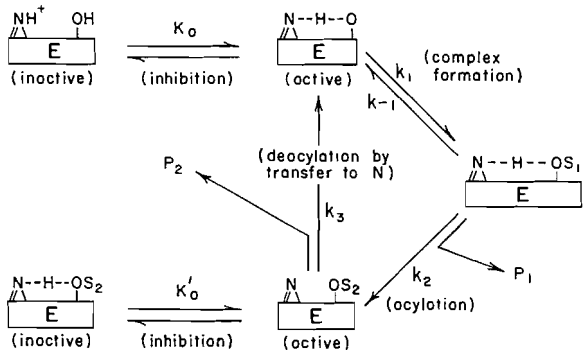

FIG. 5. The mechanism of enzymatic ester hydrolysis.

reaction, the absence of this transfer is the main difference in the two schemes. Thus, the rate constant k_3 for deacetylation is a composite constant involving two stages: the transfer of acetyl to nitrogen and its subsequent release.

In the scheme as shown in Fig. 5 the enzyme is inactive to complex formation unless a proton is released from the active site, and explains why inhibition is competitive rather than non-competitive. On examination of equation [1] it is seen that under certain conditions competitive inhibition may not be realized. This is especially true when the rate constants of acetylation and deacetylation are of the same order of magnitude. A Lineweaver–Burk plot of the data will not produce a straight line with constant intercept, and competitive inhibition may appear to be non-competitive.

The initial point of attack of substrate is the hydroxyl group of serine where the complex undergoes partial decomposition, releasing phenol. The hydroxyl group becomes acetylated, but before deacetylation can proceed there must be a transfer of the acetyl group to the nitrogen. The stability of certain acylated enzymes at low pH has been reported (5, 21, 22). This can be explained on the basis that transfer from the hydroxyl only takes place at higher pH values where the nitrogen does not have the inhibiting hydrogen intact. Therefore, proton inhibition at the deacylation stage accounts for this inactivity and stability of acetyltrypsin and chymotrypsin below a pH of 5 to 6.

A similar approach may be used to explain inhibition by certain organophosphorus compounds. For instance, in the case of DFP the hydroxyl group of a serine residue in the enzyme is phosphorylated, but transfer of this phosphoryl group to the nitrogen is difficult, resulting in an inactive enzyme.

Nature of the Catalytic Site

Tracer experiments show that DIP^{32} (diisopropyl phosphate) is attached to the hydroxyl group of a serine residue and no histidine (imidazole) occurs in the vicinity (8, 9). However, Westheimer (23) presents in detail the necessary orientation of the active site of chymotrypsin that enables the imidazolyl and hydroxyl groups to come together by folding. Also, spectrophotometric evidence has been published to show that acetyl-imidazolyl is an intermediate when acetyl-chymotrypsin decomposes (7).

The lack of histidine in the neighborhood of DIP^{32}–serine, and the differences in the pK values and the degree of activity of trypsin and chymotrypsin (see Table I) has led us to postulate that other groups might also function in partnership with the hydroxyl group to constitute an active site. As for model hydrolysis (24) the facts present the possibility that the basicity of the nitrogen containing group of the active site may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

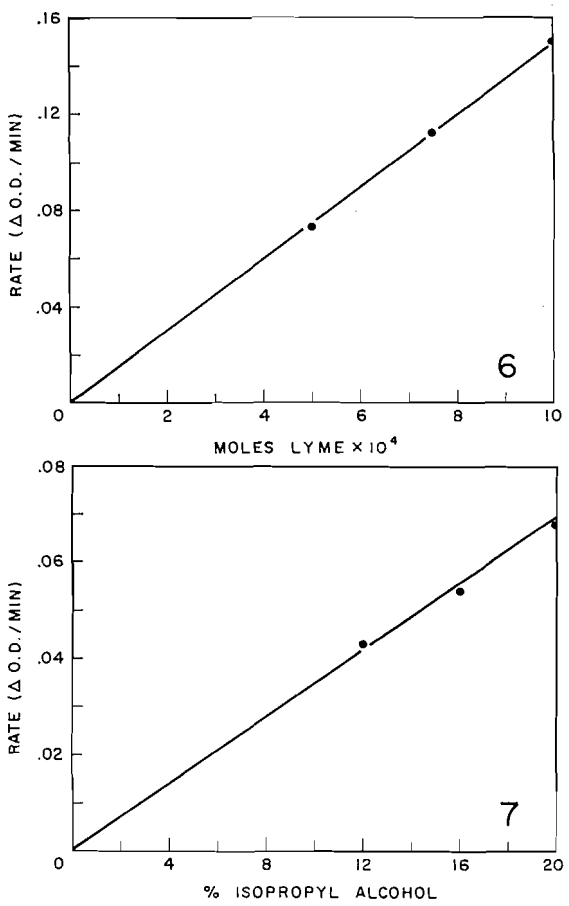

FIG. 6. The effect of LYME on the rate of hydrolysis of NPA in the presence of 20% (v/v) isopropyl alcohol.

FIG. 7. The effect of isopropyl alcohol on the rate of hydrolysis of NPA in the presence of 4×10^{-4} *M* LYME.

be the important factor. Since the pK of a free α-amino group in an ester is in the neighborhood of the pK for the active site of trypsin, lysine methyl ester (LYME) was tested and found to influence the rate of hydrolysis of NPA under conditions comparable to enzymatic hydrolysis. This effect is demonstrated in Fig. 6, where the rate of hydrolysis of NPA is proportional to the amino acid concentration. The same result was obtained by varying the isopropyl alcohol concentration and is given in Fig. 7. These results show that the aliphatic hydroxyl and amino groups could play a significant part in the constitution of an enzymatic site. Further evidence to support this hypothesis can be secured from the literature. Hartley and Kilby (2) have reported that the phenolic hydroxyl and the aliphatic amino groups may act as acceptors of the acetyl group. The work of Balls and co-workers reveals that chymotrypsin mediates the transfer of acetyl to ethanol (22) or trimethylacetyl to *n*-butanol (25), illustrating the importance of hydroxyl; while the significance of an amino group is shown by the transfer of acetyl from chymotrypsin to hydroxylamine (22) and the fact that certain monoacylated chymotrypsin derivatives are reactivated by tyrosine ethyl ester (25). Also, Wagner-Jauregg and Hackley (26) discovered during an investigation of the model hydrolysis

For personal use only.

of organophosphorus inhibitors that certain amino and hydroxyl substituted pyridines, and such compounds as catechol, increased the rate of hydrolysis as compared to pyridine.

Finally, some results were obtained by infrared spectroscopy using the KBr-pellet technique which indicate the α-amino group is acetylated when NPA is allowed to hydrolyze in the presence of tyrosine ethyl ester (TYEE). From the infrared spectra in Fig. 8 it is seen that both acetyl-TYEE and the system of NPA hydrolyzed in the presence of TYEE possess appreciable absorbance at 1660 cm^{-1}, while TYEE and hydrolyzed NPA do not; thereby disclosing that tyrosine ethyl ester is acetylated during the hydrolysis of NPA.

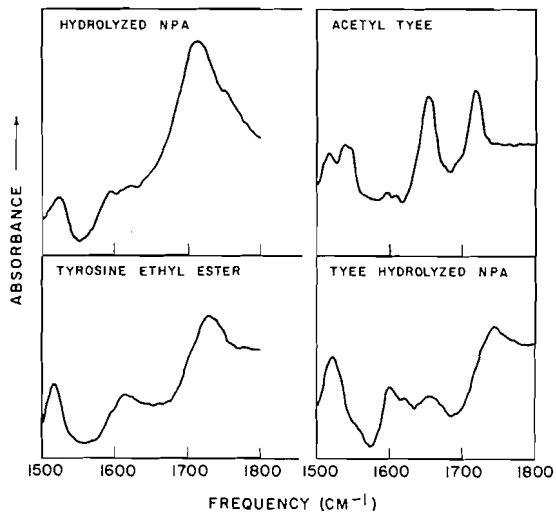

FIG. 8. The infrared spectra of freeze-dried solutions of hydrolyzed NPA, TYEE, acetyl-TYEE, and NPA hydrolyzed in the presence of TYEE; each containing 20% (v/v) isopropyl alcohol and 0.05 *M* phosphate pH 7.8.

CONCLUSIONS

The rate constant related to the acetylation stage during the trypsin or chymotrypsin catalyzed hydrolysis of NPA appears to be pH independent. The mechanism implied by the result is in agreement with the postulated mechanism of Cunningham. There is some degree of suggestion that this three-step scheme might be general, and in the instance of other enzyme systems the Michaelis constant may be a composite of a larger number of constants than formerly anticipated. Even though it has been shown that hydroxyl groups and amino groups influence the rate of hydrolysis of NPA, further investigations will be required before definitely establishing the nature of their relationship to enzymatic hydrolysis. This is particularly true in the case of the free α-amino group. Although the pK of this group in an ester and possibly a peptide would be in agreement with the pK reported for the active site of trypsin, free α-amino groups are believed to exist only in the terminal residues of proteins.

ACKNOWLEDGMENT

We wish to thank the National Research Council of Canada for their financial support of a portion of this research.

THE STEREOCHEMISTRY OF THE PIMARIC ACIDS[1,2]

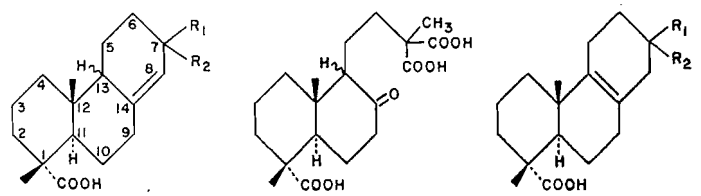
O. E. EDWARDS AND R. HOWE[3]

ABSTRACT

Isodextropimaric and dextropimaric acids have been shown to have the same stereochemistry at C_1, C_{11}, and C_{12}, but to be epimeric at C_7. A critical survey is made of the present evidence with regard to the stereochemistry at C_{13} in these acids. Preliminary experiments on the action of formic acid on isodextropimaric acid are reported.

In view of the current interest in the stereochemistry of the tetracarbocyclic diterpenes, e.g. rimuene (2, 3), phyllocladene (3, 4, 5, 6), mirene (3, 7), steviol (6, 8), cafestol (6, 9, 10) and gibberellic acid (11), and also the tetracarbocyclic diterpene alkaloids, e.g. the *Garrya* alkaloids (6, 10, 12), atisine (13), and ajaconine (14), the question of whether their close relatives, the pimaric acids, belonged to one steric group became of outstanding interest.

While the skeleton I (R_1 = vinyl; R_2 = methyl) and stereochemistry at C_1, C_{11}, and C_{12} of dextropimaric acid have been well established (15, 16), the stereochemistry at C_7 and C_{13} has remained in doubt. Isodextropimaric acid, which occurs with dextropimaric acid in the oleoresin of *Pinus palustris* (17), has been shown to have the same basic skeleton as dextropimaric acid by Harris and Sanderson (18). However, their



I II III

degradation products were optically inactive and the possibility existed that epimerization at the asymmetric center adjacent to the carbonyl group of the keto-tricarboxylic acid II might have taken place (3). Hence the only safe conclusion which may be drawn from their experiments is that isodextropimaric acid is identical at C_1, C_{11}, and C_{12} to dextropimaric acid, or bears an over-all mirror image relation to it at these centers.

The evidence presented below establishes that the two acids are identical at C_1, C_{11}, and C_{12}, and that they are epimeric at C_7 as originally suggested by Harris and Sanderson (18) on equivocal evidence, but allows no certain conclusion about the stereochemistry at C_{13}. Since our preliminary communication (1), Wenkert and Chamberlin (19), and Green, Harris, and Whalley (20) have announced the same and further conclusions (see below for a critical discussion).

As a preliminary to our work it was necessary to re-examine the properties of the dihydro- and tetrahydro-derivatives of both acids, because of the conflicting data in the literature. The vinyl double bond in both acids was readily reduced in the presence

For personal use only.

of presaturated palladized charcoal. Dihydroisodextropimaric acid was purified by chromatography on silica gel and recrystallization of its cyclohexylamine salt. It melted at 173–175° and had $[\alpha]_D$ −7°. (The literature values are m.p. 173–175°, $[\alpha]_D$ ±0° (EtOH) (18) and m.p. 173.5°, $[\alpha]_D$ −16° (chloroform–acetone, 1 : 1) (21).) The dihydrodextropimaric acid was isolated directly from Staybelite Resin by a modification[4] of the method of Hasselstrom and Bogert (22). It melted at 243–245° and had $[\alpha]_D$ +22°. The infrared spectrum of both acids (nujol mull) contained medium bands at 825 cm^{-1}, corresponding to the trisubstituted double bonds.

Dihydroisodextropimaric acid slowly took up 0.76 mole of hydrogen over Adams' catalyst in acetic acid giving a product with $[\alpha]_D$ +30°. This took up a further 0.27 mole of hydrogen in the presence of fresh catalyst. The tetrahydro-acid had m.p. 172–173° and $[\alpha]_D$ +24° (EtOH), +21° ($CHCl_3$). Ukita *et al.* (23) report a melting point of 172–172.5° (no rotation).

A similar hydrogenation of dihydrodextropimaric acid gave tetrahydrodextropimaric acid, m.p. 238–240°, $[\alpha]_D$ +18°, in agreement with Ruzicka *et al.* (24), who report a melting point of 236–237° (no rotation). Le-Van-Thoi and Ourgaud (25) report a melting point of 198° with $[\alpha]_J$ +55° for tetrahydrodextropimaric acid. This appears to be a mixture of Δ^{13}-dihydrodextropimaric acid (see below) and the tetrahydro-acid which we now report. (Their analytical figures fit $C_{20}H_{32}O_2$ rather than $C_{20}H_{34}O_2$.) When dihydrodextropimaric acid was allowed to absorb 0.25 mole of hydrogen the total product melted at 193–197° and had $[\alpha]_D$ +53° in excellent agreement with their product. On complete reduction this mixture gave pure tetrahydro-acid, m.p. 238–240°, $[\alpha]_D$ +19°.

In order to compare the asymmetry at C_7, methods were sought for eliminating or rendering identical the asymmetry at C_{13} in dextro- and isodextro-pimaric acids and their derivatives. The action of strong acids on the pimaric acids could possibly cyclize the diene to a tetracarbocyclic system, isomerize the nuclear double bond to the Δ^{13}-position, produce γ- and δ-lactones (e.g. IV and V), and convert the C_7-substituents to an isopropylidene group. In the isodextropimaric acid series, conditions have been found for producing all these changes except the cyclization of the diene system.

The easiest method of destroying the asymmetry at C_{13} appeared to be by isomerizing the $\Delta^{8,14}$-ethylenic bond to the Δ^{13}-position. When isodextropimaric acid was refluxed with *p*-toluenesulphonic acid in dry dioxane, the desired migration was slowly brought about,[5] but it was found to be a poor preparative method. The cleanest method of isomerizing the $\Delta^{8,14}$ double bond to the Δ^{13}-position was found to be by the action of hydrogen chloride in chloroform. The method was first applied to the dihydro-acids (I; R_1 = ethyl; R_2 = methyl) in order to prevent complicating reactions due to the vinyl group.

Dihydrodextropimaric acid (I; R_1 = ethyl; R_2 = methyl) and dihydroisodextropimaric acid (I; R_1 = methyl; R_2 = ethyl) were converted by hydrogen chloride in chloroform to their Δ^{13}-isomers (III), m.p. 181.3°, $[\alpha]_D$ +73°, and m.p. 107–108°, $[\alpha]_D$ +76.7° respectively. The infrared spectra of the products lacked the 825 cm^{-1} band characteristic of the starting materials and together with the hydrogenation evidence presented below leads to the Δ^{13}-assignment for the double bond.

Hydrogenation of Δ^{13}-dihydrodextropimaric acid in acetic acid with Adams' catalyst gave the same tetrahydrodextropimaric acid as reported above, m.p. 238–240°,

[4]*We cordially thank Dr. T. H. Sanderson, of Hercules Research Center, for the resin and for kindly furnishing details of the isolation method.*

[5]*We thank Dr. D. K. R. Stewart for characterizing the isodextropimaric acid, and for preliminary experiments on the isomerization with p-toluenesulphonic acid.*

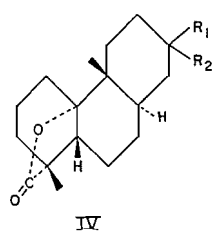
$[\alpha]_D$ +19° as the only product. Similar conditions converted Δ^{13}-dihydroisodextropimaric acid to the same tetrahydroisodextropimaric acid as reported above, m.p. 172–173°, $[\alpha]_D$ +21°. Since dihydrodextropimaric acid is recovered unchanged after refluxing with glacial acetic acid for 5 hours, the possibility of group migration or skeletal rearrangement may be precluded in both the hydrogenation experiments and during the hydrogen chloride – chloroform treatment of the dihydro-acids.

It was reported above that the intermediate product isolated during the reduction of dihydroisodextropimaric acid had a rotation which was more positive than either the starting material or the final product. This provided a valuable clue that hydrogenation was accompanied by double-bond migration to give the Δ^{13}-dihydro-acid of high positive rotation and less facile reducibility. An interpretation of Le-Van-Thoi and Ourgaud's results was also afforded. We attempted, but found that it was not possible, to obtain pure Δ^{13}-dihydrodextropimaric acid from dihydrodextropimaric acid by isomerization on the catalyst surface; conditions favoring isomerization also brought about some reduction.

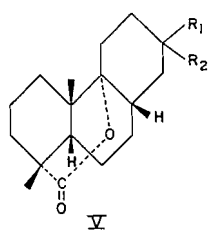
Dextropimaric acid has usually been considered to be stable to mineral acids (16), although Vesterburg (26) obtained some evidence that isomerization did occur when an ethereal solution of the acid was saturated with hydrogen chloride. Ruzicka and Balas (27) report the formation of three monohydrochlorides by long treatment of dextropimaric acid with acetic acid saturated with hydrogen chloride. When dextropimaric acid in chloroform was saturated with hydrogen chloride we found that the only product was the expected Δ^{13}-isomer, m.p. 131–132°, $[\alpha]_D$ +70°. The infrared spectrum revealed that the vinyl group had remained intact, while the trisubstituted ethylenic bond peak (825 cm^{-1}) had disappeared. Selective reduction of the vinyl group of the new Δ^{13}-acid gave the Δ^{13}-dihydrodextropimaric acid, m.p. 181–182°, $[\alpha]_D$ +75° reported above. Application of the hydrogen chloride method of isomerization to isodextropimaric acid, m.p. 162–164°, $[\alpha]_D$ ±0° produced the Δ^{13}-isomer, m.p. 106–107°, $[\alpha]_D$ +113°, the infrared spectrum showing peaks due to a vinyl group but none due to a trisubstituted ethylenic bond. Selective reduction of the vinyl group of the new Δ^{13}-acid gave Δ^{13}-dihydrodextropimaric acid, m.p. 107–108°, $[\alpha]_D$ +73° reported above.

Since our preliminary report of this work was published (1), Green, Harris, and Whalley (20) have reported Δ^{13}-isodextropimaric acid as having m.p. 118° and $[\alpha]_D$ +58°. Their isomerization appears to have been only partial, since we have prepared a synthetic mixture (*ca.* 1:1) of isodextropimaric acid and Δ^{13}-isodextropimaric acid having $[\alpha]_D$ +58° and found it to have m.p. 118–121°. In view of this the Δ^{13}-dihydroisodextropimaric acid which they report would also seem to be a mixture. Molecular rotation correlations based on the figures may well be meaningless.

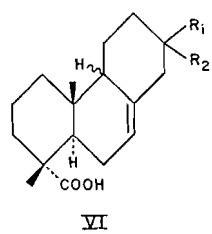
We now turn our attention to the lactones produced by more vigorous acid treatment of the dihydrodextro- and dihydroisodextro-pimaric acids. Δ^{13}-Dihydrodextropimaric acid with concentrated sulphuric acid at −5° C gave the known γ-lactone (28) (IV; R_1



IV



V



VI

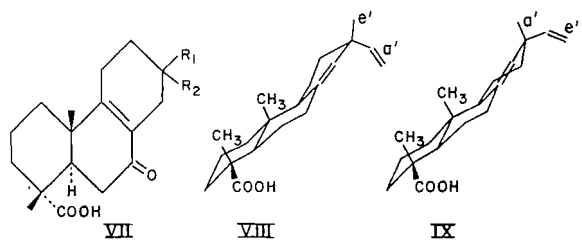
For personal use only.

= ethyl; R_2 = methyl) m.p. and mixed m.p. 100°, $[\alpha]_D$ −15°, which was also obtained from dihydrodextropimaric acid. Similar conditions converted both dihydroisodextro and Δ^{13}-dihydroisodextropimaric acid to a new γ-lactone (IV; R_1 = methyl; R_2 = ethyl) m.p. 105–106°, $[\alpha]_D$ −9°. More vigorous acid treatment, i.e. concentrated sulphuric acid at 25° C converted the γ-lactone of dihydroisodextropimaric acid to a new δ-lactone (V; R_1 = methyl; R_2 = ethyl) m.p. 72–73°, $[\alpha]_D$ −40°, which could also be obtained directly from dihydroisodextropimaric acid under similar conditions. This δ-lactone differed from the known δ-lactone (28) (V; R_1 = ethyl; R_2 = methyl) from dihydrodextropimaric acid, m.p. 142°, $[\alpha]_J$ −45°. In one experiment, the action of *p*-toluenesulphonic acid on isodextropimaric acid in dioxane solution produced a new γ-lactone IV (R_1 = methyl; R_2 = vinyl), m.p. 128–130°, $[\alpha]_D$ −1° in very poor yield.

The fact that dihydrodextropimaric and dihydroisodextropimaric acids give different Δ^{13}-derivatives, γ-lactones, and δ-lactones proves conclusively that the acids are epimeric at C_7. The correspondence of ΔM_D on going from the Δ^{13}-dihydro-acids to the γ-lactones (−268° and −260° respectively) firmly indicates the *identical* stereochemistry at C_1, C_{11}, and C_{12} in both acids. The comparable rotational change on the transformation of Δ^{13}-dihydroabietic acid (III; R_1 = isopropyl; R_2 = H) to a γ-lactone (29) (IV; R_1 = isopropyl; R_2 = H) (ΔM_D −398°) provides additional proof that the stereochemistry of ring A of the pimaric acids is correctly shown in I.

Ukita and Tsumita (21) report the isolation from the fruits of *Juniperus japonica* of isodextropimaric acid and also a new pimaric acid, m.p. 162.5–165°, $[\alpha]_D$ −8.9°, which gives tetrahydroisodextropimaric acid, m.p. 172–173° on complete hydrogenation. This new acid cannot have the Δ^{13}-structure (III; R_1 = methyl; R_2 = vinyl) which they assign to it (23), since its properties are distinct from those of Δ^{13}-isodextropimaric acid (m.p. 106–107°, $[\alpha]_D$ +113°) reported here. Through the great kindness of Professor Ukita we have been able to make further observations on this new acid. Treatment of Ukita's acid in chloroform with hydrogen chloride converted it to Δ^{13}-isodextropimaric acid, m.p. 105–107°, $[\alpha]_D$ +110°, identical with that reported above. We conclude that Ukita's acid[6] may be $\Delta^{9,14}$-isodextropimaric acid (VI; R_1 = methyl; R_2 = vinyl) or its 13-epimer. The key compound (VII; R_1 = methyl; R_2 = ethyl) in Ukita's proof of structure was derived from the corresponding allyl alcohol, which must have arisen by



VII VIII IX

allylic oxidation and double bond migration during selenium dioxide oxidation of VI (R_1 = methyl; R_2 = ethyl). Fieser (30) has reported several examples of bond migration concomitant with selenium dioxide oxidations. The infrared spectrum of Ukita's acid has peaks at 1410, 1000, and 910 cm^{-1}, characteristic of a vinyl group, but shows only a shoulder at 825 cm^{-1} due to the trisubstituted ethylenic bond. However, the corre-

[6]*The naming of Ukita's acid will be deferred until the stereochemistry at C_{13} is known, when it can be named so as to indicate its relationship to isodextropimaric acid.*

sponding dihydro-acid with the vinyl group reduced, m.p. 154–157°, $[\alpha]_D$ +18° shows the expected trisubstituted ethylenic bond peak at 825 cm^{-1}.

The change in molecular rotation on reduction of the Δ^{13}-ethylenic bond of Δ^{13}-dihydrodextropimaric and Δ^{13}-dihydroisodextropimaric acid (ΔM_D −182° and −175° respectively) indicates that hydrogenation has taken place in the same stereospecific sense in both cases. Models indicate that approach of a catalyst surface will be much more facile from the α-face, regardless of the C_7 orientation. Assuming *cis*-addition of hydrogen, this leads to a structure for the tetrahydro-acids having the C_{13} and C_{14} hydrogen atoms α-orientated. It is interesting to note that ΔM_D for the conversion of rimuene to tetrahydro-rimuene (2) (+65°) agrees better with the ΔM_D for the similar change in the isodextropimaric acid series (+72°) rather than that in the dextropimaric acid series (−199°).

Having shown that dextropimaric and isodextropimaric acid are epimeric at C_7, it remains to decide the actual stereochemistry at C_7 for each acid and to elucidate the stereochemistry at C_{13}. Wenkert and Chamberlin (19) have studied the infrared spectra of the equilibrium mixtures of γ- and δ-lactones derived from dihydrodextropimaric and dihydroisodextropimaric acids. From the percentages of γ- and δ-lactones (5±0.6% and 95±0.6%) and (3.6±0.8% and 96.4±0.8%) respectively in each equilibrium mixture, they reach the conclusion that in dextropimaric acid the vinyl group is β-orientated, and therefore in isodextropimaric acid it must be α-orientated. This result is independent of the stereochemistry at C_{13}. However, in view of the very small observed difference in the percentages of the γ- and δ-lactones in each equilibrium mixture and the intrinsic difficulty in obtaining high precision in quantitative infrared spectrophotometry, it seems to us that one should be cautious in accepting these conclusions.

From surface tension measurements, Bruun (31, 32) had previously reached the same conclusion concerning the stereochemistry at C_7 in these acids but had tacitly assumed that the C_{13} hydrogen atom is α-orientated in both acids. This seems a reasonable assumption in view of the closeness of the collapse areas for dextropimaric and the abietic acids (44.2 → 44.6 sq. Å), and isodextropimaric (43.6 sq. Å).[7] However since Bruun ignored the effect of the $\Delta^{8,14}$-ethylenic bond on the conformation of ring C (VIII and IX), his conclusions with regard to the stereochemistry at C_7 based on the film balance studies and on the intensities of absorption due to the vinyl group in the infrared (34, 35) are not necessarily correct. Furthermore, following a recent mass spectrometric study of the resin acids, Bruun, Ryhage, and Stenhagen (36) have reached the conclusion that dextropimaric and isodextropimaric acids are epimeric at C_{13} in opposition to the conclusion indicated on the basis of the film balance work.

Green, Harris, and Whalley (20), following a method reported earlier by us, agree that dextropimaric and isodextropimaric acid are epimeric at C_7 and without giving any details conclude that they are probably also epimeric at C_{13}. In dextropimaric acid, they consider that the C_{13}-hydrogen atom is α-orientated, i.e., *trans*- to the C_{12} methyl group, because dextropimaric acid is said to be stable to mineral acids. We have already shown, however, that dihydrodextropimaric acid is readily isomerized by hydrogen chloride in chloroform, and now report that dextropimaric acid behaves in a similar manner.

In view of the above uncertainties, we consider that the stereochemistry at C_{13} remains unproved for dextropimaric and isodextropimaric acids.

[7]*While no close analogue is available a somewhat comparable change of molecular shape to that involved in changing from a 13α- to a 13β-hydrogen atom in the pimaric acids is found in the cholestanol → coprostanol transformation (33). Here the effect is to increase the collapse area by ca. 3 sq.* Å.

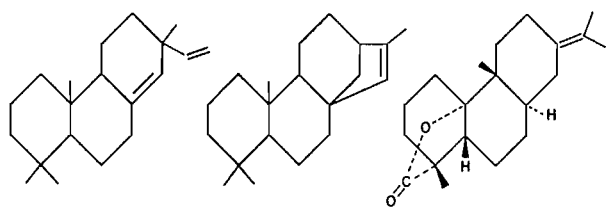
We have simultaneously measured the amount of migration in a given time of the $\Delta^{8,14}$-ethylenic bond of dihydrodextropimaric and dihydroisodextropimaric acid catalyzed by mineral acid. The conditions were not sufficiently reproducible from run to run to give the same values for any given time interval but for every run carried out dihydroisodextropimaric acid was found to isomerize faster than dihydrodextropimaric acid as shown by the representative values given in the table.

	% of Δ^{13}-isomer formed	
Time (min.)	Dihydrodextropimaric acid	Dihydroisodextropimaric acid
3	11	25
6	23	39
10	40	52
15	38	45
20	48	58
40	79	82
100	86	88

These results could point to a difference in stereochemistry at C_{13} in the two acids, but may also be a measure of the effect of the differing stereochemistry at C_7, i.e., a quasi-equatorial ethyl group becoming equatorial after migration would act as an additional driving force whereas a quasi-axial group becoming axial after migration would retard the process.

We are at present engaged in converting the vinyl group of both dextropimaric and isodextropimaric acid to a methyl group in order to eliminate the asymmetry at C_7, and thereby establish whether or not dextropimaric and isodextropimaric acid have similar or dissimilar stereochemistry at C_{13}.

Some preliminary observations have been made on the action of formic acid on isodextropimaric acid, under conditions which cyclize rimuene (X) to isophyllocladene (37) (XI). No acidic product was isolated from the reaction. The products characterized



X XI XII

are an unsaturated γ-lactone of probable structure (XII), a hydrocarbon $C_{19}H_{29}$, clearly formed by decarboxylation of the β-γ-unsaturated acid which is intermediate in the formation of the γ-lactone XII, and also the known hydroxy-γ-lactone previously obtained (38) by the action of concentrated sulphuric acid on dextropimaric acid at $-30°$ C. The γ-lactone (XII), m.p. 109.5–111°, $[\alpha]_D$ $-54°$, showed no absorption in the infrared at 825 cm^{-1} characteristic of a trisubstituted ethylenic bond, and when it was hydrogenated in acetic acid with Adams' catalyst, it formed the known saturated γ-lactone (IV; R_1 = isopropyl; R_2 = hydrogen) which may be obtained from any of the dihydroabietic acids by the action of concentrated sulphuric acid at $-5°$ (39, 40). In order to obtain a reference sample of this γ-lactone, neoabietic acid was partially hydrogenated in ethanol solution using palladized charcoal (30%). A-Dihydroabietic

For personal use only.

acid (29, 41), m.p. 149°, $[\alpha]_D$ +43°, was isolated in 25% yield and was converted by concentrated sulphuric acid at −5° into the γ-lactone IV (R_1 = isopropyl; R_2 = hydrogen). On similar treatment, the non-crystalline material from the hydrogenation afforded the same γ-lactone.

EXPERIMENTAL

Unless otherwise stated rotations were determined in absolute ethanol, and infrared spectra were determined on nujol mulls using a Perkin–Elmer model 21 double beam spectrophotometer.

Isodextropimaric Acid

WW pine gum rosin was converted to its 2-methyl-2-amino-1,3-propanediol salt in 2-butanone and the sparingly soluble salt of neoabietic acid collected (42). The mother liquors on concentration gave several crops of salt with low rotation. After three recrystallizations from 2-butanone this salt melted at 184–187° with slight preliminary sintering. The acid was liberated from the salt and recrystallized twice, giving a sample melting at 159–162° and having $[\alpha]_D$ −2±1° (*c*, 3.36). This was reconverted to the aminopropanediol salt, which after two recrystallizations melted at 184–187° after sintering slightly at 180°. The acid liberated from this had m.p. 160–163° and $[\alpha]_D$ 0° (*c*, 2.1). It did not depress an authentic specimen of isodextropimaric acid very kindly provided by Mr. R. V. Lawrence. It gave a methyl ester with diazomethane which crystallized from methanol as glistening plates, m.p. 61.5–62.5°.

Partial Hydrogenation of Isodextropimaric Acid

A solution of isodextropimaric acid (600 mg) in ethanol (25 ml) was hydrogenated in the presence of prereduced palladized charcoal catalyst (30%; 125 mg). Hydrogen (48 ml) was rapidly absorbed during 2 minutes, after which time absorption ceased abruptly. Calc. for 1 mole, 49 ml. The total product $[\alpha]_D$ −2° (*c*, 1.26; $CHCl_3$) was adsorbed on silica gel (15 g) and eluted with 50-ml portions of light petroleum – benzene (1:1) to give seven fractions as gums. Fractions 2 → 5 inclusive had similar rotations ($[\alpha]_D$ −4°) and were combined and recrystallized from methanol to give dihydroisodextropimaric acid as stout needles, m.p. 173–175° (450 mg), $[\alpha]_D$ −7° (*c*, 1.11), $[\alpha]_D$ −5° (*c*, 1.1; $CHCl_3$). Found: C, 78.61; H, 10.32. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1698 cm^{-1} (—COOH); 825 cm^{-1} (trisubstituted double bond).

The dihydro-acid (200 mg) in acetone was treated with cyclohexylamine (66 mg) in acetone to form the salt. After four recrystallizations from acetone the salt formed soft needles m.p. 203–206° (too insoluble for determination of rotation). Found: C, 77.56; H, 10.72. Calc. for $C_{21}H_{44}NO_2$ (402): C, 77.62; H, 10.95. The dihydro-acid regenerated from the pure salt had m.p. 173–175°, $[\alpha]_D$ −5° (*c*, 1.27; $CHCl_3$). The methyl ester formed plates m.p. 75° from methanol–water, $[\alpha]_D$ −5° (*c*, 2.01). Found: C, 78.89; H, 10.35. Calc. for $C_{21}H_{34}O_2$ (318): C, 79.25; H, 10.69.

Hydrogenation of Dihydroisodextropimaric Acid

A solution of dihydrodextropimaric acid (100 mg) in acetic acid (20 ml) was hydrogenated in the presence of Adams' catalyst (75 mg); 0.76 moles of hydrogen were absorbed in 24 hours. The total product, thrown out of methanol solution by water had m.p. 158–161°, $[\alpha]_D$ +30° (*c*, 0.96; $CHCl_3$) and showed some unsaturation with tetranitromethane. The total product in acetic acid (20 ml) was rehydrogenated using 125 mg of the catalyst. In 12 hours 0.27 moles of hydrogen were absorbed. The total product, thrown out of methanol solution by water, formed needles m.p. 163–167°, $[\alpha]_D$ +19°

For personal use only.

(c, 1.15; $CHCl_3$). Chromatography on silica gel (3 g) using benzene as eluting solvent gave tetrahydroisodextropimaric acid as needles m.p. 172–173° (73 mg) from methanol–water, $[\alpha]_D$ +24° (c, 0.9), $[\alpha]_D$ +21° (c, 0.95; $CHCl_3$). Found: C, 78.46; H, 11.25. Calc. for $C_{20}H_{34}O_2$ (306): C, 78.37; H, 11.18%. Infrared spectrum 1700 cm^{-1} (—COOH). The methyl ester formed needles m.p. 68–69° from methanol–water, $[\alpha]_D$ +18° (c, 0.86). Found: C, 78.67; H, 11.08. Calc. for $C_{21}H_{36}O_2$ (320): C, 78.75; H, 11.26%.

Hydrogenation of Dihydrodextropimaric Acid

A solution of dihydrodextropimaric acid (117 mg) in acetic acid (35 ml) was added to Adams' catalyst (200 mg) which had been freshly reduced in acetic acid (5 ml). One mole of hydrogen was absorbed in 20 hours. The catalyst was removed by filtration and the acetic acid evaporated under reduced pressure. The crude product with m.p. 218–223° and $[\alpha]_D$ +20° (c, 1.13) was twice recrystallized from methanol to give tetrahydrodextropimaric acid as needles m.p. 238–240° (100 mg), $[\alpha]_D$ +18° (c, 1.1). Found: C, 78.41; H, 11.09. Calc. for $C_{20}H_{34}O_2$ (306): C, 78.37; H, 11.18%. Infrared spectrum 1699 cm^{-1} (—COOH).

Isomerization of Dihydrodextropimaric Acid on the Surface of a Catalyst

(*a*) A solution of dihydrodextropimaric acid (100 mg) in acetic acid (30 ml) was added to Adams' catalyst (20 mg) which had been freshly reduced in acetic acid (5 ml). One mole of hydrogen was absorbed in 20 hours. The crude product $[\alpha]_D$ +30° (c, 1.05) was recrystallized three times from methanol to give tetrahydrodextropimaric acid as needles m.p. and mixed m.p. 238–240° (60 mg), $[\alpha]_D$ +18° (c, 0.98). The mother liquors gave plates m.p. 177–180° (28 mg), $[\alpha]_D$ +39° (c, 0.86). A similar experiment to the above was carried out but without prereduction of the catalyst. The crude product with $[\alpha]_D$ +27° (c, 0.98) gave tetrahydrodextropimaric acid (65 mg) m.p. and mixed m.p. 238–240°, $[\alpha]_D$ +18° (c, 1.08), and also some plates m.p. 177–180° (20 mg), $[\alpha]_D$ +39° (c, 0.86). The material (45 mg) m.p. 177–180° obtained from the mother liquors of the above reductions was dissolved in acetic acid (30 ml) and added to Adams' catalyst (90 mg) which had been freshly reduced in acetic acid (5 ml). Two milliliters of hydrogen was absorbed in 20 hours. The total product $[\alpha]_D$ +17° (c, 0.74) was recrystallized from methanol to give tetrahydrodextropimaric acid as needles m.p. and mixed m.p. 238–240° (37 mg), $[\alpha]_D$ +18° (c, 1.0).

(*b*) A solution of dihydrodextropimaric acid (100 mg) in acetic acid (25 ml) was added to Adams' catalyst (20 mg) which had been freshly reduced in acetic acid (5 ml). Hydrogenation was allowed to proceed for 100 minutes after which time 1.9 ml of hydrogen had been absorbed. Calc. for 1 mole, 8.2 ml. The catalyst was removed by filtration and the acetic acid evaporated to give a solid m.p. 188–191°, $[\alpha]_D$ +54° (c, 1.17). When thrown out of methanol solution by water the total product formed prisms m.p. 193–197°, $[\alpha]_D$ +53° (c, 1.17). The constants of this material are approximately those m.p. 198°, $[\alpha]_J$ +55° reported by Le-Van-Thoi and Ourgaud (25) for tetrahydrodextropimaric acid. The above material m.p. 193–197° (63 mg) in acetic acid (20 ml) was added to Adams' catalyst (150 mg) freshly reduced in acetic acid (5 ml). Five milliliters of hydrogen was absorbed overnight. The crude product, $[\alpha]_D$ +20° (c, 0.92), was recrystallized twice from methanol to give tetrahydrodextropimaric acid as needles, m.p. and mixed m.p. 238–240° (48 mg), $[\alpha]_D$ +19° (c, 0.87).

(*c*) A solution of dihydrodextropimaric acid (100 mg) in acetic acid (25 ml) was added to Adams' catalyst (20 mg) which had been freshly reduced in acetic acid (5 ml). The mixture was shaken briefly once every minute for 1 hour under hydrogen. There was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

no uptake of hydrogen and the starting material was recovered virtually unchanged, m.p. and mixed m.p. 240–242°, $[\alpha]_D$ +25° (*c*, 0.77).

(*d*) The above experiment was repeated except that this time the mixture was shaken briskly for 22 hours under nitrogen, after first reducing the catalyst in hydrogen. Starting material was recovered, m.p. and mixed m.p. 240–242°, $[\alpha]_D$ +21° (*c*, 1.06).

Isomerization of Isodextropimaric Acid Using p-Toluenesulphonic Acid

Isodextropimaric acid (440 mg) in dry dioxane (30 ml) was refluxed with *p*-toluenesulphonic acid (100 mg) under nitrogen for 4 hours and then allowed to stand overnight. The dioxane was evaporated, the viscous residue dissolved in chloroform, and washed free from *p*-toluenesulphonic acid using water. Evaporation of the dried chloroform solution gave a yellow gum $[\alpha]_D$ +82° (*c*, 2.05; $CHCl_3$). The gum was dissolved in ether and extracted with aqueous potassium carbonate, the carbonate soluble part being recovered by the addition of dilute hydrochloric acid. The acidic gum so obtained was adsorbed on a silica gel column (7.5 g) and eluted with benzene (50-ml portions) to give eight fractions. Fractions $2 \rightarrow 6$ inclusive in acetone gave solid when cooled to −10°. The solid was recrystallized four times from acetone–water to give Δ^{13}-isodextropimaric acid as clusters of prisms, m.p. 105–106° (105 mg), $[\alpha]_D$ +94° (*c*, 1.14; $CHCl_3$). Found: C, 79.74; H, 9.75. Calc. for $C_{20}H_{30}O_2$ (302): C, 79.49; H, 9.93. Infrared spectrum 1694 cm^{-1} (—COOH); 1413 cm^{-1}, and 908 cm^{-1} (vinyl group).

Several repetitions of this experiment under similar or slightly different conditions gave products having rotations between +45° and +55° from which it was not found possible to obtain pure Δ^{13}-isodextropimaric acid by either chromatography or fractional crystallization of the free acid or its cyclohexylamine or 2-aminopropan-1,3-diol salts. A better preparative method is given below.

Isomerization of Dihydrodextropimaric Acid Using Hydrogen Chloride

Dry hydrogen chloride was passed into a solution of dihydrodextropimaric acid (400 mg) in dry chloroform (50 ml) at −5° C for 4 hours. The chloroform solution was washed free from mineral acid with water and then dried (Na_2SO_4) and evaporated to give a gum (390 mg), $[\alpha]_D$ +75° (*c*, 0.95) which solidified. After five recrystallizations from methanol, Δ^{13}-dihydrodextropimaric acid formed plates, m.p. 182–183° (305 mg), $[\alpha]_D$ +73° (*c*, 1.00). Found: C, 79.05; H, 10.35. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1696 cm^{-1} (—COOH); no ethylenic absorption.

Isomerization of Dihydroisodextropimaric Acid Using Hydrogen Chloride

Dry hydrogen chloride was passed into a solution of dihydroisodextropimaric acid (210 mg) in dry chloroform (12 ml) at −5° C for 4 hours. The chloroform solution was extracted with aqueous potassium carbonate. The aqueous extract on acidification gave an acid gum (170 mg) $[\alpha]_D$ +74° (*c*, 1.03; $CHCl_3$). The gum was adsorbed on silica gel (4 g) and eluted with 30-ml portions of light petroleum – benzene (1:1) to give 10 fractions. Fractions $2 \rightarrow 8$ inclusive were combined and recrystallized three times from acetone–water to give Δ^{13}-dihydroisodextropimaric acid as needles, m.p. 107–108° (130 mg) $[\alpha]_D$ +76° (*c*, 0.92), $[\alpha]_D$ +74° (*c*, 0.99; $CHCl_3$). Found: C, 78.96; H, 10.41. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1696 cm^{-1} (—COOH); no ethylenic absorption. The methyl ester was a colorless oil, b.p. 130–135° at 2×10^{-2} mm, $[\alpha]_D$ +56° (*c*, 1.04). Found: C, 79.13; H, 10.58. Calc. for $C_{21}H_{34}O_2$ (318): C, 79.25; H, 10.69.

Rate of Isomerization Experiments

Twenty-five milligrams of each dihydropimaric acid in a finely powdered state were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

simultaneously dissolved in 7-cc portions of ethanol-free dry chloroform previously saturated with hydrogen chloride at 0°. Dry hydrogen chloride was bubbled through the solutions maintained at 0°. Reaction time was measured from the time of complete solution. The reaction was quenched by three water washes, and the chloroform solution dried and evaporated. Rotations were done in ethanol on the total product. The results of a series of runs are summarized in the table.

Hydrogenation of Δ^{13}-Dihydrodextropimaric Acid

A solution of Δ^{13}-dihydrodextropimaric acid (83 mg) in acetic acid (16 ml) was hydrogenated in the presence of Adams' catalyst (166 mg); 1.07 moles of hydrogen were absorbed in 17 hours. The catalyst was removed by filtration and then the solvent was evaporated under reduced pressure. The product was dissolved in ether, washed with water, and dried. Evaporation of the ether gave a solid product (80 mg) $[\alpha]_D$ +17° (*c*, 1.15). The product was adsorbed on silica gel (2.5 g) and eluted with benzene–ether (19:1) in 20-ml portions to give four fractions. Fraction 1 had $[\alpha]_D$ +18° (*c*, 0.84) and fraction 4 had $[\alpha]_D$ +19° (*c*, 0.9). The four fractions were combined and recrystallized four times from methanol–water to give tetrahydrodextropimaric acid as needles, m.p. and mixed m.p. 238–240° (66 mg), $[\alpha]_D$ +19° (*c*, 0.84), identical with that obtained above.

Hydrogenation of Δ^{13}-Dihydroisodextropimaric Acid

A solution of Δ^{13}-dihydroisodextropimaric acid (100 mg) in acetic acid (20 ml) was hydrogenated in the presence of Adams' catalyst (200 mg); 1.05 moles of hydrogen were absorbed in 17 hours. The catalyst was removed by filtration and the solvent was evaporated under reduced pressure. The product was dissolved in ether, washed with water, and dried. The total product, thrown out of methanol solution by means of water, formed needles, m.p. 165–168°, $[\alpha]_D$ +21° (*c*, 1.11; $CHCl_3$) and gave no coloration with tetranitromethane. Chromatography on silica gel (3 g) and elution with benzene gave tetrahydroisodextropimaric acid, m.p. and mixed m.p. 172–173° (89 mg), $[\alpha]_D$ +21° (*c*, 1.07; $CHCl_3$), identical with that obtained above.

Isomerization of Dextropimaric Acid Using Hydrogen Chloride

Dry hydrogen chloride was passed into a solution of dextropimaric acid (100 mg) in dry chloroform (30 ml) at −5° C for 4 hours. The chloroform solution was washed free from mineral acid with water and then dried and evaporated to give a gum (95 mg), $[\alpha]_D$ +69° (*c*, 0.76). The gum was adsorbed on silica and eluted with 20-ml portions of benzene – light petroleum (3:2) to give 10 fractions. Fractions $2 \rightarrow 8$ inclusive had rotations between +69° and +71° and were combined to give Δ^{13}-dextropimaric acid as prisms, m.p. 131–132° (55 mg) from methanol–water, $[\alpha]_D$ +70° (*c*, 0.94). Found: C, 79.34; H, 9.97. Calc. for $C_{20}H_{30}O_2$ (302): C, 79.49; H, 9.93. Infrared spectrum 1697 cm^{-1} (—COOH); 1408 cm^{-1}, 995 cm^{-1}, and 908 cm^{-1} (vinyl group).

Partial Hydrogenation of Δ^{13}-Dextropimaric Acid

Δ^{13}-Dextropimaric acid (26.4 mg) in ethanol (7 ml) was hydrogenated in the presence of palladized charcoal catalyst (30%) (10 mg). Hydrogen (2.14 ml) was absorbed in 8 minutes after which time absorption ceased abruptly. Calc. for 1 mole, 2.15 ml. The total product $[\alpha]_D$ +75° (*c*, 0.85) was recrystallized three times from methanol–water to give Δ^{13}-dihydrodextropimaric acid as plates, m.p. and mixed m.p. 181–182°, $[\alpha]_D$ +75° (*c*, 0.94).

Isomerization of Isodextropimaric Acid Using Hydrogen Chloride

Dry hydrogen chloride was passed into a solution of isodextropimaric acid (1.4 g) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

dry chloroform (30 ml) at −5° C for 4 hours. The chloroform solution was washed free from mineral acid with water and then dried and evaporated to give a gum (1.36 g), $[\alpha]_D$ +91° (*c*, 1.0; $CHCl_3$). The gum was adsorbed on silica gel (30 g) and eluted with 50-ml portions of light petroleum – benzene (1:1) to give nine fractions as gums. Fractions 1 → 6 inclusive had rotations between +92° and +89° and were combined (0.97 g). After six recrystallizations from acetone–water, Δ^{13}-isodextropimaric acid was obtained as clusters of prisms, m.p. 106–107° (0.6 g), $[\alpha]_D$ +113° (*c*, 0.88), $[\alpha]_D$ +96° (*c*, 1.34; $CHCl_3$). Found: C, 79.29; H, 9.74. Calc. for $C_{20}H_{30}O_2$ (302): C, 79.49; H, 9.93. A further crop of 470 mg, m.p. 104–106°, was obtained from the residues. The methyl ester formed flattened needles, m.p. 70–71° from methanol–water, $[\alpha]_D$ +118° (*c*, 0.82). Found: C, 79.75; H, 9.95. Calc. for $C_{21}H_{32}O_2$ (316): C, 79.75; H, 10.13.

Partial Hydrogenation of Δ^{13}-Isodextropimaric Acid

Δ^{13}-Isodextropimaric acid (304 mg) in ethanol (20 ml) was hydrogenated in the presence of palladized charcoal catalyst (30%) (150 mg). Hydrogen (23.9 ml) was rapidly absorbed during 2 minutes, after which time absorption ceased abruptly. Calc. for 1 mole, 24.3 ml. The total product, $[\alpha]_D$ +68° (*c*, 1.32; $CHCl_3$) was adsorbed on silica gel (7.5 g) and eluted with 50-ml portions of light petroleum – benzene (1:1) to give seven fractions. Fractions 2 → 6 inclusive were combined and recrystallized three times from acetone–water to give Δ^{13}-dihydroisodextropimaric acid as needles, m.p. and mixed m.p. 107–108° (225 mg), $[\alpha]_D$ +73° (*c*, 0.99; $CHCl_3$).

γ-Lactone of Dihydrodextropimaric Acid

(*a*) *From dihydrodextropimaric acid.*—Dihydrodextropimaric acid (400 mg) was added gradually during 15 minutes to sulphuric acid (2.5 ml, d = 1.84) cooled to −5° C. After 1 hour the reaction mixture was worked up as described previously to give a neutral gum (380 mg), $[\alpha]_D$ −20° (*c*, 1.22), which solidified. The gum was adsorbed on silica gel (10 g) and eluted with 30-ml portions of benzene–ether (19:1) to give six fractions. Fractions 1 → 4 inclusive, when precipitated from methanol solution by water, formed plate-like crystals. These were combined and recrystallized from methanol–water to give the γ-lactone of dihydrodextropimaric acid as plates, m.p. 100°, $[\alpha]_D$ −15° (*c*, 1.17). Found: C, 78.66; H, 10.35. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1763 cm^{-1} (γ-lactone). Le-Van-Thoi and Ourgaud (28) report m.p. 100° $[\alpha]_j$ −17° (EtOH). The melting point was depressed to 97° on admixture with the γ-lactone of dihydroisodextropimaric acid.

(*b*) *From Δ^{13}-dihydrodextropimaric acid.*—Δ^{13}-Dihydroisodextropimaric acid (100 mg) was added gradually during 15 minutes to sulphuric acid (1 ml, d = 1.84) cooled to −5° C. After 1 hour the reaction mixture was worked up as described previously to give a neutral gum (98 mg), $[\alpha]_D$ −22° (*c*, 1.26), which crystallized on seeding. The product was adsorbed on silica gel (2.5 g) and eluted with benzene–ether (19:1) in 30-ml portions to give seven fractions. Fractions 1 → 5 inclusive were combined and recrystallized from methanol–water to give the γ-lactone of dihydrodextropimaric acid as plates, m.p. and mixed m.p. 100° (58 mg), $[\alpha]_D$ −15° (*c*, 1.07).

γ-Lactone of Dihydroisodextropimaric Acid

(*a*) *From dihydroisodextropimaric acid.*—Dihydroisodextropimaric acid (400 mg) was added gradually during 15 minutes to sulphuric acid (2.5 ml, d = 1.84) cooled to −5° C in a mixture of ice and salt. After being kept at −5° C for 1 hour the reaction mixture was decomposed by being poured into water containing chopped ice. The organic material

For personal use only.

was extracted with ether and the extract washed with water to remove mineral acid. The ether extract was then washed with aqueous potassium carbonate (10%) to remove acidic material. The ether extract was washed with water, dried (Na_2SO_4), and evaporated to give a neutral gum (380 mg), $[\alpha]_D$ −19° (*c*, 1.1). The gum was adsorbed on silica gel (10 g) and eluted with 30-ml portions of benzene to give seven fractions. Fractions 1 → 4 inclusive, which when thrown out of methanol solution by water formed plate-like crystals, were combined and recrystallized from methanol–water to give the γ-lactone as plates, m.p. 105–106° (250 mg), $[\alpha]_D$ −90° (*c*, 1.59). Found: C, 78.57; H, 10.47. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1770 cm^{-1} (γ-lactone).

(*b*) *From Δ^{13}-dihydroisodextropimaric acid.*—Δ^{13}-Dihydroisodextropimaric acid (80 mg) was added gradually during 15 minutes to sulphuric acid (0.6 ml, d = 1.84) cooled to −5° C in a mixture of ice and salt. After being kept at −5° C for 1 hour the reaction mixture was worked up as described above to give a neutral gum (79 mg), $[\alpha]_D$ −18° (*c*, 1.01). The gum was adsorbed on silica gel (3 g) and eluted with benzene. The first fractions were recrystallized from methanol–water to give the γ-lactone as plates, m.p. and mixed m.p. 105–106° (43 mg), $[\alpha]_D$ −8° (*c*, 1.06).

δ-Lactone of Dihydroisodextropimaric Acid

(*a*) *From dihydroisodextropimaric acid.*—Dihydroisodextropimaric acid (170 mg) was added gradually during 15 minutes to sulphuric acid (3 ml, d = 1.84) at room temperature (23° C). After 5 hours the reaction mixture was poured into water containing chopped ice. The organic material was extracted with ether and washed with water to remove mineral acid. The ether extract was then washed with aqueous potassium carbonate (10%) to remove acidic material. The ether extract was washed with water, dried (Na_2SO_4), and evaporated to give a neutral gum (168 mg), $[\alpha]_D$ −31° (*c*, 1.14). The gum was adsorbed on silica gel (4 g) and eluted with 30-ml portions of benzene to give eight fractions. Fractions 4 → 8 inclusive, which when thrown out of methanol solution by water formed plate-like crystals, were combined and recrystallized from methanol–water to give the δ-lactone as plates, m.p. 74–75° (70 mg), $[\alpha]_D$ −40° (*c*, 0.93). Found: C, 79.05; H, 10.49. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1720 cm^{-1} (δ-lactone). A further crop of plates, m.p. 72–74° (30 mg) was obtained from the mother liquors.

(*b*) *From the γ-lactone.*—The γ-lactone (80 mg) was gradually added during 15 minutes to sulphuric acid (2 ml, d = 1.84) at room temperature (23° C). After 5 hours the lactonic material was isolated as described above to give a colorless gum (80 mg), $[\alpha]_D$ −29° (*c*, 0.93), which solidified on seeding. The total product was adsorbed on silica gel (2 g) and eluted with benzene in 30-ml portions to give four fractions. The last two fractions were combined and recrystallized from methanol–water to give the δ-lactone as plates, m.p. and mixed m.p. 73–74° (40 mg) $[\alpha]_D$ −39° (*c*, 0.97).

Isomerization of Ukita's Acid Using Hydrogen Chloride

Dry hydrogen chloride was passed into a solution of Ukita's acid (20 mg) in dry chloroform (15 ml) at −5° for 4 hours. The chloroform solution was washed free from mineral acid with water, and then dried, and evaporated to give a colorless gum (19 mg), $[\alpha]_D$ +108° (*c*, 0.79), which was twice recrystallized from acetone–water to give Δ^{13}-isodextropimaric acid as stout prisms (15 mg), m.p. and mixed m.p. 105–107°, $[\alpha]_D$ +110° (*c*, 1.08).

Partial Hydrogenation of Ukita's Acid

A solution of Ukita's acid (15.5 mg) in ethanol (7 ml) was hydrogenated in the presence

of pre-reduced palladized charcoal catalyst (30%, 3 mg); 1 mole of hydrogen (1.25 ml) was absorbed during 8 minutes and then absorption ceased. The crude product, m.p. 148–152° was recrystallized five times from methanol–water to give the dihydro-acid as prisms, m.p. 154–157° (9.4 mg), $[\alpha]_D$ +18° (*c*, 0.72). Found: C, 78.96; H, 10.31. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum 1700 cm^{-1} (—COOH); 825 cm^{-1} (trisubstituted double bond).

γ-Lactone of Isodextropimaric Acid

Isodextropimaric acid (200 mg) in dry dioxane (20 ml) was refluxed under nitrogen with *p*-toluenesulphonic acid (1 g) for 4 hours and then allowed to stand overnight. The dioxane was evaporated off and the viscous residue taken up in ether. Extraction of the ether solution with aqueous potassium carbonate (10%) gave only 15 mg of acidic material which was not further investigated. The ether layer was washed with water and dried (Na_2SO_4). On evaporation of the ether a neutral gum (180 mg), $[\alpha]_D$ −18° (*c*, 1.24), was obtained. The product was adsorbed on silica (4 g) and eluted with benzene in 20-ml portions to give five fractions. Fractions 4 and 5 gave some solid material with methanol–water and after several recrystallizations from methanol–water, the γ-lactone of isodextropimaric acid formed plates, m.p. 128–130° (15 mg), $[\alpha]_D$ −1° (*c*, 0.84). Found: C, 79.59; H, 9.90. Calc. for $C_{20}H_{30}O_2$ (302): C, 79.49; H, 9.93. Infrared spectrum: 1770 cm^{-1} (γ-lactone); 1480 cm^{-1}, 1000 cm^{-1}, 910 cm^{-1} (vinyl group).

Treatment of Isodextropimaric Acid with Formic Acid

Isodextropimaric acid (500 mg) was refluxed for 60 hours with formic acid (90%, 75 ml). The formic acid was evaporated under reduced pressure. Globules of oil which steam-distilled over were isolated by extracting the neutralized distillate with ether, and proved to be a mobile hydrocarbon (84 mg), $[\alpha]_D$ +4° (*c*, 0.79). The distillation residue was dissolved in ether and washed free from formic acid with water. The dried ether extract gave a brown gum (385 mg), $[\alpha]_D$ +18° (*c*, 1.5) on evaporation. Infrared spectrum ($CHCl_3$) 3520 cm^{-1} (—OH), 1780 cm^{-1} (γ-lactone), 1730 cm^{-1} (δ-lactone); absence of carboxyl and vinyl groups. The product was split into the following fractions by chromatography on neutral alumina (Grade IV, 10 g).

A. Hexane (20 ml) readily eluted a mobile hydrocarbon fraction (38 mg).

B. Hexane (200 ml) gave 10 fractions, $[\alpha]_D$ −43° to −34° which were combined (137 mg).

C. Benzene and chloroform eluted further fractions as gums (210 mg).

To fraction C was added material (60 mg) from the mother liquors of the recrystallization of fraction B. Further chromatography of this material on neutral alumina (Grade II, 5 g) gave the following fractions.

D. Hexane (100 ml) eluted material which crystallized from methanol–water (125 mg) $[\alpha]_D$ −28° (*c*, 0.98).

E. Benzene eluted non-crystalline material.

F. Benzene–chloroform (3:1) eluted material (25 mg), m.p. 170–172°, which crystallized spontaneously on evaporation of the solvent.

Investigation of the Fractions

A. The hydrocarbon fraction was combined with that from the steam distillate and warmed with aqueous sodium hydroxide (10%). The hydrocarbon, recovered by ether extraction, was dissolved in hexane and percolated through alumina. The hydrocarbon distilled as a colorless mobile oil, b.p. 90° at 0.05 mm, n_D^{24} 1.5125, $[\alpha]_D$ +6° (*c*, 1.09). Found: C, 88.21; H, 12.10. Calc. for $C_{19}H_{30}$: C, 88.30; H, 11.70.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

B. The combined material (137 mg) was recrystallized twice from methanol–water and then four times from methanol to afford prisms, m.p. 109.5–111° (70 mg), $[\alpha]_D$ −52° (*c*, 0.97). Found: C, 79.12; H, 9.60. Calc. for $C_{20}H_{30}O_2$ (302): C, 79.49; H, 9.93. Infrared spectrum 1762 cm^{-1} (γ-lactone); no bands for ethylenic bonds.

When the above γ-lactone (24.4 mg) in acetic acid (6 ml) was hydrogenated in the presence of Adams' catalyst (10 mg), 0.96 mole of hydrogen was absorbed in 1 hour. The crystalline product, recrystallized from methanol–water afforded prisms, m.p. 131–132°, $[\alpha]_D$ −5° (*c*, 0.8). Found: C, 78.78; H, 10.32. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. This material is identical (mixed m.p. 131–132°) with the known γ-lactone obtained from any of the dihydroabietic acids (see below).

D. Fraction D was recrystallized from methanol–water to give a further crop of γ-lactone, m.p. 109.5–111° (47 mg).

E. No solid material could be isolated from this fraction.

F. Recrystallization of this fraction from methanol gave needles, m.p. 179–180°, $[\alpha]_D$ −6° (*c*, 0.9). Found: C, 75.08; H, 9.83. Calc. for $C_{20}H_{32}O_3$ (320): C, 74.96; H, 10.06. Infrared spectrum: 3548 cm^{-1} (—OH), 1764 cm^{-1} (γ-lactone). This is clearly the known hydroxy-γ-lactone from dextropimaric acid (38).

Partial Hydrogenation of Neoabietic Acid

Neoabietic acid (1.035 g) in ethanol (40 ml) in the presence of palladized charcoal (30%, 200 mg) rapidly absorbed 1.07 moles of hydrogen in 11 minutes, after which time absorption became comparatively slow. The ultraviolet spectrum of the product $[\alpha]_D$ +26° (*c*, 1.2) showed the presence of less than 1% of neoabietic acid. Chromatography on silica gel using hexane as eluting solvent gave 14 fractions. Fractions 1 → 6 having rotations ranging from +12° to +25° were combined (530 mg). Fractions 7 → 14 of $[\alpha]_D$ +37° gave A-dihydroabietic acid (29) on crystallization from methanol–water (98 mg), m.p. 149°, $[\alpha]_D$ +43° (*c*, 1.03). Found: C, 78.66; H, 10.27. Calc. for $C_{30}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum: 1697 cm^{-1} (—COOH); 826 cm^{-1} (trisubstituted double bond).

Fractions 1 → 6, together with material (340 mg) from the mother liquors of the recrystallization of fractions 7 → 14, were converted to the piperidine salt and recrystallized from acetone. Two crops of the least soluble material, $[\alpha]_D$ +31° (*c*, 1.5) and $[\alpha]_D$ +27° (*c*, 0.9), were combined (350 mg) and reconverted to acid, $[\alpha]_D$ +35° (*c*, 0.94). Recrystallization from methanol–water afforded a further crop of A-dihydroabietic acid as needles (165 mg), m.p. 147–148°, $[\alpha]_D$ +39° (*c*, 0.99). The more soluble piperidine salt gave acid (580 mg), $[\alpha]_D$ +19° (*c*, 1.0).

γ-Lactone of A-Dihydroabietic Acid

A-Dihydroabietic acid (165 mg) was added gradually during 15 minutes to sulphuric acid (1 ml, d = 1.84) cooled to −5°. After 1 hour the reaction mixture was worked up as in the previous examples to give neutral material which crystallized spontaneously. Chromatography on alumina (Grade III, neutral) using hexane as eluting solvent gave the γ-lactone as prisms, m.p. 132°, $[\alpha]_D$ −4° (*c*, 1.04). Found: C, 78.96; H, 10.35. Calc. for $C_{20}H_{32}O_2$ (304): C, 78.94; H, 10.52. Infrared spectrum: 1758 cm^{-1} (γ-lactone).

The non-crystalline dihydroneoabietic acid $[\alpha]_D$ +19° afforded the same γ-lactone on similar treatment.

ACKNOWLEDGMENTS

We are indebted to Mr. R. V. Lawrence for a supply of pine gum and rosin, and

APPLICATIONS OF PROTON MAGNETIC RESONANCE SPECTRA IN FATTY ACID CHEMISTRY[1]

C. Y. Hopkins and H. J. Bernstein

ABSTRACT

An introductory study has been made of the proton magnetic resonance spectra of fatty acids, fatty acid esters, and natural glyceride oils. Characteristic signals were recorded for the hydrogens of such groupings as hydroxy, acetoxy, and epoxy; isolated, conjugated, and methylene-interrupted double bonds; and others. Examples are given of the application of this technique in identifying the fatty acids of natural glyceride oils. Semiquantitative estimations are shown to be feasible. Evidence for Nunn's formula for sterculic acid is discussed on the basis of the spectra of the acid and its derivatives.

Proton magnetic resonance measurements provide a new method of distinguishing certain groupings in fatty acid molecules. This preliminary study indicates that the method is of value in determining the structure of fatty acids and their derivatives and in estimating in a roughly quantitative manner the proportions of certain fatty acids in mixtures. Quantitative estimation is applicable in some degree to single mixed glycerides and to natural oils, which are mainly mixtures of mixed glycerides.

Small amounts of impurities are not likely to interfere, since components constituting less than 5% of the sample do not usually give a measurable signal.

In the present work measurements were made with a Varian V-4300 NMR spectrometer operating at a frequency of 40 Mc/s and equipped with a Varian Field Stabilizer. Each sample was dissolved in chloroform at sufficiently high concentration to give signals of moderate intensity. Some of the oxygenated acids were used at maximum solubility. Usually 0.2 to 0.5 g of sample was dissolved in 0.5 to 1.0 ml of chloroform. The sample tube was 5 mm o.d. and was set spinning by a jet of nitrogen.

Chemical shifts were measured from the dissolved chloroform signal or that of the long-chain CH_2 signal by the well-known side-band technique. All chemical shifts were referred to the long-chain CH_2 signal, the signals at lower applied field having negative values. All figures are displayed with applied magnetic field increasing toward the right.

MATERIALS

Oleic acid, methyl oleate, and methyl linoleate were prepared from natural oils by fractional distillation of the esters followed by low-temperature crystallization. 9,10-Diacetoxystearic acid was made by acetylating the pure dihydroxy acid. 12,13-Dihydroxyoleic acid was prepared from the seed oil of *Vernonia colorata* by Gunstone's procedure (1). Commercial ethyl ricinoleate was purified by low-temperature crystallization.

Vernonia oil and *Sterculia* oil were extracted in the laboratory from seed of *Vernonia colorata* and *Sterculia foetida* respectively. The other oils and the lauric acid were commercial products. Methyl 10,12-octadecadienoate was kindly supplied by Dr. O. S. Privett.

Sterculic acid was made by cold saponification of *Sterculia* oil, followed by repeated crystallization from acetone at low temperature. It was hydrogenated with palladium

catalyst. 9,11-Diketononadecanoic acid, m.p. 59–60°, was obtained by controlled oxidation of sterculic acid.

RESULTS AND DISCUSSION

Typical spectra are shown in Fig. 1. The saturated acid, lauric, shows the signals common to all fatty acids. The groupings and the position of the corresponding signals were as follows (parts per million): terminal CH_3, +0.43; CH_2 groups of the chain, 0; CH_2 adjacent (α) to the carboxyl group, −1.0. The position of the signal for the carboxy hydrogen (offscale to low field) is strongly affected by the degree of dilution and is not shown.

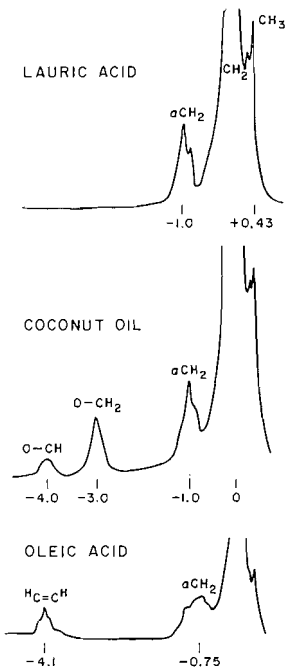

FIG. 1. Proton resonance spectra of a saturated acid, a highly saturated oil, and a monounsaturated acid. The signal for the acid proton is offscale to the left.

Coconut oil, consisting mainly of glycerides of saturated acids, shows the signals for terminal CH_3, CH_2 chain, and αCH_2, and also for the glyceryl residue.* The two $O-\overset{|}{C}H_2$ groups of the glyceryl radical appeared at −3.0 p.p.m. with intensity 4 (four protons) and the $O-\overset{|}{C}H$ at −4.0 p.p.m. with intensity 1.

Oleic acid produced a signal at −4.1 p.p.m. characteristic of the monounsaturated grouping CH=CH. The CH_2 groups adjacent to the double bond carbons contribute to the intensity of the signal at −0.75 p.p.m.

Double Bond Unsaturation

Characteristic signals for the various types of double bond groupings were observed. Those for simple monoenes, 1,4-dienes, and conjugated dienes are shown in Fig. 2.

**The identification of these signals followed by comparison with the spectrum of glyceryl triacetate.*

For personal use only.

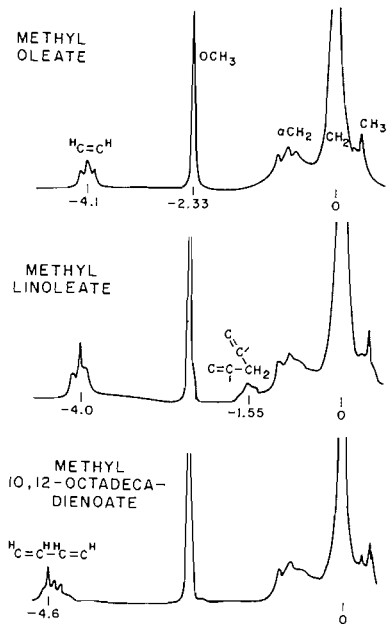

FIG. 2. Proton resonance spectra of methyl esters of a monoenoic acid, a non-conjugated dienoic acid, and a conjugated dienoic acid.

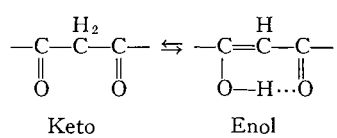
The CH_3 of the ester group in these compounds gave a sharp peak at -2.32 to -2.35 p.p.m. In the 1,4-diene, methyl linoleate, the signal at -1.55 p.p.m. for the CH_2 of the divinyl methane grouping has half the intensity of the signal for the two CH=CH groups, since the latter contain a total of four protons. In the 1,3-diene, methyl 10,12-octadecadienoate, the effect of conjugation on the ethylenic protons is to shift the signal to low field (-4.6 p.p.m.). The divinyl methane signal has disappeared.

Hydroxy- and Keto-acids

The —CHOH group in hydroxy acids is recognized by two signals, one for each hydrogen, at different frequencies (Fig. 3). Thus 12,13-dihydroxyoleic acid, in addition to the usual peaks shown by oleic acid, gave a signal at -2.2 p.p.m. due to the —CH—O groups. The position of the —OH signal varies with concentration (8), and is observed here at -4.8 p.p.m. In these experiments the concentration was not standardized. Accordingly, the —OH signal appeared at -1.2 p.p.m. in ethyl ricinoleate. The quartet and triplet characteristics of the ethyl group of the ethyl ester are clearly observed.

The spectrum of 9,11-diketononadecanoic acid indicates that enolization has taken place to a large extent. A diketone enolizes according to the mechanism:



Keto Enol

The hydrogen-bonded signal of the enol form has been found in acetylacetone to appear at very low field (2). The signal at -4.1 p.p.m. corresponds to the C=CH group in the enol form and that at about -2.1 p.p.m. to the CH_2 group of the keto form. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

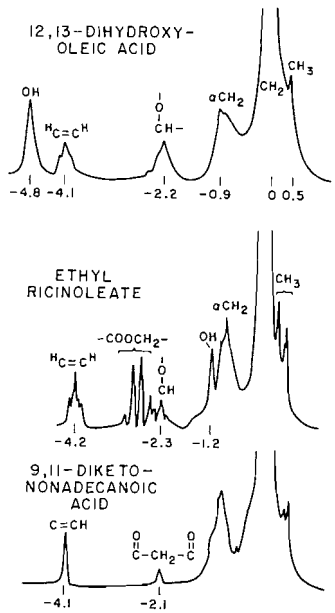


FIG. 3. Proton resonance spectra of compounds having hydroxy- and keto-groups.

is 2 p.p.m. to high field of the C=CH signal in acetylacetone also (2). From the relative areas under these signals (~1:3) the ratio of keto to enol concentration is about 1:6.

Epoxy Acids and Epoxy Oils

The epoxy group $-\underset{H}{\overset{O}{C}}-\underset{H}{C}-$ in the long-chain fatty acids produced a signal at −1.55 to −1.7 p.p.m. This has been shown in 9,10-epoxystearic acid and 12,13-epoxyoleic acid (3), and in 9,10,12,13-diepoxystearic acid.

Certain natural oils are known to contain 12,13-epoxyoleic acid as glyceride. However, detection of the epoxy group in these oils is complicated by the fact that linoleate is usually present and gives a signal at approximately the same position in the field. Thus the seed oil of *Vernonia colorata*, in which the fatty acids are approximately 70% epoxyoleic and 15% linoleic, gave a signal in the region of −1.65 p.p.m. which is due to the summation of the signals due to the epoxy group protons and the diene-activated CH_2 of the 1,4-dienoic acid (A, Fig. 4).

To resolve this difficulty, the oil was acetylated, thereby converting the epoxy group to diacetoxy. The residual intensity at −1.75 p.p.m. is due then to the contribution of the CH_2 group of the 1,4-diene, (B, Fig. 4). The acetylated oil produced a new signal at −2.3 p.p.m., attributed to the hydrogens adjacent to the acetyl groups. 9,10-Diacetoxystearic acid gave a signal at approximately the same position, −2.4 p.p.m. The triplet structure (spacing of 6.2 c/s) is probably due to spin–spin coupling with the hydrogens of the adjacent CH_2 group. The hydrogens of the two acetyl groups produced two sharp peaks in the vicinity of −0.8 p.p.m.

This acetylation procedure seems useful in detecting or confirming the presence of epoxy acids in natural oils where the amount exceeds 5% of the total acids.

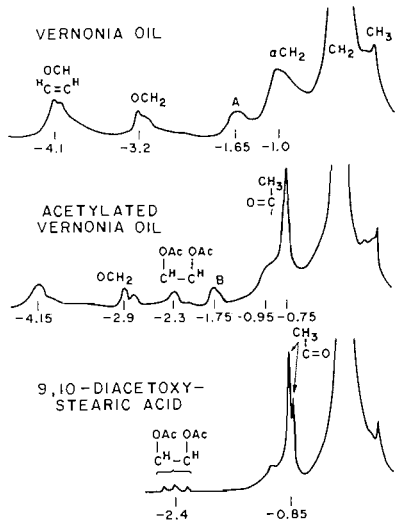

FIG. 4. Proton resonance spectra of an epoxy-acid oil, showing the effect of acetylation, and a simple diacetoxy acid.

Examination of Natural Fatty Oils

It is evident from the foregoing data that useful information on the components of natural glyceride oils can be obtained from proton magnetic resonance absorption measurements. The presence of free carboxyl, hydroxy, 1,4-diene, conjugated double bonds, and isolated double bonds can usually be determined by inspection of the spectra. By converting the oil to methyl esters and determining the spectrum of the mixed esters, the glycerol signals are eliminated and no longer interfere with the signal of the isolated double bonds.

Confirmation of the presence of the OH group can be obtained by acetylating, whereby the product gives a new signal due to the acetoxy group. Similarly, oils having a 1,4-diene grouping can be isomerized to the conjugated form, producing a new signal which is readily identified.

Quantitative applications are also possible. The intensity of a given signal is directly proportional to the number of protons contributing to it. By comparing the areas of peaks in the same spectrum, estimates can be made of the relative proportions of certain groupings in the sample. The glyceryl radical provides a useful internal reference standard for such calculations in examining the oils. Its signal A at -3.0 p.p.m. (Fig. 5) is due to the two —OCH groups and thus represents four protons. Its signal B at -4.0 (—OCH) represents only one proton.

On this basis, one can calculate the ratios of saturated: monoene: diene fatty acids in ordinary glyceride oils composed of these three types of acids. The degree of precision is of the order of ± 5 units %.

In the spectrum for cocoa butter (Fig. 5), the absence of a signal in the region of -1.55 p.p.m. shows that there is little or no 1,4-diene (actually about 2% of linoleate is present), so that for purposes of calculation the component acids are regarded as consisting of saturated and monoenoic acids. If the acid residues were entirely monoenoic the ratio of the area of B to the total area of A would be 7:4 ($3 \times$ CH=CH+OCH: $2 \times OCH_2$) since there would be three molecules of monoenoic acid to one of glycerol. The component

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

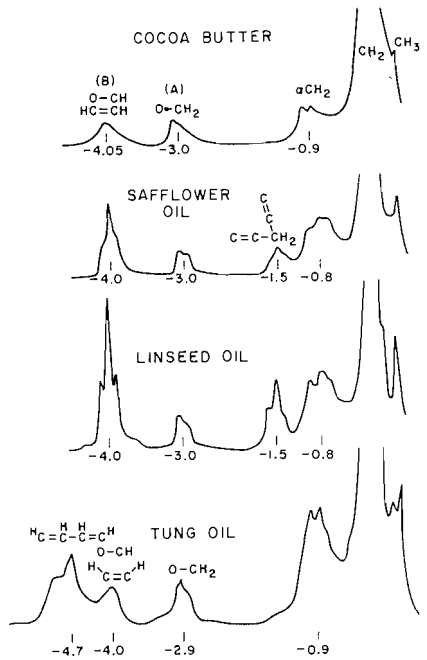

FIG. 5. Proton resonance spectra of typical oils. The increasing degree of unsaturation in the first three oils is indicated by the ratio of the areas of the B and A signals. In tung oil the total unsaturation is indicated by the peaks at −4.0 and −4.7 p.p.m.

of B due to the OCH group is one-quarter of the area of the A signal (one proton/four protons). Therefore, deducting one-quarter of the area of A from B gives the area due to the CH=CH groups. If the acids were entirely monoenoic, the ratio of this area to A would be 6:4. By actual measurement, the ratio was found to be about 2.4:4, hence the ratio of monounsaturated acids to total acids is about $(2.4 \div 6) : 1 = 0.4 : 1$ in this sample.

By extending this procedure to include the diene signal at −1.55 p.p.m., the ratios of saturated:monoene:diene in cottonseed or similar oils can be estimated. Similarly the proportion of conjugated acid, e.g. in tung oil, can be estimated by comparing the areas of the glyceryl signal and the signal at −4.7 p.p.m. In the curve for tung oil, the signal at −4.0 p.p.m. represents the non-conjugated ethylenic groups of oleic and linoleic acids present in the oil, in conjunction with the O—CH— glycerol signal.

cis- and trans-Groupings

Two pairs of *cis–trans* isomeric compounds were examined, viz. oleic and elaidic acids, and *cis-* and *trans*-9,10-epoxystearic acid. 12,13-Epoxyoleic acid, prepared by the action of peracetic acid on linoleic acid, was also compared with *Vernonia colorata* oil, which contains *cis*-12,13-epoxyoleic acid as glyceride. The difference in the positions of the double bond signals and the epoxy group signals in these pairs of compounds was not great enough to be significant. However, the possibility of a significant difference between *cis-* and *trans*-groupings under more exactly controlled conditions is not excluded.

Constitution of Sterculic Acid

The spectra of sterculic acid and some of its derivatives were examined to obtain evidence for the structure of the acid, which has been in dispute (4, 5).*

**Shortly after our work was completed, the proton resonance spectrum of sterculic acid was reported by Rinehart, Nilsson, and Whaley (6).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

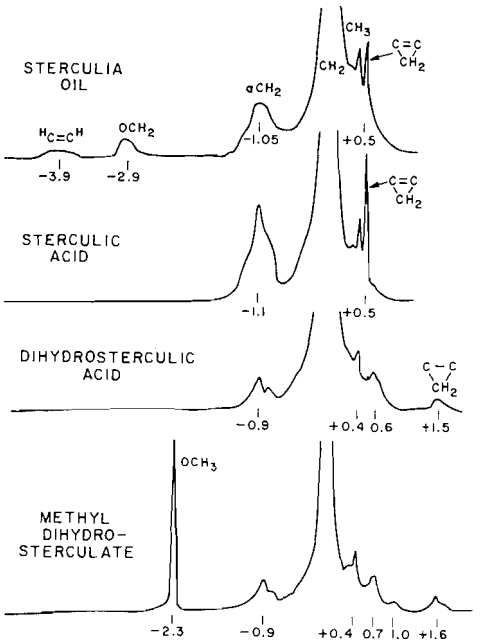

FIG. 6. Proton resonance spectra of *Sterculia* oil, sterculic acid, and two derivatives. The signal of the CH_2 group of the cyclopropane ring is at +1.5 p.p.m.

In our experiments, *Sterculia foetida* oil showed a signal of low intensity at −3.9 p.p.m. attributable to the unsaturated linkages of the small percentage of ordinary unsaturated acids in the glycerides. Sterculic acid itself, prepared by cold saponification of the oil and crystallization of the acids at low temperature, gave no signal in the region expected for isolated double bonds. Hence the proposed formula (5)

$$CH_3(CH_2)_5CH\text{—}CH\text{—}CH{=}CH(CH_2)_7COOH$$
$$\qquad\qquad\quad \diagdown\ \diagup$$
$$\qquad\qquad\quad CH_2$$

I

is judged to be incorrect. Absence of the signal for the CH_2 group of the cyclopropane ring in the region of +1.5 p.p.m. is further evidence for the rejection of formula I.

The signal at +0.5 p.p.m., attributed by Rinehart and co-workers (6) to the cyclopropene ring of Nunn's formula

$$CH_3(CH_2)_7C{=}C\text{—}(CH_2)_7COOH,$$
$$\qquad\qquad\quad \diagdown\ \diagup$$
$$\qquad\qquad\quad CH_2$$

II

can scarcely be regarded as positive proof of structure II until the position of this signal has been confirmed by examining model compounds of similar structure. However, hydrogenation of sterculic acid to dihydrosterculic acid undoubtedly gives a cyclopropane ring, as confirmed by synthesis (7) and the magnetic resonance spectrum of dihydrosterculic acid (Fig. 6) gives a signal at 1.5 p.p.m., which is characteristic of the CH_2 group in a cyclopropane ring.* Since this signal is absent in the spectrum of sterculic acid,

**Unpublished results (H.J.B.).*

For personal use only.

formula I is clearly inadmissible and the NMR evidence strongly supports formula II. The spectra of dihydrosterculic acid and its methyl ester were identical except for the carboxy and ester signals respectively. The signal at 0.7 p.p.m. has not been positively identified but is possibly associated with the CH groups of the cyclopropane ring.

ACKNOWLEDGMENT

We wish to acknowledge the assistance of J. R. Nicholson in obtaining the NMR spectra.

EFFECT OF PRESSURE ON THE SPONTANEOUS AND THE BASE-CATALYZED HYDROLYSES OF EPOXIDES[1]

J. KOSKIKALLIO[2] AND E. WHALLEY

ABSTRACT

The effect of pressures up to 3000 atm on the spontaneous and the base-catalyzed hydrolyses of ethylene and propylene oxides has been determined. It is that expected from the accepted mechanisms. The volumes of activation of ion–molecule reactions that probably occur without major change in polarity are reviewed. For all reactions that have been studied so far in which a C–O bond is formed the volumes of activation are about -5 to -10 cm^3 mole^{-1}.

1. INTRODUCTION

Epoxides hydrolyze spontaneously and by acid and base catalysis (1, 2, 3). We have already described (4) the effect of pressure on the acid-catalyzed reaction, and in this paper the effect of pressure on the base-catalyzed and the spontaneous hydrolyses is described.

2. EXPERIMENTAL METHODS

The epoxides, the pressure technique, and the method of analysis for epoxide were as described in a previous paper (4). At 1 atm, 5-ml sealed ampoules were used for the rate measurements. The concentration of epoxide was about 0.1 *M* at the start of each run. About seven samples were taken during each run.

Spontaneous hydrolysis.—The rates of hydrolysis in a buffer solution containing 0.001-*M* 2,4,6-trimethylpyridine and 0.0015-*M* 2,4,6-trimethylpyridinium perchlorate (3) (pH 7.3) were taken to be the rates of the spontaneous hydrolysis. There was a difference of only a few per cent between the rates in the buffer and in pure water.

Alkaline hydrolysis.—The alkali was carbonate-free sodium hydroxide and was usually about 0.01 *M*. The first-order rate constant k is given by

$$k = k_0 + k_b c_{OH^-},$$

where k_0 and k_a are the rate constants for the spontaneous and the base-catalyzed reactions and c_{OH^-} is the concentration of hydroxyl ion at the temperature and pressure of the experiment. The calculation of k_b is straightforward. The compression and thermal expansion of the solution were assumed to be the same as those of pure water (5).

3. RESULTS

The experimental rate constants for the spontaneous hydrolysis of ethylene and propylene oxides are given in Table I and those for the base-catalyzed hydrolysis of ethylene oxide are given in Table II. Previous measurements at 1 atm are given for comparison; the agreement is good.

The rate constants at 1 atm for the spontaneous hydrolysis were fitted graphically to the Arrhenius equation, and the Arrhenius energy E_A and the enthalpy $\Delta H^{\ddagger}$ and entropy $\Delta S^{\ddagger}$ of activation were obtained. We found:

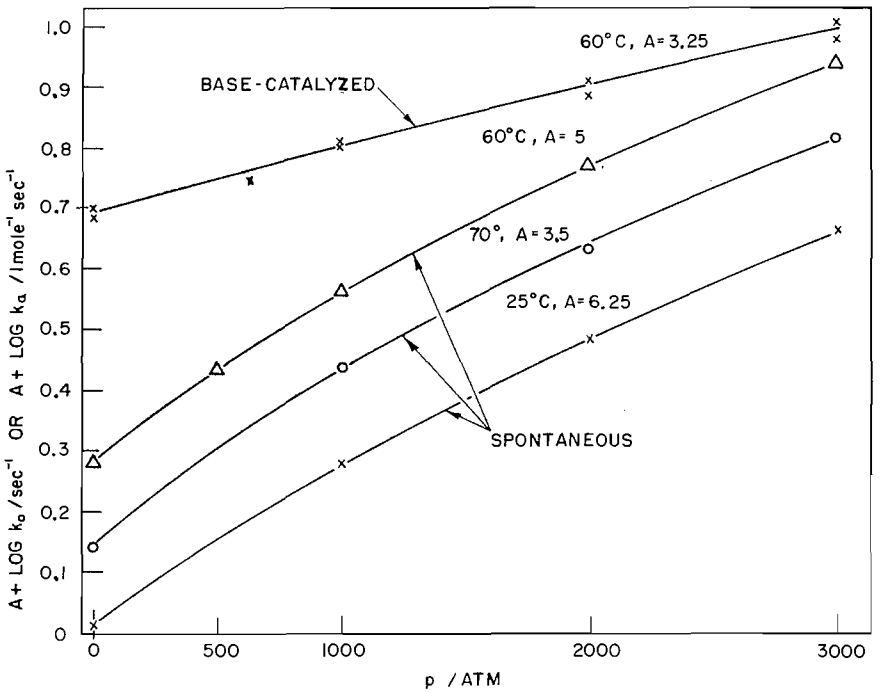

FIG. 1. Effect of pressure on the spontaneous and the base-catalyzed hydrolyses of ethylene oxide.

4. DISCUSSION

Spontaneous Hydrolysis

The volume of activation for the spontaneous hydrolysis of ethylene oxide at 60° C is $-18.9 \pm \sim 1$ cm^3 mole^{-1}. The mechanism is very likely to be (6)

[4.1] $$H_2O + \begin{matrix} H_2C \\ | \\ H_2C \end{matrix}\!\!>\!O \xrightarrow{\text{slow}} H_2O^+\!-\!CH_2 \,|\, H_2C\!-\!O^- \xrightarrow{\text{fast}} \begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix}$$

There are two effects causing a decrease of volume when the transition state is formed, the conversion of a van der Waals' interaction between water and epoxide into a partial valence bond, and the increased electrostriction of the solvent due to the separation of charges in the transition state (7). The contribution of valence-formation to the volume-decrease will presumably be similar to that in similar reactions in which no major change of electrostriction is expected. We show below that the contribution of valence-formation to the volume of activation is expected to be about -5 to -10 cm^3 mole^{-1}. The con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

tribution of valence-formation in reaction [4.1] is, therefore, likely to be about $\frac{1}{3}$ to $\frac{1}{2}$ of the total volume of activation; the remaining $\frac{2}{3}$ to $\frac{1}{2}$ is presumably due to electrostriction of the solvent.

Although the volume of activation for the spontaneous hydrolysis of propylene oxide cannot be calculated for lack of data, it is of the same order of magnitude as that for ethylene oxide, and is presumably the sum of similar contributions.

A volume of activation can be divided into an enthalpy effect and an entropy effect thus

$$\Delta V^{\ddagger} = (\partial \Delta H^{\ddagger}/\partial p)_T - T(\partial \Delta S^{\ddagger}/\partial p)_T. \qquad [4.2]$$

Using the relations

$$(\partial \Delta S^{\ddagger}/\partial p)_T = -(\partial \Delta V^{\ddagger}/\partial T)_p, \qquad [4.3]$$

$$(\partial \Delta H^{\ddagger}/\partial p)_T = -T^2 [\partial(\Delta V^{\ddagger}/T)/\partial T]_p, \qquad [4.4]$$

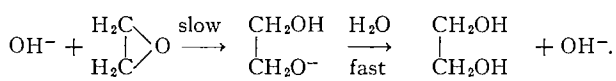
we find from our measurements that

$$\partial \Delta H^{\ddagger}/\partial p = 19 \pm \sim 10 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 25\text{–}70^\circ \text{ C and 1 atm},$$
$$T\partial \Delta S^{\ddagger}/\partial p = 38 \pm \sim 10 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 25\text{–}70^\circ \text{ C and 1 atm}.$$

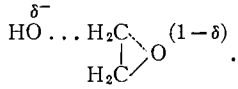
Thus both the enthalpy and the entropy of activation increase as the pressure is increased, the entropy term dominating the enthalpy term and determining the sign of $\Delta V^{\ddagger}$. Similar reactions, in which charges are created in the transition state, behave similarly (8, 9, 10).

Base-catalyzed Hydrolysis

The volume of activation for the base-catalyzed hydrolysis at 60° C is $-7.0 \pm \sim 1$ cm^3 mole^{-1}. The mechanism of the reaction is



There are two contributions to the volume of activation, the formation of a new partial valence bond between oxygen and carbon and the extension of an existing C–O bond in the epoxide, and the decreased electrostriction of the solvent due to the dispersion of the negative charge between two oxygen atoms thus



The value, -7.0 cm^3 mole^{-1}, is presumably the sum of these effects.

It is important to establish the sum of these effects for a number of similar reactions for the following reason. In a bimolecular reaction between a molecule and an ion the main contributors to the volume of activation are valence-formation and charge-dispersion as described above and electrostriction of the solvent due to newly separated charges. If the loss of volume due to valence-formation and charge-dispersion can be estimated then it should be possible to determine whether a major separation of charge occurs in the transition state. Laidler and Chen (11) have done this by assuming that the loss in volume due to valence formation is unimportant. We now examine the available evidence on the volumes of activation of ion–molecule reactions. The volume of activation will probably not depend strongly upon whether the ion is positively or negatively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

charged. In order to reduce the possibility of increased polarity in the transition state we will omit reactions that occur near a highly polarizable group such as a carbonyl group. The available information on the volumes of activation of such reactions is summarized in Table III. For some of the reactions only rough rate constants were obtained; for example, David and Hamann (15) claim an accuracy no greater than 30% in the rate constants. It is worthwhile to include these only because there are so few data at present and even rough values are better than none.

TABLE III

Volumes of activation of reactions that probably occur without major change in polarity

		60° C	$-6.6\pm\sim2$	15*
		80° C	$-9.4\pm\sim2$	15*
n-$C_3H_7Br + Br^{82-} \rightarrow n$-$C_3H_7Br^{82} + Br^-$	'90%' C_2H_5OH in H_2O	19° C	~-12	16
n-$C_3H_7I + I^{131-} \rightarrow n$-$C_3H_7I^{131} + I^-$	,,	,,	~-13	16

*The values of $\Delta V^{\ddagger}$ cited were obtained graphically from data in the reference.

All the reactions in Table III except the halogen-exchange reactions result in the formation of a bond between carbon and oxygen. The loss of volume is about -5 to -10 cm^3 mole^{-1}. It seems reasonable to conclude, therefore, on the basis of present evidence that the volume of activation of ion–molecule reactions in which a C–O bond is formed and in which no major increase in the polarity occurs is about -5 to -10 cm^3 mole^{-1}.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS

IV. THE HYDROLYSIS OF DIETHYL ETHER[1]

J. KOSKIKALLIO[2] AND E. WHALLEY

ABSTRACT

The acid-catalyzed hydrolysis of diethyl ether has been measured in the temperature range 120–160° C at low acid concentrations; the entropy of activation is $-9.0\pm\sim2.5$ cal deg^{-1} mole^{-1}. The effect of pressures up to 3000 atm has been measured at 161.2° C; the volume of activation at 1 atm is $-8.5\pm\sim2$ cm^3 mole^{-1}. These two results show that the slow step is bimolecular. The rate in concentrated acids was measured at 119° C; the rate was much more nearly proportional to the acidity function h_0 than to concentration of acid. This is contrary to the predictions of the Zucker–Hammett hypothesis, which is therefore not valid for the hydrolysis of diethyl ether.

1. INTRODUCTION

Diethyl ether hydrolyzes to ethanol by acid catalysis (see ref. 1 for review). The reaction is presumed to involve a pre-equilibrium proton-transfer to the ether though there is no compelling evidence for this. Two possible slow steps are the unimolecular decomposition of the conjugate acid (A-1 mechanism)

$$R_2OH^+ \rightarrow R^+ + ROH, \qquad [1.1]$$

or its bimolecular substitution (A-2 mechanism)

$$H_2O + R_2O^+H \rightarrow RO^+H_2 + ROH. \qquad [1.2]$$

There is no firm evidence about which mechanism is followed, though Long and Paul (2) have noted that the entropies of activation calculated from the measurements of Skrabal and Zahorka (3) are positive and say that this suggests that the mechanism for primary and secondary ethers is A-1. It was shown in Part I of this series of papers (4) that there are no grounds for thinking that entropies of activation of A-2 reactions cannot be positive, and consequently, the conclusion of Long and Paul is not valid.

It has been shown (4, 5, 6) that the A-1 and A-2 mechanisms can be distinguished by measuring reaction rates under pressure, and in this paper the technique is applied to the hydrolysis of diethyl ether. The measurements of Skrabal and Zahorka (3) of the hydrolysis of diethyl ether catalyzed by 0.5-*M* *p*-toluenesulphonic acid indicate a rapid variation with temperature of the Arrhenius energy and of the entropy of activation, and rates over a temperature range have been measured in an attempt to verify this. Measurements of the rates over a range of acid concentrations have been made in order to examine the validity of the Zucker–Hammett hypothesis.

2. EXPERIMENTAL METHODS

Because the rates of hydrolysis are slow it is necessary to measure them at fairly high temperatures, and the range 120–160° C has been used. Because ether is very volatile and not very soluble in water it is most important to avoid having a vapor-space above the reaction mixture in order to avoid loss of reactant from the solution. Consequently, all reported rate measurements were done in such a way that there was no

[1]*Manuscript received December 19, 1958.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa.
Issued as N.R.C. No. 5092.
[2]*National Research Council Postdoctorate Fellow, 1957–58. Present address: Chemistry Department, University of Helsinki, Helsinki, Finland.*

vapor-space. Some rate measurements were made using sealed ampoules as reactors, and vapor was present. The apparent rate constants were badly reproducible and were only a fraction of those obtained as described below, in which there was no vapor-space above the solution.

All reagents used were of analytical quality. The usual catalyst was perchloric acid in concentrations up to 5.65 *M*. A few runs were done with sulphuric acid and hydrochloric acid as catalysts.

High-pressure Technique

The high-pressure equipment was essentially that used in previous work (5), except that the acid solution at the high temperature needed (up to 160° C) reacted with stainless steel so that stainless-steel tubing could not be used to connect the hypodermic syringe to the valve. Consequently, a batch method was used. The reactors were 10-cm³ hypodermic syringes that had the outlets sealed off and the pistons sawn off short. The reaction mixture was thus in contact with glass only. The tubes were placed in the pressure vessel, which was then closed and placed in the thermostat, and the pressure was applied. After a suitable reaction time, which was usually 1 day or more, the vessel was cooled and opened and the three samples were analyzed. There was no evidence of oil entering the reactor or of solution leaving it. The heating of the pressure vessel after it was introduced into the bath had a half life of about 4 minutes as determined from the change in pressure in the closed system. In calculating the reaction time 20 minutes were allowed for warming.

Analysis

The rate of the reaction was followed by analyzing the ethanol produced by oxidizing it to acetic acid with potassium dichromate and sulphuric acid. Five milliliters of the reaction mixture, which was initially about 0.05 *M* in diethyl ether, were put into a mixture containing 3 ml of 96% sulphuric acid and 5 ml of potassium dichromate solution which contained about 50% excess over that required for the oxidation. The mixture was thermostated at 50° C for 20 minutes and then about 100 cm³ of distilled water and 10 cm³ of 0.1-*M* potassium iodide solution were added. The iodine liberated was titrated with 0.4-*N* sodium thiosulphate. The difference between the titer and that of a blank is proportional to the amount of ethanol present in the sample. During the oxidation of the ethanol the ether present is also slowly oxidized. When the unhydrolyzed diethyl ether solution was analyzed by the above method about 4% of the diethyl ether was oxidized; in partly hydrolyzed samples the amount of oxidation was proportionately less. A correction for this was applied to the ethanol analyses. If the sample contained much acid then less sulphuric acid was added when the sample was analyzed in order not to increase the rate of oxidation of ether and thus the correction needed.

The amount of ether initially present in the solution was found by completely oxidizing the ether to acetic acid with potassium dichromate. For this purpose samples of the solution were mixed with the potassium dichromate solution and sulphuric acid and kept in sealed ampoules in a thermostat at 99° C for 1–2 days. When a solution of acetic acid, potassium dichromate, and sulphuric acid, in the same concentrations as above was heated at 99° C for 10 days no oxidation occurred. The amount of ether found by analysis agreed with the amount calculated from the weight of ether in the sample. The 0.05-*M* solution of ether in water was also completely hydrolyzed by heating with 5.7-*M* sulphuric acid for 22 hours at 120°. The amount of ethanol found in this sample agreed within about 2% with the amount found by direct oxidation of ether.

3. RESULTS

The first-order rate constants k were calculated from the results of two analyses for ethanol. Those obtained from runs at different reaction times agreed within about 10%. The second-order constants k_a for runs with dilute acid were corrected for compression and thermal expansion of the solution by extrapolating the densities of water obtained from the literature (7); the correction factors are given in Table I. The second-order constants agreed within about 10%, and those for dilute acids are summarized in Table I. The first-order constants for concentrated solutions of acids are summarized in Table II. The accuracy is probably about 10%.

HCl	3.20	17.5

An Arrhenius plot of the second-order constants is given in Fig. 1, in which the vertical lines at each point show a 10% error. The best straight line through the points is shown; it yields for the Arrhenius energy E_A and the entropy of activation $\Delta S^{\ddagger}(= R \ln\{(A/\text{l. mole}^{-1})(h/ekT)\}$ where A is the Arrhenius frequency factor, R is the gas-constant, h is Planck's constant, k is Boltzmann's constant, and T is the temperature)

$$E_A = 31.0 \pm \sim 1 \text{ kcal mole}^{-1},$$

$$\Delta S^{\ddagger} = -9.0 \pm \sim 2.5 \text{ cal deg}^{-1} \text{ mole}^{-1}.$$

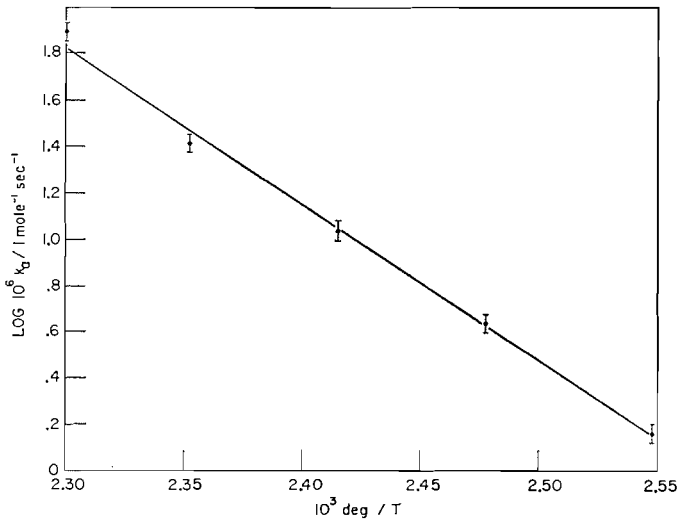

FIG. 1. Log k_a vs. $1/T$ for the acid-catalyzed hydrolysis of diethyl ether between 119 and 161° C.

The points at the highest two temperatures do not fit well with this line, though a good line of slightly smaller slope can be drawn through all but the highest-temperature point, which is about 30% higher than the extrapolated line. It is possible that the Arrhenius energy and the entropy of activation are increasing at the higher temperatures, but the accuracy of the rate constants is not high enough to be sure of it.

The second-order rate constants at 161° C are plotted against pressure in Fig. 2. They

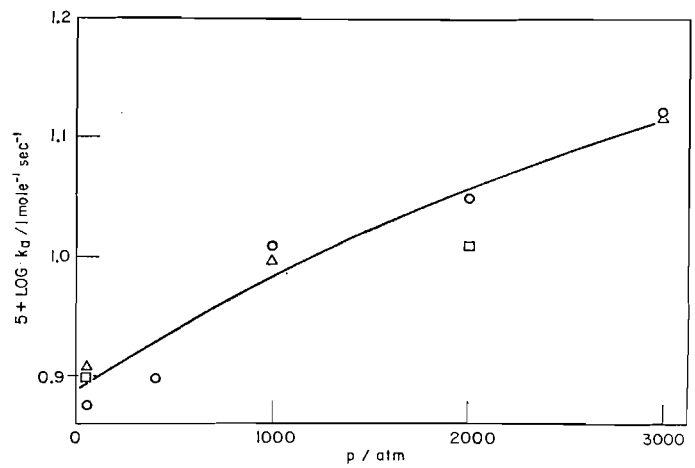

FIG. 2. Log k_a vs. p for the hydrolysis of diethyl ether catalyzed by perchloric acid at 161.2° C. The concentration of catalyst was: triangles, 0.0495 M; circles, 0.099 M; squares 0.198 M.

were fitted by the method of least squares to the equation

$$\log k_a = a+bp+cp^2,$$

and the activation volume $\Delta V^{\ddagger}$ at 1 atm obtained from

$$d \ln k/dp = -\Delta V^{\ddagger}/RT = 2.303b.$$

We found

$$\Delta V^{\ddagger} = -8.5 \pm \sim 2 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 161^\circ \text{ C, 1 atm.}$$

Our rate constants are in very poor agreement with those of Skrabal and Zahorka (3). Our measurements extrapolated to 95° C give $10^6 k_a = 0.34$ l. mole^{-1} sec^{-1} at 50 atm; Skrabal and Zahorka give for 95° C and 1 atm $10^6 k_a = 0.044$ l. mole^{-1} sec^{-1}, nearly $\frac{1}{8}$ of our value. Skrabal and Zahorka give the rate constant at 125° C, obtained by extrapolation, as 0.0785×10^{-6} l. mole^{-1} sec^{-1}; our interpolated value is 2.57×10^{-6} l. mole^{-1} sec^{-1}, 33 times Skrabal and Zahorka's value. Reduction of our rate constants from 50 atm to 1 atm would make little difference to this disagreement. They also found that in the range 65–95° C the Arrhenius law was not obeyed, the apparent Arrhenius energy decreasing with temperature, whereas we find that it is obeyed in the range 120–150° C, though there may be an *increase* in E_A above this temperature. A partial explanation of this disagreement may be as follows. Skrabal and Zahorka attempted to render small and constant the effect of the vapor-space on the rate constant by keeping the volume of the vapor-space 2 cm^3 and of reaction mixture 12 cm^3. However, the amount of ether in the vapor-space relative to that in the solution will increase as the temperature increases and this will cause the apparent rate constant to be lower than the true rate constant by an amount that increases with increasing temperature. This is at least in the right direction to account for Skrabal and Zahorka's variation of Arrhenius energy with temperature.

In a few cases the reaction mixtures were analyzed for ethylene using the method of Christensen *et al.* (8). Within the experimental error of about 0.3% of the ether initially present no ethylene was found under the following conditions: (i) 14 hours at 120° C and 50 atm in 3.57-*M* sulphuric acid with 49% of the ether hydrolyzed, and (ii) 4 hours at 120° C and 50 atm in 5.65-*M* sulphuric acid with 67% of the ether hydrolyzed. Also, the fact that ether hydrolyzed completely at 120° C, within the experimental error of 2%, to ethanol shows that ethylene is not an important product at 120° C.

DISCUSSION

The second-order constants are independent of acid concentration in dilute acids within experimental error, confirming the much less extensive measurements of Skrabal and Airoldi (9).

As pointed out in the introduction there are two likely mechanisms for the hydrolysis of ether, the A-1 mechanism which is steps [1], [2*a*], and [3*a*], and the A-2 mechanism which is steps [1], [2*b*], and [3*b*], below.

$$(C_2H_5)_2O + H_3O^+ \rightleftharpoons (C_2H_5)_2O^+H + H_2O, \qquad [1]$$

$$(C_2H_5)_2O^+H \xrightarrow{\text{slow}} C_2H_5OH + C_2H_5^+, \qquad [2a]$$

$$C_2H_5^+ + 2H_2O \xrightarrow{\text{fast}} C_2H_5OH + H_3O^+, \qquad [3a]$$

$$(C_2H_5)_2O^+H + H_2O \xrightarrow{\text{slow}} C_2H_5OH + C_2H_5O^+H_2, \qquad [2b]$$

$$C_2H_5O^+H_2 + H_2O \xrightarrow{\text{fast}} C_2H_5OH + H_3O^+. \qquad [3b]$$

The measured volume or entropy of activation is the sum of the volume or entropy change of step [1] and the volume or entropy of activation of the slow step [2*a*] or [2*b*]. It was shown in Part I of this series of papers (4) that the volume change of step [1] is probably small, so that the experimental volume of activation is determined mainly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

by the volume of activation of step [2]. If [2*a*] is the slow step then the transition state is bigger than the reactants and the volume of activation is positive or close to zero; this occurs in the acid-catalyzed hydrolysis of sucrose (4), dimethoxymethane, diethoxymethane, dimethoxyethane, and triethoxymethane (5). If [2*b*] is the mechanism then the conversion of a van der Waals' bond between water and the conjugate acid of the ether to a partial valence bond in the transition state results in a decrease of volume, and the volume of activation is expected to be negative by about 5–10 cm^3 $mole^{-1}$; this occurs in the acid-catalyzed hydrolysis of methyl acetate (4), ethylene oxide, propylene oxide, and isobutylene oxide (6). Similar arguments, which were developed in Part I, apply to the entropy of activation, except that the standard entropy change of the proton-transfer step (1) may be quite high. Consequently, we concluded that an A-1 reaction should have a positive entropy of activation and an A-2 reaction can have either a positive or a negative entropy of activation.

The volume of activation is $-8.5\pm\sim2$ cm^3 $mole^{-1}$, showing that the mechanism is A-2. The entropy of activation is $-9.0\pm\sim2.5$ cm^3 $mole^{-1}$, and this confirms the A-2 mechanism.

It is possible that if increases in E_A and $\Delta S^{\ddagger}$ are beginning to occur at the higher temperatures, as is indicated but not proved by our measurements, an A-1 mechanism is beginning to occur. More work is needed on this point. However, it seems certain that the A-2 mechanism, which is detected by the volumes of activation at 161° C and by the entropy of activation over the range 119°–160°, holds at 120° C.

If the Zucker–Hammett hypothesis (10, 2), that when rates in concentrated acids are proportional to Hammett's acidity function h_0 the mechanism is A-1 and when rates are proportional to concentration of hydrogen ion the mechanism is A-2, is correct then the rate of hydrolysis of diethyl ether should be proportional to concentration of strong acid. Values of H_0 ($= -\log h_0$) are not known for perchloric acid in water at the

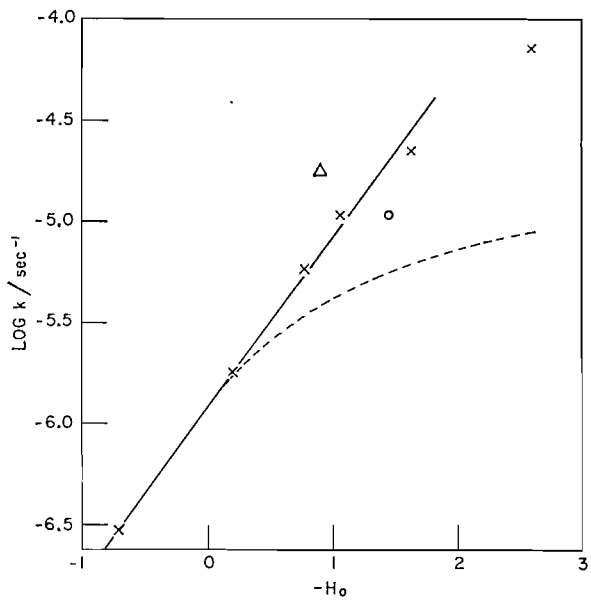

FIG. 3. Log k at 120.1° C and 50 atm vs. $-H_0$ at 25° C and 1 atm for the hydrolysis of diethyl ether catalyzed by acids. The acid was: crosses, perchloric acid; circle, sulphuric acid; triangle, hydrochloric acid. If log $k \propto \log c_{H^+}$ the points would fall near the dashed line.

For personal use only.

temperature and pressure of the measurements, 120.1° C and 50 atm. We have used, therefore, the values appropriate to 25° C and 1 atm (11). These will certainly not be accurate for 120.1° C and 50 atm, but the difference will probably not be enough to invalidate the following discussion. In Fig. 3, log k/sec^{-1} is plotted against $-H_0$, and for comparison the curve that would be obtained if the rate were proportional to concentration of acid is shown. It is quite evident that log k is much more nearly proportional to H_0 than to log c_{H^+}, though the rate at high acidities is somewhat less than strict proportionality would give. The rate in 5.65-M perchloric acid is 8.5 times faster than if it were proportional to c_{HClO_4} and 0.4 times faster than if it were proportional to h_0.

Though there is some uncertainty in the values of H_0 for 120° C and 50 atm, it seems very likely that the Zucker–Hammett hypothesis is not valid for the hydrolysis of diethyl ether. It failed also for the hydrolysis of ethylene oxide (6). The method is inherently empirical, and, since two reactions are now known for which it fails, we must conclude that the relation between rates and h_0 and hydrogen-ion concentration does not distinguish between A-1 and A-2 mechanisms.

Taft, Deno, and Skell, in a recent review (12), refer to work (13) that is not yet fully published that also refutes the Zucker–Hammett hypothesis.

REACTION OF TRICHLOROACETONITRILE WITH PRIMARY AND SECONDARY AMINES

PART II. INFRARED SPECTRA OF N-SUBSTITUTED TRICHLOROACETAMIDINES[1, 2]

JOHN C. GRIVAS[3] AND ALFRED TAURINS

ABSTRACT

A correlation between the infrared absorption spectra and the structure of 13 N-mono- and N-di-substituted trichloroacetamidines is presented. N-Alkyl- and N-aryl-trichloroacetamidines associate strongly in the liquid and solid phases, and exist only in the imino form in non-polar solvents. They can be characterized by a strong band (amidine II band) at 1510–1525 cm^{-1} and 1570–1580 cm^{-1} respectively which is attributed to the deformation vibration $\delta(\diagdown\!\diagup N—H)$ of the secondary amino group. The degree of association of N-substituted trichloroacetamidines changes in the following order of substitution:

N-alkyl- > N-aryl- > N-dialkyl.

INTRODUCTION

The free secondary amino group shows only one NH stretching absorption band between 3500 and 3300 cm^{-1}, but hydrogen bonding of this group sometimes gives rise to a second band at lower frequencies. A somewhat narrower frequency range (3400–3200 cm^{-1}) has been established for the stretching vibration, ν(N—H), of the unassociated imino group =NH as is expected from the fact that the environment around the NH group is almost always the same. The deformation vibration, δ(NH), of both secondary amino and imino groups occur between 1650 and 1550 cm^{-1}, but they are usually too weak to be used for identification purposes (1). In the aromatic amines this absorption is complicated by the fact that it occurs in the same region as the aromatic ring vibrations and often causes a modification of these. Certain combinations of structural features are likely to enhance the intensity of the deformation vibration, δ(NH), just as the NH deformation is believed by some authors to be enhanced by the presence of the carbonyl group, with a result of appearance of the amide II band. That has been recently substantiated by Barr and Haszeldine (2), who assigned the deformation vibration, δ(NH), to a strong band near 1500 cm^{-1} showed by secondary perfluoroalkylamines. The same mode has also been reported to be responsible for the absorption near 1510 cm^{-1}, which was observed in the spectra of the secondary aromatic amines (3).

Amidines of the general formula (I)

$$\begin{array}{l} R—C—NHR'' \\ \quad\| \\ \quad NR' \end{array}$$

I

show also the free stretching vibrations ν(NH), between 3440 and 3470 cm^{-1}, but a considerable amount of chemical evidence indicates that monosubstituted and symmetrically disubstituted amidines having different groups at the nitrogen atom exhibit tautomerism (4). Further support for this evidence has been provided by the infrared

studies of the amidines (I), which showed a second weaker absorption, not vanishing upon dilution, near 3400 cm^{-1} (5, 6).

Fabian, Delaroff, and Legrand (5) observed a rather strong band near 1515 cm^{-1} with solutions of the N-alkyl-N′-phenylbenzamidines. This absorption was displaced by 30–40 cm^{-1} toward the higher frequencies in solid state. This led to the conclusion that it was owing to the NH deformation vibration. However, in some cases, the band was confused with the aromatic ring modes which also occur near 1500 cm^{-1}.

Acetamidines (I) with R′,R″ = aryl groups have been reported to exhibit four bands in the region 1550–1200 cm^{-1}, which were effected by the breaking of the hydrogen bonding and deuteration (6). Two of them, near 1540 and 1330 cm^{-1}, were assumed to originate from the coupling of the deformation vibrations, δ(NH), with the antisymmetric mode of the group —C(=N)N, and the other two at 1440 and 1220 cm^{-1} from the coupling mode of the δ(NH) with the ν(N—R).

The C=N stretching vibration has been firmly established as a very strong band between 1690 and 1640 cm^{-1} for open chain compounds. Pickard and Polly (7) quote this absorption at 1655–1615 cm^{-1} for ketimines of the structure $\begin{matrix} R \\ \diagdown \\ \\ \diagup \\ R' \end{matrix}$C=NH. The range of the ν(C=N) is somewhat larger for the substituted amidines (1685–1590 cm^{-1}) and the position or intensity of this band seems to depend on the degree of substitution and the presence of electron-attracting groups attached to the amidine system (5).

The C—N stretching vibrations occur in a wide range together with the C—C skeletal vibrations. This makes the assignments uncertain in many cases. However, Colthup (8) gives a range 1100–1200 cm^{-1} for C_{alk}—N deformation frequency for the secondary aliphatic amines. This was confirmed by Hadži and Škrbljak (3), who mentioned a strong band between 1170 and 1140 cm^{-1} to be associated with skeletal vibrations, in which the C_{alk}—N bonds participate strongly. Colthup's table shows also that the $\nu(C_{ar}—N)$ of amines of the type $_{ar}$—NH—$_{alk}$ occurs at 1350–1280 cm^{-1}, and that the second band of medium intensity at 1240–1290 cm^{-1} should correspond to the $\nu(C_{alk}—N)$ of the same type of secondary amines. Finally, the $\nu(C_{ar}—N)$ was recently located at 1240–1260 cm^{-1} for a series of secondary aromatic amines (3).

EXPERIMENTAL

The trichloroacetamidines subjected to infrared analysis are represented by the formulae II and III:

$$Cl_3C—\underset{\underset{NH}{\|}}{C}—NHR$$

II R = alkyl, phenyl, or substituted phenyl,

$$Cl_3C—\underset{\underset{NH}{\|}}{C}—N\begin{matrix} R' \\ \diagdown \\ \\ \diagup \\ R' \end{matrix}$$

III R′ = alkyl.

The methods of preparation of trichloroacetamidines have been described previously (9). The solid substances were investigated in potassium bromide pellets. Liquid substances were examined by spraying a thin layer between sodium chloride plates. Solutions of the amidines were prepared by dissolving 10 mg of the substance in 1 ml of tetra-

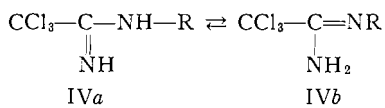
RESULTS AND DISCUSSION

I. Region 4000–1800 cm⁻¹

If trichloroacetamidines existed in two tautomeric forms IV*a* and IV*b*



IV*a* IV*b*

present in dilute solutions then more than two absorption bands should appear between 3500 and 3200 cm^{-1}. Or, if the tautomeric equilibrium had been displaced to the right completely (IV*b*), two absorption bands characteristic of the stretching vibrations of the primary amino group should appear, although modified by the double bond at the α-carbon atom. However, the infrared spectra of the N-monosubstituted trichloroacetamidines revealed only two, very sharp, absorptions at 3450–3520 cm^{-1} and at 3350–3415 cm^{-1} in dilute solutions. The intensity of the two bands showed a general increase on passing from N-alkyl- to N-phenyl-derivatives, where both were almost of the same intensity. The second absorption band was of a much lower intensity in the spectra of the N-alkyl-trichloroacetamidines. No inflections were recorded. The results indicate that amidines do not exhibit any tautomerism at least not in dilute tetrachloroethylene solutions.

Furthermore, a comparison of the infrared spectra of N-dialkyl substituted trichloroacetamidines with those of the N-alkyl homologues revealed that the first and the second stretching band of the imino group =NH appear in the same regions and are very close to each other. Thus, in dilute solution N-ethyl- and N-amyl-trichloroacetamidines showed the second band at 3350 and 3347 cm^{-1} respectively, whilst the

For personal use only.

N-dimethyl-, N-diethyl, and N-morpholyl-derivatives exhibited only one band of the free =NH group in this region at 3362, 3382, and 3365 cm^{-1} respectively.

The NH stretching vibration of the secondary amino group was thus assigned to the 3450–3520 cm^{-1} band and the ν(NH) of the imino group to 3350–3415 cm^{-1} absorption. Further evidence in favor of the above assignments was obtained from the position of the ν(C=N) in different types of substitution, which will be discussed later in this paper.

The infrared spectra of all the compounds show that hydrogen bonding is involved to a considerable extent in liquid and solid phases, except the liquid N-dialkyl substituted amidines. The general trend of the displacement of the $\nu(\rangle NH)$ and ν(=NH) to the higher frequencies is shown when the substances are diluted, in accordance with what is expected from a breaking of hydrogen bonding. This displacement is very slight for the change from the liquid to the solution and it is more pronounced in the case of the solid derivatives.

More than two bands appear in the spectra of solid or liquid compounds in addition to the two NH vibrations; their behavior resembles that of the secondary amides, since they disappear upon dilution. Many of the liquids examined possess a weak absorption near 3040 cm^{-1} and it is expected that other bands exist because of the fact that the ν(=NH) band is very broad and exhibits one or two inflections. Its intensity is also higher than the $\nu(\rangle NH)$ while the opposite is true with the spectra obtained by solutions of these substances.

The existence of these absorption bands in addition to the $\nu(\rangle NH)$ and ν(=NH) was established in four of the six solid amidines examined; i.e. N-(*p*-ethoxyphenyl)-trichloroacetamidine absorbed rather strongly at 3450, 3360, 3330, and 3110 cm^{-1}. The last two bands vanished upon dilution, while the first two were displaced to 3498 and 3398 cm^{-1} respectively. Solid N-(*m*-tolyl)trichloroacetamidine showed absorption maxima at 3470, 3365, 3320, and 3160 cm^{-1}; these four bands were replaced by only two strong absorptions at 3500 and 3400 cm^{-1} in dilute solution. The 3050 cm^{-1} weak absorption observed with the N-alkyl-trichloroacetamidines may be confused with the stretching motion of the aromatic C—H group with the N-phenyl derivatives.

Of the two hydrogen atoms of the imino and secondary amino groups, the first one seems to be involved in hydrogen bonding to a greater extent since it is the band near 3350 cm^{-1} which undergoes greater transformation on changing from the condensed phase to the solution. Although more work is necessary in this field, it can be assumed that the absorption near 3300 and 3150 cm^{-1} are due to hydrogen bonding and originate from a *trans* and *cis* arrangement respectively. These absorption bands correspond to the dimer and polymer structures (V and VI), from which the dimer may be stabilized by resonance occurring in a fashion similar to that observed with the carboxylic acids.

For personal use only.

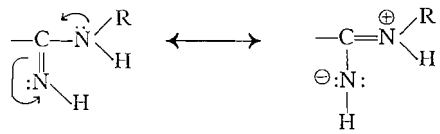
In conclusion, secondary amidines possess hydrogen bonding to a smaller extent than secondary amides and the N-alkyl-trichloroacetamidines are more strongly associated than the N-aryl derivatives.

II. Region 1800–1200 cm^{-1}

(*a*) *The Stretching,* ν(C=N), *Absorption*

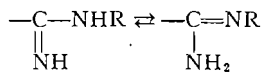
These vibrations were easily recognizable in all the spectra taken, since they appeared as a very strong band between 1590 and 1670 cm^{-1} and did not show any appreciable change in intensity and position, whether the sample was a solid, a liquid, or a solution. The small displacement (5–25 cm^{-1}) to the lower wave lengths upon dilution is quite characteristic in all cases and excludes the possibility of being any NH bending vibration. The position of the ν(C=N) seems to be a function of substitution on the amino nitrogen atom. Thus N-alkyl-trichloroacetamidines absorbed between 1630 and 1645 cm^{-1}, whereas the N-dialkyl compounds at 1590–1610 cm^{-1}. The opposite shift to higher frequencies (1650–1670 cm^{-1}) was recorded with the N-phenyl-trichloroacetamidines.

This behavior can be easily explained and it comes as additional evidence for the non-existence of tautomerism in the amidines examined. Amidines are the resonance hybrid of the following structures (VII).



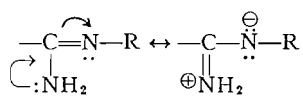
VII

Substitution of the amino hydrogen atom by another alkyl group increases the electron density around the amino nitrogen atom owing to the greater +Is effect. As a consequence the contribution of the polar structure increases, the double bond character of the C=NH double bond decreases, and hence causes a displacement of the ν(C=N) to the lower frequencies which is in fact observed. When R is an electron-attracting group (phenyl) its −Is effect should oppose such an electron movement and depress the resonance within the amidino group. As a result N-phenyl derivatives should absorb at higher frequencies than the corresponding N-alkyl derivatives in agreement with our findings. If tautomerism exists, one of the two tautomers (IX) should be present.



VIII IX

In this case the resonance hybrid can be represented as (X)



X

and the pattern of the displacement going from the N-alkyl- to the N-dialkyl- and N-phenyl-trichloroacetamidines is expected to be the opposite of that observed.

(*b*) *The Amidine II Band*, δ(N—H)

The second very strong absorption in this region appeared near 1515 cm^{-1} for all N-alkyltrichloroacetamidines, and was absent from all the infrared spectra of N-dialkyl derivatives. This immediately suggested that it could be related to the δ(NH) of the secondary amino group. The displacement of this band (1–5 cm^{-1}) to the lower frequencies upon dilution was negligible, since association is weak in the liquid phase, but was indicative of an NH deformation frequency. A rather pronounced shift to lower frequencies was recorded for the N-benzyl derivative, the only aliphatic solid which showed a strong displacement. This compound had a very strong band at 1545 cm^{-1}, in addition to the aromatic absorptions at 1602 and 1495 cm^{-1}. The 1545 cm^{-1} band was displaced to 1510 cm^{-1} upon dilution and the 1495 cm^{-1} absorption peak appeared as a distinct inflection of this band.

In the case of the N-aryl derivatives, the δ(NH) seems to be located near 1580 cm^{-1}, in addition to the two aromatic vibrations. A normal aromatic stretching mode, nevertheless, has been identified between 1600 and 1560 cm^{-1}; although it is always weak, external conjugation increases its intensity, when it becomes a readily recognizable medium band (1).

This possibility was excluded on the following grounds:

(1) The band is very strong in all the spectra.

(2) In the case of the solid N-(*p*-ethoxyphenyl)-trichloroacetamidine, which associates strongly it appeared at 1627 cm^{-1} as a strong absorption, whereas it was found at 1578 cm^{-1} upon dilution.

(3) Richards and Thompson (10) reported only two bands for the aromatic modes near 1600 and 1500 cm^{-1} with the N-aryl acetamides, for which a similar increase in intensity of the 1560–1600 cm^{-1} frequency could be expected.

(4) Since the resonance within the amidine system C(=NH)—NH is opposed to that arising from the aromatic ring, such a conjugation should be reduced greatly, if it existed at all. The assignment of the δ(NH) to the 1515 cm^{-1} absorption for the N-alkyl-trichloroacetamidines and to the 1580 cm^{-1} for the N-aryl analogues might be supported by the findings of Barr and Haszeldine and Hadži and Škrbljak, who located the δ(NH) of the secondary aromatic amines and the secondary perfluoroalkylamines in the same region. It is obvious that the otherwise weak δ(NH) is enhanced through resonance which imposes a partial positive charge on the nitrogen atom.

(*c*) *The Stretching*, ν(C—N), *Frequencies*

Amidines should give rise at least to two absorption bands related mainly to the C—N stretching vibrations. It was clearly understood that only two absorptions of strong and very strong intensity were suitable for the ν(C—N) vibrations in the 1400–1100 region for the N-aryl-substituted trichloroacetamidines, i.e. the 1330 cm^{-1} band for the $\nu(C_{ar}—N)$ and the 1240 cm^{-1} for the ν(C—N) of the amidino grouping. Both values agree with those given by Cothup's table and permit the assumption that the phenyl group "localizes" the C=N double bond to some extent; in agreement with our observation the C=N groups in the phenyl derivative absorb at higher frequencies than the N-alkyl- and N-dialkyl-derivatives.

The ν(C—N) of N-alkyl-trichloroacetamidines occur at higher frequencies; alkyl groups facilitate the resonance within the amidine system, thus imposing a partial double bond character to its (C—N) bond, which therefore should absorb at higher frequencies than the $C_{alk}—N$ bond. This was revealed from a comparison of the infrared spectra recorded for the different classes of substituted amidines on the one hand and from

their absorption in the ultraviolet region on the other. Indeed the amidine ν(C—N) was found to be located near 1310 cm^{-1}, very close to the $\nu(C_{ar}—N)$ in the aromatic compounds, whereas the 1150–1170 cm^{-1} strong absorption should involve mainly $\nu(C_{alk}—N)$ modes, with the N-alkyl-trichloroacetamidines.

No general conclusion could be drawn, for the N-disubstituted derivatives. Nevertheless, a strong band near 1270 cm^{-1} was attributed to the amidine ν(C—N) absorption and the $\nu(C_{alk}—N)$ could be related also to a strong band occurring near 1100 cm^{-1}. It should be pointed out that the ν(C—C) of the $Cl_3C—C$ group was definitely found near 1050 cm^{-1}, in agreement with the spectrum obtained for the trichloroacetonitrile which was used in the preparation of the amidines mentioned above and with the data found in the literature (11).

A SURVEY OF THERMODYNAMIC PARAMETERS FOR SOLVOLYSIS IN WATER[1]

R. E. ROBERTSON, R. L. HEPPOLETTE,[2] AND J. M. W. SCOTT[2]

ABSTRACT

A method is suggested for determining the standard state entropies ($S^0_{\neq}$) of the transition state for the neutral hydrolysis of esters in water. This has required the development of methods for approximating initial state parameters where experimental data are lacking.

Characteristic linear correlations between the entropy and enthalpy of activation are observed for hydrolysis in water, as well as for the bimolecular halide exchange reaction in acetone and for acid–base equilibria. Explanations are advanced to explain the observed trends.

From the derived standard state entropies, a method for estimating the charge development in the transition state for the methyl and isopropyl halides is proposed. With this further detailed knowledge of the transition state in the methyl halide series, reasonable values of the activation enthalpy can be calculated from available thermochemical data.

Correlations of kinetic data for reactions in solution have normally been attempted in terms of relative rates and some function of the reactant (1, 2), the solvent (3, 4, 5), or both (6, 7). There is no doubt that the effect of structural changes on the reactivity can be estimated quite fairly by relative rates, provided neither a detailed understanding of the activation process (8, 9) nor a quantitative description of the transition state is required. The next stage of refinement, however, will require a consideration of the derived thermodynamic parameters which characterize the activation process and the transition state. In principle this will require not only that rate data be determined over a wider range of temperature and with greater accuracy (10, 11) than has frequently been judged necessary but also that the corresponding parameters for the solvated initial state of the ester as well as those characterizing the gaseous state be available (8). Differences in the absolute values of the parameters so derived may then be properly analyzed and so provide a quantitative measure of the effect of structure on reactivity. The procedure may be outlined as follows. Consider the reaction:

[1] $$RX_{gas} \xrightarrow{\delta_s F} RX_{solution} \xrightarrow{\Delta F^{\neq}} RX_{transition\ state}.$$

For each ester in the gaseous state there will be an equation of the form

[2] $$F^0_g = E^0 + H^0_g - T\,S^0_g$$

where

$$H^0_g = \int_0^T C_p\,dT$$

and

$$S^0_g = \int_0^T C_p/T\,dT;$$

$S^0_0 = 0$ (third law) but E^0 is indeterminate. Similarly for the solution of the gaseous ester, there will be a corresponding equation with appropriate subscripts incorporating parameters derived from the temperature dependence of the Henry's Law constant

(omitting the zero point energy) and similarly for the transition state. Thus the entropy of the transition state will be a summation of the terms

[3] $$S^0_{\ddagger} = S^0_g + \delta_a S^0 + \Delta S^{\ddagger}$$

and an analysis of changes in $S^0_{\ddagger}$ as a consequence of structural changes will obviously require a consideration of the sum of the changes in each of the contributing terms. Such an analysis has been previously indicated by Moelwyn-Hughes for methyl bromide (12).

The general plan of this paper then follows eq. [3].

1. We propose a simple empirical method for estimating S^0_g values for certain series of esters where these are lacking.

2. Similarly an empirical method is given which provides parameters for the solution processes where the temperature dependences for the corresponding Henry's Law constants are unknown.

3. The entropy and enthalpy values ($\Delta S^{\ddagger}, \Delta H^{\ddagger}$) for the solvolytic process are correlated and related to changes in structure and to the role of the solvent.

4. The problem of charge development which is of such importance in connection with 3 is dealt with in a separate section.

5. Finally the parameters are combined as indicated in eq. [3] to give a limited characterization of the transition state for some alkyl halides and the activation energies for the methyl halides are calculated.

Values for S^0_g

The values of S^0_g (p = 1 atmosphere) have been listed for the methyl halides (13) but not for the other alkyl halides with which we are concerned in this paper. An isolated value has been given for tertiary butyl bromide by Howlett (14). Hence we have used a simple method for the estimation of gas phase entropies based on the S^0_g values of the corresponding hydrocarbons (15) for the isopropyl and tertiary butyl halides.

A term $\delta_x = S^0_g(\text{Me-X}) - S^0_g(\text{Me-H})$ is defined which gives the contribution to the standard state gaseous entropy obtained by replacing a hydrogen atom in the hydrocarbon by a halogen atom. Values for δ_x so calculated based on known values of the methyl halide (13) are given in Table I.

TABLE I

The $\delta_x S^0_g$ contribution of halogen atoms to the standard state entropy of the methyl halides (p = 1 atm)*

Halogen	$\delta_x S^0_g$ e.u.
F	8.8
Cl	11.47
Br	14.24
I	16.35

*It is only for the methyl halides that all the terms on the R.H.S. of eq. [3] have been determined experimentally. As a consequence values for S^0_g and $\delta_a S^0$ for other compounds must be regarded as tentative, especially those for S^0_g, since these have been obtained, by an approach which is undoubtedly oversimplified. Since this paper was written, a much more detailed treatment of the calculation of standard state entropies in cases where experimental values are lacking has been given by Benson and Buss (64) as well as in a recent monograph by Janz (65). It must be emphasized that this lack of precise data in no way alters the broad conclusions which we wish to establish, nor do we suggest that this is the only possible mode of treating these quantities.

To calculate S^0_g(R-X), S^0_g was combined with δ_x in the following manner:

[4] $$S^0_g(\text{RX}) = S^0_g(\text{R-H}) + \delta_x.$$

As a check on the method, the values for ethyl chloride and for *t*-BuBr were calculated, since these were both known.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Calc.	Lit.
S^0_g(EtCl) = 66.32	65.9 (ref. 13)
S^0_g(*t*-BuBr) = 84.66	80.52 (ref. 14)

Clearly the errors involved for these simple molecules are not too serious. The required values for other compounds determined by this method are recorded in Table VI and compared where possible with the corresponding values calculated by Franklin (16). There is a constant difference of *ca.* 2.6 e.u. between Franklin's values for the isopropyl halides and the values calculated by the above simplified method, but the values for the *t*-BuCl and *t*-BuBr are essentially identical.

Certain special cases arise in which a relative characterization of $F^0_{\ddagger}$ can be obtained without reference to F^0_g. Consider a reaction of a single substrate solvolyzing in a series of solvents or solvent mixtures such as the recent study of the solvolysis of *t*-butyl chloride by Winstein and Fainberg (4):

$$F^0_{\ddagger} = F^0_g + \delta_s F + \Delta F^{\ddagger}. \qquad [5]$$

Since only one compound is involved, for a change of solvent,

$$\delta_M F^0_{\ddagger} = \delta_M \delta_s F + \delta_M \Delta F^{\ddagger}, \qquad [6]$$

i.e. the changes in $F^0_{\ddagger}$ derive only from changes in the solution and activation processes. The use of this relation can be illustrated by reference to the recent data of Winstein and Fainberg (4) for the solvolysis of *t*-butyl chloride in methanol–water mixtures.

By means of the cycle

$$\begin{array}{ccccc} F^0_g & (RX)_g & \xrightarrow{\Delta F^0_g} & (R\oplus.....X^{\ominus})_g & F^0_i \\ & \uparrow \delta_e F & & \downarrow \delta_s F_i & \\ F^0_s & (RX)_s & \xrightarrow[\Delta F^0_{\ddagger}]{} & (R\oplus.....X^{\ominus})_s & F^0_{\ddagger} \end{array}$$

Winstein and Fainberg attempt a separation of the various changes in F^0_g and $F^0_{\ddagger}$ which are due to changes in the solvent. For example it is obvious that by combining the two relations from the above cycle

$$\delta_s F_i = F^0_{\ddagger} - F^0_i \qquad [7]$$

$$F^0_i = F^0_g + \Delta F^0_g \qquad [8]$$

the following relation is obtained for each solvent

$$\delta_s F_i = F^0_{\ddagger} - F^0_g - \Delta F^0_g \qquad [9]$$

and the effect of a change of solvent will be measured by difference

$$\delta_M \delta_s F_i = \delta_M F^0_{\ddagger} - \delta_M \Delta F^0_g, \qquad \delta_M F^0_g = 0. \qquad [10]$$

Clearly changes in $\delta_s F_i$ can only be compared with changes in $\delta_M F^0_{\ddagger}$ if the corresponding $\delta_M \Delta F^0_g$ values are known to $\rightarrow 0$. There is some reason to conclude that the extent of ionization along the MeOH–H_2O mixtures may vary and consequently further discussion of Winstein and Fainberg's dissected values must be postponed until further data are available. While such an approach may be useful in studying the effect of changes in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

solvent, it cannot be extended to a study of the effect of structural differences on reactivity in the absence of a knowledge of the corresponding changes in F_g^0.

TABLE II

Free energy changes for the solvolysis of *t*-butyl chloride in methanol–water mixtures $T = 298.16°$ K

Solvent	$\Delta F^{\ddagger}$	$\delta_s F^*$	$F_{\ddagger}^0$	δ_M

*Winstein and Fainberg values are corrected to the hypothetical standard state used in this paper. This involves a correction of $298.16\times19.53 = 5.823$ kcal. In this and succeeding work we shall use a standard state of 1 mole per liter in both liquid and gaseous state implying $p = 24.466$ atm at 298.16° K. This will involve a correction when comparing our data with those based on other standard states as follows:

Standard states summary

Source	c_g	c_s	p	Conversion factor
1. This paper	1 mole liter^{-1}	1 mole liter^{-1}	22.446 atm	—

†This value was calculated from an extension of the Barclay–Butler Rule (see below).

Initial State Solvation Differences

The solution process for non-electrolytes in water is dominated by the large water–water (*b–b*) interaction in contrast to similar solutions in non-associated solvents where (18) the solute–solute (*a–a*) interactions appear to govern the observed $\delta_s H$ and $\delta_s S$ values. Detailed discussions of aqueous solutions of non-electrolytes have been given by Bernal and Fowler (19), Eley (20), Frank and Evans (21), Glew and Moelwyn-Hughes (17), Feats and Ives (22). The outstanding features of such solution processes may be summarized as follows: (1) large positive ΔC_p values, (2) comparatively large negative $\delta_s H$ and $\delta_s S$ values which are found to be related for any series of alkyl groups attached to a common polar group X by a linear relation of the form

$$\delta_s H = \beta\delta_s S+\gamma, \qquad [11]$$

(3) changes in $\delta_s H$ and $\delta_s S$ appear to follow changes in the size of the solvation shell. The constant (γ) for any given series will include those specific differences in $\delta_s F$ arising as a consequence of differences in the interaction of the anionic portion of the ester with the solvent. The above regularities may be rationalized as follows. A hole must be created in the water for the solute. This will obviously vary with the size of the solute and will be related to the latent heat of evaporation as follows:

$$\delta_\epsilon H = (V_{\text{solute}}/V_{H_2O})\ 10.4 \text{ kcal} \qquad [12]$$

with corresponding values for $\delta_\epsilon S$, while through any series $\delta_R\delta_\epsilon F \simeq 0$. But this cannot be the controlling step in the solution process, since the observed values of $\delta_s H$ and $\delta_s S$ are negative, suggesting a freezing process. This conclusion is supported by the sign of the $\delta_s C_p$ for the solution process of non-electrolytes which is positive and increases with the size of the solute. These facts were noted by Eley (20) and subsequently formed

the basis of the "iceberg hypothesis" suggested by Frank and Evans (21) and developed even more specifically by Glew and Moelwyn-Hughes (17). In effect, the mere presence of a cavity removes a measure of librational freedom (20) over an area proportional to the surface area of the solute and thus leads to increased interaction between those water molecules in the solvation shell. This increased interaction as a consequence of loss of librational freedom results in the changes in $\delta_s H$ and $\delta_s S$ and $\delta_s C_p$ which are opposite in sign, and being greater in magnitude than the corresponding values for cavity formation determine the observed sign of these parameters. Finally, solute–solvent interaction must be considered. Since the alkyl groups have low polarizability (with the exception of those containing unsaturated groups) this interaction will largely depend on the polarizability (23) of the anionic portion of the ester leading to the following increasing order of interaction:

$$F < Cl < Br < I < NO_3 < \text{sulphonates} \backsim \text{phosphates}.$$

This solvent–solute interaction will make a specific negative contribution to $\delta_s F$, which is constant throughout any given series. Since it will be less than $(b–b)$ interaction this $(a–b)$ interaction will alter the solvation parameters in the sense

$$[13] \qquad -\delta_x\delta_s F_{ab} = -\delta_x\delta_s H_{ab}; \quad T\,\delta_x\delta_s S_{ab} \approx 0\,.$$

That this is but a first approximation is evident from a consideration of $\delta_s H$ and $\delta_s S$ for ethane–ethylene; MeF, MeCl, and MeBr. These regularities as well as certain deviations are illustrated in Fig. 1, which shows the correlation of $\delta_s H$ vs. $\delta_s S$ values characterizing the solution of a series of hydrocarbons, alcohols, and a series of esters. The values for the latter and some of the former have been approximated by a method to be described below.

Estimation of $\delta_s H$ and $\delta_s S$

The determination of the temperature dependence of the Henry's Law constants for the esters reported here is a long arduous task, where it is at all possible (17). While an attempt will be made to determine values for key compounds, an approximate method was needed as an interim guide for the interpretation of the kinetic data available. The proposed method is based on the interpretation of the solvation process discussed above and on the further assumption that those regularities which formed the basis of the Barclay–Butler rule (24), and hold for the alkane and alcohol series, will also be true for intermediate series. It must be emphasized that the values so determined (Tables III, IV, and VI—excluding the methyl halides) are no better than these assumptions. Frank and Evans (21) comment on the difference in slope between the alcohols and the less polar compounds while Adon, Cox, and Herrington (25) and Glew and Robertson (26) showed a definite separation between the $\delta_s H$ vs. $\delta_s S$ plots for various series of solutes. ΔF in the eq. [14]

$$[14] \qquad \delta_s S = \frac{\delta_s H}{T} - \left(\frac{\delta_s F}{T}\right)$$

depends on polarity but $\delta_s F/T$ is found to remain remarkably constant for a given series. The regularities already noted support the assumption that through each point in the $\delta_s H$–$\delta_s S$ plot corresponding to RX where R = methyl we may draw a line such that

$$[15] \qquad \delta_s S = \beta\delta_s H$$

where $\beta = f(1/T)$ and T will have a value intermediate between that for alcohols, T

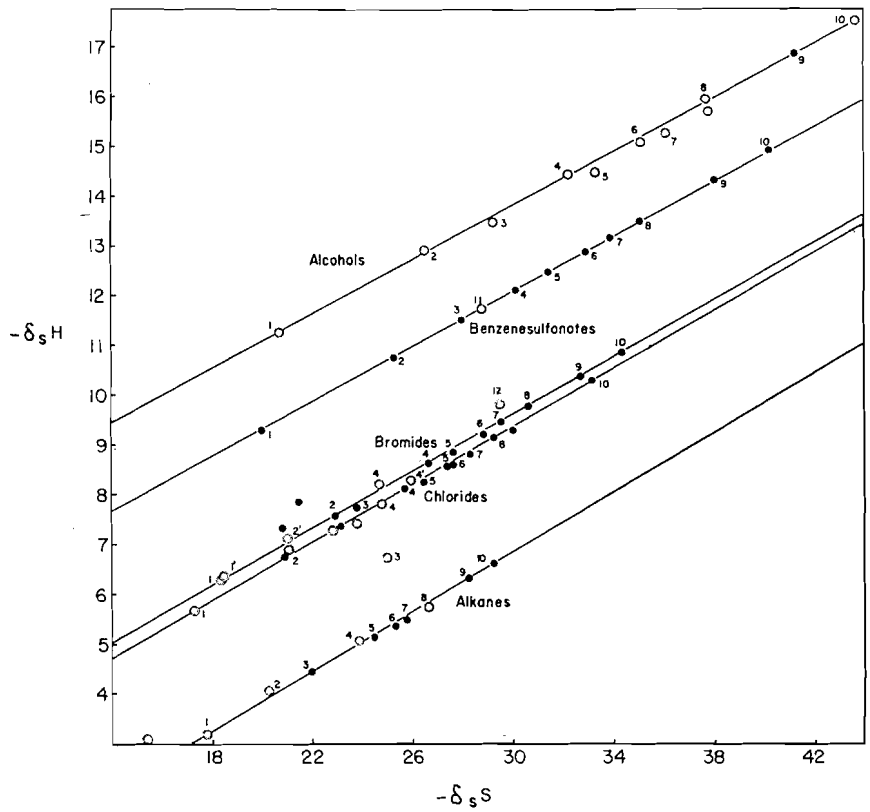

FIG. 1. Estimation of solvation parameters for compounds in water. The numbers refer to Table IV. ○Experimental. ●Estimated.

= 273, and that for the alkanes, T = 300, the variation being assumed proportional to separation along the $\delta_s H$ axis. If the Henry's Law parameters are known for a single member of a series, the $\delta_s H$ vs. $\delta_s S$ plot may be assumed to pass through this point with a slope as given above. Since the solution parameters for the methyl halides were known (17), the corresponding plots were drawn and a line joining methane and methanol was found to approximate to the MeBr and MeI points. The intersection on the chloride and fluoride line did not coincide with the experimental methyl point and the values were accordingly adjusted on the assumption that the deviation was due to some constant $\delta_s H$–$\delta_s S$ contribution associated with X. Lines joining ethane–ethanol, propane–propanol, butane–butanol gave the corresponding EtX, PrX, and BuX points. Since Butler gave $\delta_s H$ vs. $\delta_s S$ values for many alcohols, the above assumptions were used to extend the hydrocarbon plot and so to the corresponding RX values (Table III). The values $\delta_s H$ vs. $\delta_s S$ for ethylamine (27) similarly provide a basis for obtaining the corresponding values for the amines. The only experimental points for comparison are those calculated by Glew (28) from data for EtCl by Nicloux and Scotti-Foglieni (29) and for the *n*-Pr, *i*-Pr bromides and iodides from 1906 data by Rex (30). With the exception of isopropyl chloride the values fall in the predicted range. However, since the experimental values are not consistent among themselves, e.g. $\delta_s S$ (EtCl) < $\delta_s S$ (EtBr), $\delta_s S$ (EtI), $\delta_s S$ (*n*-PrCl) < $\delta_s S$ (EtBr) contrary to what would be expected from relative sizes and polarizabilities (23), we do not regard the deviations between predicted and experimental

For personal use only.

values as significant, and anticipate that more precise data will yield parameters which lie closer to the predicted points. It will be noted that any error in $\delta_s H$ will lead to a compensating error in $\delta_s S$ and displacement along the given plot.

Some idea of the influence of the considerable differences in $\delta_s H$ and $\delta_s S$ through a series on the corresponding parameters for the activation process ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$) can be judged for the normal series by comparison of the corresponding terms from weak acid–base equilibria studies. In these cases there can be no doubt of the degree of charge development in the ionic form, while in the solvolytic process the transition state has been variously estimated by some to have a charge of $\frac{1}{2}\epsilon$ and others $\rightarrow 1\epsilon$ (see below) (9, 31, 32).

Acid–Base Equilibria Entropy and Enthalpies

The initial state data for the amines can be determined as described above. Those for the acids may be determined if we assume that acetic acid is colinear with ethane and ethanol and determine the $\delta_s H$–$\delta_s S$ point along this line corresponding to $\delta_s F = 1.50$ kcal. The slope of the acid ionization plot was determined as before and, from the predicted values for propionic and butyric acids, $\delta_s F$ values were calculated which agreed (Table IV) within experimental error with the values given by Butler (27). Entropy and enthalpy values for the process of acids and amines and for the corresponding equilibria are recorded in Table IV. A comparison of $\delta_s H/\delta_s S$ with the corresponding $\Delta H/\Delta S$ shows that while the former becomes increasingly negative as the chain lengthens the corresponding ΔS values rapidly converge to a value -24 e.u. The obvious conclusion is that on ionization, reorganization of a solvent will only occur over a limited volume. In any comparison, solvation differences to be significant must occur within this volume (33, 34, 35).

This same consideration will enter into discussions of kinetic parameters where we wish to take account of initial state solvation differences, e.g. the Franklin cycle (see below). Here, too, the development of charge in the activation process results in reorganization of solvent about the "seat of reaction" only, a volume difficult of definition but obviously influenced by the degree of charge development and the structure con-

tiguous to the bond being broken. Only in the case of such simple compounds as the methyl halides can we assume that this volume includes the entire primary solvation shell characteristic of the initial state. A recognition of the above limitation becomes extremely important when thermodynamic parameters such as the entropy of hydration of ions are being correlated with parameters derived from rate data (10). For the halides it will be noted that the correlation between the $\Delta S^{\ddagger}$ and $\delta_s S$ ion (Fig. 2) is permitted because the complete solvent shell about the forming halide ion in the activation process is influenced just as it is about the corresponding ion. However, the same correlation need not necessarily hold for the nitrate, methanesulphonate, or the benzenesulphonate groups for, although the initial state solvation involves the complete group, the entire solvation shell need not be affected in the transition state (66).

A distinction must clearly be made between such comparisons as suggested in the previous paragraph and the problem of determining the thermodynamic parameters characterizing the transition state. In such calculations the experimental parameters for the solvation process will enter quite naturally as indicated by eq. [3].

Kinetic Parameters

In Table V are collected a series of parameters characterizing the uncatalyzed solvolysis of esters which have been studied in pure water with sufficient accuracy to warrant comparison. For these compounds, where an accurate determination of $\Delta C_p^{\ddagger}$ had been made, the evaluation of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for any temperature between 0 and 100° is convenient. For compounds where $\Delta C_p^{\ddagger}$ can only be estimated the following technique was used.

TABLE V*a*

The rates were determined over a small temperature range, e.g. 40°–50°–60°. The Arrhenius E_A was determined by the method of least squares and this will correspond in the case quoted to E_{50} (mid-point in the experimental range). Since

$$\Delta H^{\ddagger}_{50} = E_{A50} - R \times 323.16 \quad [16]$$

then from k_{50} and $\Delta H^{\ddagger}_{50}$, the $\Delta S^{\ddagger}_{50}$ follows from the absolute rate equation (37). It should be noted that this method does not require any knowledge of $\Delta C_p^{\ddagger}$ and will give results at 50° C of accuracy comparable to those for which $\Delta C_p^{\ddagger}$ has been determined.

Where reactivities made 50° inconvenient or impossible as a mid-point for a series (cf. technique 1 above) e.g. neopentyl bromides or *t*-butyl chloride, $\Delta H^{\ddagger}_T$ and $\Delta S^{\ddagger}_T$ were determined for the mid-point (T) of the experimental range. To evaluate $\Delta H^{\ddagger}_{50}$ and $\Delta S^{\ddagger}_{50}$ we used the formula

$$\Delta H^{\ddagger}_{T+\Delta T} = \Delta H^{\ddagger}_T + \Delta C_p^{\ddagger} \Delta T \quad [17]$$

$$\Delta S^{\ddagger}_{T_1} - \Delta S^{\ddagger}_{T_2} = \Delta C_p^{\ddagger} 2.3026 \ (\log T_1/T_2). \quad [18]$$

This requires a knowledge of $\Delta C_p^{\ddagger}$ for the respective compounds. Here we are guided by experience, the estimated values being shown in Table V*b*. When $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values are plotted (Fig. 3) a series of linear relations are apparent, revealing definite

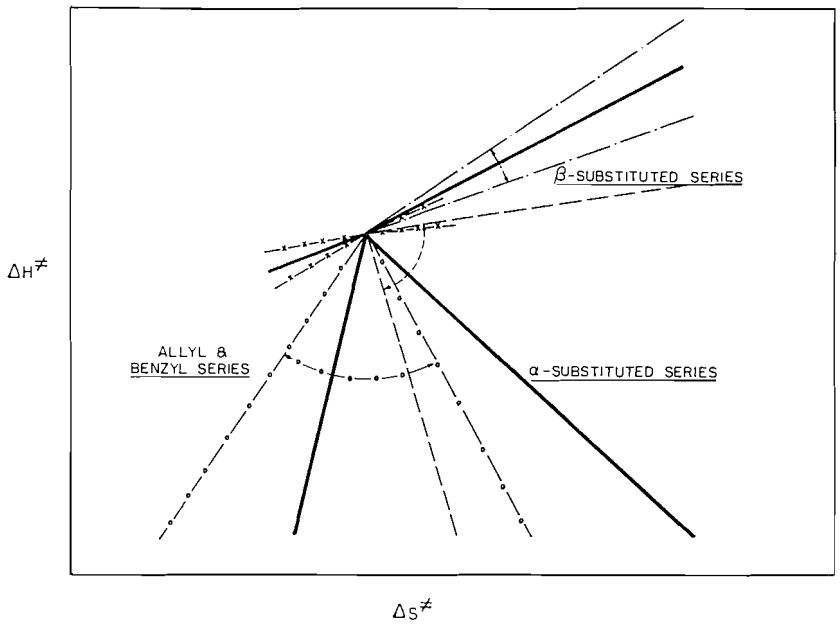

FIG. 3. General profile illustrating the effect of structure on the entropy and enthalpy of activation, for solvolysis reactions in water. The heavy lines indicate average trends; dotted lines indicate specific variations with changing anions.

correlations between the relative values of these parameters and the structure of the alkyl group. Specifically, the values of these coefficients for the α-methyl, β-methyl, straight chain, and unsaturated esters lie on distinct lines which radiate approximately from the methyl group. Functional relationships between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for other systems have been noted frequently and an extensive review on this subject has been published by Leffler (38). Hinshelwood (39) has suggested that such correlations are a consequence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

of differences in the lifetime of the transition state but such a suggestion would set kinetic processes apart from the very similar correlations observed in acid–base equilibria (see above and Fig. 4) and those for parameters derived from solution processes. Leffler

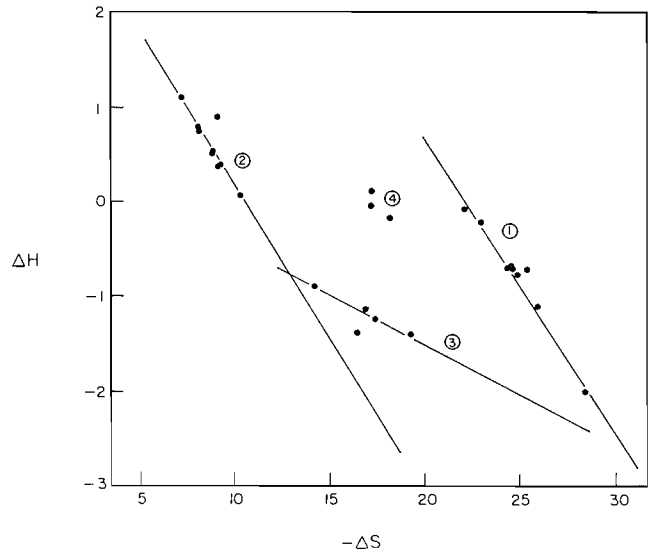

FIG. 4. Linear correlation for the thermodynamic parameters characterizing the dissociation of weak acids: 1, aliphatic acids; 2, amino acids; 3, halogeno-substituted acetic acids; 4, hydroxy acids.

noted that as a consequence of the reorganization of the solvent, on the basis of the Born equation one would expect a linear relation between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. It would appear that the same argument can be used to include the corresponding changes in enthalpy and entropy arising from solute–solvent interaction as a consequence of other types of force fields involved in the activation process. However, the implication that the linear $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ correlations may be rationalized in terms of differences in solvation is probably an oversimplification. These parameters derived from kinetic studies must include internal as well as solvation differences and a linear correlation in the former implies a similar correlation in the latter or the assumption that the internal contributions to $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are constant throughout any particular series. In order to rationalize the differences in the slopes of the $\Delta H^{\ddagger}$ and of $\Delta S^{\ddagger}$ correlation (Fig. 3) from our solvolytic data in water, it is convenient to examine, first, the corresponding plot derived from the results published by Ingold and co-workers for the halide exchange reaction in acetone (41). In these latter reactions we may assume that nucleophilic interaction is the dominant factor in the activation process, and the correlation between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ from these data (Fig. 5) can be rationalized in terms of steric hindrance to nucleophilic attack (41) or a combination of polar and steric effects with the latter predominating (42). Solvation differences must be present, but are probably less specific in organic solvents than in water.

In contrast to the halide exchange reaction, solvation effects are undoubtedly the controlling factor for hydrolysis of esters in water, and the differences evident between the correlation of reaction parameters in Fig. 5 for the halide exchange and in Figs. 3, 6, and 7 for the solvolytic reaction must be rationalized in terms of this change in the controlling factors. From the standpoint of solvation there is also the difference in charge

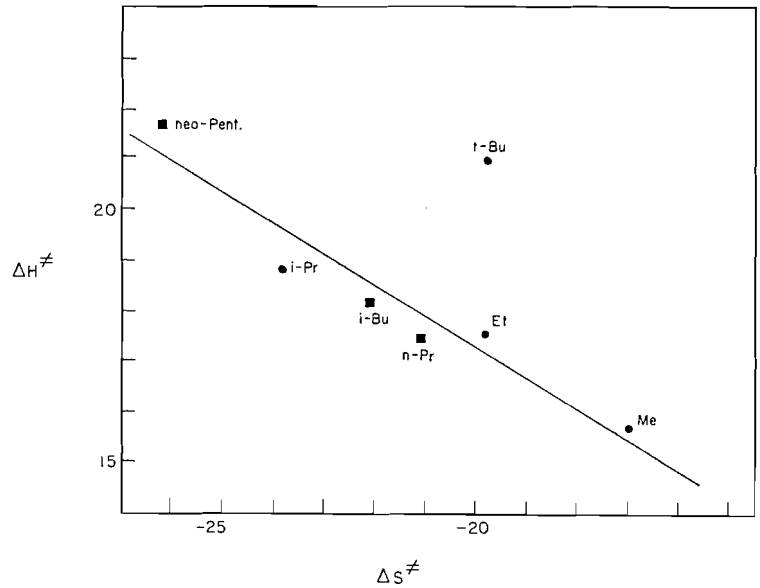

FIG. 5. Effect of structure on the entropy and enthalpy of activation for a bimolecular reaction.

type of the activation process but this is not considered responsible for the trends in the halide exchange parameters. Changes in initial state solvation, as a consequence of β-methylation for any series of esters, will result in successively moving the solvent farther from the carbon at the seat of reaction. The net result will be that, on thermal activation, interaction between the solvent and this carbon will be reduced. Consequently there will be less reorganization of the solvent about the developing carbonium ion in comparison to the reorganization of solvent about the less substituted alkyl group and hence a more positive entropy ($\Delta S^{\neq}$) for the former than for the latter.

Bond making between a particular solvent molecule and the alkyl group will likewise reduce $\Delta H^{\neq}$. Loss of such interaction will have to be compensated for by increased thermal activation and increased solvent interaction with the forming anion, but from the results we must conclude that the effect of this increased interaction on the entropy is not sufficient to compensate for the gain in entropy as a consequence of the decrease in quantum mechanical interaction with the carbonium carbon.

In the halide exchange reaction considered above the dominant driving force came from one direction only—the attack of the nucleophile. In solvolysis, by contrast, as one type of interaction is rendered less effective by structural changes in the alkyl group, alternative paths with higher activation energies become available. The effect of β-methylation in both cases was to raise the enthalpy ($\Delta H^{\neq}$) thus reducing the rate of reaction. The striking difference between the two series is evident in the accompanying entropy changes. Where bond making is dominant, the effect of β-methylation is to impose more stringent requirements on the transition state, leading to more negative entropies and further reducing the rate. In solvolysis, by contrast, as quantum mechanical interaction is reduced through structural change, alternative paths of reaction become available at higher temperatures which are characterized by less reorganization of the solvent and more positive entropy, which to a considerable degree compensates for the higher enthalpy. This difference between the two series can be illustrated by a com-

parison of the relative rates $k_{\text{methyl}}/k_{\text{neopentyl}} = 7.7\times10^{6}$ for halide exchange between Cl^- and the alkyl bromides, while the corresponding ratio from solvolysis at 80° C is 16.4. It is noted that the above argument neglects the positive shift in entropy resulting from increased charge development as well as initial state solvation differences.

Such an analysis would lead to the prediction that the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the hydrolysis of the normal series of esters would lie close to those corresponding to the

ethyl ester. Since this is not found for the benzenesulphonates (Fig. 6) we must conclude that where steric factors are approximately constant, the effect of other factors such as initial state differences becomes apparent.

Changes in the entropy and enthalpy of activation through the β-substituted primary series of toluenesulphonates solvolyzing in acetic acid (63) show the same general trends both in magnitude and sign (Fig. 7) as was found for the benzenesulphonates hydrolyzing in water. The somewhat reduced slope for the linear $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ relation for the former may arise from the reduced importance of quantum mechanical interaction as a consequence of the shift from water to acetic acid as a solvolyzing medium. The difference between the alpha and the beta series arises first from the possibility in the former of a driving force for the reaction arising from an increased tendency toward a change in hybridization from sp^3 to sp^2, which in itself would account for a lowering of the enthalpy and a positive shift in entropy. Secondly, because there is branching close to the seat of reaction, the effect of added α-methyls will exclude solvent more effectively, resulting in an even larger proportional effect by comparison with the β-esters. In addition, in so far as the initial state of the isopropyl or *t*-butyl ester is in some degree more ionic in the initial state than is the corresponding beta compound, then this will further emphasize the difference in entropy between the two series. The combined effect of the above factors will lead to a larger positive shift in the entropy of activation through the alpha series than the corresponding beta series. The difference in the complexity of the contributing factors in the two series is further reflected in the range of values for the parameters through the various series for which data are available to us; contrast the wider range for the alpha than for the beta groups (Figs. 3, 8). In the allyl and benzyl series, where varying charge development in the initial state can alter with the nature of the anionic portion of the molecules, a wider range is also found. Here, however, because the steric factors about the seat of the reaction are relatively constant, the observed changes occur largely in the enthalpy, and solvation differences probably arise from differences in charge development characteristic of the transition state.

Charge Development in the Transition State

In the preceding sections we have shown how to estimate the values of S_g^0 and $\delta_s S$ where they are not known and are now in a position to combine these values with the experimentally determined $\Delta S^{\ddagger}$ according to eq. [3] to get the standard state entropies which characterize the transition state. These values are recorded in Table VI. With the above data available it is now possible to estimate the degree of charge development present in the transition state as follows.

TABLE VI

Summary of thermodynamic parameters for the alkyl halides at 298.16° K

Compound	S_g^0	$\delta_s S$	$\Delta S^0_{\ddagger}$	$S^0_{\ddagger}$
MeF	46.95	−14.11	−8.70	24.14
MeCl	49.62	−17.13	−4.31	28.18
MeBr	52.39	−18.30	−2.91	31.18
MeI	54.50	−18.32	+0.61	36.79
i-PrCl	69.63	−23.08	−2.15	44.40
i-PrBr	72.40	−24.25	+3.11	51.26
i-PrI	74.51	−24.27	+6.67	56.91
t-BuCl	75.54	−26.33	+11.94	61.15

NOTE: We may assume that $\Delta S^{\neq} = \Delta S^0_{\ddagger}$, since the $K^{\ddagger}$ from which $\Delta S^{\ddagger}$ is derived is independent of concentration units (37)—in general this will not be true (see Appendix).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

If the transition state is quasi-ionic it is reasonable to assume

[19] $$S^0_{\ddagger} \propto S^0_R{}^{\oplus} + S^0_X{}^{\ominus} .$$

Making this equation more explicit we may write

[20] $$S^0_{\ddagger} = \mu S^0_R{}^{\oplus} + \alpha S^0_X{}^{\ominus} + c$$

where μ and α and c are constants.

The existence of similar relationships has been noted previously by Hudson and Saville (44) and by Evans and Hamman (10) but has not been set down explicitly as above. The latter, for example, showed a trend between the entropy of solvation for bromide and iodide and the corresponding entropy of activation for two alkyl halides, but such a comparison cannot be strictly true because it fails to take account of initial state differences. It will be noted that these initial state differences are included in the $S^0_{\ddagger}$ and this must be regarded as the main justification for stressing the importance of this term in comparison with the more easily available $\Delta S^{\ddagger}$ value from kinetic measurements.

TABLE VII

Estimation of standard state entropies of alkyl cations

*Calculated from experimental data.
†Semitheoretical values computed by Franklin (ref. 16).

If a plot of the $S^0_{\ddagger}$ values is made against the standard state entropy of the corresponding halogen ions (Fig. 9), two linear relationships are apparent, the methyl and isopropyl series forming two distinct lines. In the methyl halide series the three halides recently measured in this laboratory (45) gave a linear relationship which loses its precision with the methyl fluoride. This, however, might have been anticipated from the large extrapolation of the rate data required to calculate $S^0_{\ddagger}$ (298.16) for the latter compound. The parameters for these linear plots were determined by the method of least squares (neglecting the fluoride in the methyl series) leading to eqs. [21] and [22].

[21] Methyl $$S^0_{\ddagger} = 0.671\ S^0(X^{\ominus}) + 19.00$$

[22] Isopropyl $$S^0_{\ddagger} = 0.962\ S^0(X^{\ominus}) + 32.07$$

Observed and calculated entropies from these equations are compared in Table VIII, where the standard state entropies of the corresponding halogen ions are also given (13).

TABLE VIII

Comparison of observed and calculated standard state entropies by equations [21] and [22]

		Methyl halides		Isopropyl halides

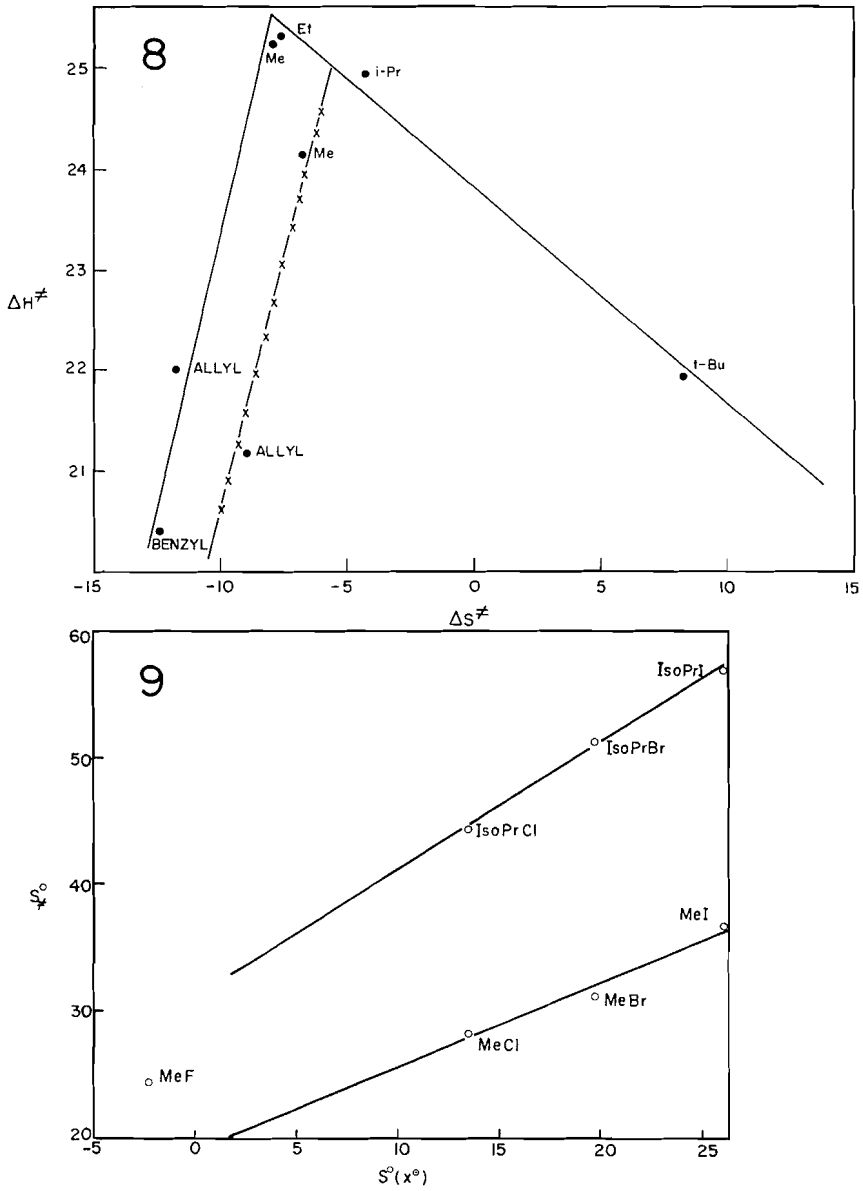

FIG. 8. Correlation of enthalpy and entropy of activation for α-substituted and unsaturated alkyl halides
———— Chlorides —×—×—×— Bromides

FIG. 9. Correlation of $S^0_{\ddagger}$ and $S^0(X^{\ominus})$ for methyl and isopropyl halides.

If we make the assumption that $\mu = \alpha$ and $c = 0$ we can calculate the standard state entropies of the methyl, isopropyl, and *t*-butyl cations ($\alpha = 1$ for the *t*-Bu series).

The coefficients of $S^0(X^{\ominus})$ in the above equations are consistent with the view that the anions are not completely formed in the transition state. Since $\alpha(\text{Me}) < \alpha(i\text{-Pr})$ it would seem that the tendency toward complete ionization increases with α substitution, as is normally assumed. We may safely assume $\alpha = 1$ for the *t*-butyl halides and from this we may calculate $S^0(t\text{-Bu}^{\oplus})$ for the single reasonably accurate value we have in the

For personal use only.

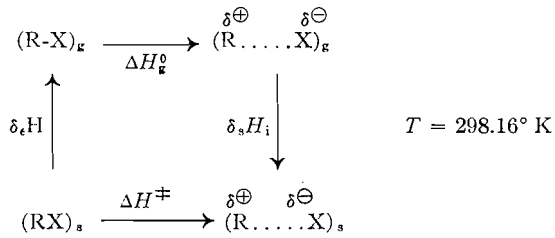
t-butyl series (*t*-BuCl). To give α any further significance must be largely speculative, since it requires a knowledge of how $S^0(X^{\ominus})$ will vary with partial charge development.[3] Currently two views are adopted. Laidler considers (46) $S^0(X^{\ominus}) \propto Z^2$ (Z = charge) and Powell and Latimer (47) consider $S^0(X^{\ominus}) \propto Z$. In this paper we shall adopt Laidler's conclusion because of the successful application by Mason (48) of the Z^2 relationship in discussing the entropy factors in the solvolysis of arylmethyl chlorides.

Thus from eqs. [21] and [22] the charge development for the methyl halides in the transition state is $(0.671)^{\frac{1}{2}}\epsilon = 0.82\epsilon$ and for the isopropyl halides is $(0.962)^{\frac{1}{2}}\epsilon = 0.98\epsilon$.

The Activation Energy for the Methyl Halides

With a guide to the charge development in the methyl halide series it becomes worth while to attempt to calculate again the activation energy for this series. (See for previous work Ogg and Polanyi (49), Evans (32), and Franklin (16).)

Following Franklin we use the cycle:



For this calculation we shall require:

(*a*) $\delta_\epsilon H$, the heat of escape of the gaseous methyl halides from solution. This has been measured by Glew and Moelwyn-Hughes (17).

(*b*) ΔH_g^0, the heat of partial ionization of R-X in the gas phase. Calculations for complete ionization are well known (42) (Table IX).

(*c*) $\delta_s H_I$, the combined heats of solution of $R^{\oplus}$ and $X^{\ominus}$ from the gas phase to solution.

The heats of solution for the halide ions have been listed by Latimer, Pitzer, and Slansky (50). These values, it must be noted, are somewhat arbitrary in that they require the total heat of solution of a *pair* of ions to be split up. How this should best be accomplished has not yet been made clear (cf. Moelwyn-Hughes (51)).

TABLE IX

Energies for the ionization of the methyl halides in the gas phase at 298.16° K

Compound	ΔH_g^{0*}		$\Delta H_g^{0\dagger}$
MeF	247.2	—	—
MeCl	223.3	220	223
MeBr	215.2	215	214
MeI	207	208	204

*This paper.
†Streitwieser (ref. 42).

The heat of solvation of the methyl cation represents a much more difficult problem. On a purely electrostatic basis Franklin (16) has estimated the heat of solution as −61 kcal/mole. This value treats the methyl cation as a thermodynamically stable entity

[3]*We are fully aware that other interpretations of the constant α are possible but these will be dealt with in a later communication.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

when it is in water. This is certainly erroneous, i.e. the methyl cation does not correspond to an ion of given radius and complete octet. We have arrived at an estimate of the heat of solution of the methyl cation which combines both the heat of solvation and the heat of reaction. We consider that both these energy terms are available as driving forces in kinetics. The heat of solvation represents the purely electrostatic portion whilst the heat of reaction is derived from backside attack of the water molecule.

Following Mason (48) we shall apply an equation of the form

$$\Delta H^{\ddagger} = \delta_e H + \alpha^{\frac{1}{2}} \Delta H_g^0 + \alpha \delta_s H_1 \qquad [23]$$

$\alpha^{\frac{1}{2}}$ being equal to the charge development in the transition state.

Values for ΔH_g^0

These have been calculated by Stevenson and quoted by Streitwieser (42). We have recalculated these values from available data (13) using the ionization potential for the methyl radical as 230 kcal/mole and the heat of formation of methyl fluoride as 64 kcal/mole, kindly provided by Dr. Bernstein of these laboratories.

Heat of Solution of the Methyl Cation

Consider the combined processes

$$\begin{array}{ccc} CH_3^{\oplus}(g) + H_2O(g) & \xrightarrow{\Delta H_b} & CH_3OH(g) + H^{\oplus}(g) \\ \downarrow \delta_s H_a & \searrow \Delta H & \downarrow \delta_s H_c \\ CH_3^{\oplus}(s) + H_2O(s) & \xrightarrow{\Delta H_d} & CH_3OH(s) + H^{\oplus}(s) \end{array}$$

We may assume

$$\delta_s H_a + \Delta H_d = \Delta H_b + \delta_s H_c = \Delta H . \qquad [24]$$

Now $\delta_s H_a = \delta_s H(CH_3^{\oplus}) + \delta_l H$ (latent heat of condensation of water),

ΔH_d = heat of reaction of 'solvated' methyl cation to give alcohol + solvated proton. Both processes may be considered to be exothermic, since the 'solvated' methyl cation would not be expected to be thermodynamically stable.

Since $\Delta H_b + \delta_s H_c$ are easily computed we can determine $\Delta H_d + \delta_s H(CH_3^{\oplus})$.

$$\begin{aligned} \Delta H_b &= \Delta H_f^0(H_g^+) + \Delta H_f^0(CH_3OH_g) - \Delta H_f^0(CH_{3g}^+) - \Delta H_f^0(H_2O)_g \\ &= 367.1 - 48.1 - 262.0 + 57.8 \text{ kcals} \\ &= 114.8 \text{ kcals.} \end{aligned}$$

The heat attending the dissolution of 1 gram molecule of hydrohalic acids *as ions* is given by Moelwyn-Hughes (51). The heats of solution of the separate halogen ions have been given by Latimer, Pitzer, and Slansky (50), therefore

$$\delta_s H\ (H^{\oplus}) = \delta_s H\ (H^{\oplus} X^{\ominus}) - \delta_s H\ (X^{\ominus}) . \qquad [25]$$

Combining the above data according to eq. [25] we obtain a mean value for the enthalpy of hydration for the proton of 254.6 kcal/mole.

Latent heat of condensation of water = -10.4 kcal.
Heat of solution of MeOH = -10.7 kcal.
$\Delta H_d + \delta_s H\ (CH_3^{\oplus}) - (-10.4) = 114.8 - 10.7 - 254.6.$
$\Delta H_d + \delta_s H\ (CH_3^{\oplus}) = -140.1$ kcal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

We can now approximate to $\delta_s H_1$ in the Franklin cycle (previous section) by combining the above figure with the heat of solvation for the appropriate anion (Latimer).

In Table X we have recorded the various quantities which are required to calculate the enthalpy of activation according to eq. [23]. Values for $\delta_s H_1$ are given by the equation

$$\delta_s H_1 = \Delta H_d + \delta_s H\ (CH_3^{\oplus}) + \delta_s H\ (X^{\ominus}).$$

Two values of α have been used: $\alpha = 0.67$ as determined by the relationship (21) for the methyl halides and a slightly higher value $\alpha = 0.74$. The value of $\Delta H^{\pm}$ calculated is extremely sensitive to the value of α adopted. It will be seen from Table X that the value of $\Delta H^{\pm}$ so calculated is in reasonable agreement with experiment, from which we may conclude that in the transition state the water molecule is strongly bonded (both covalently and electrostatically) to the carbon atom undergoing substitution.

TABLE X

Theoretically computed values for $\Delta H^{\pm}$ and associated data at 298.16° K

Compound (RX)	$\delta_s H_i(X^{\ominus})$	$\delta_\epsilon H$	ΔH_g^0 (1)	ΔH_g^0 (2)	$\delta_s H_i$ (1)	$\delta_s H_i$ (2)	Calc. $\Delta H^{\pm}$ (1)	Calc. $\Delta H^{\pm}$ (2)	Obs. $\Delta H^{\pm}$
MeF	−122.6	4.4	202.7	212.6	−176.0	−194.4	31.1	32.6	27.3
MeCl	−88.7	5.7	183.1	192	−153.3	−169.3	35.5	28.4	26.5
MeBr	−81.4	6.3	176.5	185.1	−148.4	−163.9	34.4	27.5	25.3
MeI	−72.1	6.4	169.7	178	−142.2	−157.0	33.9	27.4	27.4

$\delta_s H_i$ (1) is equal to $\alpha[\Delta H_d + \delta_s H_i\ (CH_3^{\oplus}) + \delta_s H_i\ (X^{\ominus})]$ where $\alpha = 0.67$.
$\delta_s H_i$ (2) is equal to $\alpha[\Delta H_d + \delta_s H_i\ (CH_3^{\oplus}) + \delta_s H_i\ (X^{\ominus})]$ where $\alpha = 0.74$.

ΔH_g^0 (1) is equal to $\alpha^{\frac{1}{2}}\Delta H_g^0$ where $(\alpha)^{\frac{1}{2}} = 0.82$: ΔH_i^0 given in Table IX.

ΔH_g^0 (2) is equal to $\alpha^{\frac{1}{2}}\Delta H_g^0$ where $(\alpha)^{\frac{1}{2}} = 0.86$: ΔH_i^0 given in Table IX.

The extension of the above calculations to the isopropyl and *t*-butyl and allyl and benzyl halides has not been carried out for a variety of reasons which are both practical and theoretical. On the practical side the approximate evaluation of the charge development in the *t*-butyl halides from the standard state entropies of activation ($S_{\pm}^0$) is impossible because of their high reactivity. Theoretical objections to any such calculation are equally great.

It will be noted that the ΔH_g^0 values for the isopropyl, *t*-butyl, allyl, and benzyl are considerably less than those for the corresponding methyl halides. This drop in ΔH_g^0 is mainly due to a decrease in the ionization potential of the corresponding radical accompanied by a relatively small bond energy decrease (52). The lowering of the ionization potential is attributed to resonance in the alkyl radical. This is a perfectly reasonable explanation for the gas phase reaction.

In solution, however, the charge stabilization of the forming cation can occur in two distinct ways. First, the localized charge can be solvated, or second, the delocalized charge can be stabilized by solvation. It has been shown in a most elegant paper by Mason (48) that the effect of charge delocalization is to lower the free energy of solvation to a considerable degree. A rough calculation for the benzyl cation indicates that the solvation of the delocalized charge plus the resonance energy is less than the solvation energy of the localized charge by as much as 20 kcal.

The tropylium ion, however, provides a striking example where resonance stabilization, implying delocalized charge, is more favorable than the solvation of the localized charge.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

Even in this case, where resonance stabilization is large (53), there is a definite tendency to revert to the alcohol

$$C_7H_7^{\oplus} + 2H_2O \rightleftharpoons C_7H_7OH + H_3O^{\oplus} \qquad K_{25} = 1.8\times10^{-5}$$

a reaction analogous to the specific localized solvation of a resonating carbonium ion. From the above it would appear that great care must be exercised in rationalizing changes in reactivity as arising from resonance contributions to the transition state, since the solvation of the localized charge may represent a more favorable reaction path. The reasons why we hesitate to use Stevenson's ΔH_g^0 for the gas phase reaction

$$(RX)_g \rightarrow R_g^{\oplus} + X_g^{\ominus}$$

can now be stated for the cases where R = *i*-Pr, *t*-Bu, allyl, and benzyl.

Stevenson's values contain the whole of the resonance energy, since there can be no other mode of stabilization of the positive charge in the gas phase. The only case where ΔH_g^0 can be related to solution kinetics is in the methyl halide series where resonance is negligible in the forming alkyl cation.

The above discussion of the effect of charge delocalization on the free energy of solvation suggests some important criticisms of the calculations by Franklin (16). The errors in calculating the heats and entropies of solvation of the alkyl cations in terms of their relative dimensions only has already been noted. Franklin has also used the values for ΔH_g^0 which contain the resonance energy of the forming cation, although no account has been taken of the effect of this charge distribution on the solvation parameters which as a consequence would be considerably reduced. Thus Franklin's calculations give reasonable results due to a fortuitous cancellation of several errors (4). There is good reason from the $S_{\pm}^0$ vs. $S^0(X^{\ominus})$ relationship (see above) to believe that in water only reactive compounds have reached complete ionization in the transition state ($\alpha = 1$) which Franklin assumes for all compounds. However, Franklin's calculations appear to be correct in principle and should be capable of giving good results with the proviso that the appropriate values for the thermochemical quantities required are available and the transition state is carefully defined.

It will be obvious that the argument presented here rests on the correctness of the assumption (common to all such applications of thermodynamics to kinetic data) that the transition state may be treated as though in equilibrium with the average initial state. We are unaware of any evidence to suggest that such an assumption is unjustified. It will be equally obvious that the work presented here is made possible by the happy combination of accurate kinetic data and reasonable values for the initial state parameters. While it should be possible in principle to extend this treatment to all systems, in practice almost none of the necessary data are available. In this respect we hope that this paper may point the way as well as emphasize the tremendous challenge in this field for both the experimentalist and the theoretician. Yet even if all the necessary thermodynamic parameters were determined for the reactions of interest, a detailed understanding of the activation process would still require that a satisfactory model be constructed, which would satisfy the energetic requirements so determined. In this connection it would appear that the variations in the entropy and enthalpy factors discussed above, in the particular case of hydrolysis, throw far more light on the nature of the transition state than could possibly be derived from a comparison of free energies. While hardly surprising, this needs to be emphasized as a justification for the greatly increased experimental requirements. The above treatment is presented, therefore, not as a panacea,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

but rather as an illustration of what can be done under very favorable experimental conditions and as an example of an essential link in the development of a quantitative treatment of the relation between structure and reactivity for reactions in solution.

ACKNOWLEDGMENT

We wish to acknowledge the criticism and suggestions which we received from Professors K. J. Laidler and P. M. Laughton.

APPENDIX

The following scheme for the thermodynamic operators has been adopted. For all chemical reactions (i.e. for parameters derived from rates and equilibria) the symbol Δ carries its usual meaning. For changes in thermodynamic quantities arising from physical or structural changes the following operators have been used:

δ_M = change in medium,
δ_ϵ = change from liquid to gas,
δ_R = change in structure of alkyl group,
δ_X = change in structure of anionic portion of solute,
δ_s = change from gas to solution.

The subscript i, e.g. $\delta_s H_i$, refers to the change in enthalpy in passing ions from gaseous phase to solution. For ionogenic reactions occurring in the gas phase, terms such as ΔF^0_g and ΔH^0_g have been used.

Terms such as $\Delta F^0_{\pm}$ have been used to designate the free energy of activation with respect to a defined standard state. The thermodynamic parameters derived from rate studies and collected in this paper will be independent of the standard state and hence $\Delta F^0_{\pm} = \Delta F^{\pm}$.

STERIC INHIBITION OF RESONANCE
II. BOND LENGTHS IN MESO-SUBSTITUTED ANTHRACENES*

JAMES TROTTER†

The crystal structures of several meso-substituted anthracenes have recently been determined by X-ray diffraction methods (1) and reasonably accurate values of the molecular dimensions have been obtained. These detailed investigations have shown that the molecules of 9,10-dibromo- and 9,10-dichloro-anthracene are completely planar (2, 3). In the 9-nitro and 9,10-dinitro derivatives, however, the bulkier nitro groups are markedly tilted out of the aromatic planes about the C–N bonds (4), and correlation with the characteristic nitro group infrared frequencies suggests resultant decreases in resonance interaction between the nitro groups and the aromatic π-electrons (5). The angles of tilt alone do not give directly quantitative measures of the decreases in the conjugation compared with planar models, but resonance involving ionic structures, of type I for 9-nitroanthracene for example, would impart a considerable amount of double bond character to the C–N bond, and in addition cause variations in the N–O bond lengths when compared with those in aliphatic nitro compounds, and in the bond lengths in the anthracene nucleus compared with those in the unsubstituted molecule. It has been shown that in picryl iodide the C–N distances ortho to the iodine atom correspond to single bonds, indicating resonance inhibition, while the conjugated para C–N bond is very much shorter, suggesting a considerable amount of resonance interaction (6). Examination of the bond length variations in meso-substituted anthracenes therefore may give a quantitative account of the resonance interaction, and also indicate the amount of resonance inhibition due to steric effects in those molecules with bulky substituents, such as nitro groups, in the 9 and 10 positions.

The bond lengths, together with the standard deviations, in the molecules studied are compared in Table I with the bond lengths in anthracene (7, 8), the labelling of the carbon–carbon bonds being shown in the diagram. The values in the substituted anthracenes are quoted to 0.001 Å for comparison, although as the standard deviations indicate, the accuracy is much lower than this. The C–Br, C–Cl, C–N, and N–O distances in non-conjugated molecules are included under anthracene.

TABLE I

Bond lengths and standard deviations in meso-substituted anthracenes (Å)

Bond	Anthracene	9,10-Dibromo	9,10-Dichloro	9,10-Dinitro	9-Nitro
a	1.366±0.004	1.409±0.027	1.382±0.015	1.350±0.011	1.399±0.008
b	1.433±0.003	1.417±0.027	1.411±0.015	1.413±0.011	1.434±0.008
c	1.399±0.003	1.374±0.027	1.397±0.015	1.399±0.011	1.400±0.008
d	1.419±0.006	1.463±0.038	1.401±0.021	1.400±0.016	1.413±0.011

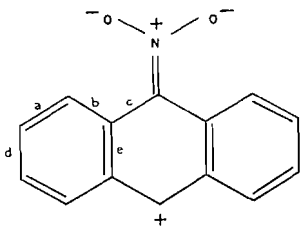
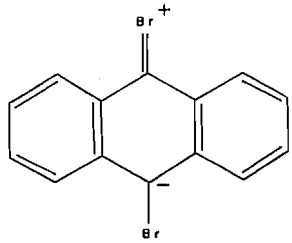
Exocyclic Bonds

Since there is no resonance inhibition in the completely planar halogen derivatives, ionic structures (II) ought to make a contribution to the ground state of the molecule. However, the weight of structures of this type, with a positive charge on the halogen atom, is quite small, and only a small contraction of the carbon–halogen bond lengths below the single bond distances would be expected. The C–Cl bond distances in 9,10-dichloroanthracene are slightly less than the normal single bond length, but the difference is scarcely significant. The ionic structures, however, are highly polar and, although their weights are small, they reduce the dipole moment in 9-bromoanthracene, for example, in comparison with a non-conjugated molecule (methyl bromide = 1.78 D, bromobenzene = 1.52 D, 9-bromoanthracene = 1.50 D).



I



II

In 9-nitroanthracene the nitro group is tilted 85° out of the plane of the aromatic rings, and the C–N bond length (1.48 Å) corresponds to a single bond, indicating that there is little or no resonance between the anthracene nucleus and the nitro group. The C–N bond lengths in 9,10-dinitroanthracene, where the tilt of the nitro groups is 64°, are 1.45 Å, so that in this molecule there is a measurable amount of resonance interaction in spite of the large deviations from planarity. A quantitative measure of the resonance, however, requires a knowledge of the C–N bond length in a fully conjugated molecule such as nitrobenzene, and this length has not been accurately measured. (The conjugated C–N bond lengths in picryl iodide (6) and *p*-nitraniline (9) have been given as 1.35 Å and 1.41 Å respectively.) The C–N bond distances in 9,10-dinitroanthracene are much closer to the single bond length than to the distances in these fully conjugated molecules, so that while there is resonance interaction between the anthracene nucleus and the nitro group, it is much less than in completely planar aromatic nitro compounds. The N–O bond lengths in these nitroanthracenes also suggest that there is little or no resonance between the aromatic rings and the nitro group in 9-nitroanthracene, and a small but measurable interaction in 9,10-dinitroanthracene.

C–C Bonds

Examination of Table I shows that there are no really significant differences between the carbon–carbon bond lengths in the meso-substituted anthracenes studied and those in the unsubstituted molecule, indicating that contributions of ionic structures are too small to effect any measurable changes in the dimensions of the anthracene skeleton.

A CRYSTALLINE DERIVATIVE OF 2-*O*-(4-*O*-METHYL-α-D-GLUCOPYRANOSYLURONIC ACID)-D-XYLOPYRANOSE

T. E. TIMELL

2-*O*-(4-*O*-Methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, the structure of which was first established by Jones and Wise (1), has so far been isolated from some thirty natural plant products. Since no crystalline derivative of this amorphous compound has hitherto been known, it has been characterized by identification of the products obtained on hydrolysis of the original and of the methylated acid. A crystalline *p*-nitrobenzoate of the derived 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl)-glycerol has been prepared (2) but the acetate of the 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl)-D-xylitol is reported to be amorphous (3). A crystalline tetraacetate of the methyl ester methyl glycoside of the aldobiouronic acid has now been prepared and characterized.

Partial hydrolysis of a 4-*O*-methyl glucuronoxylan from white birch wood yielded 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, the structure of which had previously (4) been unequivocally established. Treatment of the derived methyl ester methyl glycoside with acetic anhydride in pyridine gave a sirup, a portion of which crystallized immediately from an ethyl ether solution. After recrystallization, white, small crystals were obtained, easily soluble in acetone, chloroform, ethyl acetate, and tetrahydrofuran, but only sparingly so in ethyl ether and ethanol. The methyl 2-*O*-[methyl-(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl) uronate]-3,4-di-*O*-acetyl-D-xylopyranoside had m.p. 200–201° C, $[\alpha]_D^{20}$ +100° in chloroform, and was further characterized through its infrared spectrum and its X-ray diffraction pattern. The residual sirup had a specific rotation slightly lower than that of the crystalline portion (+85°). The data reported by Smith and co-workers (5) for the methyl ester methyl glycoside pentaacetate of two related, anomeric aldobiouronic acids would otherwise suggest that the xylopyranoside moiety was present in the β-configuration. Preparation of methyl ester methyl glycoside tetraacetates of specimens of the same aldobiouronic acid obtained from various natural products gave crystalline compounds with properties identical with those of the present derivative. The corresponding benzoate and *p*-nitrobenzoate esters were amorphous and could not be induced to crystallize.

EXPERIMENTAL

2-O-(4-O-Methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose

A 4-*O*-methyl glucuronoxylan (200 g) from white birch wood (6) was dissolved in 72% sulphuric acid (100 ml). After 24 hours at room temperature, the solution was diluted to 4000 ml and boiled under reflux for 9 hours. Neutralization with barium

The corresponding benzoate and *p*-nitrobenzoate esters were amorphous and could not be induced to crystallize.

EXPERIMENTAL

2-O-(4-O-Methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose

A 4-*O*-methyl glucuronoxylan (200 g) from white birch wood (6) was dissolved in 72% sulphuric acid (100 ml). After 24 hours at room temperature, the solution was diluted to 4000 ml and boiled under reflux for 9 hours. Neutralization with barium

hydroxide, filtration through Celite, and evaporation and treatment with Darco G-60 charcoal and Amberlite IR-120 exchange resin yielded a pale yellow solution which was added to a column of Dowex 1-X4 anion exchange resin (acetate form). Neutral sugars were eluted with water (16 liters) after which sugar acids were removed with 30% aqueous acetic acid (16 liters). Evaporation of the acidic eluate yielded a sirup (25 g) which was resolved on 60 sheets of Whatman No. 3 MM filter paper with a solvent system consisting of ethyl acetate – acetic acid – water (9:2:2 v/v). The three main components, namely galacturonic acid, an aldobiouronic acid, and 4-*O*-methyl glucuronic acid (4), were eluted with water from the appropriate strips. Evaporation, treatment with Darco G-60 and Amberlite IR-120, and evaporation to dryness from methanol of the aldobiouronic acid gave a chromatographically pure, white, amorphous powder (10 g), $[\alpha]_D^{20}$ +108° (*c*, 1.0 in water). Anal. Calc. for $C_{12}H_{20}O_{11}$: OCH_3, 9.1%; equiv. wt., 340. Found: OCH_3, 9.2%; equiv. wt., 368.

*Methyl 2-O-[Methyl(4-O-methyl-α-*D*-glucopyranosyl)uronate]-*D*-xylopyranoside*

A portion of the above aldobiouronic acid (1.2 g) was boiled under reflux with 2.5% methanolic hydrogen chloride for 10 hours. After neutralization with silver carbonate, filtration through Celite, and evaporation, a white, fluffy powder was obtained (1.3 g, 100%), $[\alpha]_D^{20}$ +77° (*c*, 1.5 in water). Anal. Calc. for $C_{14}H_{24}O_{11}$: OCH_3, 25.3%. Found: OCH_3, 25.6%.

*Methyl 2-O-[Methyl(2,3-di-O-acetyl-4-O-methyl-α-*D*-glucopyranosyl)uronate]-3,4-di-O-acetyl-*D*-xylopyranoside*

The methyl ester methyl glycoside of the aldobiouronic acid (1.2 g) was dissolved in dry pyridine (75 ml), and redistilled acetic anhydride (25 ml) was added. After 24 hours at room temperature, the solution was poured into ice water (800 ml) and the aqueous solution was extracted with chloroform. The chloroform was extracted three times with ice-cold, 10% hydrochloric acid and subsequently three times with saturated sodium bicarbonate solution. After drying over anhydrous sodium sulphate, the chloroform solution was evaporated to yield a pale yellow sirup (1.70 g, 97%), which was dissolved in boiling ethyl ether (50 ml). On cooling of the solution, crystals immediately formed. The volume was adjusted to 25 ml and crystallization was allowed to proceed at −4° C for 24 hours. The white crystals obtained (0.32 g, 18.3%), m.p. 193–197° C (corrected), $[\alpha]_D^{20}$ +100° (*c*, 1.4 in chloroform), were dissolved in 20 ml of hot, anhydrous ethanol, followed by cooling and addition of the same volume of ethyl ether. The crystals formed (0.20 g) had m.p. 200–201° C, $[\alpha]_D^{20}$ +100° (*c*, 1.5 in chloroform). Anal. Calc. for $C_{22}H_{32}O_{15}$: C, 49.2%; H, 6.02%; OCH_3, 17.3%; $OCCH_3$, 40.1%; mol. wt., 536.3. Found: C, 49.7%; H, 5.93%; OCH_3, 17.0%; $OCCH_3$, 39.8%; mol. wt., 532.

The infrared spectrum of the compound exhibited absorption maxima at the following frequencies (cm^{-1}): 2940, 1745, 1440, 1370, 1225, 1050, 965, 920, 885, 790, 745, and 655. The X-ray powder diagram had the following interplanar lattice spacings in Å:* 8.92 (vs), 6.69 (s), 6.02 (s), 5.29 (s), 4.69 (vs), 4.07 (vs), 3.36 (s), 3.01 (s), 2.62 (m), 2.34 (m), 2.23 (m), 2.10 (m), 1.98 (m), 1.85 (m), 1.75 (w).

The residual sirup had $[\alpha]_D^{20}$ +85° (*c*, 1.5 in chloroform). It could not be induced to crystallize further. Its infrared spectrum was similar, albeit not identical with that of the crystalline portion.

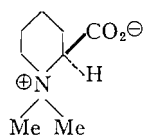
ABSOLUTE CONFIGURATION OF (−)-HOMOSTACHYDRINE*

A. V. ROBERTSON† AND LÉO MARION

Wiehler and Marion (1) isolated and identified a new alkaloid from alfalfa. The laevorotatory compound, which they called (−)-homostachydrine, was shown to be one of the enantiomers of the methyl betaine of pipecolic acid (piperidine-2-carboxylic acid). The proof of structure followed from the identity of the infrared spectra, X-ray powder diagrams, and chromatographic behavior of (−)-homostachydrine hydrochloride and the synthetic hydrochloride of racemic pipecolic acid methyl betaine.

We have now determined the configuration‡ of (−)-homostachydrine by methylating L-(−)-pipecolic acid. The methyl betaine hydrochloride had $[\alpha]_D$ −13°, identical with the value for the natural product (1). Thus (−)-homostachydrine belongs to the L-series of amino acids, and since (−)-pipecolic acid has been correlated with L-aspartic acid (2), the absolute configuration of the betaine is as shown in the formula.



EXPERIMENTAL

Melting points are corrected. The infrared absorption spectra were measured in nujol mulls on a Perkin–Elmer double beam spectrometer model 21B.

L-(−)-*Pipecolic Acid*

Pure synthetic (±)-pipecolic acid hydrochloride was available in this laboratory (1). The acid was resolved with (−)-tartaric acid, $[\alpha]_D^{25}$ −14.2° (7% in water), according to the method of Schweet, Holden, and Lowy (3) (cf. Leithe, ref. 4). (−)-Pipecolic acid-(−)-bitartrate had constant optical activity after three crystallizations, $[\alpha]_D^{25}$ −20.0° (8% in water). After decomposing the diastereoisomer on Amberlite IR-4B ion exchange resin (3), the (−)-pipecolic acid had m.p. 271–272° (copper block) and $[\alpha]_D^{25}$ −25.8° (5% in water). These constants are in good agreement with reported values for natural and synthetic (−)-pipecolic acid (5).

L-(−)-*Homostachydrine Hydrochloride*

(−)-Pipecolic acid was methylated using the procedure of Wiehler and Marion for

SEPARATION OF NICKEL AND COBALT BY PAPER CHROMATOGRAPHY*

Gerhard R. Weidmann

The R_F values of Ni and Co have been determined for *n*-tributyl phosphate (TBP) adjusted with concentrated hydrochloric acid of various concentrations. TBP is as suitable for the separation of Ni and Co by paper chromatography as other solvents mentioned in the literature (1, 2, 3). Before use the reagent was shaken with nitric acid to remove mono- and di-butyl phosphate (4), then distilled and adjusted with HCl of different molarities. Afterwards the organic phase was separated and mixed with methanol in the ratio 2:1 and 1:1.

PROCEDURE

The chromatograms were developed by ascending chromatography. The paper used was Schleicher and Schüll No. 4023*b* (Whatman No. 1). Solutions of Ni- and Co-chlorides each in quantities of 20γ were put on the paper. The process ran 4 hours at a temperature of 22° C. The flow of Co was easily identified by its blue color. On the following pictures Co was marked with α-nitroso-β-naphthol. Ni was identified with an alcoholic solution of dimethyl glyoxime.

RESULTS

The R_F values of Co recorded in Table I show a close dependence on increasing concentration of HCl used to equilibrate the TBP. Ascending concentration of HCl reduces the distance of Co from the liquid front, i.e. the R_F values increase. When working with

Gerhard R. Weidmann

The R_F values of Ni and Co have been determined for *n*-tributyl phosphate (TBP) adjusted with concentrated hydrochloric acid of various concentrations. TBP is as suitable for the separation of Ni and Co by paper chromatography as other solvents mentioned in the literature (1, 2, 3). Before use the reagent was shaken with nitric acid to remove mono- and di-butyl phosphate (4), then distilled and adjusted with HCl of different molarities. Afterwards the organic phase was separated and mixed with methanol in the ratio 2:1 and 1:1.

PROCEDURE

The chromatograms were developed by ascending chromatography. The paper used was Schleicher and Schüll No. 4023*b* (Whatman No. 1). Solutions of Ni- and Co-chlorides each in quantities of 20γ were put on the paper. The process ran 4 hours at a temperature of 22° C. The flow of Co was easily identified by its blue color. On the following pictures Co was marked with α-nitroso-β-naphthol. Ni was identified with an alcoholic solution of dimethyl glyoxime.

RESULTS

The R_F values of Co recorded in Table I show a close dependence on increasing concentration of HCl used to equilibrate the TBP. Ascending concentration of HCl reduces the distance of Co from the liquid front, i.e. the R_F values increase. When working with

highly concentrated HCl, Co will almost reach the liquid front. In this case Co does not flow as a spot any more, but has a long diffuse tail (see Fig. 1). Similar results are obtained when chromatographing Co using TBP as a solvent without admixture of methanol (see Fig. 2).

TABLE I

R_F of Co using a TBP/methanol mixture in the ratio 2:1

TBP adjusted with N HCl	5.5	6.5	7.5	8.5	9.0	9.5	10	10.5	11	11.5	12	12.5
R_F of Co	0.16	0.23	0.28	0.34	0.38	0.43	0.46	0.48	0.52	0.59	0.66	0.74

As Table II shows, the R_F values resulting thereof are considerably higher than those obtained using TBP/methanol mixtures.

TABLE II

R_F values of Co

TBP adjusted with N HCl	Ratio TBP/methanol		
	1:1	2:1	TBP pure
9 N	0.36	0.37	0.7
10 N	0.46	0.46	0.85
12.5 N	—	0.74	—

Previous tests have shown that Ni is not extracted by TBP from an aqueous solution. This effect is apparent in the chromatogram. Figure 2 shows that, when using pure HCl equilibrated TBP, Ni is immobile; and in TBP/methanol mixtures the flow rate is roughly proportional to the quantity of methanol present.

SUMMARY

Sharp chromatographing separations of Ni and Co can be obtained using HCl – equilibrated TBP. It is recommended that the TBP be treated with 9 to 10 molar HCl, and mixed with methanol in the proportion 2:1.

QUENCHING AND VIBRATIONAL-ENERGY TRANSFER OF EXCITED IODINE MOLECULES

B. STEVENS

From their investigation of the effect of foreign gases on the emission spectrum of I_2 $^3\Pi$ ($v' = 26$), Arnot and McDowell (1) obtain collisional transfer coefficients which are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

some 10–15 times greater than expected from simple collision theory if a value of 10^{-8} second is assumed for τ_0, the radiative lifetime of the excited I_2 molecule.

In the same way, Polanyi (2) concludes that the collisional transfer efficiencies of H_2 and D_2 are 1 in 55 and 1 in 11 respectively if τ_0 is taken as 3×10^{-7} second. Recently, Arnot and McDowell (3) have corrected Polanyi's results for self-quenching and show that these are consistent with collisional transfer coefficients of 3.9 (H_2) and 7.7 (D_2) times greater than the theoretical values on the assumption that $\tau_0 = 10^{-8}$ second.

Neither Polanyi nor Arnot and McDowell observed self-transfer bands in the absence of foreign gases. In view of the high efficiency of I_2 as third body in I atom recombination (4) a non-quenching collision would be expected to lead to vibrational-energy transfer, and the absence of self-transfer bands may be taken as strong evidence that the collisional efficiency, p, of self-quenching is unity. A similar argument was put forward by Vartanyan (5) in connection with the O_2 quenching of aniline vapor fluorescence.

In their recent note, Arnot and McDowell (3) quote a value of 2.0×10^5 liter mole^{-1} for the I_2 self-quenching constant k_S/k_F measured presumably at 20° C, the temperature of their transfer experiments. Thus from

$$\frac{k_S}{k_F} = p\tau_0 \frac{N}{1000}(r_1+r_2)^2\left\{8\pi RT\left(\frac{1}{M_1}+\frac{1}{M_2}\right)\right\}^{\frac{1}{2}} = 2.0\times10^5 \text{ liter mole}^{-1}$$

with $p = 1$; $r_1 = r_2 = 2.7$ Å; $T = 293°$ K; N = Avogadro number; k_S = self-quenching rate constant; and $k_F = 1/\tau_0$ = radiative decay constant, we have

$$\tau_0 = 1.6\times10^{-6} \text{ second.}$$

This value of τ_0 is some 100 times longer than that usually associated with fluorescence emission but in view of Mulliken's assignment of $^3\Pi$ to this excited state of I_2, (6), the emission is by current definition (7) a phosphorescence of short lifetime due to the heavy atom effect (8). The Z dependence of radiative intersystem transition probabilities would lead us to expect a value closer to $\sim2\times10^{-6}$ second for Cd $^3P_1$ than to $\sim1\times10^{-7}$ second for Hg $^3P_1$.

Experimental transfer coefficients k_T/k_F obtained by Arnot and McDowell both from their own and from Polanyi's results are compared with the theoretical values computed on the basis $\tau_0 = 1.6\times10^{-6}$ second in Table I. k_T is the rate constant for collisional transfer from the 26th vibrational level of I_2*. The collisional transfer efficiency p_T is now intermediate between the values $\ll 1$ obtained from sound dispersion data in the region $v \sim 0$, and unity associated with third body effects on atom recombination in the region $v \sim \infty$. Eliaschevich (9) also adopted the value $\tau_0 = 10^{-8}$ second for the excited I_2

molecule, which is reduced by self-quenching under his experimental conditions to 3.3×10^{-9} second, and obtained collisional transfer coefficients up to 100 times greater than the theoretical values. If $\tau_0 = 1.6 \times 10^{-6}$ second, the reduced lifetime due to self-quenching under the conditions he used is 9.0×10^{-7} second and his transfer coefficients should be reduced by a factor of 270, which brings them into line with the results in Table I.

It is of interest to compare the transfer efficiencies p_T with quenching efficiencies p_Q which may be obtained from the quenching constants k_Q/k_F in the same way; (k_Q is the collisional quenching rate constant). Unfortunately Arnot and McDowell do not give their numerical values for the quenching constants but for He and A these may be calculated from Figs. 3 and 4 (1), in which the slope is given by

$$(k_Q/k_F)/\{1+(k_S/k_F)[I_2]\}.$$

The relevant data are given in Table II along with values obtained for H_2 and D_2 by Arnot and McDowell (3) from Polanyi's results (2). The lower transfer efficiency p_T

TABLE II

Coefficients for quenching of excited I_2 molecules at 20° C

Gas	k_Q/k_F liter mole^{-1}		p_Q
	Experimental	Theoretical	
H_2*	8.4×10^3	7.84×10^5	0.01
D_2*	1.46×10^4	5.60×10^5	0.03
He	3.12×10^4	5.17×10^5	0.06
A	1.01×10^5	2.28×10^5	0.44

*T = 27° C.

for A compared with He may be explained if the higher quenching efficiency p_Q of A is taken into account. Comparable values $p_T{}^0$ obtained on the basis of non-quenching collisions are

$$p_T{}^0 = p_T/(1-p_Q),$$
$$= 0.10 \text{ for He, } 0.13 \text{ for A.}$$

The low transfer efficiency of O_2 can probably be explained in the same way.

It should be noted that the above calculations involve two assumptions. In the first place the collision diameters of the excited and unexcited iodine molecules are assumed to be equal, which is almost certainly not the case. The collision radius calculated from the self-quenching constant taking $\tau_0 = 10^{-8}$ second is 65.6 Å compared with 2.7 Å for the unexcited molecule. This value is unrealistic if quenching is due to a collision-induced predissociation of the excited molecule but could presumably be approached if quenching involves a sensitized predissociation of the quenching molecule as Polanyi has suggested (2). In the absence of direct measurements of τ_0 there is more justification for assigning a value of 2.7 Å to the excited molecule than for assuming a value of 10^{-8} second for its radiative lifetime in view of the electronic transition involved. Use of the larger collision diameter and shorter lifetime would not significantly affect the values of p_T and p_Q given, since in the expression from which they are obtained, the quantity $\tau_0(r_1+r_2)^2$ remains virtually unaltered.

A more serious objection may be made to the second assumption that the collision diameter of the excited I_2* molecule is the same both for quenching and for vibrational-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

energy transfer, particularly if quenching is due to sensitized predissociation at super-kinetic distances. If, however, the quenched molecule predissociates following the collisional removal of 3 or 4 vibrational quanta then quenching and vibrational-energy transfer have similar requirements and the error introduced by this second assumption may not be serious.

PYRIDINIUM BETAINES OF 1,3-INDANDIONE SERIES[1]

GERASSIMOS FRANGATOS AND ALFRED TAURINS

ABSTRACT

2-Bromo- (II) and 2,2-dibromo-1,3-indandione (III) react with pyridine, 3- and 4-methylpyridine, and 2-, 3-, and 4-pyridinecarboxylic acids to give 1-(3-hydroxy-1-oxo-2-indenyl)-pyridinium hydroxide betaines. In the betaines derived from pyridinecarboxylic acids the negative charge is located not in the carboxylic group but on the carbonyl oxygen atoms.

INTRODUCTION

Stafford (1) has obtained 1-(3-hydroxy-1-oxo-2-indenyl)pyridinium hydroxide, betaine (I), by brominating 1,3-indandione in the presence of pyridine and subsequently treating the intermediate salt with alkali. He assumed that the addition of bromine to pyridine resulted in the formation of pyridine bromide perbromide which formed 2-bromo-1,3-indandione with 1,3-indandione; the latter compound reacted further with pyridine to form a pyridinium salt. These steps appear plausible, but no experimental proof was given to support these assumptions.

It is known, however, that 1,3-indandione produces with bromine only 2,2-dibromo-1,3-indandione (2) and that 2-bromo-1,3-indandione (3) has never been isolated as an intermediate in this bromination. However, this does not exclude the presence of 2-bromo-1,3-indandione in some intermediate steps in the formation of 1-(3-hydroxy-1-oxo-2-indenyl)pyridinium bromide.

A similar reaction of pyridine with 5,5-dibromobarbituric acid produced the betaine of 1-(4-hydroxy-2,6-dioxo-5-tetrahydropyrimidyl)pyridinium hydroxide and 4-pyridylpyridinium bromide hydrobromide. 5-Bromo-5-nitrobarbituric acid and pyridine gave the same products, but 5-bromobarbituric acid did not react (4).

It has been found by Metro and Taurins (5) that 2-bromo-2-nitro-1,3-indandione reacted with pyridine by a different mechanism yielding the pyridinium salt of 2-nitro-1,3-indandione, pyridine hydrobromide, and a black tar containing nitrogen, bromine, and oxygen.

The objective of the present work was to investigate the formation of (I) and similar betaines by the direct interaction of 2-bromo- (II) and 2,2-dibromo-1,3-indandione with pyridine, methylpyridines, and pyridinecarboxylic acids.

DISCUSSION

When 2-bromo-1,3-indandione (II) was added to pyridine, a yellow solution was obtained, the color of which deepened gradually as the reaction proceeded. Upon standing at 20° for several hours, or short heating at 100°, the solution turned very dark. It was

[1]*Manuscript received January 14, 1959.*
Contribution from the Department of Chemistry, McGill University, Montreal, Quebec, with the financial assistance of the National Research Council of Canada, Ottawa, Canada.

felt that 1-(1,3-dioxo-2-indanyl)pyridinium bromide should be formed from (II) in the first step of the reaction as the result of a simple nucleophilic attack by pyridine. Therefore, attempts were made to isolate the bromide by sublimation of the residue obtained after removal of excess pyridine. On sublimation a white pyridinium hydrobromide appeared first and at a higher temperature the betaine (I) sublimed in the form of lustrous yellow crystals. The isolation of these products led to the conclusion that the intermediate 1-(1,3-dioxo-2-indanyl)pyridinium bromide is very reactive and is dehydrobrominated by pyridine in the first stages of the reaction. Furthermore, the isolation of these two products indicates that the bromine atom in (II) can be released also in the form of anion (Formulae sheet I, steps (*c*) and (*d*)).

2,2-Dibromo-1,3-indandione reacted slowly with pyridine at water bath temperature and the color of the mixture deepened gradually. From the reaction mixture two products were isolated, 1-(3-hydroxy-1-oxo-2-indenyl)pyridinium hydroxide, betaine (I), and pyridinium hydrobromide. The latter compound was isolated by removing the excess pyridine *in vacuo* and crystallizing the semisolid residue from alcohol. Both compounds could also be isolated by fractional sublimation. The residue after sublimation was a black tar which contained nitrogen and bromine.

The formation of the betaine may be considered as an elimination of two bromine atoms from each molecule of 2,2-dibromo-1,3-indandione by the action of pyridine. Steps (*c*) and (*d*) are also valid for the reaction of 2-bromo-1,3-indandione with pyridine.

The essential point in this mechanism is that the first bromine atom is removed as Br^+ leaving two electrons at the carbon atom. The second bromine is removed as Br^- in a displacement reaction with pyridine. The formation of two products (betaine I and pyridine hydrobromide) indicates that the mechanism is a two-step elimination. Protons which are necessary for step (*b*) are formed in the bromination reaction of pyridine by Br^+. There is always a black tar formation in the reaction of bromine Br_2 with pyridine (6).

We found that it was impossible to synthesize betaines of the 1,3-indandione series from three isomer methylpyridines using the Stafford procedure. In all cases, even at 0°, there was a rapid tar formation. From the black semisolid products only methylpyridine hydrobromides were isolated by sublimation. Contrary to that, the interaction of 2-bromo- and 2,2-dibromo-1,3-indandione with 3- and 4-methylpyridines gave the corresponding betaines. 2-Methylpyridine produced a black resin with both the reagents, although reactions were attempted under varying conditions of temperature, solvent, and time. 4-Methylpyridine reacted easily with 2,2-dibromo-1,3-indandione in boiling ethanol. On cooling of the red solution, a crystalline compound precipitated which was crystallized and obtained as pure yellow crystals. The reaction occurred also in toluene, but the yield was only about 40%, compared with 67% in ethanol.

3-Methylpyridine was less reactive with 2,2-dibromo-1,3-indandione than its 4-isomer and therefore a longer time and a higher temperature was necessary. Therefore the reaction was carried out in isoamyl alcohol at reflux temperature for 7 hours. The yield of the betaine under such conditions was 77%. The reaction did not occur in methyl or ethyl alcohol resulting in almost quantitative recovery of the starting materials.

The reactions of 3- and 4-methylpyridines with 2-bromo-1,3-indandione were carried out without any solvent at room temperature for 24 hours. Under such conditions 4-methylpyridine reacted with greater ease than pyridine.

The formation of betaines of 2-, 3-, and 4-pyridinecarboxylic acids with 2,2-dibromo-1,3-indandione were of interest because carboxylic groups could be considered as a potential negative center in the betaine. Since pyridinecarboxylic acids have an inner

salt structure it was expected that the reaction of 2,2-dibromo-1,3-indandione with these acids would proceed with difficulty. This was confirmed experimentally. Higher temperatures and longer reaction time in refluxing isoamyl or *n*-butyl alcohol were necessary for the reaction to be completed. When the reaction mixture had been cooled, the golden-colored product precipitated together with the unreacted excess of pyridinecarboxylic acid. The latter was removed from the mixture by extracting with boiling water or more effectively by treatment with strong mineral acids. Any unreacted 2,2-dibromo-1,3-indandione was removed by extracting with chloroform. 2-Pyridinecarboxylic acid gave a poor yield of the betaine and the reaction was accompanied by fairly strong tar formation.

The presence of the carboxylic group in these betaines was detected by infrared spectroscopy. The betaine of 2-carboxy-1-(3-hydroxy-1-oxo-2-indenyl)pyridinium hydroxide showed weak bands at 2840, 2580, 2470, 2380, and 2300 cm^{-1} given by the stretching vibrations of the hydroxyl of the carboxyl group; 3- and 4-carboxy-isomers gave similar bands at slightly different positions. Also, there was a strong band present at 1725–1732 cm^{-1} in each one of the three betaines derived from pyridinecarboxylic acids. This band was given by the carbonyl of the carboxyl group. The carbonyl absorption of the unsubstituted betaine (Stafford compound) and 4-methyl derivative was very weak at 1725 and 1733 cm^{-1} respectively.

The electronic absorption spectra of the betaines obtained from methylpyridines or pyridinecarboxylic acids were determined and a great similarity in the patterns of these spectra was revealed. In each spectrum the absorption maxima occurred in the regions of 237–243, 311–316, and 386–418 mμ, and the molecular extinction coefficients were of the same order of magnitude. 1-(3-Hydroxy-1-oxo-2-indenyl)4-methylpyridinium hydroxide, betaine, showed a fourth absorption maximum in the region of 300 mμ (Table I and Figs. 1 and 2).

TABLE I

Electronic spectra of betaines of 1-(3-hydroxy-1-oxo-2-indenyl)pyridinium hydroxides (in absolute ethanol solution)

Substituent in the pyridine ring	λ_{max}, mμ	$\log_{10} \epsilon_{max}$
4-CH_3	273, 300, 316, 386	4.53; 3.34; 3.45; 4.13
3-CH_3	241, 313, 400	4.85; 3.36; 3.95
4-COOH	243, 315, 418	4.49; 3.28; 4.09
3-COOH	241, 312, 398	4.81; 3.44; 4.05
2-COOH	240, 311, 396	4.79; 3.33; 4.04

The similarity in spectra of betaines derived from methylpyridines and those obtained from pyridinecarboxylic acids serves to confirm the structures assigned to the latter group of betaines, and leaves no doubt that the carboxylic group does not participate in the formation of the inner salt by becoming the negative center of the dipole.

The absorption spectra of the betaines were determined in absolute alcohol. When attempts were made to measure the absorption spectra in chloroform, it was found that the wavelengths at which the absorption maxima appeared were reproducible but the molecular extinction coefficients were not.

EXPERIMENTAL

For the synthesis of the pyridine betaines of the 1,3-indandione series, three procedures, A, B, and C, were used.

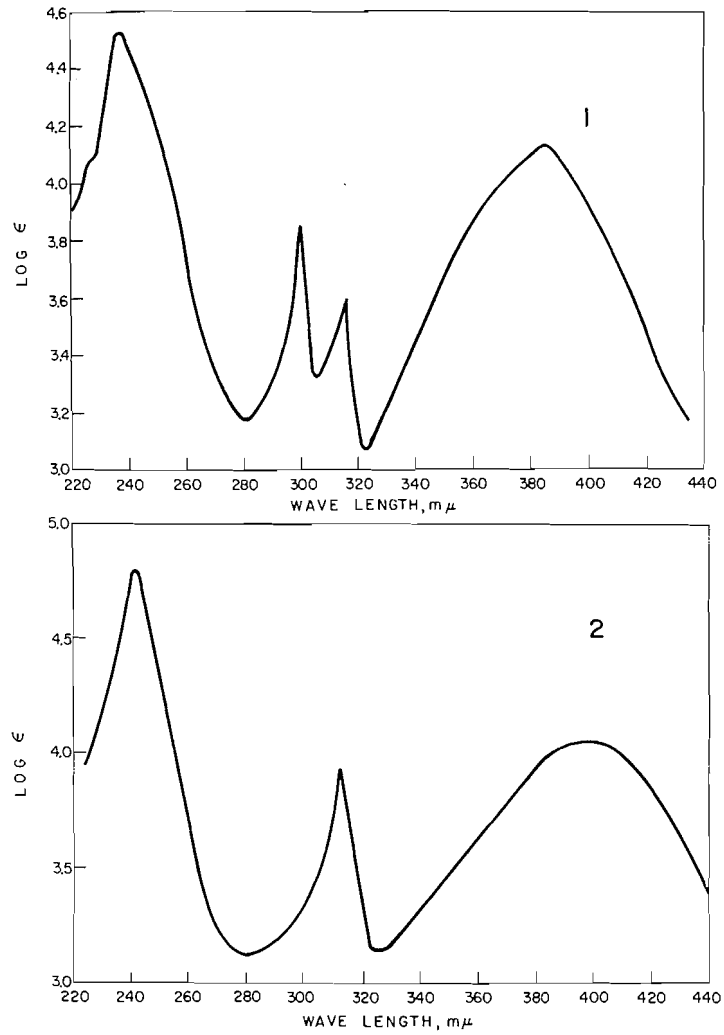

FIG. 1. Electronic absorption spectrum of 1-(3-hydroxy-1-oxo-2-indenyl)4-methylpyridinium hydroxide, betaine.

FIG. 2. Electronic absorption spectrum of 3-carboxy-1-(3-hydroxy-1-oxo-2-indenyl)pyridinium hydroxide, betaine.

Procedure A.—This procedure was applied to the reaction of 2-bromo-1,3-indandione with pyridine and methylpyridines. The method consisted of direct interaction of compounds in the absence of solvents, followed by the removal of excess unreacted materials by extraction, and isolation of the corresponding betaines. The reaction temperature was either 20° for 24 hours, or 100° for 4–6 minutes.

Procedure B.—This method consisted of the direct interaction of 2,2-dibromo-1,3-indandione with excess of pyridine and methylpyridines at 100° for several hours. The excess pyridine compound was removed by distillation in vacuum and the betaine was isolated by sublimation of the residue in vacuum.

Procedure C.—According to this method, 2,2-dibromo-1,3-indandione and pyridine derivatives were dissolved in a solvent (ethyl, *n*-butyl, or isoamyl alcohol, or toluene) and refluxed for 3 to 8 hours. The solvent was removed by distillation at reduced pressure.

1-(3-Hydroxy-1-oxo-2-indenyl)pyridinium Hydroxide, Betaine (I)

1. Reaction of 2-Bromo-1,3-indandione with Pyridine (Procedure A)

2-Bromo-1,3-indandione (1.139 g, 0.005 moles) and 3 ml of pyridine were heated on a steam bath for 6 minutes. The dark red solution was poured into 50 ml of water and refluxed for 10 minutes. After being allowed to cool to room temperature, the solution was extracted with three 10-ml portions of ether. The aqueous layer was separated and made alkaline (pH 11) with sodium hydroxide solution. On cooling for 10 hours, the solution deposited 0.75 g of the betaine in 67% yield. The melting point of the substance after crystallizing from ethanol was 257° (decomp.), in agreement with the literature (1). The betaine (I) can be also obtained if the reaction is carried out at room temperature for 24 hours.

2. Reaction of 2,2-Dibromo-1,3-indandione with Pyridine (Procedure B)

(*a*) A sample of 2,2-dibromo-1,3-indandione (1 g, 3.3 millimoles) was added to 3 ml of pyridine and the solution was heated on a steam bath for 3 hours. The excess pyridine was removed under reduced pressure. The solid dark residue was dried in a vacuum desiccator over concentrated sulphuric acid. The material was crystallized from 12 ml of ethyl alcohol and the betaine (I) was obtained in pure form, melting point 257° (decomp.). The yield of (I) was 0.34 g (46.5% of the theoretical).

(*b*) The other product of the reaction, pyridine hydrobromide, was isolated by sublimation (at 120–125° and 1 mm pressure) of the dried reaction mixture in all-glass apparatus. The yield of the substance was 0.475 g. It was purified by repeated sublimations or by recrystallization from a hot mixture of chloroform and styrene. The second fraction, betaine I (0.5 g), sublimed at 185–190° under 1 mm pressure. A black resinous material remained (0.5 g) in the sublimation apparatus. It did not crystallize from various solvents and the analysis showed the presence of nitrogen and anionic bromine.

1-(3-Hydroxy-1-oxo-2-indenyl)3-methylpyridinium Hydroxide, Betaine

1. Reaction of 2-Bromo-1,3-indandione with 3-Methylpyridine (Procedure A)

The betaine weighed 0.97 g (82% yield) and melted at 218° (decomp.).

2. Reaction of 2,2-Dibromo-1,3-indandione with 3-Methylpyridine

(*a*) *Procedure B.*—The first fraction obtained by the sublimation of the residue from the reaction mixture was 3-methylpyridine hydrobromide (yield 0.23 g). The second fraction was the betaine of 1-(3-hydroxy-1-oxo-2-indenyl)3-methylpyridinium hydroxide, melting point 218° (decomp.). The yield was 0.78 g (65.8%). The black resinous residue which did not crystallize weighed 0.64 g.

(*b*) *Procedure C.*—Five milliliters of 3-methylpyridine was added to a solution of 1.53 g (0.005 moles) of 2,2-dibromo-1,3-indandione in 40 ml of warm isoamyl alcohol. The orange reaction mixture was refluxed for 7 hours, then most of the isoamyl alcohol was distilled at reduced pressure and the viscous orange solution was cooled in an ice bath. The solid material which separated was filtered by suction and washed with two 10-ml portions of ether. On recrystallization from ethyl alcohol it melted at 218° (decomp.). The yield was 0.91 g (0.77%).

1-(3-Hydroxy-1-oxo-2-indenyl)4-methylpyridinium Hydroxide, Betaine

1. By Procedure A

The betaine crystallized from ethyl alcohol in yellow elongated prisms, melting point 258° (decomp.). The yield was 71.7%.

2. By Procedure C

(*a*) 2,2-Dibromo-1,3-indandione (1.53 g, 0.005 moles) was dissolved in 20 ml of ethyl alcohol by refluxing. To this solution 4 ml of 4-methylpyridine was added over a period of 10 minutes. The betaine was isolated in the usual way and melted at 258° with decomposition. The yield was 0.82 g (67% of the theoretical). Molecular weight determination: Calc. for $C_{15}H_{11}NO_2$: 237. Found by the Rast method: 234.

(*b*) In toluene, at reflux temperature of 110.6°, the reaction of the substances mentioned above gave the betaine in a 39% yield.

(*c*) The fractional sublimation of the reaction product gave 0.37 g of 4-methylpyridinium hydrobromide.

2-Carboxy-1-(3-hydroxy-1-oxo-2-indenyl)pyridinium Hydroxide, Betaine

Procedure C.—A sample of 2,2-dibromo-1,3-indandione (0.76 g, 2.5 millimoles) was allowed to react with an excess (2 g) of 2-pyridinecarboxylic acid in 30 ml of boiling *n*-butyl alcohol (b.p. 117°) for 3 hours. The alcohol was removed by distillation under reduced pressure. A solid residue consisting of betaine and excess 2-pyridinecarboxylic acid was left. It was extracted with 8 ml of boiling water to remove the acid. The betaine was dried in vacuum and crystallized several times from *n*-butyl alcohol. A yield of 0.18 g (27% of the theoretical) of the betaine, m.p. 312° (decomp.), was obtained.

3-Carboxy-1-(3-hydroxy-1-oxo-2-indenyl)pyridinium Hydroxide, Betaine

Procedure C.—This compound was prepared in isoamyl alcohol from 3-pyridinecarboxylic acid and 2,2-dibromo-1,3-indandione. It melted at 317° (decomp.) after crystallization from isoamyl alcohol.

4-Carboxy-1-(3-hydroxy-1-oxo-2-indenyl)pyridinium Hydroxide, Betaine

Procedure C.—The betaine was synthesized from 4-pyridinecarboxylic acid and 2,2-dibromo-1,3-indandione in isoamyl alcohol, m.p. 351°.

A GAS CHROMATOGRAPHIC STUDY OF THE ADSORPTIVE PROPERTIES OF A SERIES OF ACTIVATED CHARCOALS[1]

HENRY W. HABGOOD[2] AND JAMES F. HANLAN[3]

ABSTRACT

From measurements of the gas chromatographic retention volumes, the initial slopes of the adsorption isotherms of nitrogen and the simpler hydrocarbons on a series of steam-activated coconut charcoals were determined. The initial heats of adsorption were obtained in the usual way from the temperature dependence. It was found for all gases that both the initial slope of the isotherm and the initial heat of adsorption decreased with increasing degree of activation of the charcoal (i.e. with increasing surface area per g). This suggests that the higher affinity for the very small pores in less activated material more than counterbalances the lower total surface.

Measurements at several different carrier gas flow rates of the relative band width for the charcoals of least and of greatest activation demonstrated, as might be expected, a greater resistance to mass transfer for the former. However, the apparent diffusion coefficients calculated on the assumption that all transport is by gas phase in the pores were nearly the same for each charcoal and showed relatively little variation among the different gases.

INTRODUCTION

The technique of gas chromatography which, in recent years, has been so useful in analytical chemistry may also be applied to some problems in physical chemistry. We have used gas–solid (gas adsorption) elution chromatography to study the adsorptive properties of a series of varyingly activated coconut charcoals. A systematic investigation has been made of the elution peaks obtained for a number of simple hydrocarbon gases from columns of each of the charcoals at a series of temperatures. Each peak is characterized by two quantities, its retention volume and its relative width. The former may be readily identified with the gas–solid distribution coefficient while the latter depends in part on the rate of adsorption.

The retention volume for any given eluate is related to its distribution coefficient between the moving and stationary phases. Cremer and Prior (1) have examined this relationship for gas–solid chromatography, but the best-known development is that for gas–liquid chromatography of Martin and Synge (2). Their simple relationship may be written in the following form to apply to gas–solid chromatography:

$$[1] \qquad \alpha = (V^0_R - V^0_d)/W \cdot 273/T$$

where α is the initial slope of the adsorption isotherm in cc (S.T.P.) adsorbed per g, atm; V^0_R is the limiting value of the retention volume for small samples at column temperature, T, and pressure corrected to zero pressure drop through the column (3); V^0_d is similarly the retention volume for a non-adsorbed component; and W is the weight of adsorbent. Thus α is the net retention volume corrected to standard temperature per g of column material. Porter, Deal, and Stross (4) and others (5, 6, 7) have demonstrated the validity of the equivalent relationship for gas–liquid chromatography provided the sample volume is small compared with the total column volume.

Gas–solid chromatography has the complication of a curved isotherm—i.e. a variable distribution coefficient—and hence equation [1] will only apply to the limiting retention

volume at small sample pressure. The shape of the tail, which is characteristic of the asymmetric peaks usually found with gas–solid chromatography, may give some information about the complete isotherm (8, 9).

While the theory of gas–solid chromatography follows from that for gas–liquid chromatography, it may also be developed directly in terms of the apparent volume of the adsorbate in the presence of the adsorbent (10) by applying the Steele and Halsey equation of state approach to high temperature physical adsorption (11, 12).

The heat of adsorption is obtained from the slope of the log α–$1/RT$ plot. From the definition of α this is seen to be the limiting value at zero coverage of the isosteric heat of adsorption.[4,5]

Generally speaking, the initial slope of the adsorption isotherm is proportional to the product of two quantities, the total surface area and the affinity of the sorbate for the surface. Since the latter is directly related to the heat of adsorption, it is possible, in principle, given a particular model for the adsorption process, to determine the surface area from measurements of α at various temperatures. Steele and Halsey (11, 12), assuming an inverse third power attraction between hard spheres and a smooth surface, fitted the initial slopes of isotherms of the noble gases over a range of temperatures to surface areas fairly close to standard Brunauer–Emmett–Teller areas. Hanlan and Freeman in a paper to be published (10) have applied this method with some additional refinements to the present chromatographic data.

The use of gas–solid chromatography to study the rates of adsorption is based on an interpretation of the relative band widths which follows from the analysis of van Deemter, Zuiderweg, and Klinkenberg (14). These authors, from a development of the "plate" theory of chromatography, related the height equivalent to a theoretical plate, H, to the relative band width, $\Delta S^0/V^0_R$ where ΔS^0 is the volume of carrier gas corresponding to the base of the chromatographic elution peak and V^0_R is the volume to the maximum of the peak. For very small sample volumes giving symmetrical Gaussian peaks the relationship assumes the simple form:

$$[2] \qquad H = L(\Delta S^0/V^0_R)^2/16$$

where L is the length of the column.

The authors showed, from a comparison of the "plate" and "rate" theories, that H is expected to be a function of carrier gas velocity, u, as follows:

$$[3] \qquad H = A + B/u + Cu$$

where A, B, and C are constants for any particular system and may be interpreted respectively in terms of "eddy diffusion", molecular diffusion, and resistance to mass transfer. The last of these determines the rate of adsorption in gas–solid chromatography. A variation of H with u of the form of equation [3] has been obtained by several workers for gas–liquid chromatography (14, 15, 16, 17).

In the present work a tentative interpretation of C in terms of an apparent gas phase diffusion coefficient in the charcoal pores is attempted.

Figure 1 shows a typical chromatogram replotted from the chart record to illustrate the quantities α and H. This chromatogram also illustrates the small but distinct asym-

[4]*Cremer and Prior (1) and more recently Greene and Pust (13) have plotted what is equivalent to log αT against $1/T$ and accordingly obtained a ΔH which is smaller by an amount RT. This difference was not sufficient to influence the linearity of the plots obtained nor the comparison of the ΔH's with literature values.*

[5]*In gas–liquid chromatography an equivalent procedure, i.e. a plot of the logarithm of the retention volume corrected to standard temperature against reciprocal temperature, gives the heat of solution of the solute in the stationary liquid (4).*

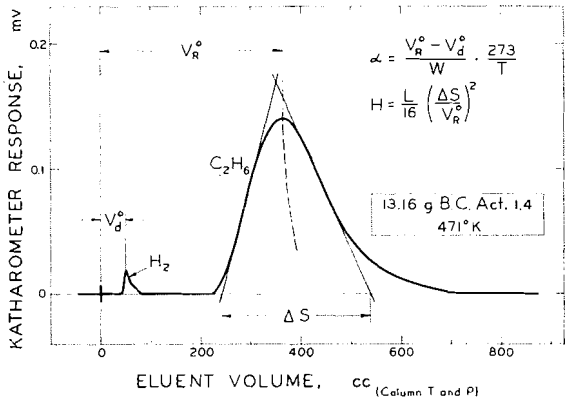

FIG. 1. A typical chromatogram obtained for a mixture of ethane and hydrogen. The usual time–base record is replotted in terms of carrier gas volume. The shoulder on the hydrogen peak results from a trace of air.

metry similar to that generally found with gas–solid chromatograms. Although the treatment referred to above was developed only for symmetrical elution chromatograms we were encouraged to apply it in the present case by the fact that H was found to be independent of sample size over a considerable range.

A major experimental advantage of gas chromatography is its relative speed and simplicity. It is best suited to conditions of fairly mild interaction in order that excessive band broadening and asymmetry do not obscure the center of the peak. This also corresponds to adsorption at temperatures well above the critical where the initial curvature of the isotherm is slight. However, by proper choice of the amount of adsorbent and of the gas flow rate a considerable range of temperatures may be covered.

The activated charcoals used in this study were taken from a series of coconut charcoals which had been steam-activated to varying degrees.[6] Lemieux and Morrison (18), Nay and Morrison (19), and Morrison and Miller (20) had previously studied the adsorptive properties of similar series of charcoals.[7] Their results suggested molecular sieve effects with the charcoals of lower activation; for example, the apparent surface areas for small molecules such as methane and nitrogen were found to be larger than for propane and butane.

By way of confirming the method, measurements were made on a sample of Columbia L-activated coconut charcoal[8] for comparison with the published isotherms of Ray and Box (21).

EXPERIMENTAL

The chromatography column was a copper tube 26 cm long by 1.015 cm inside diameter. It was preceded by a 15-in. length of coiled $\frac{1}{8}$-in. copper tubing and the whole was contained inside a 30-in. furnace made from a copper tube wound uniformly with resistance wire and insulated. There were thermocouples at each end of the column and a thermocouple well ran the length of the heater. The maximum temperature variation over the column was less than 1.0° and usually less than 0.5°.

[6]*These charcoals were kindly provided by Dr. J. L. Morrison of the Department of Chemistry, University of Alberta (now with Connaught Medical Research Laboratories, Toronto), who had obtained them from the Barnebey-Cheney Company, Cassady at Eighth, Columbus 19, Ohio.*

[7]*Unlike the earlier series these new charcoals were not prepared entirely from a single batch of nut shells. There is, therefore, some possibility of non-systematic variation through the series although the results of our work show no indication of this.*

Helium was used as a carrier gas, and flows were measured with a soap-bubble manometer corrected for the vapor pressure of the soap solution. The usual flow rate was around 100 cc per minute and retention volumes were found to be independent of flow rate over a considerable range around this value. A Gow-Mac katharometer was used as detector in conjunction with a 1-mv recorder.

The sample volume, 0.185 cc, was the volume of the bore of a two-way stopcock plug which was fitted into the shell of a three-way T-stopcock, the midtube of which led to the gas inlet and a manometer. A constant volume of sample at a known pressure could thus be introduced into the helium stream by turning the plug through 90° while simultaneously closing the helium bypass.

The Barnebey-Cheney charcoals were received as $-6+14$ mesh. This is much coarser than usually used for chromatography. Some preliminary investigations were made to determine the effect of grinding on the chromatographic properties of the charcoal. The finer fractions behaved generally like charcoals of higher activity in the series. Presumably the more highly activated portions of the granules are more fragile and easily broken up. All tests were subsequently carried out with the original material screened to exclude particles larger than 8 mesh. It was hoped that the slight degree of fractionation involved here would not invalidate comparison with conventional measurements made on the whole sample. The relatively large diameter column permitted a fairly uniform packing of this rather coarse material. Furthermore, the use of large particles magnified the effects of diffusional resistances in the charcoal pores.

Each charcoal was dried at 300° and chromatograms were determined at approximately 50° intervals down to as low a temperature as would yield measurable peaks for each gas.

Each solute was introduced as a mixture with hydrogen. While one might introduce a mixture of several non-overlapping gases at once, it is possible that the resultant volumes would be low due to competition for the available surface. Some brief studies of this point, although rather inconclusive, suggested that such effects were slight.

In many cases, particularly with the less active charcoals, several samples of each gas were run at various pressures down to the lowest pressure which would give a detectable peak (from 3–4 mm to 10 cm, depending on the retention volume and subsequent band broadening). It was thus possible to extrapolate the retention volumes to zero concentration. The variation in retention volume was usually less than 1 or 2% but in a few cases with the less active charcoals variations of up to 10% were noted and the limiting values were consequently more uncertain.

EXPERIMENTAL RESULTS

Retention volumes of nitrogen, methane, ethane, propane, the butanes, acetylene, ethylene, and propylene were measured for a sample of Columbia L-activated coconut charcoal, 35–50 mesh. The corresponding values of α from equation [1] are plotted on a logarithmic scale against reciprocal temperature in Fig. 2. Measurements made with a small glass column holding approximately one quarter as much charcoal yielded α's coincident with those from the copper column. For comparison, several values of the estimated initial slopes of the isotherms of Ray and Box (19) are included. The measurements of these authors did not always extend to low adsorbate concentrations, so that except at the higher temperatures there is some uncertainty in drawing the initial slopes. Nevertheless, the general agreement is satisfactory.

The results of Ray and Box for propane and propylene were rather surprising. At 38° and 66° C the adsorption of propylene was greater than that of propane at all pressures

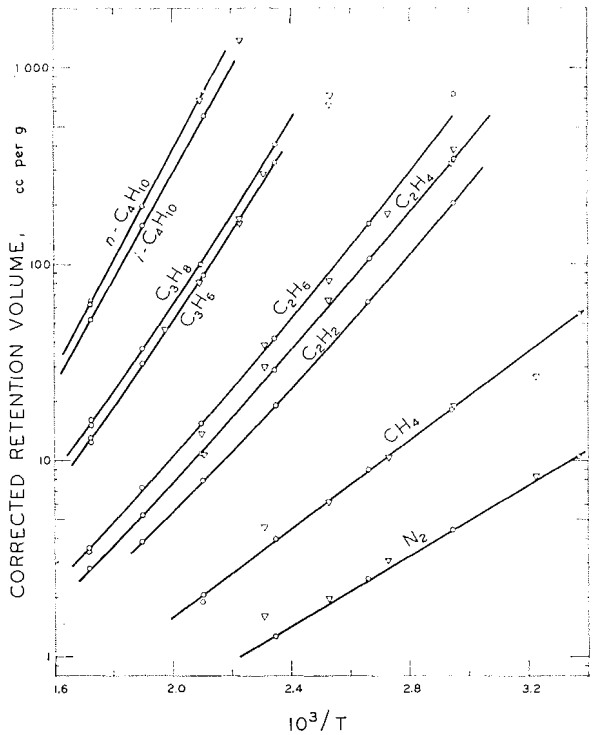

FIG. 2. Corrected retention volume per g (= α from equation [1]) vs. reciprocal temperature for Columbia L charcoal. Also shown (▽) are initial slopes of the isotherms of Ray and Box (21) for all gases except i-C_4H_{10} and C_2H_2. (Only two points are given for C_3H_6 and these lie just below the corresponding C_3H_8 points.)

investigated. At 93° the two were almost identical and at higher temperatures the propane isotherm lay above that of propylene. Lewis, Gilliland, Chertow, and Cadogan (22) found propylene to be more strongly adsorbed at 25°. They suggested that this indicated a special affinity of the carbon surface for double bonds such as that shown by silica gel. However, it may possibly reflect only a greater monolayer capacity resulting from a smaller molecular adsorption area for propylene—the methyl group perhaps projecting free of the surface. The chromatographic measurements are in the region where propane lies above propylene but the slopes of the plot do not give any suggestion of a crossing over at lower temperatures.

The limiting values of the isosteric heats of adsorption at zero coverage follow from the slopes in Fig. 2. The slight curvature in some of the plots is in the direction of decreasing ΔH with temperature. The average heat of adsorption over the interval 200–300° C is plotted in Fig. 3 against the number of carbons in the adsorbate. For comparison the figure includes the calorimetric differential heats of adsorption at 5% coverage for the normal paraffins from ethane to pentane on channel black (Spheron 6) as determined by Schaeffer, Polley, and Smith (23) at 0° C. There does not seem to be any comparable set of measurements reported for activated coconut charcoal. As noted below, the initial isosteric heats of adsorption determined for the Barnebey-Cheney charcoals vary with degree of activation over a range of around twenty-five per cent. Consequently precise agreement with the measurements on carbon black is not to be expected for any particular charcoal.

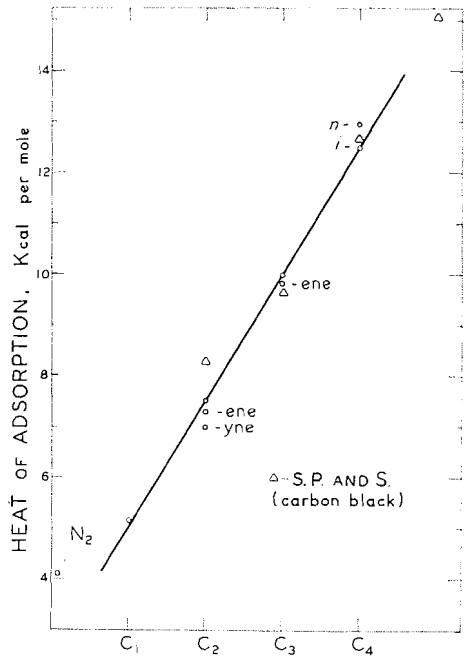

FIG. 3. The initial heats of adsorption on Columbia L charcoal compared with calorimetric values for carbon black at 5% coverage.

The charcoals in the Barnebey-Cheney series on which measurements were made had chloropicrin activities of 0, 1.4, 4.5, 9.5, 51.7, and 89.6. These numbers are times in minutes to break-through for the accelerated chloropicrin test in a standard procedure (air containing 0.286 moles per liter chloropicrin, flowing at 1 liter per minute per cm^2 through a 10-cm column). Since this test is based on a unit volume of packed charcoal the activities were converted to a weight basis using the densities reported by the manufacturer. For comparison with the α values the activities were then expressed as average concentrations at break-through in cc (S.T.P. assuming ideal gas behavior) per g of charcoal and the respective values are then 0, 1.4, 4.7, 10.1, 59.4, 149.0.[9]

For each charcoal a plot similar to Fig. 2 was obtained, and nearly all plots were straight lines. The results with acetylene were erratic. Frequently no peak appeared above 100° and measurements were not continued due to fear of possible polymerization affecting the charcoal surface. The difficulty may have been reaction with the copper tubing. The measurements with the Columbia charcoal which were made near the beginning of the work gave peaks up to 250° C.

The results are summarized in Figs. 4 and 5. Figure 4 shows the values of α for two selected temperatures plotted as functions of the revised chloropicrin activity. Figure 5 shows the heat of adsorption also against activity. Measurements with nitrogen were not always made to low enough temperatures to permit accurate slopes to be drawn.

Morrison and Myshok (24), using conventional methods, studied the adsorption at room temperature and lower of nitrogen and the C_2 hydrocarbons by some charcoals of this series and observed similar trends in initial isotherm slopes and in isosteric heats of adsorption. Their work is being prepared for publication but they have, in the mean-

[9]*The chloropicrin activity of Columbia L charcoal is given by the manufacturers as between 40 and 60 minutes, which corresponds to an average concentration at break-through of 61 to 76 cc/g.*

time, provided us with values for the nitrogen monolayer capacities at 77° K for several of the charcoals and these are shown in Fig. 4*a*.

The zero activity charcoal which presumably had been only carbonized but not steam-activated showed some traces of slow adsorption. The retention volumes were within a few cubic centimeters of that of hydrogen in all cases but the peaks showed marked tailing. Conventional adsorption measurements (24) showed that adsorption was very slow but apparently quite considerable.

The variation in relative band width with flow rate was investigated for the charcoals of activities 1.4 and 149 cc/g. Some of the properties of these charcoals are summarized in Table I. The height equivalent to a theoretical plate, H as given by equation [2], was

TABLE I

Characteristics of charcoals of least and greatest activation

ness of the peaks (cf. Fig. 1) the retention volume is not identical with the volume corresponding to the intersection of the inflection point tangents and we have for convenience used the retention volume in calculating H. The band-spreading in the connecting tubing has also been neglected but the effect on H of these two factors is likely to be small. It was difficult to get enough measurements at low velocities to determine B in equation [3] so that the values of A and C which are summarized in Table II were obtained from the limiting tangent at high velocities. With few exceptions the A values are close to the limiting H for a non-sorbing gas, 0.10 to 0.15 cm.

(a) Based on pore volume from helium density.
(b) Based on pore volume from carbon tetrachloride density.

To further interpret the coefficient C we have assumed the total resistance to mass transfer to lie in diffusion along the charcoal pores and have calculated apparent gas phase diffusion coefficients to describe such movement. Use was made of the following equation developed by van Deemter *et al.* (14, equation [49]) for ion-exchange chromatography which describes the resistance due to diffusion in a spherical particle of ion exchange resin:

$$C = \frac{d^2}{2\pi^2} \frac{F_I}{(1-F_I)} \frac{K}{D_{II}} \frac{1}{(1+KF_I/F_{II})^2}$$

where d = particle diameter,
F_I = volume fraction of moving phase,
F_{II} = volume fraction of stationary phase,
K = distribution coefficient, concentration in moving phase/concentration in stationary phase,
and D_{II} = diffusion coefficient in the stationary phase.

To modify this equation to fit the present case the ratio D_{II}/K which describes diffusion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

in the stationary phase in terms of equivalent concentrations in the moving phase was replaced by D_p which accordingly refers directly to gas phase diffusion in the pores. At the same time a factor ϵ was introduced to represent the fraction of external particle surface represented by pore mouths together with a tortuosity factor $\sqrt{2}$ to allow for the greater diffusion path along a system of random pores and the quantity KF_I/F_{II} was replaced by the equivalent expression for gas–solid chromatography. Thus the following expression was obtained:

$$[4] \qquad C = \frac{d^2}{\sqrt{2}\pi^2} \frac{F_I}{(1-F_I)} \frac{1}{\epsilon D_p} \frac{1}{(1+273F_I/\alpha T\rho_b)^2}$$

where ϵ = void fraction in a single granule determined from the densities in mercury and helium or carbon tetrachloride,

D_p = apparent gas phase diffusion coefficient in the charcoal pores, (i.e. all movement along a pore is assumed to occur via the gas phase),

ρ_b = density of the packed bed,

and α = distribution coefficient as given by equation [1].

Values of D_p calculated according to equation [4] are included in Table II. For the 1.4-activity charcoal two sets of values are calculated corresponding to ϵ's determined from the helium and carbon tetrachloride densities.

DISCUSSION

Equilibrium Properties

The somewhat unexpected finding from this work is that the initial slopes of the isotherms all decrease with increasing surface areas of the charcoals. Qualitatively this means that the specific affinity decreases more rapidly than the surface area increases in order that the product of the two should decrease. This decrease in affinity is, of course, reflected in the decreasing heat of adsorption with increasing activation.

As pointed out earlier, α, ΔH, and the surface area are related quantities. It may be shown in the following way that the chromatographically determined α's and ΔH's are consistent with the conventionally measured nitrogen monolayer capacities at 77° K. Consider a simplified form of the initial part of the Langmuir isotherm (25):

$$\alpha = v_m A(T) e^{\Delta H/RT}$$

where v_m is the adsorbate monolayer capacity in cc (S.T.P.) per g. For any given adsorbate at a particular temperature v_m may reasonably be assumed to be a constant fraction of the nitrogen monolayer capacity at 77° K (apart from molecular sieve exclusion effects which may operate with the finer charcoals), and $A(T)$ should be reasonably constant for all charcoals. Consequently the following relationship should hold:

$$\log \alpha - \log v_{m,N_2\,77°} = \text{constant} + \Delta H/RT.$$

Figure 7 shows plots of the left-hand side for the α's and nitrogen monolayer values shown in Fig. 4 against the corresponding ΔH's. The straight lines are arbitrarily drawn in at the correct slopes and, at least for the higher activity charcoals, they fit the points reasonably well. It is doubtful whether any significance should be attached to the actual values of the intercepts, although they seem to be of approximately the correct order of magnitude required by the relationship of Fowler and Guggenheim referred to above (25). The success of this rather crude correlation encourages one to hope that surface areas could in some cases be determined from chromatographic measurements alone.

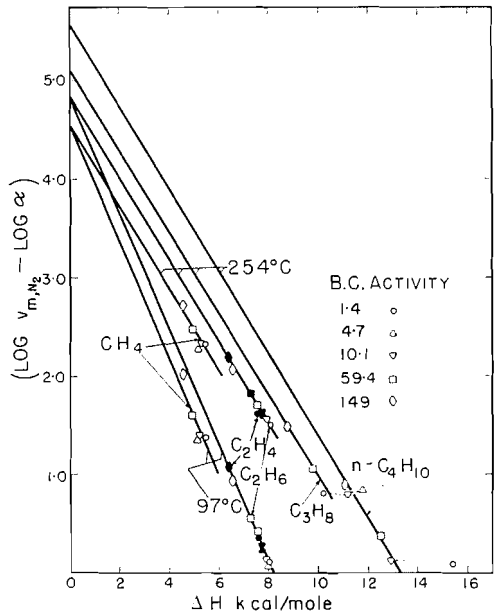

FIG. 7. A test of consistency of the α, ΔH, and nitrogen monolayer capacities (at 77° K) for $1/T = 1.90$ and 2.70×10^{-3}.

This possibility is examined in more detail from a somewhat different point of view in a paper to be published (10).

There is no reason to assume any difference in the chemical nature of the surface as the result of further activation. Therefore, the higher heat of adsorption for the lower activity charcoals is probably due to stronger adsorption in the narrower pores. The initial heat of adsorption with graphitic adsorbents is frequently almost twice the limiting value at higher concentrations, suggesting that the first adsorbate molecules are held by both sides of a narrow crevice. Similar sites will be present, although in smaller proportion, even on the most fully activated charcoals and consequently the range of initial heats is relatively small.

As can be seen from Fig. 4, the variation in surface area (to nitrogen) is much less than the variation in chloropicrin activity. For the most active charcoal the average chloropicrin adsorption at break-through is 149 cc/g. The chloropicrin monolayer capacity was estimated from rough measurements to be around 180 cc/g, which is consistent with the nitrogen monolayer capacity of 630 cc/g. However, when the average chloropicrin concentration at break-through is only 5 cc/g the nitrogen monolayer value is still over 200 cc/g. This discrepancy probably reflects both the slower rates of diffusion in the less active charcoals as well as a relatively lower surface area for chloropicrin due to its exclusion from the smallest pores. By comparing the nitrogen surface areas with those for the previous charcoal series (19), it would appear that significant exclusion of butane would be found only in charcoals of activity less than 5. Exclusion of chloropicrin which is not much larger would hardly extend to much higher activities so that the main reason for the increasing disparity between chloropicrin activities and nitrogen monolayer values must be slower diffusion.

It is perhaps worth considering a little further to what extent a dynamic chromatographic measurement can reflect the true equilibrium adsorption relationship. The

For personal use only.

usual argument is that equilibrium exists at the center of a peak because here the overall rate of transfer is zero (26). This is probably true for a uniform stationary phase. However, each charcoal contains a range of pore sizes. Diffusion in and out of the smaller pores is very slow and consequently broadens the peak but, since this diffusion also opens up a larger surface for adsorption, the broadening is asymmetric in the direction of larger retention volume. In an extreme case, as with the inactivated charcoal, the broadening may be so great as to become indistinguishable from the base line. Thus the asymmetry of a gas–solid chromatogram is at least partly due to the nature of the solid as well as to the curvature of the adsorption isotherm.

This suggests that our method of extrapolation of the peak retention volume to zero sample pressure may be inadequate fully to take account of the retention in the narrowest pores. An alternative procedure considered was to draw in the center line of the peak and take as the retention volume its intersection with the base line. This point was found to be very uncertain, particularly with the less active charcoals, due to the curvature of the center line near the base. We feel, in any case, that the use of such a refinement would change the results relatively little. The direction of any change would be to increase the α's, more so for the less active charcoals and at lower temperatures. Consequently the trend in α and the trend in ΔH may be somewhat stronger than shown in Figs. 4 and 5.

Diffusion Coefficients

The apparent gas phase diffusion coefficients in Table II have been calculated on the assumption of pores of a single size extending through the charcoal granule. For this simplified picture the diffusion coefficients for the 1.4-activity charcoal are slightly larger than those for the 149-activity (taking the values based on the carbon tetrachloride void volumes since transport through channels inaccessible to carbon tetrachloride is likely to be negligible). This is in contrast to the much larger transfer resistance, as shown by the H values, for the 1.4-activity charcoal. However, this resistance, as expressed by C, depends on the total transfer load per unit volume of bed as well as on the specific resistance. The lower α's and lower density of the high-activity charcoal make this load smaller while the greater pore volume increases the cross section for transfer.

The extreme simplifications involved in this picture (e.g. the neglect of the macropore system in the charcoal structure) cast considerable uncertainty on the absolute values of D_p. However, the approximate equality of the values for the two charcoals is consistent with the rather limited range in micropore diameters which appears to be characteristic of steam-activated coconut charcoals. Measurements on an earlier series showed for each charcoal a very narrow spread in micropore sizes around a median diameter which increased only from 18 Å to 25 Å over the series (20).

The mechanism of transient gas flow in small capillaries is usually assumed to be a process of Knudsen diffusion modified by adsorption on the pore walls and by diffusion of the adsorbed phase (27). The apparent gas phase diffusion coefficients corresponding to Knudsen diffusion are decreased by adsorption on the pore walls and increased by diffusion in the adsorbed film. The experimental coefficients vary only a little for the various gases which cover more than a 100-fold range in α values. This suggests that the two factors must nearly balance each other and that diffusion in the adsorbed film is probably quite considerable for strongly adsorbed gases. At these relatively high temperatures this is not unreasonable.

For personal use only.

A more detailed analysis of transport properties in these charcoals is not warranted by the present measurements. We believe, however, that this work has demonstrated the usefulness of gas chromatography in the study of kinetic as well as equilibrium aspects of adsorption.

ACKNOWLEDGMENTS

We wish to thank Dr. J. L. Morrison for his co-operation during this work as well as for giving us samples of the charcoals and, together with Mr. N. W. Myshok, making available some experimental measurements prior to publication. We are grateful to Dr. M. P. Freeman for several helpful suggestions. The co-operation of the Barnebey-Cheney Company in preparing this series of charcoals is also appreciated.

THE PARTIAL STRUCTURES OF ACONITINE AND ACONITOLINE[1]

HANS MAYER[2] AND LÉO MARION

ABSTRACT

In aconitoline ($C_{33}H_{41}O_{10}N$), the product of the oxidation of aconitine with chromic acid, the presence of an $\alpha\beta$-unsaturated carbonyl group has been confirmed. The determination of the basic strengths of aconitoline and its various hydrolytic and reduction products revealed a very strong influence of the carbonyl on the basicity of the alkaloid. It was concluded that the secondary hydroxyl that becomes oxidized must be located in close proximity to the nitrogen. Partial structures are suggested to represent both aconitine and aconitoline.

The alkaloid aconitine ($C_{34}H_{47}O_{11}N$) is known to contain three free hydroxyls, four methoxyl groups, an acetate, and a benzoate group. It has further been shown to contain an N-ethyl group so that its empirical formula can be expanded to $C_{19}H_{19}N.C_2H_5$-$(OH)_3(OCH_3)_4(O.COCH_3)(O.COC_6H_5)$ (cf. ref. 1). If in this formula all the oxygenated substituents be replaced by hydrogen the resulting compound would be expressed by $C_{21}H_{33}N$. Similarly, the alkaloid lycoctonine ($C_{25}H_{41}O_7N$) is also expressed by $C_{21}H_{33}N$ when its oxygenated substituents are replaced by hydrogen. It therefore seems legitimate to assume that there is a great deal of similarity between the carbon–nitrogen skeletons of both alkaloids.

Indeed, Schneider (2) has assumed that aconitine possesses the same carbon–nitrogen skeleton as that derived for lycoctonine by X-ray crystallography (3). Of the nine oxygenated substituents of aconitine he has assumed that seven occupied the same positions as the seven oxygenated substituents in lycoctonine, and has assigned to the remaining two positions on the heterocyclic ring I (2, 4). Further, because of the inertness of aconitine towards lead tetraacetate and periodic acid (5), he arranged the substituents in such a way as to avoid the presence of a vicinal glycol in the alkaloid.

It has long been known that aconitine is oxidized by chromic acid to the ketone aconitinone (6), which very readily loses the elements of methanol and gives rise to aconitoline (6, 7, 8). Since β-methoxy ketones were known to eliminate methanol readily and thus gave rise to $\alpha\beta$-unsaturated ketones, Majima and Tamura (6) concluded that aconitoline was an $\alpha\beta$-unsaturated ketone, and that aconitine contained a β-methoxy secondary alcohol system. Schneider (4), who also prepared aconitoline, claimed that the characteristic absorption of the carbonyl group in the infrared and ultraviolet spectra confirmed the presence of an $\alpha\beta$-unsaturated ketone, and he proposed to represent aconitoline by structure II.

In order to find further evidence regarding the location of the two substituents which by oxidation and loss of methanol give rise to an unsaturated ketone, a fresh study of the oxidation of aconitine with chromic acid has been undertaken.

In our hands the oxidation of aconitine with chromic acid always gave aconitoline directly. The analytical figures confirmed the empirical formula ($C_{33}H_{41}O_{10}N$) already reported (6, 8) and the melting point agreed with that given in the literature. The infrared spectrum of aconitoline contained, besides the ester carbonyl absorption at 1720 and 1730 cm^{-1}, bands at 1677 cm^{-1} (carbonyl) and 720 cm^{-1} (double bond). The ultraviolet spectrum contained four maxima including λ_{max} 232 mμ, log ϵ 4.35 and λ_{max} 305 mμ, log ϵ 2.35. Saponification of aconitoline removed the acetyl and benzoyl groups and gave rise to demethanolaconinone, $C_{24}H_{35}O_8N$, which in the infrared showed a single strong band at 1680 cm^{-1} (carbonyl). Its ultraviolet spectrum showed two maxima (λ_{max} 236 mμ, log ϵ 3.99; λ_{max} 310 mμ, log ϵ 2.34). It has been established that $\alpha\beta$-unsaturation caused a shift of *ca.* 30–40 wave-numbers in the carbonyl absorption in the infrared of six-membered cyclic ketones (9) and the ultraviolet spectrum of demethanolaconinone is characteristic of that of an $\alpha\beta$-unsaturated ketone. Indeed, dihydrodemethanolaconinone ($C_{24}H_{37}O_8N$), the product of the catalytic hydrogenation of demethanolaconinone, in which the double bond is no longer present, shows in the infrared a carbonyl absorption band at 1710 cm^{-1}. This is displaced by 30 wave-numbers from the carbonyl band in the infrared spectrum of demethanolaconinone. β-Methoxy-ketones are known to eliminate the elements of methanol readily and give rise to $\alpha\beta$-unsaturated ketones. Hence aconitine must contain a secondary hydroxyl located in β-position to a methoxyl, as other workers had previously concluded (4, 6, 8).

We have now observed that whereas the pK_a of aconitine is 7.72, that of aconitoline is 3.85. This very marked influence on the basic strength is due to the formation of the carbonyl group, since dihydrodemethanolaconitinone, $C_{33}H_{43}O_{10}N$, prepared by the catalytic hydrogenation of aconitoline, in which the double bond is no longer present has a pK_a 3.85. Furthermore, the action of sodium borohydride either on aconitoline or on dihydrodemethanolaconitinone gave rise to dihydrodemethanolaconitine, $C_{33}H_{45}O_{10}N$, which contained no double bond and in which the carbonyl group had been converted back to a secondary alcohol, and the pK_a of this compound was 6.0. Its ultraviolet absorption spectrum was essentially the same as that of aconitine, and its saponification product, dihydrodemethanolaconine, $C_{24}H_{39}O_8N$, isolated as its hydrochloride, showed no carbonyl absorption in the infrared.

The alkaloid delcosine, which is very closely related to lycoctonine (10, 11), has a pK_a 6.49. It contains a secondary hydroxyl in position 10 (formula I) which[3] is remote from the nitrogen, and when this is oxidized to a carbonyl group (dehydrodelcosine) the pK_a drops to 5.75. The drop in pK_a is only 0.75 unit, whereas a drop of 3.87 units accompanies the formation of aconitoline. Such a dramatic effect on the basic strength indicates that the secondary hydroxyl that becomes oxidized to a carbonyl must be located close to the nitrogen. Hence the location by Schneider of the β-methoxy secondary alcohol system involved in the formation of aconitoline in positions as remote to the nitrogen as carbons 8 and 19 (structure II) is not compatible with these observations.

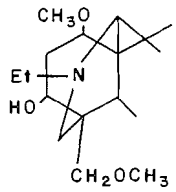
A β-aminoketone has a much lower basic strength than the hydroxylic base from which it arises, as illustrated by tropine (pK_a 9.80) and tropinone (pK_a 6.98).[4] If then,

[3]*The numbering of the lycoctonine carbon–nitrogen skeleton has been arrived at in consultation with Professor R. C. Cookson and Dr. O. E. Edwards.*

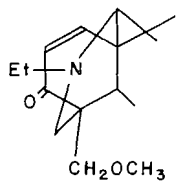
[4]*The basic strengths of tropine and tropinone were determined in 50% ethanol by titration with .055 N p-toluenesulphonic acid in 50% ethanol.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

like Schneider (2) we assume as a working hypothesis that the carbon–nitrogen structure of aconitine be the same as that of lycoctonine, it appears highly probable that the β-methoxy alcohol system involved in the oxidation to aconitoline is located in ring A, and that that ring is substituted as in partial structure III. That the methoxyl and hydroxyl groups should be as shown in III, and not in the reversed positions, is apparent from the fact that the presence of a hydroxyl in position 1, provided it has the right orientation, should on oxidation lead to the formation of an internal ether as in delcosine (10) and in delsoline (12) and such an internal ether has not been obtained from aconitine. Consequently, aconitoline is represented as IV which is a β-aminoketone.



III



IV

The wave-length at which the maximum (λ_{max} 236 mμ, log ϵ 3.99) occurred in the ultraviolet spectrum of demethanolaconinone, however, indicated a possible further substituent in the α or β position of the $\alpha\beta$-unsaturated ketone system of aconitoline. Since in aconitine the β-position is already substituted with a methoxyl, a second substituent would be more likely to be found in the α-position. Furthermore, such a substituent should be a methoxyl, since were it a hydroxyl it would have been oxidized in the course of the formation of aconitoline. It is well known that α-methoxy-$\alpha\beta$-unsaturated ketones are readily hydrolyzed by acids to α-diketones but aconitoline was recovered quantitatively from such a treatment. Also, the Wolff–Kishner reaction on α-methoxyketones is accompanied by elimination of the methoxyl and formation of a double bond (13). Dihydrodemethanolaconinone was, therefore, reduced by the Wolff–Kishner reaction but the product, $C_{24}H_{39}O_7N$, which showed no carbonyl absorption in the infrared, had the same number of methoxyl groups as the starting material. Hence, there is no substituent between the hydroxyl and methoxyl of ring A in aconitine, and aconitoline is IV.

The location of the acetoxy group in Schneider's proposed structure on the α-position to the nitrogen in the heterocylic ring is also unacceptable. Were the acetoxy group to occupy that position, the hydrochloride of benzoylaconine should be an anhydronium salt and the spectroscopic and other evidence, to be discussed in a later communication, clearly indicate that it is not.

EXPERIMENTAL

All infrared absorption spectra were determined on nujol mulls, unless otherwise mentioned, with a Perkin–Elmer Model 21B spectrometer. For the measurement of the ultraviolet spectra the substances were dissolved in methanol. Basic strengths were determined by titration with .05 *N* *p*-toluenesulphonic acid of solutions of the compounds in 95% ethanol (except when otherwise mentioned).

The aconitine used in the following experiments was recrystallized from methanol–water from which it separated as colorless prisms, m.p. 198–199°[5] (decomp.), when

[5]*Melting points are uncorrected.*

immersed in the bath at 180°. Its pK_a was 7.7, $[\alpha]_D^{24}$ +18.2° (*c*, 1.5 in chloroform). Infrared absorption: 3470 cm^{-1} (OH), 1718 cm^{-1} (ester carbonyls), 1610, 710 cm^{-1} (benzene ring). The homogeneity of the base was tested with a paper chromatogram developed with the organic phase of the mixture isoamyl alcohol, glacial acetic acid, and water (40:15:45). The chromatogram gave only one spot (R_F 0.84).

Aconitoline (Demethanolaconitinone)

Aconitine (4.493 g) was dissolved in acetone (100 ml) and cooled in ice and salt. To the cold solution chromium trioxide (4.50 g) dissolved in cooled acetone (50 ml) was added. The reaction mixture was allowed to stand at room temperature for 3 days, after which the solvent was evaporated under reduced pressure. The dark brown residue was triturated with sulphurous acid (100 ml), sulphur dioxide was bubbled into the mixture, and the resulting dark green solution was extracted with ether (500 ml).

The aqueous liquor was then alkalized with finely powdered sodium carbonate and the precipitate filtered and dried. The dried precipitate was extracted with chloroform (100 ml) in a Soxhlet apparatus. The filtrate was extracted with chloroform (250 ml) and the two chloroform extracts combined and evaporated to dryness. There was left a light yellow froth (3.64 g, 85.5%) that crystallized in contact with ether and *n*-hexane. The product melted at 105–110°, resolidified, and melted again at 205–210° (decomp.). After two recrystallizations from methanol–water, it consisted of colorless prisms (wt., 2.506 g), m.p. 218–220°, $[\alpha]_D^{25}$ +69.0° (*c*, 1.85 in chloroform), pK_a 3.85. Found: C, 64.96; H, 6.75; N, 2.33. Calc. for $C_{33}H_{41}O_{10}N$: C, 64.80; H, 6.76; N, 2.29%. Infrared absorption: 3470 cm^{-1} (OH), 1730, 1720 cm^{-1} (ester carbonyls), 1677 cm^{-1} (six-membered $\alpha\beta$-unsaturated ketone), 1605 and 720 cm^{-1} (benzene).

Ultraviolet spectrum: λ_{max} 232 mμ, log ϵ 4.35; λ_{max} 273 mμ, log ϵ 3.09; λ_{max} 281 mμ, log ϵ 3.0; λ_{max} 305 mμ, log ϵ 2.35.

Aconitoline formed a hydriodide which crystallized in long needles from acetone–ether, m.p. 225–226° (decomp.) when immersed at 200°.

Demethanolaconinone

To a solution of aconitoline (155 mg) in ethanol (10 ml), heated to boiling in a slow stream of nitrogen, was added dropwise an alcoholic *N*-potassium hydroxide solution (0.56 ml), and the reaction mixture was refluxed for 2 hours. The light yellow solution was evaporated to dryness *in vacuo*, water (10 ml) was added, and the solution brought to pH 6 by the dropwise addition of 2 *N* hydrochloric acid. The solution was extracted five times with 25 ml of ether, saturated with sodium carbonate, and extracted five times with 25 ml of chloroform. After drying with sodium sulphate, the chloroform solution was evaporated to dryness *in vacuo*. It left a crystalline froth (115.5 mg, 98% yield) that could not be induced to crystallize.

The froth was dissolved in water (10 ml), the solution was filtered and brought to pH 6 with 2 *N* hydrochloric acid. After evaporation *in vacuo* there remained 126 mg (99% yield) of demethanolaconinone hydrochloride, which crystallized on contact with absolute ethanol, m.p. 220–221° (decomp.). After two recrystallizations from absolute ethanol – ether the colorless needles (95 mg) melted at 220–221° (decomp.), $[\alpha]_D^{24}$ +66.5° (*c*, 1.97 in water). Found: C, 57.37; H, 7.15. Calc. for $C_{24}H_{35}O_8N.HCl$: C, 57.42; H, 7.23%. Infrared absorption: 3320, 3160 cm^{-1} (OH), and a sharp band at 1680 cm^{-1} (six-membered $\alpha\beta$-unsaturated ketone), 720 cm^{-1} (double bond). Ultraviolet spectrum: λ_{max} 229 mμ, log ϵ 3.94; λ_{max} 301 mμ, log ϵ 2.62.

Some of the hydrochloride (38 mg) was dissolved in water (5 ml), the solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

saturated with sodium carbonate and extracted five times with 20 ml of chloroform. Evaporation of the chloroform left a residue of 34.5 mg (98% yield) of pure demethanolaconinone, which could not be induced to crystallize. Its ultraviolet spectrum showed λ_{max} 236 mμ, log ϵ 3.99; λ_{max} 310 mμ, log ϵ 2.34.

A quantity of demethanolaconinone was converted to the hydriodide, which crystallized from methanol–ether as colorless prismatic needles, m.p. 240–241° (decomp.) when immersed at 220°. The salt crystallized as a hydrate from which it was not possible to remove all the water. The hydrate dried in air only was used for analysis, $[\alpha]_D^{25}$ +59.2° ±1.5° (*c*, 1.04 in water). Found: C, 44.91; H, 6.53. Calc. for $C_{24}H_{35}O_8N.HI.3H_2O$: C, 44.53; H, 6.54%. Infrared absorption: 3320, 3420 cm^{-1} (OH, H_2O), 1650 cm^{-1} (H_2O), 1680 cm^{-1} (six-membered $\alpha\beta$-unsaturated ketone).

Dihydrodemethanolaconitinone

Aconitoline (113 mg) dissolved in 95% ethanol (5 ml) was hydrogenated at room temperature in the presence of 30% palladium–charcoal (28 mg). After 3.5 hours the reaction was completed (hydrogen uptake 4.28 ml; calc. for 1 mole, 4.55 ml). The catalyst was removed by filtration and the filtrate evaporated to dryness. There was left a colorless froth, 114 mg, which crystallized in contact with ether. After three recrystallizations from aqueous methanol, the product consisted of colorless needles (73 mg), m.p. 220–221° (decomp.) when immersed at 180°, $[\alpha]_D^{25}$ −50° (*c*, 1.1 in chloroform), pK_a 3.85. Found: C, 64.97; H, 7.40. Calc. for $C_{33}H_{43}O_{10}N$: C, 64.58; H, 7.06%. Infrared absorption (fluorolube mull): 3470 cm^{-1} (OH), 1720, 1733 cm^{-1} (ester carbonyl), shoulder at 1705 cm^{-1} (six-membered ketone).

Dihydrodemethanolaconinone

To a solution of dihydrodemethanolaconitinone (363 mg) in ethanol (20 ml) under reflux in a stream of nitrogen, 1.3 ml (2.2 equiv.) of *N*-alcoholic potassium hydroxide was added dropwise and the refluxing continued for 2 hours. The solution was evaporated to dryness *in vacuo* and the residue dissolved in water (10 ml). The aqueous solution was acidified with 10% hydrochloric acid, extracted five times with 20 ml of ether, saturated with sodium carbonate, and extracted five times with 20 ml of chloroform. On evaporation the chloroform solution left a colorless gum (271 mg, 98% yield) which crystallized from acetone – *n*-hexane. After recrystallization from the same mixture, the product consisted of colorless rhombohedral leaflets (255 mg), m.p. 131–133° (decomp.), $[\alpha]_D^{25}$ −52.2° (*c*, 1.11 in chloroform). Found: C, 60.31; H, 7.80. Calc. for $C_{24}H_{37}O_8N.\frac{1}{2}H_2O$: C, 60.48; H, 8.03%. It was not possible to remove all the water by drying *in vacuo* without causing some decomposition. Infrared absorption (in chloroform): 3420 cm^{-1} (OH) and 1710 cm^{-1} (six-membered cyclic ketone).

Dihydrodemethanolaconitine

(*a*) *Reduction of Aconitoline with Sodium Borohydride*

Sodium borohydride (200 mg) was added to a solution of aconitoline (498 mg) in 80% aqueous methanol (40 ml). After the reaction mixture had been left for 1 hour at room temperature the solution was evaporated to dryness *in vacuo* and the residue dissolved in 2 *N* sulphuric acid (20 ml). The solution was extracted five times with 25 ml of ether, saturated with sodium carbonate, and extracted five times with 25 ml of chloroform. Evaporation of the chloroform extract gave a colorless froth (500 mg) which crystallized in contact with ether. The product was recrystallized twice from methanol–water, from which it separated as colorless prisms (321 mg), m.p. 173–174 (decomp.), $[\alpha]_D^{27}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

+23° (*c*, 1.31 in chloroform), pK_a 6.0±0.1. Found: C, 64.53; H, 7.51. Calc. for $C_{33}H_{45}O_{10}N$: C, 64.38; H, 7.37%. Infrared absorption: 3460 cm^{-1} (OH), 1715, 1730 cm^{-1} (ester carbonyls), 1608 and 702 cm^{-1} (benzene ring). Ultraviolet spectrum: λ_{max} 230 mμ, log ε 4.24; λ_{max} 274 mμ, log ε 3.09; λ_{max} 281 mμ, log ε 3.02.

(*b*) *Reduction of Dihydrodemethanolaconitinone with Sodium Borohydride*

To a solution of dihydrodemethanolaconitinone (101 mg) in 80% aqueous methanol (10 ml), sodium borohydride (50 mg) was added. After the solution had been left for 1 hour at room temperature, it was evaporated to dryness and the residue dissolved in 2 *N* sulphuric acid (10 ml). The solution was washed five times with 20 ml of ether, saturated with sodium carbonate, and extracted five times with 20 ml of chloroform. On evaporation the dried chloroform solution yielded a colorless froth (101 mg) which crystallized when triturated with ether – *n*-hexane. After two recrystallizations from methanol–water the product (47 mg) consisted of colorless prismatic needles, m.p. 171–173° (decomp.), $[\alpha]_D^{27}$ +23.7° (*c*, 1.42 in chloroform). Found: C, 64.48; H, 7.18. Calc. for $C_{33}H_{45}O_{10}N$: C, 64.38; H, 7.37%. The melting point was unchanged by mixture with the dihydrodemethanolaconitine obtained above (*a*) and the infrared absorption spectra were superimposable.

Dihydrodemethanolaconine Hydrochloride

Pure dihydrodemethanolaconitine (148 mg) was hydrolyzed in alkaline solution, as described under demethanolaconinone. The product (106 mg, 95% yield) was a colorless froth. It was dissolved in water (5 ml) and the solution made just acid by the dropwise addition of 10% hydrochloric acid. Evaporation of the acid solution left a colorless froth which crystallized after addition of a few drops of methanol. The crystalline product (108 mg) was recrystallized three times from methanol–ether from which it separated as colorless needles, m.p. 212–213° (decomp.), $[\alpha]_D^{25}$ −19.0±0.6° (*c*, 1.72 in water). Found: C, 56.91; H, 7.87. Calc. for $C_{24}H_{39}O_8N.HCl$: C, 56.96; H, 7.97%. The infrared spectrum contained no absorption attributable to carbonyl or unsaturation.

Attempted Saponification of Demethanolaconinone Hydrochloride

Pure demethanolaconinone hydrochloride (69 mg) was dissolved in 2 *N* hydrochloric acid (10 ml), and the solution refluxed for 2 hours. The solution was then evaporated and the residual colorless froth crystallized from ethanol, from which it separated as colorless needles, m.p. 220–221° when immersed at 200° (decomp.) either alone or in admixture with the starting material. The infrared spectrum of the product was identical with that of the starting material and so was its optical rotation, $[\alpha]_D^{24}$ +66.8° (*c*, 1.53 in water).

Wolff–Kishner Reduction of Dihydrodemethanolaconinone

A mixture of dihydrodemethanolaconinone (101 mg), triethylene glycol (3 ml), and 95% hydrazine (1.2 ml) was immersed in a metal bath preheated to 145°, the temperature raised to 150° and maintained for 1 hour. Potassium hydroxide (520 mg) was then added, the temperature raised gradually to 190°, and maintained between 190–195° for a further 3 hours while a slow stream of nitrogen was passed into the reaction flask. After cooling, the light yellow solution was diluted with water (20 ml), acidified with 2 *N* sulphuric acid, and extracted 10 times with 20 ml of chloroform. The aqueous solution was then alkalized and saturated with solid sodium carbonate and extracted five times with 20 ml of ether. The ether extract when evaporated left a colorless oil which crystallized on addition of some drops of acetone and water (54 mg, yield 55%), colorless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

needles, m.p. 104° (decomp., after beginning to shrink at 80°). Recrystallization from a very concentrated acetone solution gave dihydrodemethanoldehydroxyaconine as rhombohedral leaflets, m.p. 104–106° (decomp.), $[\alpha]_D^{22}$ +21.4° (*c*, 1.04 in chloroform). Found: C, 62.97; H, 8.41; OCH_3, 20.65. Calc. for $C_{24}H_{39}O_7N$: C, 63.55; H, 8.67; 3 OCH_3, 20.53%. The infrared spectrum contained no carbonyl absorption.

ACKNOWLEDGMENTS

We are indebted to Mr. R. Lauzon and Mr. H. Seguin of these laboratories for preparing the infrared spectra and for the microanalyses, respectively. We wish to express our gratitude to Dr. Raymond Paul, Rhône-Poulenc, Paris, who kindly helped us in securing our first supply of aconitine.

CARBONYL AND THIOCARBONYL COMPOUNDS

I *a*. REACTION OF 9-DIAZOXANTHENE WITH *o*-QUINONES

b. THE DIRECT PREPARATION OF HALOGENATED CYCLIC ETHERS FROM CERTAIN THIONES AND THEIR MOLLUSCICIDAL ACTIVITY[1]

NAZIH LATIF AND IBRAHIM FATHY

ABSTRACT

The preparation and properties of 9-diazoxanthene are described. It reacts with tetrachloro- and tetrabromo-*o*-benzoquinone, 4-triphenylmethyl-1,2-benzoquinone, and phenanthraquinone to give the cyclic ethers III*a*, III*b*, IV, and V respectively. The action of hydrochloric acid – dioxane solution on the products is stressed.

Tetrachloro- and tetrabromo-*o*-benzoquinone react with xanthione forming the halogenated cyclic ethers III*a* and III*b* respectively. A 1,2-benzopyran derivative IX is obtained by the action of tetrachloro-*o*-quinone on coumarin-2-thione. IX is toxic to *Biomphalaria boissi* snails in high dilution.

Reaction of 9-Diazoxanthene with o-Quinones

The reactions of diazomethane and diphenyldiazomethane with *o*-quinones have been described by various authors (1). Schönberg and Latif (2) investigated the action of 9-diazofluorene on *o*-quinones and found that it reacts readily with *o*-benzoquinone and *β*-naphthoquinone derivatives to give methylenedioxy derivatives in good yield, but it fails to react with phenanthraquinone under the same conditions.

9-Diazoxanthene has not been described before. It could be prepared by the oxidation of xanthone hydrazone with mercuric oxide in the presence of alkali at room temperature. However, microanalysis could not be carried out, since the substance decomposes at room temperature with the formation of the ketazine. In contrast to diazofluorene, it reacts readily with phenanthraquinone to give the cyclic ether V. It also reacts, but more vigorously, with tetrachloro- I*a*, and tetrabromo-*o*-benzoquinone I*b*, and 4-tri-

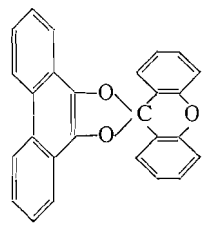
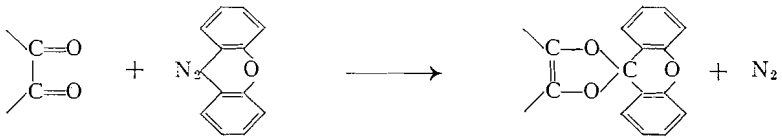
III*a*; R = Cl
III*b*; R = Br



V

phenylmethyl-1,2-benzoquinone II, to give, in excellent yield, the analogous products III*a*, III*b*, and IV, respectively, according to scheme A (2).

[1]*Manuscript received December 9, 1958.*
Contribution from the Organic Chemistry Department, National Research Centre, Dokki, Cairo, Egypt, U.A.R.



A

The constitution of the products formed is based on the following facts:

(*a*) they are colorless or nearly so,

(*b*) they are readily hydrolyzed by acids, and

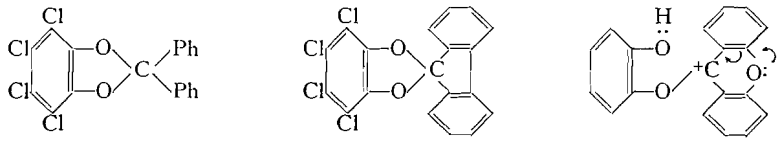
(*c*) III*a* and III*b* can be obtained by the reaction between 9,9-dichloroxanthene and the corresponding tetrahalogenocatechol according to scheme B.

The identity of the products obtained from reactions A and B is established by analysis, melting point and mixed melting point, and by their identical infrared spectra.

R = Cl or Br

B

It is observed that all the cyclic ethers obtained in this reaction are readily and quantitatively cleaved by hydrochloric acid in dioxane; for example, when III*a* or III*b* are boiled for 30 minutes with a mixture of concentrated hydrochloric acid and dioxane (1:5), xanthone and the corresponding catechol are obtained in quantitative yield. In the case of V, xanthone and phenanthraquinone are obtained after air oxidation. This is rather remarkable as the analogous products VI and VII obtained by the action of diphenyl- (3) and diphenylene-diazomethane (2) on tetrachloro-*o*-quinone are not similarly attacked. This may be explained by assuming that the proton attacks first the ethereal



VI VII VIII

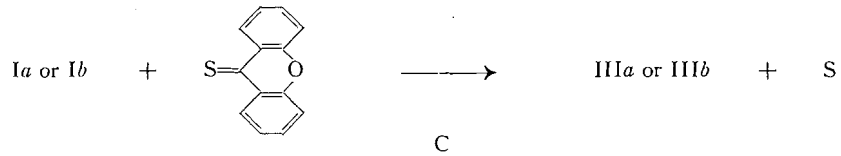
oxygen atom and this is followed by the heterolytic fission of the C–O bond, to give a carbonium ion which is stabilized by resonance with the unshared electron pair of the oxygen of the xanthyl residue (4) (cf. VIII for III*a*). However, it is observed that these products are not appreciably cleaved by concentrated sulphuric acid at room temperature, as usually happens with the other methylenedioxy derivatives obtained by the action of diazomethanes on *o*-quinones. This may be attributed to the formation of an oxonium salt which is rather stable under the conditions of the experiment, a property generally shown by xanthenes.

The Direct Preparation of Halogenated Cyclic Ethers from Certain Thiones

Several reactions of thioketones have been described (5), but it is believed that nothing is mentioned about the action of *o*-quinones on cyclic thiones. It is found that the high potential quinones, tetrachloro- and tetrabromo-*o*-benzoquinone, react with xanthione

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

in dry benzene at room temperature with the formation of III*a* and III*b*, respectively, according to scheme C.

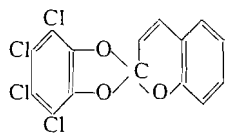


C

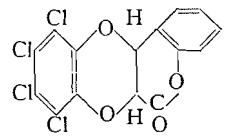
However, the reaction is slow at room temperature, but is remarkably accelerated by heat. Thus when I*a* and xanthione are boiled in dry benzene for 1 hour, an 80% yield of III*a* is obtained, whereas, at room temperature, a 75% yield is reached only after 5 days. The reaction of I*b* with xanthione is affected by temperature in almost a similar way. III*a* can also be obtained by heating I*a* and xanthione without a solvent in a carbon dioxide atmosphere.

The identity of the compounds obtained in this reaction with those obtained by either reaction A or B is established by analysis, melting point and mixed melting point, and by similar infrared spectra.

It is found also that tetrachloro-*o*-quinone reacts similarly with coumarin-2-thione in boiling benzene with the formation of a 1,2-benzopyran derivative IX in good yield. The constitution of the product obtained is based on analogy, as well as on the fact that it is colorless and easily hydrolyzed by hydrochloric acid in dioxane to coumarin and tetrachlorocatechol. The absence of sulphur and of the characteristic frequency band of a *d*-lactone (1755 cm^{-1} nujol) (6) shown by coumarin excludes structure X of a 1,4-dioxane, which may result by the addition of the quinone to the double bond of the lactone ring. Addition of *o*-quinones to the double bond in ethylenes, benzofurans, isocoumarins, etc. is well known. However, it is reported that coumarin fails to react with phenathraquinone (7).



IX



X

The Molluscicidal Activity of Halogenated Cyclic Ethers

Halawani and Latif (8) found that halogenated *o*-benzoquinone and benzodioxole derivatives are toxic to *Biomphalaria boissi* snails—the intermediate host of *Schistosoma mansoni* in Egypt—in high dilutions. The toxicity of the above-mentioned halogenated cyclic ethers has been investigated. It is found that IX kills the snails in concentrations as low as 20 p.p.m. in water during a 24-hour-exposure period to the drug followed by a 72-hour-observation period in fresh water. III*a*, III*b*, IV, and V could not be tested, since they are almost insoluble in the solvents usually used for the test. Details of these experiments will be published separately.

EXPERIMENTAL

Melting points are not corrected. Microanalyses were carried out by A. Bernhardt, Germany.

Preparation of 9-diazoxanthene.—Xanthone hydrazone (4 g), mercuric oxide (7 g), and anhydrous sodium sulphate (1 g) were ground together in a dry mortar, and transferred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

to a dry 100-ml R.B.F. guarded with a calcium chloride tube and containing 50 ml dry ether. One milliliter of a freshly prepared saturated solution of potassium hydroxide in absolute alcohol was added while shaking the mixture for 2 minutes at room temperature (20° C), then stirring for 30 minutes at 10°. The green ethereal solution was filtered off and the residue washed with dry ether. The combined ethereal solutions were concentrated under reduced pressure in the cold, when green crystals of 9-diazoxanthene separated, and filtered. The compound is soluble in most organic solvents in the cold, melts with decomposition at about 60° C (red melt), and turns orange-red when left at room temperature for a few hours.

Xanthone ketazine.—9-Diazoxanthene (0.1 g) was left in a watch glass exposed to air for 24 hours. The orange-red crystals formed were washed with ether and recrystallized from benzene when xanthone ketazine was obtained (m.p. 285° not depressed when admixed with an authentic sample prepared according to Schönberg and Stolpp (9)).

Reaction of tetrachloro-o-quinone with 9-diazoxanthene.—Tetrachloro-*o*-quinone (10) (0.8 g) was added slowly to a dry ethereal solution of diazoxanthene (1.1 g). A vigorous reaction with evolution of gas took place and after a few seconds a yellowish crystalline solid separated. On recrystallization from xylene 9,9-(tetrachloro-*o*-phenylenedioxy) xanthene III*a* separated in colorless crystals,* m.p. 286° (yield almost quantitative). It is difficultly soluble in cold alcohol, acetone, or benzene. Calc. for $C_{19}H_8O_3Cl_4$: C, 53.52; H, 1.87; Cl, 33.3. Found: C, 53.43; H, 2.17; Cl, 32.87%. It dissolves in concentrated sulphuric acid with a deep yellow color and when the solution was kept overnight at room temperature (20° C) and then poured into ice, above 75% of the substance was recovered unchanged.

Hydrolysis of IIIa.—To a solution of concentrated hydrochloric acid (sp. gr. 1.19) (1 ml) in dioxane (5 ml) was added III*a* (0.15 g), the mixture boiled for 30 minutes, and then left to cool. It was then poured into ice and the colorless precipitate formed was filtered, dried, and dissolved in the least amount of boiling methyl alcohol and left to cool. The colorless crystals separated proved to be xanthone (m.p. and mixed m.p. 174°). On addition of dilute hydrochloric acid to the mother liquor a white precipitate was formed. After filtering, drying, and refluxing with acetic anhydride for 30 minutes, the mixture was left to cool, and then poured into ice. The solid formed was recrystallized from methyl alcohol and proved to be the diacetyl derivative of tetrachlorocatechol (melting point and mixed melting point). Using methyl alcohol instead of dioxane, hydrolysis was partial and about 50% of the substance was recovered unchanged.

Reaction between tetrachlorocatechol and 9,9-dichloroxanthene.—Tetrachlorocatechol (0.1 mole) and 9,9-dichloroxanthene (0.1 mole from thionyl chloride and xanthone) were heated together in a test tube protected from moisture at 150° (oil bath) for 1 hour. The reaction mixture was left to cool, washed several times with acetone, and recrystallized from xylene when III*a* was obtained (m.p. 286° undepressed when admixed with an authentic sample prepared by the action of diazoxanthene on tetrachloro-*o*-quinone) (yield about 80%). The product and the authentic sample have identical infrared spectra. Calc. for $C_{19}H_8O_3Cl_4$: C, 53.52; H, 1.87; Cl, 33.3. Found: C, 54.32; H, 2.08; Cl, 32.6%.

Reaction of tetrabromo-o-quinone with 9-diazoxanthene.—Tetrabromo-*o*-quinone (11) (1 g) was added to a crude ethereal solution of diazoxanthene (from 2 g of xanthone hydrazone). A vigorous reaction took place with evolution of gas and the immediate separation of a yellowish deposit. This was filtered off, washed with boiling acetone,

**In a parallel experiment carried out using the crude ethereal solution obtained from the oxidation of xanthone hydrazone as described above, instead of diazoxanthene crystals, the same yield of IIIa was obtained. In the coming experiments this crude ethereal solution will be generally used.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

and recrystallized from xylene (using charcoal) when 9,9-(tetrabromo-*o*-phenylenedioxy) xanthene III*b* separated in almost colorless crystals, m.p. 280° (decomp.). Yield almost quantitative. The compound dissolves in concentrated sulphuric acid with a yellow color and most of it was recovered unchanged when poured into ice as in the case of the chloro-analogue. Calc. for $C_{19}H_8O_3Br_4$: C, 37.74; H, 1.32; Br, 52.98. Found: C, 37.68; H, 1.75; Br, 53.24%. When III*b* was boiled with concentrated hydrochloric acid – dioxane as in the case of the chloro-analogue, xanthone and tetrabromocatechol (identified as its diacetyl derivative) were obtained.

Reaction of tetrabromocatechol with 9,9-dichloroxanthene.—Tetrabromocatechol (4 g) and dichloroxanthene (from 2 g of xanthone and thionyl chloride) were dissolved in dry benzene (20 ml), and a few drops of piperidine added. The mixture was refluxed for 3 hours, concentrated, and left to cool. The solid separated was washed with boiling acetone and recrystallized from xylene (using charcoal) when III*b* was obtained in colorless crystals, m.p. 280° (decomp.). Its infrared spectrum is identical with that of the product obtained from diazoxanthene.

Reaction of 4-triphenylmethyl-1,2-benzoquinone with 9-diazoxanthene.—The quinone (12) (1.2 g) was added in very small portions to a crude ethereal solution of diazoxanthene (from 2 g of xanthone hydrazone). A new portion was only added when the reaction from a previous addition had subsided. After all the quinone was added, the reaction mixture was left for 2 hours at room temperature with occasional shaking. The color of the quinone disappeared and a colorless solid was formed. This was recrystallized from xylene when 9,9-(4-triphenylmethyl-*o*-phenylenedioxy) xanthene IV was obtained in colorless crystals, m.p. 264° (yield about 60%). Calc. for $C_{38}H_{26}O_3$: C, 86.01; H, 4.94. Found: C, 86.45; H, 5.28%.

Reaction of phenanthraquinone with 9-diazoxanthene.—The quinone (0.5 g) was added in very small portions to a crude ethereal solution of diazoxanthene (from 2 g xanthone hydrazone) with mild stirring at 37°. When all the quinone had been added, stirring of the reaction mixture was continued for 2 hours. The yellowish solid formed was washed several times with boiling acetone and recrystallized from xylene when (V) was obtained in almost colorless crystals, m.p. 298°. It is insoluble in most organic solvents and gives a deep yellow color with concentrated sulphuric acid. Calc. for $C_{27}H_{16}O_3$: C, 83.5; H, 4.15. Found: C, 84.1; H, 4.35%. V (0.2 g) was refluxed with hydrochloric acid – dioxane solution as above, the reaction mixture was left to cool and then poured into ice. The yellowish solid formed was filtered off using the pump and suction was allowed to continue for 1 hour to facilitate air oxidation. The product was then pressed on a porous plate and recrystallized from benzene. The resulting orange crystals proved to be phenanthraquinone (melting point and mixed melting point). It gives olive green color with concentrated sulphuric acid.

Reaction of tetrachloro-o-quinone with xanthione.—Method "a". The quinone (2.4 g) and xanthione (2.2 g) in dry benzene (15 ml) were refluxed together for 1 hour on the water bath. The red color of the quinone disappeared and the solution became dark brown; it was left to cool. The crystalline solid formed was filtered off and the mother liquor concentrated to obtain another crop of crystalline solid.* The whole crude reaction product was washed with acetone several times and recrystallized from xylene in colorless crystals which proved to be III*a* (m.p. 286° undepressed when admixed with an authentic sample prepared in the above experiments. The product and the authentic sample have

**When the mother liquor was evaporated to dryness under reduced pressure and the residue heated in a carbon dioxide atmosphere at 150° (oil bath) for 1 hour, sulphur collected on the cooler parts of the reaction vessel. Xanthione is stable when heated alone under the same conditions.*

identical infrared spectra.). Yield above 80%. Calc. for $C_{19}H_8O_3Cl_4$: C, 53.52; H, 1.87; Cl, 33.3. Found: C, 53.51; H, 2.07; Cl, 33.04%. *Method "b"*. Tetrachloro-*o*-quinone (0.61 g) and xanthione (0.5 g) were mixed together in a dry test tube protected from moisture. The mixture was heated for 2 hours at 200° (oil bath) while passing carbon dioxide, and then left to cool. The solid mass obtained was ground well, washed with acetone, and recrystallized from xylene (using charcoal) when III*a* was obtained in colorless crystals, m.p. 286° (yield about 50%).

Reaction of tetrabromo-o-quinone with xanthione.—The quinone (1 g) and xanthione (0.5 g) in dry benzene (20 ml) were refluxed together for 1 hour on the water bath. The reaction mixture became dark brown, and yellowish crystals separated. These were filtered off, and the filtrate concentrated and left to cool when another crop of crystals was obtained. The combined crude product was washed with boiling acetone and recrystallized from xylene (using charcoal) when III*b* was obtained in almost colorless crystals, m.p. 280° (decomp.). Its infrared spectrum is identical with that of the products obtained by reactions A and B.

When the quinone and the thione in dry benzene were kept at room temperature in a carbon dioxide atmosphere for 3 days about 75% yield of III*b* separated.

Reaction of tetrachloro-o-quinone with coumarin-2-thione.—The quinone (1.2 g) and the thione (0.8 g) in dry benzene (10 ml) were refluxed for 3 hours. The reaction mixture was filtered while hot, concentrated, and left to cool. The crystals that separated were washed with acetone and recrystallized from benzene when 2,2-(tetrachloro-*o*-phenylenedioxy) benzopyran IX was obtained in colorless crystals, m.p. 214° C. It is soluble in hot acetone, benzene, and chloroform, difficultly soluble in alcohol. Calc. for $C_{15}H_6O_3Cl_4$: C, 47.87; H, 1.59; Cl, 37.7. Found: C, 47.88; H, 1.64; Cl, 37.38%.

Hydrolysis of IX.—IX (0.2 g) was refluxed with a solution of hydrochloric acid in dioxane as usual. The reaction mixture was then poured into ice and filtered and the filtrate left to concentrate slowly at room temperature. The separated colorless crystals were recrystallized from petroleum ether (30–50°) and proved to be coumarin (melting point and mixed melting point). Diluted hydrochloric acid was added to the mother liquor and the white solid obtained was filtered off, dried, and refluxed with acetic anhydride when the diacetyl derivative of tetrachlorocatechol was obtained.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. E. Bickert, Max-Planck Institut fur Biochemie, München, and to Professor F. G. Baddar, Faculty of Science, A'in Schams University, Cairo, for the determination of infrared spectra.

INFRARED SPECTRA OF ORGANO-PHOSPHORUS COMPOUNDS

III. PHOSPHORAMIDATES, PHOSPHORAMIDOTHIONATES, AND RELATED COMPOUNDS[1, 2]

R. A. McIvor and C. E. Hubley

ABSTRACT

Examination of a number of new phosphorus compounds has provided additional confirmation for many of the group frequencies reported previously. In certain cases additional information has been obtained on the effect of environment on the band positions, and some previously unassigned bands have been attributed to specific structures. In particular, bands previously assigned to P(S), P(S)X, C—H deformation, P—O—(C), P—C, P—S—H, P—S(P), P—N, C—S(P), and C—N(P) are discussed.

INTRODUCTION

In Parts I and II of this series, characteristic bands were given for various functional groups of organo-phosphorus compounds, in particular P—O—P, P→S, P—O—(C), and P—Cl. A number of new compounds containing P—N bonds has been examined, in addition to those previously discussed, which makes further and revised group frequency assignments possible.

These assignments are simply empirical, based on observations of compounds containing particular atomic groupings. No fundamental studies have been carried out by us to test which particular parts, if any, of the large groupings are responsible for the bands. Thus, for example, while it is always possible to say that compounds containing an isopropoxy group attached to phosphorus will exhibit a triplet of bands between 1100 and 1200 cm^{-1}, the assignment of these bands to specific vibrations has not been attempted and for convenience they have been grouped under R—O—(P), since many other authors in this field have considered at least one band in this region as being a C—O—(P) absorption. Where groups of bands occur in a specific region for many closely related compounds, it is often convenient to discuss all such bands together. More recently, however (1, 2), the strong 1000–1100 cm^{-1} band has been postulated as the C—O—(P) band, while bands near 830 cm^{-1} are considered to be P—O—(C) stretching bands. This C—O assignment seems more in line with the absorption of this grouping in non-phosphorus compounds, but not consistent with the assignment of a 940 cm^{-1} band to P—O(P) and P—O—(H). It should also be noted that the 1000–1100 cm^{-1} band occurs at progressively lower frequencies in the series MeOP, EtOP, *i*-PrOP, whereas the band attributed to C—O stretching in alcohols shifts to higher frequencies with increasing substitution (3).

EXPERIMENTAL

The preparation of some of these compounds is described elsewhere (4, 5). A Baird double-beam recording spectrophotometer was used for all spectra. Band positions are cited to the nearest 0.01 μ for sharp bands and to the nearest 0.05 μ for broad bands. All but three samples, which are marked in the tables, were run as thin films. The solid samples were run as KBr pellets. These were prepared by mixing one part of the sample with 100 parts of KBr in an agate mortar for approximately 1 minute, and then pressing at 75,000–90,000 lb/in.^{2} in a Hilger & Watts evacuated die.

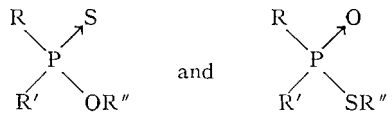
RESULTS AND DISCUSSION

(*a*) P→S

An additional 43 compounds containing P→S have been examined. These compounds have bands in the 740–830 cm^{-1} region with various intensities. However, since the corresponding P→O compounds frequently have similar bands in this region, our earlier assignment of this band to P→S seems less certain. The spectra of most P→S compounds containing *n*-PrO do not have bands in the 770–830 cm^{-1} region, but have one in the 715–770 cm^{-1} region.

A number of compounds of types I and II have been examined both here and in other laboratories (5, 6, 7). I can be converted to II by heating, and the progress of the isomerization can be followed in the infrared. During the isomerization of these compounds there



I II

is usually a disappearance of one or more bands in the 740–830 cm^{-1} region with concomitant appearance of P—O and C—S—P bands (see section (*k*) below). Thus compound I (R = Me_2N; R′ = *n*-PrO; R″ = CH_2—CH_2NEt_2) has a very weak band at 790 cm^{-1} which disappears on conversion to the corresponding II isomer.

Since this work was completed a paper by Hooge and Christen (8) has assigned the band discussed in section (*b*) to the P→S link, and related its frequency to the mass of the remaining substituents. This seems to be an excellent suggestion, and consistent with all our observations. The nature of the 740–830 cm^{-1} band remains in doubt.

The 740–830 cm^{-1} band is particularly intense in compounds containing MeO and EtO groups, which usually have an additional strong band in this region, attributed recently to P—O—(C) stretching (1, 2). Such intensification has been frequently noted when two bands associated with the same small group of atoms have closely related frequencies. In this case, however, the effect may be one of simple summation of two superimposed bands. *n*-Propyl and *n*-butyl phosphorus esters have no strong band in this region.

Several additional observations have been made concerning this absorption. As a general rule acids absorb below 770 cm^{-1}. Dichlorides absorb at lower frequencies than the corresponding full esters for any one ester group. For the ester groups absorption usually occurs in this region in the following order of increasing frequency: *n*-propyl > isopropyl > ethyl > methyl. Compounds containing alkyl groups attached to P absorb at lower frequencies than the corresponding phosphates, but since many methylphosphonates have a sharp band near 794 cm^{-1} and a broad one near 758 cm^{-1} the association of either of these with the P→S grouping is dubious. Bands believed to be characteristic are listed in Table I.

(*b*) (O)—P—Cl, (O)—P—S—
↓ ↓
S S

Many new compounds have been examined containing these groupings which are particularly useful for analytical purposes. Further to the information previously reported (7), more examples of phosphonate half-esters are available, all of which absorb

For personal use only.

strongly in the 630 to 641 cm^{-1} region, and two dimethylphosphoramidochloridothionates which absorb near 633 cm^{-1} in contrast with simple phosphorothionates and thionyl dichlorides which absorb near 666 cm^{-1}. Phosphonothionic acids and phosphorothionic acids also absorb in this region but with somewhat lesser intensity. As these compounds probably have the P(S)OH structure primarily, this band (which occurs near 606 cm^{-1} in the phosphonothioic acids) is probably of this type rather than a P—S—(H) stretching as suggested previously (7). Two compounds which possibly contain P—S—P groupings have a doublet at 658 cm^{-1} and 630 cm^{-1}, the components of which retain the same relative intensities during purification procedures. Compounds containing the structure $P(S)CF_3$ also exhibit this band. This band has recently been assigned by Hooge and Christen (8) to the P→S stretching vibration.

Observed bands are listed in Table I.

*In this and subsequent tables the symbol ? indicates that the cited band is beyond the normal range for this grouping, or is one of several possible choices. wk = Weak, sh = shoulder, br = broad.

†(P) indicates the spectrum was run as KBr pellet.

(*c*) C—H *Deformation*

Some additional observations have been made in this region, and the characteristic band positions are listed in Table II.

TABLE II
C—H Deformations

Group	Observed bands in cm^{-1}	
Et—P(O)	1460 1399	
Et—P(S)	1453 1389 sh	1381
Me_2N—P	1481 sh 1453	1412 v wk
Et_2N—P(S)	1453 1389 sh	1381
i-Pr_2N—P(S)	1462 1406	1389 sh or wk 1366

Me_2N—P(O) and Me_2N—P(S) absorb at the same positions but in P(S) compounds the 1481 cm^{-1} shoulder is only about one-half the intensity of the neighboring band, whereas in P(O) compounds it is of approximately equal intensity.

(*d*) P—O—(H) *and* P—O—(C) (*900 to 1100 cm*$^{-1}$)

1. EtO *Bands.*—In an earlier paper (7) the occurrence of two bands was mentioned, one between 1100 and 1000 cm^{-1} and another between 1000 and 900 cm^{-1}. Since most Et-containing compounds without EtO—P groupings have weak bands between 1000 and 900 cm^{-1} thought to be associated with a C—C vibration, it is postulated that in P—O—Et compounds this second band is intensified by interaction with the vibration giving rise to the strong absorption between 1000 and 1100 cm^{-1}. P—OEt groups and possibly P—N—C—C groups are the only ones examined that invariably give a band or shoulder in the 962–980 cm^{-1} region for pentavalent compounds and near 917 cm^{-1} for trivalent P compounds. β-Fluoroethoxy phosphorus compounds (two examples) have bands in this region.

2. Acidic compounds.—POOH and PSOH acids and salts generally have a band near 943 cm^{-1} which may be a symmetric P—O stretching for the ions and a P—O(H) stretching in the acids.

(*e*) P—C (*Alkyl*) *and* C—C (*Alkyl*) *Bands*

Examination of more than a dozen new compounds has confirmed the earlier assignments for P—methyl and P—ethyl bands (7). In addition, all compounds containing isopropyl groups (either P—O—*i*-Pr or P—N—*i*-Pr) also have a medium intensity band near 893 cm^{-1} for O—*i*-Pr and near 877 cm^{-1} for P—N—*i*-Pr compounds. P—N—*i*-Pr compounds also have two medium intensity bands in the 625–666 cm^{-1} region. These bands are listed in Table III.

(*f*) P—S—(H)

A number of new examples have been obtained and are listed with other dithioic acids in Table IV.

(*g*) P—S—(P)

Two compounds, although not analytically pure, obtained by reacting dicyclohexylcarbodiimide with diethyl and diisopropyl phosphorodithioic acids had spectra which were different from those of the starting material and the corresponding OOS-trialkyl

phosphorodithioate (which cannot be completely excluded as a by-product however) and contained weak diffuse bands near 488 cm^{-1}.

(*h*) P—Cl

New observations recorded in Table V confirm previous assignments.

(*i*) P—N—(C)

Holmstedt and Larsson (9) and Mayhood and Harvey (10) note two bands in P—N-containing compounds, one between 1006 and 989 cm^{-1} and the other between 730 and 704 cm^{-1}. They attribute the latter to P—N stretching, and Larsson (11) has shown that on hydrolysis of the P—N bond the intensity of this band is inversely proportional to the extent of hydrolysis. Mayhood and Harvey noted additional characteristic bands in the 2849–2747 cm^{-1} region for Me_2N and in the 2905–2890 cm^{-1} region for Et_2N compounds.

From electronegativity and mass considerations it is estimated that the P—N—(C) stretching vibration should be very close to the P—O(C) stretching bands. If the 1050 cm^{-1} bands can be attributed to the latter, the band near 1000 cm^{-1} would be the more likely candidate for the P—N stretching vibration. The "absence" of this band in Et_2N compounds noted by Mayhood and Harvey may be due to a perturbation by the 962 cm^{-1} C—C band mentioned earlier, and the P—N stretching is possibly contained in the 1030 cm^{-1} P—O or the 962 cm^{-1} C—C band. Et_2N—P compounds generally have three bands in this region near 1025, 952, and 926 cm^{-1}. In the P—N isopropyl compounds the band near 1000 cm^{-1} is again present.

Since the question of assignments of P—O—(C) and C—O—(P) stretching bands is still controversial, analogies based on these bands are not too useful for assigning P—N—(C) and C—N—(P) bands. The strong band near 943 cm^{-1} in all compounds containing a P—O—P link is consistent with the assignment of P—O—(C) to the 1000–1100 cm^{-1} band. This band is usually not symmetrical, and it is conceivable that the C—O—(P) band should also absorb in this region, particularly since the P—O—(C) band possesses a certain amount of "double bond character".

The 714–770 cm^{-1} band in our experience is mainly associated with N-dimethylamino groups, where it appears in the range 704–725 cm^{-1} for $Me_2NP(O)$ compounds and near 740–769 cm^{-1} for $Me_2NP(S)$ compounds. In $Et_2NP(S)$ compounds a band appears at 714–719 cm^{-1} and in *i*-Pr_2N—P(S) compounds the doublet mentioned previously in section (*e*) is found. From Mayhood and Harvey's work, it appears that the low frequency band is shifted bathochromically when C—P or additional Me_2NP links are present. Band positions are listed in Table VI.

(*j*) C—N—(P)

Bands attributed to groups containing this structure are very strong and tend to hide neighboring bands arising from similar R—O—alkyl structures. The position of these bands suggests that they arise from similar vibration modes as those for P—O—C compounds, previously discussed under R—O—(C) stretching.

1. Me_2N.—Mayhood and Harvey (10) mention bands at 1282–1316, 1190, and 1064 cm^{-1} as characteristic for C—N in Me_2N. All of these bands occur in regions where other absorptions take place so have to be interpreted with caution. Our examples are in agreement with these assignments.

2. Et_2N *and* *i*-Pr_2N.—Et_2N—P compounds all have intense bands near 1210 and 1175 cm^{-1} which are characteristic for this grouping. *i*-Pr_2N—P Compounds have a set

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of five medium intensity bands near 1200, 1183, 1160, 1139 sh, and 1129 cm^{-1}, in addition to those mentioned for other regions of the spectrum. All compounds examined with these two groups contained P(S) as well, so there is a possibility of shifts in the spectra of the corresponding P(O) compounds.

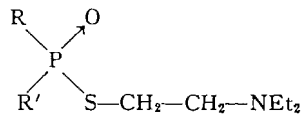
(*k*) C—S—(P)

In an earlier paper (7) we attributed a weak band near 641 cm^{-1} to the C—S(P) vibration. Further studies with compounds of type III have indicated that the intensity of a weak band between 667 and 714 cm^{-1} decreases with rupture of the P—S link. This band is tentatively assigned to the P—S—C grouping. It is weak or absent in compounds



III

where R = R′ = alkoxy, but stronger where R = alkyl and R′ = alkoxy (6), and very prominent where R = Me_2N and R′ = alkoxy (5). Of the phosphonates, Et—P compounds give the strongest band. This may result from either addition to the Et—P and $Me_2NP(O)$ bands or an interaction as described in section (*a*) with concomitant increase in intensity. The formation of a very strong doublet at 714 and 694 cm^{-1} [P—S(C) and $Me_2NP(O)$] (Table VI) with disappearance of bands near 820 and 746 cm^{-1} [P(S) and Me_2N—P(S)] is the most characteristic spectral change during the isomerism IV→V.

THE SYNTHESIS OF 2-KETOCYCLOHEXYLSUCCINIC ACID AND RELATED SUBSTANCES

IV. STUDIES ON SOME *CIS*- AND *TRANS*-FUSED γ-LACTONES[1]

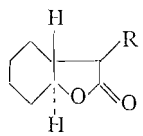
E. H. Charlesworth, H. J. Campbell, and D. L. Stachiw

ABSTRACT

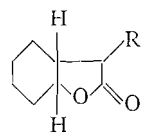
The *cis* and *trans* lactones of cyclohexanol-2-acetic acid and cyclohexanol-2-α-propionic acid have been subjected to alkaline hydrolysis to determine the relative ease of ring opening. In addition, a new synthesis by way of a Reformatsky reaction followed by dehydration and cyclization has been shown to yield the *cis* lactone. Finally, the first overtone band of the fundamental carbonyl stretching frequency has been identified.

INTRODUCTION

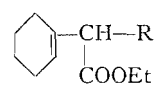
The reaction of sodiomalonic ester with cyclohexene oxide, followed by hydrolysis and decarboxylation, affords the *trans* lactone (I*a*) (1). An isomeric *cis* lactone (I*b*) is obtained by catalytic reduction of cyclohexanone-2-acetic acid (2).



I*a*, R = H
II*a*, R = CH_3



I*b*, R = H
II*b*, R = CH_3



III*a*, R = H
III*b*, R = CH_3

This investigation has shown the latter compound to be identical with the lactone obtained by the acid-catalyzed cyclization of ethyl cyclohexene-1-acetate (III*a*). This substance was produced by a Reformatsky reaction between cyclohexanone and ethyl bromoacetate, followed by dehydration of the β-hydroxy ester with phosphorus pentoxide.

The *cis* and *trans* configurations shown for the lactones follow from (*a*) the known stereochemistry of the reaction of nucleophiles with epoxides (3); (*b*) the known stereochemistry of the catalytic reduction of substituted cyclohexanones (4); and (*c*) the greater ease with which (I*b*) is formed from the corresponding hydroxy acid (2, cf. 5). Similar arguments apply to the lactones (II*a*) (6) and (II*b*), available by essentially the same reactions.

Further support for these configurational assignments is given by studies on the rates of ring opening by alkali. In both cases the isomer assigned the *trans* configuration hydrolyzed more rapidly, as shown in Fig. 1. This was to be expected in view of the less stable *trans* configuration. The greater stability of the methyl-substituted ring is in accordance with the many analogous cases in the literature (7).

All lactones showed peak absorption at about 2.8 μ in the infrared region accessible to the Beckmann D.K. recording spectrophotometer. This is undoubtedly the first overtone (8) of the powerful carbonyl adsorption band observed for (I*a*) and (I*b*) at 5.62 μ and 5.70 μ respectively, by Brewster and Kucera (9). As in the case of the fundamental frequencies, a wavelength shift was observed for these 2.8 μ bands indicating the more strained condition of the *trans* form. Rasmussen and Brattain (10) noticed absorption in this 2.8 μ region by several lactones, but suggested that it might be due to traces of

water. However, in a re-examination of the spectrum of γ-valerolactone in carbon tetrachloride, we find the peak at 2.8 μ to be unaffected by drying the solvent, while a less prominent band at 2.71 μ diminishes (but could not be eliminated altogether). The latter band is undoubtedly due to water, which in carbon tetrachloride alone causes absorption at 2.696 μ; the shift to longer wavelength in the presence of lactones is evidence of hydrogen-bonding between the two molecules.

EXPERIMENTAL

Reformatsky Reactions and Subsequent Procedure

Ethyl 1-Cyclohexanolacetate

Cyclohexanone (49 g), zinc filings (33 g), and dry benzene (200 ml) were placed in a 1-l. three-necked flask equipped with a stirrer and condenser. The mixture was heated to boiling and the addition of ethyl bromoacetate (167 g) containing a trace of iodine was begun. At the first sign of reaction, heating was discontinued, the stirrer started, and the addition continued at such a rate that moderate refluxing was maintained. Following addition of the ester, refluxing was continued for a further half hour. No attempt should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

be made to dissolve the unreacted zinc by prolonged heating, as this decreases the yield and quality of the product. A little ice was added to the cooled solution and with the stirrer running, cold sulphuric acid (250 ml, 6 *N*) was added slowly. After half an hour the benzene layer was separated, washed with water and sodium carbonate solution, and dried over calcium chloride. The benzene was removed and the ethyl 1-cyclohexanolacetate (66.5 g, 72% yield) distilled *in vacuo* at 108–118° C (11 mm). Auwers and Ellinger (11) report 141° C (33 mm) and Charlesworth *et al.* (12) 143–146° C (37 mm).

Ethyl Cyclohexene-1-acetate (III*a*)

Ethyl 1-cyclohexanolacetate (50 g) was dissolved in dry benzene (150 ml), and phosphorus pentoxide (40 g) was added to the solution. It was refluxed on the water bath for 3 hours and allowed to cool. The benzene solution was decanted, the porous residue rinsed twice with benzene (25-ml portions), and the washings combined with the main solution. The benzene was removed and the unsaturated ester (30.5 g, 68%) was distilled at 93–95° C (10 mm). Wallach (13) reports 100° C (12 mm).

Lactone of cis-Cyclohexanol-2-acetic Acid (I*b*)

Ethyl cyclohexene-1-acetate (10 g) and sulphuric acid (60 ml, 50% by volume) were heated on the water bath under reflux with stirring for 1 hour. By this time the oily layer had disappeared and the solution was yellow-orange in color. Only a small amount of polymeric material clinging to the walls of the flask was observed. The solution was allowed to cool, water (150 ml) was added, and the solution heated to boiling. It was cooled and extracted four times with ether (50-ml portions). The ethereal extract was washed with saturated salt solution, sodium carbonate solution, and thoroughly dried with anhydrous potassium carbonate. The ether was removed and distillation gave a colorless liquid (5.0 g, 60% yield) with a characteristic smell, which boiled at 129–130° C (13 mm); $n_D^{20} = 1.4784$. It was neutral to litmus and solidified at −20° C into long white needles. The original ethyl cyclohexene-1-acetate does not solidify at −80° C. Found: C, 69.1; H, 8.72%. Calc. for the lactone $C_8H_{12}O_2$: C, 68.6; H, 8.57%.

When crude cyclohexene-1-acetic acid (m.p. 34–36° C) prepared by the hydrolysis of the ester according to the directions of Wallach (13) was treated with 50% sulphuric acid according to the above directions, there was considerably more darkening than with the ester. Acidification of the sodium carbonate washings showed that very little unlactonized acid was left. Distillation gave the lactone in slightly smaller yield (43%), but with the same properties and constants as before. Found: C, 68.8; H, 8.97%. There was more dark viscous distillation residue than in the previous case.

When ethyl 1-cyclohexanolacetate was lactonized according to the above conditions there was considerably more dark polymeric material produced than in the previous cases. The lactone was isolable as before, but only in about 26% yield.

Ethyl α-(1-Cyclohexanol) Propionate

This ester was obtained in 76% yield in a Reformatsky reaction with ethyl α-bromopropionate. It distilled at 115–119° C (11 mm). Wallach reported 125–127° C (12 mm).

Ethyl Cyclohexene-1-α-propionate (III*b*)

This was obtained in 70% yield by dehydration of the previous ester. It boiled at 97–99° C (11 mm) or 68–70° C (1 mm).

Lactone of cis-Cyclohexanol-2-α-propionic Acid (II*b*)

This was obtained in 66% yield by cyclization of the previous unsaturated ester with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

50% sulphuric acid. It boiled at 131–134° C (11 mm); $n_D^{20} = 1.4756$. It did not solidify at −20° C. Found: C, 69.5; H, 9.24%. Calc. for $C_9H_{14}O_2$: C, 70.0; H, 9.15%.

γ-Lactones (Other than by Reformatsky Method)

The preparation of the *cis* lactones by the Reformatsky method (D. L. Stachiw) is described above. These samples were compared with *cis* lactones prepared from the corresponding keto acids by the catalytic hydrogenation method of Newman and Van der Werf (2) and found to be identical in all respects (Table I).

The *trans* lactones (I*a* and II*a*) were prepared by the method of Coffey (1) and of McRae, Charlesworth, and Alexander (6) from cyclohexene oxide.

γ-Lactone of trans-Cyclohexanol-2-methylmalonic Acid

This product was isolated prior to the decarboxylation step in the cyclohexene oxide synthesis of the *trans* lactone (II*a*). After recrystallization from benzene–ligroin, white crystals were obtained melting at 151–152° C. Found: C, 60.98; H, 7.22%; neut. equiv., 198.0. Calc. for $C_{10}H_{14}O_4$: C, 60.6; H, 7.12%; neut. equiv., 198.2.

trans-Cyclohexanol-2-acetic Acid

Upon alkaline hydrolysis and acidification of the *trans* lactone (I*a*) Newman and Van der Werf (2) obtained an acid of m.p. 105–106° C. They claimed that their product was not identical with the 97–102° melting acid obtained by Coffey (1) by hydrogen chloride treatment of the potassium salt of (I*a*) because the latter had a tendency to relactonize in solution. The two methods were repeated and, although several recrystallizations failed to raise the melting point of Coffey's product, a mixed melting point revealed little or no depression. It seems more reasonable, therefore, to view the instability of this low-melting acid as resulting merely from its impurity.

trans-Cyclohexanol-2-α-propionic Acid

The method previously outlined (2) was used to obtain an acid which, after recrystallization from water, melted at 110° C. Found: C, 63.0; H, 9.16%; neut. equiv., 173.5. Calc. for $C_9H_{16}O_3$: C, 62.8; H, 9.31%; neut. equiv., 172.2.

Hydrazide Derivatives

The method described by Coffey (1) was used. A 10% solution of the lactone in alcohol was boiled with hydrazine (95%) for a few minutes. When the solution was cooled, the hydrazide separated.

The Reformatsky-produced lactone (III*a* → I*b*) and the Newman *cis* lactone (I*b*) both gave a hydrazide which, when recrystallized from benzene–ligroin, melted at 140–141° C. Found: N, 16.12%. Calc. for $C_8H_{16}O_2N_2$: N, 16.26%. This derivative was far more soluble in polar and non-polar solvents than the corresponding *trans* hydrazide, which melted at 167.5°, as reported by Coffey (1).

The *trans* lactone of cyclohexanol-2-α-propionic acid (II*a*) gave a derivative which, upon recrystallization from water, melted at 191–192° C. Found: N, 14.76%. Calc. for $C_9H_{18}O_2N_2$: N, 15.04%.

The Reformatsky-produced *cis* lactone (III*b* → II*b*) yielded a hydrazide which, after two recrystallizations from benzene–ligroin, melted at 136–137° C. Found: N, 15.15%. Calc. for $C_9H_{18}O_2N_2$: N, 15.04%.

N-Benzylamide Derivatives

The method used was that of Dermer and King (14). The Reformatsky-produced lactone (1 g) was refluxed with benzylamine (3 ml) in the presence of ammonium chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

(1 g). The amide, when recrystallized from benzene–ligroin, melted at 97–98° C. Brewster and Kucera (9) reported an identical melting point for the N-benzylamide prepared from Newman's *cis* lactone.

Hydrolyses of γ-Lactones

The technique used was adapted from that described by Kendall, Osterberg, and MacKenzie (15) for the determination of the rate of ring opening of a γ-lactone. The lactone (1/200 mole) was dissolved in ethanol (25 ml) and introduced into a flask containing .0860 *N* sodium hydroxide (200 ml), stirred gently, and thermostated at 20° C. At periodic intervals, 20-ml portions were withdrawn and run into hydrochloric acid (20 ml, .0896 *N*). The excess acid was then titrated with standard alkali and the hydrolysis rate plotted (Fig. 1).

Infrared Spectra

A Beckmann D.K. recording spectrophotometer was used to investigate the small portion of the infrared region up to 2.85 μ. A pair of quartz cells were used whose 100% line did not deviate more than 3% on either side. The lactone samples were weighed directly into the cell and a measured amount of solvent carbon tetrachloride added.

ON THE COUPLING BETWEEN F^{19} AND H^1 NUCLEI IN *p*-FLUOROTOLUENE[1]

T. SCHAEFER

ABSTRACT

The proton and fluorine high resolution nuclear magnetic resonance spectra of *p*-fluorotoluene are discussed in terms of the case $A_2A_2'X$. The 4×4 submatrices are diagonalized in analytical form and therefore explicit values for all energy levels can be obtained. The spectra are consistent with $J_m^{HF} = J_o^{HF}$, which may be of theoretical interest.

INTRODUCTION

The analysis of high resolution nuclear magnetic resonance spectra normally yields values of the spin–spin coupling constants and of the relative chemical shifts of the resonating nuclei. However, in some special cases the distribution of lines in the spectrum depends only on the sum of the coupling constants. The simplest example of this occurs in the case ABB' (terminology of Bernstein, Pople, and Schneider (1)), in which two nuclei seeing a field H_B may be unequally coupled to a third nucleus seeing a field H_A. Richards and Schaefer (2) analyzed the proton spectrum of 2,5-dichloronitrobenzene and showed that the protons at position 3 and 4 have the same shift and that the line splittings are equal to the average of the coupling constant between protons 3 and 6 and between 4 and 6: $(1/2)(J_m^{HH}+J_p^{HH})$. It does not follow that $J_m^{HH} = J_p^{HH}$.

The proton and fluorine spectra of fluorobenzene indicate a negligible shift between the protons. From the shape of the spectra Baker (3) suggested that the H–F coupling constants are equal. In general the coupling decreases as the number of bonds between the nuclei increases. In view of the work of Gutowsky *et al.* (4) a more likely explanation appears to be that of Roux (5), who interprets the splittings as the average of the H–F coupling constants $(1/5)(2J_o^{HF}+2J_m^{HF}+J_p^{HF})$ without analyzing the spectrum. This interpretation contains the implicit assumption that the signs of the coupling constants are equal. This need not be so (4).

A glance at the proton and fluorine spectra of *p*-fluorotoluene (Fig. 1) would suggest that here also the splittings are given by the average of the H–F coupling constants $(1/2)(J_o^{HF}+J_m^{HF})$. It is the purpose of the present work to show from an explicit analysis that, in fact, $J_o^{HF} = J_m^{HF}$ for this compound. Such a result may be of theoretical interest.

EXPERIMENTAL

p-Fluorotoluene of known purity was kindly loaned by Dr. H. W. Thompson. The proton and fluorine spectra of the pure compound were taken on the high resolution spectrometer in Dr. R. E. Richards' laboratory at Oxford (6). The proton resonance occurs at 29.92000 Mc.p.s. The measurement of line separations is accurate to 1%, while the intensity measurements are good to about 10%.

RESULTS

The proton and fluorine spectra are shown in Fig. 1. The line separations are given in c.p.s. and the number of the lines is such as is convenient for the discussion below.

[1]*Manuscript received January 22, 1959.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.

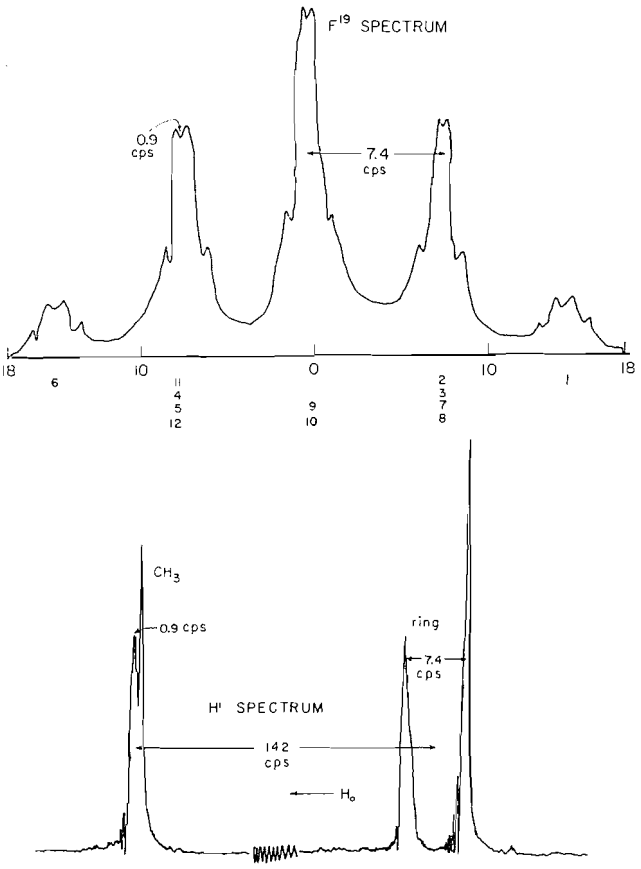

FIG. 1. Fluorine and proton resonance spectra of *p*-fluorotoluene.

DISCUSSION

The ring proton spectrum indicates a negligibly small chemical shift between the protons ortho and meta to the fluorine atom. The intensities of the two lines are the same within experimental error but one is slightly broader and this indicates a very small shift which can be neglected for our purposes. Protons in a methyl group situated ortho or para to a fluorine atom in the benzene ring are normally weakly coupled only to the fluorine nucleus but not to the ring protons (7). In the present instance this coupling is 0.9 c.p.s. Each line in the fluorine spectrum will therefore actually be a quadruplet, while the methyl resonance is a doublet. The splittings due to this coupling are the same in c.p.s., although, of course, not in gauss.

We are interested, however, primarily in the coupling between ring protons and the F^{19} nucleus. Information of a definite nature on this point requires the analysis of the case $A_2A_2'X$.

1. *Analysis of the Case* $A_2A_2'X$

We shall label the protons of the aromatic ring A and A' as shown in Fig. 2 and we shall call the fluorine atom X. The positions in the ring are numbered 1 to 5. Let the field experienced by nuclei A and A' be H_A such that in an applied field H_0, $H_A = H_0(1-\sigma_A)$, and similarly $H_x = H_0(1-\sigma_x)$. There are 10 coupling constants between these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

nuclei and from symmetry we can write:

$$J_{14} = J_{23}, \quad J_{45} = J_{35};$$
$$J_{25} = J_{15}, \quad J_{24} = J_{13};$$
$$J_{12} = J_{34}.$$

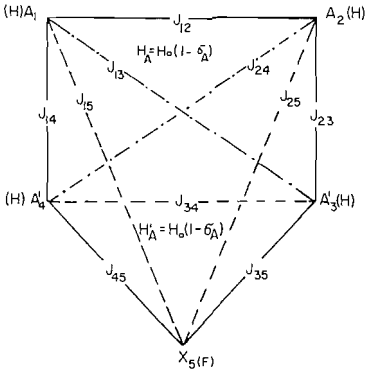

FIG. 2. Model for $A_2A_2'X$.

In the magnetic field H_0, a nucleus of magnetogyric ratio γ will have a nuclear resonance frequency ν_0, such that $\nu_0 = (\gamma/2\pi)H_0$. We shall use ν_0 for the resonance frequency for protons in the applied field and ν_0' for the frequency of the X nucleus resonance.

The initial wave functions are given in Table I together with the diagonal matrix elements. The off-diagonal elements are given in Table II. The matrix is similar to that given by Richards and Schaefer for the case A_2B_2X (8). It is given in full because reference will be made to specific matrix elements later on.

The initial choice of wave functions factorizes the secular determinant considerably. Further simplification arises from the condition that $\nu_0'\sigma_x$ is much larger than any of the spin coupling constants. This condition is of course amply fulfilled when X is fluorine. The determinant resolves itself into four 1×1, ten 2×2, and two 4×4 determinants.

Define positive quantities A, B, C, D, and angles θ, ϕ, ψ, γ, by:

$$\begin{aligned}
A\cos 2\theta &= (1/4)(J_{35}-J_{15}),\\
A\sin 2\theta &= (1/2)(J_{23}+J_{13});\\
B\cos 2\phi &= (1/4)(J_{15}-J_{35}),\\
B\sin 2\phi &= (1/2)(J_{23}+J_{13});\\
C\cos 2\psi &= (1/2)(J_{35}-J_{15}),\\
C\sin 2\psi &= (1/2)(J_{23}-J_{13});\\
D\cos 2\gamma &= (1/4)(J_{15}-J_{35}),\\
D\sin 2\gamma &= (1/2)(J_{13}-J_{23}).
\end{aligned} \qquad [1]$$

When the indicated orthogonal transformations are carried out, we obtain the stationary wave functions and energies given in Tables III and IV. Selection rules allow a maximum number of 110 transitions for the five nuclei. Of these, 46 are combination lines which, because of their weak intensity, will not be further considered. This leaves 16 transitions originating with the X nuclei, 12 of which can now be written down explicitly, whatever the value of the coupling constants. Similarly the A and A' nuclei give rise to 48 lines and 24 of these may now be explicitly tabulated. The 36 transitions are given in Tables V and VI. Later on we shall find explicit values for the other transitions for *p*-fluorotoluene in terms of the experimental parameters.

37	$30' \rightarrow 25$	$+(1/4)(2J_{13}-2J_{23}+J_{15}+J_{35})+C$	$1+\sin 2\psi$
38	$30' \rightarrow 26$	$+(1/4)(-2J_{13}+2J_{23}+J_{15}+J_{35})+C$	$1-\sin 2\psi$
39	$32' \rightarrow 28$	$+(1/4)(-2J_{13}+2J_{32}-J_{15}-J_{35})+D$	$1+\sin 2\gamma$
40	$32' \rightarrow 27$	$+(1/4)(2J_{13}-2J_{23}-J_{15}-J_{35})+D$	$1-\sin 2\gamma$

A possible assignment is shown in Fig. 1. The four transitions involving the F^{19} nucleus which have not yet been calculated will have relative intensities of one and zero energies relative to $\nu_0'(1-\sigma_x)$ for consistency. This remains to be shown.

(*b*) *Proton Resonance Spectrum*

Of the 24 transitions in Table VI, 12 are of nonzero intensity under the conditions [2]. It is to be noted that these have energies $\pm(1/4)(J_{15}+J_{35})$ relative to $\nu_0(1-\sigma_A)$.

In order to calculate energies and intensities for the other 24 proton lines and the 4 flourine lines, the two 4×4 determinants must be solved. This is usually done numerically and would involve an assumption as to the values of J_{23}, J_{13}, and J_{12}. However, a solution in analytical form can be achieved in this case on the assumption that $J_{13} \leqslant 0.5$ c.p.s. and that J_{13} can therefore be neglected. This assumption is in accord with the same result obtained in a variety of other aromatic compounds. Orthogonal matrices can then be found which will diagonalize the two 4×4 matrices. The energies and corresponding eigenfunctions found in this way are given in Table VII. In Table VII quantities a, b, c, d, are related to experimental parameters by:

$$\begin{aligned} a &= J_{12}(-J_{23}+K)^{-1}, & b &= J_{23}(-J_{12}+K)^{-1};\\ c &= J_{12}(J_{23}+K)^{-1}, & d &= J_{23}(J_{12}+K)^{-1}; \end{aligned}$$

with

$$K = (J_{12}^2+J_{23}^2-J_{12}J_{23})^{\frac{1}{2}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Remembering that $\sin 2\phi = \sin 2\theta = 1$ and noting that $(1-c-d) = (1-ac-bd) = 0$, the only transitions with nonzero intensity involving these eight states are given in Table VIII. None of these depend on J_{12}. Counting of intensities in Tables V–VIII shows that the distribution and intensity of the predicted lines tallies with experiment. The predicted spectrum depends explicitly on the assumption that $J_o^{HF} = J_m^{HF}$.

THE LIMITING CONDUCTANCE OF AQUEOUS SOLUTIONS OF POTASSIUM IODATE, POTASSIUM CHLORATE, AND SILVER NITRATE AT 35.00° C[1]

E. Bock and A. N. Campbell

ABSTRACT

Measurements have been made of the equivalent conductances of aqueous solutions of potassium iodate, potassium chlorate, and silver nitrate at 35.00° C at concentrations ranging from 0.8×10^{-4} to 16×10^{-4} N. From these, the limiting equivalent conductances and association constants A as obtained by the use of the Fuoss–Shedlovsky extrapolation procedure were found to be at 35.0° C:

$\Lambda_0KIO_3 = 138.62$ mhos, $A = 0.8$ l.,
$\Lambda_0KClO_3 = 165.70$ mhos, $A = 0.5$ l.,
$\Lambda_0AgNO_3 = 161.53$ mhos, $A = 0.9$ l.

INTRODUCTION

The fact that aqueous solutions of some salts, especially salts of the oxyacids, behave as moderately strong electrolytes has long been recognized. Several attempts have been made to calculate the association constants of these electrolytes, from conductance data. The various suggested treatments of the experimental data differ from one another in the way in which the effect of ionic attraction on the equivalent conductance is calculated. Thus, in the method proposed by Davis (1), K, the dissociation constant, is obtained through the use of a modified Ostwald dilution law, viz.,

$$K = \frac{\Lambda^2 f_\pm^2}{\Lambda'(\Lambda' - \Lambda)}. \qquad [1]$$

Here Λ is the experimentally determined equivalent conductance at concentration c, Λ' the conductance of one equivalent of free ions, calculated by means of an empirical equation, and f the mean activity coefficient of the electrolyte, usually obtained by means of the Debye-Hückel relationship or modification thereof.

Another treatment, that adopted in the present paper, was suggested by Fuoss and Shedlovsky (2). These authors use a slightly modified Onsager equation in which resistance instead of conductance is considered in its derivation, in combination with the law of mass action. The association constant as well as the limiting equivalent conductance is obtained from a plot of ΛS vs. $c(\Lambda^2 S^2 f_\pm^2)$ where

$$\Lambda S = \Lambda_0 - [c(\Lambda^2 S^2 f_\pm^2)/K\Lambda_0]. \qquad [2]$$

Here Λ, Λ_0, c, and $f_\pm$ have their usual meaning. S is the Shedlovsky (2) function and K is the dissociation constant.

In the present paper Λ_0 and A for the three electrolytes were determined through the use of eq. [2]; the activity coefficient in each case was calculated from the Debye–Hückel approximation

$$\log_{10} f_\pm = -0.5190\sqrt{(\theta c)} \qquad [3]$$

where $\theta = S(\Lambda/\Lambda_0)$ is the degree of dissociation.

EXPERIMENTAL

The experimental technique has been described elsewhere (3). Potassium iodate and potassium chlorate, both Fisher certified reagents of the highest purity, whose total impurities—mostly ionic in nature—were less than 0.01%, were dried carefully at 150° C and stored over phosphorus pentoxide. The silver nitrate, also a high quality Fisher certified reagent, was fused in darkness and also stored over phosphorus pentoxide.

EXPERIMENTAL RESULTS

Our results are contained in Tables I, II, and III given below.

DISCUSSION

Potassium Iodate

When the results for potassium iodate given in Table I are plotted in the form Λ versus $\sqrt{c}$ the usual straight line plot is obtained. When the best straight line (derived by the method of least squares) is drawn and extrapolated to zero concentration Λ_0 results as 138.62_2 mhos and the slope of the line has a value of -108.03. The Onsager tangent on the other hand has the value -107.43. Thus, to use the language of Fuoss (4), the phoreogram is catabatic to the latter, indicating ion association. When the conductance results are plotted, using eq. [2], a straight line plot again results which on extrapolation yields $\Lambda_0 = 138.61_7$ mhos. The mean deviation from the line, again obtained by the method of least squares as were all subsequent lines, is less than 0.01 of a ΛS unit. The difference between the two Λ_0's is within the experimental error, which is estimated to be 0.01% to 0.02%. This agreement is not surprising since as $c \rightarrow 0$, $S \rightarrow \mathbf{1}$ and $\Lambda \rightarrow \Lambda_0$, so that the intercepts should be identical. Taking the value for the limiting conductance for the potassium ion to be 88.21 mhos (5) the limiting conductance of the iodate ion follows as 50.41 mhos. The association constant as obtained from the slope of the graph of eq. [2] is equal to 0.8 l. It should be pointed out, however, that this association constant is forced to carry all the inadequacy or approximations of eq. [2]. A more realistic association constant and perhaps a slightly better value for Λ_0 would have been obtained

*These points were not included in the least square calculation since their deviation from the mean is greater than three times the mean deviation.

if the recently proposed treatment of conductance data, derived by Fuoss (6) and based on the latest extension of the conductance equation by Fuoss and Onsager (7), had been employed, but this treatment requires, especially for moderately strong electrolytes whose association constant approaches unity, conductance data in low dielectric constant media, and these are at present lacking. The value of Λ_0 may be taken with confidence to be within 0.02% of its "true" value, but the association constant gives only the order of magnitude.

We greatly regret that in our recent paper (3) on the conductance of potassium iodate at 25° C we overlooked the work of Krieger and Kilpatrick (8), Monk (9), and Spiro (10) on the same subject. We did not encounter the difficulties in the dilute region of concentration experienced by Krieger and Kilpatrick and by Monk. Neither did we observe a scatter as noticed by the former workers nor did we find a change in slope of the curve ΛS vs. $c(\Lambda^2 S^2 f_\pm^2)$ with increase in dilution as reported by Monk, either at 25° C or at 35° C. The mean deviation of ΛS when plotted versus $c(\Lambda^2 S^2 f_\pm^2)$ from a straight line was found to be less than 0.01 of a ΛS unit. The dissociation constant for potassium iodate at 25° C calculated from our data results as 2.0 l.$^{-1}$, a value intermediate between those obtained by the above workers.

Potassium Chlorate and Silver Nitrate

The behavior of these electrolytes was found to be, in general, similar to that of potassium iodate. In both cases the limiting conductances, as obtained by the two

*See footnote of Table I.

extrapolation methods, agree to within the experimental error. Thus for potassium chlorate, Λ_0 derived from the Λ vs. $\sqrt{c}$ plot is 165.45_3 mhos whereas Λ_0 obtained by extrapolation of eq. [2] is 165.47 mhos. Similarly for silver nitrate, Λ_0 obtained by the former procedure, 161.55_3 mhos, is identical within the experimental error, with Λ_0 derived by employing the latter procedure, viz. 161.53_1 mhos. The association constants for potassium chlorate and silver nitrate were found to be 0.5 l. and 0.9 l. respectively. The phoreogram for potassium chlorate was found to be anabatic to the Onsager tangent. Yet the fact that A is equal to 0.5 would seem to indicate that potassium chlorate is associated. A similar behavior was noticed by Fuoss and Kraus (11) for sodium bromate. Moreover, if conductance values for potassium chloride (12), a salt usually taken to be completely dissociated in dilute aqueous solutions, are plotted using eq. [2] a very small A, in fact, one approaching zero, is obtained. Thus it seems that whenever

*See footnote of Table I.

eq. [2] yields a slope of reasonable magnitude one is justified in suspecting ion association. For silver nitrate the phoreogram was found to be catabatic to the Onsager tangent, indicating ion association unequivocally.

CONCLUSION

Since the graph obtained by plotting eq. [2] is much more sensitive to errors, especially in the ordinates, than is the graph obtained by plotting Λ vs. $\sqrt{c}$ it is suggested that the limiting equivalent conductance derived from the former be taken as being closer to its "true" value than that derived from the latter. Subtracting from the limiting conductance of potassium iodate and of potassium chlorate the limiting conductance of the potassium ion (viz. 88.2_1 mhos) and from that of silver nitrate the known value of the nitrate ion (13) (viz. 85.48 mhos) there result the following individual limiting ionic conductances at 35.00° C:

$$\lambda_0 IO_3^- = 50.41 \text{ mhos}$$
$$\lambda_0 ClO_3^- = 77.50 \text{ mhos}$$
$$\lambda_0 Ag^+ = 76.05 \text{ mhos}.$$

THE CONSTITUTION OF A HEMICELLULOSE FROM SUGAR MAPLE (ACER SACCHARUM)[1]

T. E. TIMELL

ABSTRACT

Partial hydrolysis of the main hemicellulose constituent of sugar maple (*Acer saccharum*) has yielded D-xylose, D-galacturonic acid, 4-*O*-methyl-D-glucuronic acid, and 2-*O*-(4-*O*-methyl-α-D-glucosyluronic acid)-D-xylose. Hydrolysis of the fully methylated polysaccharide gave a mixture of 2-*O*- and 3-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2,3,4-tri-*O*-methyl-D-xylose, and 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucosyluronic acid)-3-*O*-methyl-D-xylose in a mole ratio of 3:111:1:12. The number-average degrees of polymerization of the native and the methylated polysaccharide were 205 and 149, respectively. These data indicate that the hemicellulose is composed of a linear chain of 1,4-linked β-D-xylose residues and that on the average every tenth residue of the chain carries a terminal 4-*O*-methyl-D-glucuronic acid residue attached through its C_2. The structure of the polysaccharide is similar to that of the main hemicellulose component of European beech, white birch, and yellow birch.

Sugar maple is an important hardwood species in the northeastern part of this continent. Ritter and co-workers (1, 2) have studied the general composition of various hemicellulose fractions from this wood and chromatographic evidence for the presence of 4-*O*-methyl glucuronic acid has been reported by Nelson and Schuerch (3). The structure of the same hemicellulose has been studied by Neubauer and Purves (4), who concluded that the polysaccharide was composed of a branched backbone of 1,4-linked xylose residues, some of which carried terminal *O*-methyl glucuronic acid residues. In a previous investigation (5) the molecular properties of a native cellulose from sugar maple were studied. The present paper is concerned with the constitution and properties of the main hemicellulose component of this species.

RESULTS AND DISCUSSION

The high pentosan content of the wood (18.5%) indicated that the preponderant hemicellulose was a xylan. When the wood was extracted with alkali, a hemicellulose was obtained in a yield of 12.4%, giving D-xylose and three uronic acid compounds on partial hydrolysis. The sugar acids were separated from the xylose on an anion exchange resin and the mixture obtained was resolved on a charcoal column to yield galacturonic acid, 4-*O*-methyl glucuronic acid, and an aldobiouronic acid. The hexuronic acids were identified chromatographically whereas the structure of the aldobiouronic acid was proved by the following experiments.

Reduction of the methyl glycoside methyl ester of the aldobiouronic acid followed by hydrolysis gave D-xylose and 4-*O*-methyl-D-glucose. When the neutral disaccharide was methylated to completion and hydrolyzed, 3,4-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose were obtained. This evidence, together with the specific rotation of the compound (+100°) (6), showed that the acid was 2-*O*-(4-*O*-methyl-α-D-glucosyluronic acid)-D-xylose.

Methanolysis of the fully methylated hemicellulose gave a mixture of glycosides which was saponified and resolved into an acidic and a neutral fraction on an exchange resin. The acid fraction contained only one compound, the ester glycoside of which was reduced with lithium aluminum hydride to yield a crystalline disaccharide, identified as methyl

[1]*Manuscript received January 20, 1959.*
Contribution from the Division of Industrial and Cellulose Chemistry, McGill University, and the Wood Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Quebec.

2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucosyl)-3-*O*-methyl-D-xylopyranoside. Hydrolysis of this compound gave the expected 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose.

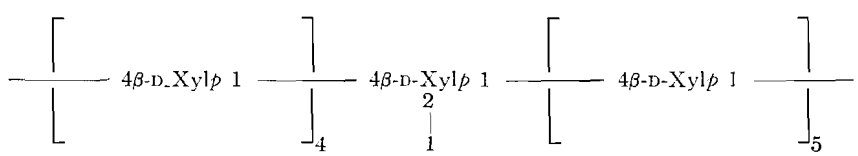
The mixture of neutral glycosides was hydrolyzed and resolved by paper chromatography to yield a mixture of 2-*O*- and 3-*O*-methyl-D-xylose, which could be resolved by paper ionophoresis, 2,3-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-xylose. A quantitative estimation (7), together with the weight of the acidic fraction, indicated a molar ratio of 3:111:1:12 between the mono-, di-, and tri-*O*-methylated xyloses and the latter.

The large quantity of 2,3-di-*O*-methyl-D-xylose, together with the high negative rotation (−80°) of the hemicellulose as well as its consumption of periodate, indicated the presence of 1,4-linked β-D-xylose residues, while the 2,3,4-tri-*O*-methyl-D-xylose undoubtedly originated from the non-reducing end groups. Since no monouronic acids were formed during the methanolysis, the presence of the mono-*O*-methyl xyloses could be accounted for only by incomplete methylation, demethylation, or branching. The fact that their number exceeded that of the tri-*O*-methyl xylose made it certain that branching was not the only factor involved. When the molecular weight of the methylated hemicellulose was determined by osmometry, a value of 27,300 was obtained, corresponding to a number-average degree of polymerization of 149. This was a value somewhat higher than that indicated by the number of non-reducing end groups present (127) and showed that no branching was involved. The mono-*O*-methyl xyloses were therefore artifacts, probably caused by demethylation (8, 9).

The structure of the aldobiouronic acid indicated that the hemicellulose contained residues of 4-*O*-methyl-α-D-glucuronic acid linked by 1,2-glycosidic bonds to the anhydroxylose units. The fact that the 4-hydroxyl was unsubstituted in the xylose moiety of the partly methylated aldobiouronic acid obtained from the methylated hemicellulose, while a methoxyl group was present in this position in the corresponding, fully methylated acid, showed that the acid groups were linked *directly* to the xylan framework. The methoxyl and uronic anhydride content, the yield of aldobiouronic acid from the methylated polysaccharide, and the amount of periodate consumed on oxidation of the hemicellulose all indicated the presence of an average number of 10 xylose residues per acid side chain.

The number-average molecular weight of the acetate derivative of the hemicellulose was 49,300, corresponding to a degree of polymerization of 205. Values of 205 and 217 were obtained from viscosity measurements in cupriethylenediamine and dimethyl sulphoxide, respectively.

Summarizing the above evidence, a tentative structure can now be assigned to the 4-*O*-methyl glucuronoxylan present in sugar maple wood. This polysaccharide consists of a linear framework of approximately 200 1,4-linked β-D-xylose residues. Every tenth residue on the average is linked through its 2-position to a single side chain of 4-*O*-methyl-α-D-glucuronic acid. From recent evidence (10, 11) it appears probable that the polysaccharide contains acetyl groups in its native state and the possibility that at least a portion of it is linked to lignin cannot be excluded (12, 13).



4-*O*-Me-α-D-G*p*A

The present polysaccharide is very similar to the 4-*O*-methyl glucuronoxylans previously isolated from the woods of European beech (14), white birch (15), and yellow birch (16) and it is also similar to the main hemicellulose components of Finnish birch (17) and white elm (18). The corresponding polysaccharide of American beech (19), on the other hand, has been claimed to possess a branched xylan backbone and that of trembling aspen (20) evidently contains terminal L-arabofuranose residues. The number-average molecular weight of the hemicellulose is approximately the same as that of other hardwood glucuronoxylans so far studied (21). It is not known, however, whether the alkali used in the extraction of the hemicellulose from the wood has any noticeable depolymerizing effect (22, 23), nor has the weight-average degree of polymerization been determined for any native, undegraded xylan.

EXPERIMENTAL

General experimental conditions were the same as described previously (24). Solvents (v/v) used for separating sugars on the paper chromatogram were (A) ethyl acetate – acetic acid – water (9:2:2), (B) butan-1-ol – pyridine – water (10:3:3), (C) butan-1-ol – ethanol – water (40:11:19), and (D) butan-2-one – water (89:11).

Composition of the Wood

Analyses according to standard methods (9, 15) indicated the following composition of the wood: pentosan (18.5), lignin (22.7), acetyl (2.9), ash (0.3), uronic anhydride (4.4), galactan (trace), glucan (51.7), mannan (2.3), araban (0.8), and xylan (14.8%).

Isolation of the Hemicellulose

Extractive-free wood meal from a sound, 25-year-old specimen of sugar maple* (500 g, 40–60 mesh) was exhaustively extracted by shaking with 24% (w/w) aqueous potassium hydroxide (3.5 liters) as described previously (15, 16, 24). The recovered product was dried from petroleum ether *in vacuo* to give 57 g (12.3%) of a white powder. Anal.: uronic anhydride, 12.05%; methoxyl, 2.09%; $[\alpha]_D^{20}$ −80° (*c*, 1.0 in 2.5% sodium hydroxide). Examination by paper chromatography (solvents A and B) of the hydrolyzate of the hemicellulose suggested the presence of xylose and three uronic acids, two of which corresponded chromatographically to galacturonic acid and 4-*O*-methyl glucuronic acid.

Isolation of the Aldobiouronic Acid

Wood meal (500 g) was treated with 72% sulphuric acid (100 ml) for 24 hours after which the solution was diluted to 2 liters and boiled under reflux for 10 hours. After neutralization with barium hydroxide, filtration through Celite, and evaporation, the solution was added to the top of a cocoanut charcoal column (7.5×25 cm) (25). Most of the neutral sugars were removed with water. Elution with 2% aqueous ethanol removed galacturonic acid and a portion of the 4-*O*-methyl glucuronic acid. Further elution with 4% and 10% ethanol yielded a chromatographically pure aldobiouronic acid (5 g). Anal. Calc. for $C_{12}H_{20}O_{11}$: OCH_3, 9.1; equiv. wt., 340. Found: OCH_3, 9.1; equiv. wt., 326; $[\alpha]_D^{20}$ +100° (*c*, 1.0 in water).

Identification of Hydrolysis Products from the Reduced Aldobiouronic Acid

The aldobiouronic acid (4 g) was boiled under reflux with 2.5% methanolic hydrogen chloride (150 ml) for 7 hours. After neutralization with silver carbonate and filtration through Celite and evaporation, the sirupy ester glycoside was reduced with lithium

**Kindly donated by Mr. Ken Murray, Fitch Bay, Quebec.*

aluminum hydride (4 g) (26) in dry tetrahydrofuran (100 ml) to yield a sirup (3.6 g). A portion of the reduced glycoside (1.2 g) was hydrolyzed with *N* sulphuric acid to give a sugar mixture (1.1 g) which was resolved on sheets of filter paper (solvent A) to yield D-xylose $[\alpha]_D^{20}$ +18° (*c*, 1.0 in water), and 4-*O*-methyl-D-glucose, $[\alpha]_D^{20}$ +58° (*c*, 1.0 in water). The xylose dibenzylidene dimethyl acetal (27) had m.p. and mixed m.p. 210° C and the 4-*O*-methyl-D-glucosazone had m.p. and mixed m.p. 157° C. The infrared spectrum of the latter was identical with that of an authentic specimen.

Methylation and Hydrolysis of the Ester Glycoside of the Aldobiouronic Acid

The ester glycoside of the aldobiouronic acid (2.0 g) was dissolved in dry dimethyl formamide (100 ml) and shaken in the dark with methyl iodide (10 ml) and silver oxide (10 g) (28). The product was recovered as described by Kuhn (28). After addition of chloroform to the reaction mixture, silver salts were removed by filtration. Extraction with aqueous potassium cyanide followed by three extractions with water gave a chloroform solution which was dried with anhydrous sodium sulphate and evaporated to dryness to yield a yellow sirup. Anal. Calc. for $C_{18}H_{34}O_{10}$: OCH_3, 52.8%. Found: OCH_3, 51.0%. The ester glycoside was reduced with lithium aluminum hydride to yield a sugar mixture which was resolved by paper chromatography (solvent C) to give two compounds, chromatographically indistinguishable from a di-*O*-methyl xylose (110 mg) and a tetra-*O*-methyl glucose (130 mg).

*Identification of 3,4-Di-O-methyl-*D*-xylose and 2,3,4,6-Tetra-O-methyl-*D*-glucose*

The di-*O*-methyl xylose, $[\alpha]_D^{20}$ +15° (*c*, 1.0 in water), gave a crystalline 3,4-di-*O*-methyl-*N*-phenyl-D-xylosylamine, m.p. 115° C (29). The tetra-*O*-methyl glucose, $[\alpha]_D^{20}$ +83° (*c*, 3.1 in water), crystallized, melting point and mixed melting point after three recrystallizations from petroleum ether 88–90° C. Anal. Calc. for $C_{10}H_{20}O_6$: OCH_3, 52.7%. Found: OCH_3, 50.0%. The 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine had m.p. and mixed m.p. 135–136° C.

Methylation of the Hemicellulose

The hemicellulose (20 g) was dissolved in 40% (w/w) aqueous sodium hydroxide (300 ml) in an atmosphere of nitrogen, after which dimethyl sulphate (200 ml) was added dropwise at 0° C over a period of 8 hours. This treatment was repeated six times at room temperature. The recovered product was dissolved in tetrahydrofuran (2 liters) and powdered sodium hydroxide (200 g) and dimethyl sulphate (300 ml) were added (30). This treatment was repeated twice. The solvent was removed by distillation, and the remainder was washed with water and dissolved in chloroform. The solution was dried and poured into petroleum ether to yield a white, fluffy product (22 g). Anal. Calc. for the fully methylated sodium salt of the hemicellulose: OCH_3, 37.3%. Found: OCH_3, 37.8%. The infrared spectrum indicated the absence of hydroxyl groups.

Hydrolysis and Separation of Acidic and Neutral Sugars

Methylated hemicellulose (10 g) was treated with methanolic hydrogen chloride and the mixture of glycosides (10.8 g) was de-esterified with barium hydroxide (31). The mixture obtained was resolved on a column of Dowex 1-X4 anion exchange resin (acetate form) to yield a mixture of neutral sugars (7.8 g) and an acidic compound (1.7 g).

*Identification of Methyl 2-O-(2,3,4-Tri-O-methyl-α-*D*-glucosyl)-3-O-methyl-α,β-*D*-xylopyranoside*

The above acid compound was converted to its methyl ester methyl glycoside which was reduced with lithium aluminum hydride. The colorless sirup obtained crystallized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

immediately, m.p. and mixed m.p. 167–168° C after recrystallization from ethyl acetate. Anal. Calc. for $C_{16}H_{30}O_{10}$: OCH_3, 40.6%. Found: OCH_3, 40.4%; $[\alpha]_D^{20}$ +93° (*c*, 1.0 in water). The infrared spectrum and the X-ray powder diagram were identical with those of an authentic (31) specimen of methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)-3-*O*-methyl-α,β-D-xylopyranoside.

A portion of the disaccharide (600 mg) was hydrolyzed to yield a mixture of methylated sugars which was resolved on the paper chromatogram (solvent D), giving two compounds chromatographically identical with a mono-*O*-methyl xylose and a tri-*O*-methyl glucose. 3-*O*-Methyl-D-xylose, $[\alpha]_D^{20}$ +15° (*c*, 1.0 in water) gave a crystalline aniline derivative, m.p. 134°. The 2,3,4-tri-*O*-methyl-D-glucose had $[\alpha]_D^{20}$ +78° (*c*, 1.0 in water) and aniline derivative with m.p. and mixed m.p. 143°.

Separation and Identification of the Neutral Components

The mixture of neutral glycosides was hydrolyzed and resolved by paper chromatography (solvent D) to yield three fractions. One was a mixture of 2-*O*- and 3-*O*-methyl-D-xylose, resolvable by paper ionophoresis in a borate buffer (32). The main fraction consisted of 2,3-di-*O*-methyl-D-xylose, $[\alpha]_D^{20}$ +25° (*c*, 3.0 in water). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.9%. Found: OCH_3, 35.0%. The 2,3-di-*O*-methyl-*N*-phenyl-D-xylopyranosylamine had m.p. 126–127° C. The last fraction, 2,3,4-tri-*O*-methyl-D-xylose could not be induced to crystallize. Anal. Calc. for $C_8H_{16}O_5$: OCH_3, 48.4%. Found: OCH_3, 47.2%. The infrared spectrum of the sirupy aniline derivative was indistinguishable from that of an authentic specimen.

Quantitative Analysis of the Neutral Components

A small portion of the mixture of neutral sugars was resolved on the paper chromatogram with solvent mixture C. Each paper strip was eluted with water and the concentration of the sugar was determined by the *o*-aminodiphenyl method (7). The average value of three determinations was used. With solvent system D high paper blanks were obtained.

Periodate Oxidation of the Hemicellulose

Periodate oxidations were carried out in the dark with 0.05 *M* solutions of both trisodium paraperiodate and sodium metaperiodate. The amount of periodate consumed, as determined by the arsenite method, was extrapolated to zero time, giving in both cases a consumption of 10.5 mole of oxidant per repeating unit.

Acetylation of the Hemicellulose

Acetylation of the hemicellulose was carried out as described previously (24) essentially according to the method of Carson and Maclay (33). Two acetylations gave a product soluble in chloroform–ethanol (9:1 v/v). Anal. Calc. for the fully acetylated hemicellulose: acetyl, 37.8%. Found: acetyl, 38.3%.

Determination of Molecular Weights

The molecular weights of the original hemicellulose and of its methyl derivative were carried out by osmotic pressure measurements as described elsewhere (24, 34). The results obtained are presented in Table I. Degrees of polymerization were calculated as shown earlier (15).

Estimation of the Intrinsic Viscosity of the Hemicellulose

Intrinsic viscosities were determined with a Craig–Henderson (35) viscometer in *M* cupriethylenediamine and in anhydrous dimethyl sulphoxide as described elsewhere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

(34). The relationship $\bar{P}_n = K[\eta]$, where $[\eta]$ was the intrinsic viscosity and K was 212 and 346, respectively, was used for estimating the degree of polymerization ($\bar{P}_n$).

ISOTHERMS OF BROMINE ON GRAPHITE[1]

J. G. HOOLEY

ABSTRACT

The isotherms of bromine on eight carbon blacks and on natural graphite have been related to the known structures of these materials. The surface areas can be calculated from the adsorption isotherms and the size of the graphite crystals can be estimated from the extent of hysteresis on desorption. The isosteric heats of adsorption on the surface and between the layers are each 11 kcal mole^{-1}. The formation of residue compounds displaces the isotherms equally at all pressures.

INTRODUCTION

The isotherm of bromine on a natural graphite at 28.8° C has been determined by Reyerson (6) along with the changes in magnetic susceptibility that occur during the process. The purpose of the present work was to study the isotherm at various temperatures and to include carbon blacks of various areas and crystal sizes. A recording vacuum thermobalance (3) and spoon gauge (4) were specially designed for such measurements with bromine and other corrosive vapors.

MATERIALS

1. Carbon black.—G. Cabot Inc., of Boston, donated samples from three sources, each heat-treated to two or three different temperatures. The data supplied with them included an estimate from X-ray data of the average thickness L_c and width L_a of the volumes in which the carbon atoms had the graphite structure. The area of the aggregates of these crystals per gram as calculated from electron microscope data and from B.E.T. adsorption data for N_2 was also given. The effect of heat-treatment on these properties is described elsewhere (7).

2. Graphite.—Natural crystals about 2 mm across were obtained through G. Cabot Inc. from a deposit near Willsboro, N.Y.

3. Bromine.—Analytical material was doubly distilled.

PROCEDURE

A 0.5- to 1-gram sample was weighed, suspended in the balance, evacuated to 0.001 cm, and thermostated to the desired temperature. The positions of the weight- and pressure-measuring transformers were then adjusted and the primary voltage to be applied to each was selected to give suitable sensitivities—all as described in refs. 3 and 4. When the recorded weight had settled down to a constant value, bromine was admitted at any desired pressure up to the saturation value. The pressure and the sample weight were then followed as a function of time by application of the known conversion factors to the millivolt records. At any time the bromine pressure could be increased by opening the tap to the reservoir or decreased by opening the tap to a liquid nitrogen trap at 0.001 cm. Leaving this latter tap open is referred to as reducing the pressure to zero.

For all runs a weight sensitivity of 3.4 mv mg^{-1} and a pressure sensitivity of 3.6 mv mm^{-1} was used. With no sample on the balance pan, any variation in the weight record was less than 0.2 mv over a period of several days. With a sample at 0.001 cm the record was equally constant after any initial loss of volatile material. The buoyancy correction

[1]*Manuscript received January 26, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, with financial assistance from the National Research Council of Canada.

for the spring-pan system was found to be 0.33 mg per cm of mercury of bromine vapor with the reactor tube at 80° C or 25° C. No buoyancy correction was applied to the sample itself because its maximum value would be equivalent to only 0.1 atoms of bromine per 1000 carbon atoms. Adsorption and desorption isotherms were determined at temperatures from 0° C to 80° C. The uptake was plotted as gram atoms of bromine per 1000 g-atoms of carbon and will be referred to as the number of bromine atoms.

RESULTS

The following aspects of the isotherms are related where possible to other known properties of the adsorbent.

1. Hysteresis

(a) Natural Graphite, Untreated

This material showed rapid, reversible but only relatively slight bromine adsorption below a critical pressure dependent on temperature. Thus at 25° C less than 0.5 atoms of bromine (per 1000 carbon atoms) were adsorbed below 1 cm pressure. The critical pressures at 50°, 60°, and 80° C were 6 cm, 12 cm, and above 18 cm, respectively. Above these critical pressures bromine was very slowly adsorbed to a maximum value which increased with the pressure and with the reciprocal of temperature. Then on reducing the pressure, bromine slowly left the material until at zero pressure an amount remained that was independent of time and of temperatures up to 120° C. This is the residue compound studied by Hennig (2). When the cycles were repeated with a single sample of the residue compound obtained by debromination from 15 cm at 25° C the points in Fig. 1 were obtained. Below the critical pressure at a given temperature, less than 0.5 additional bromine atoms were adsorbed and above this pressure a slow adsorption occurred, followed by a hysteresis loop on desorption. The residue composition after each cycle was the same value of 30 bromine atoms. The two loops at 50° and 60° are reproducible in any order if sufficient time is allowed to establish equilibrium. This was as high as 24 hours for large amounts of bromine. For points that are critical in establishing the general shape of a loop, it was shown that no further change occurred in an additional 12 hours. The desorption side of the loop does not close at the critical pressure where adsorption started but continues on down to 2 cm or less before reaching the residue composition. There are five points in this region at 50° and 60° and their compositions were shown to be constant for 24 hours. The curves for 25° were not completed because of the great time required for the larger amounts of bromine adsorbed at this temperature.

(b) Carbon Blacks

These materials showed a rapid adsorption even at the lowest pressure used—0.03 cm. The subsequent isotherm showed hysteresis only if the pressure exceeded the critical value noted for natural graphite. Thus there was no hysteresis at 80° below at least 18 cm and none at 25° below 1 cm. Isotherms at three temperatures for Sterling M.T. 3100 are shown in Fig. 2. The equilibrium values involving hysteresis were reached in an hour or less, which is very rapid compared with the time required for natural graphite. Similar curves were obtained for other carbon blacks, although the amount of hysteresis varied. If the maximum vertical distance between adsorption and desorption curves at 25° C is taken as a measure of hysteresis then its value, listed in Table I, increases with crystal size. Unfortunately the data are insufficient to evaluate the relationship. All that can be said is that the defined hysteresis is proportional to a power of L_a between one and two.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Hysteresis was also observed when the temperature was changed at constant pressure. The compositions were simply those found on the adsorption and desorption curves for the particular pressure used. With natural graphite the change from one curve to another at constant pressure was extremely slow. Even after 24 hours the change from a 50° curve in Fig. 1 to a 60° curve had progressed only half way and was not followed any further because its rate had dropped to such a low value.

2. Residue Compounds

This refers to the bromine that is not removed to a liquid nitrogen trap in a system at 0.001 cm pressure. The time required to reach equilibrium varied up to 24 hours and the final composition was a function of the following conditions. For a given material it increased with the amount of bromine adsorbed before reducing the pressure to zero and with the time of exposure to bromine as reported by Hennig (2). The uptake after 24 hours was zero or very small. The source of carbon black and the temperature of heat-treatment before bromination are also factors. This is shown in Table I where the residue compositions are those obtained after 24 hours' exposure to bromine at 17 cm and 25° C. The values show that for a given source of carbon black the residual bromine content decreases as the temperature of heat-treatment increases.

The effect of the formation of these residue compounds on the isotherms was simply to displace them vertically by an amount equal to the residual bromine content. Any additional effect was not detected. As a result adsorption isotherms were only reproduced in case nothing was done to change the residue composition. In the subsequent use of the isotherms to determine area and isosteric heats only the amount of bromine adsorbed in excess of the residual amount was used in the calculations.

TABLE I

3. Area Calculations

The B.E.T. equation was applied to the carbon black isotherms at 80° by plotting $p\{\mathrm{Br}/\mathrm{C}(p_0-p)\}^{-1}$ against p/p_0 between partial pressures of 0.03 and 0.12. From the slope of this straight line the areas in Table I were calculated using 12.2 Å^2 as the average area covered per atom of bromine. Except for Sterling F.T. Original the values average (5±10)% higher than the areas from N_2 adsorption data and (10±20)% lower than the electron microscope areas. When similar calculations were made for adsorption isotherms below 80°, larger areas were obtained whenever the plot included pressures above the critical value. Thus the area of Sterling M.T. 3100° calculated from the 0° isotherm was 12.4 and from the 25° isotherm 7.9 meter^2 g^{-1}. The higher values are caused by lamellar adsorption, which will be shown later to occur only above the critical pressure.

4. Isosteric Heats

These were calculated from the adsorption isotherms at 25°, 50°, and 80°. The results are summarized in Table I, where each recorded value is the average for a range of Br/C values from 0.2 to 1.5 monolayers. For Spheron 6 2700° the linearity of the Arrhenius plot is excellent and the standard deviation of the calculated heats at various Br/C values is only 2%. This good behavior is a result of the relatively large surface area, negligible hysteresis, and low residue composition associated with the sample. These combine to make lamellar adsorption and errors in the weighing and in the residue composition less significant. The situation is somewhat less satisfactory for the other carbon blacks. There is, however, no detectable trend of the heat with Br/C content or with temperature. Only on desorption from the two largest crystals and natural graphite is a trend with Br/C content noticeable and that toward lower values as bromine is removed. In Table I the average slopes above and below the monolayer value are used to calculate the two recorded heats of desorption for each of these three samples. All that can be said is that the value is the same as for adsorption below the monolayer value and higher by about 6 kcal per mole above it.

CONCLUSIONS

Because the critical pressure above which hysteresis occurs is the same for natural graphite and for all the carbon blacks it is concluded that the common lamellar structure of these materials is responsible for this behavior. Specifically, intercalation of bromine between the layers occurs only above the critical pressure and because the reverse process is hindered there is hysteresis. As one would expect, the hysteresis increases with the area of the carbon lamella and indeed the extent of hysteresis can be used to estimate the crystal dimension normal to the C axis. Furthermore the transport of bromine in and out of the layers should be and is much slower than the surface adsorption that is the main process below the critical pressure.

The isotherm for this surface adsorption can be used to calculate the surface area from the B.E.T. equation. The values for eight carbon blacks are, with one unexplained exception, within experimental error of the areas calculated from nitrogen adsorption data at low temperature or from electron microscope measurements of the size of the aggregates of graphite crystals. The average area occupied per bromine atom is of course critical in this calculation. The value of 12.2 $Å^2$ used is calculated from the density of the liquid assuming six co-ordination. However, one could equally well use the 11.8 $Å^2$ area per bromine atom in the halogen complexes of violanthrene studied by Professor H. Akamatu (1). He found evidence for a complex with two molecules of bromine to one molecule of the above hydrocarbon with its nine benzene rings. It is also interesting to note that placing bromine molecules over alternate pairs of graphite hexagons gives an average area per bromine atom of 10.5 Å. The atoms would be 0.09 Å from the center of each hexagon.

The isosteric heats in Table I show that the value for adsorption on the surface is within 10% of the value for adsorption between the layers. The best value for the carbon blacks of 11.2 ± 0.2 kcal $mole^{-1}$ agrees well with the 11.4 kcal $mole^{-1}$ reported by Reyerson (5) for adsorption on steam-activated charcoal. These values are only about 4 kcal higher than the heat of vaporization of bromine.

The bromine content of the residue compound increases with the pressure of bromine to which the sample had been exposed. However, the various isotherms for these different contents can be brought to coincidence by subtracting the residue composition at all pressures. This means that the total area available to bromine on the outer surfaces of

the crystal aggregates and the intercalating properties of the carbon layers are not changed noticeably by formation of the residue compound.

STERIC INHIBITION OF RESONANCE

III. CALCULATION OF RESONANCE ENERGIES AND BOND LENGTHS[1]

JAMES TROTTER[2]

ABSTRACT

In many aromatic nitro compounds steric effects prevent the attainment of complete coplanarity and inhibit resonance interaction between the nitro group and the aromatic π-electrons. The variations with nitro group tilt of resonance energy, electron distribution, and π-bond order in this type of molecule have been calculated by molecular orbital methods, and the corresponding bond length variations have been deduced. The calculated bond lengths for 9,10-dinitroanthracene and 9-nitroanthracene are compared with those measured by X-ray analyses.

INTRODUCTION

Investigations of the crystal and molecular structures of 9-nitroanthracene and 9,10-dinitroanthracene have shown that the nitro groups are tilted markedly out of the planes of the aromatic rings due to the steric effects of neighboring carbon and hydrogen atoms (1, 2), and the resultant decreases in resonance interaction between the nitro groups and the aromatic π-electrons have been correlated with the variations in the characteristic vibration frequencies of the nitro groups (3). Further detailed examination of the bond lengths in these molecules, especially the C–N distances, suggests that the resonance is almost completely inhibited in 9-nitroanthracene, where the nitro group is tilted about the C–N bond 85° from the coplanar position, but that in the 9,10-dinitro derivative, where the tilts are 64°, there is a small but measurable resonance interaction (4).

The changes in the resonance energy and in the bond lengths in aromatic nitro compounds when the nitro group is tilted out of the plane of the aromatic ring may be calculated by molecular orbital methods, and the first section of the present paper describes the calculation of the variation of resonance energy and bond lengths with nitro group tilt (θ) in aromatic nitro compounds in general, nitrobenzene being used as a simple example. Subsequent sections describe the application of these methods to 9-nitroanthracene and 9,10-dinitroanthracene.

NITROBENZENE

In nitrobenzene (Fig. 1) each carbon and oxygen atom contributes one p_z electron to the π-molecular-orbital system, while the nitrogen atom contributes two, so that nine molecular orbitals accommodate 10 electrons. The secular equations

$$\sum c_r^i(H_{rs}-ES_{rs}) = 0$$

were set up in the usual way, using the parameters given in Table I, overlap integrals being taken as zero, and inductive effects neglected (this point will be discussed later). Since the nitrogen atom contributes two electrons its coulomb integral has been taken as $\alpha + \beta$ instead of the usual $\alpha + \frac{1}{2}\beta$ (8). The resonance integral H_{17} varies of course with the angle of tilt, being a maximum when $\theta = 0°$ and a minimum when $\theta = 90°$. By resolving the p_z atomic orbitals along axes at right angles, it can be shown that the value of this resonance integral for any value of θ is given approximately by

$$\beta^\theta = \beta^0 . \cos\theta.$$

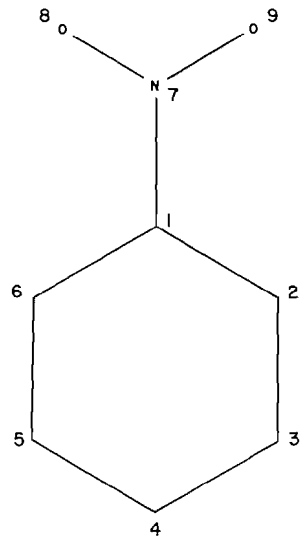

FIG. 1. Numbering used in the computations for nitrobenzene.

TABLE I

Parameters for nitrobenzene

	Coulomb integrals		Resonance integrals
H_{11}	α	H_{12}	β
H_{22}	α	H_{23}	β
H_{33}	α	H_{34}	β
H_{44}	α	H_{45}	β
H_{55}	α	H_{56}	β
H_{66}	α	H_{61}	β
H_{77}	$\alpha+\beta$	H_{17}	$\beta.\cos\theta$
H_{88}	$\alpha+\beta$	H_{78}	$\sqrt{2}\beta$
H_{99}	$\alpha+\beta$	H_{79}	$\sqrt{2}\beta$

The determinant Δ formed by the coefficients of the c_r^i is of the ninth order, and by writing $x = (\alpha - E_i)/\beta$ the molecular energy levels were obtained in terms of β by solving the equation $\Delta = 0$. Using determinants of the variety known as continuants, as described by Goodwin and Vand (5), the secular determinant for nitrobenzene was readily expanded to

$$\Delta_{\text{nitrobenzene}} = \Delta_{\text{benzene}} \cdot \Delta_{\text{nitro group}} - \cos^2\theta(x+1)^2 \cdot P_5$$
$$= (x+1)^3(x-1)[P_5+P_4-5P_3+2P_2+7P_1-11P_0-\cos^2\theta(P_3-P_1)].$$

The energy levels E_i for $\cos\theta = 0, 0.25, 0.50, 0.75, 1.00$ were evaluated, and are listed in Table II. The total π-electron energies and the resonance energies (E_R) due to interaction between the nitro group and the aromatic π-electrons were calculated and are included in the table. The final values of E_R in kcal were obtained by taking $\beta = -20$ kcal/mole.

The variation of E_R with θ is shown in Fig. 2, which indicates that E_R is approximately proportional to $\cos^2\theta$. The curve shows that at a nitro-group tilt of about 60° the energy of resonance interaction between a nitro group and the aromatic π-electrons is about $1\frac{1}{2}$ kcal/mole, compared with about $6\frac{1}{2}$ kcal/mole in a completely planar aromatic nitro compound, so that it is small but not negligible. Guy (6) has calculated for diphenyl

derivatives a much more rapid decrease in resonance interaction with increasing θ, and in fact his resonance energy is proportional to $\cos^4\theta$, so that it is quite small at $\theta = 60°$ (about 0.4 kcal/mole). However, he makes the initial assumption that the resonance integral $w(\theta)$ is given by $w(\theta) = w(0)[1+\cos 2\theta]/2$, that is β^θ is proportional to $\cos^2\theta$, and hence his resonance energy is inevitably proportional to $\cos^4\theta$. Dewar (7) on the other hand takes β^θ proportional to $\cos\theta$, and shows that the resonance energy is proportional to $\cos^2\theta$.

In nitrobenzene the most stable configuration has $\theta = 0°$, but in a molecule in which the steric effects of neighboring atoms or groups prevent the attainment of a completely coplanar arrangement, the most stable configuration is determined not only by the resonance energy E_R, but also by the repulsive forces between the oxygen atoms and neighboring groups. The energies of van der Waals attraction and electronic repulsion can be represented by a curve of the form

$$E_v = -\frac{a}{r^6} + \frac{b}{r^n} \qquad (n > 6).$$

The variation of this energy with θ in nitro derivatives of mesitylene and durene is shown in Fig. 3; the energy passes through a slight minimum at the angle corresponding to van der Waals separation, and increases very markedly at smaller θ due to rapidly increasing repulsive forces. The variation of the combined energies, E_R and E_v, with θ is also shown in Fig. 3; there is a minimum in the curve in the region of $\theta = 65°$, so that this is the most stable configuration of the isolated molecules.

Inductive Effects

In heterocyclic molecules uncertainty about the exact values of the various coulomb and resonance integrals generally makes the reliability of the calculated energies rather uncertain. In the present calculations, however, while variation of the parameters changes the values of the energy levels E_i, the resonance energies are changed only slightly. The inductive effect of the nitro group on the carbon parameters, for example, can be allowed for by writing the coulomb integrals of the carbon atoms as $\alpha + m\beta$, where m decreases with increase in the number of bonds between the carbon atom and nitro group. The calculations of the energy levels were repeated taking $m = 0.6$ for carbon atom 1, and zero for the other carbon atoms, the results (for $\theta = 0°$ and 90°) being listed in Table III. Comparison with the values of Table II shows that while the energy levels have

changed, the energy of resonance interaction between a nitro group and aromatic π-electrons differs little from the value calculated neglecting the inductive effect.

Electron Distributions and Mobile Bond Orders

The coefficients c_r^i for each energy level were then evaluated by means of continuants and the π-electron distributions (q_r) and mobile bond orders (p_{rs}) evaluated from the expressions

$$q_r = \sum_i n(c_r^i)^2 \qquad \text{and} \qquad p_{rs} = \sum_i nc_r^i c_s^i \qquad (n = 2).$$

The values for $\theta = 0°$, 60°, 90° are listed in Tables IV and V. The values at $\theta = 0°$ and 90° for $m_1 = 0.6$ are included, and these show that while allowance for the inductive effect of the nitro group changes the charges on the carbon atoms, it produces only quite small differences in the bond orders.

To derive the bond lengths from the calculated bond orders, correlation curves were drawn as described below.

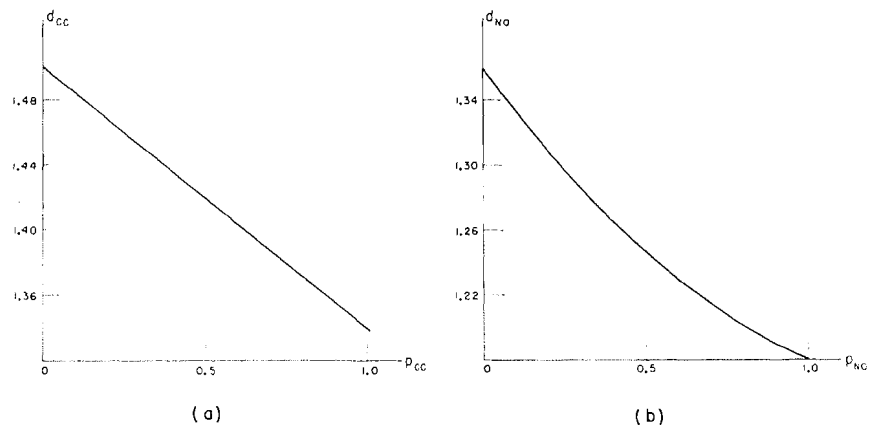
Carbon–Carbon Bonds

Since the carbon–carbon bond orders in nitrobenzene differ only slightly from those in benzene, only the region of the bond order – bond length curve near the benzene point is of importance, and a linear correlation (Fig. 4*a*) between the single-bond distance for sp^2 hybridization (1.50 Å) and the double-bond distance (1.34 Å) was used, this line passing close to the benzene point (0.667, 1.397).



(a) (b)

FIG. 4. Bond order – bond length correlation curves for (*a*) C–C bonds and (*b*) N–O bonds.

Nitrogen–Oxygen Bonds

A curve was drawn (Fig. 4*b*) from the point (0, 1.36) representing the single-bond length to (1.0, 1.18) representing the double-bond distance, and passing close to the point for a non-conjugated nitro compound (0.707, 1.21). Only the range of bond orders around 0.7 is of importance in the present computations.

Carbon–Nitrogen Bonds

Since the mobile bond order of the C–N bonds in aromatic nitro compounds changes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

considerably with the angle of tilt of the nitro group (Table V), the exact form of this correlation curve is of more importance. The curve shown as a full line in Fig. 5 was

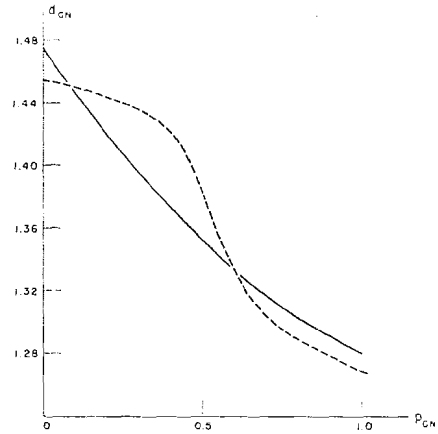


FIG. 5. Correlation curves for C–N bonds.

drawn through (0, 1.475), (0.600, 1.336), and (1.000, 1.280), since Goodwin and Porte (8) have deduced from a consideration of bond orders and lengths in a number of molecules that any reasonable curve must pass close to the point (0.600, 1.336). These authors also suggest that the length of a pure single bond be taken as 1.435 Å to allow for the sp^2 hybridization. However, in aliphatic nitro compounds the C–N distance is about 1.475 Å and since the nitrogen atom is already in a state of sp^2 hybridization, application of a correction for change of hybridization of the carbon atom would give 1.455 Å for the single-bond length to be used in aromatic nitro compounds. An alternative curve using this single-bond distance and of the form suggested by Goodwin and Porte is shown as a broken line in Fig. 5. The two curves differ significantly in the range of bond orders encountered in nitro compounds ($0 \rightarrow 0.3$), and it would be possible to decide between them if some accurate bond length measurements in the bond order range $0 \rightarrow 0.3$ were available. The C–N distance in 9-nitroanthracene (1.482 Å) would suggest that the full curve is more acceptable for nitro compounds, although this length is not known with great accuracy (standard deviation 0.015 Å). An accurate value of the C–N bond length in nitrobenzene would distinguish between the curves, since the lengths corresponding to $p_{CN} = 0.322$ are significantly different (1.391 Å and 1.433 Å) and work is being undertaken to measure this value (and incidentally investigate any possible deviations from exact planarity in this molecule). Meanwhile the full curve will be used in deriving bond lengths, with the bond lengths derived from the broken curve generally being noted for comparison.

The values of the bond lengths for all the bond orders in Table V were read off from the correlation curves, and these are listed in Table VI. The variations of the lengths of the C–C bonds with nitro group tilt are very small, the maximum difference being 0.006 Å (0.009 Å with allowance for the inductive effect, taking $m_1 = 0.6$); similarly the maximum variation for the N–O bonds is 0.007 Å. These variations are generally too small to be measured accurately by X-ray crystal analyses. For the C–N bonds, however, the lengths are 1.475 Å for $\theta = 90°$ and 1.391 Å for $\theta = 0°$ (using the full curve of Fig. 5) and it should be possible to detect this type of variation quite readily. (If the broken correlation curve is used the range is only 1.455 Å to 1.433 Å, but even this variation could be detected by accurate X-ray analysis.)

MESONITROANTHRACENES

The application of the methods described above to aromatic nitro compounds in which resonance between nitro group and aromatic π-electrons is inhibited due to steric effects requires that some estimation of the C–N resonance integral be made, and this integral is approximately proportional to $\cos\theta$. The angle θ has been accurately measured for 9,10-dinitroanthracene and 9-nitroanthracene in the solid state using X-ray diffraction methods (1, 2), and these values may now be used in computing bond orders, and hence in deriving bond lengths for comparison with those measured by the X-ray methods.

9,10-Dinitroanthracene

In 9,10-dinitroanthracene (Fig. 6) each carbon and oxygen atom contributes one p_z

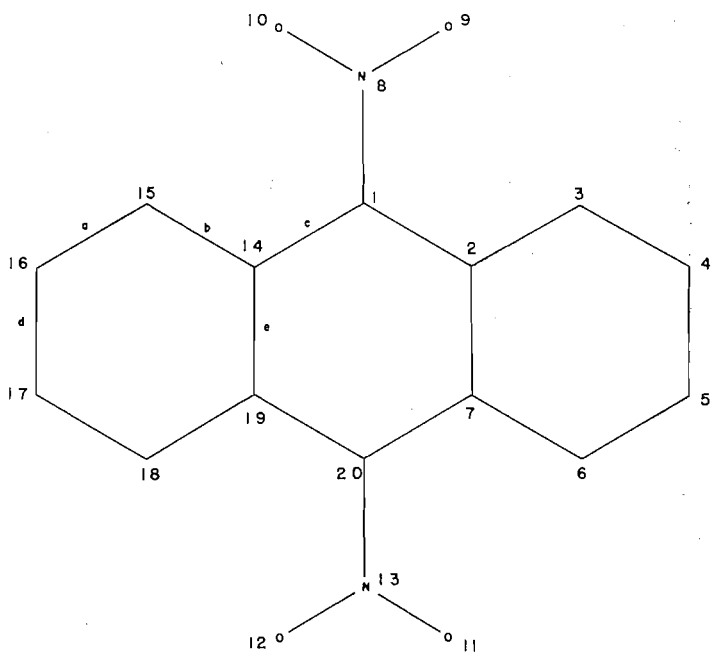

FIG. 6. Numbering used in the computations for 9,10-dinitroanthracene.

electron to the π-molecular-orbital system, while the nitrogen atoms each contribute two, so that 20 molecular orbitals accommodate 22 electrons. The secular equations were set up in the usual way. X-ray analysis has shown that $\theta = 63.7°$, so that the C–N resonance integrals are 0.44β. Overlap integrals were taken as zero, and the inductive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

effects of the nitro groups were neglected since, as shown above, their inclusion causes only small variations in the bond orders and bond lengths.

The secular determinant is of the 20th order, but since the molecule has a center of symmetry, the 20th-order determinant was at once factorized into two 10th-order determinants according as $c_r = \pm c_{21-r}$. Using continuants these determinants were readily expanded to

$$\Delta_{\text{symmetrical}} = (x+1)^2(x-1)^2(x-2)[(P_5+5P_4+7P_3+2P_2+P_1+3P_0) - 0.20(P_3+4P_2+7P_1+6P_0)]$$

$$\Delta_{\text{antisymmetrical}} = (x+1)^2(x-1)^2(x+2)[(P_5+P_4-5P_3-2P_2+P_1+3P_0) - 0.20(P_3-P_1-2P_0)].$$

The π-electron molecular-orbital energy levels, E_i, were evaluated for 9,10-dinitroanthracene, and also, for comparison, for anthracene and the nitro groups separately, corresponding to no resonance interaction ($\theta = 90°$). The energy levels are listed in Table VII, together with the total π-electron energy and resonance energy due to resonance interaction between the nitro groups and the anthracene nucleus. Taking $\beta = -20$ kcal/mole this resonance energy is 2.92 kcal/mole (1.46 kcal/nitro group).

The c_r^i were then evaluated for each energy level and the π-electron distribution and mobile bond orders are listed in Tables VIII and IX. The calculated bond lengths were then derived, using the C–N and N–O correlation curves of the previous section; for C–C bonds however, a best linear correlation was drawn through the points representing the calculated bond orders and observed bond lengths for anthracene (Fig. 7).

9-Nitroanthracene

In 9-nitroanthracene 17 molecular orbitals accommodate 18 electrons, and the secular equations were set up using similar parameters to those for the dinitro derivative. X-ray

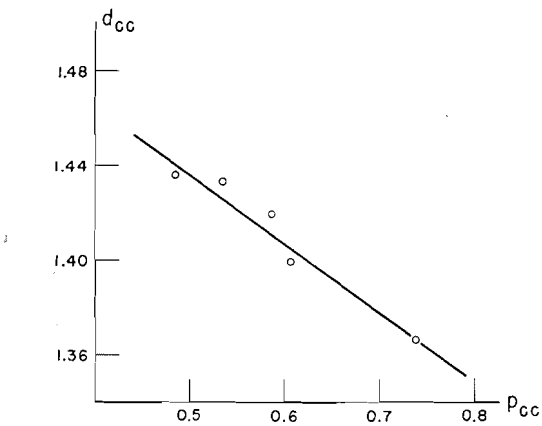

FIG. 7. Correlation curve for C–C bonds, based on the points for anthracene.

analysis has shown that the nitro group is tilted 84.7° out of the aromatic plane so that the C–N resonance integral is 0.09β. The secular determinant is of the 17th order, but since $\cos^2\theta$ is quite small, the energy levels differ little from those in anthracene and a non-conjugated nitro group, and the complete calculations were not carried out. The energy of resonance interaction between the nitro group and the aromatic π-electrons is 0.06 kcal/mole, the C–C and N–O bond orders do not differ significantly from those in the separate, non-conjugated anthracene molecule and nitro group, and the C–N bond order (approximately proportional to $\cos\theta$) is about 0.034. The calculated bond lengths were derived from the same curves as those for 9,10-dinitroanthracene.

DISCUSSION

The energy of resonance interaction between the nitro groups and the anthracene nucleus in 9,10-dinitroanthracene is 2.92 kcal/mole. When the variation of resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

energy with nitro-group tilt is combined with the energies of van der Waals attraction and electronic repulsion between the oxygen atoms and neighboring carbon and hydrogen atoms, a curve of the type shown in Fig. 3 is obtained, with a minimum in the region of $\theta = 65°$, in good agreement with the measured tilt (64°). This structure is about 3 kcal/mole more stable than that with $\theta = 90°$. The most stable configuration for 9-nitroanthracene should have the nitro group tilted 64° out of the anthracene plane, but in the solid state crystal forces apparently give minimum energy when $\theta = 85°$.

The calculated bond lengths for anthracene, 9,10-dinitroanthracene, and 9-nitroanthracene are compared in Table X with the distances measured by X-ray crystal

analyses, the differences (Δ) and root mean square Δ being included in the table. For anthracene the measured and calculated distances for the various bonds are of course very similar, since the calculated bond orders and observed bond lengths in anthracene have been used in deriving the carbon–carbon correlation curve. The agreement for the C–C bonds in the nitro derivatives is quite satisfactory; only for the *a* bond in 9-nitroanthracene is the difference apparently greater than the estimated experimental error (4), and this latter has probably been slightly underestimated (2). The calculated N–O bond length in 9-nitroanthracene is in very good agreement with the measured value. For 9,10-dinitroanthracene the agreement is not quite so good, although the difference is just within the limits of experimental error.

For the C–N bonds, while the agreement is reasonable, it is still not possible to decide between the two correlation curves shown in Fig. 5. In 9-nitroanthracene the agreement is significantly better when the full curve is used for bond order – bond length correlation, but the broken curve gives better agreement for the dinitro derivative. Further accurate measures of C–N bond lengths in the bond order range $0 \rightarrow 0.3$ are required to establish better correlation for the C–N bonds in nitro compounds, and present investigations by X-ray diffraction methods of the crystal structures of nitro derivatives of mesitylene and durene, and of nitrobenzene, may supply some useful data.

THE KINETICS OF HYDROGEN CHEMISORPTION ON AN IRIDIUM CATALYST[1]

MANFRED J. D. LOW AND H. AUSTIN TAYLOR

ABSTRACT

The kinetics of the chemisorption of hydrogen on an iridium catalyst have been studied at various temperatures and pressures. The rate of adsorption is well defined by the Elovich equation. Isothermal anomalies have been observed and were found to be a function of temperature and initial gas pressure.

Recently it has been shown (1) that the Elovich equation,

$$dq/dt = a\, e^{-\alpha q},$$

will accurately reflect the variation of the amount adsorbed, q, with time, t, in many chemisorption processes. The constants (a) and α were found to vary with temperature, but there was no indication of a pressure dependence. More recently (2, 3) such a pressure dependence has been found in several systems and, in order to investigate further the influence of initial gas pressure on the Elovich parameters, the present investigation was undertaken.

EXPERIMENTAL

The measurements of rates of adsorption were carried out by admitting a known amount of hydrogen to a sample of the catalyst which had been suitably evacuated, and measuring the change of pressure in the constant-volume system. A commercial hydrogenation catalyst, purchased from Baker and Co., Inc., was used as adsorbent. The catalyst consisted of 0.5% iridium supported on the surface of 3×5-mm γ-alumina extrudates.

The catalyst (20.10 g) was placed in a Vycor tube and sealed to the all-Pyrex system. A copious evolution of water and of gas took place on heating the catalyst to 500° C. After an overnight pumping period at that temperature the pressure within the system had fallen to 10^{-6} mm Hg. The catalyst was then treated with palladium-filtered hydrogen at 500° C at a pressure of 60 cm dibutyl phthalate (DBP). After 2 hours the gas was removed, and the adsorbent was pumped on overnight at 500°. This hydrogen treatment was repeated six times. It was found that on pumping at 500°, a vacuum of 10^{-6} mm Hg, or less, could be obtained and maintained after a period of about 6 hours. A minimum pump-off period of 10 hours at 500° was therefore chosen.

It was noticed that the color of the untreated catalyst was black. After pumping, but before the hydrogen treatment, the color was still black. After the first contact with hydrogen, however, the catalyst had turned gray, and remained that color until the end of the series of experiments.

Dead spaces were measured by expansion of helium purified by passage through a charcoal trap cooled with liquid nitrogen. The catalyst was thermostatted at a desired temperature by surrounding the chamber with a Dewar flask filled with solid CO_2, ice, or with the vapors of a boiling liquid. The experiments reported here were made at different initial pressures, P_0, at any one temperature, T, and were numbered consecutively in order of their execution.

Contribution from The Nichols Laboratory, New York University, New York 53, New York.

RESULTS AND DISCUSSION

A total of 38 experiments at seven different temperatures were made. It was found that the data of each experiment could be precisely described by use of the Elovich equation. Isothermal anomalies (1) were found. The $q - \log t$ plots of the data appeared as straight lines which, after a certain time, t_b, abruptly changed in slope. These discontinuities, or "breaks", are illustrated by Fig. 1. The data of three sample runs are

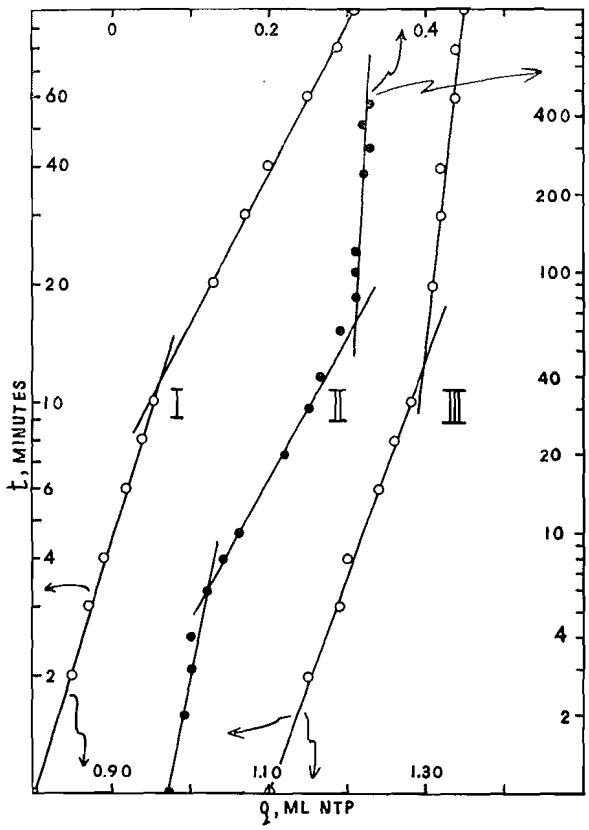

FIG. 1. Adsorption of H_2 on $Ir.Al_2O_3$. Typical runs: I. Run 2, 147°, 34.5 cm DBP; II. Run 28, 257°, 10.4 cm DBP; III. Run 38, −78.5°, 8.8 cm DBP.

shown to be internally consistent. Circles represent experimental points, and the lines were calculated using the equation,

$$q = (2.3/\alpha) \log_{10} (1+a\alpha t).$$

Constants were calculated by a previously described method (4), and are summarized in Table I. The subscripts 1, 2, and 3 identify the parameters corresponding to the 1st, 2nd, or 3rd branches of the curve. The co-ordinates of the break, q_b and t_b, result from the intersection of the 1st and 2nd branches.

It is to be noted that, with the exception of run 38, the slopes of the $q - \log t$ plots increased after t_b. In a few cases, notably with experiments at low pressures, this region of increased slope was followed by one of decreased slope (plot II, Fig. 1). This is not unexpected, since the slope must eventually become zero. The fact that these 3rd branches

are linear on a $q - \log t$ plot may be of significance, and suggests that rate measurements be continued to zero rate. Most of the present experiments were terminated after about 100 minutes because the rate of adsorption became quite slow. Thus in run 28, 0.309 ml was adsorbed at 100 minutes, and only 0.325 ml was adsorbed after 420 minutes.

Breaks of a similar nature are to be found in the plots of P_0 versus q_t, the amount adsorbed at time t at 100° C. The plots of Fig. 2 show breaks in the region of $P_0 \sim 10$ cm. This phenomenon was previously observed in the case of the systems H_2 – Ni. kieselguhr (2) and H_2 – Ru. Al_2O_3 (3).

Effect of Initial Pressure

From the data in Table I it can be seen that both α_1 and α_2 are dependent on the initial pressure at each temperature. These dependencies are representable by the equations

$$\alpha_1 = B_1 + C_1 P_0$$

$$\alpha_2 = B_2 + C_2 P_0$$

and Table II lists the values of the constants B and C at the four principal tempera-

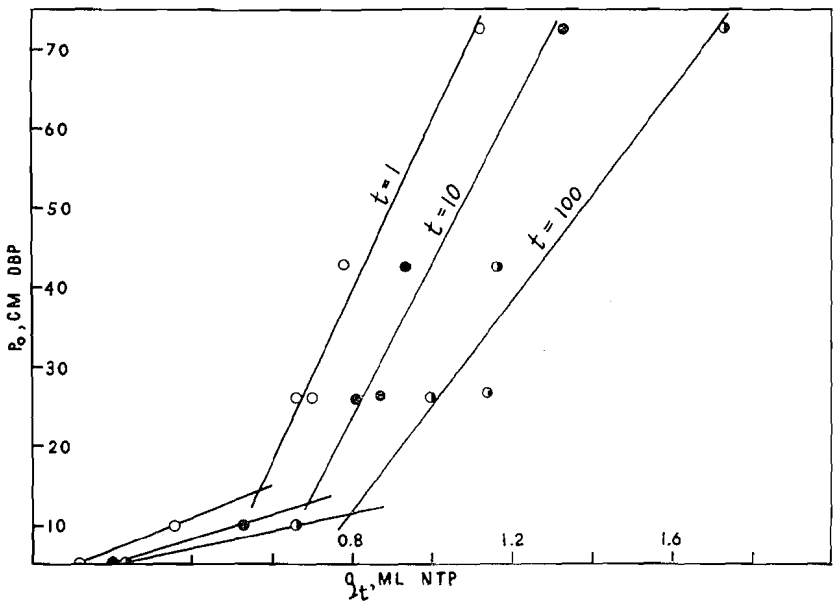

FIG. 2. The variation of q_t with P_0 at 100° C.

tures. In previous studies (2, 3) discontinuities were usually observed in such $\alpha - P_0$ plots, the slope changing abruptly at lower pressures. In the present study a discontinuity was found only at 100° C. Figure 3 shows a plot of both α_1 and α_2 as a function of P_0 at 100°. The data in Table II for 100° refer to the data above 10 cm. Below 10 cm at 100°, $\alpha_1 = 49.41 - 2.94P_0$ and $\alpha_2 = 51.18 - 4.12P_0$. At the other temperatures the constants in Table II cover the whole pressure range studied.

The variation of $\log a_1$ and $\log a_1\alpha_1$ with P_0 followed a pattern similar to that of α, and may be represented by the equations;

$$\log_{10} a_1\alpha_1 = K + LP_0$$

$$\log_{10} a_1 = M + NP_0,$$

the values of the constants at four temperatures being given in Table II. Breaks occurred in the low-pressure region. At 100°, $\log_{10} a_1\alpha_1 = 0.269 + 0.286P_0$; at 200°, $\log_{10} a_1\alpha_1 = 0.522$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

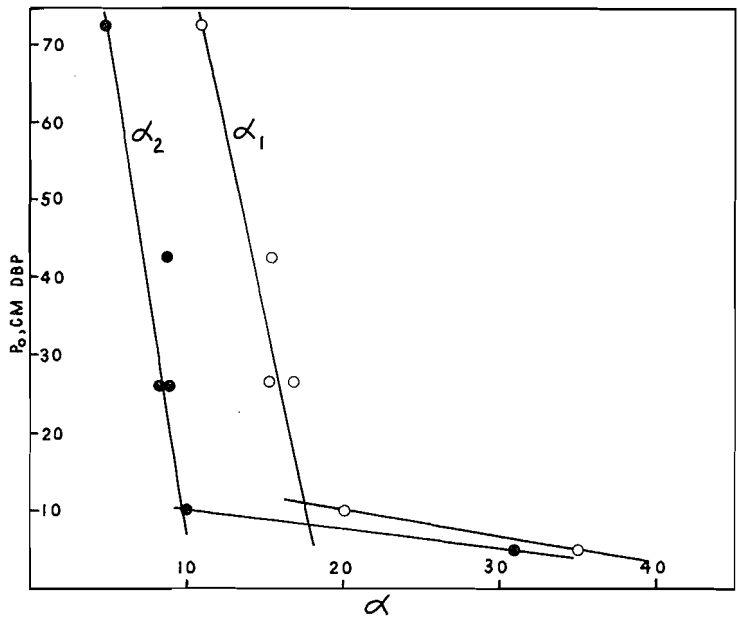

FIG. 3. The variation of α with P_0 at 100° C.

$+0.156P_0$. Since α showed breaks only at 100° but $\log a_1\alpha_1$ has breaks at all temperatures, plots of $\log a_1$ vs. P_0, as expected, showed breaks at all temperatures. The constants of the equation,

$$\log_{10} a_1 = m+nP_0,$$

describing the low-pressure region, are given in Table II. The variation of $\log a_2$ and $\log a_2\alpha_2$ with P_0 is not clearly defined.

It has been noted that breaks occurred in all isotherms. It is interesting that the time of occurrence of the break, t_b, as well as the amount adsorbed at the time of occurrence, q_t, increase linearly with increasing P_0 according to the equations,

$$t_b = F+GP_0,$$
$$q_b = D+EP_0.$$

The values of the constants of these equations at four temperatures are given in Table II. The data at 100° show a break at a P_0 of about 10 cm in a fashion similar to that of α_1 and α_2. Below 10 cm, $q_b = -0.122+0.0554P_0$.

The Influence of Temperature on Parameter Values

In the previous studies it was found that α and $\log a\alpha$ were linear in the reciprocal of the temperature. Since the pressure dependencies of both parameters are more marked in the present study, values of α_1 and $\log a_1\alpha_1$ have been calculated from the previous equations for P_0 values of 60 and 40 cm DBP at each of the four highest temperatures. Since only two runs were made at each of the three lowest temperatures, the pressure dependence is too uncertain to justify a similar treatment. The least square straight line through the four points at each initial pressure expresses the relations, $\alpha_1 = U+V/T$, and $\log_{10} a_1\alpha_1 = X+Y/T$. The values of U, V, X, and Y at each of the initial pressures 60 and 40 cm DBP are given in Table III. The energy of activation of adsorption as

usually calculated has previously been shown to be expressible as: $E = R(Vq - Y)$, where R is the gas constant. From the values of V and Y it is found that at $P_0 = 60$ cm, $E = -12.36q - 2.97$, and at $P_0 = 40$ cm, $E = 22.88q - 3.48$. Over the whole range of adsorption values of q, E is negative.

Comparison with previous studies on Ni and Ru shows that the values of V and Y may be either positive or negative. The magnitude and the direction of variation of E with coverage, q, present four possibilities which are illustrated in Fig. 4. Case I with

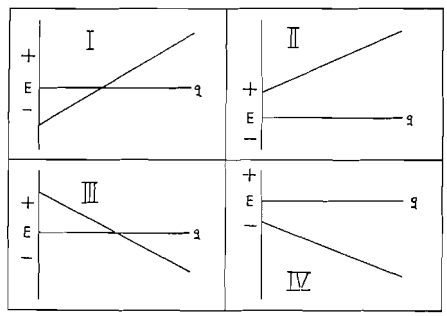

FIG. 4. Linear variation of activation energy with coverage.

V and Y both positive was found in the Ni.kieselguhr system. Case III, with V and Y both negative, was found with Ru.Al_2O_3. Case IV, with V negative and Y positive, is the present study. Case II is approximated by the data of Burwell and Taylor (5) for the adsorption of H_2 on Cr_2O_3. Taking their data, treated by the Elovich equation, given in Table IV of Taylor and Thon (1), for 0.5 atm it is found that $\alpha = (23700/T) - 45.5$, and $\log_{10} a\alpha = (1000/T) - 6$, whence $E = 47q - 2$ kcal. Although V and Y are both positive, the low value of Y leaves E positive except for very small values of q, thus approximating Case II. It is obvious that the interpretation of E as a simple energy of activation is not necessarily an argument for multiplicity of adsorption sites. On the other hand, it would appear inescapable that the changes in adsorption rate, here accentuated as "breaks," as well as the pressure dependencies found, cannot be attributed to a single type of adsorption site. Two or possibly three such types, rather than a spectrum of types, would appear sufficient to account for the observations.

The change in magnitude of a parameter with temperature may be connected with the region of the isobar under consideration. Figure 5 shows estimates of amounts adsorbed at 100 minutes, suggesting that the present experiments were made on the decreasing portion of the isobar. In view of the complexity of the relations it seems too early to comment on the possible physical significance of parameters such as a_2, the mathematical initial rate of the 2nd kinetic stage, or to attempt a general interpretation, much less to attempt to identify the sites concerned. Additional work on other gas–solid systems seems to be required.

THE CONSTITUTION OF A METHYL GLUCURONOXYLAN FROM KAPOK (CEIBA PENTANDRA)[1]

A. L. Currie and T. E. Timell

ABSTRACT

The seed hairs of kapok (*Ceiba pentandra*) on alkaline extraction have yielded a hemicellulose composed of xylose and uronic acid residues. Partial hydrolysis of the polysaccharide gave 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, 4-*O*-methyl-D-glucuronic acid, and, probably, galacturonic acid. Hydrolysis of the fully methylated hemicellulose yielded a mixture of 2-*O*- and 3-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2,3,4-tri-*O*-methyl-D-xylose, and 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronic acid)-3-*O*-methyl-D-xylopyranose in a molar ratio of 1.1:38:1:6. The number-average D.P. of the native and the methylated polysaccharides was 177 and 124, respectively. On the basis of this and other evidence it is suggested that the average hemicellulose molecule contains approximately 180 1,4-linked β-D-xylopyranose residues, one eighth of which carry a single terminal side chain of 4-*O*-methyl-D-glucuronic acid, attached through an α-glycosidic bond to C_2 of the xylose. The xylan framework contains, on the average, slightly less than two branching points per macromolecule, most of them probably originating from C_3. The number of acid side chains and branches is twice as large as that of the otherwise similar 4-*O*-methyl glucuronoxylan present in the seed hairs of milkweed floss.

In previous investigations the general chemical composition of the seed hairs of kapok was studied (1) as well as the molecular characteristics of their cellulose component (2, 3). The present paper is concerned with the structure and properties of the main hemicellulose constituent.

RESULTS AND DISCUSSION

The high pentosan content (24.4%) of the extractive-free seed hairs indicated that the predominant hemicellulose was based on xylose residues. The considerable amounts of acetyl (8.0%) and uronic anhydride (6.6%) groups present as well as the formation of a methylated glucuronic acid on hydrolysis of the fibers suggested that the polysaccharide in its native state was a partially acetylated methyl glucuronoxylan. When kapok fibers were extracted with aqueous alkali a deacetylated product was obtained in a yield of 18.8%, containing 83.3% pentosan and with $[\alpha]_D^{20}$ −68° in water. Its content of ash, methoxyl, and uronic anhydride indicated the presence of an average of 7.8 anhydroxylose units per methylated uronic acid.

Partial acid hydrolysis of the hemicellulose gave a mixture of sugars which was resolved into a neutral and an acidic portion on a column of anion exchange resin. The neutral part contained mostly D-xylose which crystallized but also traces of glucose, mannose, arabinose, and rhamnose. Elution of the column with dilute acetic acid yielded three sugar acids, namely a monouronic acid, chromatographically identical with galacturonic acid, an aldobiouronic acid, and a mono-*O*-methyl monouronic acid.

The methoxyl content and equivalent weight of the aldobiouronic acid suggested that it consisted of a methoxyuronic acid linked to a pentose residue. A portion of the acid was converted to the corresponding methyl ester methyl glycoside, which was reduced with lithium aluminum hydride and hydrolyzed to yield D-xylose, which crystallized, and 4-*O*-methyl-D-glucose, which was identified through its crystalline osazone (4, 5). The methyl ester methyl glycoside of the aldobiouronic acid was completely methylated, reduced, and hydrolyzed. The mixture of methylated sugars obtained was resolved on a cocoanut charcoal column to yield 3,4-di-*O*-methyl-D-xylose and 2,3,4-tri-

[1]*Manuscript received January 6, 1959.*
Contribution from McGill University and Pulp and Paper Research Institute of Canada, Montreal, Quebec.

O-methyl-D-glucose, both of which were identified through their crystalline aniline derivatives (6, 7). The methylated and reduced glycoside of the aldobiouronic acid was therefore methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)-3,4-di-*O*-methyl-D-xylopyranoside. This evidence shows that the aldobiouronic acid was 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose. Its high positive rotation (+100° in water) in conjunction with other evidence (8, 9) indicated that the biose linkage was present in the α-configuration.

Reduction and subsequent hydrolysis of the methyl ester methyl glycoside of the mono-*O*-methyl uronic acid gave 4-*O*-methyl-D-glucose, thus showing that the compound was 4-*O*-methyl-D-glucuronic acid.

The hemicellulose was methylated to completion and hydrolyzed with dilute acetic acid. The acidic and neutral sugars formed were separated on an anion exchange resin. The acid fraction contained only one component, namely a partially methylated aldobiouronic acid. Reduction of its methyl ester methyl glycoside yielded a crystalline compound, which was identified through its melting point, specific rotation, infrared spectrum, and X-ray powder diagram as methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)-3-*O*-methyl-α,β-D-xylopyranoside, previously isolated from western hemlock (10), sugar maple, and yellow birch (11) wood. Methanolysis of the disaccharide followed by hydrolysis gave a mixture of methylated sugars which was resolved by fractional extraction with chloroform of its aqueous solution. The two sugars obtained were 2,3,4-tri-*O*-methyl-D-glucose and 3-*O*-methyl-D-xylose, both of which were characterized through their aniline derivatives.

The aqueous solution of the neutral sugars was fractionally extracted with chloroform. The first compound removed was chromatographically identical with 2,3,4-tri-*O*-methyl-D-xylose and was tentatively characterized through its infrared spectrum. The second and main portion was 2,3-di-*O*-methyl-D-xylose, identified as its crystalline aniline derivative. The residual aqueous solution contained a mixture of sugars which was resolved by paper ionophoresis to give 2-*O*-methyl-D-xylose together with a smaller quantity of 3-*O*-methyl-D-xylose. A portion of the mixture of neutral sugars was resolved by paper chromatography and subjected to quantitative analysis (12). The molar ratio of mono-, di-, and tri-*O*-substituted xyloses was 1.1: 38:1. The yield of the partially methylated aldobiouronic acid indicated the presence of 6 moles of aldobiouronic acid per mole of tri-*O*-methyl xylose, corresponding to 8 moles of xylose residues per acid group, in accordance with the above evidence.

The large quantity of 2,3-di-*O*-methyl-D-xylose isolated showed that the backbone of the polysaccharide was composed of D-xylopyranose residues linked through positions 1 and 4 and this conclusion was corroborated by results obtained on periodate oxidation of the hemicellulose. The high negative rotation of the original and of the methylated (−57° in chloroform) polysaccharide strongly suggested that the xylose residues were present in the β-configuration. The 2,3,4-tri-*O*-methyl-D-xylose apparently originated from the non-reducing end groups. The fact that the 4-position was unsubstituted in the crystalline, partly methylated aldobiouronic acid, obtained on partial hydrolysis of the methylated hemicellulose, whereas the methylated aldobiouronic acid itself was substituted in this position, indicated that the 4-*O*-methyl-D-glucuronic acid residues were attached *directly* to the framework of the 1,4-linked xylose residues. The structure of the aldobiouronic acid showed that the side chains were present in the α-configuration and were linked to C_2.

None of the acid side groups were evidently removed during the hydrolysis of the

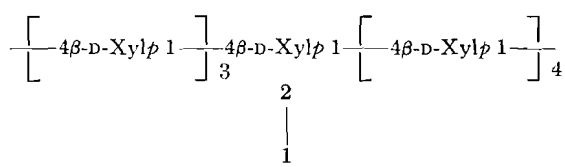
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

methylated hemicellulose. The presence of the two mono-*O*-methyl xyloses was therefore due to either incomplete methylation, demethylation, or branching. While some demethylation probably occurred (13, 14), the possibility of branching could not be excluded, especially in view of the fact that one of the mono-*O*-methyl xyloses predominated.

When the number-average molecular weight of the methylated hemicellulose was determined by osmometry (13, 15), a value of 23,400 was obtained. With one 4-*O*-methyl-D-glucuronic acid residue present for every eighth anhydroxylose unit, this corresponded to a degree of polymerization (number of xylose residues in the main chain) of 124. Each methylated macromolecule thus contained on the average 3.0 mono-*O*-methylated, 118 di-*O*-methylated, and 2.7 tri-*O*-methylated xylose residues. This corresponded to the presence of 1.7 branch points per molecule, most of them probably originating from the 3-position of the xylose residues.

A portion of the hemicellulose was converted to the fully substituted acetate derivative which was soluble in chloroform–ethanol. Osmotic pressure measurements gave a number-average molecular weight of 43,700, corresponding to a $\bar{P}_n$ of 177 for the native polymer.

From the above evidence a simplified structure can now be suggested for the main hemicellulose component of the seed hairs of kapok. The xylan framework of this polysaccharide contains an average number of approximately 180 β-D-xylopyranose residues, connected by 1,4-glycosidic bonds and with, on the average, slightly less than two branching points per molecule, most of them probably located at C_3. Every eighth xylose residue has a single, terminal side chain of 4-*O*-methyl-D-glucuronic acid, linked by an α-glycosidic bond to C_2. The exact nature of the branching is unknown.



4-*O*-Me-α-D-GpA

The only other seed hair hemicellulose hitherto investigated appears to be that present in the floss of the common milkweed (16). This 4-*O*-methyl glucuronoxylan is similar to, albeit not identical with, that found in kapok, the latter polysaccharide having almost twice as many side chains and branching points as the former. Hemicelluloses containing a branched framework of 1,4-β-linked anhydroxylose units have been isolated also from corncob (17), esparto grass (18), and wheat straw (19, 20). In the dicotyledons, however, the 4-*O*-methyl glucuronoxylans are almost invariably linear (21). Whether the same applies to the related gymnosperm xylans is still uncertain (22). Many xylans have been found to contain single side chains of L-arabofuranose residues, for example those present in cereal straws and in coniferous woods. The absence of such groups in the seed hair xylans so far studied is notable. The molecular weight of the native kapok xylan is approximately the same as that of the corresponding polysaccharides present in milkweed floss (16) and in deciduous woods (21).

EXPERIMENTAL

All specific rotations are equilibrium values and melting points are corrected. Evaporations were carried out *in vacuo* at 40–50° C.

Paper Chromatography

Solvents (v/v) used for separating the sugars were (*a*) ethyl acetate – acetic acid – water (9:2:2), (*b*) butan-1-ol–pyridine–water (10:3:3), (*c*) butan-2-one–ethanol–water (20:5:2), (*d*) butan-1-ol–ethanol–water (40:11:19), and (*e*) butan-1-ol–benzene–ethanol–water (6:3:2:1). Whatman No. 1 and No. 3MM filter papers were used and *o*-aminodiphenyl was the preferred spray reagent (12).

Isolation of the Hemicellulose

Kapok seed hairs (1) were exhaustively extracted with ethanol–benzene (1:2, v/v) and subsequently with cold water. The fibers (400 g) were cut into small pieces and shaken with 24% (w/w) aqueous potassium hydroxide (7.6 liters) in an atmosphere of nitrogen for 2 hours. After filtration through sintered glass, the filtrate and the washings were added to a mixture of ethanol (30 liters) and acetic acid (2.6 liters). The precipitate was washed successively on the centrifuge with 80% aqueous methanol, anhydrous methanol, and petroleum ether (b.p. 30–60° C). The product was dried over calcium chloride *in vacuo* for 1 week to yield 75 g of a white, fluffy material, corresponding to 18.8% of the original extractive-free fibers.

Hydrolysis, followed by examination by paper chromatography indicated the presence of mostly xylose and uronic acids. Anal. Pentosan, 83.3%; uronic anhydride, 14.0%; methoxyl, 2.45%; sulphate ash (as potassium), 3.15%; $[\alpha]_D^{20}$ −68° (*c*, 1.0 in 5% sodium hydroxide).

Isolation of Neutral Sugars

The hemicellulose (51 g) was treated with 72% sulphuric acid (120 ml) at room temperature for 2 hours, after which the solution was diluted to 3 liters and boiled under reflux for 6 hours. The solution was neutralized with barium hydroxide, filtered through Celite, and treated with Amberlite IR-120 cation exchange resin for removal of barium ions. Half of the hydrolyzate was slowly passed through a column (5.5×110 cm) of Dowex 1-X4 anion exchange resin. Washing with water removed neutral sugars. On evaporation of the eluate, crystals were obtained which, after recrystallization from 80% ethanol, yielded D-xylose, m.p. and mixed m.p. 144–145° C, $[\alpha]_D^{20}$ +19 (*c*, 1.1 in water). The remaining sirup was resolved on the paper chromatogram (solvent A) to give xylose together with minor quantities of glucose, mannose, arabinose, and rhamnose.

Separation of Sugar Acids

The mixture of sugar acids remaining on the column of exchange resin was resolved by elution with *N* acetic acid to yield two compounds, one being an aldobiouronic acid and the other corresponding in rate of movement on the paper chromatogram (solvent A) and in color produced with the spray reagent to galacturonic acid. Evaporation of the former fraction gave a white, amorphous powder (2.00 g), the infrared spectrum of which was indistinguishable from that of an authentic specimen of 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose. Anal. Calc. for $C_{12}H_{20}O_{11}$: OCH_3, 9.1%; equiv. wt., 340. Found: OCH_3, 8.9%; equiv. wt., 351; $[\alpha]_D^{20}$ +100° (*c*, 2.4 in water).

Further elution of the column with 3 *N* acetic acid gave a third sugar acid, chromatographically identical with 4-*O*-methyl glucuronic acid. Anal. Calc. for $C_7H_{12}O_7$: OCH_3, 14.9%; equiv. wt., 208. Found: OCH_3, 13.9%; equiv. wt., 209; $[\alpha]_D^{20}$ +48° (*c*, 1.4 in water).

Reduction and Hydrolysis of the Aldobiouronic Acid

The aldobiouronic acid (0.80 g) was boiled under reflux with 2% methanolic hydrogen

chloride (50 ml) for 11 hours. After neutralization with silver carbonate and treatment with hydrogen sulphide, filtration through Celite and evaporation yielded a clear sirup which was dissolved in dry tetrahydrofuran (100 ml) and reduced with lithium aluminum hydride (2.4 g) in 100 ml of the same solvent. The reduced glycoside was recovered in the usual way and hydrolyzed with *N* sulphuric acid.

Identification of Hydrolysis Products

The mixture of reducing sugars obtained after the hydrolysis was added to a cocoanut charcoal (23) column (3.5×23 cm). Elution with 3% and 10% aqueous ethanol yielded two compounds, corresponding in rate of movement on the paper chromatogram (solvent C) to xylose and 4-*O*-methyl glucose. The xylose (210 mg) crystallized, m.p. 143–144° C, $[\alpha]_D^{20}$ +19° (*c*, 0.8 in water). The 4-*O*-methyl-D-glucose (300 mg), $[\alpha]_D^{20}$ +68° (*c*, 3.0 in water) was converted to the phenylosazone derivative, m.p. and mixed m.p. 156–157° C.

Methylation, Reduction, and Hydrolysis of the Aldobiouronic Acid

A portion of the aldobiouronic acid (1.13 g) was converted to the methyl ester methyl glycoside. The dry sirup obtained was dissolved in dry dimethyl formamide (20 ml) according to Kuhn (24) and methyl iodide (5 ml) and silver oxide (5 g) were added. After shaking for 24 hours, the product was recovered in the usual way and the methylation procedure was repeated twice. The final product had an infrared spectrum which indicated the absence of hydroxyl groups. The sirup (1.02 g) was reduced in ethyl ether (65 ml) with lithium aluminum hydride (2.5 g) to yield a sirup (1.00 g) which was boiled under reflux for 12 hours with 5% methanolic hydrogen chloride followed by refluxing for 10 hours with 0.5 *N* hydrochloric acid.

Identification of 3,4-Di-O-methyl-D-xylose and 2,3,4-Tri-O-methyl-D-glucose

The acid hydrolyzate was added directly to a cocoanut charcoal column (2×13 cm) which was washed with water until the eluate was neutral. Elution with 6% and 10% ethanol gave two compounds, chromatographically (solvent B and D) indistinguishable from 3,4-di-*O*-methyl xylose and 2,3,4-tri-*O*-methyl glucose, respectively. The di-*O*-methyl xylose, electrophoretically (25, 26) identical with the 3,4-di-*O*-methyl derivative, $[\alpha]_D^{20}$ +15° (*c*, 1.1 in chloroform), was converted to the aniline derivative by treatment with aniline dissolved in absolute ethanol at room temperature. After recrystallization from petroleum ether, the 3,4-di-*O*-methyl-*N*-phenyl-D-xylosylamine had m.p. 122.5–123.5° C. The tri-*O*-methyl glucose, $[\alpha]_D^{20}$ +78° (*c*, 2.0 in water), gave crystalline 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. and mixed m.p. 144–145° C.

Identification of 4-O-Methyl-D-glucuronic Acid

The mono-*O*-methyl hexuronic acid obtained from the column of anion exchange resin was converted to the ester glycoside, reduced with lithium aluminum hydride in tetrahydrofuran, and hydrolyzed with *N* sulphuric acid. Evaporation yielded a sirup, chromatographically (solvent B) identical with 4-*O*-methyl-D-glucose, $[\alpha]_D^{20}$ +56° (*c*, 1.7 in water). The 4-*O*-methyl-D-glucosazone had m.p. and mixed m.p. 156–157° C.

Methylation of the Hemicellulose

The hemicellulose (20 g) was stirred overnight with water (75 ml) and 40% (w/w) sodium hydroxide (100 ml) in an atmosphere of nitrogen, after which dimethyl sulphate (90 ml) was added dropwise over a period of 12 hours. The treatment with alkali and dimethyl sulphate was repeated nine times. The recovered, partially methylated hemicellulose was suspended in tetrahydrofuran (500 ml) and dried over anhydrous sodium sulphate. After removal of the drying agent by filtration, dry dimethyl formamide (500 ml), methyl iodide (5 ml), and silver oxide (5 g) were added (24) and the mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

shaken for 12 hours, after which the same quantities of methylating agents were added and methylation was allowed to proceed for another 12 hours. Tetrahydrofuran was removed by evaporation, chloroform (1000 ml) was added, and dimethyl formamide was removed by continuous extraction with water for 3 days. The dry chloroform extract was concentrated, centrifuged, and poured into petroleum ether (4 liters) to yield a methylated hemicellulose, OCH_3, 37.3% (17.7 g, 80%). Another methylation according to Kuhn (24) failed to raise the methoxyl content of the product. Anal. OCH_3, 37.3%; ash, 0.33%; $[\alpha]_D^{20}$ −57° (*c*, 1.0 in chloroform). The infrared spectrum indicated the absence of hydroxyl groups.

Hydrolysis and Separation of Acidic and Neutral Sugars

A portion of the methylated hemicellulose (7.0 g) was dissolved in glacial acetic acid (75 ml). After addition of water (75 ml), the solution was boiled under reflux for 33 hours, when its rotation was constant. Acetic acid was removed by evaporation and an aqueous solution (500 ml) of the hydrolyzate was added to a column of Dowex 1-X4 exchange resin (acetate form). Neutral sugars were eluted with water after which an acidic compound was removed with 3 *N* acetic acid (1.62 g). Anal. Calc. for $C_{15}H_{26}O_{11}$: OCH_3, 32.5; equiv. wt., 382. Found: OCH_3, 32.3; equiv. wt., 382.

Preparation and Identification of Methyl 2-O-(2,3,4-Tri-O-methyl-α-D-glucopyranosyl)-3-O-methyl-α,β-D-xylopyranoside

The partially methylated aldobiouronic acid (1.38 g) was converted to its methyl ester methyl glycoside, which was reduced with lithium aluminum hydride (1.5 g) in diethyl ether (50 ml). After addition of ethyl acetate and water, the reduced disaccharide was recovered by extraction with chloroform to yield a sirup (1.18 g, 86%) which crystallized on standing. After recrystallization from ethyl acetate, it had a m.p. of 166.5–167.5° C, undepressed on admixture with an authentic specimen of methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)-3-*O*-methyl-D-xylopyranoside.* The melting point, infrared spectrum, and X-ray diagram of the material were also identical with those of another authentic specimen, isolated from yellow birch wood (27). Anal. Calc. for $C_{16}H_{30}O_{10}$: OCH_3, 40.6%. Found: OCH_3, 39.0%; $[\alpha]_D^{20}$ +95° (*c*, 0.7 in water). The compound was probably a mixture of the α- and β-xylopyranosides.

A portion (160 mg) of the disaccharide was subjected to methanolysis and subsequent hydrolysis to give an aqueous solution, which, on chromatographic resolution (solvent B), appeared to contain equal amounts of a mono-*O*-methyl xylose and a tri-*O*-methyl glucose. Extraction with chloroform gave a sirup, chromatographically identical with 2,3,4-tri-*O*-methyl-D-glucose (solvent E). The 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine had m.p. and mixed m.p. 146–147° C. Evaporation of the remaining aqueous solution gave a compound which was chromatographically identical with 3-*O*-methyl-D-xylose (solvent E). The aniline derivative had an infrared spectrum indistinguishable from that of an authentic specimen. Anal. Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 18.8%; $[\alpha]_D^{20}$ +18° (*c*, 1.6 in water).

Separation of the Neutral Components of the Methylated Hemicellulose

The aqueous solution of the neutral sugars from the column of exchange resin was reduced to 500 ml and shaken with chloroform (50 ml) for 3 hours. After having been shaken with water for another 3 hours, the chloroform layer contained only a tri-*O*-methyl xylose (166 mg). The original aqueous solution was extracted continuously with chloroform for 18 hours, the extract was discarded and extraction was continued for another

*The authors are thankful to Professor Fred Smith, University of Minnesota, for providing this sample.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

3 days, yielding a chromatographically pure di-*O*-methyl xylose (1.86 g). The remaining aqueous solution was extracted three times with 20-ml portions of hot ethanol to yield a mixture of mono-*O*-methylated xyloses (154 mg).

Preliminary Characterization of Mono-O-methyl Xyloses

This fraction, $[\alpha]_D^{20}$ +23° (*c*, 2.8 in water), had a methoxyl content (16.3%) somewhat lower than that required for a mono-*O*-methyl xylose. Results obtained on ionophoresis in a borate buffer solution suggested the presence of 2-*O*- and 3-*O*-methyl-D-xylose in an approximate ratio of 2:1.

Identification of 2,3-Di-O-methyl-D-xylose

When seeded with authentic crystals of 2,3-di-*O*-methyl-D-xylose (28), this fraction appeared to crystallize, but the m.p. was 20° higher than expected (96–99° C). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 33.1%; $[\alpha]_D^{20}$ +26° (*c*, 1.0 in water). The 2,3-di-*O*-methyl-*N*-phenyl-D-xylosylamine, when recrystallized once from ethyl acetate, had m.p. 126–127° C. Slow evaporation of an ethyl acetate – petroleum ether solution gave needles, m.p. 130–131° C. The material is known to be dimorphic (29).

Partial Identification of 2,3,4-Tri-O-methyl-D-xylose

Neither the original compound nor its aniline derivative could be induced to crystallize. The infrared spectra of both were indistinguishable from those of authentic samples.

Quantitative Analysis of the Neutral Components

A small portion of the mixture of neutral sugars was resolved on the paper chromatogram with solvent mixture D. The appropriate paper strips were eluted with water and the concentration of each sugar solution was determined by the *o*-aminodiphenyl method (12). The average value of six determinations was used.

Periodate Oxidation of the Hemicellulose

Periodate oxidations were carried out in the dark with 0.05 *M* sodium metaperiodate containing 2 mg of hemicellulose per ml of solution. Aliquots were taken every day for 6 days and the amount of periodate consumed was determined by the arsenite method. The average consumption after 3–4 days was 8.2 moles per repeating unit, corresponding to a calculated value of 7.8.

Preparation of the Acetylated Hemicellulose

Dry hemicellulose (2 g) was swollen or partially dissolved in dry formamide (40 ml) by shaking for 5 hours. Dry pyridine (80 ml) was added, followed by redistilled acetic anhydride (60 ml). The reaction mixture was cooled with tap water for the first half hour and then shaken mechanically at room temperature for 5 hours, after which it was kept at +4° C for 3 days, the reaction flask being opened occasionally during this time. The mixture was poured into ice water (3 liters) with vigorous stirring and washed on a large Buechner funnel, first with ice-cold 2% hydrochloric acid (30) and subsequently with cold distilled water until neutrality. After the water had been replaced by ethanol and the alcohol by petroleum ether (b.p. 30–60° C), the white product was dried *in vacuo* over calcium chloride for 1 week. A second esterification was carried out in the same way although without the addition of formamide. Anal. Calc. for the fully acetylated hemicellulose: acetyl, 37.3%. Found: acetyl, 37.0% (31).

Determination of the Molecular Weight of the Methyl and Acetyl Derivatives of the Hemicellulose

The osmometer used was of the Zimm–Myerson (15) type as modified by Stabin and

Immergut (32). Gel cellophane membranes were used, the solvent was a mixture of chloroform and ethanol (9:1, v/v), and the temperature was 30±0.01° C. The osmotic height was measured at five different concentrations by the static method and the values of h/w, the reduced osmotic pressure, were linearly extrapolated to zero concentrations. The results are presented in Table I. The number-average molecular weight and degree of polymerization were calculated as described elsewhere (28).

PHOTOCHEMICAL SEPARATION OF MERCURY ISOTOPES

III. THE REACTION OF $Hg^{202}6(^3P_1)$ ATOMS, PHOTOEXCITED IN NATURAL MERCURY VAPOR, WITH HYDROGEN CHLORIDE[1]

C. C. McDonald,[2] J. R. McDowell,[3] and H. E. Gunning[3]

ABSTRACT

An investigation has been made of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in natural mercury vapor, with flowing hydrogen chloride at 28–30° C. Emphasis has been placed on the effect of reaction parameters on the Hg^{202} content of the calomel product of the reaction.

Under fast-flow conditions it has been found that the calomel product contains 44% Hg^{202}, corresponding to an enrichment of 48% over the normal abundance of 29.8%.

In the presence of unsaturated compounds such as butadiene and benzene the enrichment is markedly increased. With butadiene and benzene as addends, the maximum enrichments were 98% and 85% respectively.

The reaction with pure hydrogen chloride can be explained in terms of the sequence:

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202}Cl + H \quad [1]$$

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202} + Cl + H \quad [2]$$

$$Cl + Hg^N + M \rightarrow Hg^NCl + M \quad [3]$$

$$H + HCl \rightarrow H_2 + Cl \quad [4]$$

$$H + Cl + M \rightarrow HCl + M \quad [5]$$

where Hg^N is natural mercury and M is a third body, including the wall.

In the presence of unsaturated compounds (U), additional reactions are postulated to occur:

$$Cl + U \rightarrow \text{products} \quad [6]$$

$$H + U \rightarrow \text{products}. \quad [7]$$

The increased enrichment in the presence of unsaturated addends is explained by the reduced rate of formation of Hg^NCl through cleanup of chlorine and hydrogen atoms by reactions [6] and [7].

Under static conditions, the pure hydrogen chloride reaction formed a calomel product of normal Hg^{202} abundance. This finding is explained as a localized depletion of the unexcited mercury in Hg^{202}, through reaction [1]. With increasing linear flow rate the depletion effect gradually disappears and enrichments maximize at high flow rates.

The Hg^{202} enrichment was found to be very sensitive to the wall temperature of the Hg^{202} source. In a 50:50 v/v mixture of hydrogen chloride and butadiene the enrichment was found to decrease from 68% to 24% as the lamp temperature was raised from 25.5° C to 50° C. The effect is explained by temperature broadening of the emission line leading to overlap of the emission line on absorption contours adjacent to that of Hg^{202}.

Both the rate of deposition of the calomel product and the Hg^{202} enrichment were found to depend upon the concentration of natural mercury in the gas stream for hydrogen chloride – butadiene mixtures. Optimum conditions corresponded to a slight supersaturation of the stream with mercury vapor.

INTRODUCTION

In previous studies in this series (1), conditions have been experimentally defined for the photoexcitation, in natural mercury vapor (Hg^N), of a single isotopic species to the $6(^3P_1)$ state. This technique has been recently applied in a study of the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with water vapor (2, 3). In the water reaction it has been found that the HgO product of the reaction contains 80–90% Hg^{202} when addends are present, such as butadiene-1,3, to suppress the secondary formation of Hg^NO.

The present paper reports the first in a series of studies on the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with hydrogen chloride. Emphasis has been placed on the effects of reaction

parameters on the Hg^{202} content of the calomel product of the reaction. Enrichment in Hg^{202} in this product would be evidence for primary formation of calomel, presumably by the reaction:

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202}Cl + H. \quad [1]$$

The details of the investigation follow.

EXPERIMENTAL

The general experimental procedure has been previously described (1, 3). In this study a special rectangular reaction cell was used with faces 2.5×8.0 cm, and an internal path length of 0.10 cm. The cell had two side-arms, terminating in 2/5-spherical joints, for attachment to the flow system. The entire cell was fashioned of Vycor 7910 glass to prevent radiation of wavelength less than 2200 Å from entering the cell.

The source consisted of a quartz electrodeless discharge lamp containing mercury, 98.3 atom per cent in Hg^{202}. The lamp was maintained at 25.5±0.1° C unless otherwise specified. The lamp-cooling assembly has been described (1). The intensity of the radiation at 2537 Å incident upon the cell was monitored by a Westinghouse WL-775 phototube. The photometric unit was identical with that used in the mercury isotope analysis system previously described (4).

The mercury saturator consisted of a 500-cc bulb partially filled with mercury, to which two Liebig condensers were sealed in reflux position. The inner tube of the gas entrance condenser extended into the flask to a point about 1 cm above the mercury surface. In operation the gases entered at the top of the entrance condenser, passed over the refluxing mercury, and left the saturator through the top of the exit condenser. The reaction cell was connected to the exit condenser via a scratched stopcock. The temperatures of the water circulating through exit and entrance condensers were separately controlled from thermostats. The condensers were normally maintained at 30.0±0.1° C.

The gases used in the investigation were the highest-purity grades obtainable from the Matheson Company, East Rutherford, N.J. The benzene used was Fisher A.C.S. grade.

RESULTS

For pure hydrogen chloride a large number of exploratory runs were first performed to determine whether the calomel product of the reaction contained more than the normal abundance of Hg^{202}.

Several runs were first made under static conditions. Analysis showed that the calomel product contained the normal abundance (29.8%) of Hg^{202}, within the experimental error. Under flow conditions, however, the calomel product was found to be consistently enriched in Hg^{202}. The enrichments obtained in these runs varied from 20 to 40%. A systematic study was therefore made of the effect of reaction parameters on the Hg^{202} content of the calomel product.

In Table I the results are given for a series of runs at varying pressures of hydrogen chloride. The linear flow rate was held constant at 600 cm/sec. The light intensity was measured relatively by the photocell response as in the analytical system (4). For this series the incident intensity was 60 units.

Throughout this investigation difficulty was encountered in obtaining good reproducibility for runs done under apparently identical conditions. While the actual absorption measurements were reproducible to ±0.5%, maximum variations of ±5% were encountered, at times, for identical runs.

TABLE I

The effect of varying substrate pressure on the Hg^{202} enrichment in the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with flowing hydrogen chloride (Linear flow rate = 600 cm/sec. Incident light intensity = 60 units)

Pressure, mm	% Hg^{202}	Fractional enrichment
0.4	37	1.2
1.0	37	1.2
3.0	40	1.3
11.0	38	1.3
17.0	40	1.3
50.0	38	1.3

From Table I, it can be seen that the enrichment is constant within the experimental error over the pressure range, 0.4 to 50 mm. Pressures exceeding 50 mm were avoided to prevent Lorentz-broadening of the hyperfine absorption contours (1).

For the data given in Table I, the mercury saturator was operated under very gentle reflux. With the mercury boiling vigorously, it was found that the enrichments increased by approximately 10%. All ensuing runs were therefore performed under vigorous reflux conditions.

For the data in Table II, the pressure was maintained essentially constant, while

TABLE II

The effect of varying linear flow rate on the Hg^{202} enrichment in the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with flowing hydrogen chloride (Incident light intensity = 60 units)

Pressure, mm	Linear flow rate, cm/sec	% Hg^{202}	Fractional enrichment
4.0	375	41	1.4
1.4	425	43	1.4
1.1	475	43	1.4
1.4	1500	42	1.4
2.3	1500	44	1.5
2.8	1500	44	1.5

the linear flow rate was varied from 375 to 1500 cm/sec. It will be observed that there is a slight increase in enrichment with increasing linear flow rate to a maximum value of 48% at 1500 cm/sec.

Since it was suspected that $Hg^{202}6(^3P_0)$ atoms might be involved in the isotopically specific primary process, the effect of added nitrogen on the enrichment was studied. Representative data are given in Table III. While there appears to be a slight increase in enrichment with increasing nitrogen concentration in the stream, the effect is only slightly larger than the experimental reproducibility.

The failure to obtain pure $Hg^{202}Cl$ in the hydrogen chloride reaction implies that Hg^NCl is also being formed by some mechanism. On the hypothesis that the Hg^NCl arose by the interaction of free chlorine atoms with unexcited Hg^N, various additives were studied to reduce the chlorine-atom concentration.

In Table IV it can be seen that benzene has a marked effect on the Hg^{202} enrichment. With benzene concentrations exceeding approximately 30 mole per cent, the minimum enrichment was 70%. The benzene additive appears maximally effective at concentrations of 70 mole per cent, corresponding to an enrichment of 85%.

3.8	65	35	51	1.7
4.3	37	63	50	1.7
3.6	30	70	55	1.8
8.4	18	82	51	1.7

A number of runs were also done with chlorobenzene as additive. The data are summarized in Table V. The effect of chlorobenzene is quite the reverse of benzene, leading

TABLE V

The effect of varying chlorobenzene concentration on the Hg^{202} enrichment in the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with flowing hydrogen chloride (Linear flow rate = 375 cm/sec. Incident light intensity = 60 units)

Pressure, mm	Comp. mole %		% Hg^{202}	Fractional enrichment

6.0	66	34	40	1.3
5.4	50	50	38	1.3
4.0	34	66	38	1.3
6.7	20	80	35	1.2

to a decreased enrichment with increasing mole fraction of chlorobenzene. It is apparent that the photoexcited mercury isotope is being quenched by chlorobenzene with the formation of chlorine atoms. The rate of Hg^NCl formation would therefore be increased over that for pure hydrogen chloride, with a resulting decrease in the Hg^{202} enrichment.

As might be expected, butadiene-1,3 proved to be even more effective than benzene in enhancing the Hg^{202} enrichment. Since butadiene was the most efficient additive encountered in this investigation, it was studied in some detail.

In Table VI, the effect of total pressure on the enrichment is recorded for a mixture containing 50 mole per cent butadiene. The data show clearly that the enrichment reaches a maximum of 98% at a pressure of 5–6 mm. These data were measured at a flow rate of 1500 cm/sec. At lower flow rates the butadiene is less effective. In Table

VII the enrichments are given as a function of total pressure for the same mixture, at a flow rate of 94 cm/sec. The maximum enrichment of 74% occurs at 6–7 mm.

There are many isotopically degradative secondary processes which can be adduced to explain the fact that pure $Hg^{202}Cl$ is not obtained even in the presence of Cl-atom acceptors, such as butadiene. The most obvious of these degradative processes would be the gas phase exchange between $Hg^{202}Cl$ and Hg^N. Some information on the importance of this reaction was obtained by determining the effect upon the enrichment of subliming the calomel deposit a number of times during reaction. This sublimation procedure was carried out for a number of runs, and no difference could be detected, within the experimental error, from those runs in which the calomel product was allowed to accumulate during reaction. An example of the effect of sublimation is given in Table VIII.

The results of a number of runs at various butadiene concentrations and total reaction pressures are given in Table VIII. In none of the runs did the Hg^{202} content of the solid product exceed 59%, corresponding to an enrichment of 98%. From Table VIII it can be seen that higher butadiene concentrations are required at higher total pressures to achieve maximum enrichment.

In order to prevent overlap of the emission line on adjacent hyperfine absorption contours, the temperature of the lamp must be kept below 30° C (1). In this investigation the lamp temperature was maintained constant at 25.5±0.1° C. The uncooled lamp was found to operate at a temperature of approximately 50° C. The decrease in enrichment caused by using an uncooled source is shown in Table VIII. For a mixture containing 50 mole per cent of butadiene, at a total pressure of 4 mm, the enrichment dropped from 68% to 24%, when the cooling water to the lamp was shut off.

Since traces of air are difficult to eliminate completely in fast-flow systems, a study was made of the effect of adding known concentrations of dry air to various mixtures of hydrogen chloride and butadiene. The results are summarized in Table IX. It is

TABLE IX

The effect of varying concentrations of dry air on the Hg^{202} enrichment in the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with flowing hydrogen chloride – butadiene mixtures (Linear flow rate = 1500 cm/sec. Incident light intensity = 65 units)

Pressure, mm	Comp. mole %			% Hg^{202}	Fractional enrichment

apparent that concentrations of air in the 10–20 mole per cent range decrease slightly the maximum enrichment obtained. However, the effect is only slightly greater than the experimental reproducibility. It is therefore unlikely that traces of air would have any detectable effect on the enrichment values.

In Table X, the effect of varying linear flow rate is shown, for a mixture containing 50 mole per cent of butadiene, at a total reaction pressure of 16.0 mm. In comparing these data with those in previous tables for hydrogen chloride – butadiene mixtures, it should be noted that the light intensity is 60 units for the runs reported in Table X. Previous runs were made at a light intensity of 65 units. It will be noted from Table X that the Hg^{202} enrichment is independent of flow rate up to 750 cm/sec, at a value of $51 \pm 3\%$. However, at 1500 cm/sec, the enrichment has increased to 67%. The enrichment-enhancing effect of increasing linear flow rate is also apparent in comparing the

intensity over the entire range of intensities studied.

The final reaction parameter studied was the effect of mercury saturation conditions on the enrichment. In the runs reported to this point in this study the condensers of the mercury saturator were maintained at 30.0±0.1° C. Six feet of pyrex tubing connected the top of the exit condenser to the reaction cell. In order to vary saturation conditions, the 6 ft of connecting tubing were enclosed in a water jacket. To abbreviate the description, the temperature of the exit condenser of the saturator will be referred to as T_c and that of the water-jacketed connecting tubing as T_T.

Normal procedure would correspond closely to $T_c = T_T = 30°$ C, since the uncooled connecting tubing was operated at laboratory temperature, which varied in our case from 28–30° C.

For the mercury saturation studies, a 50:50 v/v mixture of hydrogen chloride and butadiene was used, at a reaction pressure of 4.3 mm, a linear flow rate of 1500 cm/sec, and an incident light intensity of 60 units.

At $T_c = T_T = 30°$ C, sufficient calomel for analysis was obtained in 30 minutes. The average of four runs gave an Hg^{202} abundance of 56±2%. However, as the temperatures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of the water jackets were reduced the rate of deposition of calomel in the reaction zone was observed to decrease markedly. Thus with $T_c = T_T = 16°$ C, no calomel deposit was observed in four hours of irradiation. With $T_c = T_T = 20°$ C, two hours of irradiation were required before deposition was observed. With $T_c = 20°$ C, and $T_T = 28°$ C, sufficient calomel for analysis was obtained in 80 minutes of irradiation. The Hg^{202} content of the product was 50%. When both T_c and T_T were again raised to 30° C, sufficient calomel for analysis was again obtained in 30 minutes. The Hg^{202} content of the calomel was 58%.

In the final experiment on mercury saturation, the water was drained from the exit condenser of the saturator, and the water-jacketed connecting tubing was replaced by a short piece of uncooled tubing. Under these conditions droplets of mercury formed in the reaction cell, indicating supersaturation of the gas stream with mercury vapor. The average of three runs gave an Hg^{202} abundance of 56±1.5%.

DISCUSSION

In the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with flowing hydrogen chloride, the fact that a calomel product is formed which is enriched in Hg^{202} can most obviously be explained by a dual primary process mechanism:

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202}Cl + H \quad [1]$$
$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202} + H + Cl \quad [2]$$
$$Cl + Hg^N + M \rightarrow Hg^NCl + M. \quad [3]$$

Reaction [3] would of course require a third body M to remove heat of recombination.

On the basis of the above sequence, the relative rates of the two primary processes can be estimated from the enrichment data. From the mechanism it follows that the relative rate ratio:

$$R_{Hg^{202}Cl}/R_{Hg^NCl} = \Phi_1/\Phi_2$$

where Φ_1 and Φ_2 are the fractions of the absorbed radiation partitioned to reactions [1] and [2] respectively. The ratio Φ_1/Φ_2 can be calculated from the abundance data, since

$$R_{Hg^{202}Cl}/R_{Hg^NCl} = (A - 29.8)/(100 - A)$$

where A is the percentage abundance of Hg^{202} in the calomel, and 29.8 is the normal Hg^{202} abundance. From our data, the maximum value for $A = 44\%$, whence $\Phi_1/\Phi_2 = 0.25$. In short, reaction [2] is four times more important than reaction [1] at laboratory temperature.

The above calculations are based on the assumption that no isotopic degradation occurs either during reaction or during the recovery of the mercury for analysis. If we allow a maximum uncertainty of ±10% in the A value, the ratio of Φ_2/Φ_1 must be in the range of 3–6. A more detailed investigation of the hydrogen chloride reaction is now in progress in the laboratories of one of us (H.E.G.), as one result of which this ratio should be established more precisely.

The results, given in Table III, indicate that the Hg^{202} enrichment is unaffected by added nitrogen in concentrations up to 80 mole per cent. Although the quenching cross section of hydrogen chloride for $Hg6(^3P_1)$ atoms has not been measured, its value should be at least as large as that for methyl chloride. For methyl chloride and nitrogen, values of 24×10^{-16} cm^2 and 0.274×10^{-16} cm^2 respectively have been obtained (5). Assuming hydrogen chloride to have a quenching cross section of 24×10^{-16} cm^2, hydrogen chloride would be responsible for approximately 96% of the quenching in a mixture containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

80 mole per cent of nitrogen. Hence it would be necessary to study mixtures very much richer in nitrogen before the role of $Hg^{202}6(^3P_0)$ atoms in the reaction could be assessed.

The three-step sequence proposed for the reaction in pure substrate takes no specific cognizance of the fate of the H atoms produced in reactions [1] and [2]. Rodebush and Speakman (6) have postulated the reaction

$$H + HCl \rightarrow H_2 + Cl \qquad [4]$$

in the mechanism of recombination of H atoms in the presence of hydrogen chloride. If reaction [4] is included in the mechanism, the ratio Φ_1/Φ_2 would be increased from 0.25 to 0.67, since the steady-state calculation leads to the relation:

$$R_{Hg^{202}Cl}/R_{Hg^{N}Cl} = \Phi_1/(1+\Phi_2).$$

If we assume further that a recombination process of the type

$$H + Cl + M \rightarrow HCl + M \qquad [5]$$

occurs, the ratio Φ_1/Φ_2 will lie between 0.25 and 0.67. Studies now in progress should shed light on the importance of steps [4] and [5] to the isotopically specific reaction.

The marked enhancement of the enrichment occurring upon the addition of unsaturated compounds (U), such as butadiene and benzene, to the hydrogen chloride stream could involve reactions of both H atoms and Cl atoms with the unsaturated compounds:

$$Cl + U \rightarrow \text{Products}, \qquad [6]$$
$$H + U \rightarrow \text{Products}. \qquad [7]$$

The rapid reaction of H atoms with unsaturated compounds would be very important if reaction [4] has an appreciable effect on the Cl-atom concentration.

The fact that maximum enrichments of 98% were obtained with butadiene as addend, whereas benzene gave a maximum value of 85%, may indicate that reactions [6] and [7] are faster for butadiene than benzene.

When the lamp–wall temperature was raised from 25 to 50° C, a marked decrease in enrichment occurred. This effect is now being systematically investigated. Since the Doppler-broadening is proportional to the square root of the absolute temperature, it can be shown that an increase of 25° in lamp temperature would result in an increase of emission line width of only 0.1 mÅ. The separation of adjacent hyperfine absorption contours from that of Hg^{202} is about 10 mÅ (1). Hence, at this time, it is apparent that Doppler-broadening alone is insufficient to explain the effect of lamp temperature on the enrichment.

The fact that the addition of chlorobenzene to the hydrogen chloride stream depresses the enrichment indirectly substantiates the proposed mechanism. Quenching of the photoexcited mercury atoms by chlorobenzene apparently leads to the formation of chlorine atoms. The rate of $Hg^{N}Cl$ formation by reaction [3] would therefore be increased, and the over-all enrichment would be reduced.

Since sublimation of the calomel product during reaction did not significantly alter the enrichment, it appears unlikely that exchange reactions of the type:

$$Hg^{202}Cl + Hg^{N} \rightarrow Hg^{N}Cl + Hg^{202} \qquad [8]$$

are important in degrading the isotopic calomel before dimerization on the wall.

The failure to obtain enrichment under static conditions can be explained simply on the basis of the proposed mechanism. Under static conditions the unexcited mercury will become impoverished in Hg^{202} through reaction [1]. Hence the calomel formed in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

reaction [3] will contain less than the normal abundance of Hg^{202}. The enrichment caused by reaction [1] will just correspond to the depletion by reaction [3]. The recovered calomel will therefore contain the normal abundance of Hg^{202}. Now as the linear flow rate is increased the Hg^{202}-depleting effect of reaction [1] on the unexcited mercury will become less and less important. The increase in enrichment with increasing linear flow rate therefore follows from this explanation.

Our findings indicate that, at high flow rates, the enrichment increases with increasing incident light intensity for the hydrogen chloride – butadiene mixtures. The explanation of this effect is not readily forthcoming from the proposed mechanism. It would appear wiser to postpone comment on the light intensity dependence until a more detailed study has been made of the hydrogen chloride – butadiene reaction.

The dependence of both the rate of calomel deposition and the Hg^{202} enrichment on the mercury concentration in the stream for the hydrogen chloride – butadiene reaction again emphasizes the complexity of this system. Since maximum enrichment and efficient calomel deposition are obtained only when the stream is slightly supersaturated with mercury vapor it appears that a layer of natural mercury must be adsorbed on the walls of the reaction vessel before the calomel can deposit. Further studies must be carried out on this system before an adequate explanation can be given for this behavior.

CONCLUSIONS

As a result of this investigation it has been firmly established that a fraction of the quenching collisions between $Hg^{202}6(^3P_1)$ atoms and hydrogen chloride forms a solid mercury compound. From stability considerations it is likely that the primary compound is $Hg^{202}Cl$ rather than $Hg^{202}H$.

From the Hg^{202}-enrichment data, and an assumed mechanism, it can be calculated that the isotopically specific portion of the primary reaction at 28–30° C is in the range 20–40%. It is likely that the two primary processes involve a common intermediate, Hg^{202}–Cl–H*. It would be expected that increasing reaction temperature would favor Cl-atom formation. Studies are now under way at the University of Alberta on the temperature coefficient of the primary reaction.

Further investigations are also in progress on the kinetics of the hydrogen chloride reaction in the presence of unsaturated addends.

ACKNOWLEDGMENTS

The authors would like to express their deep appreciation to Dr. Kenton R. Osborn, Dr. Willard F. Allen, and Mr. John A. Poole for many valuable discussions.

REARRANGEMENT STUDIES WITH C^{14}

VII. THE ACETOLYSIS OF METHYL-C^{14}-ISOPROPYLCARBINYL *p*-TOLUENESULPHONATE[1]

A. J. Finlayson and C. C. Lee

ABSTRACT

Acetolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) at reflux temperature gave a mixture of 2-methyl-2-butene (II), 2-methyl-1-butene (III), and 3-methyl-1-butene (IV) with no isolatable quantity of substitution product. The relative amounts of olefins II, III, and IV were measured by gas–liquid chromatography to be 80%, 18%, and 2%, respectively, and these were substantially verified by estimations with the isotope dilution technique. When the acetolysis was carried out at 50° C, besides olefins II, III, and IV, present in relative amounts of 83%, 16%, and 1%, respectively, as determined by gas–liquid chromatography, a small quantity of substitution product, *t*-amyl acetate (V), was obtained. Under the conditions of acetolysis at reflux temperature, however, V was found to decompose to olefins II and III. Degradation of the olefinic products of acetolysis gave, among other compounds, radioactive acetone. Since acetone was derived from the chief product, II, its activity could be attributed to an isotope position rearrangement resulting from a 1,2-methide shift as one of the processes that gave rise to olefin II. This rearrangement amounted to about 2.5% and 0.9%, respectively, in olefin II from acetolysis at reflux temperature and at 50° C. Considering all these results, it may be concluded that both substitution and elimination reactions could take place during acetolysis of I. The substitution reaction proceeded with neighboring hydrogen participation to yield *t*-amyl acetate, which would decompose to olefins II and III at reflux temperature under the acetolysis conditions. In the E_1 reaction during acetolysis of I, processes involving no neighboring group participation to give olefins II and IV, with neighboring hydrogen participation to give olefins II and III, and with neighboring methyl participation to give isotopically rearranged olefins II and IV, all occurred, the process with neighboring hydrogen participation being predominant.

First-order reaction rates for the formolysis of methylisopropylcarbinyl *p*-toluenesulphonate and the acetolysis and formolysis of methylisopropylcarbinyl *p*-bromobenzenesulphonate have been reported by Winstein and Marshall (1) in connection with their studies on neighboring hydrogen and carbon participation. From considerations of relative rates for a series of related secondary sulphonates, it was concluded that there is some assistance to ionization from neighboring group participation during solvolyses of methylisopropylcarbinyl derivatives, though the driving force associated with participation in this system was said to be small (1). No clear-cut differentiation was made on whether participation was from neighboring hydrogen or carbon, nor were any reaction products isolated. In the present work, the acetolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I) was carried out, the reaction products identified, and the degrees of isotope position rearrangement determined so as to shed some light on the different routes the reaction may follow during acetolysis.

RESULTS AND DISCUSSIONS

Methyl-C^{14}-isopropylcarbinol was prepared from reaction of isobutyraldehyde with methyl-C^{14}-magnesium iodide. On subjecting this carbinol to the haloform reaction, nonradioactive isobutyric acid was obtained, indicating that all the C^{14} activity was on the methyl carbon. Conversion of the carbinol to sulphonate I was effected by treatment with *p*-toluenesulphonyl chloride in pyridine.

Acetolysis of I at reflux temperature yielded only olefinic products. No acetate fraction could be isolated. The olefins were shown by gas–liquid chromatographic analysis (2), and verified by isotope dilution, to be a mixture of 2-methyl-2-butene (II), 2-methyl-1-

[1]*Manuscript received January 16, 1959.*

butene (III), and 3-methyl-1-butene (IV), the relative proportions of these are given in Table I. When the acetolysis was carried out at 50° C, besides olefins II, III, and IV (Table I), a small amount of *t*-amyl acetate (V), but no methylisopropylcarbinyl acetate (VI), was obtained. On subjecting V to treatment under conditions as in the acetolysis at reflux temperature, V decomposed to olefins II and III. There was no decomposition of VI under a similar treatment.

TABLE I

Relative amounts of olefins from acetolyses of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate

		% Composition		
		Analyzed by gas chromato-graphy	Analyzed by radioactivity

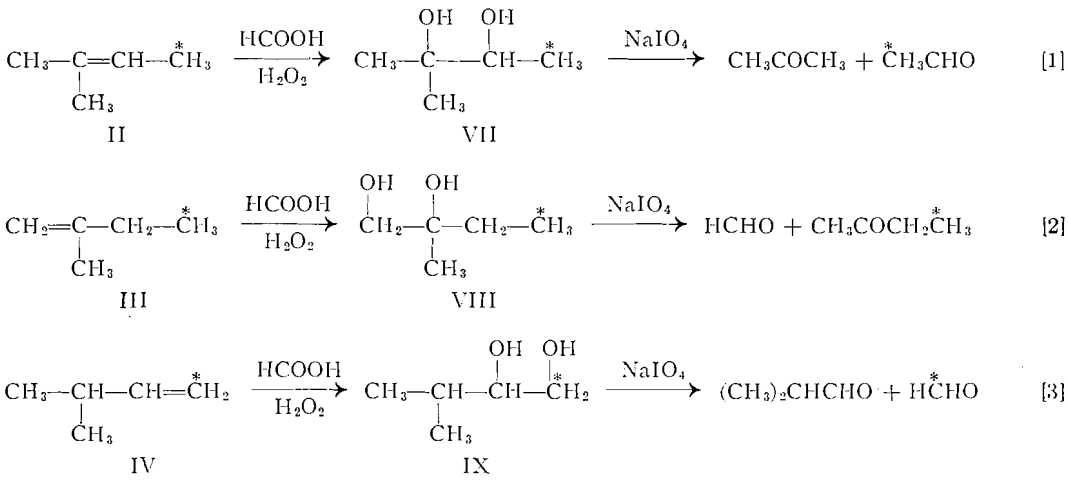
Degradations of olefins II, III, and IV are shown by reaction sequences 1–3, the C^{14} labels being indicated on positions as if there were no isotope position rearrangement.



[1] [2] [3]

When a mixture of II, III, and IV was degraded according to these schemes, the products consisted of a mixture of formaldehyde, acetaldehyde, isobutyraldehyde, acetone, and methyl ethyl ketone. Separation of these carbonyl compounds as their 2,4-dinitrophenylhydrazones was effected by adsorption chromatography in a column packed with a 2:1 mixture of silicic acid and celite (3). Desired bands of individual 2,4-dinitrophenylhydrazones were recovered by elution with petroleum ether containing some diethyl ether. Alternatively, the aldehydes in the mixture of carbonyl compounds were first oxidized with potassium permanganate (4) before the chromatographic separation of acetone and methyl ethyl ketone as their 2,4-dinitrophenylhydrazones.

For measurements of relative amounts of II, III, and IV by isotope dilution, non-labeled olefin II was obtained by distillation of the commercial material through a long column. Non-labeled olefins III and IV were prepared by the Chugaev reaction with *sec*-butylcarbinol and isobutylcarbinol, respectively (5). From these olefins, inactive glycols VII, VIII, and IX were obtained. The purity of each of these glycols was demonstrated by their cleavage with sodium metaperiodate to give only the expected carbonyl compounds.

The isotope dilution experiments were carried out by adding a known quantity of inactive glycol VII, VIII, or IX to a weighed mixture of VII, VIII, and IX derived from the olefins obtained in an acetolysis. The diluted mixture was cleaved with sodium metaperiodate and the 2,4-dinitrophenylhydrazones of the most abundant products isolated from the chromatographic column. Radioactivity assays of these diluted products of degradation provided data from which the relative amounts of II, III, and IV in the original products of acetolysis can be calculated. For example, in isotope dilution run No. 1, the mixture of olefins II, III, and IV from an acetolysis at reflux temperature was converted to a mixture of glycols VII, VIII, and IX. To 0.0580 g of this glycol mixture, 0.2279 g of inactive VII was added. After degradation and separation by adsorption chromatography, the 2,4-dinitrophenylhydrazones of acetaldehyde and acetone were isolated. Radioactivity assay gave specific activity of 8704 c.p.m. on a molar basis[2] for the 2,4-dinitrophenylhydrazone of acetaldehyde. Since gas–liquid chromatography indicated 80% II in the olefin mixture from acetolysis at reflux temperature, it is reasonable to assume that of the 0.0580 g of undiluted active glycol mixture, 80% was VII. Hence the total activity of the acetaldehyde from 0.0580 g of undiluted glycol mixture is equivalent to $8704\times(0.2279+0.80\times0.0580)$ c.p.m. Correcting to a common basis of 1 g of undiluted active glycol mixture, the corrected activity for the acetaldehyde fraction would be

$$\frac{8704\times(0.2279+0.80\times0.0580)}{0.0580} = 41{,}200 \text{ c.p.m.}$$

Similarly, the corrected activity for the acetone was found to be 1120 c.p.m.

In an analogous way, the active glycol mixture was diluted with inactive VIII or IX. From dilution with VIII, the 2,4-dinitrophenylhydrazones of methyl ethyl ketone and formaldehyde were isolated, while from dilution with IX, only the 2,4-dinitrophenylhydrazone of formaldehyde was eluted for activity assay. Radioactivity data from these experiments as well as from a duplicate run are summarized in Table II.

Since formaldehyde is formed from degradation of both VIII and IX, the activity in the formaldehyde would be derived from both VIII and IX in the undiluted active glycol mixture. The corrected activity for formaldehyde from dilution experiment with either inactive VIII or IX should, therefore, be identical. The actual data (Table II) showed small differences in corrected activities calculated for the two formaldehyde samples from each run. Possibly, in the chromatographic separation of the 2,4-dinitrophenylhydrazones, slight contamination of the formaldehyde derivative by the more highly active derivative of acetaldehyde may contribute to these differences. In any case, the magnitude of the differences between corrected activities of formaldehyde samples, of the order of 300 c.p.m. compared to the total corrected activities for all fractions of around 40,000 to 50,000 c.p.m., should not materially affect the over-all calculation of the relative amounts of olefins II, III, and IV.

*From reaction of ketonic products with bromine and sodium hydroxide.

†Specific activities in c.p.m. on a molar basis were determined by converting all compounds to barium carbonate and counted as infinitely thick samples of constant geometry in a gas flow Geiger counter. Correction for the presence of non-labeled carbon atoms was made by multiplying the observed activity with the number of carbon atoms per molecule in the compound assayed (6). In the case of CBr_4, the observed activity was multiplied by 2, since acetone has two equivalent methyl groups. All samples were counted for sufficient lengths of time so that statistical errors were within ±2% of the observed activities.

‡The total activity was taken as the sum of the corrected activities of CH_3CHO, CH_3COCH_3, $CH_3COCH_2CH_3$, and HCHO from dilution with inactive 3-methyl-1,2-butanediol. The percentage of total activity in CH_3CHO and CH_3COCH_3 is a measure of the amount of 2-methyl-2-butene in the mixture of olefins from the acetolysis. The percentage of total activity in $CH_3COCH_2CH_3$ and in HCHO from dilution with inactive 3-methyl-1,2-butanediol is taken as measures of 2-methyl-1-butene and 3-methyl-1-butene, respectively.

For the estimation of the relative amounts of olefins II, III, and IV in the original acetolysis products, the total corrected activities of acetaldehyde, acetone, methyl ethyl ketone, and one sample of formaldehyde were taken as representing the total activity of olefins II, III, and IV. The sum of the corrected activities of acetaldehyde and acetone was used as a measure of II, while the corrected activities of methyl ethyl ketone and formaldehyde were used as measures of III and IV, respectively. Since formaldehyde could actually be derived from both III and IV, and since any active formaldehyde from III would have to arise from an isotopically rearranged III, it may be reasonably assumed that any activity of the formaldehyde from III would be small compared to the activity of methyl ethyl ketone. The use of the corrected activity of methyl ethyl ketone alone as a measure of III is, therefore, an acceptable approximation. For these same reasons, the use of the corrected activity of formaldehyde as a measure of IV is also only a good approximation. Furthermore, it should also be pointed out that although the degradation of IV should give rise to formaldehyde and isobutyraldehyde, the activity in the isobutyraldehyde, if any, should be negligibly small, as active isobutyr-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

aldehyde could only result from an isotopically rearranged IV. In Table II, the corrected activities of a number of degradation products are expressed as percentages of total activity. The percentage of total activity for both acetaldehyde and acetone together would be equivalent to the amount of II and the percentages of total activity for methyl ethyl ketone and formaldehyde would be equivalent to the amounts of III and IV, respectively, in the original acetolysis products. These estimated relative amounts of II, III, and IV are also given in Table I for comparison with results from gas–liquid chromatography.

The fact that there was some activity in the acetone fraction from these isotope dilution experiments indicated that there was some isotope position rearrangement in the major acetolysis product, 2-methyl-2-butene (II). For acetolysis at reflux temperature run No. 1, this rearrangement amounted to

$$\frac{1120}{1120+41200}\times 100 = 2.6\%.$$

In the duplicate run, the rearrangement was 2.4% (Table II). This rearrangement very likely arose from a 1,2-methide shift, or neighboring methyl participation, resulting in an acetone with C^{14} on the methyl carbons:

$$CH_3-\underset{\displaystyle CH_3}{\underset{|}{CH}}-\overset{+}{C}H-\overset{*}{C}H_3 \xrightleftharpoons{CH_3\ \text{shift}} CH_3-\overset{+}{C}H-\underset{\displaystyle CH_3}{\underset{|}{CH}}-\overset{*}{C}H_3$$

Collaboration of such a reaction path may be deduced from the following experiment. A sample of the active mixture of glycols VII, VIII, and IX derived from the products of an acetolysis at reflux temperature was diluted with inactive VII and then cleaved with sodium metaperiodate. The resulting mixture of carbonyl compounds was treated with neutral potassium permanganate to destroy the aldehydes (4). An aqueous solution of the remaining acetone and methyl ethyl ketone was recovered by distillation and then treated with bromine and sodium hydroxide to give carbon tetrabromide. The corrected activities of the carbon tetrabromide samples are also included in Table II. If much of the acetone activity were located on the carbonyl carbon, one would expect the corrected activity of the carbon tetrabromide to be less than that of the acetone. Actually, for a given run, carbon tetrabromide showed somewhat greater activity than acetone (Table II). This extra activity in the carbon tetrabromide very likely was derived from the methyl group of methyl ethyl ketone, indicating that there was also a small degree of isotope position rearrangement in 2-methyl-1-butene (III), another product from the acetolysis of I.

When acetolysis of I was carried out at 50° C, as mentioned earlier, a small amount of *t*-amyl acetate was obtained besides a mixture of olefins II, III, and IV. The relative amounts of II, III, and IV, as measured by gas–liquid chromatography, are given in Table I. In addition, the major product, II, was estimated by radioactivity measurements. As before, olefins II, III, and IV from a given run were converted to the glycol mixture, VII, VIII, and IX. This mixture, without dilution, was degraded in the usual manner and the 2,4-dinitrophenylhydrazones of acetaldehyde and acetone isolated from the adsorption chromatographic column. Activity assays on these degradation products as well as on the glycol mixture were carried out. The results from duplicate acetolyses at 50° C are tabulated in Table III. From these results, the isotope position rearrangement in II, as indicated by the activity of the acetone, was calculated (Table III). The sum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the activities of acetaldehyde and acetone in a given run is, of course, a measure of the amount of II in the original mixture of olefins II, III, and IV. This estimate of II is also listed in Table I for comparison with gas–liquid chromatographic data.

CONCLUSIONS

From the results presented in the foregoing sections and summarized in Tables I, II, and III, it is clear that a number of reaction routes may be followed in the acetolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I). At 50° C, some substitution involving neighboring hydrogen participation took place, giving rise to *t*-amyl acetate (V) as depicted in reaction [4]:

$$\underset{\text{I}}{CH_3{-}CH(CH_3){-}CH(OTs){-}{}^{*}CH_3} + HOAc \longrightarrow \underset{\text{V}}{CH_3{-}C(OAc)(CH_3){-}CH_2{-}{}^{*}CH_3} + TsOH \qquad [4]$$

At reflux temperature, if such a substitution reaction did occur, the product, V, would decompose to olefins II and III. By far the major part of the acetolysis products resulted from elimination reactions. To explain the formation of the various elimination products, processes similar to some of those involved in the E_1 reaction in the acetolysis of the diastereoisomers of 3-phenyl-2-butyl *p*-toluenesulphonate (7) may be postulated. Three processes, depicted by reaction sequences 5, 6, and 7, definitely occurred.

$$I \xrightarrow{-OTs^-} \underset{\text{X}}{CH_3{-}CH(CH_3){-}{}^{+}CH{-}{}^{*}CH_3} \xrightarrow{-H^+} \underset{\text{II}}{CH_3{-}C(CH_3){=}CH{-}{}^{*}CH_3} + \underset{\text{IV}}{CH_3{-}CH(CH_3){-}CH{=}{}^{*}CH_2} \qquad [5]$$

$$I \xrightarrow{-OTs^-} \underset{\text{XI}}{CH_3{-}{}^{+}C(CH_3){-}CH_2{-}{}^{*}CH_3} \xrightarrow{-H^+} \underset{\text{II}}{CH_3{-}C(CH_3){=}CH{-}{}^{*}CH_3} + \underset{\text{III}}{CH_2{=}C(CH_3){-}CH_2{-}{}^{*}CH_3} \qquad [6]$$

$$I \xrightarrow{-OTs^-} \underset{\text{X}_r}{CH_3{-}{}^{+}CH{-}CH(CH_3){-}{}^{*}CH_3} \longrightarrow \underset{\text{II}_r}{CH_3{-}CH{=}C(CH_3){-}{}^{*}CH_3} + \underset{\text{IV}_r}{CH_2{=}CH{-}CH(CH_3){-}{}^{*}CH_3} \qquad [7]$$

(Subscript r is used to denote isotopically rearranged X, II, and IV.)

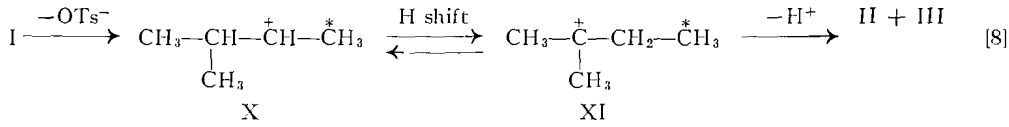
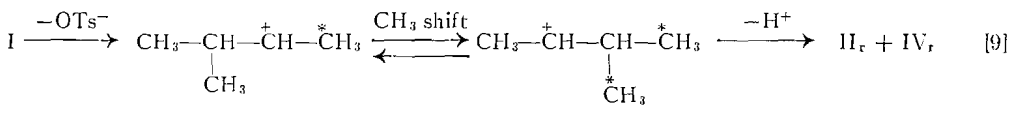
For personal use only.

Reaction [5] involves ionization of I without anchimeric assistance to secondary carbonium ion X, which gave rise to olefins II and IV. Reaction [6] involves ionization of I with anchimeric assistance from neighboring hydrogen participation resulting in tertiary carbonium ion XI, which gave olefins II and III. Reaction [7] involves ionization of I with anchimeric assistance from neighboring methyl participation to give isotopically rearranged X_r, which resulted in the formation of isotopically rearranged olefins II_r and IV_r. According to Saytzeff's rule (8), one would expect a greater amount of II (or II_r) formed in each of these processes. It is, therefore, not surprising to have found that olefin II was the chief isolatable product from the acetolysis mixture. Of these processes of elimination, reaction [6] may be considered as most important, or as having occurred to the greatest extent, since olefin IV, a measure of reaction [5], and isotopically rearranged II_r, a measure of reaction [7], each amounted to only 2–4% of the over-all reaction products for acetolysis at reflux temperature. Still less IV and II_r, in the order of 1%, were found in the products of acetolysis at 50° C.

On the basis of the present results, it is, of course, not possible to differentiate, that in the neighboring hydrogen and methyl participations, whether the processes involved a series of 1,2-shifts in concrete stages with ion X as the first intermediate (reaction sequences 8 and 9), or whether ions XI and X_r were formed directly from I. Nor can one decide whether non-classical carbonium ions XII and XIII play any role in these reactions, for the present results can be explained with or without postulating the existence of XII and XIII.



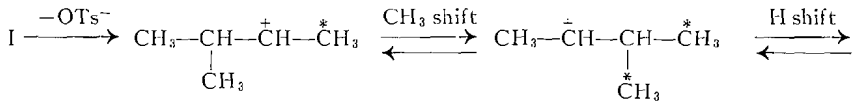
X XI



X X_r

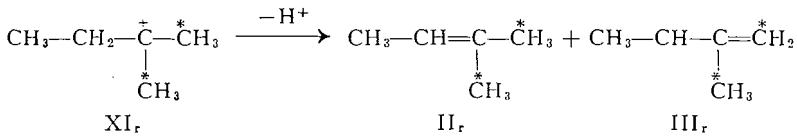
XII XIII

It may be recalled that in the degradation of acetone and methyl ethyl ketone to carbon tetrabromide in acetolysis runs 1 and 2 at reflux temperature (Table II), the corrected activity of the carbon tetrabromide was somewhat higher than that of the corresponding acetone. If one were to consider this difference significant and attribute the extra activity in the carbon tetrabromide as arising from the methyl carbon of methyl ethyl ketone, a process involving first a 1,2-methide shift followed by a 1,2-hydride shift would have to be postulated (reaction sequence [10]):



X X_r

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.



[10]

Methyl ethyl ketone with C^{14} activity on the methyl carbon would thus result from the isotopically rearranged olefin III_r.

In summary, it may be concluded that in the acetolysis of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate (I), both substitution and elimination reactions take place. The substitution proceeds with neighboring hydrogen participation, resulting in the formation of *t*-amyl acetate, which will decompose to olefins at reflux temperature under the acetolysis conditions. In the E_1 reaction during the acetolysis of I, processes involving no neighboring group participation, neighboring hydrogen participation, and neighboring methyl participation all occur, with neighboring hydrogen participation predominant. A process involving first a 1,2-methide shift followed by a 1,2-hydride shift before olefin formation may also take place, though the experimental results only indicate a probability, without an unequivocal proof, of such a reaction route. These conclusions are in excellent agreement with the recent finding of Winstein and Takahashi (9) that the acetolysis of I has a relatively high value of k_Δ/k_s, the ratio of rate constants for anchimerically assisted and unassisted solvolysis processes. These workers attributed k_Δ to neighboring hydrogen participation and accounted for the earlier observation of a low degree of rate acceleration (1) on conformational considerations. Their kinetic studies, however, failed to show the smaller contribution to k_Δ from neighboring methyl participation clearly demonstrated by the present data.

EXPERIMENTAL

Methyl-C^{14}-isopropylcarbinol

Methyl-C^{14}-isopropylcarbinol was prepared by the reaction of isobutyraldehyde with methyl-C^{14}-magnesium iodide. The procedure used was similar to that described for the synthesis of 2-butanol-1-C^{14} (10). A typical preparation is as follows:

Methyl-C^{14}-magnesium iodide, prepared from 13.0 g (0.092 moles) of methyl-C^{14} iodide and 2.9 g (0.12 moles) of magnesium in 180 ml of anhydrous ether, was maintained at −20° C in a dry-ice bath. A solution of 10.8 g (0.15 moles) of freshly distilled isobutyraldehyde in 180 ml of anhydrous ether was added dropwise over a period of 2 hours. The mixture was brought to 0° C and 20 ml of a saturated solution of ammonium chloride was added. The ether layer was separated and the aqueous layer and the precipitated salts were extracted several times with ether. The combined extract was dried over magnesium sulphate, the ether removed, and the residue distilled to give 5.30 g (66%) of the carbinol, b.p. 107–109° C (uncorrected), 3,5-dinitrobenzoate derivative, m.p. 74–75° C (lit. (11*a*), m.p. 76° C).

Isobutyric Acid from Methyl-C^{14}-isopropylcarbinol

A haloform reaction between the carbinol and bromine in sodium hydroxide solution was carried out using a procedure analogous to that employed in the preparation of trimethylacetic acid from pinacolone (12). From 2.80 g (0.032 moles) of methyl-C^{14}-isopropylcarbinol, 1.85 g (65%) of isobutyric acid was obtained. A derivative, the *p*-bromophenacyl ester, showed a m.p. of 77° C (lit. (11*b*), m.p. 77° C). Radioactivity assay showed that this isobutyric acid contained no activity, indicating that all the C^{14} was located on the methyl carbon of methylisopropylcarbinol.

Methyl-C^{14}-isopropylcarbinyl p-Toluenesulphonate

Methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate was prepared from the carbinol by treatment with *p*-toluenesulphonyl chloride in pyridine (13). The product, recrystallized twice from petroleum ether chilled in a dry-ice bath, melted at 20–21° C (lit. (1), m.p. 20.1–20.8° C); the yields obtained were in the order of 60% of theoretical.

Acetolysis of Methyl-C^{14}-isopropylcarbinyl p-Toluenesulphonate

Anhydrous acetic acid containing 0.1 *M* potassium acetate was prepared by refluxing freshly distilled acetic acid, acetic anhydride, and potassium carbonate as described by Cram and Allinger (14). This solution was used for all acetolysis runs. Duplicate acetolyses at reflux temperature and at 50° C were carried out. Typical procedures are given below:

A. Acetolysis at Reflux Temperature

A mixture of 7.15 g (0.030 moles) of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate, 60 ml of anhydrous acetic acid containing 0.1 *M* potassium acetate, and an additional 3.0 g (0.031 moles) of potassium acetate sufficient to neutralize all liberated *p*-toluenesulphonic acid was heated under reflux for 3.5 hours. During the refluxing, the system was flushed with dry nitrogen and any condensable products entrained by the nitrogen were recovered in a dry-ice cooled trap. After the refluxing, the reaction mixture was cooled and extracted with a 3:1 mixture of petroleum ether and ether. The extract was washed with dilute sodium carbonate solution and dried, and the solvent removed. No residue remained, indicating no isolatable quantity of substitution product.

The olefin mixture recovered in the dry-ice cooled trap weighed 1.70 g (82%). It decolorized bromine in carbon tetrachloride very readily. It was distilled once, b.p. 35–38° C, before being used for subsequent analyses by gas chromatography and isotope dilution.

B. Acetolysis at 50° C

A mixture of 13 g (0.054 moles) of methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate, 130 ml of anhydrous acetic acid containing 0.1 *M* potassium acetate, and an additional 6.0 g (0.061 moles) of potassium acetate was maintained at 50±1° C and constantly stirred for 14 hours. The olefins formed (1.25 g) were swept out by nitrogen and collected in a dry-ice cooled trap. These olefins were also distilled once, b.p. 35–38° C, before being analyzed.

For the recovery of the product of substitution, the reaction mixture from the acetolysis was poured into 250 g of ice and water and extracted with ether. The extract was washed with water and with dilute sodium carbonate until the washing remained basic. The washed extract was dried and the ether removed. From the colorless residue, a fraction (0.220 g) boiling at 117–118° C was obtained. Its infrared spectrum was identical with that of *t*-amyl acetate and different from that of methylisopropylcarbinyl acetate.

The residue remaining after the distillation of the acetate weighed 4.6 g. On crystallization, 4.0 g of unreacted methyl-C^{14}-isopropylcarbinyl *p*-toluenesulphonate was recovered. Based on the 9.0 g of sulphonate that was not recovered, the yield of olefins was 48% and the yield of *t*-amyl acetate was 4.6%.

Treatment of t-Amyl Acetate in Refluxing Acetolysis Mixture

A mixture of 6.0 g (0.046 moles) of *t*-amyl acetate, prepared from a reaction of *t*-amyl alcohol with acetic anhydride in the presence of zinc chloride (15), 60 ml of anhydrous acetic acid containing 0.1 *M* potassium acetate, and an additional 3.0 g of potassium acetate was gently refluxed for 3.5 hours. The volatile product, which proved to be a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

60:40 mixture of 2-methyl-2-butene (II) and 2-methyl-1-butene (III) according to gas–liquid chromatographic analysis, was swept out by nitrogen and collected in a dry-ice cooled trap as in the acetolysis. The appearance of this olefinic mixture at various time intervals is recorded below:

Time (hours)	Weight of olefins (g)	% Yield
1.5	0.54	17
2.5	0.81	25
3.5	0.97	30

From the reaction mixture, 2.31 g (39%) of unchanged *t*-amyl acetate was recovered.

Treatment of Methylisopropylcarbinyl Acetate in Refluxing Acetolysis Mixture

Methylisopropylcarbinyl acetate was prepared from acetylation of the alcohol with acetyl chloride in pyridine. Treatment of this acetate in the refluxing acetolysis mixture as described for *t*-amyl acetate gave no olefinic product in 3 hours. On working up of the resulting mixture, unchanged acetate was recovered in 80% yield.

Gas–Liquid Chromatography

The olefinic mixture from acetolysis at reflux temperature or at 50° C was analyzed by gas–liquid chromatography. The column was packed with dinonyl phthalate supported on ground firebrick. The olefins passed through the column with helium as carrier gas. The effluent was analyzed by a thermal conductivity cell with the results automatically recorded. Three peaks were obtained corresponding to the three olefins, 2-methyl-2-butene (II), 2-methyl-1-butene (III), and 3-methyl-1-butene (IV). The areas under these peaks were used as measures of the relative amounts of these olefins. The results are tabulated in Table I.

The olefinic product from the treatment of *t*-amyl acetate in the refluxing acetolysis mixture was also analyzed. Only two peaks, corresponding to a 60:40 mixture of II and III, were observed.

Preparations of Non-radioactive Olefins II, III, and IV

2-Methyl-2-butene (II) was obtained from a commercial sample by careful fractionation through an efficient column (16). 2-Methyl-1-butene (III) and 3-methyl-1-butene (IV) were prepared from *sec*-butylcarbinol and isobutylcarbinol, respectively, by the Chugaev reaction according to the modified method described by Whitmore and Simpson (5). These authors (5) reported the details on the reaction with isobutylcarbinol. In the reaction with *sec*-butylcarbinol, from 22.5 g (0.26 moles) of the carbinol treated with equimolar quantities of sodium hydroxide, carbon disulphide, and methyl iodide, the methylxanthate of *sec*-butylcarbinol obtained weighed 32.8 g (73%), b.p. 107–110° C at 15–17 mm, n_D^{25} 1.5225. Anal. Calc. for $C_7H_{14}OS_2$: C, 47.2%; H, 7.92%; S, 36.0%. Found: C, 47.1%; H, 7.72%; S, 35.8%. This xanthate was decomposed at reflux temperature to give a 42% yield of 2-methyl-1-butene (III).

Degradation of Olefins II, III, and IV

Olefin II, III, or IV was degraded by conversion to the corresponding glycol with performic acid (formic acid and hydrogen peroxide) followed by the cleavage of the glycol with sodium metaperiodate to give carbonyl compounds. The procedures used were similar to those described by Roberts, McMahon, and Hine (4) for their degradation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of isotopically labeled 2-methyl-2-butene (II). The carbonyl compounds, recovered as an aqueous solution by distillation after the reaction with sodium metaperiodate, were converted to the 2,4-dinitrophenylhydrazones which were, in turn, separated by adsorption chromatography. A typical chromatographic separation is as follows:

The chromatographic column, 2.2 cm in diameter and 25 cm in length, was packed with a mixture of silicic acid and celite (2:1 by weight) as described by Gordon and co-workers (3). A 20-mg sample of the 2,4-dinitrophenylhydrazones derived from the degradation of 2-methyl-1-butene (III) was dissolved in 3 ml of chloroform and placed on the top of the column. After the material was adsorbed, 100 ml of low-boiling petroleum ether was added and allowed to percolate into the column under a slight nitrogen pressure. The bands of 2,4-dinitrophenylhydrazones were developed with a 2% solution of diethyl ether in petroleum ether and then eluted by gradually increasing the diethyl ether concentration to 12%. Flow of the solvent was aided by maintaining a nitrogen pressure of about 2 p.s.i.g. on the reservoir of solvent on top of the column. Two bands were eluted. The eluant containing each band was concentrated to about 10 ml whereby the 2,4-dinitrophenylhydrazone crystallized. From the first band, 12.5 mg (90%) of methyl ethyl ketone – 2,4-dinitrophenylhydrazone was recovered. It melted alone and on admixture with an authentic sample at 116–117° C. The second band gave 5.0 mg (80%) of formaldehyde – 2,4-dinitrophenylhydrazone which melted at 161° C. It did not show any melting-point depression when mixed with an authentic sample. No other material was recovered from the column, indicating that the 2-methyl-1-butene (III) degraded was pure.

Similarly, degradation of 2-methyl-2-butene (II) or 3-methyl-1-butene (IV) gave only the 2,4-dinitrophenylhydrazones of the expected carbonyl compounds after the chromatographic separation.

Isotope Dilutions and Degradations of Olefinic Products from Acetolyses at Reflux Temperature

The mixture of radioactive olefins II, III, and IV obtained from each of the duplicate acetolyses at reflux temperature was converted to the corresponding mixture of active glycols, 2-methyl-2,3-butanediol (VII), 2-methyl-1,2-butanediol (VIII), and 3-methyl-1,2-butanediol (IX) by treatment with performic acid (4). Known quantities of this mixture were diluted with weighed amounts of non-radioactive glycol VII, VIII, or IX and then cleaved to give carbonyl compounds. The cleavage was effected by the method of Reeves (17) instead of that of Roberts and co-workers (4) because the former method gave better yields. Details of a typical dilution and degradation are given below:

To 0.0580 g (0.00056 moles) of the mixture of active glycols, derived from acetolysis at reflux temperature run No. 1, was added 0.2279 g (0.0022 moles) of inactive 2-methyl-2,3-butanediol (VII). This diluted glycol mixture was dissolved in 10 ml of water and treated with 10 ml of 0.03 *N* periodic acid and 10 ml of 1 *N* sodium bicarbonate. After it had been left standing at room temperature for 1 hour, the reaction mixture was treated with 10 ml of 1 *N* hydrochloric acid and 10 ml of 1 *N* sodium arsenite solution to destroy the iodine formed. The resulting solution was distilled and the distillate containing the carbonyl compounds was trapped in a dry-ice cooled receiver. This distillate was poured into 250 ml of 2 *N* hydrochloric acid containing 1.20 g (0.006 moles) of 2,4-dinitrophenylhydrazine and allowed to stand for 1 hour at 0° C. The 2,4-dinitrophenylhydrazones formed weighed 1.00 g (79% of the theoretical calculated on the assumption that the diluted glycol mixture was pure 2-methyl-2,3-butanediol). Part of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

these 2,4-dinitrophenylhydrazones was separated, in 50-mg lots, by chromatography in the silicic acid – celite column as previously described. In this particular dilution experiment in which the diluent was inactive VII, the 2,4-dinitrophenylhydrazones of the major degradation products, acetaldehyde and acetone, were isolated from the column and assayed for radioactivity.

Similarly, other portions of the same mixture of active glycols were diluted with inactive glycol VIII or IX and cleaved to give carbonyl compounds which were separated as their 2,4-dinitrophenylhydrazones by chromatography. A fresh silicic acid – celite column was used for each separation. In the dilution with inactive 2-methyl-1,2-butanediol (VIII), the 2,4-dinitrophenylhydrazones of formaldehyde and methyl ethyl ketone were recovered for radioactivity assays. In the dilution with inactive 3-methyl-1,2-butanediol (IX), only the 2,4-dinitrophenylhydrazone of formaldehyde was recovered and its radioactivity measured.

The entire process was repeated using the mixture of active glycols derived from acetolysis at reflux temperature run No. 2.

The radioactivity data are summarized in Table II.

Carbon Tetrabromide from the Ketonic Degradation Products

A portion (0.1078 g) of the mixture of active glycols derived from acetolysis at reflux temperature run No. 1 was diluted with 0.1853 g of inactive 2-methyl-2,3-butanediol (VII) and then cleaved with periodic acid as described above. The solution of carbonyl compound obtained was treated with dilute potassium permanganate solution until the purple color persisted for 1 hour. The excess permanganate was reduced by a few drops of 4% sodium bisulphite and the manganese dioxide removed by filtration. This treatment effectively destroyed all the aldehydes (4). The filtrate was distilled to give a solution containing only the ketonic degradation products, acetone and methyl ethyl ketone. This distillate was added dropwise to a stirred solution of 3.5 g of bromine in 65 ml of 10% sodium hydroxide maintained at 5° C. After the addition, stirring was continued at room temperature for 3 hours. The precipitated carbon tetrabromide was recovered by steam distillation and purified by sublimation. The yield was 0.25 g, m.p. 91–92° C (lit. (11*c*), m.p. 92° C).

A similar reaction using the mixture of active glycols derived from acetolysis at reflux temperature run No. 2 was also carried out.

The radioactivity data are included in Table II.

Degradation of the Olefinic Products from Acetolyses at 50° C

The mixture of active olefins II, III, and IV obtained from each of the duplicate acetolyses at 50° C was converted to the corresponding mixture of active glycols VII, VIII, and IX. Without any dilution with inactive glycol, this mixture was cleaved with periodic acid and the resulting carbonyl compounds subjected to chromatographic separation as their 2,4-dinitrophenylhydrazones. The chief components, the 2,4-dinitrophenylhydrazones of acetaldehyde and acetone, were recovered. Radioactivity assays were carried out on these two 2,4-dinitrophenylhydrazones and on the original mixture of active glycols VII, VIII, and IX. The results are summarized in Table III.

THE EFFECT OF MOLECULAR OXYGEN ON THE REACTION OF OXYGEN ATOMS WITH *cis*-2-PENTENE[1]

S. SATO[2] AND R. J. CVETANOVIĆ

ABSTRACT

The effect of the presence of nitrogen, oxygen, and nitric oxide on the reaction between *cis*-2-pentene and oxygen atoms has been investigated at room temperature (25±2° C). For production of oxygen atoms use was made of mercury-photosensitized decomposition of nitrous oxide and of the photolysis of nitrogen dioxide at 3660 Å.

In the N_2O work, the presence of molecular oxygen induced the formation of acetaldehyde, propanal, methanol, and ethanol. In the NO_2 work, the amounts of acetaldehyde, propanal, and ethyl nitrate formed increased rapidly with increasing pressure of molecular oxygen. Possible reaction mechanisms for the formation of these compounds are discussed.

Additional information was obtained on the pressure-independent fragmentation in the reaction of oxygen atoms with *cis*-2-pentene.

INTRODUCTION

The reactions of oxygen atoms with various mono-olefins have been extensively investigated in this laboratory and the main features of the reactions have been established (1). As the source of oxygen atoms use was made of mercury-photosensitized decomposition of nitrous oxide (1), photolysis of nitrogen dioxide (2), and activation of oxygen molecules by electrical discharge (3). In the last method, however, excess oxygen molecules present participated in the reaction and led to considerable complexities. Ozone formation was postulated to explain the formation of some of the observed products.

In the photo-oxidation of hydrocarbons by nitrogen dioxide in the air, Haagen-Smit demonstrated the formation of large amounts of ozone (4). Possible mechanisms have been recently reviewed and discussed in some detail by Leighton and Perkins in connection with "smog" formation in the Los Angeles area (5).

The authors have briefly mentioned in a previous paper (2) that photo-oxidation of 1-butene, isobutene, and 2-butene by nitrogen dioxide in the presence of oxygen gives large amounts of propionaldehyde, acetone, and acetaldehyde, respectively, under certain conditions (for example, 3 mm NO_2, 3 mm olefin, and 50 mm oxygen), although the amounts of the main addition products formed remain almost constant in the presence of either nitrogen or oxygen.

A study of the reactions of ozone with a number of olefins in the gas phase is in progress in this laboratory (6). It has been established that ozone produces mainly propanal and formaldehyde from 1-butene, acetone and formaldehyde from isobutene, and propanal and acetaldehyde from 2-pentene. It appears possible then that an intermediate formation of ozone is responsible for some of the major products in the photochemical oxidation of olefins by nitrogen dioxide in the presence of molecular oxygen.

According to Benson and Axworthy (7) and Herron and Schiff (8), the formation of ozone by the third-body reaction

$$O + O_2 + M \rightarrow O_3 + M \qquad [1]$$

is very slow compared with the reactions of oxygen atoms with olefins under conditions stated above. If the aldehydes observed in the photo-oxidation of butenes by nitrogen

[1]*Manuscript received February 3, 1959.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 5146.
[2]*National Research Council Postdoctorate Fellow 1956–1958. Present address: Laboratory of Physical Chemistry, Tokyo Institute of Technology, Tokyo, Japan.*

dioxide in the presence of molecular oxygen result from the reactions between ozone and the butenes, there must be another mechanism of formation of ozone. This, perhaps, may involve some radicals (R·) formed in these processes and the following reaction sequence (4, 5):

$$R\cdot + O_2 \rightarrow RO_2\cdot, \quad [2]$$

$$RO_2\cdot + O_2 \rightarrow RO\cdot + O_3. \quad [3]$$

The object of the present work has been to obtain further experimental information on these processes. *cis*-2-Pentene was chosen for the study because the main features of its reaction with oxygen atoms are known and the major products of the reaction with ozone in the gas phase are acetaldehyde and propionaldehyde, both of which are easily measured quantitatively. Photo-oxidation of this olefin by nitrogen dioxide in the presence of nitrogen, nitric oxide, and oxygen was investigated at room temperature and using the wave length of 3660 Å. Also, some additional aspects of the reaction with oxygen atoms produced by mercury-photosensitized decomposition of nitrous oxide were investigated with and without molecular oxygen added with a view of gaining further insight into the mechanism of formation of free radicals by pressure-independent fragmentation in this reaction.

EXPERIMENTAL

The experimental arrangements employed in the two methods of production of oxygen atoms, the mercury-photosensitized decomposition of nitrous oxide (1) and the photolysis of nitrogen dioxide (2), have been reported in the previous papers.

cis-2-Pentene was obtained from the National Bureau of Standards, Washington (impurity 0.07 ± 0.02 mole %). This olefin, nitrogen (Linde Air Products Co.), and nitric oxide (Matheson Co., Inc.) were used without further purification. Oxygen (Dominion Oxygen Co.) was passed through a tube packed with molecular sieve granules to remove traces of water. The method of purification of nitrogen dioxide was the same as reported previously (2).

In the N_2O work, the reaction products were transferred to a LeRoy still (9), and the fraction condensable at $-140°$ C was analyzed by means of gas chromatography (GLC) (10). In the NO_2 work, the products were pumped off at liquid nitrogen temperature and were transferred to a sampling tube containing a drop of mercury. After completion of the reaction of the excess nitrogen dioxide present with mercury, the products were again pumped off at liquid nitrogen temperature and analyzed by GLC. The identity of the reaction products separated by GLC was further confirmed by infrared and mass spectrometric analyses. The amounts of products were measured from the GLC peak areas.

Since a variety of reaction products are formed in these reactions, several GLC columns were used: dimethyl sulpholane (DMS) on glass beads (3 wt. % DMS, 8 ft), dinonyl phthalate (DNP) on glass beads (4 wt. % DNP, 8 ft), and Tricresyl phosphate (TCP) on firebricks (40 wt. % TCP, 40 ft). The last column was used at 90° C and the others at room temperature. The carrier gas was helium.

When the reaction products were passed through the DMS column first, several pairs of compounds remained unresolved: *cis*-2-pentene and acetaldehyde, *trans*-β-pentene oxide and ethyl alcohol, *cis*-β-pentene oxide and methyl nitrate. The first pair was then separated on the TCP column and the last two on the DNP column.

The isolation and identification of *n*-butane formed in the N_2O work was kindly done by Dr. N. F. Foster on a 40-ft GLC column (40 wt. % DMS on firebrick) operated at

room temperature. Figure 1 shows typical GLC peaks obtained by the DMS column (8 ft).

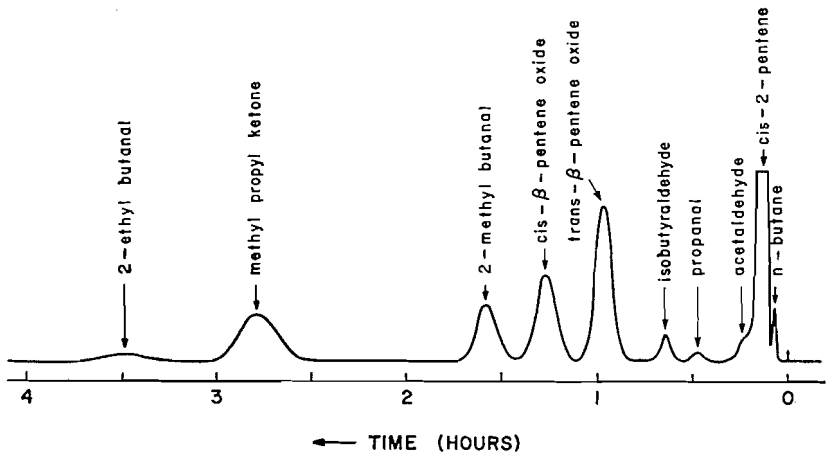

FIG. 1. Typical GL chromatogram obtained using the 8-ft DMS column for the analysis of products of the reaction of oxygen atoms with *cis*-2-pentene.

RESULTS AND DISCUSSION

The Nature of the Pressure-independent Fragmentation in the Reaction of Oxygen Atoms with cis-2-Pentene

As already reported (1), the principal products of the reaction between oxygen atoms and *cis*-2-pentene are *trans*- and *cis*-β-pentene oxide, methyl propyl ketone, and 2-methyl butanal. The first three compounds are produced by internal rearrangements (non-radical mechanisms), while 2-methyl butanal is partly formed by "external" rearrangement (free-radical mechanism). This last process is a consequence of a certain amount of pressure-independent fragmentation which occurs in these reactions (1). (The pressure-dependent fragmentation of the "hot" addition products formed is suppressed already at relatively quite low pressures, except in the case of ethylene and propylene (1, 2).)

In order to obtain further information on the nature of the pressure-independent fragmentation, additional experiments with *cis*-2-pentene and oxygen atoms produced by mercury-photosensitized decomposition of N_2O have been carried out with and without molecular oxygen added. The particular object has been to establish more thoroughly the type of the minor products formed. The results are shown in Table I.

TABLE I

The products of the reaction of oxygen atoms with *cis*-2-pentene
(Oxygen atoms produced by mercury-photosensitized decomposition of N_2O, irradiation time 15 minutes, 25±2° C)

N_2O, mm	*c*-Pe, mm	O_2, mm	GLC peak areas of the products (arbitrary units)											
			t-PO	*c*-PO	2MB	MPK	But	AcA	PrA	*i*-BA	2EB	MeOH	EtOH	H_2O

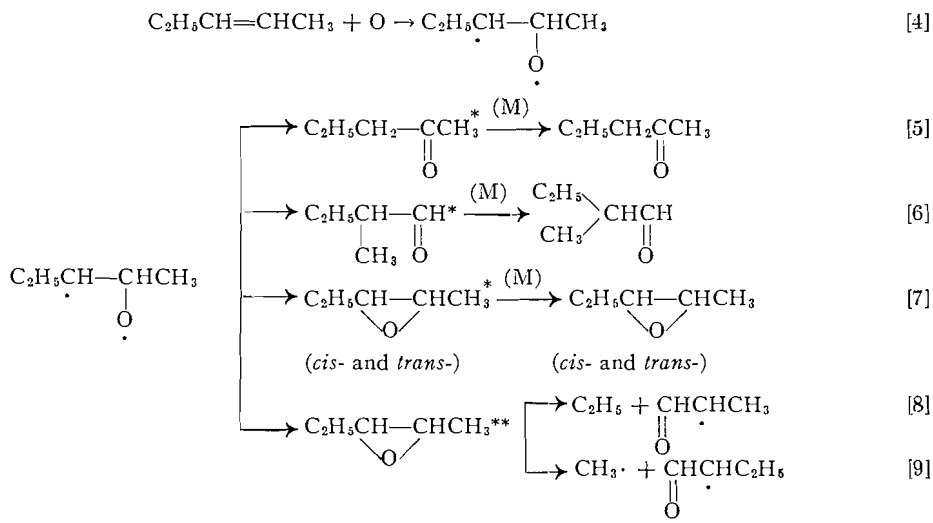
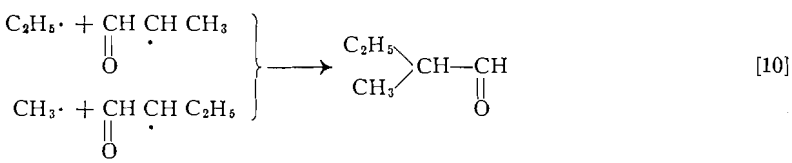
In the absence of oxygen, small amounts of butane, propanal, isobutyraldehyde, and 2-ethyl butanal[3] are formed besides the large amounts of the four main addition products. It is significant that these minor products clearly indicate formation not only of free CH_3 but also of free C_2H_5 radicals in the pressure-independent fragmentation. This is also confirmed by the results in the presence of molecular oxygen, which will be discussed further below. In view of this it is suggested that the pressure-independent fragmentation probably results from the decomposition of a very short-lived excited epoxide molecule ($C_2H_5 \cdot CH—CH \cdot CH_3$**), i.e. reactions [8] and [9] in the following scheme:



The formation of 2-methyl butanal by "external" rearrangement (1) is then due to the radical combinations

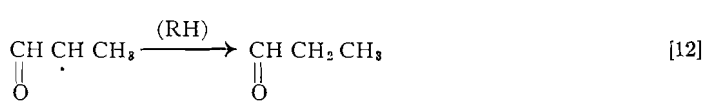


The above mechanism is identical with the general mechanism of addition of oxygen atoms to olefins given previously (1), except that a more detailed course is now postulated for the pressure-independent fragmentation, i.e. reactions [8] and [9]. The presence of both free CH_3 and C_2H_5 radicals is thus accounted for, and the formation of the minor products can then be readily explained by the reactions

$$C_2H_5\cdot + C_2H_5\cdot \rightarrow C_4H_{10} \qquad [11a]$$

$$C_2H_5\cdot + CH_3\cdot \rightarrow C_3H_8 \qquad [11b]$$

$$CH_3\cdot + CH_3\cdot \rightarrow C_2H_6 \qquad [11c]$$



[3]*Mass spectrometer analysis of the fraction isolated by GLC as 2-ethyl butanal indicated also the presence of some unidentified impurities.*

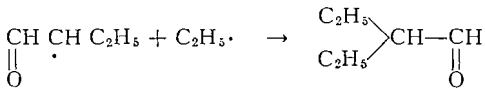
[13]

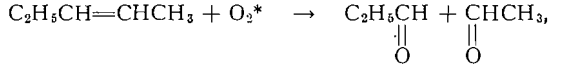


[14]

Since ethane has been observed in the previous work (1) and no analysis for propane could be made in the presence of the huge excess of N_2O, essentially all the observed products are predicted by this scheme.[4]

In the presence of oxygen, large amounts of methyl alcohol, ethyl alcohol, acetaldehyde, and propanal were observed instead of the larger part of 2-methyl butanal (the part formed by "external", free-radical rearrangement), *n*-butane, isobutanal, and 2-ethyl butanal, as shown in Table I. These products did not result from the quenching reaction of oxygen molecules, although the table shows that some quenching reactions involving oxygen molecules in the absence of nitrous oxide occurred, perhaps

[15]



[16]

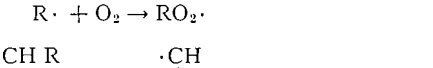
or

[17]

These reactions (and further reactions of O and O_3) could explain the small amount of products formed in the absence of N_2O.

In the presence of a large amount of nitrous oxide, excited mercury atoms are essentially exclusively quenched by nitrous oxide and the molecular oxygen acts as an efficient scavenger for the free radicals formed in the pressure-independent fragmentation reactions [8] and [9].

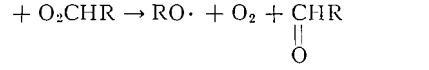
The processes which occur in the presence of molecular oxygen are of considerable complexity and are as yet not fully understood. The formation of the alcohols and the aldehydes may be explained tentatively by the following reactions:



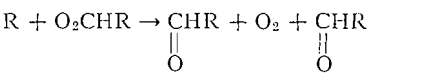
[2]

[18]

[19]

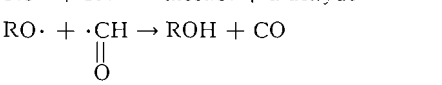


[20]



[21]

[22]



[23]

[4] *Undoubtedly some disproportionation of ethyl radicals occurs as well, but the amount of ethylene thus formed must be relatively quite small and difficult to estimate with certainty by mass spectrometric analysis of the ethane fraction.*

$$O_2CHR + O_2 \rightarrow \underset{\underset{O}{\|}}{CHR} + O_3 \qquad [24]$$

$$RCH{=}CHR + O_3 \rightarrow \underset{\underset{O}{\|}}{RCH} + O_2CHR \qquad [25]$$

Here R· stands for CH_3· or C_2H_5. Reaction [18] is somewhat similar to the generally assumed initial splitting of an olefin molecule on interaction with ozone (reaction [25]), and O_2CHR is the "zwitter ion" assumed to be formed in this latter process (5). An inspection of the amounts of products in Table I indicates that reactions [2] and [18–23] are capable of explaining the aldehydes and alcohols formed in the presence of oxygen. There is no need then to assume in this case chain processes involving ozone, such as sequences of reactions [2], [3], and [25], or [24] and [25].

Experiments with higher pressures of oxygen have not been attempted in the nitrous oxide work because the quenching reaction [15] is very likely to become important and some additional complications could affect the quantitative aspect of the results.

Photo-oxidation of cis-2-Pentene by Nitrogen Dioxide

Light of wave length of 3660 Å dissociates nitrogen dioxide into nitric oxide and a ground-state oxygen atom (^3P), and the reaction scheme outlined in the previous section should, therefore, be applicable. In this case, however, nitrogen dioxide competes with *cis*-2-pentene for oxygen atoms and also acts as an efficient scavenger for the free radicals formed by the pressure-independent fragmentation, reactions [8] and [9]. As a result a greater complexity of products has to be expected. Figure 2 shows the results of experiments with 3 mm of nitrogen dioxide and 3 mm of *cis*-2-pentene at various irradiation

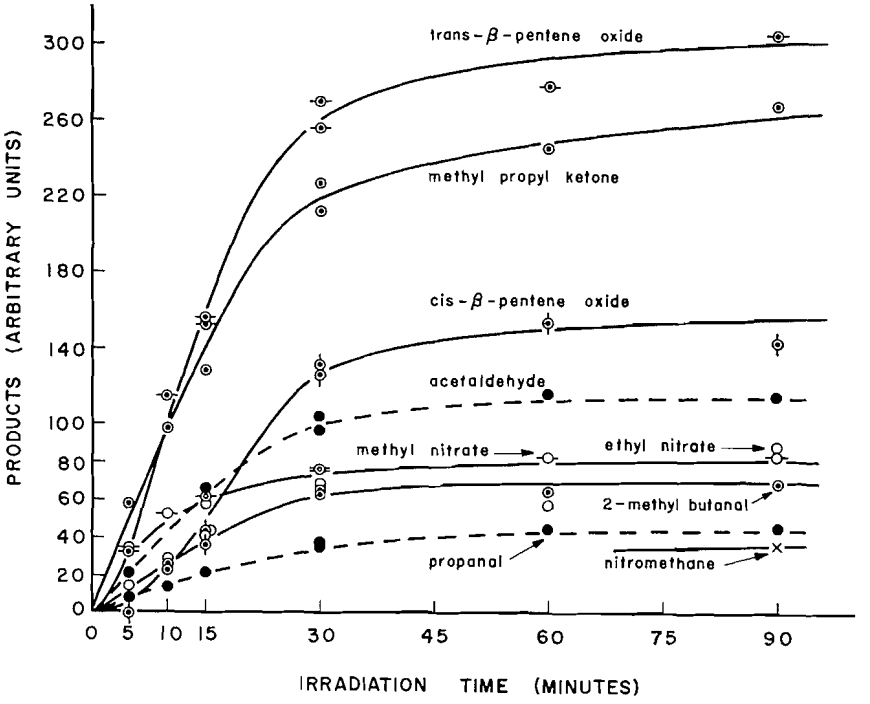

FIG. 2. Yield of the products as a function of irradiation time in the photo-oxidation of *cis*-2-pentene (3 mm) by nitrogen dioxide (3 mm), 25±2° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

times. The products formed are *trans*- and *cis*-β-pentene oxide, 2-methyl butanal, methyl propyl ketone, acetaldehyde, propanal, methyl nitrate, ethyl nitrate, nitromethane, and probably nitroethane. The first four compounds are the main products observed in the N_2O work. The curves for *trans*- and *cis*-β-pentene oxide in Fig. 2 show apparent induction periods. These are explainable by a certain amount of thermal reaction between nitrogen dioxide and the pentene oxides formed in the photo-oxidation, as discussed previously (2). The rates of the thermal reactions of butene oxides with nitrogen dioxide are believed to be in the following order: isobutene oxide > *cis*-β-butene oxide > *trans*-β-butene oxide > α-butene oxide. β-Pentene oxides are believed to behave similarly to β-butene oxides.

In order to obtain information on the consumption of nitrogen dioxide under various conditions, a RCA 935 vacuum phototube was placed behind the reaction cell and the intensity of the transmitted light was measured by means of an electronic circuit. Figure 3 shows the fraction of the initially taken 3 mm of nitrogen dioxide consumed at various

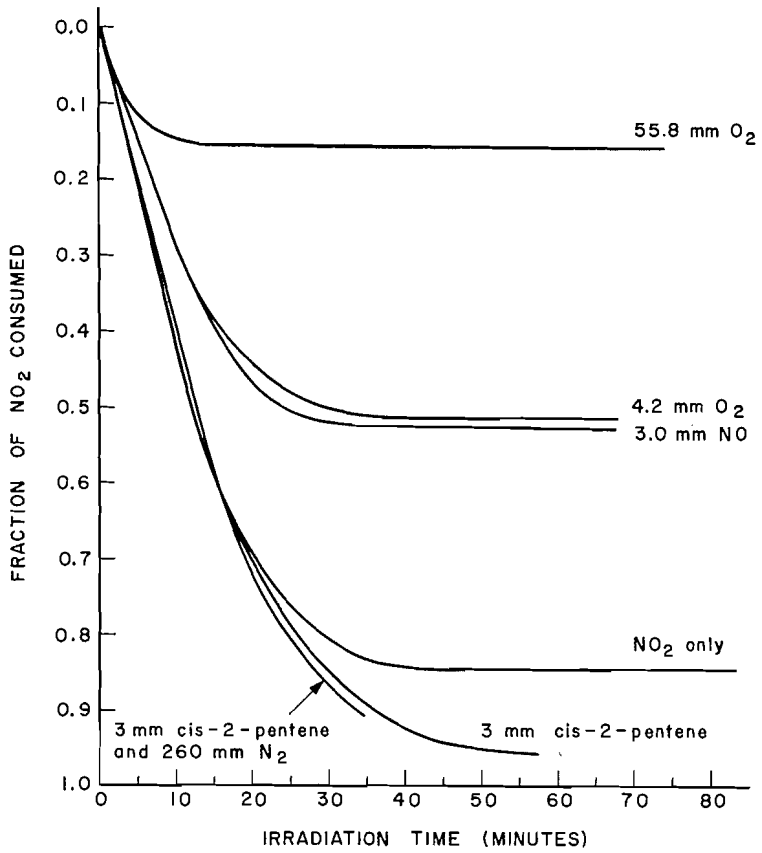

FIG. 3. Consumption of NO_2 as a function of irradiation time. (Initial NO_2 pressure 3 mm, the pressures of added gases are indicated on the curves.)

irradiation times. The greatest part of nitrogen dioxide (in the absence of other compounds) was consumed in about 20 to 30 minutes. In the presence of oxygen or nitric oxide, the consumption was much slower because of more rapid regeneration of nitrogen dioxide when excess of either of these two compounds was added initially.

Figure 4 shows that pressure effects in the photo-oxidation of *cis*-2-pentene are negligible in the investigated range from 6 to 400 mm, while the photo-oxidations of 1-butene and isobutene showed pressure effects below about 10 mm. Yet, the amounts of acetaldehyde and propanal are seen in Fig. 4 to increase appreciably at pressures below about 10 mm without a noticeable compensating decline in the addition products. This could perhaps be ascribed to a reaction between *cis*-2-pentene and excited oxygen molecules formed in the reaction

$$O + NO_2 \rightarrow NO + O_2^*. \qquad [26]$$

However, nothing definite is known about reactions of this type. There is some scatter of points for the addition products formed, Fig. 4, and some pressure-dependent fragmentation at very low pressures is not ruled out. This view is supported by the observation that the amount of methyl nitrate also increases below about 10 mm.

According to Ford and Endow (11) the three-body reaction

$$O + NO_2 + M \rightarrow NO_3 + M \qquad [27]$$

can successfully compete with reaction [26]. From the values of the rate constants given by these authors for these two reactions, R_{26}/R_{27} is about unity at a pressure of 400 mm when nitrogen is the third body. However, no pressure effect is shown in Fig. 4 at higher pressures, suggesting that reaction [27] is relatively unimportant. These two findings are obviously contradictory except if NO_3 molecules produced in reaction [27] react with *cis*-2-pentene in the same manner as oxygen atoms. This appears somewhat unlikely in view of the following.

Since NO_3 presumably reacts very rapidly with nitric oxide, the effect of additions of nitric oxide was examined as shown in Table II. It is evident from Fig. 3 that with the

TABLE II

Yield of the reaction products as a function of the pressure of nitric oxide

3.0	3.0	100	121	20	83	284	(72)	ind.	(130)	0	ind.

c-Pe = *cis*-2-pentene, *t*-PO = *trans*-β-pentene oxide, *c*-PO = *cis*-β-pentene oxide, 2MB = 2-methyl butanal, MPK = methyl propyl ketone, AcA = acetaldehyde, PrA = propanal, $MeNO_2$ = nitromethane, $MeNO_3$ = methyl nitrate, $EtNO_3$ = ethyl nitrate, ind. = indication. The values in parentheses are of low accuracy.

short irradiation times of 5 minutes used in these experiments there could be little variation in the average concentration of nitrogen dioxide as the amount of NO added is varied. The amounts of methyl propyl ketone and 2-methyl butanal remained relatively little affected as the pressure of NO was increased. The observed variations introduce some uncertainty into the quantitative validity of this argument, although they are explainable by the experimental errors and a certain amount of competitive consumption of oxygen atoms in the reaction

$$O + NO + M \rightarrow NO_2 + M.$$

The rapid decline in the two epoxides with increasing amounts of NO added may be ascribed to the considerable reactivity of these compounds. The trends in the amounts of the other products in Table II are of interest for the understanding of the mechanism of their formation and will be discussed further below.

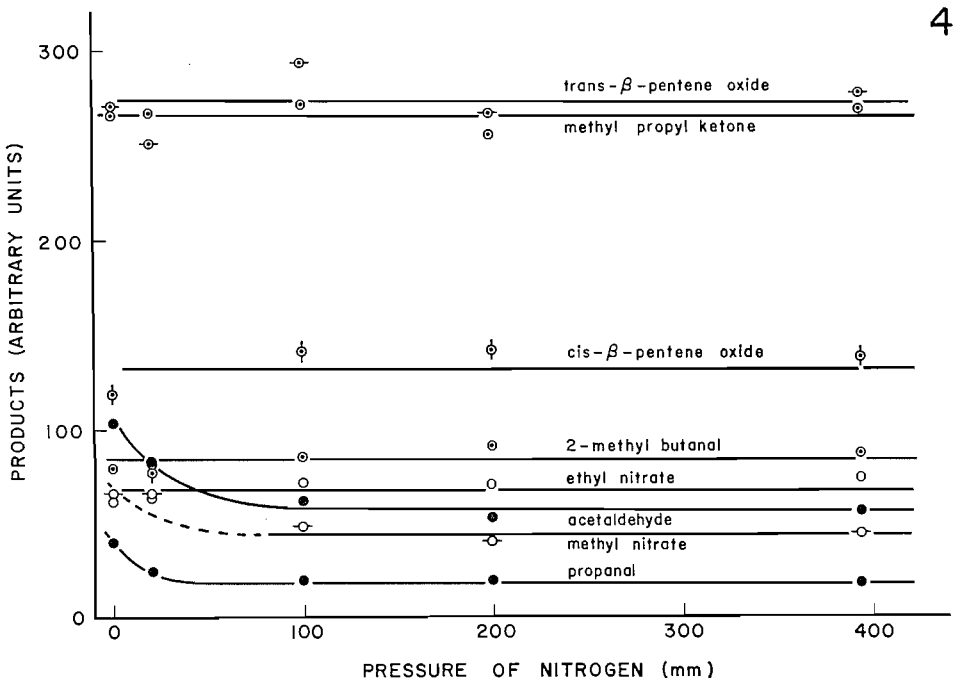

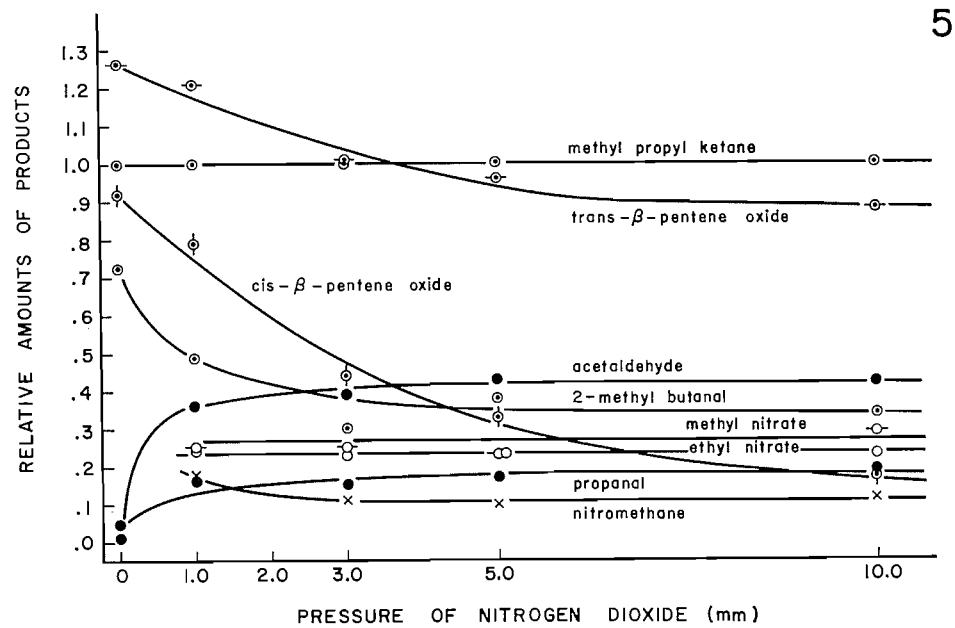

FIG. 4. The effect of pressure on the products formed in the photo-oxidation of *cis*-2-pentene (3 mm initially) by nitrogen dioxide (3 mm initially). Irradiation time 30 minutes, 25±2° C.

FIG. 5. Relative yields of products as a function of initial pressures of nitrogen dioxide in the photo-oxidation of *cis*-2-pentene (3 mm initially). The amounts of methyl propyl ketone formed are taken as unity. Irradiation time 30 minutes, 25±2° C. The points on the ordinate represent the relative amounts of acetaldehyde, propionaldehyde, and the four major addition products observed in the N_2O work, as given in Table I.

The dependence of the relative amounts of products formed (taking methyl propyl ketone as unity) on the pressure of the initially taken nitrogen dioxide is shown in Fig. 5. The decrease in pentene oxides is explained by the thermal reaction of these products with excess nitrogen dioxide. With decreasing NO_2 pressure the relative amounts of these two products tend, within the experimental error, to the relative values found in the N_2O work. The latter are indicated on the ordinate together with the relative values for 2-methyl butanal, acetaldehyde, and propanal (methyl propyl ketone is again taken as unity). The part of 2-methyl butanal formed by external migration (free-radical combination) is completely suppressed already at quite low NO_2 pressure and the part formed by internal migration of methyl radicals remains unaffected by further increasing NO_2 pressure. This is in full agreement with the internal rearrangements described previously (1) and there is no need to discuss here again the mechanism of formation of the four direct addition products. A mechanism for the formation of the products resulting from fragmentation can be proposed with much less certainty and the following scheme is of a tentative character (R· stands for CH_3 and C_2H_5):

$$R\cdot + NO_2 \rightarrow RNO_2, \qquad [28]$$

$$R\cdot + NO_2 \rightarrow RO\cdot + NO, \qquad [29]$$

$$RO\cdot + NO_2 \rightarrow RONO_2, \qquad [30]$$

$$\underset{\cdot}{\mathrm{RCHCH}}\!\!\underset{\mathrm{O}}{\|} + NO_2 \rightarrow \mathrm{RC}\underset{\mathrm{O}}{\overset{\|}{\mathrm{H}}} + CHO\cdot + NO, \qquad [31]$$

$$\underset{\cdot}{\mathrm{RCHCH}}\!\!\underset{\mathrm{O}}{\|} + NO_2 \rightarrow \mathrm{RC}\underset{NO_2\ \mathrm{O}}{\overset{\cdot\ \ \|}{\mathrm{H}}}, \qquad [32]$$

$$CHO\cdot + NO_2 \rightarrow CO + HNO_2. \qquad [33]$$

The radicals are initially formed in the pressure-independent fragmentation reactions [8] and [9]. The products of the last two reactions and nitroethane have not been identified. The observed products are consistent with the reaction scheme. In the presence of added excess NO the following reactions are assumed to occur:

$$R\cdot + NO \rightarrow RNO, \qquad [34]$$

$$RNO + NO_2 \rightarrow RNO_2 + NO, \qquad [35]$$

$$\underset{\cdot}{\mathrm{RCHCH}}\!\!\underset{\mathrm{O}}{\|} + NO \rightarrow \mathrm{RC}\underset{NO\ \mathrm{O}}{\overset{\cdot\ \ \|}{\mathrm{H}}}. \qquad [36]$$

These reactions explain the observed increase in CH_3NO_2 and suppression of the nitrates, propanal, and acetaldehyde (Table II). The product of reaction [36] has not been identified.

The Effect of Molecular Oxygen on the Photo-oxidation of cis-2-Pentene by Nitrogen Dioxide

Photolysis of nitrogen dioxide in the presence of olefins and oxygen in air has been shown to be responsible for "smog" formation in some places on this continent (4, 5). This process is characterized by a remarkable complexity of the recoverable condensable material and is accompanied by appreciable ozone formation. The photolysis of nitrogen dioxide in the presence of *cis*-2-pentene and molecular oxygen studied in the present work is superficially similar to the conditions in polluted atmosphere leading to smog formation. However, the concentrations of NO_2 and the olefin have been very much larger and, as a result, it is difficult to say how much there is in common between the two processes. Nevertheless, it is considered of some interest to report briefly the results of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the experiments carried out inasmuch as they show the type of products formed under the particular conditions employed.

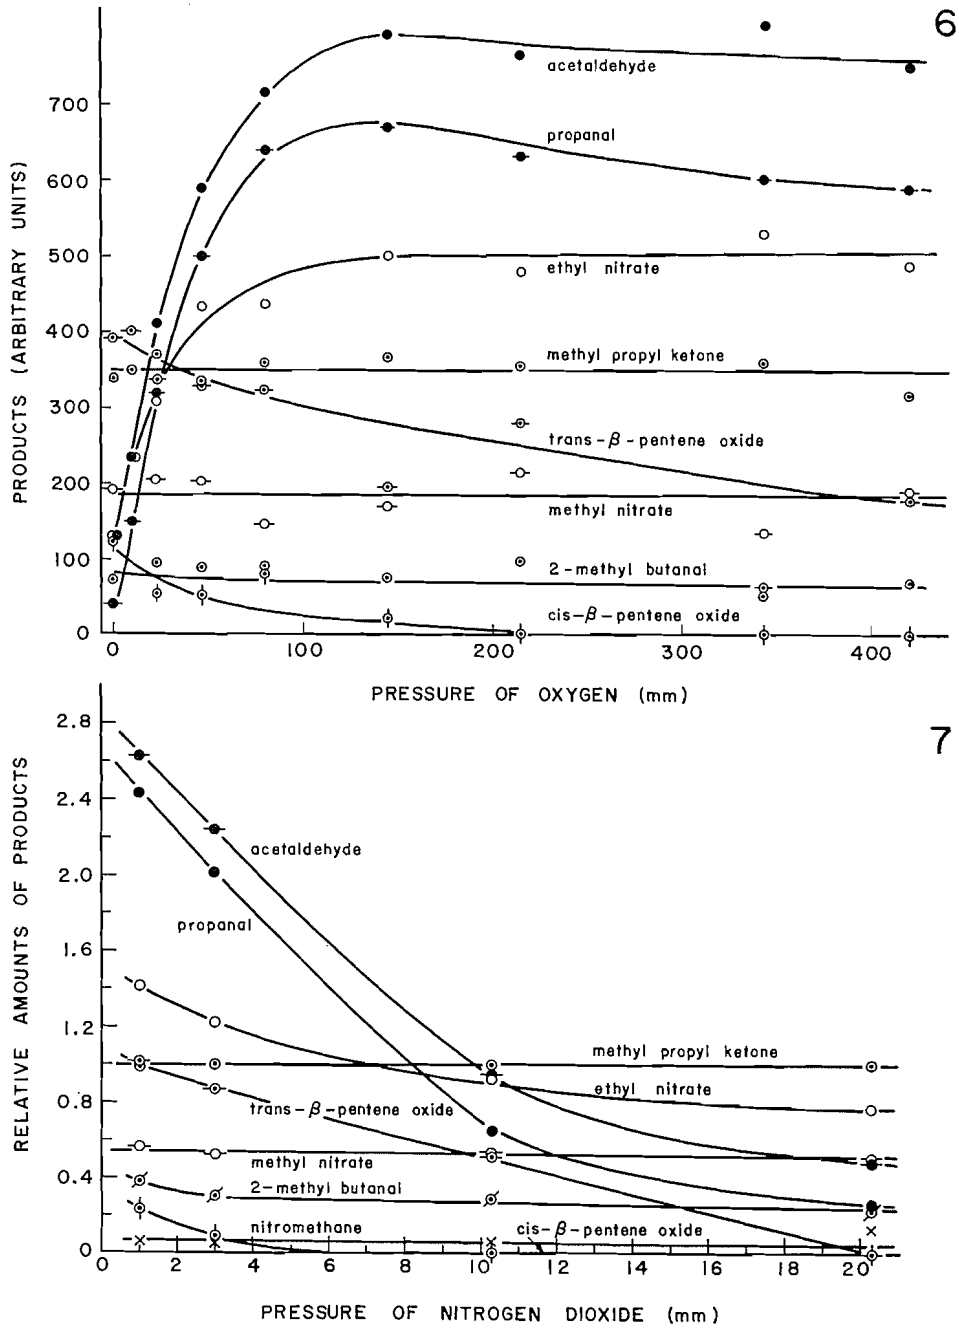

FIG. 6. The amounts of products formed as a function of oxygen pressure (3 mm NO_2, 3 mm *cis*-2-pentene, 25±2° C).

FIG. 7. Relative yields of products in the presence of 100 mm of oxygen as a function of initial pressures of nitrogen dioxide. The amounts of methyl propyl ketone formed are taken as unity (3 mm *cis*-2-pentene, irradiation time 15 minutes, 25±2° C).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The experimental results are plotted in Figs. 6 and 7, which should be contrasted with Figs. 4 and 5, respectively. It is clear from Fig. 6 that the presence of molecular oxygen induces formation of large amounts of acetaldehyde, propionaldehyde, and ethyl nitrate, although the amounts of the other compounds formed, with the exception of the epoxides, remain constant. The amounts of the two epoxides decrease with increasing oxygen pressure.

The effect of the initial pressure of nitrogen dioxide on the relative yields of products in the presence of 100 mm of oxygen is shown in Fig. 7. It is clear that the formation of acetaldehyde, propionaldehyde, and ethyl nitrate is particularly large at smaller nitrogen dioxide concentrations. The amounts of the two epoxides decline again with increasing NO_2 pressure.

As has already been mentioned, reaction of ozone with 2-pentene in the vapor phase leads to the predominant formation of acetaldehyde and propionaldehyde (6). It is significant that in the photo-oxidation of 1-butene, 2-butene, and isobutene, respectively, in the presence of molecular oxygen large amounts of propionaldehyde, of acetaldehyde, and of acetone are formed and the same compounds are again the predominant products (observed by GLC analysis) in the vapor-phase reaction of ozone with these olefins (6). In view of this, it is probable that in the photo-oxidation experiments carried out in the presence of large amounts of molecular oxygen there was an intermediate formation of ozone, which was, in the case of 2-pentene, responsible for the major part of acetaldehyde and propionaldehyde formed. Here again it is most likely that ozone is not formed to any extent directly from oxygen atoms and molecular oxygen. In the vapor-phase reaction of ozone with *cis*-2-pentene in addition to large amounts of propionaldehyde and acetaldehyde a residue of lower volatility is also formed, the nature of which is being further investigated (6). In one experiment, this residue[5] (after removal of acetaldehyde and propionaldehyde at $-80°$ C) was transferred to the reaction cell containing 3 mm of NO_2. The two were allowed to react thermally for 5 minutes at room temperature and then the product analysis was carried out in the usual manner. The GLC analysis showed peaks in the position of methyl nitrate, ethyl nitrate, *cis*-β-pentene oxide, and methyl propyl ketone and no *trans*-β-pentene oxide nor 2-methyl butanal. This experiment suggests that there are perhaps two potential sources of methyl propyl ketone and gives an example of the complex character of the studied process. In view of the observed complexities it is felt that a detailed discussion of the experimental results will become possible only after considerable additional background knowledge on the reactions of this type is accumulated.

ACKNOWLEDGMENTS

The authors are indebted to Dr. A. W. Tickner for the mass spectrometer analyses and to the Analytical Section of this Division for the infrared analyses.

THE TEMPERATURE DEPENDENCE OF THE HYDROLYSIS OF METHYL ESTERS OF CERTAIN ALKYL-SUBSTITUTED BENZENESULPHONATES IN WATER[1]

G. A. HAMILTON[2] AND R. E. ROBERTSON

ABSTRACT

Rate data for the hydrolysis of a series of alkyl-substituted methyl benzenesulphonates are presented and the resulting differences in derived parameters are compared and discussed in an analysis of substituent effects.

Coincident with the hydrolysis studies to be reported on toluenesulphonates (1) a survey was made of the changes in rate and derived parameters for a series of alkyl-substituted benzenesulphonates with the aim of discovering the effect of systematic increase in the size of the anion being produced while the "mechanism" was kept constant through use of the methyl ester. With the realization that the solvent reorganization accompanying the activation process did not necessarily include the total initial solvation shell of the ester (2), the more extensive study of the effect of such groups on solvation was discontinued and the data already determined are published here.

The importance of solvation on the rates of reactions in solution has long been recognized in principle (3) and the general trends analyzed in terms of charge development or distribution. While far from optimum, the benzenesulphonic system provides a means of examining the effect of a substituent on the rate and thermodynamic parameters where there is no steric interference with solvation (para substitution) and where the solvation is altered through the competition of more effective intramolecular interaction (ortho substitution). It is recognized that the latter is not equivalent to the simple screening of a charge by an alkyl group as considered by Everett and Wynne-Jones (4) in discussing the changes in solvation of anions with alkyl substitution but is more closely allied to the effect considered by Evans (5) and Franklin (6) in calculating the heat of solvation of the series $\overset{+}{\text{Me}} \rightarrow t\text{-}\overset{+}{\text{Bu}}$ carbonium ions, where the loss of solvation through solvent exclusion was compensated for by internal resonance effects.

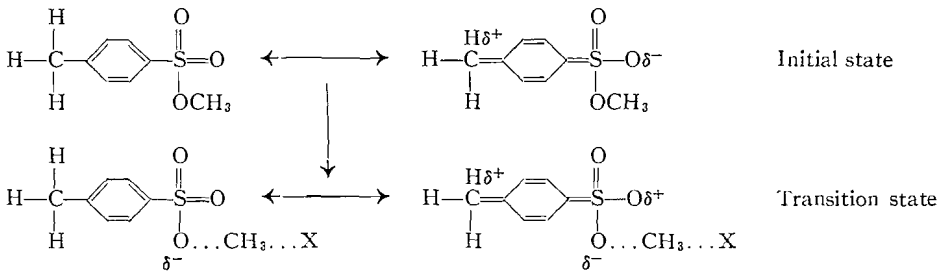
Whether an alkyl substituent group in a benzenesulphonate will be expected to interfere or in fact increase the solvation of the developing sulphonic anion in the activation process leading to hydrolysis will depend not only on its position and size, but also on the electronic nature of its effect, i.e., whether the effect is simply inductive, or shows evidence of hyperconjugation, or both. To evaluate the possible effect of hyperconjugation one must look for stabilizing influences arising from this cause both in the initial and in the transition states. Formal presentation of typical resonance contributors to the stabilization of these two states are as follows:



It will be obvious from the above that resonance contributors will be more important in the initial state than in the transition state, since in the latter the developing negative charge will oppose any such electronic shift. Thus we anticipate the initial state for the para-methyl-substituted ester will be stabilized compared to the corresponding state for the unsubstituted ester, and the rate correspondingly reduced. This does not exclude the operation of an inductive effect toward the same end, but evidence that a hyperconjugative effect is present may be gained from a comparison of the relative rates of solvolysis for a series of esters in ethanol and in water (Table I).

If the effect of the methyl group were purely inductive the rate for the meta methyl ester would be the same or slower than that for the para methyl ester. Were the effect purely hyperconjugative, the substituent effect of the meta methyl should be negligible. From Table I it is seen that the relative effect of the para methyl and ortho methyl are about additive to give the value for the 2,4-dimethyl hydrolyzing in ethanol and water of 0.49 (calc.) in both cases and 0.52 and 0.53 (obs.) respectively. If the effect of the para methyl were completely inductive, then the meta methyl should have approximately the same effect and we would anticipate the relative rate values for the 3,4-dimethyl to be 0.30 and 0.42 (calc.) compared with the observed values of 0.53 and 0.60 in ethanol and water, respectively. Hence it may be argued that some considerable fraction of the effect of the para methyl group must be attributed to hyperconjugative stabilization of the initial state.

For the 2,4,6-trimethyl ester, it might be expected the second ortho methyl would not interact with the sulphonic group to the same extent as the first ortho methyl but would have an effect somewhat like an additional para methyl group. Thus the relative rate for the 2,4,6-trimethyl ester might be expected to be intermediate between that calculated assuming the second ortho methyl to duplicate the first (calculated relative rate in ethanol 0.33, in water 0.27) and assuming it is a para methyl (calculated relative rate in ethanol 0.14 and in water 0.20). The observed values of 0.25 and 0.27 in ethanol and water respectively are in fair agreement with this analysis.

The fact that the para methyl substituent may be changed to other para alkyl sub-

stituents with no change in relative rates (Table II) compared with the unsubstituted ester may be taken as further evidence of compensation between the inductive and hyperconjugative effects. Taft (13) has explained the apparent constancy of the ionization constants of the 4-alkyl-substituted pyridines by a similar balancing of inductive and hyperconjugative effects and our results are in qualitative as well as quantitative agreement with his.

While comparisons of relative rates such as above give a valuable indication of trends, and largely provide the basis for our knowledge of the relation between structure and reaction rates, the fact that these ratios are temperature dependent encourages a more detailed examination in terms of the parameters derived from the temperature dependence of the rate. In Table III are given the rate data for three methyl esters over a range of

in Table IV. These constants may be interpreted as follows:

$$A = -(\Delta H_0^{\ddagger}/2.303\ R),$$
$$B = (\Delta C_p^{\ddagger}/R)+1,$$
$$C = (\Delta S_0^{\ddagger}-\Delta C_p^{\ddagger})/2.303\ R + \log_{10} k/h,$$

but it is well to recall that this interpretation finally rests on the assumption that an equilibrium exists between the initial and the transition state. Further, in our evaluation of $\Delta S^{\ddagger}$ we assume a frequency factor of $\log kT/h$ which is constant throughout a series and in fact throughout all series. Since we normally are considering $\Delta\Delta S^{\ddagger}$ values within a given series such an assumption is probably acceptable at this preliminary stage of comparison.

TABLE IV

Summary of constants for equation [1]

Benzenesulphonate	*A*	*B*	*C*
Me-3,4-dimethyl	−7408.282	−19.3250	67.48493
Me-2,4-dimethyl	−7067.916	−17.7061	62.33737
Me-2,4,6-trimethyl	−6776.710	−15.1235	54.64063

The thermodynamic parameters calculated from the above data are given in Table V.

TABLE V

Thermodynamic constants at 25° C

Benzenesulphonate	Me-3,4-diMe	Me-2,4-diMe	Me-2,4,6-triMe
k_1 sec$^{-1}\times 10^5$	0.660	0.6596	0.309
$\Delta F^{\ddagger}$ cal/mole	24,514	24,512	24,962
$\Delta H_0^{\ddagger}$ cal/mole	33,898	32,340	31,010
$\Delta H^{\ddagger}_{298.16}$ cal/mole	21,855	21,257	21,455
$-\Delta C_p^{\ddagger}$ cal/mole deg	40.39	37.17	−32.04
$-\Delta S^{\ddagger}$	8.94	10.95	11.64

In Table VI are given the difference functions with unsubstituted methyl benzenesulphonate as the standard. From these a much clearer picture can be gained of the effect of the substituent on the detailed mechanism than was possible from a consideration of relative rates.

TABLE VI

Effect of methyl substitution on thermodynamic constants for the hydrolysis of benzenesulphonic esters in water at 25° C

Ester	k_1 sec$^{-1}\times 10^5$	$\delta_x\Delta H^{\ddagger}_{\text{cal}}$	$\delta_x\Delta C_p^{\ddagger}$	$\delta_x\Delta S^{\ddagger}$
Me-*p*-H	1.166 (1)	0	0	0
Me-*p*-Me	0.799 (0.69)	+197	−2.0	−0.03
Me-*o*-Me	0.998 (0.86)	−540	+6.4	−2.46
Me-3,4-diMe	0.660 (0.57)	+435	−7.0	+0.35
Me-2,4-diMe	0.660 (0.57)	−163	−3.8	+1.66
Me-2,4,6-triMe	0.309 (0.27)	+ 35	+1.4	−2.35

We have noted elsewhere (1) that the *p*-Me raises $\Delta H^{\ddagger}$ by ~200 cal while *o*-Me lowers $\Delta H^{\ddagger}$ by ~−500 cal. If we may assume, on the basis of the above evidence, that the solvation of the para alkyl group is not altered during the activation process, aside from the possibility of a small hyperconjugation effect (and the small $\Delta\Delta S^{\ddagger}$ supports this assumption), then the effect of the *p*-group is to increase the bond energy requiring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

greater thermal activation to achieve the critical charge level characteristic of the transition state. The 3-Me group probably has a somewhat greater inductive effect (7), say $\Delta\Delta H^{\ddagger}$ +225 cal, while if the trend is maintained ortho methyl would be expected to raise $\Delta H^{\ddagger}$ by 275∼300 cal (8). On this basis, the shift to be expected in $\Delta H^{\ddagger}$ for the 2,4-dimethyl will be (+200−500) = −300 compared to the observed value of −175 cal. To rationalize the value of $\Delta H^{\ddagger}$ for the 2,4,6-trimethyl ester we note from an examination of models that if a single ortho methyl interacts with the sulphonic group, the second ortho methyl will not be orientated for interaction. The second ortho methyl will then resemble a more effective (275∼300 cal) para methyl. The interaction of the first ortho methyl will cause a decrease in rotational entropy ($\delta_z\Delta S^{\ddagger}$ ∼2 e.u.) but this will not be duplicated by the second. Thus the predicted $\delta_z\Delta H^{\ddagger}$ will be (+200+275−500) = −25 cal; observed +24 cal, and the $\delta_z\Delta S^{\ddagger}$ is of the same sign and magnitude as for a single ortho methyl. It will be noted that these results are in essential agreement with the additivity relations noted for the relative rates.

Qualitatively, the differences in the heat capacity of activation are in accord with this analysis, but the crude state of our knowledge of the factors influencing this term limits interpretation of small differences. If the $\Delta C_p^{\ddagger}$ observed in hydrolysis arises from the temperature dependence of the $\Delta H^{\ddagger}$ required to break the solvation shell, then it is probable that the observed differences in $\Delta C_p^{\ddagger}$ reflect differences in the degree of involvement of the solvent. As has been noted elsewhere, such large heat capacity differences can hardly be attributed to the solute alone. The changes in $\Delta C_p^{\ddagger}$ are approximately additive. However, even considering the larger experimental error characterizing this parameter, the 2,4-dimethyl value for $\Delta C_p^{\ddagger}$ appears anomalous.

EXPERIMENTAL

Solvents.—Ethanol (absolute) and water were as previously described (9, 2). To acetic acid (reagent) was added sufficient acetic anhydride so that after heating overnight at 100° C approximately 0.05% remained according to analysis of S. Bruckstein (10).

Esters.—The constants characterizing the sulphonyl chloride and the esters are recorded in Table VII. There was no kinetic evidence (non-linear plots) of the presence of any competing impurity in the esters studied.

TABLE VII

Physical constants of methyl esters

THE ACETOLYSIS OF SOME HYDROXYTETRAHYDRO-2-PYRANS[1]

THOMAS FRANCIS[2] AND E. VON RUDLOFF

ABSTRACT

The reaction between acetic anhydride and several hydroxytetrahydropyrans in the presence of boron trifluoride has been studied. 2-Methyl-3-hydroxytetrahydropyran, 2-hydroxymethyl-4,5-dihydroxytetrahydropyran, and 3,4-dihydroxytetrahydropyran all underwent normal acetolysis to the expected straight-chain polyol acetates. Optically active forms of *cis*- and *trans*- 3,4-dihydroxytetrahydropyran gave the same, inactive pentanetetrol, showing that racemization of the active centers had accompanied ring cleavage. 2-Hydroxymethyltetrahydropyran gave 1,3,6-hexanetriol besides the expected 1,2,6-isomer. The reagent did not cleave 4-hydroxytetrahydropyran nor dihydro-D-galactal, but the latter underwent hydroxyl inversion to give dihydro-D-altral. 1,5-Anhydro-D-sorbitol (polygalitol) appeared to undergo both ring fission and inversion.

INTRODUCTION

The isolation of several hydroxylated derivatives of tetrahydro-2-pyran from the hydrogenolysis of methyl glycopyranosides (1, 2, 3) stimulated an interest in ring cleavage of this type of cyclic ether as a possible aid in determining their structure and configuration. Relatively few examples of this reaction are cited in the literature (4), in contrast to extensive studies on tetrahydrofurans (4, 5), but it is generally accepted that tetrahydropyrans are much more resistant to cleavage than are their five-membered ring analogues (4, 5). Of the reagents generally used to effect fission of cyclic ethers (4), those involving the use of acetic anhydride and an acid catalyst appeared most attractive, since the cleavage products could be deacetylated readily and the free polyols thus obtained conveniently examined by paper chromatography and periodic acid oxidation.

In preliminary experiments, several different catalysts were used to study the acetolysis of 2-hydroxymethyltetrahydropyran and 3,4-dihydroxytetrahydropyran. The cleavage of 2-hydroxymethyltetrahydropyran using zinc chloride and acetic anhydride for 8 hours at reflux temperature has been reported (6) to yield 1,2,6-hexanetriol triacetate. Re-examination of this reaction now showed that 85% of the starting material was recoverable as its acetate after 4 hours' refluxing and 75% with a reaction period of 28 hours. No trace of cleavage was detected when 3,4-dihydroxytetrahydropyran was subjected to the same conditions for 4 hours. Mixtures of sulphuric acid and acetic anhydride were found to cause some cleavage of 2-hydroxymethyltetrahydropyran but decomposition was extensive and the effect of these reagents on other tetrahydropyrans was not investigated. Trifluoroacetic anhydride promoted acetylation of each of these tetrahydropyrans but there was no evidence of ring opening. However, boron trifluoride was found to catalyze the cleavage without too much general decomposition and its use in the acetolysis of hydroxytetrahydropyrans was, therefore, examined in detail.

DL-*trans*-3,4-Dihydroxytetrahydropyran, treated with excess acetic anhydride saturated with boron trifluoride, split to an extent of 25% with a reaction time of 18 hours at room temperature and to 50% at 100° C for 1 hour, whereas at the higher temperature fission was virtually complete in 4 hours. The cleavage product, after deacetylation and purification, was the expected 1,2,3,5-pentanetetrol. D-*trans*-3,4-Dihydroxytetrahydropyran

and L-*cis*-3,4-dihydroxytetrahydropyran were found to yield the same optically inactive pentanetetrol, showing that racemization of the optically active centers had accompanied ring fission. Under similar reaction conditions the triacetate of 2-hydroxymethyl-4,5-dihydroxytetrahydropyran gave a 25% yield of the expected 1,2,3,5,6-hexanepentol, which did not give a solid benzoate or *p*-nitrobenzoate and formed a sirupy pentaacetate.

Cleavage of 2-hydroxymethyltetrahydropyran was complete in 2 hours at room temperature, whilst at 100° C decomposition was extensive. The product from the reaction at room temperature, or lower, was an oil which could not be separated into more than one component by counter-current distribution (210 transfers). The deacetylated product was shown to be a sirupy hexanetriol. However, when oxidized with periodic acid, the material consumed only 0.4 moles of oxidant with the release of 0.4 moles of formaldehyde, indicating that it was a mixture of the expected 1,2,6-hexanetriol and an isomer having no vicinal hydroxyl groups. This mixture of isomers could not be resolved by column chromatography, nor by counter-current distribution (120 transfers), but the isomeric triol was isolated from the mixture by decomposition of the 1,2,6-isomer with periodate. The sirupy product had an infrared spectrum which was similar to that of the 1,2,6-isomer and formed a crystalline tris-*p*-nitrobenzoate having similar spectral properties to those of the 1,2,6-derivative. These data, together with the results from C-methyl determinations, suggested that the compound was most likely 1,3,6-hexanetriol. 1,3,6-Triacetoxyhexane was prepared from tetrahydrofuran-2-acetic acid (7) by lithium aluminum hydride reduction to tetrahydrofuran-2-ethanol and subsequent ring cleavage (8). The triol obtained on deacetylation was shown to be identical with that obtained from 2-hydroxymethyltetrahydropyran. The formation of 1,3,6-hexanetriol besides the 1,2,6-isomer is unexpected, since tetrahydrofuranyl carbinols have given rise to only one triacetate on acetolysis with zinc chloride as catalyst (5). Since the starting material was found to be pure, it could not have been derived from a major impurity, such as tetrahydrofuran-2-ethanol.

Cleavage of a fraction isolated from the hydrogenolysis of α-methyl-D-glucopyranoside and thought to be a hydroxytetrahydropyran derivative (2) was readily effected with the reagent at room temperature in 18 hours. The product, after deacetylation, was 1,4,5-hexanetriol, since it consumed 1.0 mole of periodic acid with the production of 1.0 mole of acetaldehyde, and yielded a tris-*p*-nitrobenzoate. Thus, if no rearrangement had taken place during acetolysis (this assumption is justified, since no isomeric products were isolated) the starting material must have been 2-methyl-3-hydroxytetrahydropyran, a product not unexpected from the hydrogenolysis reaction. The ready cleavage of this 2-alkyl derivative is in accord with the findings on 2-alkyl tetrahydrofurans by Paul (5). The formation of olefinic intermediates presumably was suppressed by the 3-hydroxyl substituent.

4-Hydroxytetrahydropyran was not cleaved to any extent at room temperature, at 65° C, or at 100° C, charring being extensive at the latter temperature. This result was unexpected and cannot be explained by the proposed mechanisms of ether cleavage (4). Similar results were obtained with dihydro-D-galactal and dihydro-D-glucal. When dihydro-D-galactal was first acetylated and then treated with excess reagent at 100° C ring cleavage was also not obtained, showing that the formation of acetic acid in the initial acetylation of the free polyol is not the cause of this failure to cleave the ether. However, after a 10-hour treatment at 100° C dihydro-D-galactal yielded a small amount of dihydro-D-altral. Paper chromatographic analysis of the deacetylated product obtained from dihydro-D-glucal showed the presence of compounds with R_f values corre-

For personal use only.

sponding to dihydrogalactal and dihydroaltral. A similar examination of the reaction product from a small amount of 1,5-anhydro-D-sorbitol (polygalitol) indicated the presence of both fission products (hexitols) and inversion products, besides unreacted starting material.

Burwell (4) proposed as the first step in the catalytic acetolysis of aliphatic ethers the addition of an acetyl cation to the ether oxygen. Presumably this mechanism is also operative in the acetolysis of tetrahydropyrans in the presence of boron trifluoride. The subsequent cleavage of a carbon–oxygen bond of the ether linkage and addition of an acetyl anion to the residual carbonium ion is more difficult to reconcile with the divergent results obtained. An intermediate cation, having the positive charge distributed between the oxygen atom and the carbon atoms in positions 2 and 3, analogous to the cation proposed in the acid-catalyzed cyclization of terpenes (11), would explain, for example, the formation of 1,3,6-hexanetriol in addition to the 1,2,6-isomer from 2-hydroxymethyltetrahydropyran. Such a cation could either cleave directly to such end products, or produce an intermediate olefin, analogous to those isolated by Paul (5) from 2-alkyl tetrahydrofurans. The olefinic diacetate could then be acetylated in the presence of boron trifluoride (12), or might recyclize to tetrahydrofuran-2-ethanol, which would undergo readily ring fission to 1,3,6-hexanetriol. Hydroxyl groups in the 3 position would prevent the formation of such intermediates and lead only to a single, expected product, which is in agreement with the present findings. However, such a mechanism would not explain the resistance to cleavage of the dihydroglycals and 4-hydroxytetrahydropyran. The failure of the former compounds to undergo ring fission may be explained (9) by boron complex formation of the type reported by Angyal and McHugh (10). Aliphatic ethers are known to form stable complexes with boron trifluoride (4) and it is conceivable that complex formation of one type or another prevents the cleavage reaction with some hydroxytetrahydropyrans.

It is concluded that although boron trifluoride is an excellent catalyst for the acetolysis of some tetrahydropyrans, the unexpected results obtained in other cases show that its action is not of a general nature.

EXPERIMENTAL

Paper chromatography was carried out using Whatman No. 1 paper and 1-butanol – ethanol – water (40:11:19, v/v) as solvent. The chromatograms were developed with ammoniacal silver nitrate spray reagent (13) and the distances travelled by compounds relative to rhamnose (R_{Rh}) were measured. Column chromatography was carried out on cellulose using benzene–ethanol–water (500:50:1, v/v) (A), 1-butanol (B), or 1-butanol $\frac{1}{4}$ saturated with water (C) as solvents. In counter-current distribution, a modified 100-tube E.C. Apparatus Co. fractionator was used (14). Deacetylation of polyol acetates was carried out in the manner previously described (2).

3,4-Dihydroxytetrahydropyran

(*a*) DL-*trans-3,4-Dihydroxytetrahydropyran* (*Dihydro*-DL-*xylal*)

A mixture of the diol (1.1 g) and acetic anhydride (10 ml) was saturated with boron trifluoride at such a rate that the internal temperature did not exceed 60° C. The reaction mixture was then heated on a steam bath for 4 hours, cooled, and poured into an ice-cold excess of saturated aqueous sodium carbonate or bicarbonate solution. The mixture was filtered and the residue and filtrate were extracted thoroughly with chloroform which was washed once with water, dried over calcium chloride, and evaporated. After distillation at 170–180° C and 0.5 mm, the cleavage product (2.05 g) was deacetylated.

Paper chromatography of the residue indicated a major component, R_{Rh} 1.14, and a minor component, R_{Rh} 1.73, the latter corresponding to unchanged starting material. The mixture was resolved by column chromatography using solvent B, and the cleavage product was thus obtained as a colorless sirup (0.9 g, 72%), b.p. 175–185° C (air bath) at 0.1 mm. Calculated for $C_5H_{12}O_4$: C, 44.11%; H, 8.88%. Found: C, 44.18%; H, 8.83%. The tetrol consumed 2.0 moles of periodic acid with the liberation of 1.0 mole of formaldehyde (15). The tetraacetate of the tetrol, prepared with sodium acetate and acetic anhydride, was a colorless oil, b.p. 175–180° C (air bath) at 0.5 mm; n_D^{20} 1.4442. Calculated for $C_5H_8(OCOCH_3)_4$: C, 51.31%; H, 6.63%; $COCH_3$, 56.6%. Found: C, 51.64%; H, 6.77%; $COCH_3$, 57.1%. The derived tetra-*p*-nitrobenzoate separated as light yellow crystals, m.p. 187° C, from acetone – ethyl acetate. Calculated for $C_{33}H_{24}N_4O_{16}$: C, 54.10%; H, 3.30%; N, 7.65%. Found: C, 54.47%; H, 3.54%; N, 7.68%.

When the cleavage reaction was carried out at 0° C for 18 hours and at room temperature for 24 hours, the product contained about 25% and 50%, respectively, of the tetrol.

(*b*) D-*trans-3,4-Dihydroxytetrahydropyran* (*Dihydro*-D-*xylal*)

Diacetyldihydro-D-xylal (2.0 g) was treated with acetic anhydride (7.5 ml) and boron trifluoride and the resulting tetrol (0.9 g, 67%) was isolated and purified as described above. Periodic acid oxidation of the polyol and analyses of the free polyol and its tetraacetate were consistent with a 1,2,3,5-pentanetetrol structure. The tetrol had no optical rotation in saturated aqueous sodium borate and its derived tetra-*p*-nitrobenzoate was shown by melting point, mixed melting point, and X-ray powder diagram comparison to be identical with that of the tetrol from dihydro-DL-xylal.

(*c*) L-*cis-3,4-Dihydroxytetrahydropyran* (*Dihydro*-L-*arabinal*)

Dihydro-L-arabinal (0.5 g) was cleaved and the derived tetrol (0.3 g, 52%) isolated and purified as described above. The tetrol had no optical rotation in saturated aqueous sodium borate and its tetra-*p*-nitrobenzoate derivative was identical with those of the tetrols from dihydro-D- and dihydro-DL-xylal (melting point, mixed melting point, infrared spectrum, and X-ray powder diagram).

2-Hydroxymethyl-4,5-dihydroxytetrahydropyran

The triacetate of this triol (3.8 g) was treated with acetic anhydride (5 ml) and boron trifluoride at 100° C for 4 hours and the product isolated and purified in the usual way. Paper chromatography of the product indicated that it was a mixture of the starting material and a hexanepentol (R_{Rh} 0.66). The pentol was isolated by column chromatography using solvent C and was a colorless sirup (0.58 g, 25%), n_D^{20} 1.4860. Calculated for $C_6H_{14}O_5$: C, 43.36%; H, 8.49%. Found: C, 43.60%; H, 8.48%. The substance consumed 3.2 moles of periodic acid with the production of 1.8 moles of formaldehyde showing that it was essentially 1,2,3,5,6-hexanepentol. It failed to give a solid benzoate or *p*-nitrobenzoate. The pentaacetate, prepared with sodium acetate and acetic anhydride, was a pale yellow sirup, n_D^{20} 1.4488. Calculated for $C_6H_9(OCOCH_3)_5$: C, 51.06%; H, 6.43%; $COCH_3$, 57.1%. Found: C, 51.08%; H, 6.80%; $COCH_3$, 57.4%.

2-Methyl-3-hydroxytetrahydropyran

One gram of a tetrahydropyran fraction obtained from hydrogenolysis of α-methyl-D-glucopyranoside (2) was treated with acetic anhydride (6 ml) and boron trifluoride at room temperature for 18 hours. The crude product was distilled at 160–170° C (air bath) and 12 mm and was then deacetylated. Paper chromatography of the product indicated that cleavage was complete and that the product was a hexanetriol (R_{Rh} 1.73). The triol was purified by column chromatography in solvent A and by distillation at

130–135° C (air bath) and 0.1 mm giving a colorless sirup (0.64 g, 55%), n_D^{20} 1.4738. Calculated for $C_6H_{14}O_3$: C, 53.71%; H, 10.52%; C-methyl, 20.2%. Found: C, 53.43%; H, 10.50%; C-methyl, 20.2%. The triol consumed 1.0 mole of periodic acid and yielded 1.0 mole of acetaldehyde (16).

The triacetate was a colorless oil, b.p. 105° C (air bath) and 0.1 mm with n_D^{20} 1.4366 (Paul (5) reported n_D^{10} 1.44029; found n_D^{10} 1.4403). Calculated for $C_6H_{11}(OCOCH_3)_3$: C, 55.37%; H, 7.75%; $COCH_3$, 49.6%. Found: C, 54.97%; H, 7.90%; $COCH_3$, 50.7%.

The derived tris-*p*-nitrobenzoate, after several recrystallizations from methanol–acetone, had m.p. 149–150° C. Calculated for $C_{27}H_{23}O_{12}N_3$: C, 55.77%; H, 3.99%; N, 7.23%. Found: C, 55.95%; H, 3.90%; N, 7.24%.

4-Hydroxytetrahydropyran

γ-Pyrone (12.5 g) was hydrogenated in ethanol (75 ml) with Raney nickel (0.6 g) at 100° C and 80 atmospheres pressure for 10 hours. The residual oil, after evaporation of the solvent, was fractionally distilled, yielding 4-hydroxytetrahydropyran (8.5 g), b.p. 90–92° C at 12 mm, n_D^{20} 1.4590. This tetrahydropyran was recovered unchanged from the reaction with boron trifluoride and acetic anhydride at room temperature for 18 hours, at 65° C and at 100° C for 2 hours. At the elevated temperatures charring took place and at 100° C a very small amount of an oil, b.p. 125–130° C (air bath) and 0.1 mm was obtained. The deacetylated product had R_{Rh} 1.62, corresponding to a hexanetriol. The amount obtained was too small for further identification.

Dihydro-D-galactal

Dihydro-D-galactal (0.5 g) was treated with acetic anhydride (5.0 ml) and boron trifluoride at 100° C for 10 hours. The crude product, after deacetylation, showed two major spots, R_{Rh} 1.12 and 1.37, and a weak spot, R_{Rh} 0.74, on paper chromatography. Unchanged dihydrogalactal (0.15 g, R_{Rh} 1.12) was removed from the reaction product by crystallization from methanol – ethyl acetate and the residue was then chromatographed using solvent A. By this means, the material with R_{Rh} 1.37 was isolated and after crystallization from ethyl acetate was identified as dihydro-D-altral by means of mixed m.p. 101–103° C, and by comparison of its X-ray powder diagram with that of an authentic specimen (3). A similar result was obtained using triacetyldihydro-D-galactal and a large excess of acetic anhydride and boron trifluoride.

Dihydro-D-glucal and 1,5-Anhydro-D-sorbitol (Polygalitol)

The product from the reaction of dihydro-D-glucal (R_{Rh} 1.24) with excess acetic anhydride and boron trifluoride at 100° C for 4 hours was deacetylated and paper chromatography of the product showed two major components having R_{Rh} 1.37 and 1.12 and a trace component, R_{Rh} 0.76.

Polygalitol (R_{Rh} 0.74), when similarly treated, yielded a mixture of substances having R_{Rh} values of 0.85, 0.74, 0.45, corresponding to an isomerization product, unchanged starting material, and a hexitol respectively.

2-Hydroxymethyltetrahydropyran

The reaction between 2-hydroxymethyltetrahydropyran (5 g) and acetic anhydride (15 ml) and boron trifluoride was complete in 2 hours at room temperature. The crude acetate mixture was distilled at 117–128° C and 0.5 mm to give a pale yellow oil (6.4 g, 57%) n_D^{20} 1.4472, which failed to separate into more than one component when subjected to counter-current distribution between 70% acetone/petrol (b.p. 60–70° C) when 210 transfers were applied (14). The same oil resulted when the reaction was carried out at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

room temperature for 24 hours and also when the acetate of the starting material (6.5 g) was similarly reacted with acetic anhydride (9 ml) and boron trifluoride. At 100° C, decomposition was extensive and only a small amount of the oil was isolated. Calculated for $C_6H_{11}(OCOCH_3)_3$: C, 55.37%; H, 7.75%. Found: C, 55.40%; H, 7.85%.

Deacetylation of the above oil yielded a pale yellow sirup, n_D^{20} 1.4720, which did not separate into more than one component on column chromatography using solvent A or on counter-current distribution between water and *n*-butanol with 120 transfers. On paper chromatography it showed a single spot R_{Rh} 1.73, corresponding to a hexanetriol. Calculated for $C_6H_{14}O_3$: C, 53.71%; H, 10.52%. Found: C, 53.89%; H, 10.40%. Oxidation of the sirup with periodic acid resulted in the uptake of 0.4 mole of oxidant and the formation of 0.4 mole of formaldehyde.

The triol mixture (0.5 g) in water (20 ml) and periodic acid (0.5 g) in water (10 ml) was left to stand at room temperature for 2 hours and was then treated with Dowex-1 – bicarbonate until it gave a negative reaction to starch/KI paper. The mixture was filtered and evaporated and formaldehyde removed from the residue by steam distillation. The residue was then dissolved in water, extracted several times with ether, and recovered by evaporation of the aqueous solution. Distillation of the residual material afforded a colorless sirup (0.2 g), b.p. 135° C (air bath) at 0.1 mm, having R_{Rh} 1.73, n_D^{20} 1.4696, and low reducing power to the silver nitrate spray. C alculated for $C_6H_{14}O_3$: C, 53.71%; H, 10.50%. Found: C, 53.40%; H, 10.58%.

The derived tris-*p*-nitrobenzoate, m.p. 130–131° C, crystallized from ethyl acetate. Calculated for $C_{27}H_{23}O_{12}N_3$: C, 55.77%; H, 3.99%; N, 7.23%. Found: C, 56.09%; H, 3.89%; N, 7.23%.

Synthesis of Tetrahydrofuran-2-ethanol

A solution of tetrahydrofuran-2-acetic acid, prepared from tetrahydrofurfuryl bromide (17) by the method of Barger *et al.* (7), (10.5 g) in dry ether (200 ml) was added slowly with stirring to a mixture of lithium aluminum hydride (3.59 g) and dry ether (150 ml). When addition was complete, the mixture was stirred at room temperature for 18 hours and the excess lithium aluminum hydride was then decomposed by careful addition of water. The mixture was then shaken with excess dilute sulphuric acid and the ethereal phase was extracted with aqueous sodium bicarbonate and the aqueous phase again extracted with ether for 18 hours. The ethereal solution of the neutral products was evaporated and the residue distilled at 115–120° C (air bath) and 20 mm giving tetrahydrofuran-2-ethanol (8.0 g, 85%) as a colorless mobile oil n_D^{20} 1.4545. Calculated for $C_6H_{12}O_2$: C, 62.04%; H, 10.41%. Found: C, 61.66%; H, 10.56%.

1,3,6-Hexanetriol from Tetrahydrofuran-2-ethanol

Tetrahydrofuran-2-ethanol (4.06 g) in acetic anhydride (5 ml) was added slowly with stirring to a refluxing mixture of acetic anhydride (15 ml) and zinc chloride (0.3 g) (8). The mixture was refluxed for a further 18 hours and most of the excess anhydride was removed by distillation. The residue was cooled and poured into cold saturated aqueous sodium carbonate. The product was extracted into chloroform, which was washed once with water and dried over calcium chloride and evaporated. The residue was distilled at 120–130° C and 0.5 mm to give 6.5 g (71%) of an oil having n_D^{20} 1.4408. Calculated for $C_6H_{11}(OCOCH_3)_3$: C, 55.37%; H, 7.75%; $COCH_3$, 49.6%. Found: C, 55.58%; H, 7.52%; $COCH_3$, 49.5%.

The oil was deacetylated in the usual way and the triol was purified by column chromatography in solvent A and by distillation at 135° C (air bath) and 0.1 mm. The infrared

spectrum of the sirup, n_D^{20} 1.4753, was indistinguishable from that of the triol of 2-hydroxymethyltetrahydropyran. Confirmation of this identity was obtained by mixed melting point determination and infrared spectra comparison of the derived *p*-nitrobenzoate.

ACKNOWLEDGMENTS

We are grateful to Mr. M. Granat for infrared analyses, to Mr. T. M. Mallard for X-ray powder diagram determinations, to Mr. M. Mazurek and Mr. J. A. Baignée for microanalyses, and also to Dr. A. S. Perlin for his advice and criticism.

THE DECOMPOSITION OF SOLID POTASSIUM CHLORATE BY X RAYS[1]

H. G. HEAL[2]

ABSTRACT

Potassium chlorate irradiated with X rays has been found to contain chloride, chlorite, hypochlorite, and occluded oxygen, and probably also substantial amounts of dichlorine hexoxide and a trace of chlorine dioxide. The chlorite and hypochlorite appear to decompose during irradiation to chloride. *G* values are given for 25° and −196°. They vary little with temperature or dose rate.

INTRODUCTION

There has been no previous detailed study of the decomposition of solid potassium chlorate by ionizing radiation. In 1953, however, Hennig, Lees, and Matheson (9) published *G* values for the formation of oxygen when this salt is irradiated in a nuclear reactor, and in the same year the present writer published a brief note mentioning the finding of chlorite, hypochlorite, and chloride in X-irradiated potassium chlorate (6). One of the aims of the investigation reported here was to determine the nature of the decomposition products, which had not been more than tentatively identified. This is not a particularly straightforward matter, since the usual analytical methods only show what is present in a *solution* of the irradiated salt; the substances present in the original crystal are quite likely to be different (7, 8). We have now tried to identify these by examining the absorption spectra of the crystals, in conjunction with ordinary analysis. The other main purpose of this study was to learn what we could about the reaction mechanisms from a rough survey of the kinetics of decomposition.

EXPERIMENTAL

Reagent grade potassium chlorate was recrystallized once by cooling a hot aqueous solution. Rapid cooling gave small platelets, averaging 0.02 mm thick. These were dried for a week at 160°; they then melted quietly when heated, without any trace of decrepitation, showing the absence of water. These crystals were employed in studies of chemical decomposition. Slower cooling gave larger plates from 0.04 mm to 0.15 mm thick, selected specimens of which were used for plotting absorption spectra.

A Machlett OEG-60 X-ray tube, with tungsten target, was the source of radiation employed in the work on chemical decomposition. It was run at 50 kvp, 28 ma, with rectified but not filtered 60-cycle high voltage supply. The sample holder is shown in Fig. 1. Each sample weighed 1.2 to 1.6 mg. It was spread out over the bottom (5 mm in diameter) of a dish pressed from 0.017-mm aluminum foil. Typical samples were seen under the microscope to consist of platelets 0.01 mm to 0.03 mm thick, stacked two or three deep in many places. In order to achieve reasonably uniform rates of energy absorption in such samples, it was necessary to filter out the softer X radiation from the beam. The more filtration is used, the more uniform the rate of energy absorption through the sample, but the lower the dose rate. In the best series of irradiations, only negligible portions of the sample received energy at rates differing by more than 6% from the average for the whole sample. This entailed heavy filtration (294 mg/cm^2 of aluminum) and long irradiations (up to 75 hours). In another series of irradiations with filtration 84 mg/cm^2 of aluminum, the average dose rate was three times as great, but

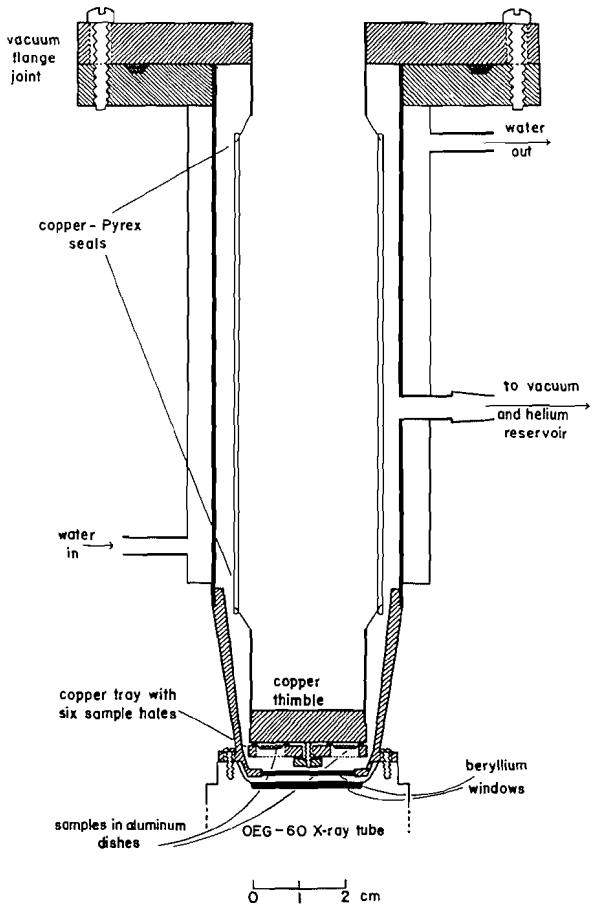

FIG. 1. Irradiation vessel for chemical decomposition studies. The filters are omitted for the sake of clarity. They consisted of aluminum disks which were placed between the two beryllium windows.

some parts of the sample received energy at rates up to 15% different from the average. Most irradiations were performed at 25°±1° under 0.5–1.0 mm of dry helium, which served to conduct away heat generated in the sample by the radiation, and prevented any appreciable rise of temperature. Results quoted for −196° were obtained from single crystals about 0.1 mm thick, which were cemented along one edge to the bottom of the central copper thimble of the irradiation vessel. The vessel was evacuated and the thimble filled with liquid nitrogen.

The absolute energy flux at the position of the samples was measured calorimetrically as described in an earlier publication (6), and the rate of energy absorption in the samples computed using tables of mass absorption coefficients, along with De Waard's formula for the spectral energy distribution of the X rays (1).

The apparatus used for plotting absorption spectra is shown in Fig. 2. The sample, a single crystal plate, was cemented across a hole 3 mm square in a copper block, which was maintained at the desired temperature. This crystal could be made to face either a small beryllium window through which the X-ray beam entered, or, by rotation through 90° on a standard taper joint, a pair of quartz windows through which the light beam of the spectrophotometer passed. The apparatus could be coupled to the

For personal use only.

X-ray tube, a Machlett AEG-50-T, or fitted into the cell compartment of a Cary Model 14 recording spectrophotometer, by arrangements not shown in the diagram. As in the chemical work, the radiation was heavily filtered to ensure a nearly uniform dose rate throughout the crystal.

All sample weighings were done with a Cahn electrobalance sensitive to ± 2 μg.

For the spectrophotometric determination of chlorite and hypochlorite in solutions of irradiated chlorate, the solutions were placed in special quartz optical cells with a light path of 1 cm, but requiring only 0.5 ml of solution. The spectrophotometer was again the Cary Model 14. For the turbidimetric determination of chloride, the transmission of the samples was measured with a Bausch and Lomb Spectronic 20 calorimeter, run from a constant voltage transformer. For convenience, the other details of these procedures are described in the next section.

In order to minimize analytical errors when the degree of decomposition was small, up to six similarly irradiated samples were often combined for one analysis.

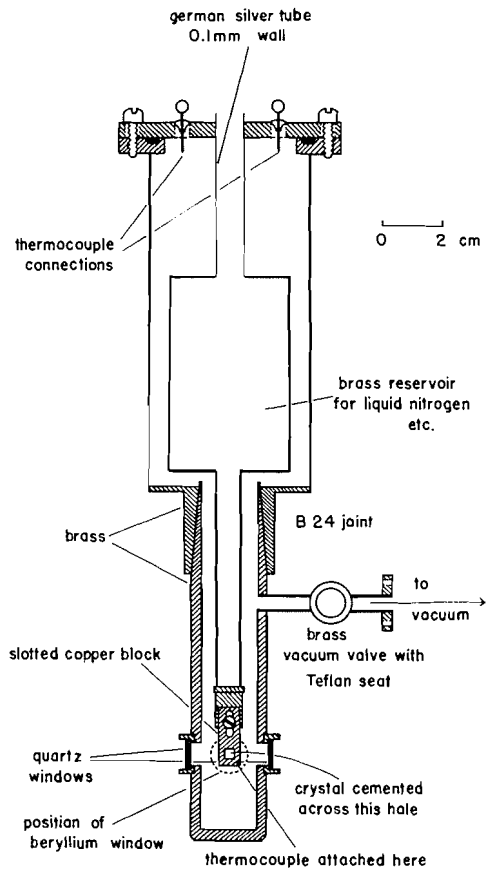

FIG. 2. Irradiation vessel used in the study of absorption spectra.

RESULTS

During irradiation at 25° the crystals darken gradually to a golden-brown tint. Up to about 8% decomposition, practically all the oxygen gas formed remains occluded within the crystals, as shown by the constancy of their weight. Above about 10% decompo-

For personal use only.

sition the crystals "pop" or decrepitate at the slightest touch, presumably because of the oxygen pressure. Hennig, Lees, and Matheson also observed this phenomenon (9). With continued irradiation the crystals disintegrate to a light, fluffy, nearly white powder.

The decomposition products identified with reasonable certainty in irradiated potassium chlorate were oxygen, chloride, chlorite, and hypochlorite ions. Perchlorate ion was probably also present. Other products present in smaller amounts were tentatively identified as dichlorine hexoxide and chlorine dioxide. The methods by which these substances were identified and analyzed for will now be described.

Gas occluded in the irradiated crystals was determined by the microscope slide method described in an earlier publication (5). The crystals were dissolved in 0.025 *M* sodium carbonate which had been saturated with oxygen gas, by bubbling, immediately beforehand, with the object of minimizing errors due to the solubility of oxygen. The gas collected was assumed to be *oxygen*, since chlorine and all its oxides would have dissolved in or reacted with the sodium carbonate solution.

Considering next the *chlorite* and *hypochlorite*, Fig. 3 shows the absorption spectrum of a typical sample of irradiated chlorate, dissolved in 0.025 *M* sodium carbonate (pH

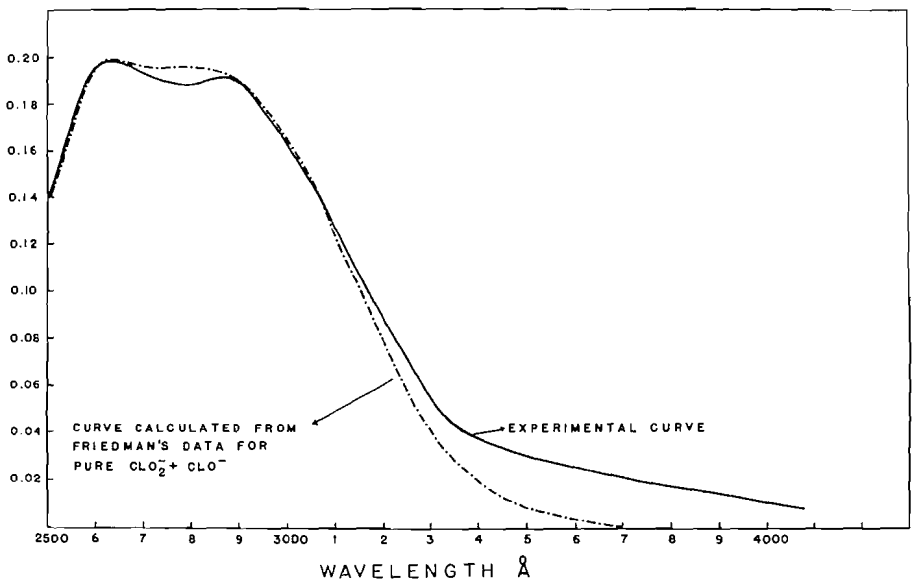

FIG. 3. Spectrum of a solution of irradiated $KClO_3$ in 0.025 *M* Na_2CO_3, compared with the spectrum for an appropriate ClO^-/ClO_2^- mixture from Friedman (ref. 2).

11 approximately). The peak at 2610 Å probably arises from chlorite ion, and the one at 2900 Å from hypochlorite ion. As the figure shows, the experimental spectrum agrees well with that calculated for an appropriate mixture of chlorite and hypochlorite, using Friedman's data for these ions (2). The only serious divergence is in the region 3300 Å to 4000 Å, where the samples always showed a weak absorption not attributable to chlorite or hypochlorite. This disappeared gradually over an hour or so. We attribute it to *chlorine dioxide*, which has an absorption maximum at about 3600 Å and is stated to hydrolyze slowly. The spectra appeared as depicted immediately after the samples were dissolved, suggesting that the chlorite was mostly present as such in the crystals,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

and was not formed by the hydrolysis of chlorine dioxide present in the crystals. The absorption spectra of irradiated crystals themselves support this conclusion. Figure 4 shows a series of spectra for a crystal irradiated at 25°. Peaks developed at 2600 Å and

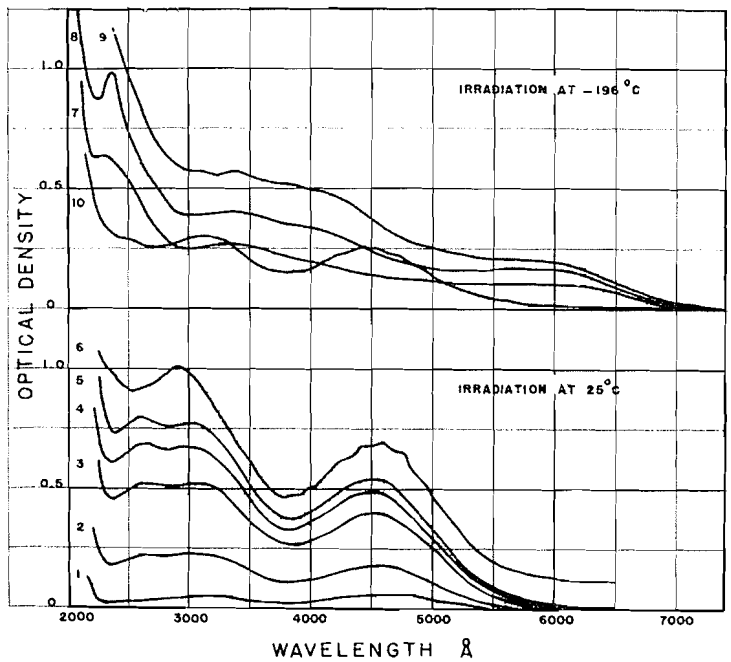

FIG. 4. Absorption spectra of irradiated $KClO_3$ crystals. (All optical densities relative to the unirradiated crystal.)

(7) After 1 hour and 40 minutes' irradiation (0.86×10^{23} ev/mole).
(8) After 2 hours and 50 minutes' irradiation (1.46×10^{23} ev/mole).
(9) After 4 hours and 50 minutes' irradiation (2.49×10^{23} ev/mole).
(10) After 8 hours' irradiation at −196°, crystal warmed to room temperature for 2 hours, then cooled to −196° again for plotting spectrum (total dose 4.14×10^{23} ev/mole).

3100 Å, which we attribute to chlorite and hypochlorite respectively. The optical densities at the peaks agree within 15% with the values expected from the amounts of chlorite and hypochlorite found by analysis in the crystal, assuming the extinction coefficients in the solid to be the same as in solution. Quantitative analyses for chlorite and hypochlorite were carried out by dissolving the irradiated sample in 0.5 ml of 0.025 *M* sodium carbonate, and measuring optical densities at 2610 Å and 2900 Å. The absorption bands of the two ions overlap, so the amounts of chlorite and hypochlorite were calculated as solutions of a pair of simultaneous equations, using molar extinction coefficients from Friedman's paper.

Chloride could not be tested for by the usual reagent, silver ion in nitric acid solution, since the chlorite already known to be there disproportionates to an uncertain extent to chloride in acid pH's; moreover, silver ion is stated to precipitate silver chloride from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

For personal use only.

hypochlorite solutions (3). Instead, the chloride was allowed to react with silver ion in a weakly alkaline medium (0.01 *M* borax, pH about 9). At this pH, neither silver oxide nor silver borate precipitates, and we established spectrophotometrically that chlorite–hypochlorite mixtures are stable indefinitely. We ascertained by trial that after adding excess silver nitrate, in a very small volume, to a solution of irradiated chlorate in 0.01 *M* borax, and allowing the precipitate of silver chloride to settle, the chlorite and hypochlorite bands appeared in the absorption spectrum of the supernatant liquid exactly as they had been before adding the silver nitrate. This shows that silver nitrate precipitates chloride alone, without interference from chlorite or hypochlorite, in 0.01 *M* borax. For the quantitative estimation of chloride, the sample was dissolved in 1.0 ml 0.01 *M* borax. Water (0.5 ml) was added, followed by 1.5 ml of millimolar silver nitrate, shaking well at each stage. At the same time, a reference solution and two standards were made up. Each contained unirradiated potassium chlorate equal in weight to the sample. The standards contained, in addition, appropriate volumes of millimolar potassium chloride in place of some or all of the water. The quantities of chloride in the standards were chosen to "bracket" that expected for the sample, which had been roughly determined in earlier runs. All solutions were in 10-ml colorimeter test tubes which we had matched. After the solutions were shaken and left to stand for half an hour in the dark, the optical densities of all suspensions were measured at 375 mμ. Control experiments had established that the optical densities in the range we worked with were proportional to the amount of chloride, and (in confirmation of published work (11)) that they reached a maximum steady value in a few minutes less than the half-hour waiting period, at the laboratory temperature (26°).

The amount of gaseous oxygen recovered was less than equivalent to the hypochlorite, chloride, and chlorite, by an amount exceeding any likely experimental error. The most obvious explanation is that some *perchlorate* was formed. This ion could not be directly determined because there appears to be no simple micromethod applicable in the given circumstances. The infrared absorption spectrum of an irradiated sample believed from the material balance to contain 2 mole % of perchlorate was taken by the potassium chloride disk method. It showed a small peak at 1113 cm^{-1} not visible in the spectrum of unirradiated potassium chlorate. This falls close to the main maximum in the spectrum of pure potassium perchlorate (about 1100 cm^{-1}). This observation cannot be considered reliable evidence of perchlorate, since the side of the very strong main chlorate band extends into this region and tends to obscure small structural features. Nevertheless, we consider the formation of perchlorate to be the most likely explanation of the oxygen deficiency, especially in view of Sharman and McCallum's observation that pile-irradiated sodium chlorate contains substantial amounts of perchlorate (14).

The evidence for *dichlorine hexoxide* in irradiated potassium chlorate is derived solely from the absorption spectra of crystals. This substance hydrolyzes to chloric and perchloric acids when dissolved in water, so could not have been detected by any simple chemical method. Figure 4 shows the spectra in question. Besides the bands attributed to chlorite and hypochlorite already mentioned, irradiation at 25° produced a strong band with maximum at 4500 Å, which was responsible for the brown color of the crystals. When the crystal was cooled to −196°, this band developed a structure, as shown. Since this structure only appeared on cooling, it cannot have been an optical effect arising from polarization as described by Pringsheim (13), but must have been a true vibrational structure. The spacing of the subsidiary maxima was irregular and ranged from 570 to 680 cm^{-1}. The structure shows that this band came from a molecular

species, and not a color center. According to published information, no band anywhere near this position is to be found in the spectrum of chlorine or of any of the chlorine oxyanions or oxides, with the exception of Cl_2O_6 (12). The spectrum of this oxide has not been fully investigated, but the long wavelength edge of its absorption band, as described by Goodeve and Richardson (4) corresponds with the long wavelength side of our 4500 Å band.

The spectrum of crystals irradiated at −196°, and then allowed to warm up to 25°, was quite different (Fig. 4). The 4500 Å band was missing, and there was absorption over a considerable range of wavelengths, with one well-defined maximum at 2400 Å and several other ill-defined maxima. When the crystals were warmed to room temperature, the 2400 Å maximum and most of the remaining absorption disappeared, being replaced by a spectrum very similar to that obtained by irradiation at room temperature, including a strong band at 4500 Å. This developed structure on cooling of the crystal, and was obviously due to the same substance as the 4500 Å band produced by irradiation at 25°.

Our data on the *kinetics* of the decomposition are summarized in Fig. 5 and Table I. The figure shows the results of the best series of runs at 25°, viz. those done with the most heavily filtered radiation, and consequently the most nearly uniform dose rate. The main facts about Fig. 5 are as follows. Chlorite and hypochlorite were generated

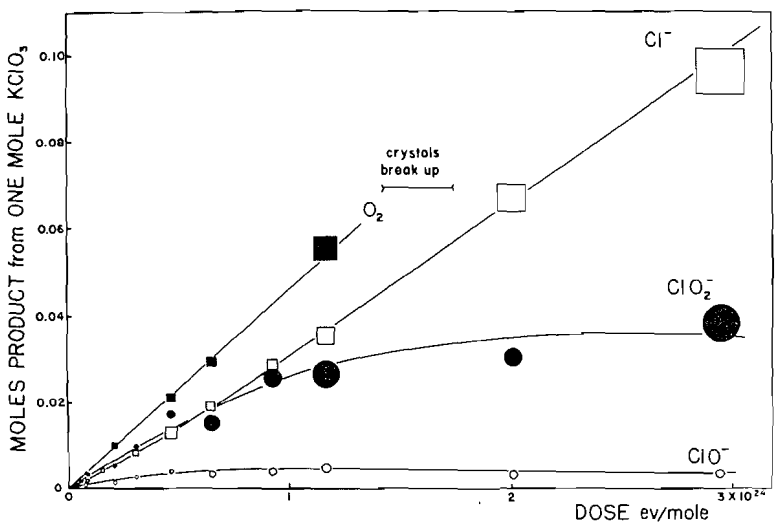

FIG. 5. Yields of chloride, hypochlorite, chlorite, and oxygen on dissolving $KClO_3$ irradiated for various times at 25° (dose rate 0.39×10^{23} ev/mole per hour). Sizes of experimental points represent possible analytical errors.

at rates which decreased with time until their concentrations became roughly steady. Chloride was formed at a rate increasing somewhat with time at first, and then (after a dose of about 10^{24} ev/mole) roughly constant. The final slope of the chloride line is about 25% greater than the initial slope. The rate of formation of oxygen was approximately constant up to the point where it began to escape from the crystals, and could no longer be determined. Some of the points of the chlorite curve are scattered more widely than would be expected from analytical errors alone; the reason is unknown. The general picture for the higher dose rate at 25°, and for the runs at −196° (not plotted, but data given in Table I), was very similar in all respects.

TABLE I

Initial G values (molecules per 100 ev absorbed) for the formation of products in the X irradiation of potassium chlorate

Temp., ° C	Dose rate, ev/mole per hour	G_{Cl^-}	G_{ClO^-}	$G_{ClO_2^-}$	G_{O_2}	$G_{Cl_2O_6}$	G_{ClO_2}
25	1.24×10^{23}	1.9	0.7	2.6	2.9	—	≈0.2
	0.39×10^{23}	1.3	0.5	2.0	2.5	—	
−196	0.12×10^{23}	—	—	—	—	1.4*	
	0.38×10^{23}	1.1	0.5	1.5	2.0	Not formed	

*Value estimated from optical density of crystal at 5460 Å, using $\epsilon = 80$ (Goodeve and Richardson, ref. 4) (see also ref. 10).

DISCUSSION

Chloride, hypochlorite, and chlorite all appear to be formed at the earliest stages of decomposition accessible to our measurements, viz. a few tenths of one per cent. Probably they all arise directly from chlorate by alternative processes of excitation and subsequent breakdown. The bodies decomposing cannot be positively identified, but are probably not ClO_3 molecules or radicals in their ground state, which are stable. The reactions occurring are likely to be:

$$ClO_3^{-*} \rightarrow Cl^- + O_2 + O \quad [1]$$
$$ClO_3^{-*} \rightarrow ClO^- + O_2 \quad [2]$$
$$ClO_3^{-*} \rightarrow ClO_2^- + O. \quad [3]$$

The perchlorate thought from the material balance to be present might be formed by a reaction between unexcited chlorate ions and O atoms from [1] and [3]:

$$ClO_3^- + O \rightarrow ClO_4^-. \quad [4]$$

The maximum possible yield of perchlorate (taking for discussion the figures for the lower dose rate at 25°) which could be associated with the observed oxygen deficiency is $G_{ClO_4^-} = 1.9$. The yield of O atoms from [1] and [3] is given by $G_O = 3.3$, considerably more than adequate to account for any perchlorate present.

The other main reaction product, thought to be Cl_2O_6, might arise as follows. Irradiation gives rise to positive holes (equivalent to ClO_3 radicals) and electrons in the conduction band. We suggest that at −196° these positive holes do not migrate rapidly, and that the strong ultraviolet absorption observed at this temperature is partly due to ClO_3, which is known to absorb with a maximum just below 3000 Å (12). The spectrum, however, gives no indication of the usual types of trapped electron centers, which would absorb in the region upwards of 5000 Å, and there is a question as to the fate of the electrons. We suggest that these are trapped by some of the O atoms from [1] and [3], which are not accounted for by [4], giving O^- or $O^=$ ions. The oxygen atom has an electron affinity of about 2.2 v, so that it should trap electrons efficiently. The wavelength at which the resulting O ion begins to absorb light would depend on its environment, but is not outside the range of the optical absorption observed in crystals irradiated at −196°. When the crystals are warmed up, some of the positive holes would be annihilated by electrons, while others may migrate together in pairs, forming Cl_2O_6 molecules, which are known to be very stable.

The drop in the net rates of formation of chlorite and hypochlorite as irradiation continues (Fig. 5) can best be explained by the secondary decomposition of these ions to chloride by the radiation:

$$\left.\begin{aligned} ClO_2^{-*} &\rightarrow Cl^- + O_2 \\ ClO^{-*} &\rightarrow Cl^- + O. \end{aligned}\right\} \quad [5]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

This might be expected to lead to an increase in the total rate of formation of chloride as irradiation continues. Such an increase is observed, but cannot be given any simple quantitative interpretation. Examination of the data of Fig. 5, for example, discloses that when the concentrations of ClO_2^- and ClO^- are steady, the rates of destruction, and hence also the rates of formation, of these ions must be considerably less than their initial rates of formation; for in this region, the total G_{Cl^-} is only 1.6. If the initial rates of formation of ClO_2^- and ClO^- persisted into the steady state, the rate of formation of chloride from reactions [5] alone would equal $(G_{ClO_2^-}+G_{ClO^-})_{initial} = 2.5$. It seems that the excitons produced by the radiation are used at first mainly in reactions [1] to [3]. Soon, however, the ClO^- and ClO_2^- ions formed in [2] and [3] begin to trap a considerable proportion of the excitons, and use them in reactions [5], causing the yields from [1], [2], and [3] to diminish. ClO^- and ClO_2^- should trap excitons efficiently, since their excitation energies (as shown by their optical absorption) are lower than the minimum excitation energies of ClO_3^- and ClO_4^-. The experimental data do not suffice to give a more detailed picture of exciton utilization. It is interesting to note that the variation of chlorite and hypochlorite concentration with dose in potassium perchlorate (reported in an earlier paper (6)) is very much like that found in potassium chlorate, probably for similar reasons.

The assumption made in the preceding discussion, that all the primary chemical steps are initiated by single excitons, is justified by the small effect of dose rate on the G values (Table I). Reactions involving pairs of excitons would usually proceed at rates proportional to intensity squared, or, what is equivalent, their G values would be proportional to dose rate. Experimentally, all the G values do seem to increase somewhat with dose rate, but not nearly in proportion to it. Since the dose rate was regulated by varying the filtration, this small apparent variation of G values may well be due to systematic errors in the calculations of energy absorption, due among other causes to insufficiently accurate knowledge of the spectral energy distribution of the X rays. The variation of G with temperature over the enormous range from 25° to −196° is so small that none of the reactions can require thermal activation in the ordinary sense.

Our G values for the generation of oxygen (2.5 and 2.9 at 25°) agree well with the values 2.5 and 2.6 reported for pile-irradiated potassium chlorate by Hennig, Lees, and Matheson (9).

ACKNOWLEDGMENT

It is a pleasure to acknowledge the generous support for this investigation received from the Defence Research Board of Canada.

PREPARATION OF SOME FLUORINE-CONTAINING TRISUBSTITUTED AROMATIC HYDROXYLAMINES[1]

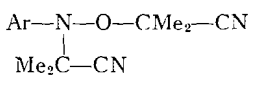
B. A. GINGRAS AND C. H. BAYLEY

ABSTRACT

The preparation and properties of aryl dialkyl hydroxylamines in which the aryl group is a fluorobenzene derivative, and the two alkyl substituents are 2-cyano-2-propyl groups, are described.

Fluorine and its inorganic derivatives have been known for some time to be toxic to many live species (1) and, more recently, the high toxicity of fluoroacetic acid and many of its derivatives has been demonstrated (2). Although aromatic fluorine compounds have been prepared in good yields since 1927 (3), it was not until 1949 that the first systematic investigation of their fungistatic properties was undertaken (4). It was found that a number of monofluorinated quinones and nitrophenols showed good activity against the organisms *A. niger*, *A. terreus*, *M. verrucaria*, and *C. globosum*, the last two being cellulolytic. Addition of a second fluorine atom resulted in a decrease in potency and, for the fluoronitrophenols, a loss of activity was obtained by addition of another nitro group. However, in the aromatic hydrocarbon series, addition of a second nitro group markedly increased the potency, the most powerful compound being 2,4-dinitro-5-fluorotoluene (5). There are some indications that with multiple halogen dissimilar halogens give higher potencies, the most effective of all the compounds studied being 1-fluoro-3-bromo-4,6-dinitrobenzene, which, in concentration of 0.8 p.p.m., prevented growth of *A. niger* (6).

Most aromatic fluorinated nitro compounds have a yellow color and impart this to materials to which they are applied. This may be an objectionable feature, especially in the treatment of textile fibers for the suppression of microbiological attack. In the search for new antifungal compounds for this latter type of application, a series of colorless derivatives of fluoronitrobenzene have been prepared. These are O,N,N-trisubstituted hydroxylamines (I), similar to those reported by Gingras and Waters (7).



I

They are prepared through a free radical reaction from aromatic *C*-nitroso compounds and 2-cyano-2-propyl free radicals as follows. An aromatic amine (II) is first diazotized and then transformed into the fluorine derivative (IV) through a Schiemann reaction (3, 8). Nitration, followed by mild reduction gives the nitroso compound (VI), which is in turn reduced to the tertiary hydroxylamine (VIII) with two 2-cyano-2-propyl radicals (VII), the latter being produced by thermal dissociation of 2,2′-azo-bis-isobutyronitrile (IX) in solution (9).

In some instances, especially when the resulting mixture from nitration was difficult to separate into pure products, a nitroamine was used as starting material. In these

[1]*Manuscript received February 5, 1959.*

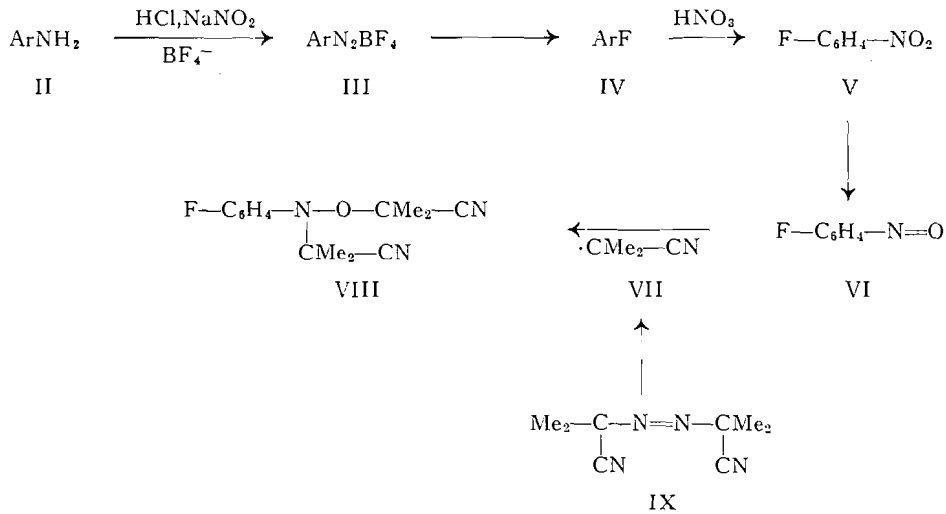
Issued as N.R.C. No. 5148.



cases, special precautions had to be taken as thermal decomposition of benzene diazonium fluoborates (III) containing a nitro group is difficult to control with resultant possibility of poor yields (8).

The tertiary hydroxylamines together with the intermediate nitro compounds are listed in the table. Except for 2,4-dimethyl-6-nitrofluorobenzene, all the nitro compounds had been previously described.

The fluorohydroxylamines are white solids, easily purified by chromatography and crystallization. They are practically insoluble in water, but dissolve in most organic solvents. Infrared spectra are of requisite character and, as expected, they are very similar to those obtained for the corresponding chlorine analogs (7). They all show the typical nitrile band at 4.5 μ, a band at 6.25 μ due to vibrations of the aromatic ring, and among others, a medium or strong band in the 9 μ region. Although the latter is indicative of $\diagdown\!\!\diagup$C—F grouping (10), no conclusion can be drawn here, as this region is also characteristic of the C—O and N—O stretching frequencies. Furthermore, the chlorine analogs also show a strong band in this region (7) and hence, it is probable that this is due to some covalencies of the system $\begin{matrix}\text{C}\diagdown\\ \text{C}\diagup\end{matrix}$N—O—C of the hydroxylamines.

Preliminary examination shows that reduction of the nitro compounds to the substituted hydroxylamines resulted in a decrease of potency. Other types of fluorine compounds are being examined simultaneously and it is hoped that a full discussion of the biological results will be published elsewhere.

EXPERIMENTAL

2,2′-Azo-bis-isobutyronitrile was the commercial product Porophor N, (Westville laboratories) and was recrystallized before use, from ethyl acetate, to m.p. 104° C; lit. m.p. 103–104° (16). Diazonium fluoborates were prepared and decomposed by the method of Balz and Schiemann (3, 8). Nitro compounds were reduced to the corresponding nitroso compounds by the method of Lutz and Lytton (17). All melting points were taken on a Fisher–Johns apparatus and are corrected.

p-Fluoronitro- and p-Fluoronitroso-benzene

p-Nitroaniline (34.6 g, 0.25 mole) was converted into *p*-fluoronitrobenzene (15.2 g, 45%) by the Schiemann reaction (8). The preparation of *p*-fluoronitrosobenzene is typical and is described in detail. *p*-Fluoronitrobenzene (14.1 g, 0.1 mole) was dissolved in a mixture of alcohol (42 ml) and water (24 ml) and powdered calcium chloride (1.5 g) was added. The mixture was heated to boiling and zinc dust (20 g) was added in small portions. At the end, the solid residue was removed by filtration and the filtrate was poured into an ice-cold solution of ferric chloride (37 g) in water (600 ml). The dark green precipitate of nitroso compound that formed was separated by filtration, and washed with ice-cold water. The product was purified by steam distillation; yield: 6.5 g (52%).

Reaction between p-Nitrosofluorobenzene and 2,2′-Azo-bis-isobutyronitrile

p-Nitrosofluorobenzene (6.5 g, 0.05 mole) and 2,2′-azo-bis-isobutyronitrile (16.4 g, 0.1 mole) were dissolved in toluene (150 ml) and the solution was heated to 80° C. The azo compound was decomposed and the green color of the nitroso compound soon disappeared. Heating was continued under reflux for 2 hours to assure complete decomposition of the azobutyronitrile. The toluene and radical dimer (tetramethylsuccinonitrile formed by combination of two free radicals VII) (9) were distilled with steam and the residue taken up in ether and dried. After evaporation of the ether, the residue was chromatographed through a column of silica gel. A mixture of benzene and ethyl ether 9:1 eluted ON-di-(2-cyano-2-propyl)-N-(*p*-fluorophenyl) hydroxylamine (5.31 g, 40% from the nitroso compound; 8% over-all yield from original amine; m.p. 121°). The product was recrystallized from aqueous alcohol 80%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

o-Fluoronitro- and o-Fluoronitroso-benzene

o-Nitroaniline (34.6 g, 0.25 mole) gave 4.4 g (14%) of *o*-fluoronitrobenzene. This gave, by the method previously described, 1.8 g (46%) *o*-fluoronitrosobenzene.

Reaction between o-Fluoronitrosobenzene and 2,2′-Azo-bis-isobutyronitrile

This reaction was carried out as above using 1.8 g (0.15 mole) *o*-fluoronitrosobenzene, 5 g (0.03 mole) azobutyronitrile, and 50 ml toluene. The solution was heated during $2\frac{1}{2}$ hours under reflux and then steam-distilled. The residue from the steam distillation weighed 1.2 g. Chromatographic separation of this residue yielded ON-di-(2-cyano-2-propyl)-N-(*o*-fluorophenyl) hydroxylamine (0.75 g, 20% from the nitroso compound). After recrystallization from aqueous alcohol it had m.p. 117.5°.

3-Fluoro-4-methylnitro- and 3-Fluoro-4-methylnitroso-benzene

2-Methyl-5-nitroaniline (38 g, 0.25 mole) gave 2-methyl-5-nitrobenzenediazonium fluoborate (58 g, 93%) which when decomposed yielded 2-methyl-5-nitrofluorobenzene (25.5 g, 70%). The corresponding 2-methyl-5-nitrosofluorobenzene was obtained in 50% yield (*ca.* 7 g) from 15.5 g (0.1 mole) of nitro compound.

Reaction between 2-Methyl-5-nitrosofluorobenzene and 2,2′-Azo-bis-isobutyronitrile

The nitroso compound (7 g, 0.05 mole) and the azonitrile (16.4 g, 0.1 mole) were dissolved in toluene (100 ml). After the usual $2\frac{1}{2}$ hours' reflux and steam distillation, the residue (4.8 g) was chromatographed. There was obtained from mixtures of benzene: ethyl ether, 4:1 and 2:1, ON-di-(2-cyano-2-propyl)-N-(3-fluoro-4-methylphenyl) hydroxylamine (3.8 g, 28%) which was recrystallized from *n*-hexane to constant m.p. 79°.

2-Fluoro-3,5-dimethylnitro- and 2-Fluoro-3,5-dimethylnitroso-benzene

2,4-Dimethyl-6-nitroaniline (41.5 g, 0.25 mole) gave the corresponding diazonium fluoborate (36.5 g, 55%). The latter decomposed at 220° C to give 2-fluoro-3,5-dimethylnitrobenzene (7.8 g, 25%; m.p. 70°). Calc. for $C_8H_8FNO_2$, mol. wt. 169: C, 56.8; H, 4.8; N, 8.3. Found: C, 57.8; H, 5.2; N, 8.3. Reduction of 5.6 g (0.03 mole) of the nitro compound gave 2-fluoro-3,5-dimethylnitrosobenzene (*ca.* 5 g).

ON-*Di-(2-cyano-2-propyl)*-N-*(2-fluoro-3,5-dimethylphenyl) Hydroxylamine*

Reaction of 2-fluoro-3,5-dimethylnitrosobenzene (*ca.* 5 g, 0.03 mole) and 2,2′-azo-bis-isobutyronitrile (11.5 g, 0.07 mole) in toluene (125 ml) gave 1 g (12%) of the tertiary hydroxylamine. The product was recrystallized from aqueous alcohol; m.p. 88°.

3-Methyl-4-fluoronitro- and 3-Methyl-4-fluoronitroso-benzene

Nitration of *o*-fluorotoluene (60 g, 0.54 mole) with fuming nitric acid (66 ml, sp. gr. 1.5) by the method of Schiemann (11) afforded 3-methyl-4-fluoronitrobenzene (57 g, 67%, b.p. 120° at 25 mm Hg). Reduction of the nitro compound (15.5 g, 0.1 mole) gave the corresponding nitroso compound (*ca.* 7 g, 50%).

ON-*Di-(2-cyano-2-propyl)*-N-*(3-methyl-4-fluorophenyl) Hydroxylamine*

This reaction was carried out as above using 3-methyl-4-fluoronitrosobenzene (*ca.* 7 g, 0.05 mole) and 2,2′-azo-bis-isobutyronitrile (16.4 g, 0.1 mole) in toluene (150 ml). After usual heating, steam distillation, and chromatography, there was obtained the tertiary hydroxylamine (4.8 g, 35%) which was recrystallized from absolute ethyl alcohol to constant m.p. 86.5°.

2-Methyl-4-fluoronitro- and 2-Methyl-4-fluoronitroso-benzene

m-Fluorotoluene (13.4 g) was nitrated with nitric acid (15 g, sp. gr. 1.42) and concen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

trated sulphuric acid (45 g) to give 2-methyl-4-fluoronitrobenzene (12 g, 70%, b.p. 111° at 21 mm). This was reduced to the corresponding nitroso compound by the usual method.

Reaction between 2-Methyl-4-fluoronitrosobenzene and 2,2'-Azo-bis-isobutyronitrile

This reaction was carried out as before and gave the expected ON-di-(2-cyano-2-propyl)-N-(2-methyl-4-fluorophenyl) hydroxylamine (2.9 g, 25%) which was best recrystallized from ethyl alcohol; m.p. 100°.

2-Methoxy-5-fluoronitro- and 2-Methoxy-5-fluoronitroso-benzene

p-Fluoroanisole (20 g, 0.15 mole) was nitrated by the method of Swarts (15) to give 2-methoxy-5-fluoronitrobenzene (15.7 g, 60%, m.p. 62°). Reduction of the latter (15.7 g, 0.09 mole) gave 2-methoxy-5-fluoronitrosobenzene (7.7 g, 54%).

ON-*Di-(2-cyano-2-propyl)*-N-*(2-methoxy-5-fluorophenyl) Hydroxylamine*

Reaction of 2-methoxy-5-fluoronitrosobenzene (7.7 g, 0.05 mole) with 2,2'-azo-bis-isobutyronitrile (16.4 g, 0.1 mole) gave the expected tertiary hydroxylamine (5 g, 33%), which was recrystallized from *n*-hexane; m.p. 97.5°.

NOTES

SZILARD CHALMERS REACTION IN POTASSIUM MANGANATE

R. A. MACKENZIE AND K. J. MCCALLUM

Several investigators have studied the chemical effects following neutron capture by the manganese nucleus in potassium permanganate. Libby (1) showed that when the irradiated solid was dissolved in water, most of the radioactive manganese could be separated with manganese dioxide, but a certain percentage, termed the retention, remained in the form of permanganate ion. The retention was observed to increase when the pH of the solution in which the solid was dissolved was high. Libby postulated that, while some of the radioactive manganese was present in the solid as permanganate ion, some existed as species formed by the loss of one or more oxygen ions from the permanganate ion, such as MnO_3^+ or MnO_2^{+++}. He assumed that these would be reduced to manganese dioxide by water, but would react with hydroxyl ions to form permanganate, thus leading to the observed increase in retention in basic solutions. Later investigations (2, 3) have verified the nature of the observed changes in retention, and have given results which are consistent with the reactions postulated by Libby.

If similar changes occur following neutron capture in potassium manganate, the species trapped in the solid would be of the type MnO_3 or MnO_2^{++}. Libby (1) made preliminary measurements of retention, following the neutron activation of sodium manganate dissolved in basic solution. The retention was less than that observed for permanganates under the same conditions, indicating that the recoil species differed in their behavior under these conditions.

The present note reports the results of a study on the effect of the normality of sodium hydroxide in the solvent on the retention for solid potassium manganate.

Potassium manganate was prepared by boiling a solution of potassium permanganate and potassium hydroxide. The compound was recrystallized from potassium hydroxide solution, the crystals being washed with absolute methanol containing a small amount of dissolved potassium hydroxide, and then with anhydrous ether. The oxidation equivalent of the product corresponded to 95–98% K_2MnO_4 in different preparations.

The solid was exposed to neutrons from a Ra–Be neutron source in a paraffin block. It was then dissolved in sodium hydroxide solutions of known normality, the retention then being determined by methods previously used for studies on potassium permanganate (2).

The results are given in Table I.

TABLE I

Retention in potassium manganate

Solution	% Retention	Solution	% Retention
1 *N* NaOH	46	7.5 *N* NaOH	87
3 *N* NaOH	55	8.5 *N* NaOH	92
5 *N* NaOH	66	10 *N* NaOH	97

The results indicate that the retention increases with increase in concentration of the hydroxyl ion, as was found for potassium permanganate. The recoil species then show

the same general chemical behavior for both salts. Measurements of retention in acid solutions might serve to reveal differences between the species. The disproportionation of manganate ion that occurs in such solutions makes necessary a different method of determining retentions. Attempts to establish a satisfactory method are in progress.

ELECTRON SPIN RESONANCE ABSORPTION OF ULTRAMARINE: EFFECT OF CATIONS

YOSHIO MATSUNAGA*

Although the origin of the intense blue color of ultramarine is still unexplained, it has been generally accepted that the color is associated with the presence of regulated amounts of alkali and sulphur and the latter seems to be in the form of polysulphide sulphur (1). Gardner and Fraenkel (2) found that ultramarines show E.S.R. absorption and suggested that the paramagnetism arises from some type of sulphur radical. On the other hand, it is well known that the alkali in ultramarine is exchangeable for other bases and the color depends on the kind and the amount of bases. Here we wish to present the results of a study of the effect of cations on E.S.R. absorption of ultramarine.

The synthetic ultramarine supplied by Fisher Scientific Co. (Catalog No. U-1) was used as starting material and treated with large excess of silver nitrate and small amount of water in a sealed tube at 120–140° C for 15 hours. By this method we can replace sodium nearly completely with silver (3, 4). The other ultramarines were prepared by the treatment of the silver derivative with the halide of the desired metal as described by Jaeger (4). E.S.R. absorption was measured at room temperature at a frequency of 9 k Mc/s. The results are given in Table I. The line width is given by the distance in gauss between the points of maximum slope.

TABLE I

E.S.R. absorption of substituted ultramarines

Cation	Color	Line width	*g*-Value	Intensity

Contrary to the replacement of sodium with silver, the exchange of cation in the reverse direction is incomplete. In addition, the loss of a part of the sulphur and the change of oxidation state by the prolonged treatments must be taken into consideration. Although the quantitative explanation of the results is thus complicated by these facts, we can conclude that the concentration of unpaired electrons and the *g*-value depend on the kind of cation. The intensity of E.S.R. absorption is decreased by a factor of 20 to 30 accompanying the replacement of sodium by silver, but the paramagnetism of silver ultramarine can be increased about ten times by treatment with alkali halide. The color of ultramarine also changes nearly reversibly by these replacements. As to the ultramarines containing divalent cations, the replacement of silver seems to be more incomplete (4). However, generally the color of these ultramarines is far from blue and the concentration of unpaired electrons in these samples is less than alkali ultramarines.

It appears that not only the color of ultramarine but also the concentration of unpaired electrons depends on the kind of cation. Besides, the shift of *g*-value by cation exchange suggests that the spin–orbit interaction can be modified by the cation. Therefore, the paramagnetic species is not an isolated sulphur radical but is a complex containing cations. In accordance with the view which regards the color as being due to incompletely oxidized sulphur, it is very likely that unpaired electrons arise from polysulphide ions, however, they can apparently interact with each other through cations. The ability of the cation to couple unpaired electrons seems to be related to its polarizability and its valency. Alkali ions are not so effective for such an interaction.

THE ADDITION OF ETHYL RADICALS TO ETHYLENE

F. W. Lampe and F. H. Field

In a recent study (1) of the reaction of ethyl free radicals generated by the photolysis of diethyl ketone, James and Steacie reported the activation energy (assuming zero activation energy for radical coupling) for addition to 1-alkene-type olefins to be 7.0 ± 0.2 kcal/mole. This value is consistent with the value of 7 kcal/mole found by Mandelcorn and Steacie (2) for the addition of methyl radicals to ethylene but is somewhat higher than the value found by Pinder and LeRoy (3) for ethyl radical addition to ethylene. These latter authors generated ethyl radicals by utilizing the mercury-photosensitized decomposition of hydrogen in the presence of ethylene and found an activation energy of 5.5 kcal/mole and a steric factor ratio of 5.0×10^{-5}. A "low" value of 4.6 kcal/mole for the addition of methyl radicals to ethylene can be derived (2) from the data of Raal and Danby (4).

We wish to report here the results of some studies, on the photolysis of azoethane in the presence of ethylene, that support the lower values for the activation energy of the addition reactions.

EXPERIMENTAL

Azoethane was prepared by the method of Leitch (5). Ethylene was Phillips Research Grade, had a stated purity of 99.9+ mole %, and was used without further purification.

The photolyses were carried out in an annular reaction vessel constructed entirely of quartz. The annular space which contained the reacting gases had a thickness (light-path distance) of about 1.5 cm and a length of about 25 cm. The light source, positioned in the center of the vessel, consisted of two 8-watt G.E. "Black-lights" connected in series. The emitted radiation of the "Black-light" peaks at 3660 Å and emits negligible intensity below 3000 Å, thus eliminating the possibility of mercury-sensitized reactions. The gases were circulated by a two-stage Toepler pump, with the dead-space volume being about 20% of the total volume of reaction system.

In all experiments the azoethane pressure was held constant at 40 mm of Hg while the ethylene pressure was varied from 5 to 25 mm of Hg. Nitrogen was measured by assuming it to be the only noncondensible gas at −195° C. After its measurement the nitrogen was removed and the gases condensible at −195° C were analyzed by vapor–liquid partition chromatography.

RESULTS AND DISCUSSION

In all photolyses the only major reaction products observed were nitrogen, ethane, *n*-butane, and *n*-hexane. At the highest conversions in the runs at 175° C, small amounts of butylene were detected. No appreciable amounts of octane or higher hydrocarbons were found.

The main features of the mechanism involved in the photolysis of azoethane have been established (6, 7). The reactions of most importance to this discussion are:

$$C_2H_5N{=}NC_2H_5 + h\nu \rightarrow 2C_2H_5 + N_2 \qquad [R1]$$

$$C_2H_5 + C_2H_5N{=}NC_2H_5 \rightarrow C_2H_6 + C_2H_5N{=}NCH_2CH_2\cdot \qquad [R2]$$

$$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \qquad [R3]$$

$$C_2H_5 + C_2H_5 \rightarrow C_2H_4 + C_2H_6. \qquad [R3']$$

If ethylene is added to the system, some of the ethyl radicals formed in [R1] will add to it to form butyl radicals, i.e.,

$$C_2H_5 + C_2H_4 \rightarrow C_4H_9. \qquad [R4]$$

The absence of significant amounts of octane indicates, under our experimental conditions, that there is no appreciable addition of butyl radicals to ethylene nor coupling of butyl radicals. Since there is no appreciable addition of butyl radicals to ethylene, it seems reasonable to assume that butyl radicals will not abstract hydrogen from azoethane under these conditions. Also, since there is no appreciable coupling of butyl radicals, it is reasonable to assume that butyl radicals do not couple appreciably with the azoethyl radicals produced in [R2]. Thus, as an approximation, we assume that butyl radicals react only with ethyl radicals, i.e.,

$$C_2H_5 + C_4H_9 \rightarrow C_6H_{14} \qquad [R5]$$

$$C_2H_5 + C_4H_9 \rightarrow C_2H_6 + C_4H_8 \qquad [R6]$$

$$C_2H_5 + C_4H_9 \rightarrow C_2H_4 + C_4H_{10}. \qquad [R7]$$

The usual steady state approximation leads to

$$(1/[C_2H_4])(R_{C_6H_{14}}/R^{\frac{1}{2}}_{C_4H_{10}}) = P_C(k_4/k_3^{\frac{1}{2}}) \qquad [E1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

when the R's denote rates of formation, k's specific reaction rates, and P_C is the probability that in [R5]–[R7] coupling occurs, i.e.,

[E2] $$P_C = k_5/(k_5+k_6+k_7).$$

In Table I we show the results of the photolyses. Each value of $P_C(k_4/k_3^{\frac{1}{2}})$ is the average obtained from at least five experiments with irradiation times varying from 15 to 70 minutes. In the calculation of $P_C(k_4/k_3^{\frac{1}{2}})$, initial ethylene concentrations were used.

TABLE I

Addition of ethyl radicals to ethylene

Temp. (° K)	$[C_2H_4]_0$ (mm at T° K)	$P_C(k_4/k_3^{\frac{1}{2}})\times10^{12}$ (cc/molecule-sec)$^{\frac{1}{2}}$
398	10.2	2.54
398	15.5	2.67
398	20.0	2.64
398	25.0	2.47
423	5.0	3.79
423	10.1	3.71
423	15.0	3.81
423	20.0	3.88
448	5.0	5.62

This does not introduce any error greater than that involved in the analyses, because in all runs the ethylene conversion was below 10% and generally of the order of 2–6%.

The absence of significant amounts of butylene and the fact that [R6] is thermodynamically favored over [R7] suggests that P_C is very close to unity. Assigning P_C a value of unity (an approximation that is not in error by more than 5 or 10%) enables us to make the usual type Arrhenius plot of the rate constant ratios in Table I. Such a plot is shown in Fig. 1 and leads to a value for the activation energy difference, $E_4-\frac{1}{2}E_3$, of 5.5 kcal/mole. The ratio of the pre-exponential factors, $A_4/A_3^{\frac{1}{2}}$, is 2.6×10^{-9} which, upon assumption of a mean collision diameter of 4.0 Å, leads to a steric factor ratio, $P_4/P_3^{\frac{1}{2}}$, of 1.3×10^{-4}.

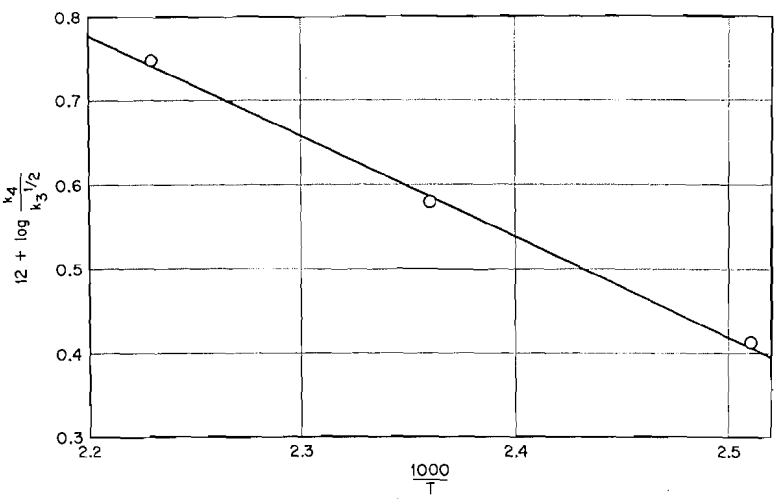

FIG. 1. Arrhenius plot for the addition of ethyl radicals to ethylene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The activation energy difference of 5.5 kcal/mole is in excellent agreement with the results of Pinder and LeRoy (3), and consistent with the low value of 4.6 kcal/mole found by Raal and Danby (4) for the addition of methyl radicals to ethylene. Our value of the steric factor ratio is larger than that found by Pinder and LeRoy (3) by a factor greater than two. We can advance no explanation for this difference.

ACKNOWLEDGMENTS

We are indebted to Dr. D. E. Bown for the synthesis of the azoethane and to Mr. J. C. Leutwyler for assistance in the measurements.

NOTE ON THE DETERMINATION OF CRYSTALLINITY INDEX OF CELLULOSE

M. Kouris, H. Ruck, and S. G. Mason

In a recent communication (1) it was shown that the maximum intensity of air scattering can be used as a reference intensity in determining the X-ray crystallinity index of cellulose. The successful application of the method requires that the following conditions are met:

1. The sample mass must be kept constant to within $\pm 3\%$.
2. I_{as} must be comparable with I_{002}, the intensity of the A_4 cellulose interference.

It now appears that in the earlier work the correct experimental conditions for satisfying the second requirement were fortuitously established.

The purpose of the present note is to draw attention to the recently discovered fact that the second requirement above is satisfied when the thickness of the irradiated sample is about one-third of the optimum thickness as defined by the relation (2)

$$t_m = 1/\mu$$

where μ is the linear absorption coefficient of the sample.

If the optimum sample thickness is used, the absorption of the primary beam will be at a maximum, and the intensity of the air scattering will therefore be disproportionately weak with respect to I_{002} to be used as a reference interference. By reducing the sample thickness to $t_m/3$ the relative intensity of air scattering with respect to I_{002} is increased threefold and I_{as} becomes comparable with I_{002}.

It may also be of interest to point out that preliminary experiments were unable to detect any change in I_{as} with normal variations in atmospheric pressure.

2. I_{as} must be comparable with I_{002}, the intensity of the A_4 cellulose interference.

It now appears that in the earlier work the correct experimental conditions for satisfying the second requirement were fortuitously established.

The purpose of the present note is to draw attention to the recently discovered fact that the second requirement above is satisfied when the thickness of the irradiated sample is about one-third of the optimum thickness as defined by the relation (2)

$$t_m = 1/\mu$$

where μ is the linear absorption coefficient of the sample.

If the optimum sample thickness is used, the absorption of the primary beam will be at a maximum, and the intensity of the air scattering will therefore be disproportionately weak with respect to I_{002} to be used as a reference interference. By reducing the sample thickness to $t_m/3$ the relative intensity of air scattering with respect to I_{002} is increased threefold and I_{as} becomes comparable with I_{002}.

It may also be of interest to point out that preliminary experiments were unable to detect any change in I_{as} with normal variations in atmospheric pressure.

STRUCTURE AND REACTIVITY OF C_3H_3 RADICAL*

G. GIACOMETTI†

Recent mass spectroscopic work by Collin and Lossing (1) on the mercury photosensitized decomposition of allene led to the production of the C_3H_3 radical. The latter was then allowed to react with CH_3 radicals, produced thermally from $Hg(CH_3)_2$, and the analysis of the products showed that all the radicals react to form 1-butyne (CH_3—CH_2—CC≡H) and none of the allenic isomer CH_2=C=CH—CH_3.

This fact is to be considered evidence for the structure of the C_3H_3 radical being of the resonant type

$$\dot{\underset{1}{C}}H_2—\underset{2}{C}\equiv\underset{3}{CH} \longleftrightarrow \underset{1}{CH_2}=\underset{2}{C}=\dot{\underset{3}{C}}H \qquad [I]$$

rather than of the pure allenic type

$$CH_2=C=\dot{C}H. \qquad [II]$$

The structure of the radical is actually going to be different in the two cases because if [I] is correct, the two bonds have certainly different lengths, while if [II] is valid, the two bond distances must be approximately the same.

Though one might feel intuitively that resonance is making structure [I] more stable, it is of interest to show that structure [I] is indeed predicted by a very crude molecular orbital approach.

We shall assume that the simple LCAO, MO theory (2) is applicable, neglecting overlap and also π_x–π_y electron interaction. We shall consider equal all the coulomb integrals and take the exchange integrals as a decreasing function of the bond distance (in absolute value).

Indicating by a the C—C bond in [II] and by b and c those in [I], we have:

$$|\beta_b| < |\beta_a| \leqslant |\beta_c|.$$

The total π electron energy for [II] is simply:

$$E_{II} = 4\beta_a$$

while for [I] we have:‡

$$E_I = 2\beta_c + 2\beta_c \left|\sqrt{\left(1 + \frac{\beta_b^2}{\beta_c^2}\right)}\right| \approx 4\beta_c + \beta.$$

Structure [I] is lower in energy than [II] by an amount at least of the order of β, which corresponds to approximately 20–30 kcal/mole. It is then quite clear that the C_3H_3 radical formed from an excited allene molecule is best represented by formulation [I] and has two different bond lengths.

*Issued as N.R.C. No. 5139.
†*National Research Council Postdoctorate Fellow 1957–58. Present address: Instituto di Chimica Fisica, Università di Padova, Padova, Italy.*
‡*The β's are negative quantities. The coulomb integral is taken as zero of the energy scale.*

The experimentally found reactivity at carbon 1 follows in a straightforward way. Both the free valence index and the localization energy criteria, as used for radical addition to unsaturated molecules (3), agree with addition to carbon 1.

Indicating by k the ratio $\frac{\beta_c}{\beta_b} > 1$ we have the free valence indices:

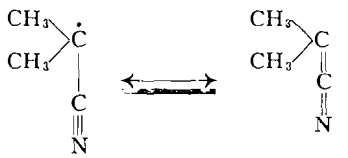
$$f_1 = N_{max} - \frac{1}{\sqrt{(1+k^2)}}, \qquad f_3 = N_{max} - \frac{k}{\sqrt{(1+k^2)}}, \qquad \text{hence } f_1 > f_3$$

and the localization energies (in units of β):

$$E_1 = \sqrt{(1+k^2)} - k, \qquad E_3 = \sqrt{(1+k^2)} - 1, \qquad \text{hence } E_1 < E_3.$$

Of course, this simple theory does not exclude completely addition to carbon 3, the extent of the latter reaction depending mainly on the value to be attributed to k.

Addition to position "three" actually occurs in the case of the cyanoisopropyl radicals:



whose π electron system is similar to the one for C_3H_3 radical. They have been found to recombine mainly carbon to carbon but some of the products correspond also to recombination carbon to nitrogen, the ratio being approximately 2:1 (4). In this case, however, the different electronegativities of nitrogen and of the methyl-substituted carbon atom may also play an important role.

to 23 years and in 1931 the International Radium Standards Commission (1) adopted a value of 22 years.

Since the β^- rays from RaD are so soft, the measurements were not made directly on the RaD, but usually on the Bi^{210} (RaE) daughter in equilibrium with it or on the latter's Po^{210} (RaF) granddaughter, which emits α radiation. A very painstaking measurement of the last type was made by Joliot-Curie (2), who obtained a value of 23 years.

Wagner (3), using an ion chamber, obtained a value of 25 years from a measurement which was carried out for a period of 250 days. In 1955 Tobaillem (4), using a differential ionization chamber, compensated against radium, followed the decay of RaD source for 121 days, and obtained a half-life of 19.4±0.35 years. Merritt, Campion, and Hawkings (5), using a $4\pi\beta$ proportional counter, obtained a value of 22.4±0.4 years for measurements observed over a period of $5\frac{1}{2}$ years. Unfortunately this measurement is not quoted in either the title or the abstract of their paper, and this value became known to us after our series of measurements was completed.

We, in our laboratory, initially used RaD as a standard to monitor the performance of a $4\pi\beta$ proportional counter described previously (6). It soon became apparent that this instrument was sufficiently stable to be used to measure, with good accuracy, the half-lives of long-lived radionuclides.

The Pb^{210} source was chemically purified using standard methods and then sandwiched between aluminum sufficiently thick to absorb all the radiation emitted, other than the β radiation from Bi^{210}. Adequate sealing ensured the exclusion of moisture. This was further checked by intersource comparisons from time to time to ensure source constancy on a short-time basis. The aluminum was thick enough so that no change in geometrical shape could occur which would remove the source from the position of 100% efficiency in the counter (6).

The dead time of the counter was determined from time to time by the well-known 'paired-source' technique, and the correction due to this was of the order of 0.5%. The count rate was great enough so that background and statistical variations in counting rate could be adequately treated.

Activity measurements were carried on for a period of 5 years. Frequency of measurements varied from daily to weekly, so that a large amount of data was accumulated.

The data were analyzed by the method of least squares and yielded a half-life of 23.30 years. The results were broken down into a yearly basis to see whether any consistent variation was occurring which would attest to source impurity. The deviations were random and were of the order of 0.1 year. It is difficult to assess a systematic error to this series of measurements and a value five times this deviation has been used. This yields a value of 23.3±0.5 years in good agreement with Joliot-Curie (2) and Merritt *et al.* (5) but not with Tobaillem (4).

LOW TEMPERATURE IRRADIATION OF MIXTURES OF HBr AND C_2H_4

D. A. ARMSTRONG* AND J. W. T. SPINKS

A 90-c Co^{60} source was used to irradiate solid equimolar mixtures of HBr and C_2H_4 in a 0.5-cm diameter Pyrex cell at liquid nitrogen and liquid oxygen temperature. A few irradiations of liquid equimolar mixtures just above their freezing point (−165° C) (1) were also performed.

An addition reaction was observed at all three temperatures. The product was identified from its vapor pressure and refractive index to be virtually pure ethyl bromide. The addition was followed by evaporating the mixture at given time intervals and measuring its total pressure. For successive irradiations of the same sample, the pressure decreased until it had fallen to 50% of the initial value, i.e., until the addition was complete.

The pressure decrease (as a percentage of the initial pressure of the HBr–C_2H_4 mixture) versus time of irradiation curves for samples which were irradiated continuously are given in Fig. 1. From the dose rate, estimated by ferrous sulphate dosimetry,† an initial G value of about 10^5 was calculated for addition in the liquid samples. For the frozen samples the G values were lower and fell off rapidly with increasing time of irradiation, especially for those irradiated at liquid nitrogen temperature.

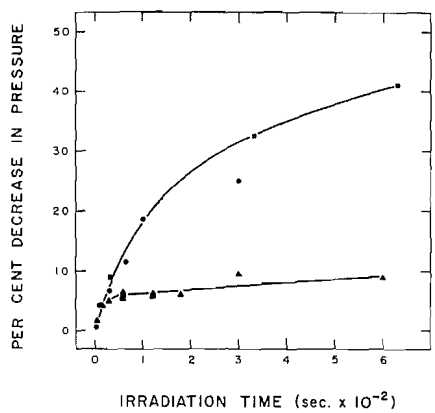

FIG. 1. Percentage decrease in pressure as a function of irradiation time; ■ liquid phase; ● solid phase at liquid oxygen temperature; ▲ solid phase at liquid nitrogen temperature. Dose rate, 450 r per minute.

Unirradiated samples of mixtures of ethylene and hydrogen bromide were stable (cf. (1)), and no addition was observed when an HBr–C_2H_4 mixture was condensed in an empty Pyrex cell which had been previously irradiated.

The high G values are indicative of a chain reaction and it would appear that the radiation produced reactive entities (possibly free radicals, cf. 2, 3, 4, 5) in the liquid and frozen mixtures which subsequently initiated the chain addition. It would seem that for frozen samples the chain reaction must have occurred during melting. In support of this, it was found that the reaction could be initiated in an unirradiated mixture by condensing it onto an irradiated mixture at liquid nitrogen temperature and then melting the combined samples, e.g., when equal amounts of unirradiated and irradiated mixtures

ELECTRON SPIN RESONANCE ABSORPTION OF BINAPHTHOQUINONES

YOSHIO MATSUNAGA*

Previously we examined the diamagnetic susceptibilities of a number of condensed polycyclic aromatic hydrocarbons and quinones and found that some of them have anomalously small values of susceptibility (1). It was pointed out that this anomaly is characteristic of perylene and its analogues. The localization of π-electrons due to the characteristic molecular structure† and the appearance of a paramagnetic state were suggested as the causes. Although the former suggestion seemed to be in accordance with the predicted tendency for diamagnetic anisotropy given by London's method‡ and no E.S.R. absorption was detected in perylene (2), the existence of unpaired electrons in violanthrone (3, 4) and mesonaphthodianthrene (5) was confirmed by the E.S.R. method. The above-mentioned paramagnetic quinone is dark violet and the hydrocarbon is bluish green; therefore it seemed interesting to know whether the deeply colored polycyclic compounds of a different type can be paramagnetic or not.

Three binaphthoquinones were examined by an E.S.R. spectrometer at a frequency of 9 k Mc/s. Dimethoxybinaphthoquinone (X=OCH_3) was prepared by the oxidation of 1,4-naphthohydroquinone monomethylether with ferricyanide ion as described by Russig (6) and recrystallized from toluene. The sample shows E.S.R. absorption with a line width of 5.6 gauss at a half power. The g-value, estimated by comparison with DPPH, is 2.0036 ± 0.0003. There is one unpaired electron for about 400 molecules of quinone. If this compound is analogous to Chichibabin's hydrocarbon type of carbon biradical, as suggested by Leffler (7), the molecule should be more paramagnetic in the dissolved state. However we could not find E.S.R. absorption from a benzene solution of this compound. The appearance of paramagnetism seems to be limited to the solid state. Unlike Chichibabin's hydrocarbon and Bourdon and Calvin's hindered biphenoquinone (8), the present compound is stable towards oxygen in the solid and in the dissolved states. Binaphthoquinone may belong to the same group of paramagnetic organic compounds as violanthrone (3, 4), mesonaphthodianthrene (5), and metal-free phthalocyanine (9, 10).

*N.R.C. Postdoctoral Fellow, 1957–.

†*In the sense of VB theory the central two or more single bonds can be double only in the excited states.*

‡*Among the compounds of this type, only the anisotropy of perylene was examined by London's method. The predicted value is 1.88 times that of naphthalene. The value given in ref. 1 is in arithmetical error.*

Winslow *et al.* (10) suggested that enough thermal energy can be absorbed at room temperature to produce unpaired electrons in crystals of highly conjugated molecules. However, Akamatu *et al.* (4) found that the spin concentration in violanthrone does not decrease by cooling to liquid nitrogen temperature and considered that the molecules with unpaired electrons are not in excited states. It is well known that polycyclic aromatic compounds are semiconductive and the positive charge carriers in these compounds have high mobility. Therefore, the appearance of unpaired electrons in these cases may have some correlation with the presence of a strong intermolecular charge-transfer force* (11), and unpaired electrons may be trapped at some kind of imperfection in the crystal lattice.

Dichloro- and dibromo-binaphthoquinones (12) were also examined and both of them were found to be paramagnetic to about the same extent as the dimethoxy-derivative. These two compounds are too unstable to be recrystallized, therefore we cannot exclude the possibility that E.S.R. absorption is due to paramagnetic impurities. However, it is very likely that these two quinones have similar magnetic behavior to the well-defined dimethoxy-derivative.

I wish to thank Professor C. A. McDowell for his interest in this work. This research was supported by grants from the National Research Council of Canada.

Winslow *et al.* (10) suggested that enough thermal energy can be absorbed at room temperature to produce unpaired electrons in crystals of highly conjugated molecules. However, Akamatu *et al.* (4) found that the spin concentration in violanthrone does not decrease by cooling to liquid nitrogen temperature and considered that the molecules with unpaired electrons are not in excited states. It is well known that polycyclic aromatic compounds are semiconductive and the positive charge carriers in these compounds have high mobility. Therefore, the appearance of unpaired electrons in these cases may have some correlation with the presence of a strong intermolecular charge-transfer force* (11), and unpaired electrons may be trapped at some kind of imperfection in the crystal lattice.

Dichloro- and dibromo-binaphthoquinones (12) were also examined and both of them were found to be paramagnetic to about the same extent as the dimethoxy-derivative. These two compounds are too unstable to be recrystallized, therefore we cannot exclude the possibility that E.S.R. absorption is due to paramagnetic impurities. However, it is very likely that these two quinones have similar magnetic behavior to the well-defined dimethoxy-derivative.

I wish to thank Professor C. A. McDowell for his interest in this work. This research was supported by grants from the National Research Council of Canada.

means of a variety of nucleophylic reagents such as ammonia and amines (3), thiophenoxide ion (4), and diethyl malonate ion (2) invariably is accompanied by inversion of configuration at C-3. When 3β,6β-dihydroxyallosteroids were treated (1, 5) with mesyl chloride, the corresponding dimesylates were obtained; acetolysis of the latter compounds with acetate ion in acetic acid proceeded with retention of configuration at C-3, giving rise to 3β-acetoxy-Δ^5-steroids. These results can readily be understood by postulating that the 3β-monotosylates undergo a bimolecular substitution reaction which is accompanied by inversion at C-3. On the other hand, with a 3β,6β-dimesylate, dehydromesylation is the initial event leading to the intermediary 3β-mesyloxy-Δ^5-steroid; this unsaturated derivative, under the influence of the π-electrons, is believed (6) to undergo unimolecular heterolysis to provide the stabilized 3β-cation. The latter finally reacts with the weakly nucleophylic acetate ion to yield, with retention of configuration, the 3β-acetoxy-Δ^5-steroid.

The present study describes an analogous case involving methyl 3β,6β-dihydroxyallocholanate (I*a*). Mesylation of I*a* provided the dimesylate I*c*, which, with potassium acetate in aqueous dimethylformamide and subsequent saponification, was converted to 3β-hydroxy-Δ^5-cholenic acid (II). For further characterization, compound II was transformed to the methyl ester. Tosylation of I*a* provided the monotosylate I*b* as well as smaller amounts of the corresponding 3β,6β-ditosylate; acetolysis of I*b* under the same conditions as were used with I*c* and subsequent saponification of the products afforded 3α,6β-dihydroxyallocholanic acid (III). This acid, derived from 3α-hydroxy-6-oxo-allocholanic acid or its acetate methyl ester by catalytic hydrogenation, was previously reported (7, 8, 9) to have melting points in the range 246–251°. Our product, m.p. 248–252°, did not give a depression on mixed melting point with an authentic specimen of III;* elemental analyses of III, even when the sample was dried at 200° in a high vacuum, indicated that the compound retained half a mole of water.* Chromic acid oxidation of this acid provided 3,6-dioxo-allocholanic acid, identified by mixed melting point and conversion to the corresponding methyl ester.

EXPERIMENTAL

Methyl 3β,6β-Dimesyloxyallocholanate (I*c*)

Compound I*a* (3 g) dissolved in pyridine (20 ml) was treated at 3° with methanesulphonyl chloride (3.4 g). The mixture was kept at that temperature for 20 hours, the excess reagent was decomposed by addition of a small amount of ice, and the solution was then poured into ice-cold dilute hydrochloric acid. The resulting precipitate was

**Kindly supplied by Dr. A. Schubert of VEB Jenapharm, Jena, East Germany, who also informed us that elemental analyses of his acid III indicated the retention of half a mole of water.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

filtered off, washed with water, dried, and finally recrystallized from ethyl acetate – ether to afford 3.05 g of I*c*, m.p. 125° (decomp.). Two further recrystallizations from the same solvent system gave the analytical specimen, m.p. 125–127° (decomp.). Anal. Calc. for $C_{27}H_{46}O_8S_2$: C, 57.62; H, 8.24; S, 11.39; OCH_3, 5.51. Found: C, 57.54, 57.57; H, 8.32, 8.26; S, 11.50; OCH_3, 5.69, 5.77.

3β-Hydroxy-Δ⁵-cholenic Acid (II)

A solution of I*c* (3 g) and potassium acetate (7.3 g) in water (4 ml) and dimethylformamide (40 ml) was kept at 120–125° for 5 hours. The mixture was then poured into dilute hydrochloric acid, the resulting precipitate was filtered off, and washed with water. Saponification of the wet solid by refluxing with 4% methanolic potassium hydroxide (40 ml) for 2 hours, followed by addition of dilute mineral acid, provided a solid which was separated by filtration. Crystallization from ethyl acetate afforded 680 mg of substance, m.p. 226–228°, giving an insoluble digitonide and a yellow color with tetranitromethane. Two more recrystallizations from the same solvent gave m.p. 231–233°. Methylation of II with diazomethane and crystallization of the product from hexane gave the methyl ester of II, m.p. 142–143° and $[\alpha]_D^{24}$ −36.2° (*c*, 1.02, dioxane).

Tosylation of Methyl 3β,6β-Dihydroxyallocholanate (I*a*)

To I*a* (2.15 g) dissolved in pyridine (10 ml) was added tosyl chloride (3 g). After 22 hours at 25°, the excess reagent was decomposed by a small amount of ice, the mixture was poured into dilute hydrochloric acid, and the products were extracted with ether–chloroform. The solvent extract was washed with water, dried over sodium sulphate, and evaporated. Crystallization of the residue (3.04 g) from ether (20 ml) yielded 690 mg of material, m.p. 135–140° (decomp.); this was recrystallized from ethyl acetate – ether to give the analytical sample of methyl 3β,6β-ditosyloxyallocholanate, m.p. 133–136° (decomp.). Anal. Calc. for $C_{39}H_{54}O_8S_2$: C, 65.51; H, 7.61; S, 8.97; OCH_3, 4.34. Found: C, 65.45, 65.64; H, 7.60, 7.47; S, 9.11; OCH_3, 4.62, 4.60.

The filtrate from the first crop of ditosylate yielded, on refrigeration, 1.85 g of material, m.p. 140–148°. Three recrystallizations from ethyl acetate – hexane gave pure I*b*, m.p. 150–152° (decomp.) and $[\alpha]_D^{24}$ −13.6° (*c*, 1.75, dioxane). Anal. Calc. for $C_{32}H_{48}O_6S$: C, 68.53; H, 8.63; S, 5.72; OCH_3, 5.53. Found: C, 68.66, 68.70; H, 8.57, 8.65; S, 6.02; OCH_3, 5.75, 5.80.

3α,6β-Dihydroxyallocholanic Acid (III)

Potassium acetate (2.6 g), water (1.3 ml), and dimethylformamide (14 ml) were heated to 110°. After addition of I*b* (1.12 g), the solution was kept at that temperature for 4 hours, whereupon the reaction products were treated with dilute mineral acid and extracted with ether. The residue, obtained from the solvent extract after washing, drying, and evaporating, was refluxed for 2 hours with 4% methanolic potassium hydroxide (50 ml). The saponified mixture was then poured into dilute hydrochloric acid, the precipitate was filtered off, washed with water, and dried. Crystallization of the solid from ethyl acetate afforded 596 mg of material, m.p. 243–245°. Successive recrystallization from methanol, acetone, and ethyl acetate yielded the analytical specimen of III, m.p. 248–252° and $[\alpha]_D^{23}$ +10.7° (*c*, 0.991, dioxane). This compound failed to give an insoluble digitonide and did not react with tetranitromethane. Anal. Calc. for $C_{24}H_{40}O_4 . \frac{1}{2}H_2O$: C, 71.78; H, 10.29. Found: C, 71.86, 72.06, 71.70, 71.74; H, 10.30, 10.17, 10.05, 10.38. These analytical data remained unchanged after a sample had been boiled with sodium hydroxide solution and, after neutralization, had been dried at

For personal use only.

200° in a high vacuum. The methyl ester of III could not be obtained in crystalline form.

Oxidation of III (235 mg) in acetic acid (5 ml) with a solution of chromic acid (150 mg) in water (0.12 ml) and acetic acid (2.5 ml) was carried out at 10° for 1.5 hours. The mixture was then diluted by gradual addition of ice water, whereupon a granular precipitate appeared; this was filtered off, washed with water, dried, and then crystallized twice from ethanol to yield 178 mg of 3,6-dioxo-allocholanic acid, m.p. 206–208°. Methylation of this compound with diazomethane and crystallization of the ester from methanol showed m.p. 149–151.5°. Mixed melting points, both of the acid and the ester, with authentic specimens showed no depressions.

STERIC INHIBITION OF RESONANCE

IV. FURTHER SPECTROSCOPIC STUDIES OF 9-NITROANTHRACENE AND 9,10-DINITROANTHRACENE[1]

JAMES TROTTER[2]

ABSTRACT

The frequencies of the NO_2 symmetrical stretching vibrations, and the ultraviolet absorption spectra, of solutions of 9-nitroanthracene and 9,10-dinitroanthracene have been measured and correlated with the deviations from coplanarity and resultant resonance inhibition.

INTRODUCTION

Detailed X-ray analyses of the crystal and molecular structures of 9-nitroanthracene and 9,10-dinitroanthracene have shown that the nitro groups are twisted* out of the planes of the aromatic rings due to the steric effects of neighboring carbon and hydrogen atoms (1, 2, 3). The variations of the characteristic vibration frequencies of the nitro group indicate resultant decreases in the resonance interactions between the groups and the aromatic π-electrons (4), and further detailed examination of the bond lengths in these molecules suggests that this resonance is almost completely inhibited in 9-nitroanthracene in the solid state, where the nitro group is rotated about the C–N bond 85° from the coplanar position, but that in crystals of the 9,10-dinitro derivative, where the twists are 64°, there is a small but measurable resonance interaction (5).

Calculations by molecular orbital methods (6) have shown that the energy of resonance interaction (E_R) between the nitro group and the aromatic rings in this type of molecule varies as $\cos^2\theta$, where θ is the angle between the planes of the rings and the nitro group. The most stable state of the molecules is determined not only by this resonance energy, but also by the van der Waals attractive and electronic repulsive forces (energy E_v) between the oxygen atoms and neighboring carbon and hydrogen atoms. There is a minimum in the E_v curve at about $\theta = 70°$, the angle corresponding to oxygen–carbon and oxygen–hydrogen separations equal to the sums of the corresponding van der Waals radii (1.7 Å for carbon, 1.4 Å for oxygen, 1.0–1.2 Å for hydrogen). Combination of resonance and van der Waals energies gives a curve with a minimum at about $\theta = 65°$, and the measured deviation from coplanarity in crystals of 9,10-dinitroanthracene (64°) is in excellent agreement with this calculated value. The most stable configuration for an isolated molecule of 9-nitroanthracene should have the nitro group twisted 64° out

[1]*Manuscript received February 3, 1959.*

[2]*National Research Council Postdoctorate Fellow.*
**The deviation from coplanarity has been called "twist", rather than "tilt" as in previous communications, since a referee has pointed out that "tilt" tends to suggest a deviation which involves an inclination of the* C–NO_2 *axis from the plane of the aromatic ring system, while the displacement in the molecules studied involves of course a torsional motion of the nitro group about the* C–NO_2 *axis.*

of the anthracene plane, but in the solid state crystal forces apparently result in minimum energy when $\theta = 85°$.

In solution the nitro group twists should be the same in both molecules, 64°, but probably with some oscillation of the groups through $\theta = 90°$, since the potential barrier is only about $1\frac{1}{2}$ kcal/mole (for each nitro group). The angles measured by X-ray diffraction of the crystals have been correlated very nicely with the frequencies of the NO_2 symmetrical stretching vibrations in the solid state, and these frequencies have now been measured in solution to investigate the postulation of equal twists in both molecules. The ultraviolet spectra have also been measured for correlation with the resonance inhibition.

EXPERIMENTAL

The frequencies of the NO_2 symmetrical stretching vibrations of 9-nitroanthracene and 9,10-dinitroanthracene in carbon tetrachloride solution were measured with a Perkin–Elmer model 21 infrared spectrophotometer with a rock salt prism.

The ultraviolet spectrum of 9-nitroanthracene in ethanol solution was measured with a Beckmann D.U. spectrophotometer. Since 9,10-dinitroanthracene is only very sparingly soluble in ethanol, a chloroform–ethanol mixture was used as solvent in measuring its spectrum.

DISCUSSION

The frequencies of the NO_2 symmetrical stretching vibrations in crystals of 9-nitroanthracene and 9,10-dinitroanthracene are 1374 cm^{-1} and 1367 cm^{-1} respectively (4), corresponding to nitro group twists of 85° and 64° (Table I). The corresponding frequencies in carbon tetrachloride solution are 1372 cm^{-1} for both molecules, so that the

TABLE I

NO_2 symmetrical stretching frequencies and nitro group twists

		9-Nitroanthracene	9,10-Dinitroanthracene
Crystals	NO_2 frequency	1374 cm^{-1}	1367 cm^{-1}
	Measured twist	85°	64°
Solutions	NO_2 frequency	1372 cm^{-1}	1372 cm^{-1}
	Deduced twist	64° → 90°	64° → 90°

twists are the same in both molecules in solution. The frequencies in solution cannot however be compared quantitatively with those in the solid state due to the effect of crystal forces, which generally make vibration frequencies a few wave numbers lower than the corresponding frequencies in solution. All that can be deduced is that the twists in both molecules in solution are between 64° and 90°, the value in the most stable configuration possibly depending not only on resonance and van der Waals energies (which would suggest $\theta = 64°$) but also on the effects of solvent–solute interactions.

The positions and intensities of the ultraviolet absorption bands of anthracene (7), 9-nitroanthracene, and 9,10-dinitroanthracene in ethanol solution are listed in Table II. In Table III the frequency shifts of the anthracene absorption maxima resulting from substitution are compared for the 9-cyano- (7), 9-nitro-, and 9,10-dinitro-derivatives. In 9-cyanoanthracene there is no possibility of resonance inhibition due to steric effects, and the cyano group causes a considerable displacement to longer wavelengths of the

	G	27,250	810
	H	25,840	800

E-, *F*-, *G*-, *H*-bands. The corresponding shifts in the 9-nitro derivative are only[1] of about one quarter the magnitude, and those in the 9,10-dinitro about half, of the shifts in the cyano derivative. Although the cyano and nitro derivatives cannot be directly compared, these figures suggest that resonance interaction between a nitro group and the anthracene rings in 9-nitroanthracene and 9,10-dinitroanthracene is about one quarter of the interaction which would be expected in completely planar models. The resonance interaction estimated from the $\cos^2\theta$ relationship is about one fifth ($\cos^2 64°$) that in completely planar molecules, in reasonable agreement with the value deduced from the ultraviolet spectra. The intensities of the bands in the nitro derivatives are significantly lower than in anthracene, again supporting resonance inhibition.

A MANNAN PRODUCED BY BACILLUS POLYMYXA[1]

D. H. BALL[2] AND G. A. ADAMS

ABSTRACT

During the fermentation of glucose, sucrose, or lactose by *Bacillus polymyxa*, a mixture of polysaccharides is formed, one of which has been isolated by mild procedures and shown to contain mannose as the only sugar together with approximately 13% protein. Acid hydrolysis of the methylated mannan gave 2,3,4,6-tetra-*O*-methyl-D-mannose, 2,4,6-tri-*O*-methyl-D-mannose, 3,4,6-tri-*O*-methyl-D-mannose, and 3,4-di-*O*-methyl-D-mannose in the approximate ratio 2:1:1:2. Periodate oxidation results are in agreement with the methylation data and indicate a molecular weight of approximately 3000.

Bacillus polymyxa C3-2* has been studied previously in connection with its ability to ferment carbohydrates to butane-2,3-diol and this organism is of especial interest because it can utilize starch directly (1). The "polymyxins", a series of closely related antibiotics with polypeptide structures, are also produced by various strains of *B. polymyxa* (2). Polysaccharides are formed by these organisms under certain growth conditions and Misaki and co-workers have made a detailed study of the production of polysaccharides by *B. polymyxa* var. *lactoviscosus* (3). This strain, grown on lactose, produced a polysaccharide containing L-rhamnose and D-galactose in the approximate ratio of 2:1. When *B. polymyxa* C3-2 is grown with sucrose as the carbon source, a fructan is formed, presumably by a transfructosidation because this polysaccharide does not occur if glucose or lactose is used. The structure of the fructan was established by Murphy (4) and a preliminary communication reported the isolation of a mannan (5) produced by the same organism. The present paper describes the isolation of this mannan by a mild procedure and investigation of its structure.

B. polymyxa C3-2 was grown on a buffered yeast extract – salts medium with glucose, sucrose, or lactose as the carbon source. A mannan was isolated by the following procedure which was considered unlikely to cause depolymerization or to affect the reducing end group. A mannose-containing polysaccharide fraction was obtained from the cell-free medium by precipitation with ethanol and this material was dissolved in water to give a highly viscous solution. Addition of aqueous Cetavlon (cetyltrimethylammonium bromide) (6, 7) to this solution precipitated the cetyltrimethylammonium salt of an acidic polysaccharide and greatly decreased the viscosity of the residual solution. Addition of sodium borate solution to the latter gave an insoluble cetyltrimethylammonium salt of a polysaccharide–borate complex (8, 9). This precipitate was dissolved in cold 0.1 *N* hydrochloric acid and the free polysaccharide was precipitated by ethanol. It was then redissolved in water and the solution was deionized on columns of ion-exchange resins and lyophilized. This material was very hygroscopic, had $[\alpha]_D$ +82°, and migrated as a single sharp peak on electrophoresis in borate buffer. Mannose was the only sugar present in an acid hydrolyzate. Several amino acids were observed chromatographically after hydrolysis with 6 *N* hydrochloric acid, and nitrogen analysis and a mannose estimation indicated that the preparation contained approximately 13% protein. Methylation of the mannan with methyl sulphate and sodium hydroxide and with silver oxide and methyl iodide in dimethylformamide (10) gave a product which could not be fractionated with

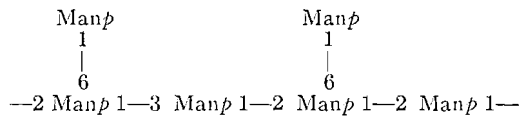
chloroform – light petroleum. The methylated mannan, which showed no hydroxyl absorption in the infrared, was hydrolyzed with formic acid and the neutralized hydrolyzate was fractionated on thick filter paper into di-, tri-, and tetra-*O*-methyl-D-mannose fractions which were present in approximately equal proportions. The syrupy tetra-*O*-methyl-D-mannose was oxidized with bromine water and converted to the crystalline phenylhydrazide of 2,3,4,6-tetra-*O*-methyl-D-mannonic acid. The trimethyl fraction was separated by filter paper electrophoresis into crystalline 3,4,6-tri-*O*-methyl-D-mannose and crystalline 2,4,6-tri-*O*-methyl-D-mannose, present in approximately equal proportions. The dimethyl fraction crystallized and was identified as 3,4-di-*O*-methyl-D-mannose.

On periodate oxidation, the mannan consumed 1.31 mole periodate and liberated 0.46 mole acid per anhydro hexose unit (assuming the presence of 13% protein not attacked by periodate). The oxidized polysaccharide was reduced with potassium borohydride and hydrolyzed. Mannose and glycerol, but not erythritol, were detected in the hydrolyzate indicating the absence in the original polysaccharide of mannose units linked through positions 1 and 4 only (11). The formaldehyde liberated during periodate oxidation at pH 8 was measured by the chromotropic acid method (12) and the results are shown in Fig. 1. The occurrence of overoxidation indicated that the predominant linkage was not 1,6 (13). After reduction of the polysaccharide with potassium borohydride, overoxidation was not observed (Fig. 2), indicating that the reducing end group was linked through position 2 (14). Calculation of the molecular weight from these results (14, 15) gave a value of 2850 and, allowing for 13% protein, this gives an average of 15 mannose units per molecule. The value of 2850 would be minimal because some terminal $1 \rightarrow 2$ linked units may be joined through C_6 position and would not give rise to formaldehyde on periodate oxidation.

These results indicate that the mannan is very similar in structure to that obtained by autolysis of yeast which gives identical methylation results (16, 17, 18). The slime polysaccharide produced by *Saccharomyces rouxii* appears to differ in containing a small proportion only of 1,3 linkages (19). On the basis of methylation data and periodate oxidation, the linkages found to be present in the *B. polymyxa* mannan are shown in the following structure.



Haworth *et al.* (17) have proposed three possible repeating units for yeast mannan, one of which is the same as shown above.

EXPERIMENTAL

Solutions were concentrated under reduced pressure at 40° C. Optical rotations were determined in water at 23°±3° C unless otherwise stated. Paper chromatography was carried out by the descending method (20) on Whatman No. 1 filter paper using the following solvent systems: (*a*) butan-1-ol–ethanol–water (3:1:1), (*b*) butan-1-ol–pyridine–water (19:3:3), and (*c*) methyl ethyl ketone saturated with water. Sugars were located on chromatograms either by the *p*-anisidine hydrochloride spray (21) or by the silver nitrate and alkali sprays of Trevelyan *et al.* (22).

Preparation of a Mannose-containing Polysaccharide Fraction

The organism, *B. polymyxa* C3-2, was grown on the following medium: Difco yeast extract (5 g), K_2HPO_4 (0.5 g), KH_2PO_4 (0.5 g), $MgSO_4.7H_2O$ (0.2 g), sucrose (70 g) (or

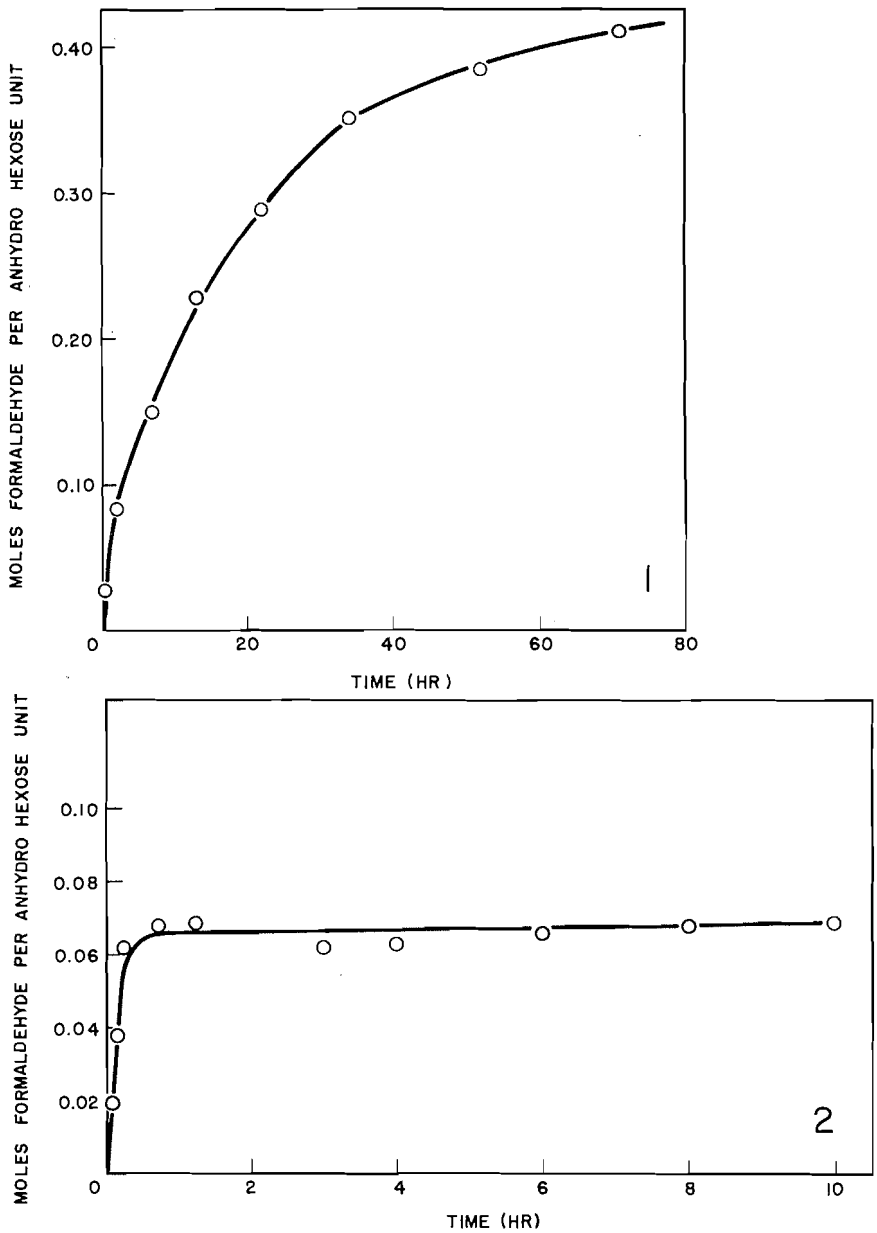


FIG. 1. Liberation of formaldehyde during periodate oxidation of the mannan at 26° C in $M/15$ phosphate buffer, pH 8.

FIG. 2. Liberation of formaldehyde during periodate oxidation of the reduced mannan at 21° C in $M/15$ phosphate buffer, pH 8.

glucose (50 g) or lactose (70 g)), water (1 l.). The medium was sterilized for 15 minutes at 15 p.s.i. in a 3-l. Fernbach flask. Sterile calcium carbonate (16 g) was added to the cooled solution. The inoculum was grown for 24 hours on the same medium (without calcium carbonate), the flask being shaken at 30° C. The inoculum (5 ml) was added to each Fernbach flask and the culture was kept at 30° C and shaken twice daily. The disappearance of sugar was followed on paper chromatograms and, in the case of glucose or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

lactose, by determination of reducing sugar. Fermentations were judged to be complete after 9–10 days (sucrose), 5 days (glucose), 11 days (lactose). The media were then sterilized by heating to 90° C, filtered through cloth, and clarified on a Sharples centrifuge. The clear solution was then concentrated to 1/3 volume and the mannose-containing polysaccharide fraction was precipitated with ethanol (2/3 volume) and collected by centrifugation. Hydrolysis of a portion followed by paper-chromatographic examination indicated the presence of mannose, glucose, and galactose.

Fractionation of the Polysaccharides

To a stirred, viscous solution of the mannose-containing fraction (2.50 g) in water (500 ml) was slowly added a solution of Cetavlon (cetyltrimethylammonium bromide, 10% w/v). Precipitation occurred immediately and was complete after the addition of 10 ml. There was also a marked decrease in viscosity of the solution. The precipitate (fraction A) was collected by centrifugation, washed with water, and the washings were added to the centrifugate. Cetavlon solution (90 ml) was then added and 0.05 *M* sodium borate solution (100 ml) was run in slowly with stirring with precipitation commencing after the addition of 50 ml. The precipitate (fraction B) was collected by centrifugation and washed with water. The supernatant solution was dialyzed and poured into ethanol (4 volume). No further polysaccharide material was precipitated.

Fraction A.—The cetyltrimethylammonium salt of an acidic polysaccharide (fraction A) was not further examined.

Fraction B.—The cetyltrimethylammonium salt of a polysaccharide–borate complex (fraction B) was dissolved in cold 0.1 *N* hydrochloric acid (50 ml) and the free polysaccharide was recovered by precipitation with ethanol (300 ml). The precipitate was recovered by centrifugation, redissolved in water, and the solution was deionized by passage down columns of Amberlite resins IR 120 (H) and IR 45 (OH). The neutral effluent was lyophilized. The product (1.48 g) was hygroscopic and had $[\alpha]_D$ +82°. Found: N, 1.50%. It gave one sharp peak on electrophoresis in 0.05 *M* sodium borate with a mean mobility $\mu = 8.56 \times 10^{-8}$ cm^2 sec^{-1} v^{-1}. After hydrolysis of a portion with dilute acid, mannose was the only sugar detected on paper chromatograms. After hydrolysis with 6 *N* hydrochloric acid at 100° C for 25 hours, paper chromatograms sprayed with ninhydrin indicated the presence of several amino acids. The mannose content of the mannan as determined gravimetrically via the phenylhydrazone (23) was 87.4%.

Methylation of the Mannan

The mannan (1.9 g) was dissolved in water (15 ml) and to the vigorously stirred solution, contained in a three-necked flask under an atmosphere of nitrogen, methyl sulphate (5 ml) and 30% w/v sodium hydroxide solution (15 ml) were added simultaneously and dropwise. After 3 hours, these additions were repeated and the mixture was stirred for a further 12 hours. The solution was then heated on a hot water-bath to destroy residual methyl sulphate and remove methanol. This methylation cycle was repeated twice, water was then added to dissolve sodium sulphate and the mixture was extracted continuously with chloroform. The extracts were dried (Na_2SO_4) and concentrated to a syrup (2.6 g). This was dissolved in dry dimethylformamide (50 ml) and to the solution was added methyl iodide (20 ml) and silver oxide (20 g) (10). The mixture was shaken mechanically at room temperature in the dark for 65 hours. It was then filtered, the grey residue was washed with dimethylformamide, and to the combined filtrate and washings was added the above amounts of methyl iodide and silver oxide and the mixture was shaken for a further 24 hours. The brown-silver residues were removed by filtration, and water (100 ml) was added to the pale yellow solution. Precipitated silver salts were redissolved by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

addition of potassium cyanide solution and the turbid solution was extracted eight times with chloroform, to recover the methylated product. The methylation procedure using methyl iodide and silver oxide was repeated four times. The methylated mannan was recovered as a syrup (2.0 g) which showed no hydroxyl absorption in the infrared and which could not be fractionated with chloroform – light petroleum (b.p. 65–110° C). The syrup had $[\alpha]_D$ +92° (*c*, 2.5 in $CHCl_3$); N, 1.97% and OCH_3, 38.2%.

Hydrolysis of the Methylated Mannan and Separation of the Methyl Ethers

The methylated mannan (1.5 g) was dissolved in 88% formic acid (50 ml) and the solution was heated at 90° C for 18 hours. Formic acid was then removed by evaporation, the residual syrup was taken up in 0.1 *N* hydrochloric acid, and the solution was heated at 90° C for a further 20 hours. The solution was cooled, neutralized by passage down a column of Amberlite resin IR 45 (OH), and concentrated to a syrup which was fractionated on Whatman No. 3MM filter paper, first in solvent *a* and then in solvent *c*. Three fractions were obtained: (*a*) tetra-*O*-methyl-D-mannose (0.41 g), (*b*) tri-*O*-methyl-D-mannose (0.37 g), and (*c*) di-*O*-methyl-D-mannose (0.33 g). These fractions are in a molar ratio of 1.03:1.00:0.95.

2,3,4,6-Tetra-O-methyl-D-mannose

The syrup (100 mg) which had $[\alpha]_D$ +5.6° was oxidized with bromine water. The product was isolated in the usual way and lactonized and the syrupy lactone was converted to the crystalline phenylhydrazide of 2,3,4,6-tetra-*O*-methyl-D-mannonic acid. After recrystallization from benzene, the product had m.p. 183–184° C, not depressed by admixture with an authentic sample, and $[\alpha]_D$ −25° C (*c*, 1.0 in $CHCl_3$) which were in good agreement with the reported values (24).

Tri-O-methyl-D-mannose Fraction

This fraction was separated into two components by electrophoresis on Whatman No. 3MM filter paper in 0.1 *M* sodium borate solution. The components were located by means of guide strips and eluted from the paper with cold water. The aqueous solutions were passed down short columns of Amberlite resin IR 120 (H) and evaporated to syrups which were evaporated three times from methanol to remove borate ions as methyl borate.

Fraction 1.—Fraction 1 gave a brown color with the *p*-anisidine spray and had M_G 0.12 (movement relative to glucose on a paper electrophorogram). It crystallized readily and after recrystallization from ether–*n*-hexane had m.p. 100–102° C not depressed by admixture with authentic 3,4,6-tri-*O*-methyl-D-mannose; $[\alpha]_D$ +21° → +8° (const., 20 hours). These values are in agreement with those reported for this sugar (25).

Fraction 2.—Fraction 2 gave a red color with the *p*-anisidine spray and had M_G 0.0. The syrup crystallized when seeded with authentic 2,4,6-tri-*O*-methyl-D-mannose monohydrate (26) and after recrystallization from ether–*n*-hexane had m.p. and mixed m.p. 63–65° C and $[\alpha]_D$ +17° (no mutarotation).

3,4-Di-O-methyl-D-mannose

The dimethyl mannose crystallized as the monohydrate and after two recrystallizations from ethyl acetate had m.p. 70–73° C not depressed by admixture with an authentic sample (19). $[\alpha]_D$ +17.6° (10 minutes) → +10° (const., 2 hours). Anal.: Calc. for $C_8H_{16}O_6.H_2O$: C, 42.48%; H, 8.02%. Found: C, 42.47%; H, 7.76%.

Periodate Oxidation of the Mannan

Oxidation of the mannan with 0.03 *M* sodium metaperiodate solution at room temperature was complete after 60 hours with the consumption of 1.31 mole of periodate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

and the liberation of 0.46 mole of acid per anhydro hexose unit (all values given are corrected to allow for the 13% protein present). The oxidized polysaccharide was reduced with excess potassium borohydride without prior isolation. After 24 hours at room temperature, the solution was acidified with sulphuric acid and heated at 100° C for 6 hours to hydrolyze the polyol. Chromatographic examination of the deionized hydrolyzate indicated mannose and glycerol only. Erythritol was absent.

The mannan was also oxidized at 27° C with 0.03 *M* sodium metaperiodate in *M*/15 phosphate buffer, pH 8.0, and the formaldehyde liberated was determined by the chromotropic acid method (12). The results, shown in Fig. 1, indicate that extensive overoxidation occurred. After borohydride reduction of the polysaccharide, overoxidation was not observed (Fig. 2). Because only 1 mole of formaldehyde is liberated per mole of polymer, these results give an average molecular weight of 2850 and, allowing for 13% protein, this gives an average of 15 mannose units per molecule.

ACKNOWLEDGMENTS

The authors are grateful to Miss M. T. Clement for assistance with the fermentations, to Professor J. K. N. Jones for samples of 2,4,6- and 3,4,6-tri-*O*-methyl-D-mannose, and to Dr. P. A. J. Gorin for a sample of 3,4-di-*O*-methyl-D-mannose.

5,6-DIDEOXY-L-ARABINO-HEXOSE (5-DEOXY-5-*C*-METHYL-L-ARABINOSE)[1]

D. J. Ball, A. E. Flood, and J. K. N. Jones

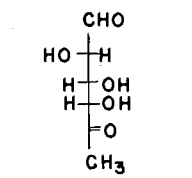
ABSTRACT

A synthesis of 5,6-dideoxy-L-*arabino*-hexose (II) from methyl β-D-galactofuranoside is described.

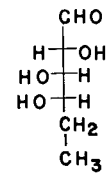
INTRODUCTION

The isolation of 6-deoxy-5-keto-D-*arabino*-hexose (6-deoxy-D-*arabino*-hexos-5-ulose) (I) from hygromycin has recently been described (1). This substance was converted by reduction to 5,6-dideoxy-D-*arabino*-hexose, which was then characterized as its dithioacetal (1). The purpose of this communication is to describe the synthesis of its optical isomer, 5,6-dideoxy-L-*arabino*-hexose (II). The elimination of tosyloxy (tolyl-*p*-sulphonyloxy) groups situated on vicinal primary and secondary alcoholic groups by heating the esters with sodium iodide is a general reaction (2) which has been observed in the hexitol (3), hexose (4), and inositol series (5).

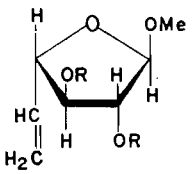
Crystalline derivatives of ethyl α- and β-D-galactofuranosides are known, but their preparation is tedious. It was observed that an impure syrupy preparation of methyl β-D-galactofuranoside (6) which had been converted to the 2,3,5,6-tetra-toluene-*p*-sulphonate gave, when heated with a solution of sodium iodide in acetone, a crystalline methyl 5,6-didehydroxy-2,3-di-*O*-tosyl-α-L-*arabino*-hexoside (III; R = tosyl = tolyl-*p*-sulphonyl).



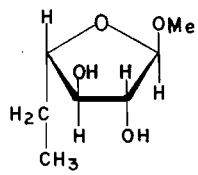
(I)



(II)



(III)



(IV)

Removal of the tosyl groups by reductive saponification yielded crystalline methyl 5,6-didehydroxy-α-L-*arabino*-hexoside (III; R = H) which, when it was reduced (Raney nickel catalyst), furnished 5,6-dideoxy-α-L-*arabino*-hexoside (IV). This substance (IV) was also produced when the unsaturated tosyl derivative of III was reduced by boiling its solution in ethanol in the presence of Raney nickel, followed by reductive saponification of the tosyl groups.

[1]*Manuscript received September 30, 1958.*
Contribution from the Department of Organic Chemistry, Queen's University, Kingston, Ontario.

Tosylation of IV yielded a product indistinguishable from the substance III (R = H) produced by reduction of III (R = tosyl). This experiment proved that inversion of hydroxyl groups had not occurred during removal of the tolyl-*p*-sulphonyl groups in the preparation of III (R = H) and IV.

Both III (R = H) and IV were oxidized by aqueous sodium metaperiodate and yielded significant quantities of iodoform when the oxidized products were allowed to stand in iodine solution. When IV was shaken with ethanethiol and concentrated hydrochloric acid it yielded the diethyl dithioacetal of II. The D-isomer of this derivative was isolated from hygromycin.

When III (R = tosyl) was shaken with silver nitrate and iodine in acetonitrile solution (7), a crystalline deoxy-iodonitrate of III (R = tosyl) was produced. The location of the iodine group in this new product is undecided, as is the decision as to whether the substance is a derivative of L-altrose or of D-galactose.

EXPERIMENTAL

Solutions were evaporated under reduced pressure; optical rotations were determined at 20°±2° C (unless otherwise stated).

*Synthesis of Methyl 5,6-Didehydroxy-2,3-di-O-tolyl-p-sulphonyl-α-*L*-arabino-hexoside* (III; R = Tosyl)

Crude methyl β-D-galactofuranoside (from 50 g of D-galactose (6)) was dissolved in pyridine (500 ml), and toluene-*p*-sulphonyl chloride (250 g) was added to the solution. After 20 hours, the solution was poured (with stirring) onto crushed ice. The syrupy tosyl derivatives were isolated in the usual way. The syrup, without further purification, was heated in acetone solution (500 ml) with sodium iodide (70 g) under reflux. The solution rapidly became brown because of the separation of iodine, and sodium toluene-*p*-sulphonate precipitated. The mixture was filtered at intervals to minimize uneven boiling. (Yield of the sodium salt of toluene-*p*-sulphonic acid, 36.5 g.)

The acetone was removed and the residue was extracted with chloroform. The extracts were washed successively with a solution of sodium thiosulphate and then with water. The chloroform extract was dried ($MgSO_4$) and evaporated to a syrup which rapidly crystallized. The crystals (32 g) were recrystallized from methanol, m.p. 109–110° C, $[\alpha]_D$ −62°±2° (*c*, 0.5 in chloroform). Anal. Calc. for $C_{21}H_{24}O_8S_2$: C, 53.8; H, 5.1; S, 13.7; OMe, 6.5. Found: C, 53.7; H, 5.5; S, 14.7; OMe, 6.5.

*Methyl 5,6-Didehydroxy-α-*L*-arabino-hexoside* (III; R = H)

The di-*O*-tosyl derivative (above) (1 g) was dissolved in ethanol (100 ml), and sodium amalgam (100 g of 3%) was added portionwise with stirring. During the addition, water (150 ml) was added at such a rate that precipitation of the tosyl derivative was avoided. After 12 hours, the solution was made neutral with sulphuric acid and evaporated to dryness. The solid residue was extracted exhaustively with acetone and the extracts were evaporated. The crude crystalline residue (0.21 g) was volatile at 100° C and accordingly it was purified by sublimation at 12 mm/100° C. The product, after sublimation, had m.p. 60° C, $[\alpha]_D^{23}$ −110°±2° (*c*, 0.67), and was analytically pure. The substance moved at 2.4 times the speed of rhamnose in *n*-butyl alcohol – ethanol – water (9:2:2) solvent, and gave a yellow coloration when it was heated with *p*-anisidine hydrochloride. Anal. Calc. for $C_7H_{12}O_4$: C, 52.5; H, 7.6; OMe, 19.4. Found: C, 52.4; H, 7.8; OMe, 22.3.

Methyl 5,6-Dideoxy-α-L-arabino-hexoside (IV) (*Methyl 5-Deoxy-5-C-methyl-α-L-arabinoside*)

The unsaturated arabinoside derivative (above, 89 mg) was dissolved in methanol and hydrogenated at 20° in the presence of a Raney nickel catalyst (0.5 g). After 20 minutes, the hydrogen uptake (53.4 ml at S.T.P.) was constant. The solution was filtered and the filtrate evaporated. The product was purified by sublimation at 16 mm/100° C. The product had m.p. 63° C and $[\alpha]_D$ 126°±6° (*c*, 0.18). Anal. Calc. for $C_7H_{14}O_4$: C, 51.8; H, 8.7; OMe, 19.1. Found: C, 51.9; H, 8.7; OMe, 19.8.

Both this compound and the unsaturated glycoside were oxidized by sodium metaperiodate solution, with the consumption of more than one mole of reagent, per mole, and with the formation of iodine and iodoform. No formic acid was detected.

Methyl 5,6-Dideoxy-2,3-di-O-tosyl-α-L-arabino-hexoside

The unsaturated tosyl derivative (III; R = tosyl) (116 mg) was dissolved in ethanol (20 ml) and boiled under reflux in the presence of Raney nickel catalyst (0.5 g) for 4 hours. The odor of acetaldehyde was detectable during the reaction. The solution was cooled and filtered, and the filtrate evaporated to a crystalline solid which was purified by recrystallization from ethanol. The product had m.p. 93–94° C, $[\alpha]_D$ −61° (*c*, 2.23 in chloroform). A product which had the same properties was produced when methyl 5,6-dideoxy-α-L-*arabino*-hexoside (IV; 0.1 g) was allowed to react with toluene-*p*-sulphonyl chloride (0.3 g) in pyridine (5 ml) solution overnight. The substance, which was isolated after the pyridine solution had been poured onto ice, weighed 0.21 g and had m.p. 93–94° C, not depressed on admixture with an authentic specimen. Anal. Calc. for $C_{21}H_{26}O_8S_2$: C, 53.6; H, 5.6; S, 13.6; OMe, 6.6. Found: C, 53.8; H, 6.0; S, 12.9; OMe, 6.6.

5,6-Didehydroxy-L-arabino-hexose Diethyl Dithioacetal

Methyl 5,6-dideoxy-α-L-*arabino*-hexoside (0.1 g) was shaken with ethanethiol (0.5 ml) and 6 *N* hydrochloric acid (0.5 ml) for 5 hours. The mixture was twice extracted with chloroform (2-ml portions) and the extracts were washed with sodium bicarbonate solution and then dried ($MgSO_4$). Removal of the chloroform left a syrupy diethyl dithioacetal which crystallized. It was recrystallized from water and had m.p. 110°. Anal. Calc. for $C_{10}H_{22}O_3S_2$: C, 47.3; H, 8.7; S, 25.2. Found: C, 47.4; H, 8.8; S, 24.8.

Iodonitration of Methyl 5,6-Didehydroxy-2,3-di-O-tolyl-p-sulphonyl-α-L-arabino-hexoside

Methyl 5,6-didehydroxy-2,3-di-*O*-tolyl-*p*-sulphonyl-α-L-*arabino*-hexoside (2.34 g; 5 millimole) was dissolved in acetonitrile (50 ml), and to the solution was added silver nitrate (1.70 g; 10 millimole) and iodine (1.27 g; 5 millimole). An immediate precipitate of silver iodide was observed. The mixture was shaken at room temperature for 7 days in a stoppered flask from which light was excluded. The mixture was then filtered and the silver iodide was washed with acetonitrile and air-dried; yield 1.22 g. (The reaction of silver nitrate with iodine to give silver iodide and iodonium nitrate would give 1.17 g of silver iodide from the above amounts of reactants.)

The filtrate was boiled under reflux for 24 hours and a light precipitate was removed by filtration. Concentration of the filtrate afforded a yellow syrup which yielded a further precipitate (probably silver nitrate) when diluted with chloroform. The mixture was again filtered and the filtrate was evaporated to a syrup which crystallized from chloroform – light petroleum (b.p. 60–80° C). Total yield 0.36 g after recrystallization from the same solvents; i.e. 11.0% calculated as the iodonitrate. The compound had

m.p. 125–126° C and $[\alpha]_D$ −49° (*c*, 5.0 in chloroform). Anal. Calc. for $C_{21}H_{24}INO_{11}S_2$: C, 38.4; H, 3.7; I, 19.3; N, 2.1; S, 9.8. Found: C, 38.4; H, 3.8; I, 18.6; N, 2.6; S, 9.5.

The infrared absorption spectrum showed a strong band at 1642 cm^{-1} which was absent from the spectrum of the parent olefinic compound and is presumably due to the nitrate group. The residual syrup (1.85 g) gave an infrared absorption spectrum with bands of the same relative intensity and therefore probably contains one or more of the other three possible iodonitrates.

A portion of the crystalline iodonitrate (0.10 g) was dissolved in hot ethanol and the solution was refluxed for 90 minutes with hydrazine hydrate (0.03 ml) (8). Excess hydrazine was destroyed by boiling the solution for a further 15 minutes with Raney nickel. The mixture was then filtered and the filtrate was concentrated to an oil which was soluble in water but not soluble in chloroform. The properties of this product indicate that nitrate and tolyl-*p*-sulphonyl groups had both been removed. It was not further examined.

The authors thank the National Research Council for a grant which made this work possible.

IRRADIATION OF AQUEOUS CHLORAL HYDRATE WITH Sr^{90}–Y^{90} BETA RAYS[1]

R. F. Platford and J. W. T. Spinks

ABSTRACT

Air-saturated aqueous chloral hydrate has been irradiated with beta rays and the acid yield as determined by titration has been studied as a function of dose rate, temperature, and initial concentration of the chloral hydrate.

The average lifetime of the intermediates has been found, by means of the rotating sector technique, to be about 0.5 second. Propagation and termination rate constants for the reaction have been calculated and an effort has been made to explain the results observed in terms of a free radical chain reaction.

INTRODUCTION

In 1950 Andrews and Shore (1) reported that aqueous chloral hydrate was decomposed by X rays to yield HCl and other products. The acid yield, measured conductometrically, was found to be linear with radiation dose, and to increase with increasing temperature and initial chloral hydrate concentration, but was reported to be independent of dose rate. Because of the large acid yield, these workers used the system as a sensitive radiation dosimeter.

Freeman *et al.* in 1953 (2) irradiated the same system with Co^{60} γ-rays and found essentially the same results as Andrews and Shore except that they found the acid yield to be dependent on $(\text{dose rate})^{-1/2}$. Freeman also found the radiation yield in air-free solutions to be about one fifth of that in aerated solutions.

Andrews *et al.* (3) have used an agar gel containing chloral hydrate and methyl red as a dosimeter for Van de Graaff electrons.

In the present work the decomposition of chloral hydrate by beta rays is compared with that resulting from gamma rays.

EXPERIMENTAL

Apparatus

Irradiations were carried out with a 40-mc Sr^{90}–Y^{90} medical applicator. The activity was confined to an area of 1 cm^2 and was plated on one face of an aluminum disk to the back of which was attached a rod serving as a handle. Solutions were irradiated in 10-ml pyrex beakers immersed in a thermostat, above which the source was suspended. The dose rate received by the solution was controlled by varying the separation between source and solution.

A rotating sector with a light:dark ratio of 1:2 was constructed from brass of thickness 1335 mg/cm^2. The sector was driven through a reduction drive by a 240-r.p.m. synchronous motor.

Materials

All chemicals were reagent grade or better; the chloral hydrate was Fisher U.S.P. grade. All water was distilled once from alkaline permanganate and once from acidic dichromate solution.

Procedure

The reaction was followed by titration of the acid produced on irradiation. Samples

[1]*Manuscript received February 9, 1959.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.

were titrated with *ca.* 10^{-2} *N* NaOH from a microburette which could be read to 5×10^{-4} ml. Irradiated solutions were titrated to the same color as unirradiated blanks using bromocresol purple as an indicator.

The energy absorbed on irradiation was estimated by means of the ferrous sulphate dosimeter (0.8 *N* H_2SO_4, 10^{-2} *M* NaCl, 10^{-3} *M* $(NH_4)_2SO_4.FeSO_4.6H_2O$ in air-saturated water). The *G* value (molecules of Fe^{++} oxidized per 100 ev of energy absorbed) was assumed to be 15.5 (4, 5, 6). The Fe^{+++} produced on irradiation was measured by means of its absorption peak at 304 mμ. Dose rates are expressed in rad/min, where 1 rad ≡ 100 erg/g.

Because the densities of irradiated solutions differed from that of the ferrous sulphate solution, a small correction was applied to compensate for differences in stopping power between the two solutions. The stopping power for electrons was assumed proportional to the solution density.

RESULTS

Effect of Dose Rate

The *G* value (molecules of acid produced per 100 ev of energy absorbed) was found to be dependent on dose rate. Also, because of the strong attenuation of beta rays by the solution, the dose rate varied with depth of solution and hence the *G* value was dependent on solution depth (or volume, since the cross sectional area of the solutions was constant). The acid yield vs. dose is shown as a function of dose rate for two different volumes of solution in Figs. 1 and 2. The *G* value, which is equal to 965×(acid yield)/(dose in rad), is shown in Table I as a function of dose rate, and *G* vs. (dose rate)$^{-1/2}$ is plotted in Fig. 3. For comparison, a plot of *G* vs. (dose rate)$^{-1/2}$ is shown for chloral hydrate irradiated with Co^{60} γ-rays for which attenuation of radiation by the solution was very small.

TABLE I

G value as a function of dose rate for 1 *M* chloral hydrate irradiated at 25° C

Dose rate (rad/min)	*G* value (molecules/100 ev)
1-ml solution (thickness = 2.7 mm)	
129 ±6	220±15
99 ±4	270±15
71.5±2.5	300±20
44.0±1	390±20
28.5±0.7	445±25
17.3±0.4	600±25
5-ml solution (thickness = 13.5 mm)	
37.5±0.8	300±15
22.5±0.4	390±20
12.0±0.4	545±20

Temperature Coefficient

The *G* value was determined at three temperatures and the results are shown in Table II. The temperature coefficient for the reaction was 3.3% per ° C at 25° C, which corresponded to an activation energy of 5.5±1 kcal/mole.

TABLE II

Effect of temperature on *G* value for 1 *M* aqueous chloral hydrate irradiated at 44.0 rad/min (1-ml solution)

Temperature (° C)	*G* value
15.5±0.2	285±20
25 ±0.2	390±20
35 ±0.2	540±20

Effect of Concentration

The results showing the dependence of *G* value on concentration are shown in Table III and in Fig. 4. Since the densities of the more concentrated solutions were so much

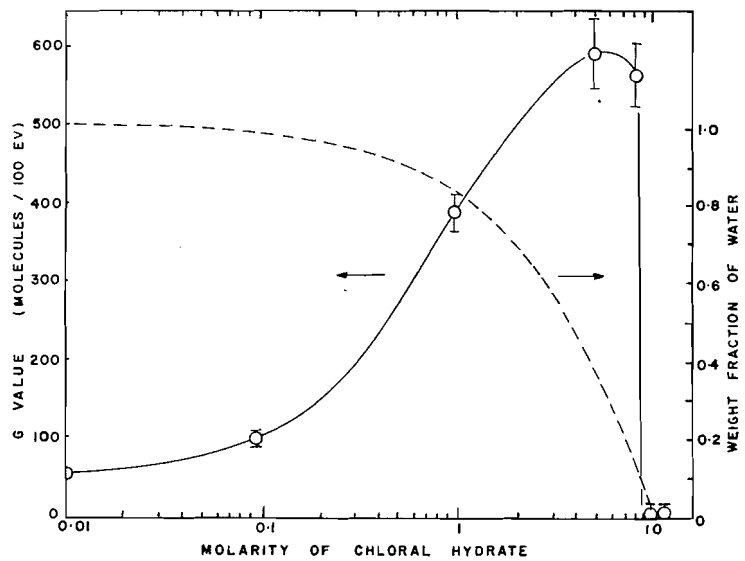

FIG. 4. Effect of initial concentration of chloral hydrate on *G* value for dose rates of 45 rad/min.

For personal use only.

different from that of the dosimeter solution, different dose rates resulted in the two solutions, due to differences in stopping powers per unit *volume*. It was assumed that the stopping power per unit *weight* was the same in both the chloral hydrate and dosimeter solution and that the dose rate in the concentrated chloral hydrate solution was the same as that in an equal weight of dosimeter solution.

The 10 *M* solution was saturated at about 35° C and when cooled to 25° C formed a solid solution which was irradiated in this state.

TABLE III

Effect of concentration on *G* value for chloral hydrate irradiated at 25° C (1-ml solution)

Concentration	*G* value
Dose rate = 45.0 rad/min	
0.01 *M*	53±5
0.1 *M*	100±10
Dose rate = 44.0 rad/min	
1.0 *M*	390±20
5 *M*	600±40
8 *M* (satd.)	570±40
10 *M* (solid soln.)	<25
Solid chloral hydrate	<25

It will be observed that the standard deviations are larger in more concentrated solutions; this was due to a less certain titration end point in the more highly concentrated solutions.

Effect of Intermittent Irradiation

Solutions of 1 *M* chloral hydrate at 25° C were irradiated with pulsed radiation, produced by interposing a rotating sector between source and solution. The effect of pulse time on *G* value is shown in Fig. 5. The reduction in *G* value occurs when the pulse time is about equal to the mean lifetime of the reaction intermediates (7).

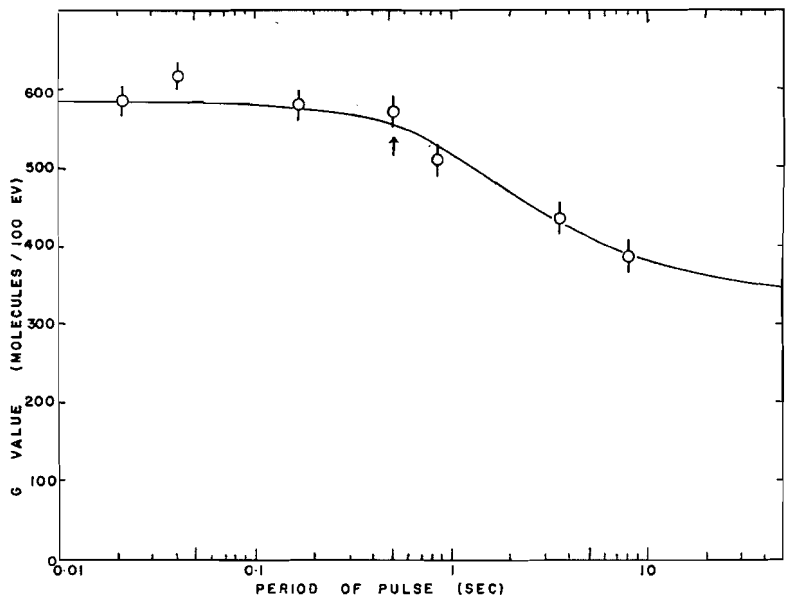

FIG. 5. Effect of intermittent radiation on *G* value. The dose rate with the sector rotating was 18 rad/min The average lifetime of the intermediates corresponds to the period of pulse shown by the arrow.

DISCUSSION

The large dose rate dependent G values indicate a chain reaction as the mechanism by which the beta radiolysis proceeds. The dependence of G value on (dose rate)$^{-1/2}$ means that a second-order recombination is responsible for removal of the chain-propagating intermediates. Lack of knowledge of reaction products, however, precluded setting up a reaction mechanism.

The dependence of G on thickness of solution irradiated was explained by assuming that the dose rate varied exponentially with solution depth and that the reaction velocity V varied with the (dose rate)$^{1/2}$ (this is tantamount to saying $G \propto$ (dose rate)$^{-1/2}$).

These conditions give:

$$V_x = KI_x^{\frac{1}{2}}$$

where V_x = reaction rate at depth x in solution,
K = a constant,
I_x = dose rate at depth x in solution,

where x is expressed in g/cm^2.

Also:

$$I_x = I_0\, e^{-\mu x},$$

where I_0 = surface dose rate,
μ = mass absorption coefficient in cm^2/g.

Now we have:

$$V_x = KI_0^{\frac{1}{2}}\, e^{-\mu x/2}.$$

The average reaction rate $\bar{V}$ in a solution of thickness t is given by:

$$\bar{V} = \frac{1}{t}\int_0^t V_x dx = \frac{1}{t}\,(2KI_0^{\frac{1}{2}}/\mu)\,(1-e^{-\mu t/2}).$$

The average dose rate $\bar{I}$ is given by:

$$\bar{I} = I_0(1-e^{-\mu t})/\mu t.$$

Therefore the G value in such a solution is given by:

$$G = \bar{V}/\bar{I} = \frac{2KI_0^{\frac{1}{2}}(1-e^{-\mu t/2})/\mu t}{I_0\,(1-e^{-\mu t})/\mu t},$$

$$G = 2K/[I_0^{\frac{1}{2}}(1+e^{-\mu t/2})].$$

Now $\mu = 6.1$ cm^2/g for solutions used here and $e^{-\mu t/2} = 0.43$ for the 1-ml solution (thickness = 0.27 g/cm^2).

Because absorption of the beta rays was complete in this thickness of solution (1.40 g/cm^2), $\mu t \rightarrow \infty$ for 5-ml solutions.

The *surface* dose rates for 1-ml and 5-ml solutions irradiated at the same *average* dose rates were found by extrapolation of a plot of dose rate vs. solution thickness to zero solution thickness. These dose rates were found to be in the ratio:

$$\frac{I_0\,(1\text{ ml})}{I_0\,(5\text{ ml})} = \frac{1}{3.1}.$$

Substitution into the expression for G value gave:

$$\frac{G\,(1\text{ ml})}{G\,(5\text{ ml})} = \frac{I_0^{\frac{1}{2}}(5\text{ ml})\,(1+e^{-\mu t/2})\,(5\text{ ml})}{I_0^{\frac{1}{2}}(1\text{ ml})\,(1+e^{-\mu t/2})\,(1\text{ ml})} = \frac{\sqrt{3.1}}{1}\,\frac{1}{1.43} = 1.23.$$

The experimental value of the above ratio was found by taking the ratios of the slopes of the 1-ml and 5-ml lines in Fig. 3. This ratio was found to be 1.20. The above explanation accounts for the observed dependence of G value on thickness of solution. The difference between G values for γ-radiation and beta radiation seen in Fig. 3 may also be due to such an effect since the gamma radiation is attenuated even less than beta radiation in a 1-ml solution of the thickness used here.

The dependence of G value on concentration shown in Fig. 4 may be explained by saying that at lower concentrations the probability of reaction of chain-initiating radicals with chloral molecules increased with chloral hydrate concentration; at high chloral hydrate concentrations the water concentration falls off rapidly and very few radicals are produced from the water per unit volume of solution.

The mean lifetime of the reaction intermediates was found to be about 0.5 second and from this figure approximate propagation and termination rate constants were calculated. It can be shown (8) that the termination rate constant k_t is given by:

$$k_t = 1/\tau^2\phi I,$$

where τ = mean lifetime of the free radical intermediates (here = 0.5 second),
ϕ = G value for radical initiation (taken to be 5 radicals/100 ev),
I = dose rate,
k_t = 2.5×10^9 l./mole-sec.

Also, it was assumed that V, the reaction velocity, was given by:

$$V = k_p\,[C](\phi I/k_t)^{\frac{1}{2}},$$

where k_p = propagation rate constant,
$[C]$ = chloral hydrate concentration.

The reaction rate $V = 2.0\times10^{-7}$ mole/l.-sec, $k_p = 2.5\times10^2$ l./mole-sec at a dose rate of 18.0 rad/min.

It would appear that no great difference exists between the beta and gamma radiolysis of aqueous chloral hydrate except for effects due to attenuation of the radiation. This is to be expected since the processes by which chain-initiating radicals are produced are the same in each case.

SOME SPECIFIC FEATURES IN AUTOXIDATION OF METHYL LINOLEATE[1]

N. A. KHAN

ABSTRACT

A scheme of manual counter-current extraction, ingeniously devised, has facilitated quantitative isolation of initial products from autoxidized methyl linoleate under controlled conditions. A sole product of monomeric monohydroperoxide with one spatial configuration has been shown to be the outcome of interactions of oxygen molecule with methyl linoleate. The physical and chemical analyses prove this product as conjugated *cis,trans* methyl linoleate hydroperoxide. The fractionations of its derivative, hydroxystearic acid, and its scission products go to establish the formation of two positional isomers (9- and 13-) exclusively for this *cis,trans* product. Such positional isomers leave no doubt about two possibilities of attack by oxygen on the two 3-C segments in the 5-C system of methyl linoleate containing mobile π electrons. A mechanism has been proposed relevant to the experimental findings. Such initiation processes offer the missing link between neutral methyl linoleate and formation of its hydroperoxide without decomposition. These investigations, thus, emphasize the fact that the initiation processes must be distinguished from the main autoxidation reactions.

In continuation of the previous studies (9) it is necessary to describe the carefully outlined procedures for the isolation of methyl linoleate hydroperoxides. The quantitative isolation of pure hydroperoxides, formed exclusively during the initial stages of autoxidation reactions of methyl linoleate, has been successfully carried out. The purity of such products has also been established through preparation of several derivatives and relevant scission products. Infrared studies on the fatty acid esters and their hydroperoxides have revealed many clues to the mechanism of autoxidation reactions. On the basis of these data and the other experimental facts, the mechanism of the initial attack by oxygen molecule on methylene-interrupted double bonds (5-C system of methyl linoleate) has been presented.

Methyl linoleate (545 g) was freshly prepared from sesame oil acids by bromination and debromination procedures. The *trans* isomers (isolated *trans* absorbing at 10.32 μ) formed during debromination were practically removed through multiple urea complex formation under different conditions. One per cent solution of linoleate sample in methanol was each time saturated at 30° C and crops of crystals were obtained at 4° C, yielding 4.6, 5.9, 7.3, 4.2, and 2.6% of the substance taken. The solution concentration at 1% was restored by evaporation under vacuum at room temperatures 26–31° C. The last filtrate was then passed through a powdered urea column (5 in. × 1/2 in.). After proper elution, 64.7% of methyl linoleate was recovered. Methyl linoleate, thus obtained, was analyzed: I.N. (iodine number), 172.4; isolated *trans*, nil (absorption at 10.32 μ); hydrogen absorption, 1.98 mole/mole. All samples were kept under (dry and oxygen-free) nitrogen and vacuum, below 0° C.

Since we are concerned with the initiation processes only, the extent of oxidation was scrupulously controlled and was not allowed to exceed certain limits. From the previous experiments (10), this limit was set at about 10% oxidation (absorption of 0.1 mole of oxygen per mole which is equivalent to 10% hydroperoxide formation). Consequently, autoxidation of methyl linoleate (50 g) to 10.0% hydroperoxides content was carried out at 0.0° C in 500-ml Erlenmeyer flasks open with loose lids. The quantitative isolation of these hydroperoxides formed at such initial stages and their characterization have been

[1]*Manuscript received January 14, 1959.*
Contribution from the Division of Foods and Nutrition, East Regional Laboratories, Pakistan Council of Scientific and Industrial Research, Tejgaon, Dacca, Pakistan.

considered essential to establish the nature of interactions between oxygen and methyl linoleate containing methylene-interrupted double bonds in a 5-C system. This paper thus deals with the peroxide-forming periods, A and B, and not the final main autoxidation periods, C and D, involving intricate mechanisms with free radicals (10).

Among the methods attempted for isolation of peroxides, the counter-current extraction was found to be the most suitable for keeping the peroxides intact during the isolation procedures. The counter-current extraction between two immiscible solvents was found to be effective in concentrating the oxygenated products. Unluckily, the standard procedures for the counter-current extraction (6) distribute the peroxides over several fractions, and under no conditions is the recovery quantitative. Hence, a scheme of manual counter-current extraction, as represented in Fig. 1, was improvised to separate the

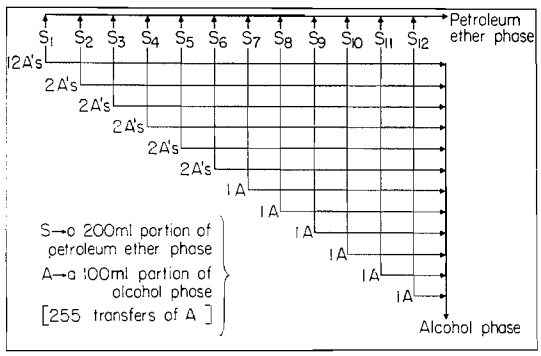

FIG. 1. A scheme of manual counter-current extraction.

oxidized from the unoxidized fraction quantitatively. Two immiscible solvents were first obtained by mixing absolute alcohol (distilled over KOH and zinc dust), petroleum ether (b.p. 30–60° C and free from unsaturable materials (13)), and water in the proportions 5:6:1. The resulting petroleum ether and alcohol phases were allowed to separate and were used as stock solvents. Both the phases were then cooled to 0° C. In Fig. 1, the S rows are 12 separatory funnels, each containing 200 ml of the cold petroleum ether phase. The partially oxidized fatty acid ester was dissolved in the 200 ml of petroleum ether in S_1. Twelve extractions, each with a 100-ml portion (A) of the cold alcohol phase, removed all peroxides from S_1. The subsequent extractions, carried out successively in S_2 through S_{12} by each of these alcohol portions (12 A's, Fig. 1), recovered the majority of peroxides and distributed all unoxidized fatty acid ester together with some peroxides in the petroleum ether phase. These remaining peroxides, in S_2 to S_{12}, inclusive, were extracted by the number of alcohol portions (2 A's and 1 A) indicated at the end of the vertical lines extending from the corresponding petroleum ether phase. This additional extraction of peroxides by fresh solvent is not feasible with the standard counter-current procedures (6). Determination of peroxide values at different steps indicated the efficiency of separation. The peroxide-containing phase of alcohol was kept cooled below 0° C. The precooled oxygen-free nitrogen was bubbled through the above alcohol phase as an added protection. The alcohol phase yielded, in general, 99.0–99.9% of the oxygenated products formed during the autoxidation of fatty acid esters. The unoxidized fraction obtained from the petroleum ether phase contained only 0.0–0.7% of oxygenated products entirely from the unoxidized fatty acid esters, so that the oxygenated products may represent the initial autoxidation process involved. For the convenience of analysis, an aliquot portion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of the oxygenated products was reduced in a 1% alcohol solution by stannous chloride (5 moles/mole of peroxide), agitating with oxygen-free nitrogen.

Methyl linoleate autoxidized at 0° without agitation gave a peroxide concentrate representing 99.9% of the oxygenated products formed during the autoxidation reactions. The corresponding unoxidized fraction isolated was found to be pure methyl linoleate by the following analysis: hydrogen absorption, 1.98 mole/mole; hydroxyl, 0.0; acid value, 0.0; carbonyl value, 0.0; and polymer, 0.0. Elementary analysis: C, 77.47 and H, 11.52. Calculated for methyl linoleate: C, 77.55 and H, 11.56. The polymer contents were measured by the special microtechnique in distillation (15). The peroxide concentrate having the peroxide value of 6115 meq/kg (theory for methyl linoleate monohydroperoxide, 6125 meq/kg was hydrogenated with 2.92 moles H_2 to yield monohydroxystearic acids (m.p. 75.0–77.5° C (3); hydroxyl, 1.04 moles/mole). The preliminary polarographic studies indicated that peroxide concentrate consists of 100.5% of hydroperoxide. The reduced peroxide concentrate gave the following analysis: hydrogen absorption, 1.99 mole/mole; hydroxyl, 1.02 mole/mole; acid value, 0.0; carbonyl value, 0.0 (17); and polymer, 0.0. Elementary analysis: C, 73.41 and H, 10.89. Calculated for monohydroxy methyl linoleate: C, 73.51 and H, 10.97. The infrared analysis of the above samples also indicated production of almost 100% *cis,trans*-conjugated isomers. Two other samples of peroxide concentrates obtained from methyl linoleate autoxidized under identical conditions gave peroxide values of 6100 and 6135 meq/kg respectively. From these data, the initial autoxidation of methyl linoleate (up to extent of 10% used) gives rise to only monomeric hydroperoxides and no other products. The unoxidized fraction has also been isolated as pure methyl linoleate as shown above and by spectrophotometric analyses. Further confirmation of methyl linoleate monomeric hydroperoxides and its specific isomers has been made through the following experiments.

The infrared absorption of the isolated hydroperoxides at 10.55 μ and 10.15 μ for *cis,trans* isomers was compared with that of pure *cis,trans* isomer of methyl linoleate (under the courtesy of the General Mills' Research Laboratory of Minnesota, U.S.A.). Methyl linoleate hydroperoxides were thus proved to consist of only *cis,trans* isomer. Our attempts to separate other isomers, *trans,trans* in particular, from these methyl linoleate hydroperoxides under suitable conditions, ended in failure. About 90 ml of methanol was saturated with urea at 32° C and mixed with cold 10-ml solution of methyl hydroxy linoleates obtained by reduction of linoleate hydroperoxides (2.54 g). It was left to crystallize at 0° C. The crystals were also washed with cold (−10° C) methanol. The washings and mother liquors were combined and reduced in volume to saturation at about 15–20° C under vacuum. The second crop of crystals was collected under the same conditions. The extractions through cold heptane solvent (80–90° C) from cold aqueous solutions gave three fractions, each of which was found to contain *cis,trans* isomers absorbing at 10.15 μ and 10.55 μ. These experiments from the isolation of peroxides were completed in the course of 14 hours on the same day with a well-planned program. The isolated samples sealed under vacuum were kept in dry ice, wherever possible. (N.B. Such hurried activities in these analyses of *cis,trans* isomers were made possible during the tenure of stay by the author in Minneapolis, Minnesota, U.S.A.) A change was definitely found to occur in the *cis,trans* to *trans,trans* ratios of purified autoxidation products (cf. linoleate hydroperoxides and reduced products) after storage for a certain period of time. During the period of experiments, the samples kept under vacuum below 0° C and used occasionally for analyses showed appreciable conversion to *trans,trans* isomers which rose to almost 10% in amounts within the span

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of a week. Even storage below −50° under vacuum did not stop such conversion. The *trans,trans* isomer (more than 25%) was obtained in all samples in a period of 6–9 months. Hence, it is quite apparent that the experimental conditions, unless scrupulously controlled, may change the true picture of autoxidation products consisting of only *cis,trans* isomer at the initial stages. The survey of literature (3, 5) indicates that all workers who studied kinetics or proposed theories did not consider these initial stages of autoxidation as important and never maintained conditions for keeping the peroxides intact in structure. Consequently, they dealt with only main autoxidation reactions involving decomposition of these peroxides and the resultant free radicals. Our point is related to only where and how autoxidation begins and, hence, much importance is attributed to the initial products unchanged and their energy of formation (10).

Characterization of Methyl Hydroxy Linoleates

Methyl hydroxy linoleates obtained by reduction of hydroperoxides from initial autoxidation of methyl linoleate have been previously shown to be *cis,trans*-conjugated isomers only through infrared analyses. Such products (250 mg) were quantitatively hydrogenated by Adam's platinum catalyst (1) to absorb 1.97 moles H_2 per mole. Methyl hydroxy stearates were subjected to resolution by column chromatography. Alumina was washed with 2 *N* HCl, then with water until neutral, and finally with ethanol. On activation at 150° C for 6 hours, the alumina was poured into a tube (1.0 cm × 110.0 cm) filled with petroleum ether (freed of the unsaturable materials and b.p. 80–90° C). Elution was carried on through petroleum ether containing 0–14% chloroform. Suitable fractions were collected and, through selections, the representative samples were made up. Methyl hydroxy stearates were thus resolved into two fractions (yield, 98.1% of that used) of almost equal weight. These had melting points: first 52.8–51.1° C (found: C, 72.4; H, 12.8; $C_{19}H_{33}O_3$ requires: C, 72.6; H, 12.1) and second 50.8–51.2° C (found: C, 73.2; H, 12.4). They were identified as methyl-, 13-, and 9-hydroxy stearates as done by Bergstrom (4).

Monohydroxystearic acids (40–50 mg) from methyl esters were added to 25% sulphuric acid (3.5 ml) containing 8% chromic acid. Steam was passed through the mixture for about 55 minutes with volume kept constant by additional controlled heating. The distillate was neutralized with alkali. After some concentration under vacuum, the acids were regenerated by sodium bisulphate and extracted with *n*-butanol. The scheme of partition paper chromatography (12) was utilized to analyze these acids; three well-defined intense spots were obtained, two of which had R_f values identical with those of *n*-pentanoic and *n*-hexanoic acids, and the third spot was in a some doubtful position of acids greater than C_8 in chain length. The other faint spots were neglected. For further confirmation, the method of Michael and Schweppe (14) was employed for detecting acids of chain length C_5–C_{18}. The butanol extracts were esterified by means of diazomethane (2) and the corresponding hydroxamic acids were prepared, and the acids *n*-pentanoic, *n*-hexanoic, *n*-nonanoic, and *n*-decanoic were identified. These four acids: C_5, C_6, C_9, and C_{10} can only result from the 9- and 13-hydroxystearic acids, confirming our results in the foregoing section.

Some Concepts on Mechanisms of Autoxidation of Methyl Linoleate

From the above findings, it can be asserted that only two *cis,trans*-conjugated isomers of 9- and 13-linoleate hydroperoxides are formed during autoxidation reactions. No 11-hydroperoxide has been detected in the products. Hence, the formation of 11-peroxide radical ($R^{11}O_2$) and transfer of O_2 to 9- and 13-position seems to be absurd from the modern concepts (cf. transfer of atoms) of electronic interpretation (8, 16). Furthermore,

the initiation of reaction through free radicals on the 5-C systems of linoleate does not eliminate the formation of 11-isomer. This has been confirmed by the excellent work on free radicals attacking such 5-C systems by Harrison and Wheeler (7). The question of energy to start off the first radical during the interactions of oxygen and linoleate can not be easily thrown off (10, 11).

It is, thus, quite apparent that complex formation already proposed for simple systems (10) may be applied to 5-C systems of methyl linoleate with some modifications. The concepts of non-localization and spread of π electrons (8) have made it possible to present the processes of activation and polarization of 5-C systems and oxygen molecules in the steps I–III of Fig. 2. The first stages of activated complex formation (IV) may involve

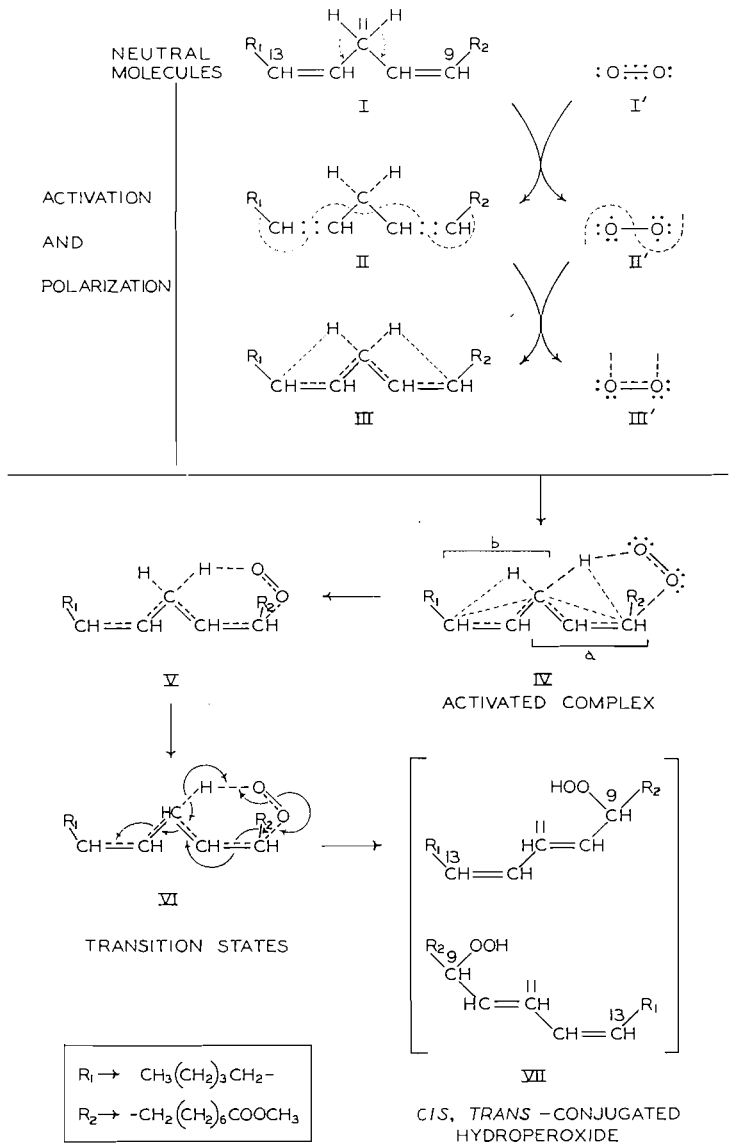

FIG. 2. Mechanism of autoxidation of methyl linoleate.

For personal use only.

either *a* or *b* segment of the 5-C system. The activated complex through *a* (IV) gets its π electrons spread over the whole sphere of reactions including oxygen molecule (V) and then initiates shift of electrons as in VI, Fig. 2, only to give rise to the isomer, 9-hydroperoxide. Similarly, the activated complex through segment *b* (IV) will form 13-isomer of hydroperoxide. That the *cis* to *trans* conversion occurs only in one affected double bond next to hydroperoxide group, is evident from VI–VII, Fig. 2, showing spatial possibilities for 9-isomer. The foregoing mechanisms proposed for methylene-interrupted double bonds (5-C system) of methyl linoleate may account for the clear-cut formation of two conjugated isomers: 9- and 13-*cis*,*trans*-hydroperoxides that have been found as the reaction products of oxygen and methyl linoleate at the initial stages of autoxidation.

It may be noted here that it is of particular interest to consider the above mechanisms as the missing link between neutral methyl linoleate and the formation of its hydroperoxides without decomposition. After peroxide formation, many complicated processes including free radicals may be involved for the main autoxidation reactions which have been studied by various workers, kinetically or otherwise (3, 5). Hence, the proposed mechanisms for the initial reactions do not replace the ideas of free radicals, but these processes only supplement free radical mechanisms that play roles quite later and, consequently, demand careful kinetic studies from a different angle of approach under the conditions prescribed in this paper. Our future plans include such kinetic investigations. Moreover, the mode of complex formation, ahead of free radical reactions, is not new and has been found in many other reaction processes (18). Further details will be published later.

A COMPARISON OF SLATER'S THEORY OF UNIMOLECULAR REACTIONS WITH EXPERIMENTAL DATA[1]

EVERETT THIELE AND DAVID J. WILSON

ABSTRACT

Slater's theory of unimolecular reactions is tested by comparing theoretical and experimental values of the pressure at which the rate constant has fallen off from the high-pressure limit by 5%. A simplified method is used for calculating lower bounds to the theoretical value of this pressure. Agreement with experimental data on cyclobutane, cyclobutene, and nitrogen pentoxide is rather poor; experimental values are lower than the calculated lower bounds.

Slater has set forth a detailed theory of unimolecular gas reactions which is based on a model of a vibrating molecule with a quadratic potential function (1, 2, 3). The molecule reacts when one particular internal co-ordinate (the reaction co-ordinate) attains a critical value. Slater derives an expression for the value of the rate constant at any pressure (k) divided by the value of the rate constant at infinite pressure (k_∞). His expression is $k/k_\infty = I_n(\theta)$, where the right-hand side is an integral depending on n, the number of normal co-ordinates contributing to the reaction co-ordinate, and on θ, which is proportional to pressure. Slater has evaluated this integral for $n = 3, 5, \ldots 13$ at increments of one of $\log_{10}\theta$. For our purposes it is sufficient to determine the value of θ for which $k/k_\infty = 0.95$, from which we shall determine the pressure (P_5) at which the reaction rate has dropped off 5% from its value at the high-pressure limit. Slater has also tabulated these values (3).

The exact application of Slater's theory to a reaction requires a detailed vibrational analysis, a knowledge of the experimental activation energy and of the reaction co-ordinate, and values for the collision diameters of the reactant and any added inert gases. In general, the larger the value of n, the lower is the predicted value of P_5. One upper bound for n is obviously the total number of normal modes of vibration possessed by the reactant molecule. In a molecule possessing symmetry, however, n may be considerably smaller than this if the reaction co-ordinate belongs to one of the symmetry species of the molecule. Even when this is not the case, an upper bound for n can often be determined by considering the symmetry of the less symmetrical molecule resulting when the molecule is distorted by giving the reaction co-ordinate a large value.

For Slater's quantity ν (for definitions of Slater's parameters the reader is referred to ref. 3) one can substitute the high-pressure limit of the pre-exponential factor. This leaves undetermined only the value of Slater's $\Pi_i\mu_i$. A maximum value of this quantity makes P/θ, and also P_5, a minimum. This maximum value is given by Slater (3) as $n^{-\frac{1}{2}n}$, and is obtained by assigning to all the μ_i an equal value. Physically this means that all pertinent normal modes contribute equally to the reaction co-ordinate. Slater has also defined a "representative spread" of the μ_i in such a way that they form a geometric progression with $\mu_1 = 5\mu_n$. P_5 has been calculated for both cases (and is defined as $P_{5\,\mathrm{min}}$ and $P_{5\,\mathrm{rep}}$, respectively) for three unimolecular reactions: the isomerization of cyclobutene, the decomposition of cyclobutane, and the decomposition of nitrogen pentoxide.

Cooper and Walters (4) concluded that the isomerization of cyclobutene to 1,3-butadiene proceeds unimolecularly without the formation of free radicals. If one assumes

[1]*Manuscript received January 29, 1959.*
Contribution from Department of Chemistry, University of Rochester, Rochester 20, New York.

C_{2v} symmetry for the molecule, the reaction co-ordinate is probably of symmetry species A_1. (One expects the reaction co-ordinate to be a simultaneous lengthening of the CH_2—CH_2 and CH=CH bonds and shortening of the CH_2—CH bonds; hydrogen migration seems unlikely and would lead to a too-large pre-exponential factor.) There are eight normal co-ordinates belonging to this species; therefore no more than eight normal vibrations can contribute to the reaction co-ordinate.

The decomposition of cyclobutane has been investigated by several authors (5, 6 *a*) and is thought to be elementary unimolecular. A possible reaction co-ordinate is the simultaneous expansion of two opposite C—C bonds. Although Slater's theory does not apply directly to such a case, we can hypothesize that the sum of these two bond lengths must reach a critical value in order for the reaction to take place. If one considers cyclobutane in such a stretched position prior to reaction, and assumes D_{2h} symmetry, the reaction co-ordinate is a member of the A_g symmetry species, which contains five normal modes.

Alternatively, the stretching of only one C—C bond may be necessary for reaction, in which case the distorted molecule prior to reaction has C_{2v} symmetry. The reaction co-ordinate is of symmetry species A_1, and thus no more than nine normal modes can contribute to it.

An argument against the participation of hydrogen migration to the reaction co-ordinate of cyclobutane is the result of recent unpublished work by Srinivasan and Kellner (both at the University of Rochester), who found that the thermal decomposition of 1,1,2,2-tetradeuterocyclobutane produced essentially no ethylene species of odd molecular weight. We are grateful to these workers for permission to quote their results. (It might be remarked in passing that the work of Rabinovitch and co-workers on dideuterocyclopropane (6 *b*) casts some doubt on the use of a hydrogen migration reaction co-ordinate in the analysis of data on the isomerization of cyclopropane.)

The rate-controlling step in the decomposition of nitrogen pentoxide in the presence of nitric oxide has been found to be unimolecular (7, 8, 9, 10). The reaction co-ordinate might be taken to be the antisymmetric migration of the central oxygen atom away from one nitrogen and toward the other. If, for purposes of computation, the molecule is fixed in a planar configuration, it possesses C_{2v} symmetry. The reaction co-ordinate belongs to symmetry species B_1, and so can be a combination of no more than five normal modes.

Alternatively, the reaction co-ordinate might be the stretching of one N—O bond. For a planar configuration, the distorted molecule possesses C_s symmetry, and 11 normal modes can contribute to the reaction co-ordinate.

Values of $P_{5\ \mathrm{min}}$ and $P_{5\ \mathrm{max}}$ can then be computed for these reactions by means of Slater's tables. (θ_5 for $n = 8$ was calculated by interpolation in Slater's table.) A collision diameter of five Angstroms was used in all calculations.

In two cases there exists a duplication of equivalent reaction co-ordinates within the molecule. Slater has shown that the effect of such a duplication is approximately equal to a multiplication of the over-all rate constant by the degree of duplication (11). Hence no change in the pressure at which $k/k_\infty = 0.95$ should be expected because of this duplication. The results of these calculations and the parameters used are listed in Table I.

It might be noted that, assuming C—C bond stretching is the reaction co-ordinate, Slater's theory is unable to account for the high pre-exponential factor found for cyclobutane. Other examples of "high" pre-exponential factors are known. It has also been

found experimentally that deactivation does not necessarily occur on every collision of an activated molecule with a foreign gas molecule (12, 13); hence the estimate of five Angstroms for the effective collision diameter may well be too high. This would introduce even larger discrepancies between the results of theory and experiment given in Table I.

One concludes that Slater's theory, although certainly the most detailed of the available theories of unimolecular reactions, may require some modifications—perhaps the inclusion of fairly substantial anharmonic interactions between the normal modes, and perhaps the use of a different type of collisional activation mechanism.

THE WAX OF THE LEAVES OF PICEA PUNGENS (COLORADO SPRUCE)[1]

E. VON RUDLOFF

ABSTRACT

A chloroform-soluble, neutral wax was isolated from the leaves of Colorado spruce, collected during fall and winter months. The wax was found to consist of sabinic, 14-hydroxytetradecanoic, and juniperic acids, with only minor amounts of non-saponifiables and *n*-fatty acids. 14-Hydroxytetradecanoic acid has not been found before in naturally occurring waxes. A cyclic structure rather than the linear etholides proposed for other conifer waxes is in accord with the analytical data. In the spring and summer months the wax was accompanied by an acidic fraction.

A wax isolated from the leaves of Colorado spruce (*Picea pungens* Engelm.) has been found to differ from the waxes of other conifer leaves (1–7). Leaves harvested in the fall or winter yielded a virtually neutral wax which contained only minor amounts of non-saponifiable material. One of its main constituents is 14-hydroxytetradecanoic acid, which has apparently not been found in natural waxes before. Samples obtained during the spring or summer months, however, had much higher acid values, indicating that seasonal changes occur. Yields of the wax and analytical data are shown in Table I.

The neutral wax, after purification, was saponified and the mixture of acids obtained on acidification was fractionated by countercurrent distribution (8). Three distinct fractions, comprising about 90% of the mixture, were obtained after applying 300 or more transfers, and were found to contain sabinic, 14-hydroxytetradecanoic, and juniperic acids, respectively (see Table II). The remaining 10% of the acid mixture was distributed broadly without forming a distinct peak. This was due in part to emulsion formation in tubes containing the less polar material (i.e. normal fatty acids). When the methyl esters were similarly fractionated no emulsification was encountered and the partition of the hydroxy compounds was more favorable, but again no distinct peak was obtained for the less polar compounds. Analysis by vapor-phase chromatography showed that normal fatty acids from lauric to stearic acids were present (see Table II). A substantial seasonal variation was found in the composition of the ω-hydroxy and normal fatty acid

[1]*Manuscript received February 16, 1959.*

mixtures. When the acidic wax isolated in the spring was chromatographed on a silicic acid – celite column a high proportion was recovered as a neutral wax having a composition similar to that isolated in the fall. The small amount (1–4%) of non-saponifiable material isolated had an infrared spectrum which resembled that of *n*-octadecanol; however vapor-phase chromatography showed it to be a mixture of at least four compounds.

*Countercurrent distribution.
†Vapor-phase chromatography.

The neutrality of the wax, the small percentage of non-saponifiable material present, and the molecular weight of 850 to 950 suggest that the pure wax is composed of about four molecules of the three ω-hydroxy acids, esterified with each other in form of a cyclic polymer. Bougault and Bourdier (1) concluded that the waxes which they isolated consisted of similar esters but in the form of linear polymers, which they named etholides. Such an etholide (m.p. 87.5–88° C) has been prepared from juniperic acid by heat condensation (9). Kariyone *et al.* (5) deduced from their data that such etholides are composed of three to five molecules of juniperic and sabinic acids. A linear polymer would require one free hydroxyl and one free carboxyl group for each molecule. Assuming an average composition corresponding to a linear tetramer of 14-hydroxytetradecanoic acid, the calculated acid value, neutral equivalent, saponification value, and saponification equivalent after acetylation would be 60.7, 923.4, 230.8, and 965.4 respectively. These data do not correspond with those found for either the neutral or acidic wax from Colorado spruce (Table I). Infrared spectra of the neutral wax showed no free hydroxyl groups, and only a small peak for the acidic wax. It is suggested, therefore, that the neutral wax is composed mainly of a cyclic polymer of the ω-hydroxy acids and that the seasonal changes in acidity are caused, in part at least, by ring opening or closure.

Bougault and Cattelain (10) and Tong (7) have suggested that juniperic acid could be used for the production of compounds having musk odor, but the former authors thought the yields too small to be of practical value. Since 14-hydroxytetradecanoic acid forms a 1,14-tetradecanolide having musk odor (11), the same suggestion would apply to the wax from Colorado spruce leaves.

EXPERIMENTAL

Melting points were measured with a Leitz hot stage microscope. Vapor-phase chromatography was carried out with a Beckman GC-2 gas chromatograph using a 2-foot long, $\frac{1}{4}$-inch diameter column of washed silicone on C-22 firebrick (12) and helium as carrier gas. A modified E-C Apparatus Co. Fractionator, Model EC 510, was used in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

countercurrent distribution experiments (13). Molecular weights were determined by the Rast and isothermal distillation methods (14). Acid values (neutralization equivalents) and saponification equivalents were determined in the usual way, using 90% ethanol as solvent. Because of the low solubility of the waxes, a small amount of chloroform was added and titrations were carried out at 50–60° C. Acetylations were carried out with acetyl chloride and pyridine or dimethylaniline.

Isolation of the Wax

Leaves harvested in the fall of 1957 and spring of 1958 were treated as follows: fresh leaves, 200 g (dry weight approx. 90 g), were macerated in hot 40–60% aqueous alcohol, 1500 ml, with the aid of a 1-gal Waring blendor. The mixture was filtered and the residual pulp extracted similarly with hot benzene – ethanol (2:1 v/v). Both solutions, on reduction to a small volume and cooling, precipitated waxy material which was filtered off. The crude wax was found to be soluble in cold chloroform, hot ethanol, hot acetone, hot benzene, and hot carbon tetrachloride, and was insoluble in water, ether, and petrol.

In later work, the cuticle wax was isolated directly by steeping the fresh needles, 100 g, in chloroform, 500 ml. After it had been left standing for 2 to 3 hours the mixture was filtered and evaporated *in vacuo* (water pump) in a 1-liter flask. The residual material, 1.5 g, formed a thin film along the walls of the flask and was triturated with ether to remove ether-soluble impurities, 0.9 g.

The yields of crude wax at different times of the year are shown in Table I.

Purification of the Wax

The crude wax, 1 g, was dissolved in hot 75% aqueous alcohol (100 ml), and to the solution at 50–60° C was added an equal volume of petrol (b.p. 60–70° C). The mixture was stirred carefully and allowed to cool to room temperature, and the precipitated wax was filtered off. If the wax still had a light green color, the procedure was repeated. The wax was then recrystallized from acetone two or three times to give a constant melting product. If the wax was then further recrystallized from ethanol, ethanol–acetone, or petrol, the melting-point range did not decrease. The constants and analytical data for waxes isolated at various times are shown in Table I.

Separation into Components

The neutral wax (isolated in the fall of 1957, neutral equivalent 267), 1.000 g, was saponified by heating under reflux in 80% aqueous ethanol, 50 ml, containing potassium hydroxide, 1.0 g, for 6 to 8 hours. The non-saponifiable portion was recovered quantitatively by extracting the cold, diluted ethanolic solution three times with an equal volume of petrol (b.p. 60–70° C). The petrol extract was dried over anhydrous sodium sulphate, filtered, and evaporated to dryness. The residue, 0.010 g, had m.p. 51–70° C and an infrared spectrum resembling that of *n*-octadecanol, though not as well defined. Vapor-phase chromatography showed the presence of at least four compounds.

The ethanolic soap solution was evaporated to a small volume, acidified with 10% sulphuric acid solution, and quantitatively extracted with ether. The dried, filtered ethereal solution was evaporated to dryness to yield the free acids, 1.037 g (97.2% of theory, assuming the wax to be composed of etholides only). In another experiment the yield of non-saponifiables was 0.032 g and that of acids 1.040 g (97.6%).

The mixture of acids, 2.0 g, was fractionated by countercurrent distribution, using 60% aqueous ethanol – petrol (b.p. 60–70° C) as solvent system. When 200 transfers were applied three major peaks were obtained (weight analysis) which were not well

separated. Applying 400 transfers (withdrawal technique) a better than 90% separation of each component was obtained. Emulsification was troublesome in the most advanced tubes, and a better fractionation was obtained when the methyl esters were used (see below). The amount of each component was calculated and the material at and adjacent to the maxima was combined, evaporated, and recrystallized from acetone. Fraction I (tubes 0–18), 0.42 g (21%), m.p. 82–83.5° C, corresponding to sabinic acid, m.p. 84° C, 84–85° C (1, 9). Calculated for $C_{12}H_{24}O_3$: C, 66.63%; H, 11.18%; neutral equivalent, 216.31. Found: C, 66.91%; H, 11.18%; neutral equivalent, 218.2. The methyl ester was prepared with diazomethane, giving a compound m.p. 31–34° C after three crystallizations from petrol and methanol–water; reported m.p. 34–34.5° C (9). Calculated for $C_{13}H_{26}O_3$: C, 67.78%; H, 11.38%; saponification equivalent, 230.34. Found: C, 68.01%; H, 11.45%; saponification equivalent, 238.3. Acetyl derivative m.p. 42–43.5° C after three crystallizations from petrol (b.p. 60–70° C); reported m.p. 45° C (9).

Fraction II (tubes 19–40), 0.80 g (40%), m.p. 89.5–91.0° C; reported for 14-hydroxytetradecanoic acid, m.p. 91.0–91.5° C (9). Calculated for $C_{14}H_{28}O_3$: C, 68.81%; H, 11.55%; neutral equivalent, 244.36. Found: C, 68.54%; H, 11.35%; neutral equivalent, 246.36. Methyl ester: m.p. 45.5–46.0° C; reported m.p. 47° C (9). Calculated for $C_{15}H_{30}O_3$: C, 69.72%; H, 11.70%; saponification equivalent, 258.39. Found: C, 69.93%; H, 11.79%; saponification equivalent, 259.2. Acetyl derivative: m.p. 53.5–54.5° C; reported m.p. 54–54.5° C (9).

Fraction III (tubes 41–66), 0.56 g (28%), m.p. 94.5–95.5° C; reported for juniperic acid m.p. 95° C (1, 9). Calculated for $C_{16}H_{32}O_3$: C, 70.54%; H, 11.84%; neutral equivalent, 272.42. Found: C, 70.26%; H, 11.60%; neutral equivalent, 274.5. Methyl ester: m.p. 54.5–55.0° C; reported m.p. 55–55.5° C (1, 9). Calculated for $C_{17}H_{34}O_3$: C, 71.28%; H, 11.96%; saponification equivalent, 286.44. Found: C, 71.17%; H, 11.62%; saponification equivalent, 283.5. Acetyl derivative: m.p. 62–64° C; reported m.p. 63° C (9).

The material in tubes 67 and higher, 0.15 g (7.5%), formed no distinct peak. It was combined, esterified, and analyzed by vapor-phase chromatography. Peaks corresponding to lauric (approximately 5%), myristic (20%), palmitic (35%), and stearic (40%) acids were obtained.

The mixture of acids was also fractionated by countercurrent distribution in form of their methyl esters. A satisfactory separation into three hydroxy esters was obtained with 200 transfers using 75% aqueous ethanol – petrol (b.p. 60–70° C) as solvent system. The partition ratios for the C_{12}, C_{14}, and C_{16} ω-hydroxy esters were 0.18, 0.33, and 0.48, respectively, and the relative amounts of each component were practically the same as those found for the free acids.

Chromatography of Acidic Wax

The acidic wax (isolated in the spring of 1958, acid value 56), 1.000 g, was chromatographed on a column, 2.0 cm diameter, of silicic acid – celite (2:1), 50 g, using chloroform as eluent. Fractions of 25 ml were collected. Fractions 5 to 11 yielded 0.93 g of practically neutral wax, m.p. 70–75° C. Found: C, 74.36%; H, 11.81%; acid value 3–5; saponification equivalent, 267; molecular weight, 940–970. Saponification equivalent after acetylation, 272. A small aliquot was saponified and the free acids converted to their methyl esters with diazomethane. The percentage composition of the mixture of methyl esters is shown in Table II.

Vapor-phase Chromatography

All material investigated was injected as concentrated ethereal solutions of the methyl

esters, or, in the case of the non-saponifiables, as dilute ethanolic solutions of the free alcohols. The methyl esters were analyzed at 220° C and 30 p.s.i. pressure (flowrate = 82.55 cc per minute, soap bubble counter). The time of emergence, measured on the chart paper as the distance from the start (solvent peak) to the maximum of each peak, was 1.8, 3.5, 7.0, and 13.9 (±0.2) cm for methyl laurate, myristate, palmitate, and stearate and 5.4, 9.7, and 20.1 (±0.2) cm for the methyl esters of the C_{12}, C_{14}, and C_{16} ω-hydroxy acids, respectively. The areas under the curves were obtained by the triangulation method and the percentage of each component was calculated from its area as compared with the sum of the peak areas. The error on runs with mixture of known amounts of normal fatty acid esters was ±1%. When the non-saponifiable material was analyzed on the same column and at the same temperature, four peaks were recorded.

ACKNOWLEDGMENTS

The author is grateful to Mr. M. Mazurek for carrying out the microanalyses and to Mr. M. Granat for technical assistance and recording the infrared spectra.

THE BIOGENESIS OF ALKALOIDS

XXI. THE BIOGENESIS OF (−)-HOMOSTACHYDRINE AND THE OCCURRENCE OF TRIGONELLINE IN ALFALFA[1]

A. V. ROBERTSON[2] AND LÉO MARION

ABSTRACT

In an attempt to find the precursor of the piperidine ring in homostachydrine, young alfalfa shoots were fed (*a*) lysine-2-^{14}C, (*b*) lysine-2-^{14}C with pyridoxine, (*c*) lysine-2-^{14}C with pyridoxine and folic acid, and finally (*d*) lysine-2-^{14}C with pyridoxine, folic acid, and methionine. In all cases the homostachydrine isolated from the harvested plants showed no radioactivity. It is shown that homostachydrine is not synthesized at the stage of growth at which the experiments were carried out. Alfalfa has been found to contain a hitherto unreported alkaloid shown to be trigonelline by comparison with an authentic sample. Both homostachydrine and trigonelline are found in the seeds, and are not actively synthesized in the plant until seed formation. Asparagine has also been isolated in relatively high yield.

In the course of experiments on the biosynthesis of stachydrine in alfalfa (*Medicago sativa* L. Grimm) Wiehler and Marion isolated a new alkaloid which they called (−)-homostachydrine (1). The compound was identified as the laevorotatory methyl betaine of pipecolic acid, and it has since been shown to belong to the L-series of amino acids by correlation with L-(−)-pipecolic acid (2, 3).

It has been suggested (1) that homostachydrine is formed in the plant by ring closure of lysine to pipecolic acid followed by the methylation to the betaine. Lysine is known to be a precursor of pipecolic acid in *Phaseolus vulgaris* (4, 5), *Neurospora* (6), and the intact rat (7), and the intermediates of the process have been studied with the aid of enzyme preparations from rat tissue, *Neurospora*, *Pisum sativum*, and *Phaseolus radiatus* (8, 9). The presence of pipecolic acid in alfalfa has yet to be demonstrated but in view of its occurrence in other legumes (10, 11, 12) it would not be surprising if it were found as a nonprotein nitrogen constituent of alfalfa.

We have attempted to provide evidence for the biosynthetic pathway proposed for homostachydrine by feeding lysine-2-^{14}C to 2-week-old alfalfa. A week later the plants were harvested and extracted, but the homostachydrine isolated was radioinactive. In previous experiments on the biosynthesis of stachydrine it was found that ornithine-2-^{14}C was not converted to proline in alfalfa unless pyridoxine was also administered, but even then the stachydrine did not become radioactive (13). In case similar conditions prevailed for the ring closure of lysine, an experiment was performed in which lysine-2-^{14}C and pyridoxine were fed to 2-week-old alfalfa, but again the crystalline alkaloid fraction isolated from the plants a week later was not radioactive. Following the ideas of Wiehler and Marion (14) on stachydrine biosynthesis, folic acid was fed together with lysine-2-^{14}C and pyridoxine in an attempt to stimulate the biological methylation of pipecolic acid, but no radioactivity was incorporated in the homostachydrine subsequently isolated. In a final experiment to influence the biosynthesis of homostachydrine along the proposed route by enhancing the probability of methylation, lysine-2-^{14}C was fed in conjunction with pyridoxine, folic acid, and methionine, but again the alkaloid remained inactive.

These negative results might be interpreted to mean either that lysine is not a pre-

cursor of homostachydrine, or that the synthesis of the alkaloid takes place at a later stage of development of the plant, in which case the homostachydrine isolated would have been material stored in the seeds. The second of these interpretations is supported by a result described by Wiehler and Marion (14), who found that after feeding methionine-Me-^{14}C, pyridoxine, and folic acid to alfalfa seedlings, stachydrine became radioactive whereas homostachydrine did not. Assuming that the enzymes controlling methylation of the nitrogen heterocycles are similar, this clearly indicates that only the stachydrine is being synthesized at a plant age of 2 to 3 weeks.

In the last of the experiments with radioactive lysine, the crude betaine hydrochlorides from the reineckate separation were recrystallized without the usual purification through a mercuric chloride complex. The first crop was expected to be homostachydrine hydrochloride (m.p. 217°), but it melted at 240–246°, and after several recrystallizations at 247–250° (decomp.). Elemental analysis of this hydrochloride indicated the formula $C_7H_7O_2N.HCl$, and the ultraviolet spectrum showed aromatic absorption. Since the substance was isolated from the stachydrine fraction from which the stronger bases had already been removed, it was assumed to be a betaine. Thus the choice of structure was reduced to one of the betaines of the three isomeric pyridinecarboxylic acids. Homarine, the α-isomer, was eliminated because its hydrochloride melts at 170° (15). Since the γ-isomer has not been found naturally, trigonelline, the β-isomer, seemed the more likely of the two remaining possibilities. The complete identity of the ultraviolet and infrared spectra, X-ray powder pattern and paper chromatographic properties for the natural sample, and synthetic trigonelline hydrochloride confirmed the structure. Synthetic trigonelline hydrochloride had m.p. 259–260° (decomp.) after softening at 257°, but the melting point of the natural material could not be raised above 250°. Other low-melting samples of trigonelline hydrochloride isolated from natural sources have been reported (16, 17, 18).

In the mercuric chloride precipitation normally used as a final purification step for stachydrine and homostachydrine, trigonelline does not precipitate with the reagent (20% hydrochloric acid saturated with mercuric chloride). Thus in previous work on alfalfa in this laboratory (1, 13, 14, 19) had trigonelline been present it would have remained unnoticed in the filtrate. To see if trigonelline is a normal constituent of the plant, alfalfa seedlings 16 days old and grown with the usual 30 g of seeds per tray (14, 19) were extracted, but trigonelline could not be detected. In the experiment described above in which trigonelline was isolated, 40 g of seeds per tray were used, and experience gained since suggests that this quantity overloads the trays so that although good germination occurred, some seeds did not grow because those already sprouting formed a light shield. This observation suggested that trigonelline may occur in alfalfa seeds and a direct extraction confirmed the idea. Indeed it is present in the betaine fraction of the seeds in a larger amount (38%) than stachydrine (33%) or homostachydrine (29%). It was not discovered in the extraction of seeds by Wiehler and Marion (1) because they used a final mercuric chloride purification. Furthermore, in the butanol – dilute hydrochloric acid system which they used for separating stachydrine (R_F 0.50) and homostachydrine (R_F 0.58) by paper chromatography, trigonelline has the same R_F as choline (0.41). Trigonelline (R_F 0.37) is readily separated from choline (R_F 0.57) in ethanol–ammonia (20). In this system homostachydrine has R_F 0.56 and stachydrine R_F 0.50.

Trigonelline and homostachydrine seem to be formed in alfalfa at the time of seed formation. The trigonelline stored in the seed is used up in the first few days of growth and the homostachydrine disappears between 1 and 5 months, since an extraction of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

plants 5 months old showed stachydrine as the only betaine. Hence the biosynthesis of homostachydrine must take place during the flowering and seed-setting period. The proposed biosynthetic scheme remains as a working hypothesis, but no greater credence can be attached to it in view of recent findings that proline is not involved in the biosynthesis of stachydrine (21).

After removing the proteins in the alfalfa extractions the betaines were separated from the water-soluble residue by leaching with alcohol. The fraction insoluble in alcohol partly crystallized and the recrystallized compound was identified by its elemental analysis, infrared spectrum, and X-ray powder pattern as asparagine. The yield was 2.5% of the weight of the dry plant. Asparagine had been isolated from alfalfa previously (22) but the ease of isolation and the high yield in the present experiments are noteworthy.

EXPERIMENTAL

Melting points are corrected. The infrared absorption spectra were measured in nujol mulls on a Perkin–Elmer double beam spectrometer model 21B.

Feeding Experiments with Lysine-2-^{14}C

Alfalfa seeds were germinated on glass wool as previously described (14, 19) using 300 g in 10 trays (20×30 cm) for the first three experiments and 400 g for the fourth. It was found that discarding the nutrient solution and washing with distilled water each week (14, 19) made the plants too wet and was unnecessary for good growth to an age of 3 weeks.

Experiment 1.—On the 14th day 8.0 mg DL-lysine-2-^{14}C-monohydrochloride (purchased from Tracerlab Inc.) with a total activity of 3.2×10^7 d.p.m. in 500 ml nutrient solution was administered. Plants were harvested on the 20th day.

Experiment 2.—On the 14th day a mixture of 8.5 mg radioactive lysine, total activity 3.5×10^7 d.p.m., and 1 mg pyridoxine hydrochloride in 500 ml nutrient solution was administered. Plants were harvested on the 19th day.

Experiment 3.—On the 10th day a mixture of 7.6 mg radioactive lysine, total activity 3.0×10^7 d.p.m., 1 mg pyridoxine hydrochloride in nutrient solution, and 1 mg folic acid in sodium bicarbonate solution (23) was administered. Plants were harvested on the 20th day.

Experiment 4.—Nutrient solutions containing a total of 22 mg radioactive lysine, total activity 1.8×10^8 d.p.m., 3 mg pyridoxine, 5 mg folic acid in aqueous sodium bicarbonate, and 250 mg (±)-methionine were administered in three portions on the 7th, 11th, and 16th day. Plants were harvested on the 20th day.

Extraction Procedure (cf. 1, 13, 14, 19)

Preliminary defatting of the dried plant material by refluxing (4 hours) with petroleum ether (b.p. 75–90°) was advantageous in avoiding emulsions and giving sharper fractions in subsequent stages. This was particularly important during an extraction of alfalfa seeds. The plant material was boiled with three lots of 70% alcohol, but the extracts were not diluted with water (1) before precipitation of the proteins with lead acetate. After removing the excess of lead as sulphide, the filtrate was evaporated to dryness using octyl alcohol as required to prevent frothing. The alcohol-soluble substances in the resulting dark brown gum could not be obtained by direct extraction on account of the impermeable nature of the material. Of the several methods tried, the best was to dissolve the gum in an equal volume of hot water and slowly add 10 volumes of hot alcohol with vigorous swirling. Most of the material precipitated and after being cooled to 0° the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

supernatant liquid was decanted. This process was repeated twice more. Frequently the gum which was precipitated on adding alcohol crystallized spontaneously, and after recrystallization of the solid from water, large white rhombs having m.p. 234° (decomp.) were obtained in yields from 2–3% of the dry plant weight. The compound was identified as (−)-asparagine hydrate by comparison of its infrared spectrum and X-ray powder pattern with those of an authentic specimen. Found for the anhydrous compound: C, 36.1; H, 6.0; N, 20.8. Calc. for $C_4H_8N_2O_3$: C, 36.4; H, 6.1; N, 21.2%; $[\alpha]_D^{25}$ −5.2° (*c*, 2.0 in water).

The choline and betaine reineckates were separated from the decanted alcoholic extract in the usual way (20, 24, 25, 26). A quicker method of obtaining the hydrochlorides from the reineckates than the precipitation technique (27) was ion exchange chromatography. Amberlite IRA 401 ion exchange resin was rinsed through two cycles with aqueous sodium hydroxide and hydrochloric acid. The chloride form was washed with methanol and a 50-ml tube was filled with the resin. The reineckate (0.50 g) was dissolved in boiling acetone (20 ml) and diluted with methanol (40 ml). The cooled solution was percolated rapidly through the column and eluted with methanol (100 ml), the operation being completed in 10 minutes. If slower flow rates were used, the absorbed reineckate ion began to decompose on the column, discharging an orange impurity. Removal of solvent from the eluate left a quantitative yield of the mixed betaine hydrochlorides, which were best separated by fractional crystallization. Trigonelline hydrochloride is far less soluble than the other two betaines so when present it was separated by using the minimum volume of boiling absolute ethanol for solution. The filtrate after removal of trigonelline was boiled, and successive additions of hot ethyl acetate gave fractions consisting of almost pure homostachydrine hydrochloride. The stachydrine remaining in the filtrate was very difficult to crystallize because contamination due to the homostachydrine still present rendered the mixture much more soluble than pure stachydrine hydrochloride. In the absence of trigonelline the usual mercuric chloride precipitation was very useful in purifying the betaine fraction.

Extraction Results

In the first three experiments with radioactive lysine, the average yield of betaine hydrochlorides was 0.35 g and the mixture was shown by paper chromatography to consist of stachydrine and homostachydrine in a ratio of *ca.* 1:1. In the fourth experiment, using 400 g of seeds, the yield of betaine hydrochlorides was 0.56 g. The first crystalline fraction (0.14 g) after further recrystallization from alcohol had m.p. 247–250° (decomp.). Found: C, 48.9; H, 4.8; N, 7.7; Cl, 20.3. Calc. for $C_7H_7NO_2.HCl$: C, 48.5; H, 4.65; N, 8.1; Cl, 20.4%. Ultraviolet spectrum in ethanol 0.2 *M* with respect to hydrochloric acid, λ_{max} 266 mμ, log ε 3.67. The ultraviolet and infrared spectra, X-ray powder pattern, and paper chromatograms of the natural sample were completely superimposable on those of a synthetic specimen of trigonelline hydrochloride, prepared by methylation of nicotinic acid according to the procedure of Cornforth and Henry (28). The synthetic material had m.p. 259–260° after softening at 257°. None of the above betaine fractions was radioactive.

R_F values of these compounds in butanol – concentrated hydrochloric acid – water (100:20:39) were: homostachydrine, 0.58; stachydrine, 0.50; trigonelline, 0.41; choline, 0.41; and in 95% ethanol – concentrated aqueous ammonia (95:5) were: homostachydrine, 0.56; stachydrine, 0.50; trigonelline, 0.37; choline, 0.57. Descending chromatography was used and the solvent front travelled *ca.* 18 inches, taking 40 hours in the acid system and 18 hours in the alkaline system. The spots were developed with a modi-

For personal use only.

fied Dragendorff's reagent (29) in which the shade of color produced with fresh reagent was characteristic for these compounds. The reagent was made by dissolving potassium iodide (10 g) in water (10 ml) and glacial acetic acid (20 ml). Bismuth subnitrate (3.4 g) was dissolved in small portions with stirring. If necessary, the solution was filtered and then made up to 60 ml with water. For spraying, this stock solution (1 vol) was diluted with 30% acid (9 vol).

In the extraction of trigonelline from 300 g of alfalfa seeds, 0.52 g of betaine hydrochlorides was obtained (0.17% yield). By fractional crystallization 206 mg of trigonelline and 85 mg of homostachydrine hydrochlorides were separated. The remaining stachydrine fraction (0.23 g) was estimated by the intensity of spots on paper chromatograms to be one third homostachydrine, giving the following analysis of the betaine fraction: trigonelline, 38%; stachydrine, 33%; homostachydrine, 29%.

In the extraction of alfalfa 5 months old, 50 plants grown in soil were used, and the roots and aerial portions were treated separately. The former (dry weight 10 g) yielded 15 mg of stachydrine hydrochloride and the latter (dry weight 43 g) yielded 140 mg. No homostachydrine or trigonelline was detected by paper chromatography.

THE ACTION OF SODIUM IODIDE ON *O*-*p*-TOLUENE-SULPHONYL-1,4;3,6-DIANHYDRIDES OF D-MANNITOL, D-GLUCITOL, AND L-IDITOL[1]

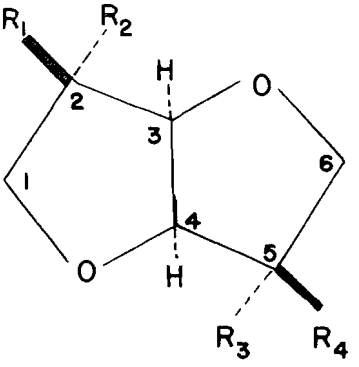
M. JACKSON AND L. D. HAYWARD

ABSTRACT

In the displacement reaction with sodium iodide in acetic anhydride solution the rates of reaction of four isohexide tosyl esters were compared to that of an *O*-acetyl-*O*-tosylisosorbide recently described. The tosyloxy group in the latter compound was replaced rapidly and was therefore in the 5-*endo*-position, the compound being correctly named 2-*O*-acetyl-5-*O*-*p*-toluenesulphonyl-1,4;3,6-dianhydro-D-glucitol. The product of the reaction was isolated as a crystalline material, and was identified as 2-*O*-acetyl-5-deoxy-5-iodo-1,4;3,6-dianhydro-L-iditol.

INTRODUCTION

The 1,4;3,6-dianhydrides of D-mannitol, D-glucitol, and L-iditol (isomannide (I), isosorbide (II), and isoidide (III)) represent a useful series of compounds for the study of reaction mechanisms from a steric point of view. These compounds possess two fused five-membered rings having a *cis*-arrangement of the ring junction. The rings, being nearly planar, are inclined to one another at an angle of about 120°. Substituents on carbon atoms 2 and 5 can either be on the outside of the V formed by the rings when they are called *exo* (R_2, R_3) or on the inside and named *endo* (R_1, R_4). The conformation of the ring system is rigid in as much as it cannot undergo inversion of the type occurring in cyclohexane conformations and the shape and dimensions of the molecules are therefore fairly well known (2).



I	R_1 = OH	R_2 = H	R_3 = H	R_4 = OH
II	H	OH	H	OH
III	H	OH	OH	H

The reaction of sodium iodide with the isohexide di-*O*-*p*-toluenesulphonates (di-*O*-tosylates) has been studied on a qualitative basis by several workers. Hockett *et al.* (3, 4) prepared the 2,5-dideoxy-2,5-diiodo derivative from isomannide di-*O*-tosylate (IV) and a monodeoxy-monoiodo derivative from the isosorbide isomer (V). Matheson and Angyal (5) compared the reaction of these compounds with that of other secondary tosylates by isolating the sodium *p*-toluenesulphonate formed but not the other organic products. These authors found that, in the D-mannitol derivative (IV), both tosyloxy groups are readily replaceable by iodine, but in the D-glucitol derivative (V) only one, and in the L-iditol derivative (VI) neither, tosyloxy group was replaceable. Wiggins and Wood (6), by isolating the dianhydro products, obtained a parallel series of results from reactions of the di-*O*-tosyl and di-*O*-mesyl derivatives with sodium iodide and with lithium chloride respectively. These results confirm that both sulphonoxy groups of the isomannide derivatives and one in the isosorbide derivatives are readily replaced by halide ion, whereas the second group of the isosorbide derivatives and both groups of the isoidide derivatives failed to react under the same conditions.

This behavior was explained (5) by an S_N2 mechanism with attack by the halide ion at the face of the carbon atom opposite the sulphonoxyl group. It may be seen from models that this mode of attack is hindered by the ring system when the group to be displaced is in the *exo* position, as in isoidide derivatives and the 2-position of isosorbide. When the group is *endo*, however, the attack is relatively easy and this situation is found in isomannide derivatives and the 5-position of isosorbide. Other reactions in the isohexide series having an S_N2 mechanism show a similar selectivity (7).

Cope and Shen (1) recently described the preparation of a crystalline *O*-acetyl-*O*-tosyl isosorbide by partial tosylation of the parent compound (II) followed by acetylation. The 2-position was assigned to the *O*-tosyl group since it was considered probable that the *exo*-C_2-hydroxy group was preferentially tosylated.

In the present work the rates of the reaction with sodium iodide of the di-*O*-tosyl isohexides (IV, V, and VI) and of the 2-*O*-tosyl-5-deoxy-5-iodoisoidide (VII) obtained from V were compared to that of the *O*-acetyl-*O*-tosylisosorbide of Cope and Shen in order to show the position of the *O*-tosyl group in the latter compound. Both the sodium *p*-toluenesulphonate and the isohexide products were isolated.

RESULTS AND DISCUSSION

The tosyl esters were treated in acetic anhydride solution at reflux temperature with sodium iodide in the ratio of 1.2 moles of iodide to 1 of *O*-tosyl group. The reaction was stopped at 2, 4, and 8 hours and, after cooling, the precipitated sodium *p*-toluenesulphonate was filtered off and weighed. The yields of the salt obtained are shown in Fig. 1.

The rate curve for the replacement of the tosyloxy group in the *O*-acetyl-*O*-tosylisosorbide closely followed those for the reaction of an *endo* group (IV and one tosyloxy group in V) whereas it was distinctly different from those of the *exo*-tosyl groups (VI and VII). Thus the tosyloxy group in this compound must occupy an *endo* position. In isosorbide this is found at the 5-position and the compound prepared by Cope and Shen (1) was therefore 2-*O*-acetyl-5-*O*-*p*-toluenesulphonyl-1,4;3,6-dianhydro-D-glucitol (VIII).

Confirmation of the rate study came from the isolation in high yield (87%) of a crystalline iodo-compound from the reaction products. This compound melted at 44.0–44.5° C and analyzed correctly for a deoxyiodo-*O*-acetylisohexide. The infrared spectrum con-

(*a*) Sodium iodide, 1.2 moles per mole V; yields calculated for one *O*-tosyl group. With 2.5 moles sodium iodide per mole V the curve was displaced upwards due to the slow reaction of the second tosyloxy group.
(*b*) Acetyldeoxyiodoisoidide isolated in 74% yield.

firmed the presence of the *O*-acetyl group and of the tetrahydrofuran rings. The isoidide configuration was assigned to this compound from comparison with other reactions in this series and the compound was therefore 2-*O*-acetyl-5-deoxy-5-iodo-1,4;3,6-dianhydro-L-iditol (IX).

Cope and Shen (1) found that treatment of the *O*-acetyl-*O*-tosylisosorbide with sodium *t*-butoxide gave a good yield of 1,4;2,5;3,6-trianhydro-D-mannitol and it was proposed that this reaction took place via a normal anhydro-ring-formation reaction, i.e. by an internal displacement of the tosyloxy group by the alkoxide ion formed from the hydrolysis of the *O*-acetyl group. This mechanism is not possible with the *O*-tosyl group in the *endo* position and the *O*-acetyl in the *exo* position. The reaction must therefore proceed via the initial hydrolysis of the *O*-tosyl group followed by the displacement of the *O*-acetyl group or by some transesterification mechanism of the type proposed by Cope and Shen (1).

EXPERIMENTAL

Reaction of the p-Toluenesulphonate Esters of the Isohexides with Sodium Iodide

The sulphur contents, melting points, and specific rotations of the esters together with the reported constants are shown in Table I.

The *O*-tosyl compound (0.005 mole) was dissolved in acetic anhydride (dried and redistilled, 25 ml) and sodium iodide (A.R. grade, 0.0062 or 0.0124 mole) added. The mixture was refluxed for 2 hours, cooled, and left to stand for 30 minutes. The crystalline precipitate was collected by filtration into a weighed sintered glass funnel. The precipitate was washed with acetic anhydride (10 ml) and dried at 100° C to constant weight. The filtrate and washings were combined, refluxed for a further 2 hours, and the precipitate collected as before. The solution from this stage was refluxed for 4 hours before isolation of the final precipitate and the isohexide products.

Isosorbide	OAc	OTs	VIII[e]	9.35	9.2	64–65	+77.9	64–65	+50.5	(1)

[a]Determined by "oxygen flask" method of Lysyj and Zarembo (10).
[b]Compounds were recrystallized from methanol to constant melting points, which are uncorrected.
[c]In chloroform, *c*, 1.1 to 2.0.
[d]Prepared from the reaction of 2.4 moles of sodium iodide on V.
[e]Prepared by partial tosylation of isosorbide following the method of Cope and Shen (1).

After excess acetic anhydride was removed by distillation under reduced pressure, the reaction mixture was shaken with water and chloroform and the aqueous layer was washed with further amounts of chloroform. The combined chloroform extracts were washed with saturated sodium bicarbonate solution, sodium thiosulphate solution (10%), and water, then dried, and evaporated. The resulting syrups crystallized after rubbing at 0° C.

2-O-Acetyl-5-deoxy-5-iodo-1,4;3,6-dianhydro-L-*iditol* (IX)

Treatment of 2-*O*-acetyl-5-*O*-*p*-toluenesulphonyl-1,4;3,6-dianhydro-D-glucitol (2-*O*-acetyl-5-*O*-tosylisosorbide) (VIII) with 1.5 mole excess of sodium iodide as described above gave an 87% yield of crystalline compound. With a 0.24 mole excess of sodium iodide the yield was 74%. Recrystallization several times from methanol gave a product melting at 44.0–44.5° C (uncorr.), $[\alpha]_D^{22}$ +100.5° (*c*, 0.83 in chloroform). Anal. Calc. for a mono-*O*-acetyl-monodeoxy-monoiodoisohexide, $C_8H_{11}IO_4$: C, 32.23; H, 3.72; I, 42.59%. Found: C, 32.46; H, 3.57; I, 42.38%.

The infrared spectrum of the compound (KBr window) showed absorption at 1240, 1370, and 1746 cm^{-1} corresponding to the acetyl group and at 845, 874, and 930 cm^{-1} corresponding to the tetrahydrofuran rings (11).

2,5-Dideoxy-2,5-diiodo-1,4;3,6-dianhydro-L-*iditol* (X)

This compound was isolated from the reaction of 2,5-di-*O*-tosylisomannide (IV) with 0.24 mole excess of sodium iodide. After several recrystallizations from methanol it melted at 65–66° C (uncorr.) and had $[\alpha]_D^{22}$ +110° (*c*, 0.645 in chloroform). Hockett and co-workers (4) had reported m.p. 61–62° C; Wiggins and Wood (6) m.p. 61–63° C, $[\alpha]_D^{19}$ +107.9° (*c*, 1.97 in chloroform).

IONIZATION POTENTIALS OF METHYLAMINES AND ETHYLAMINES BY ELECTRON IMPACT[1]

JACQUES COLLIN

ABSTRACT

Recent determinations of the ionization potentials of methylamines and ethylamines obtained by electron impact have been compared with photoionization results and discussed in relation to the Franck–Condon principle. It seems that the observed discrepancies are mainly due to differences in the sensitivities of the detecting devices.

Six different sets of data on the ionization potentials of aliphatic amines have been published, showing a surprising spread of values going from 0.68 v for methylamine, to 1.60 v for triethylamine, which is much higher than the expected errors of such determinations.

We have therefore remeasured these ionization potentials with a Nier-type mass spectrometer[2] using the semilog method of interpreting the results (1).

TABLE

Ionization potentials of methylamines and ethylamines (in ev)

	Photon impact		Electron impact				
Molecule	(*a*)	(*b*)	(*c*)	(*d*)	(*e*)	(*f*)	This work
Ammonia	10.15	—	—	10.52	—	—	10.34±0.07*
Methylamine	8.97	—	9.8	9.41	9.41	9.65	9.41±0.08
Dimethylamine	8.24	—	9.6	—	9.21	9.5	8.93±0.03
Trimethylamine	7.82	—	9.4	—	9.02	9.2	8.32±0.02
Ethylamine	8.86	<8.8†	—	9.32	—	9.6	9.19±0.05
Diethylamine	8.01	—	—	—	—	9.5	8.44±0.01
Triethylamine	7.50	—	—	—	—	9.1	7.85±0.07

*The errors indicated are precision errors; they only give an idea of the reproducibility of the measurements. The absolute errors can not, of course, be given since no definite interpretation can be given as yet.

†Estimated adlabatic ionization potential; the estimated vertical ionization potential given by the authors is 9.5 v.

(*f*) Collin, J. Bull. soc. chim. Belges, **62**, 411 (1953).

Our values as well as all previously existing data are given in the table, and the following may be said about them:

1. Our new electron impact results are markedly lower than previous data obtained by the same technique, with the exception of methylamine. All ionization curves were very steep and their initial curvature was practically the same as that of the reference rare gases. This is shown by the fact that the results obtained by taking the 0.1% of 50-v abundance value or the 1% of 50-v abundance value are the same within 0.03 v with the exception of methylamine using krypton as a reference gas, where the difference was 0.08 v.

2. Our results are considerably higher than the photon impact values and the explana-

[1]*Manuscript received November 28, 1958.*
Contribution from Institut de Chimie Générale, Université de Liège, 1b, Quai Fr. Roosevelt, Liège, Belgium.
[2]*These measurements were performed in the laboratories of the National Research Council, Ottawa, Canada.*

tion of the important differences observed is not straightforward. The significance of the values depends mainly on the relative position and shape of the potential energy surfaces for the ion and the molecule. If the internuclear distances are the same for both species no such discrepancies should be observed, both photon and electron impact processes being of the Franck–Condon type. This is, however, no more the case if the equilibrium distances are not the same, the discrepancies arising then from the differences in the sensitivities of the detecting devices. The problem is to find the reasons why such modification of internuclear distances occur in the ion.

It is theoretically thought (2) that the ionization of amines proceeds by removal of a non-bonding electron of the nitrogen lone pair. Another possibility is, however, that the ionization is due to the removal of a σ-bonding electron, as has recently been suggested by Hurzeler, Inghram, and Morrison (3) on the basis of their differential interpretation of photon impact data. These authors have also shown that no adiabatic ionization potential could be obtained from the direct experimental ionization curves, for ethylamine and *n*-propylamine. This would explain the literature discrepancies. Since the C–N, C–C, and C–H bond energies are very much the same in amines and hydrocarbons, however, it does not seem that the removal of a bonding electron from the C–N bond would be so much easier in amines than in hydrocarbons (where for instance $I(C_2H_6)$ = 11.76 v and $I(C_3H_8)$ = 11.21 v (4)). The same argument may be applied to the removal of a bonding electron from a C–H or N–H bond, which must have rather higher ionization potentials since $I(CH_4)$ = 13.12 v (4) on one hand, and since in ammonia the corresponding ionization potential is 15.31 v (5) on the other hand. Moreover the small variation of the ionization potential with the length of the hydrocarbon chain in aliphatic amines (6) compared to a considerable one in hydrocarbons (4) is rather in favor of an ionization process on the nitrogen atom.*

In any case, however, the ionization must bring about a change in the state of hybridization of the nitrogen atom which might be responsible for the modification of internuclear distances, and thus of the potential energy surfaces.

The great variation of ionization potentials with substitution on the nitrogen remains to be explained. It should be remembered that the hybridized valence state of the nitrogen atom in these molecules may be represented by the formulas

$$\text{I} \qquad [\mathrm{N}(1s)^2(2s + \delta 2p)^2(2p + \delta' 2s)^3]$$

and

$$\text{II} \qquad [\mathrm{N}(1s)^2(2s + \delta 2p)^2(2p + \delta' 2s)^2(2p + \delta'' 2s)].$$

State I applies to NH_3 and NR_3 types, with different values of the δ parameter according to the nature of the substituent radical R, and state II applies to NRR_2' types, such as encountered in primary and secondary amines, the values of the δ parameters depending again on the nature of R and R′. Therefore, according to the nature of the radicals R, the non-bonding N atomic orbital $(2s+\delta 2p)$ will have different p character and its energy will not be the same. This is the case for the series NH_3, RNH_2, R_2NH, R_3N and the ionization potentials are expected to vary.

It does not seem probable that electrostatic factors arising from the existence of important dipole moments in those molecules may play a significant role in the ionization processes.

**The cause of the considerable differences between mass spectrometric results, although not evident, should probably mainly be attributed to differences in sensitivity of the mass spectrometers used, as indicated above, and, to a certain extent, to the interpretation of the results by different methods. However, the general trend of variation of ionization potentials with hydrocarbon chain length, as indicated in the work of Morrison and Nicholson, is still of application, notwithstanding the correctness of the absolute values.*

3. Except for ethylamine and *n*-propylamine where the photon impact evidence seems conclusive (3) and brings information on the relative positions of the potential surfaces for the ground molecular and ionic states, no definite conclusions as to the real meaning of the available data can be given. It seems, however, that electron impact values, being considerably higher than photoionization ones, refer to vertical transition to a vibrationally excited ion; the true reason for the modification of internuclear distances in the ion is not evident.

THE PROTON RESONANCE SPECTRA OF FURAN AND PYRROLE[1]

R. J. Abraham and H. J. Bernstein

ABSTRACT

Interpretation of the fine structure of the NMR spectra of some five-membered "aromatic" heterocyclic ring compounds indicates that spin coupling constants between adjacent protons on the ring and those across the ring are approximately equal. This is in contrast to the situation in six-membered rings where coupling constants between protons ortho to one another are much larger than those in the meta position.

Quadrupole effects of the N^{14} nucleus in pyrrole broaden the NH signal but do not interfere with the spin coupling of the NH proton with other protons. The surprising result is obtained that the spin couplings of the NH proton with α and β protons in the ring are very nearly equal in magnitude.

The analysis and interpretation of the high resolution proton magnetic resonance spectra of non-benzenoid aromatics have been largely neglected. Corey *et al.* (1) have shown that the magnetic resonance spectra of natural compounds containing furan rings are of considerable help in determining the structure of these compounds, as the position of substitution in the furan ring can be found by inspection of the chemical shift data. Anderson (2) has measured the coupling constants and chemical shifts for 2-bromo-5-chlorothiophen, but no systematic high resolution studies have so far been reported for 5-membered ring compounds.

It is the purpose of this work to present the complete analysis of the spectra of the heterocyclic molecules furan and pyrrole and also to investigate the effect of substitution on the magnitude of the spin–spin coupling constants in these molecules. We shall show that the coupling constants obtained by the analysis of these spectra are very different from those found for benzene systems.

For the analysis of these complex spectra we have employed two simplifying techniques. Firstly, that of substitution to reduce the number of interacting protons: deuterium substitution is preferable as the magnetic constants remain unchanged, but methyl substitution can also be used in many cases since it only changes the coupling constants by a small amount. Secondly, by observing the spectrum of the molecule dissolved in a suitable solvent: very often one group of protons may be more affected by medium effects than the others and this may increase the chemical shift difference between the groups and simplify the fine structure considerably. In particular, the intensity distribution becomes more amenable to simple analytical treatment. This process does not appear to affect the size of the spin coupling constants appreciably, only the chemical shifts. Also, these solution spectra help in an understanding of the nature of the molecular complexes formed in solution and some preliminary investigations of these effects have been made here.

EXPERIMENTAL

The spectra were measured with a Varian V-4300 high resolution spectrometer, incorporating a field stabilizer and operating at 40 Mc/s. A spinning sample tube of 5 mm outside diameter was used. The standard side-band technique was employed to measure the signal separations.

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. This paper was presented at the Symposium on Molecular Structure, Columbus, Ohio, June 1958.
Issued as N.R.C. No. 5178.

The chemical shifts, expressed here in c.p.s. relative to water as an external reference, were measured with a dioxane or cyclohexane reference capillary, adding 58 c.p.s. to the values measured relative to dioxane, and 142 c.p.s. to those measured relative to cyclohexane.

The accuracy of the chemical shift measurements was estimated to be ± 1 c.p.s. and of the coupling constants, ± 0.1 c.p.s.

The furan compounds used are the commercially available samples. The methylated pyrroles were kindly supplied by Dr. E. Bullock and the deuterated pyrrole by Dr. L. Leitch.

RESULTS AND DISCUSSION

(*a*) *Furans*

We shall consider first the spectra of furan and its derivatives. These spectra are simplified by the large chemical shift difference between the 2,5 and 3,4 protons of the ring due to the strongly electronegative oxygen atom. (This numbering procedure is much more convenient than using α and β when discussing derivatives.)

The spectra of furan and 2-furfurol together establish completely the assignments and coupling constants in these compounds. The spectrum of furan (Fig. 1) consists of two

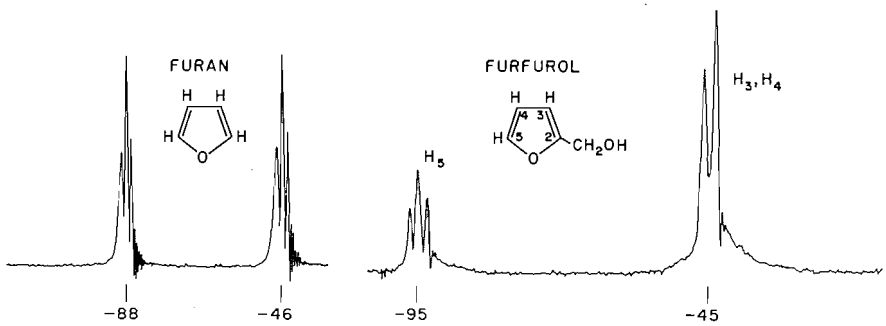

FIG. 1. The proton magnetic resonance spectra of liquid furan and furfurol. The spectrum of the CH_2OH group is not shown. In all figures the direction of increasing applied field is to the right.

widely separated triplets of equal intensity in agreement with earlier observations (1), due obviously to the 2,5 and 3,4 protons of the ring. The spectrum of the ring protons of 2-furfurol (Fig. 1), in which the 2 proton has been replaced by the —CH_2OH group, consists of a low field triplet and a high field doublet of twice the intensity. The intensity distribution immediately shows that the 5 proton is to low field.

The spectrum of furan is of the type A_2X_2 (the nomenclature and full treatment of such systems follows that of Pople, Bernstein, and Schneider (3)). From this analysis, the triplet structure of the component groups in furan can arise when $J_{23} = J_{24}$. The spin coupling constant is then given by the triplet separation and is equal to 1.3 c.p.s. This is confirmed by the spectrum of 2-furfurol. The doublet pattern of the 3 and 4 protons and the triplet structure of the 5 proton are to be expected if $J_{23} = J_{24}$, and from the spectrum the coupling constant is found to be equal to that in furan (1.3 c.p.s.).

Thus in these compounds the adjacent or ortho coupling constant (J_{23}) is almost the same as the cross ring or meta coupling constant (J_{24}), in contrast to the situation in benzene derivatives, where the ortho, meta, and para proton coupling constants are about 8, 2, and 0.5 c.p.s. respectively (4).

The methylene and hydroxyl peaks of 2-furfurol are not shown in Fig. 1. They are to high field and are single peaks. Presumably any coupling between the methylene and hydroxyl proton is quenched by the rapid exchange of the hydroxyl proton. There is also no coupling between the methylene and the ring protons. This is in contrast to the behavior of other groups in this position (see below). Also the $-CH_2OH$ group does not alter the chemical shift of the 3 proton with respect to the 4 proton of the ring. This is again in contrast to the behavior of other groups in this position. For example, in the case of 2-methyl furan and 2-furfural, the 3 and 4 protons have different chemical shifts, giving rise to an ABX-type spectrum (5), and also the 3 proton spin couples with the protons of the substituent group to further complicate the spectrum.

The spectrum of 2-methyl furan is shown in Fig. 2. On the basis of the chemical shift data obtained for furan and 2-furfurol, we assign the low field peak to the 5 proton. This

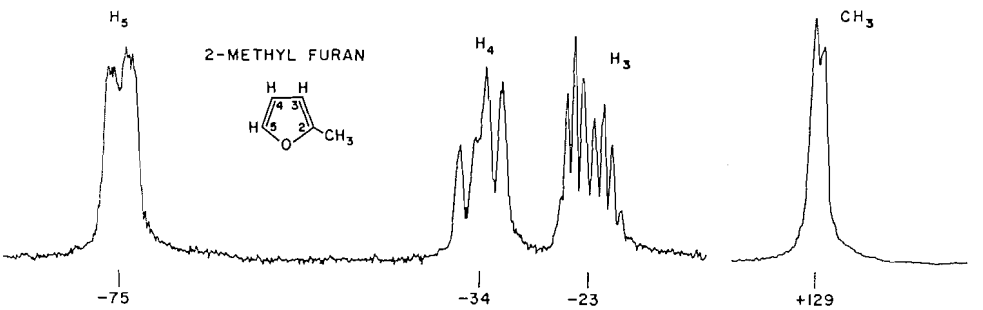

FIG. 2. The proton magnetic resonance spectrum of liquid 2-methyl furan.

is reasonable as the methyl group would not be expected to have any great effect on the electron distribution in the ring. Of the remaining peaks, one of the normal quartet patterns typical of each proton in an ABX-type spectrum (5) is split into more lines by interaction with the methyl group. This group of signals is assigned to the 3 proton since it is reasonable to expect strongest coupling with the proton nearest to the methyl group. The methyl group interaction splits each of the four original lines of this signal into quartets (intensity ratio 1:3:3:1) but the weaker lines will not be observed except on the extreme edges of the signal, so that the main part can be regarded as a quartet split into doublets. However, the splitting due to the methyl is equal to that between the outside pairs of the original quartet so that some overlapping occurs, and thus the complete signal consists of two main triplets with two weak outer lines. The value of the spin coupling constant between CH_3 and H_3 is given directly by the doublet splitting of the methyl group of 0.9 c.p.s. The calculated energies and intensities (i.e. peak heights) for this spectrum are shown along with the observed ones in Table I. Protons 4, 3, and 5 correspond to A, B, and X respectively. Transitions occurring with less than 0.3 c.p.s. separation have been grouped together, as this represents the limit of resolution of the instrument. The intensities for the B group have been normalized separately. The agreement is well within the experimental limits of accuracy. The chemical shifts and spin coupling constants derived from this analysis are given in Table II. The low field signal of proton 5 is not resolved completely into the expected four components, but is more complex and unresolved. This is probably due to a very small interaction of the methyl group with this proton via the oxygen atom. This interaction would be expected to be less than 0.2 c.p.s. and therefore below the limits of resolution of the instrument.

TABLE II

Chemical shifts and coupling constants for furans (shift relative to water (c.p.s.))

	J_{45}	J_{35}	J_{34}	α	β			
Furan	1.3	1.3		−88	−46			
Furfurol	1.3	1.3		−91	−45	OH +4		CH_2 +38
2-Methyl furan	1.7	1.1	3.5	−75	−34, −23		CH_3 +129	
Furfural	1.5	0.9	3.4	−94	−76, −48		CHO −169	
5-Chlormethyl furfural*			3.8		−76, −50		CHO −166	CH_2 +30

*A bulk susceptibility correction of +15 c.p.s. has been added to the chemical shifts. This value was obtained by a comparison of the chemical shifts in furfural and 5-chlormethyl furfural referred to an internal standard.

The spectrum of furfural is shown in Fig. 3. In this spectrum both the individual groups and their component lines are well separated and thus the formal analysis is quite straightforward. However, the complete assignment cannot be made. The spectrum is an *ABX*-type spectrum modified by the coupling of the aldehyde proton to one of the ring protons. This gives rise to the extra fine structure of the low field signal. The coupling constant

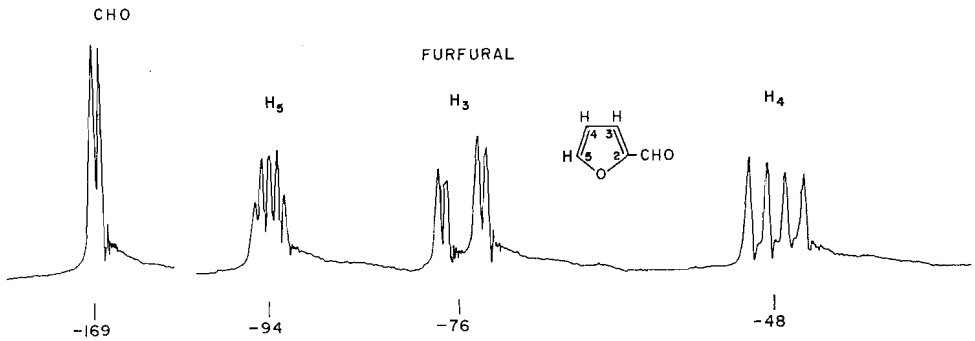

FIG. 3. The proton magnetic resonance spectrum of liquid furfural.

with the aldehyde proton is approximately equal to the spacing in the unperturbed quartet. This results in a quintet of intensity ratio 1:2:2:2:1. The coupling constant is given directly by the size of the aldehyde doublet splitting of 0.7 c.p.s. The remaining chemical shifts and coupling constants for this spectrum are now easily calculated.

However, the assignment of the groups in this spectrum is not clear. On the basis of the chemical shift data, the low field signal would be expected to be that of proton 5 and Corey *et al.* have given this assignment. Further, spin–spin coupling constants are known to be very insensitive to substitution. For example, Richards *et al.* have shown that the coupling constants in a series of para-substituted benzenes vary by less than 10% over a whole range of substituent groups (6). This again supports the assignment of the low field signal in furfural to proton 5 as this would make the coupling constant J_{34} equal to 3.4 c.p.s., in excellent agreement with the value of 3.5 c.p.s. for α-methyl furan.

However, the spin–spin coupling of 0.7 c.p.s. between the aldehyde proton and the proton giving the low field signal would normally be expected to be between the aldehyde proton and the nearest neighbor proton in the ring. On this basis the low field signal would be assigned to proton 3.

This question of the assignment of the low field signal was finally resolved experimentally with the aid of the magnetic resonance spectrum of liquid 5-chlormethyl furfural. In this spectrum the signals of the H_3 and H_4 protons appeared as a quartet (AB group, $J = 3.8$ c.p.s.) and the low field signal of the ring proton spectrum of furfural was absent. This identifies the low field signal with H_5 and further, neither the H_3 proton nor the aldehyde proton showed any signs of fine structure. Thus the surprising result is obtained that fine structure of the aldehyde signal in furfural arises from spin–spin interaction of the aldehyde proton with H_5. The assignments and coupling constants for furfural and 5-chlormethyl furfural are given in Table II. Protons 3 and 4 in furfural are assigned on the basis of the similarity of the coupling constants in furfural to those in α-methyl furan, i.e. the smallest coupling constant is taken as J_{35}. This agrees with the chemical shift data as hydrogen 3 in furfural would be expected to be at lower field than hydrogen 4 due to the influence of the electronegative aldehyde group.

One of the most significant results emerging from this study is the low value of the coupling constants between adjacent protons in these compounds. There are two of these coupling constants, J_{23} and J_{34}, with values of approximately 2 and 3 c.p.s. respectively, in contrast to the value of 8 c.p.s. found in benzene derivatives. These low values we shall show are found also in the pyrrole ring and although thiophen gives a complex and as yet not analyzed spectrum, in 2-bromo-5-chlorothiophen, J_{34} equals 3.9 c.p.s. which is of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

same magnitude as the above values. Thus the magnitude of the ortho coupling appears to be a function of ring size. This is similar to the behavior in the aromatic hydrocarbon rings (7).

(*b*) *Pyrroles*

The spectrum of pyrrole (Fig. 4) consists of a very broad line at low field (not shown in the figure) due to the hydrogen in the NH group (8), and a complex eight line portion

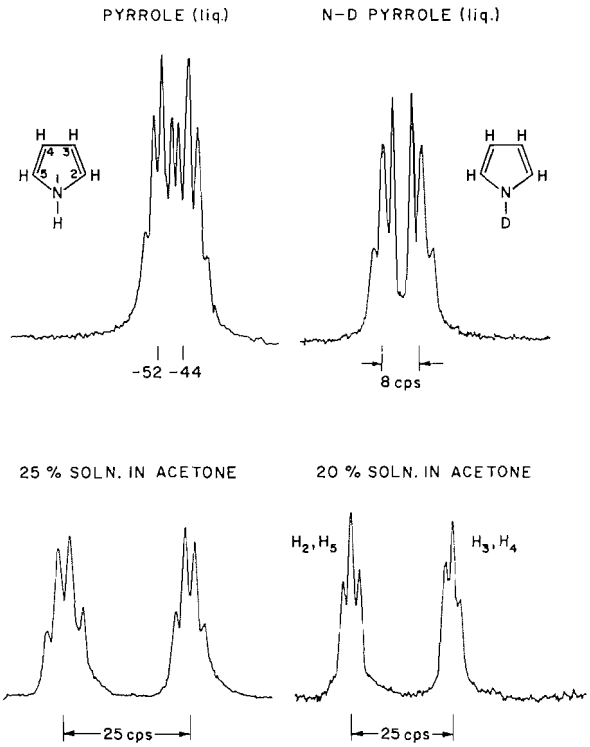

FIG. 4. The proton magnetic resonance spectra of pyrrole and N–D pyrrole. The N–H peak is at low field and not shown.

due to the ring hydrogens. The complete analysis of this A_2B_2X-type spectrum cannot be undertaken without some further experimental results. These were obtained by considering the spectra of pyrrole solutions and also pyrrole derivatives.

The chemical shift difference between the 2,5 and 3,4 protons of pyrrole increases when pyrrole is dissolved in acetone or carbon tetrachloride and the spectrum now splits into two quartets with the 1 proton line shifting to much lower fields and broadening so as to be almost undetectable, but the spacing between the lines in each quartet does not change. Although dilution has effected a considerable simplification in the spectrum, this spectrum can still be interpreted in many ways and the final solution was arrived at by considering the spectra of some methyl- and deuterium-substituted pyrroles. It is apparent that the spectrum of N-deuteropyrrole dissolved in acetone (Fig. 4) is exactly the same as that of furan. This means that in the pyrrole ring as in the furan ring, the ortho coupling constant (J_{23}) equals the meta or cross ring coupling constant (J_{24}) and is equal to the observed separation in the triplets of 1.9 c.p.s. The correct intensity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

pattern for this type of spectrum (triplet ratios 1:2:1) is observed only in the solution case, where the chemical shift is large compared with the spin coupling constant. In the spectrum of the pure liquid these intensities are altered appreciably due to the decrease in the chemical shift, although the separations between the lines remain constant. The spin coupling constants in N-deuteropyrrole must be equal to those in pyrrole and the separation between the lines of the quartets in the solution spectrum of pyrrole is indeed almost equal to this coupling. However, the quartet character in pyrrole must arise from another interaction, namely, the coupling of proton 1 with the other ring protons. In order to obtain the observed spectrum, proton 1 must couple equally to both protons 2 and 3 of the ring and this coupling must be equal to the quadruplet spacing of 2.1 c.p.s. This unexpected result was verified by considering the spectra of 2,3- and 2,5-dimethyl pyrrole (Fig. 5). In the former, protons 4 and 5 will each have a triplet fine structure due

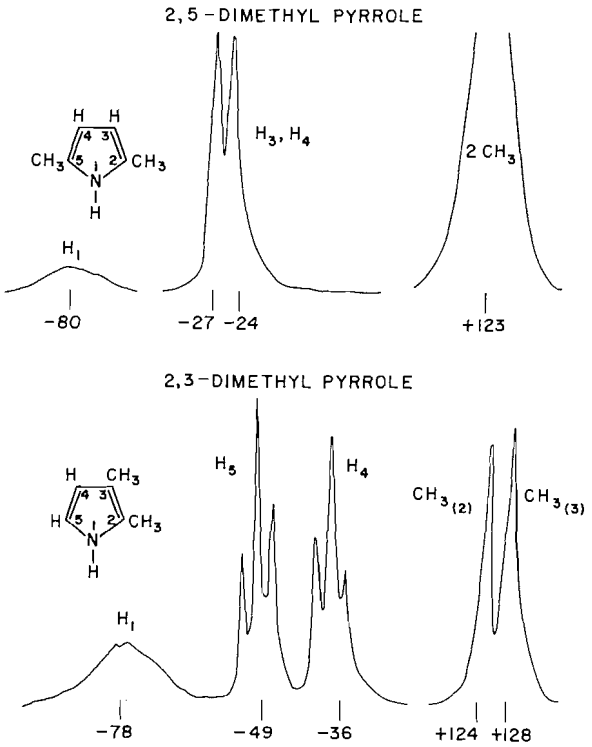

FIG. 5. The proton magnetic resonance spectra of liquid 2,3- and 2,5-dimethyl pyrrole.

to the equal coupling between themselves and proton 1, and in the latter, protons 3 and 4 will be a doublet whose splitting will give directly the coupling constant J_{13} ($=J_{14}$). The coupling constants obtained from these spectra are close to those in pyrrole (see Table III). Note that the splitting due to the spin coupling with the methyl groups is too small to be detected in these compounds. The chemical shift values for these compounds also show that in the pyrroles, as in the furans, the α protons lie to low field (Table III).

The spectrum of 2-methyl pyrrole (Fig. 6) is complicated, as is that of 2-methyl furan, by the different chemical shifts of protons 3 and 4 and the interaction of the methyl

group with proton 3. Although there are several possible assignments for this spectrum, the information obtained from the other pyrrole spectra provides the following means of interpreting this spectrum completely. The low field peak is assigned to proton 5 since the influence of the methyl group on the electron distribution in the ring is small and therefore the order of the chemical shifts would be expected to be the same as in pyrrole.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The sextet fine structure of this peak results if two of the three coupling constants involved (J_{15}, J_{35}, and J_{45}) are equal. In pyrrole all these constants are equal but in this case we assume that the cross ring coupling J_{35} has decreased whilst the others remain constant. This identifies all the three coupling constants immediately. The assignment for the other two protons is now straightforward, the high field peak is identified unambiguously as that of proton 3 by its complex structure, and the separation of the component lines gives the coupling constant $J_{H_3.CH_3}$, which is equal to 0.6 c.p.s. The quartet structure of proton 4 shows immediately that the three coupling constants (J_{14}, J_{34}, and J_{45}) are all equal. The average values for the coupling constants are given in Table III.

Two other substituted pyrroles were examined, 2,4-dimethyl pyrrole and krypto (3-ethyl-2,4-dimethyl) pyrrole. The ring proton peaks of these substances would be expected to be two triplets and a doublet respectively. In fact, they are spread out into broad humps in each case. This may well be due to some extra splitting due to interaction with the methyl groups, which would be expected to be small and therefore unresolvable.

The results of these investigations in the pyrroles are given in Table III. The coupling constants obtained show again the same characteristics as in the furan ring. The adjacent or ortho coupling (J_{23}) is about the same as the cross ring or meta coupling (J_{24}) although slightly larger than in furan. Also there is some change in the coupling constants even with methyl substitution. There are further effects to be noted here, in particular, the size of the interaction between proton 1 and the ring protons and the almost equal values of J_{12} and J_{13}. The peak for proton 1 is broadened by the quadrupole coupling of the N_{14} nucleus into a very broad single line, though it has been reported that the triplet structure characteristic of the N_{14} interaction does appear at higher temperatures (8). However, the quadrupole coupling has no effect upon the coupling of the NH hydrogen to the ring protons. This is a similar situation to that found in formamide (9).

The invariance of these coupling constants when the compound is dissolved in various solvents is well demonstrated in pyrrole. The spacing between the individual lines in the pyrrole quartets does not change when pyrrole is dissolved in carbon tetrachloride, acetone, methanol, or even glacial acetic acid, although the chemical shift separation between the quartets does change appreciably. Pyrrole is known to form weak hydrogen bonds with itself (10) (although there is still some doubt as to the exact nature of these bonds), and also with solvents like acetone, and thus the observed chemical shift changes in this solvent are very probably due to this effect. However, this hydrogen bonding does not appear to affect the value of the coupling constant between the bonded proton and the other ring protons. Also it can be shown that this hydrogen bonding is not accompanied by any rapid exchange process. The spectrum of pyrrole in methanol at 50° C has still the same pattern as at room temperature although that of the methanol consists only of two sharp peaks, since the rapid exchange of the hydroxyl proton removes any fine structure associated with it. To remove a coupling of about 2 c.p.s., proton 1 would have to have a lifetime shorter than about 0.1 second. Thus the lifetime of proton 1 is certainly longer than 0.1 second, which means the exchange rate is slow under these conditions. This proton, however, can be exchanged, since pyrrole was deuterated in this position using heavy water, although this required many processes before the exchange was complete.

NOTE ADDED IN PROOF

The spectra of furan, furfurol, and pyrrole have been interpreted on the basis that $J_{35} = J_{45}$. This is not the only interpretation of these spectra and a more detailed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

analysis (to be presented in a subsequent publication) shows that the correct coupling constants differ slightly from the values quoted above and in particular the two coupling constants are not equal. The observed splitting in these spectra instead of being equal to J_{35} or J_{45} is equal to $(J_{35}+J_{45})/2$.

THE BIOGENESIS OF ALKALOIDS

XXII. SOME INTERMEDIATE STEPS IN THE TRANSFORMATION OF TRYPTOPHAN TO GRAMINE[1]

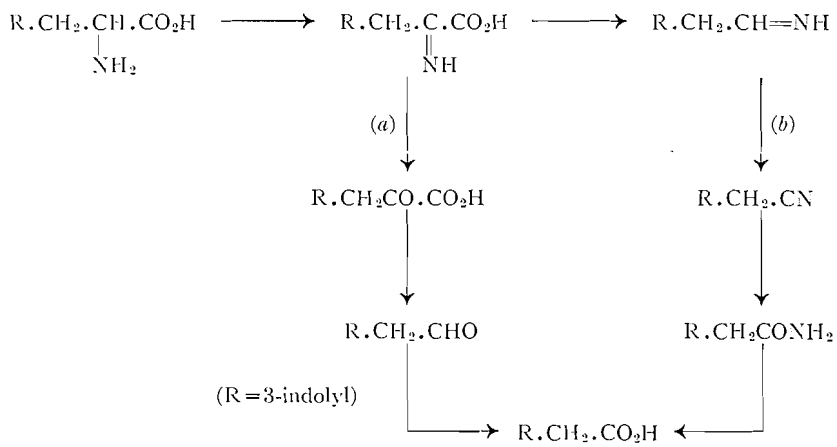
ALBERTO BRECCIA[2] AND LÉO MARION

ABSTRACT

In germinating barley it is known that tryptophan is converted into gramine. In an attempt to find the intermediate steps in this conversion, it has been established that neither 3-indolylacetic acid, 3-indolylglyoxylic acid, 3-indolylaldehyde, nor 3-indolylacetamide (all labelled with ^{14}C in the side chain) was a precursor of gramine. It has been shown, however, that both 3-indolylpyruvic acid and 3-indolylacrylic acid gave rise to radioactive gramine when fed to germinating barley. It is likely that these two acids constitute two intermediates in the pathway tryptophan–gramine.

It has been established earlier (1) that the precursor of the alkaloid gramine is tryptophan, and that the biogenesis involves scission of the side chain of the amino acid not at the indole nucleus as might have been expected, but between the α- and β-carbons (i.e., $R—CH_2—CH(NH_2)CO_2H$). We have now attempted to establish some of the intermediate steps involved in the transformation.

The metabolism of tryptophan, not involving destruction of the indole system, can take place according to Gordon (2) via two potential pathways:



In support of pathway (*a*) Wildman, Ferri, and Bonner (3) had presented evidence that 3-indolylpyruvic acid might be an intermediate in the formation of indolylacetic acid. As a result of paper chromatographic studies, the presence of indolylpyruvic acid has been reported in immature maize kernels (4) and in maize endosperms (5). It has been shown since, however, that indolylpyruvic acid is destroyed on the paper chromatogram under the conditions employed (6) whereas the substance described by Stowe and Thimann (5) is stable, and consequently could not have been indolylpyruvic acid (6).

Furthermore, according to the work of Spenser, Crawhall, and Smyth (7), who have

[1]*Manuscript received February 27, 1959.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 5186.
[2]*National Research Council of Canada Postdoctorate Fellow, 1957–58.*

studied the oxidative decarboxylation of amino acids, it is improbable that indolylpyruvic acid can be an intermediate in the conversion of tryptophan to indolylacetaldehyde.

That indolylacetaldehyde is an immediate precursor of indolylacetic acid in one pathway is indicated by the fact that when homogenates of *Phaseolus mungo* are exposed to X rays the oxidase is blocked, and the aldehyde accumulates in the homogenate while the production of indolylacetic acid decreases (2).

Concerning the second pathway (*b*), indolylacetonitrile has been reported to occur in nature (8, 9, 10), and Stowe and Thimann (11) have shown that *Avena* coleoptiles convert indolylacetonitrile into the corresponding acid.

The metabolism proceeds further, and it has been considered that 3-indolylacetic acid is converted to 3-indolylaldehyde (12) presumably via indolylglyoxylic acid. Manning and Galston (13) have shown, however, that in the presence of indolylacetic acid oxidase from pea seedlings, indolylacetic acid undergoes oxidative conversion into products which do not include 3-indolylaldehyde. They also showed that the aldehyde does not participate as an intermediate in the formation of the final products. On the other hand, their work did not preclude the possibility that in certain plants the metabolism of indolylacetic acid could be via indolylglyoxylic acid to indolylaldehyde, and it was conceivable that the acid and its metabolic products might be intermediates in the conversion of tryptophan to gramine.

When, however, 3-indolylacetic-α-^{14}C acid was fed to germinating barley under conditions identical with those previously described (14), the gramine isolated from the plants showed no radioactivity whatsoever. It was found that most of the radioactivity remained in the nutrient solution (pH 7). The small quantity of radioactivity that became incorporated into the barley was mostly found in the fraction of the extract that contained the acidic and neutral compounds. It thus appeared that the administered indolylacetic acid must have been destroyed very early in the experiment by the action of light or possibly by an oxidase that could be present in the nutrient solution. Indeed, it has been found that 3-indolylacetic acid (100 mg) added to the nutrient solution (100 ml) left after the plants had been harvested was completely destroyed in 3 hours.

In further experiments, 3-indolylglyoxylic-α,β-^{14}C acid was fed to germinating barley, both with and without ascorbic acid, which is known to act as an antagonist of oxidases. The gramine isolated failed to show any radioactivity. 3-Indolylaldehyde (labelled on the aldehydic carbon) was also fed to germinating barley, alone and also in the presence of ascorbic acid. In each case, however, the gramine isolated from the harvested plants was inactive.

In order to test the other possible pathway, 3-indolylacetamide-α-^{14}C was also fed to germinating barley, but with the same negative result.

Unless the negative results described be attributable to the failure of the labelled substances to penetrate into the plant, these results indicate that the conversion of tryptophan to gramine must proceed via a pathway that does not involve 3-indolylacetic acid. It was therefore supposed that the amination necessary for the formation of gramine took place before the rupture of the side chain, i.e., on an indolyl compound still containing a 3-carbon side chain. Such a supposition is supported by the fact that β-(3-indolyl)-acrylic acid and β-(3-indolyl)-lactic acid are known to occur in barley and other plants (9). Although the occurrence of 3-indolylpyruvic acid in plants has not been satisfactorily demonstrated (6), it has been assumed that this acid could be one of the precursors of gramine.

In subsequent experiments 3-indolylpyruvic-β-^{14}C acid was administered to germinating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

barley and the gramine was isolated from the plant after a few days as usual. The gramine thus obtained was radioactive (1.18×10^5 counts per minute per mmole); it was fused with potassium hydroxide and the resulting indolylcarboxylic acid was decarboxylated. The carbon dioxide evolved (isolated as barium carbonate) contained all the radioactivity originally present in the gramine. Hence there has been no randomization and it can be concluded that, as observed previously with tryptophan (1, 14) the β-carbon of the indolylpyruvic acid is still present in the gramine, and that the scission of the side chain of the acid occurred between the α- and β-carbons.

Experiments in which 3-indolylacrylic-β-^{14}C acid was fed to germinating barley were also performed. The results were similar to those obtained with indolylpyruvic acid, and the gramine isolated from the plants was radioactive. The radioactivity again was located on the CH_2 of the gramine, as shown by the results of the degradation of the alkaloid.

EXPERIMENTAL

Preparation of the Labelled Compounds

The indolyl derivatives were prepared by slight modifications of known methods. A sample of each compound was chromatographed on paper to make sure of its purity.

Radioactive gramine was synthesized from polyoxymethylene-^{14}C first hydrolyzed to formaldehyde and then condensed with indole and dimethylamine as described by Kuhn and Stein (15). The yield of radioactive gramine based on polyoxymethylene was 80%. Sp. act. 5.26×10^7 c.p.m. per mmole.

Indolyl-3-aldehyde was prepared via the methosulphate of gramine labelled with ^{14}C in the CH_2 of the side chain by the method of Thesing (16). Using smaller quantities of tetrahydrofuran and glacial acetic acid than those specified resulted in an increased yield of aldehyde, m.p. 196°. Yield 55%. Sp. act. 4.12×10^7 c.p.m. per mmole.

3-Indolylglyoxylic acid was prepared by the condensation of indole with diethyloxalate-1,2-^{14}C (17) obtained by esterification of silver oxalate-1,2-^{14}C with ethyliodide. Sp. act. 3.89×10^7 c.p.m. per mmole.

3-Indolylacrylic-β-^{14}C acid was prepared by condensation of radioactive indolylaldehyde with ethyl malonate in pyridine containing a small quantity of piperidine according to the well-known method. The acid, m.p. 198–200 (decomp.), was obtained in 48.2% yield and 20% of the aldehyde used was recovered. The specific activity of the 3-indolylacrylic acid was 4.32×10^7 c.p.m. per mmole. A paper chromatogram of the acid with the solvent benzene – propionic acid – water (100:70:5) was developed during 12 hours and brought out with a 1% solution of *p*-dimethylaminobenzaldehyde in *N* hydrochloric acid. It showed two spots, one with the R_f of the acid, the other with the same R_f as 3-indolylaldehyde. The radioactivity of the aldehyde spot was 100 counts per minute, and that of the acid spot was 1.0×10^4 counts per minute. Hence the radioactivity of the product is 99% due to the acid and 1% due to the aldehyde still present.

3-Indolylpyruvic-β-^{14}C acid was prepared from radioactive indolylaldehyde as described by Ellinger and Matsuoka (18). Yield 50.3%, m.p. 205–210° (decomp.). Sp. act. 5.04×10^7 c.p.m. per mmole.

3-Indolylacetamide-α-^{14}C was obtained from the action of potassium cyanide on radioactive gramine as described by Snyder and Pilgrim (19). Yield 50.4% based on the gramine, m.p. 149–150°. Sp. act. 4.30×10^7 c.p.m. per mmole.

Administration of the Radioactive Compound to the Barley

A 700-g sample of Charlottetown No. 80 barley was evenly divided among twelve 20×25 cm Pyrex glass trays. Distilled water (50 ml) was added to each of the trays,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

which were placed in a closed germination cabinet. The barley was watered daily. On the sixth day of sprouting, a solution of the labelled substance was added to each of the trays, and the barley allowed to grow for a further 5 days, all as previously described (20).

The barley was harvested on the 11th day of sprouting, the shoots worked up as described before (14), and the gramine isolated.

Because of the low solubility of 2-indolylaldehyde in water, this substance (32 mg, total activity 4.48×10^6 c.p.m.) was dissolved in 65% ethanol (10 ml) and the solution added to the trays of growing barley. After a lapse of 8 hours, distilled water (600 ml) was gradually added to the trays over a period of 6 hours.

The 3-indolylpyruvic acid (50 mg) used in the feeding experiments had a specific activity of 5.04×10^7 c.p.m. per mmole, and the gramine (121 mg) isolated had an activity of 1.18×10^5 c.p.m. per mmole.

The 3-indolylacrylic acid (71 mg) fed to the barley had an activity of 4.32×10^7 c.p.m. per mmole, and the gramine obtained from the plants treated with this acid had a specific activity of 1.86×10^5 c.p.m. per mmole.

Degradation of Gramine

(*a*) Some of the radioactive gramine obtained from the plants was converted to the methiodide and treated with sodium methoxide as described by Madinaveitia (21). The reaction was carried out as in previous cases (14) and the liberated dimethylamine isolated as ethyldimethylamine picrate showed no radioactivity.

(*b*) A quantity of gramine (13 mg) of specific activity 1.38×10^4 c.p.m. per mmole was mixed with inert gramine (150 mg) and fused with potassium hydroxide (3 g) as described previously (14) and the resulting 3-indolylcarboxylic acid was heated at 190–230° in a stream of nitrogen. The stream of nitrogen and evolved gas was bubbled through a barium hydroxide solution, and the precipitated barium carbonate was filtered and dried. It had a specific activity of 1.36×10^4 c.p.m. per mmole.

DISCUSSION

Since neither 3-indolylglyoxylic acid, 3-indolylaldehyde, nor 3-indolylacetamide are precursors of gramine in barley, it is not surprising that as now shown, and as Henry and Leete (22) have recently reported, 3-indolylacetic acid should also fail to act as a precursor of gramine. Unless it be assumed that each of these four labelled substances was destroyed in the nutrient solution instead of penetrating into the plant, as indeed indolylacetic acid was, then it must be concluded that the pathway in the transformation of tryptophan to gramine is not via indolylacetic acid.

On the other hand, both 3-indolylpyruvic acid and 3-indolylacrylic acid are precursors of gramine. Since the alkaloid, obtained from barley fed with indolylacrylic acid, was more strongly radioactive than that isolated from barley fed with indolylpyruvic acid, it is probable that indolylpyruvic acid is the precursor of indolylacrylic acid. It is assumed, therefore, that in the first step of the biogenesis tryptophan is converted by transamination to 3-indolylpyruvic acid from which at a further stage in the same pathway 3-indolylacrylic acid is formed. Experiments are underway to attempt to determine at which stage amination occurs.

THE NATURE OF PYRACONITINE[1]

D. J. McCaldin[2] and Léo Marion

ABSTRACT

A new investigation of pyraconitine and pyraconine has confirmed the presence of a skeletal carbonyl in these compounds. Reduction of pyraconitine with sodium borohydride produces a hydrolytic base which no longer contains a carbonyl group. The Wolff–Kishner reaction reduces the carbonyl in pyraconitine, eliminates the elements of methanol, and hydrogenates the resulting double bond as well as hydrolyzing off the benzoyl ester. These observations indicate the presence in aconitine of the sequence $R_2C(OAc).CHOH.CH(OCH_3)$-. On the basis of the structure of aconine previously derived from the X-ray structure of demethanolaconinone the foregoing results determine the skeletal position occupied by the labile acetoxy group in aconitine.

It has long been known (1) that aconitine ($C_{34}H_{47}O_{11}N$) when pyrolyzed eliminates acetic acid and gives rise to pyraconitine ($C_{32}H_{43}O_9N$). The loss of acetic acid has been variously interpreted as producing an epoxide (1, 2), an ethylenic linkage (3), or a carbonyl group (4). The last interpretation was based on the presence of a broad absorption band in the infrared spectrum of pyraconitine and a weak band in the spectrum of pyraconine hydrochloride. The ethylenic linkage suggested by Schneider (3) would, on the basis of his proposed structure for aconitine, require that the salts of pyraconitine be anhydronium salts, and neither the hydrochloride of pyraconitine nor that of its hydrolytic product pyraconine show the characteristic absorption of anhydronium salts in the infrared, so that this suggestion can be discarded. A new investigation of pyraconitine has therefore been undertaken, and the results obtained confirm the presence of a carbonyl in the pyrolytic products and permit the location of the acetoxy group in the carbon–nitrogen skeleton of the alkaloid.

Crystalline pyraconitine was prepared by heating aconitine to 185–190°. Its saponification product, pyraconine ($C_{25}H_{39}O_8N$), was isolated as the crystalline hydrochloride. The infrared spectrum of pyraconitine contained a split absorption band at 1696–1717 cm^{-1} due to the benzoyl ester carbonyl and a second carbonyl in a six-membered ring. The latter was confirmed by the presence of a weak band at 1709 cm^{-1} in the infrared spectrum of pyraconine, which no longer contains the benzoyl group. In order to ascertain whether this weak carbonyl band was significant a solution of pyraconine in chloroform, of known concentration, was used for the infrared spectrum. The carbonyl band had an extinction coefficient $\epsilon^{(a)}_{max}$ 300, thus showing it to be a true carbonyl absorption band, since the absorption is significant when $\epsilon^{(a)}_{max} > 200$ (5). Furthermore, this absorption peak no longer showed in the infrared spectrum of the Wolff–Kishner reduction product of pyraconitine. On treatment with sodium borohydride, pyraconitine underwent hydrolysis as well as reduction of the carbonyl group to a hydroxyl and gave rise to a compound, $C_{25}H_{41}O_8N$, which in the infrared showed no absorption in the region 1600–1850 cm^{-1}. Had the reaction not involved the reduction of a skeletal carbonyl the product should have been identical with pyraconine, but it proved to be quite different. These results, therefore, confirm the conclusion of Shima and Amiya (4) that the elimination of acetic acid in the pyrolysis of aconitine is accompanied by the formation of a carbonyl group.

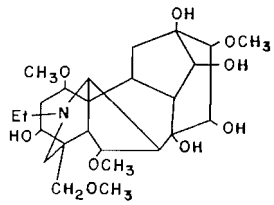
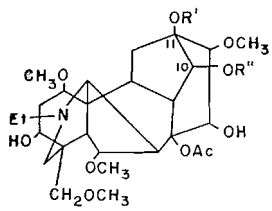
The Wolff–Kishner product of pyraconitine had the empirical formula $C_{24}H_{39}O_6N$, and contained only three methoxyl groups. Hence the reaction involved not only the reduction of the carbonyl to a methylene and saponification of the benzoyl group as expected; it also involved the loss of methanol and the hydrogenation of the resulting double bond. The absence of a double bond was evidenced by the infrared spectrum, which contained no absorption bands characteristic of such a function, and also by the attempted catalytic hydrogenation, which yielded the unchanged material. The Wolff–Kishner reaction is known to follow such a course when the carbonyl is α to a methoxyl, although in some cases the product is unsaturated (6).

In order that the elimination of acetic acid might give rise to a ketone it is necessary that the acetoxy group in aconitine be vicinal to a secondary hydroxyl, and to account for the behavior of pyraconine in the Wolff–Kishner reduction it is also necessary that this hydroxyl be vicinal to a methoxy group. It must be concluded, therefore, that aconitine contains the sequence of substituents $R_2C(OAc).CH(OH).CH(OCH_3)$- and that pyraconine contains the sequence $R_2CH.CO.CH(OCH_3)$-, which in the Wolff–Kishner reduction product becomes $R_2CH.CH_2.CH_2$-.

From the X-ray crystallographic study of demethanolaconinone hydriodide trihydrate (7) it follows that the structure of aconine is that represented by formula I. If we assume that no ring enlargement accompanies the pyrolytic reaction, then structure I presents



I



II

only one choice for the location of the acetoxy group in aconitine whose structure is shown by formula II where either R′ or R″ = C_6H_5CO and the other is H. It has previously been shown that the secondary hydroxyl in ring A is unsubstituted (8) and hence the benzoyl ester group can only be in either position 10 or 11 (cf. for numbering see ref. 8). It is hoped from current work to determine which of these two positions is occupied by the benzoyl ester group.

Aconitine possesses many points of similarity with delphinine. Like it, it possesses a bicyclo(1,2,3)octane system (9) which, however, contains one more hydroxyl group due to which the pyrolytic derivatives obtained from the two alkaloids are of a different nature. Jacobs and Pelletier (10) have shown that in delphinine it is a secondary hydroxyl on a five-membered ring that is esterified with benzoic acid. On the assumption that a similar situation exists in aconitine, the structure II (R′ = H, R″ = COC_6H_5) is preferred.

EXPERIMENTAL

All infrared absorption spectra were measured on nujol mulls, unless otherwise mentioned, with a Perkin–Elmer double beam spectrometer Model 21B. The melting points were determined on a Kofler hot stage and were not corrected.

Pyraconitine

Aconitine (1 g) was heated at 185–190° (metal bath) in a slow stream of nitrogen until effervescence ceased. The pale yellow liquid was cooled and dissolved in the minimum quantity of hot acetone. Hexane was added dropwise until a slight turbidity was observed. After some time pyraconitine crystallized as colorless needles (510 mg), m.p. 167–168° (literature gives 167.5° (1)). It had $[\alpha]_D^{24}$ −103° (*c*, 1.21 in ethanol) and pK_a 7.72 (determined in 50% ethanol). Found: C, 65.26; H, 7.21. Calc. for $C_{32}H_{43}O_9N$: C, 65.62; H, 7.46%. Infrared spectrum: 1696 cm^{-1} (skeletal carbonyl), 1717 cm^{-1} (ester carbonyl), the hydriodide crystallized as pale yellow rosettes from acetone–ether, m.p. 218–220°. Infrared spectrum: 1720 cm^{-1} (broad) due to ester and skeletal carbonyl groups.

Pyraconine

Pyraconitine was saponified with alcoholic sodium hydroxide and the product isolated as the hydrated hydrochloride, which separated from water as colorless prisms, m.p. 135° (literature (2) gives m.p. 135°), $[\alpha]_D^{22}$ −126.7° (*c*, 1.20 in water). Infrared spectrum: 1709 cm^{-1} (six-membered ring carbonyl).

Wolff–Kishner Reduction of Pyraconitine

Pyraconitine (230 mg) was dissolved in triethylene glycol (3 ml) and 95% hydrazine (2.5 ml) added to the solution. The reaction mixture was maintained at 150° for 1 hour under an atmosphere of nitrogen. Solid potassium hydroxide (1 g) was then added to the mixture and the temperature raised and maintained at 185° for a further hour. The dark reaction mixture was cooled and water (10 ml) was added. The aqueous solution was then extracted with six 20-ml portions of ether and the combined extract dried over magnesium sulphate. Evaporation of the ether extract yielded a gum (105 mg) that failed to crystallize, but formed a perchlorate that crystallized from a mixture of acetone and ether as colorless prisms, m.p. 258–259° (decomp.), $[\alpha]_D^{22}$ +61.9 (*c*, 1.25 in ethanol). Found: C, 53.70; H, 7.05; OMe, 17.03. Calc. for $C_{24}H_{39}O_6N.HClO_4$: C, 53.55; H, 7.26; $3OCH_3$, 17.36%.

Sodium Borohydride Reduction of Pyraconitine

Pyraconitine (370 mg) was dissolved in 80% methanol (10 ml) and sodium borohydride (150 mg) was added to the solution. After 1 hour, the solution was evaporated *in vacuo* and the residue dissolved in water (5 ml). The solution was extracted with five 10-ml portions of chloroform and the dried extract evaporated. There was left a gummy residue (280 mg) which formed a hydrochloride that crystallized from aqueous acetone as colorless prisms. The melting point was variable but fusion started at 155–156°, $[\alpha]_D^{21.5}$ −23.4 (*c*, 2.70 in water). Found (sample dried at 50° for 2 hours): C, 54.57; H, 8.27. Calc. for $C_{25}H_{41}O_8N.HCl.2H_2O$: C, 54.10; H, 8.27%. Found (sample dried at 100° at 0.1 mm for 3 days): C, 55.95; H, 8.45. Calc. for $C_{25}H_{41}O_8N.HCl.H_2O$: C, 55.84; H, 8.10%.

ACKNOWLEDGMENTS

We acknowledge our indebtedness to Mr. R. Lauzon and Dr. R. Norman Jones of these laboratories for the preparation of the infrared absorption spectra, and for discussions as to their interpretation.

ISOTOPIC AND HOT RADICAL EFFECTS IN THE REACTION OF HYDROGEN ATOMS WITH ETHYLENE[1]

A. H. TURNER[2] AND R. J. CVETANOVIĆ

ABSTRACT

Reactions of D atoms with C_2H_4, H atoms with C_2D_4, and H atoms with C_2H_4 at room temperature are compared. Pronounced differences in the extent of isotopic exchange have been found. The observed isotopic and pressure effects provide evidence for the importance of "hot" ethyl radicals in these reactions and their responsibility for isotopic exchange. The atoms are generated by the mercury-photosensitized decomposition of hydrogen and deuterium and their concentration is sufficiently small so that "atomic cracking" does not occur.

INTRODUCTION

Addition of a hydrogen atom to a molecule of ethylene leads to the formation of an energy-rich ethyl radical. The need to take into account the formation and subsequent reactions of such "hot" ethyl radicals in order to explain and reconcile seemingly divergent experimental information from various sources has been recently stressed by Bradley, Melville, and Robb (1).

In the present work additions of H and D atoms, respectively, to ethylene have been compared at various pressures. Similar systems have been recently studied by Toby and Schiff (2) but at very low pressures and at high atom-to-ethylene ratios so that "atomic cracking" was favored and methane was the main product, with only smaller amounts of ethane and ethylene and traces of butane and propane. In contrast to this in the present work the ratio of concentrations of the atoms and ethylene has been sufficiently small so that atom–radical reactions have been negligible and the only observed products are butane, ethane, and ethylene, resulting from combination and disproportionation of ethyl radicals.

From the observed effect of pressure on the amounts and isotopic structure of products, direct evidence has been obtained for the important role of "hot" ethyl radicals in these reactions as well as for their responsibility for the occurrence of isotopic exchange. The reactions have been carried out at room temperature where attack of thermalized free radicals on H_2 or D_2 is too slow to be of importance. In view of the difference in the strengths of CD and CH bonds an isotopic effect has been anticipated, and it has been found that isotopic exchange occurs when D atoms add to C_2H_4 but not when H atoms add to C_2D_4. As a result the *course* of the reaction in the two cases is quite different. Some information on the mechanism of disproportionation of ethyl radicals has also been obtained.

EXPERIMENTAL

A conventional high vacuum apparatus was used with a cylindrical quartz reaction cell 5 cm in diameter and 10 cm long. Mercury resonance radiation was obtained from a low pressure mercury arc situated some 20 cm from the reaction cell and was roughly collimated with a highly polished aluminum cylinder.

Research grade ethylene was employed and hydrogen was purified by passage through a heated palladium thimble. Tetradeuteroethylene, at least 99 atom % pure, was kindly supplied by Dr. L. C. Leitch of these laboratories.

RESULTS

All experiments were performed at room temperature and the results for H + C_2D_4, D + C_2H_4, and H + C_2H_4 are given in Tables I, II, and III, respectively. Large excess of hydrogen (or deuterium) and very small amounts of ethylene were used. This ensured essentially quantitative quenching of the Hg $6(^3P_1)$ atoms by hydrogen and also made feasible mass spectrometric analyses of the recovered C_2 hydrocarbons without necessitating excessively long exposures.

Butanes and C_2 hydrocarbons were condensed in liquid nitrogen and, after the unreacted excess hydrogen was pumped off, were separated by a LeRoy still (3), measured with a constant volume gas burette, and then analyzed by mass spectrometry. No products other than those shown in the tables were detected. The observed mass balance was usually slightly below 100%, in all probability due to the difficulty of quantitatively recovering C_2 hydrocarbons from the large excess of hydrogen employed. For this reason, besides the values actually observed for ethylene and ethane, the "corrected" values are also given in the Tables I–III. The latter were calculated by assuming complete recovery of butane and scaling up the C_2 fraction to obtain 100% carbon atom balance. The amount of the C_2 fraction was, therefore, assumed to be equal to the original ethylene less twice the amount of the recovered butane. The relative proportions of ethylenes and ethanes were then calculated from the mass spectrometric analyses of the recovered C_2 fraction. In general, these corrections were not particularly large.

The mass spectrometric analyses were subject to the usual uncertainties in the values of the lighter constituents, especially when they were formed in very small amounts, because of cumulative errors in the corrections for the fragment peaks of the heavier constituents present.[3] Thus in Table I, in addition to the two ethanes, C_2D_5H and $C_2D_4H_2$,

TABLE I

some $C_2D_3H_3$ is also indicated. However, the analytical uncertainty for this compound is so high that it is not certain whether it is formed at all and it has, therefore, been omitted from the table. Similarly, the figures for C_2D_3H are only approximate. The ratio of C_2D_5H and $C_2D_4H_2$, on the other hand, should be reliable. The C_4 fraction consists in this case of essentially pure $C_4D_8H_2$ (with less than 0.3% of d_9 and d_{10} butanes) and the indications are that the two H atoms are on the terminal carbon atoms. In Table II the figures for C_2H_4, C_2H_3D, C_2H_6, and C_2H_5D are probably not too accurate and, similarly, in the C_4 fraction the figures for C_4H_{10} are not too reliable.

[3]*The mass spectra of the deutero compounds from the American Petroleum Institute catalog of mass spectral data were used where available. In other cases estimates of probable fragment intensities were made by analogy with the known spectra.*

The analytical uncertainties preclude a detailed quantitative analysis of the pressure dependence of the investigated reactions and for this reason no attempt has been made at present to accumulate more extensive experimental data. Fortunately, the values for the major products formed are in general reasonably reliable. There can, as well, be little doubt of the reality of the general trends observed and in particular of the pronounced difference in the complexity of the products shown in Tables I and II, respectively. As a result a number of conclusions can be safely drawn.

DISCUSSION

A significant result of the present work is the finding that isotopic exchange takes place readily when D atoms add to C_2H_4, even at relatively high pressures of D_2, while there is no exchange when H atoms add to C_2D_4. In the former case the formation of different isotopic butanes indicates, besides C_2H_4D radicals, the presence of C_2H_5 and $C_2H_3D_2$ radicals as well. In the latter case, on the other hand, only C_2D_4H radicals are present.

The amount of isotopic exchange in the reaction of D atoms with C_2H_4 (Table II) increases at lower pressures of D_2 and the following reactions have, therefore, to be considered:

$$C_2H_4 + D \rightarrow C_2H_4D^* \quad [1]$$

$$C_2H_4D^* \rightarrow C_2H_3D + H \quad [2]$$

$$\left[\text{or} \quad C_2H_4D^* + C_2H_4 \rightarrow C_2H_3D + C_2H_5^* \quad [2a]\right]$$

and

$$C_2H_4D^* + M \rightarrow C_2H_4D + M \quad [3]$$

with subsequent reactions of the H atoms produced in reaction [2] and recombination and disproportionation of the ethyl radicals formed. Addition of H atoms to the original ethylene, C_2H_4, produces C_2H_5 and as the conversion increases, D atoms will add to C_2H_3D formed in reaction [2] to give increasing amounts of $C_2H_3D_2$. The observed trends with pressure and over-all conversion in the amounts of various butanes formed in the reaction of D atoms with C_2H_4, as shown in Table II, are in qualitative agreement with the indicated reactions.

In the reaction of H atoms with C_2D_4 (Table I) the only equivalent of reaction [2]

which occurs is

$$C_2D_4H^* \rightarrow C_2D_4 + H \qquad [4]$$

$$\left[\text{or} \quad C_2D_4H^* + C_2D_4 \rightarrow C_2D_4 + C_2D_4H^* \qquad [4a]\right]$$

but not

$$C_2D_4H^* \rightarrow C_2D_3H + D \qquad [5]$$

$$\left[\text{nor} \quad C_2D_4H^* + C_2D_4 \rightarrow C_2D_3H + C_2D_5^*. \qquad [5a]\right]$$

No isotopic exchange is therefore observed.

The difference between the two cases is readily understandable in view of the difference in the bond dissociation energies between a C–D and a C–H bond as a result of the difference in the zero point energies. When a H atom adds to C_2D_4, the hot $C_2D_4H^*$ radical possesses enough excess energy to undergo reaction [4] but not reaction [5]. When a D atom adds to C_2H_4, on the other hand, the hot $C_2H_4D^*$ radical formed possesses enough excess energy to split off a D or a H atom, and both the statistical and the energetic conditions favor the latter (reaction [2]).

The isotopic structure of the ethanes formed and the pressure effects observed in these experiments are of interest from the point of view of "disproportionation" of ethyl radicals. Under conditions of the present work, ethane could not have been formed by combination of methyl radicals because if this were so appreciable quantities of propane would have been formed as well and this was not the case. Reaction of H atoms with C_2D_4 is relatively simple and the analytical results in Table I for the two ethanes formed, C_2D_5H and $C_2D_4H_2$, are reasonably reliable. (Some $C_2H_3D_3$ might have been produced as well but this is highly uncertain.) C_2D_6 is not formed. These results are not inconsistent with the "head-to-tail" disproportionation mechanism of Wijnen and Steacie (4). The ratio $C_2D_4H_2/C_4D_8H_2$ increases at lower pressures while the ratio of $C_2D_5H/C_4D_8H_2$ is pressure-independent. The following reactions ought then to be considered:

$$C_2D_4H + C_2D_4H \rightarrow C_2D_5H + C_2D_3H \qquad [6]$$

$$C_2D_4H + C_2D_4H \rightarrow C_2D_4H_2 + C_2D_4 \qquad [7]$$

$$C_2D_4H^* + C_2D_4H \rightarrow C_2D_4 + C_2D_4H_2^* \qquad [8]$$

$$C_2D_4H_2^* + M \rightarrow C_2D_4H_2^* + M. \qquad [9]$$

Reactions [6] and [7] involve thermalized radicals and lead, therefore, to a pressure-independent ratio of $C_2D_5H/C_4D_8H_2$. Reaction [8] explains the increase in $C_2D_4H_2$ as the pressure is lowered. It appears therefore necessary to assume that under the conditions employed in these experiments an H atom is abstracted much more readily than a D atom from a hot C_2D_4H radical in spite of the more favorable statistical ratio of D atoms. It is unlikely that $C_2D_4H_2$ was formed by addition of H atoms to C_2D_4H since, if anything, the pressure dependence would then be opposite to that observed.

In contrast to the results obtained in the present work, Dills and Rabinovitch (5) obtained a more complex isotopic structure of the products in an experiment with C_2D_4 and H atoms at a total pressure of about 4 mm, using a simulated point source (nozzle) of H atoms, and maintaining a spherical diffusion reaction zone. The butanes consisted of $C_4D_8H_2$ (83%), C_4D_9H (15%), and C_4D_{10} (2%) and the ethanes of C_2D_6 (63%), C_2D_5H (18%), and $C_2D_4H_2$ (19%). This was interpreted to show that the mechanism of disproportionation is not "head-to-tail" but rather that the disproportionation takes place with more than one atom migrating. This conclusion cannot be of general validity since C_2D_6, C_4D_9H, and C_4D_{10} are not formed in the same reaction under conditions employed in the present work in which the products formed are consistent with a "head-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

to-tail" disproportionation. The more complex isotopic structure of the butane and ethane obtained by Dills and Rabinovitch appears to be due to the particular conditions employed by these authors and the reason for the greater complexity is not quite clear. Perhaps at very low pressures some exchange involving transfer of D atoms does occur. Since reaction [5] is slightly endothermic while [5*a*] is exothermic, the latter would perhaps provide the more readily acceptable mechanism of such an exchange. However, further experimental information is necessary before any firm conclusions can be drawn.

In the reaction of D atoms with C_2H_4 (Table II) no $C_2H_4D_2$ is formed at low conversions, and the disproportionation of C_2H_4D radicals (including also the reactions involving $C_2H_4D^*$) is, therefore, entirely by abstraction of a hydrogen atom.

$$C_2H_4D + C_2H_4D \rightarrow C_2H_5D + C_2H_3D \quad [10]$$

$$C_2H_4D + C_2H_4D^* \rightarrow C_2H_5D^* + C_2H_3D \quad [11]$$

$$C_2H_5D^* + M \rightarrow C_2H_5D + M \quad [12]$$

Abstraction of hydrogen atoms is here favored both statistically and energetically. Only at higher conversions $C_2H_4D_2$ is formed as a result of the eventual addition of D atoms to C_2H_3D produced in the course of the reaction. Formation of C_2H_6 is a consequence of the readily occurring isotopic exchange (reaction [2] or [2*a*]).[4]

A striking feature of the results of the performed experiments is the fact that the isotopic exchange (reactions such as [2] or [2*a*]) and the "hot radical" effects in the disproportionation (reactions such as [8] and [11]) persist to quite high H_2 or D_2 pressures. The occurrence of reactions such as [2] at high pressures could be explained by assuming very short natural lifetimes of the energy-rich radicals and perhaps, as is frequently done, a very readily occurring deactivation by collision for this particular process. The occurrence of reactions such as [8] and [11], on the other hand, must mean that the energy-rich ethyl radicals are deactivated in collisions only extremely slowly and are capable of undergoing preferential disproportionation (and exhibiting as well a strong isotopic effect in disproportionation), even after undergoing numerous collisions in the gas phase with H_2 or D_2 and with ethylene. Thus, for example, although in the reaction of H atoms and C_2D_4 the ratio of the concentrations of hydrogen at a pressure of 100 mm and C_2D_4H (calculated approximately from the rate of formation of $C_4D_8H_2$) is of the order of 10^5 to 10^6, there are still pronounced isotopic and pressure effects in the formation of ethane. Similarly, the pressure dependence of the ratio of disproportionation to combination in the reaction of H atoms with C_2H_4 (Table III) persists to quite high hydrogen pressures.

In principle, it might appear to be possible to obtain quantitative information on the lifetimes of the "hot" radicals from a study of the pressure dependence of the yields of the products. The somewhat limited experimental information on pressure effects obtained in the present work and the limitations in analytical accuracy preclude a detailed analysis of this kind. However, the data in Tables I–III appear not to be consistent with the postulates of single hot radical species the rate of deactivation of which depends linearly on pressure.

The finding that abstraction of a hydrogen atom from a hot ethyl radical takes place very readily and that when the hot radical contains both H and D atoms it is the former which are abstracted, makes it necessary, by analogy, to consider the reactions of the type [2*a*] and [4*a*] as the ones which may perhaps be responsible for the isotopic exchange. However, on the basis of the available information the two types of processes (reactions [2] and [4] as contrasted with [2*a*] and [4*a*]) cannot be differentiated. Whether reactions of the latter type occur or not should perhaps be possible to establish by producing hot C_2H_5 radicals from photolysis of mercury diethyl in the presence of C_2D_4.

The ambiguity between these two types of processes may be rather general for exchange reactions of similar kind. Thus, the isotopic exchange and deuterium atom enrichment in the methane formed in the reaction of ethylene (2) or ethane (6), under conditions where atomic cracking takes place, may be due to the reactions of the type

$$CH_3 + D \rightarrow CH_3D^* \qquad [13]$$

$$CH_3D^* \rightarrow CH_2D + H \qquad [14]$$

$$CH_3D^* + M \rightarrow CH_3D + M \qquad [15]$$

as is generally assumed (6), or instead of [14]

$$CH_3D^* + R \rightarrow CH_2D + RH^*, \qquad [14a]$$

where R is D, an ethyl or a methyl radical and RH* may still be to some extent "hot", since the excess energy would be expected to be predominantly transferred into the product (RH*) in which a bond is formed. (Energetically the process simulates to a large extent the sequence of reaction [14] followed by combination of H and R to give RH*.)

Recently Lavrovskaia *et al.* (7) have proposed the following reaction as the one responsible for isotopic exchange in free radical reactions of hydrocarbons:

$$RCH_2\cdot + D_2 \rightarrow RCHD\cdot + HD. \qquad [16]$$

However, we find[5] no isotopic exchange at room temperature between thermalized ethyl radicals (from photolysis of diethyl ketone) and D_2 or C_2D_4. Reactions of this type, therefore, do not occur under conditions of the present experiments and are in general not likely to be important when thermalized radicals are involved.[6] Whether such reactions may occur when the free radicals are "hot" cannot be said at present. In such a case reaction [16] would become analogous to reaction [2*a*], tentatively suggested as a possibility in the present work.

ACKNOWLEDGMENT

The authors are grateful to Dr. A. W. Tickner for mass spectrometer analyses and their interpretation.

THE REACTION OF POTASSIUM PERSULPHATE WITH THIOGLYCOLIC ACID IN AQUEOUS SOLUTION[1]

J. F. HENDERSON[2] AND C. A. WINKLER

ABSTRACT

The oxidation of thioglycolic acid to dithiodiglycolic acid by potassium persulphate in aqueous solution in the absence of iron did not yield reproducible results, but satisfactory data were obtained when ferrous or ferric ions were added to the system. The catalyst cycle appears to be that ferrous ion is oxidized by persulphate to ferric ion, and the ferric ion is reduced back to ferrous ion by thioglycolic acid. In the absence of persulphate, the reaction of ferric ion with thioglycolic acid in acid solution (pH <3) was second order in both ferric ion and thioglycolic acid concentrations and was markedly inhibited by hydrogen ion.

INTRODUCTION

The rate-controlling step in the thermal decomposition of persulphate ion in aqueous solution has been postulated to be the first-order homolytic dissociation of persulphate to yield sulphate ion radicals (1, 2, 3).

$$S_2O_8^{=} \rightarrow 2SO_4^{\cdot -}$$

The addition of organic compounds to solutions of persulphate in general increases the rate of decomposition of the persulphate ion, but the mechanisms of many of these reactions are not well understood (2, 4, 5, 6, 7).

The reactions of potassium persulphate with alkyl mercaptans in glacial acetic acid – water solution have been discussed in a previous paper from this laboratory (4). Secondary salt effects were observed which tended to make interpretation of the results difficult, but it seemed that persulphate decomposed unimolecularly to yield two sulphate ion radicals which either reacted with the mercaptan or recombined in a solvent "cage".

For the decomposition of persulphate ion in the presence of certain other organic compounds, e.g. methanol and hydrazobenzene, no evidence for the existence of a solvent cage has been found (2, 5, 6). Furthermore, it has been postulated that the sulphate ion radicals in these reaction mixtures were produced by direct reaction between persulphate ion and the organic compound rather than by unimolecular decomposition of persulphate ion (2, 5), though for the persulphate–methanol reaction there is now doubt that this view is correct (6).

The present investigation was planned originally with the intention of obtaining more information about the reactions of persulphate ion with organic compounds, particularly those containing the sulphydryl group. Thioglycolic acid was chosen to permit experiments in aqueous solution, hence avoiding the difficulties encountered in the earlier investigation (4).

Preliminary experiments (8), which will not be described, indicated that 2 moles of thioglycolic acid were oxidized by 1 mole of persulphate to yield 1 mole of dithiodiglycolic acid, but measurements of the reaction rate were quite erratic. Reproducible data were obtained, however, in the presence of soluble iron salts as catalyst, and it was decided to investigate this catalyzed reaction.

EXPERIMENTAL

Fisher "purified" thioglycolic acid was distilled rapidly at 8 mm Hg and 95° C, and the distillate was stored at 0° C under an atmosphere of nitrogen (9). Its purity was estimated to be 99.5% by diluting weighed quantities with water and titrating these with standard iodine solution, using starch as the indicator.

The other materials employed in this investigation, which were supplied by Brickman and Company, Montreal, were of reagent grade and were used as received.

Either ferrous or ferric ammonium sulphate was used to catalyze the reaction. The ionic strength of the reaction mixture was adjusted by adding potassium sulphate, sulphuric acid, or mixtures of the two. In calculating the ionic strength, allowance was made for the incomplete dissociation of KSO_4^- and HSO_4^- ions (10, 11).

Both the standardized solutions of the reactants and the reaction mixtures were prepared with laboratory distilled water. Prior to mixing, the reactant solutions were swept with nitrogen (99.9%) which was saturated with water vapor and used without further purification. The reaction mixtures were swept with moist nitrogen while experiments were in progress at 24.8±0.02° C.

The progress of the reaction was determined by transferring aliquots from the reaction mixture to 25 ml of approximately 20% phosphoric acid and estimating the thioglycolic acid content by titration with a standard solution of iodine in a solution of potassium iodide. The phosphoric acid, by complexing the ferric ion, served to slow the reaction and to prevent possible complications in the subsequent titration with iodine. Reaction of persulphate with iodide ion during the iodimetric titration was found to be negligible.

For experiments in 0.15 *M* sulphuric acid, both the progress of reaction and the concentration of ferric ion were determined by periodically removing aliquots from the reaction mixture and recording their ultraviolet spectra for wavelengths up to 400 mμ. From the data in Table I it may be inferred that appreciable complex formation did not occur between any of the components present in the reaction mixtures. The concentration of ferric ion in reaction mixtures was estimated from the optical density measured at 325 mμ. The optical densities at lower wavelengths were then corrected for the contri-

bution by ferric ion and, by using this corrected value, the concentrations of the remaining components in the reaction mixture at any time were calculated using the following equation,

$$[\mathrm{TSST}] = \frac{D - \epsilon_{\mathrm{TSH}}[\mathrm{TSH}]_0 - \epsilon_{S_2O_8^=}[S_2O_8^=]_0}{\epsilon_{\mathrm{TSST}} - 2\epsilon_{\mathrm{TSH}} - \epsilon_{S_2O_8^=}}$$

where D represents the corrected optical density, ϵ the respective extinction coefficients, and $[\mathrm{TSH}]_0$ and $[S_2O_8]_0$ the initial concentrations of thioglycolic acid and persulphate respectively. The results obtained using the spectrophotometric method were in excellent agreement with those obtained using the volumetric method (Fig. 4).

RESULTS

Experiments at a pH of approximately 2 showed the reaction to be first order in the persulphate concentration and zero order in the thioglycolic acid concentration. The first-order rate constant for persulphate disappearance, k_1' in Table II, was directly proportional to the concentration of iron in the system, which indicates that, in the presence of added iron, direct reaction between persulphate and thioglycolic acid was negligible. The effect of ionic strength on the calculated second-order rate constant, $k_1 = k_1'/[\mathrm{Fe}]$, is shown in Fig. 1, and it is apparent that the rate-controlling step of the reaction consists of interaction between doubly charged ions of the opposite sign.

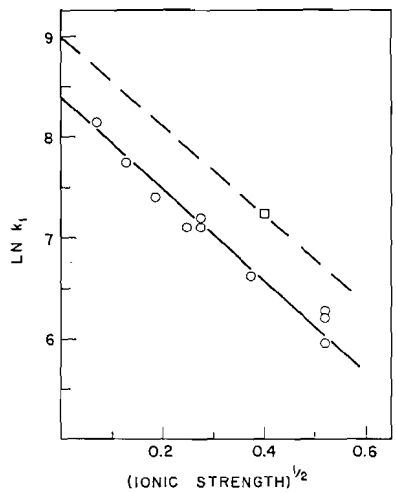

FIG. 1. Variation of the second-order rate constant, k_1, with the ionic strength: —□— see ref. (16, 17).

For reaction mixtures in which the concentration of sulphuric acid was 0.15 M and in which the iron was initially in the ferrous state, the initial rates of reaction and the first-order rate constants at zero time were functions of the initial concentrations of both the persulphate and the thioglycolic acid (Table III). Furthermore, the concentration of ferric ion reached a stationary value which increased with increasing persulphate concentration and decreased with increasing thioglycolic acid concentration (Figs. 2 and 3). Division of the rate of disappearance of persulphate in these reaction mixtures by the product of the persulphate and ferrous ion concentrations at a given instant of time yielded a second-order rate constant corresponding to k_1 which was independent of the reaction mixtures, and for which the average value (651 l. mole^{-1} min^{-1}) was in reasonable agreement with that shown in Fig. 1 at the same ionic strength. As observed

previously for pH$\sim$2, the initial rate of reaction extrapolated to zero when the initial concentration of ferrous ion was decreased to zero indicating that direct reaction between persulphate ion and thioglycolic acid was negligible.

When the added iron was initially in the ferric state, the reaction was preceded by an induction period, but following this induction the rate of reaction was the same as for experiments in which the iron was initially in the ferrous state (Fig. 4). The stationary-state concentration of ferric ion was independent of the valence state of the iron at zero time, although it was not attained for several minutes when the iron was initially in the ferric state. The rate of disappearance of ferric ion during the greater part of the induction period, i.e. before its concentration reached a stationary value, was not influenced by the presence of persulphate (Fig. 5).

To study the reaction between ferric ion and thioglycolic acid in sulphuric acid solutions, the disappearance of ferric ion was followed by the change in optical density at 305 mμ. The thioglycolic acid concentration was in sufficient excess over that of ferric ion to be considered independent of time. The slopes of the straight lines in Fig. 6, which show the second-order dependence of the reaction rate on the ferric ion concentration, are

proportional to the square of the thioglycolic acid concentration, indicating the over-all reaction to be of the fourth order. The effect of sulphuric acid concentration on the calculated fourth-order rate constant, k_4''', is shown in Table IV.

When the ferric ion and thioglycolic acid were mixed initially in these experiments, a blue complex was formed which faded rapidly as observed in earlier investigations (13, 14). However, extrapolation of the measured optical densities at 305 mμ to zero time indicated that the optical density of ferric ion was not influenced by thioglycolic acid, and hence that ferric ion – thioglycolic acid complexes were highly dissociated.

The dependence of the fourth-order rate constant on hydrogen ion concentration was

determined more exactly by making experiments at various levels of perchloric acid when the ionic strength of the reaction mixtures was adjusted to 1.00 with sodium perchlorate. The reaction was followed by periodically removing aliquots of the reaction mixture and estimating the ferric ion content colorimetrically as the thiocyanate complex (12). Again the thioglycolic acid concentration was in sufficient excess over that of ferric ion to be effectively independent of time. The fourth-order rate constant, k_4', was found to be inversely proportional to approximately the fourth power of the hydrogen ion concentration (Fig. 7). Low concentrations of sulphate ion in these reaction mixtures also caused inhibition (Table V).

NOTE: Values of k_4', which were interpolated from Fig. 7, were determined under identical experimental conditions except that sulphate ion was absent.

The fourth-order rate constant, k_4''', for the ferric ion – thioglycolic acid reaction was also determined by dividing the rate of formation of dithiodiglycolic acid in persulphate –

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

thioglycolic acid reaction mixtures by the product of the square of the ferric ion concentration and the square of the thioglycolic acid concentration. Its value in these reaction mixtures was approximately 100 times greater than that determined in systems which were identical in every way except that persulphate was absent.

A brief investigation of the reaction between persulphate ion and ferrous ion in the absence of thioglycolic acid showed (Table VI) that the reaction was second order, and

that the second-order rate constants, k_1, were in good agreement with those interpolated from Fig. 1. The rate of appearance of ferric ion in these reaction mixtures was estimated from the change in optical density at 305 mμ.

DISCUSSION

Thioglycolic acid in no way influenced the rate of the persulphate ion – ferrous ion reaction, whereas the presence of persulphate caused the reaction between ferric ion and thioglycolic acid to occur more rapidly. It is apparent that the catalyst cycle for the reaction between persulphate ion and thioglycolic acid, in the presence of iron, involves persulphate oxidation of ferrous ion to ferric ion, which is then reduced by thioglycolic acid to ferrous ion.

The mechanism for the reaction between persulphate ion and ferrous ion appears to be well established (15, 16, 17).

$$S_2O_8 + Fe^{++} \rightarrow Fe^{+++} + SO_4^{-} + SO_4^{=} \quad [1]$$

$$SO_4^{-} + Fe^{++} \rightarrow Fe^{+++} + SO_4^{=} \quad [2]$$

The calculated second-order rate constant, k_1, obtained in this investigation was approximately one-half that obtained by Williams *et al.* (16, 17). The difference might result from the much larger hydrogen ion concentrations (100- to 1000-fold) in the present experiments.

For the reaction between ferric ion and thioglycolic acid the results may be explained by postulating the existence of a complex containing two ferric ions and two thioglycolic acid molecules, the reaction rate being governed by the first-order decomposition of this complex. That complexes in the ferric ion – thioglycolic acid system do exist is indicated by the blue color that was produced when the two reactants were mixed initially. Lamfrom and Nielsen (14) have shown that the blue complex disappeared by a first-order process at $-35°$ C in a solvent consisting of 6 parts by volume of ethanol to 10 parts by volume of water. It would appear, therefore, that the blue complex might well consist of two ferric ions and two thioglycolic acid molecules.

The inhibition by hydrogen and by sulphate ions suggests that mercaptide and hydrated ferric ions were the reactive species and the proposed mechanism is as follows:

$$Fe^{+++} + SO_4^{=} \rightleftarrows FeSO_4^{+}, \quad [4]$$

$$FeSO_4^{+} + SO_4^{=} \rightleftarrows Fe(SO_4)_2^{-}, \quad [5]$$

$$Fe^{+++} + ClO_4^{-} \rightleftarrows FeClO_4^{++}, \quad [6]$$

$$Fe^{+++} + H_2O \rightleftarrows FeOH^{++} + H^{+}, \quad [7]$$

$$TSH \rightleftarrows TS^{-} + H^{+}, \quad [8]$$

$$FeOH^{++} + TS^{-} \rightleftarrows FeOHTS^{+}, \quad [9]$$

$$2FeOHTS^{+} \rightleftarrows Fe_2(OH)_2(TS)_2^{++}, \quad [10]$$

$$Fe_2(OH)_2(TS)_2^{++} \rightarrow 2Fe^{++} + {}^{-}TSST^{-} + 2H_2O. \quad [11]$$

For the experiments made in the absence of sulphate ion, the following relation is obtained,

$$k_4'\,[\text{ferric}]^2\,[\text{thioglycolic acid}]^2 = \frac{k_{11}K_{10}K_9^{\,2}K_8^{\,2}K_7^{\,2}}{[H^+]^4}\,[Fe^{+++}]^2\,[TSH]^2 \quad (i)$$

where [ferric] and [thioglycolic acid] represent the total concentrations of ferric ion and thioglycolic acid respectively in the reaction mixture. Owing to the relatively large concentrations of hydrogen ion used in these experiments, the concentrations of $FeOH^{++}$ and TS^{-} ions should be small (18, 19), and since complex formation between ferric and perchlorate ions occurs only to a very limited extent (20), it follows that

$$[\text{ferric}] \simeq [Fe^{+++}]$$

and

$$[\text{thioglycolic acid}] \simeq [TSH].$$

Therefore

$$k_4' = \frac{k_{11}K_{10}K_9^{\,2}K_8^{\,2}K_7^{\,2}}{[H^+]^4}. \quad (ii)$$

In the presence of low concentrations of sulphate ion

$$[\text{ferric}] = [Fe^{+++}][1+K_4(SO_4^{=})]$$

and

$$k_4'' = \frac{k_{11}K_{10}K_9^{\,2}K_8^{\,2}K_7^{\,2}}{[H^+]^4\,[1+K_4(SO_4^{=})]^2}. \quad (iii)$$

By combining equations (ii) and (iii),

$$K_4 = \frac{\sqrt{(k_4/k_4'')}-1}{[SO_4^{=}]}. \quad (iv)$$

The value of K_4, the association constant of the ferric ion – sulphate complex, calculated in this manner was approximately one-half that determined by Whitekar and Davidson (21).

In the reaction mixtures which were 0.05 to 0.15 M in sulphuric acid, the concentration of free ferric ion may be taken as negligible (21), i.e.

$$[\text{ferric}] = [Fe^{+++}][K_4(SO_4^{=})+K_4K_5(SO_4^{=})^2]$$

and

$$k_4''' = \frac{k_{11}K_{10}K_9^{\,2}K_8^{\,2}K_7^{\,2}}{[H^+]^4\,[K_4(SO_4^{=})+K_4K_5(SO_4^{=})^2]^2}. \quad (v)$$

It is interesting to note that the mechanism for the reaction between ferric ion and thioglycolic acid in weakly acidic and in alkaline solution differs markedly from that suggested here for the reaction in more strongly acidic solution (14, 22, 23).

If no account is taken of the relatively rapid ferric ion – thioglycolic acid reaction which occurred in the presence of persulphate, the following sequence of reactions may be suggested for the iron-catalyzed reaction between persulphate and thioglycolic acid:

$$S_2O_8 + Fe^{++} \rightarrow Fe^{+++} + SO_4 + SO_4 \quad [1]$$

$$SO_4 + Fe^{++} \rightarrow Fe^{+++} + SO_4 \quad [2]$$

$$SO_4 + TSH \rightarrow TS\cdot + HSO_4 \quad [3]$$

$$Fe^{+++} + SO_4^{=} \rightleftarrows FeSO_4^{+} \quad [4]$$

$$FeSO_4^{+} + SO_4^{=} \rightleftarrows Fe(SO_4)_2^{-} \quad [5]$$

$$Fe^{+++} + H_2O \rightleftarrows FeOH^{++} + H^{+} \quad [6]$$

$$TSH \rightleftarrows TS^{-} + H^{+} \quad [7]$$

$$FeOH^{++} + TS^{-} \rightleftarrows FeOHTS^{+} \quad [8]$$

$$2FeOHTS^{+} \rightleftarrows Fe_2(OH)_2(TS)_2^{++} \quad [9]$$

$$Fe_2(OH)_2(TS)_2^{++} \rightarrow 2Fe^{++} + {}^{-}TSST^{-} + H_2O \quad [10]$$

$$2TS\cdot \rightarrow TSST \quad [11]$$

Step [1] was rate controlling in reaction mixtures when the pH was approximately 2, but the reduction of ferric ion by thioglycolic was not rapid relative to step [1] in reaction mixtures 0.15 M in sulphuric acid. If step [2] is assumed negligible relative to [3] because of the large excess of thioglycolic acid over ferrous ion, the steady-state assumption may be applied to the concentrations of ferric and ferrous ions to yield the following relation,

$$\frac{D_m - D}{D^2} = \frac{k_4'''}{\epsilon k_1} \frac{[TSH]^2}{[S_2O_8^{=}]} \quad \text{(vi)}$$

where D represents the optical density of the reaction mixture at 325 mμ, D_m the optical density if all the iron had been in the ferric state, and ϵ the extinction coefficient of ferric ion. In actual fact the results from the experiments made in 0.15 M sulphuric acid were found to fit the empirical equation,

$$\frac{D_m - D}{D^2} = \frac{k}{\epsilon k_1 [Fe]^x [TSH]_0} \frac{[TSH]^2}{[S_2O_8^{=}]} \quad \text{(vii)}$$

where $[Fe]^x$ represents the concentration of iron in the system raised to some power x and $[TSH]_0$, the initial concentration of thioglycolic acid.

Furthermore, the values of

$$\frac{k}{k_1 [Fe]^x [TSH]_0}$$

were of the order of 100 times greater than the value of k_4'''/k_1 (Table VII), owing to the influence of persulphate ion on the ferric ion – thioglycolic reaction.

Additional steps in the reaction sequence already shown are necessary to explain, not only the marked influence of persulphate ion on the over-all rate, but also the induction period when iron was initially in the ferric state, and the lack of influence by persulphate on the rate at which ferric ion concentration is decreased to its stationary value during the induction period. A tentative proposal is that either a sulphate ion radical or a

thiyl radical reacts rapidly with a ferric ion – thioglycolic acid complex,

$$SO_4^{\cdot-} + \text{Fe (III) TSH-complex} \rightarrow Fe^{++} + H^+ + TSST + HSO_4^- \quad [12]$$

$$TS\cdot + \text{Fe (III) TSH-complex} \rightarrow Fe^{++} + TSST + H^+. \quad [13]$$

TABLE VII

Comparison of the calculated value of k_4'''/k_1 with the value $\frac{k}{k_1[Fe]^x[TSH]_0}$

Initial $[TSH]_0$ ($\times 10^3$)	$\frac{k}{k_1[Fe]^x[TSH]_0}$ ($\times 10^{-4}$)	k_4'''/k_1 ($\times 10^{-4}$)
10.95	92.3	1.85
4.36	333	1.85

In solutions in which the iron is present initially as ferric ion, free radicals will not be produced at zero time, and reactions [12] and/or [13] will not be important. Due to the production of ferrous ion, however, the persulphate – ferrous ion reaction will begin to occur, giving rise to free radicals and hence to the rapid reactions [12] and/or [13]. Therefore, during the early stages of the reaction before ferric ion and in all probability the free-radical concentrations become stationary, the rate of reduction of ferric ion by thioglycolic acid will increase with time causing a corresponding increase in the over-all reaction rate, and an induction period will result. However, when the iron is initially in the ferrous state, the sulphate ion radicals and ferric ion will be produced at zero time, and reactions [12] and/or [13] will assume an important role at the beginning.

A similar mechanism has been suggested for the uptake of oxygen by mixtures of ferric ion and thioglycolic acid in mildly acidic solution (14).

With existing information, it is extremely difficult to determine either the structure of the complex which entered into this reaction or the nature of the radical, whether sulphate ion or thiyl, which reacted with the complex. Because sulphate ion radicals may react with both ferrous ion and thioglycolic acid, the situation is even more complex, since the relative rates of these two reactions are unknown.

In conclusion, it is apparent that to investigate the uncatalyzed persulphate – thioglycolic acid reaction, as was intended originally, the concentration of dissolved iron in the reaction mixtures, and in all probability the concentration of other metallic ions, would have to be very low.

THE PURIFICATION, DETERMINATION, AND NEUTRON CAPTURE CROSS SECTION OF ACTINIUM-227[1]

M. J. CABELL[2]

ABSTRACT

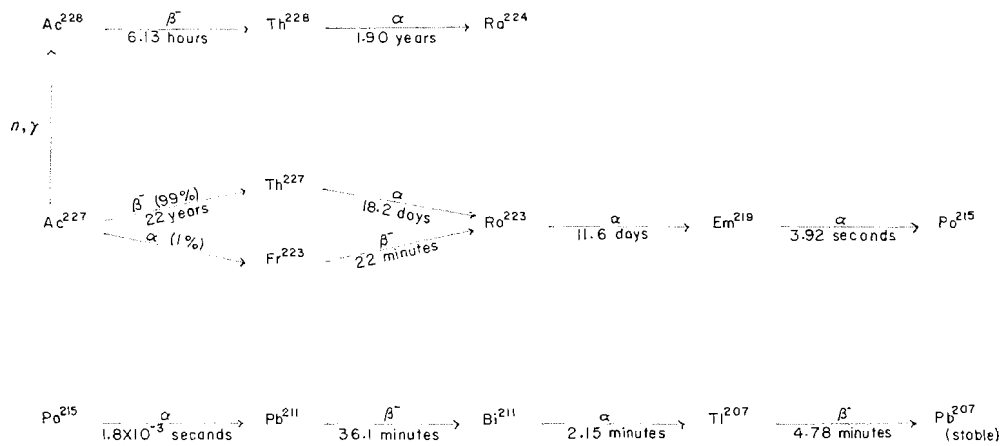
Procedures are described for (*a*) the separation by ion exchange chromatography of submicrogram quantities of Ac^{227} from its daughters and (*b*) the absolute determination of Ac^{227} by measurement of the rate of growth of α-particle emission from an initially pure source. These procedures are utilized in the determination of the reactor and thermal neutron capture cross sections and the resonance capture integral of Ac^{227} by an activation method.

Assuming 36.5 barns for the thermal neutron capture cross section of Co^{59}, a value of $\sigma_{2200} = 814 \pm 13$ barns has been obtained for Ac^{227}. The resonance capture integral (from 0.5 ev to ∞) was found to be 1177 ± 19 barns relative to 48.6 barns for the resonance capture integral of Co^{59}.

INTRODUCTION

Hughes and Schwartz (1) quote 510 ± 40 barns for the thermal neutron capture cross section of Ac^{227} as determined by a pile oscillator method and 520 ± 50 barns as determined by an activation method; no experimental data are available for either of these measurements. Timma and Russell (2), also using a pile oscillator method, obtained 493 ± 53 barns for the thermal neutron capture cross section. No measurements of differential cross sections or of the resonance capture integral of this isotope have so far been reported in the literature. This paper describes determinations of the reactor and thermal neutron capture cross sections and the resonance capture integral of Ac^{227} by an activation method.

The following nuclear reactions are involved:



The method used is similar to that described by Cabell (3) and by Cabell, Eastwood, and Campion (4) and involved the irradiation in a high flux position of the NRX reactor of submicrogram amounts of Ac^{227} (*a*) unshielded and (*b*) shielded by 0.0635 cm cadmium. Cobalt monitors were attached to measure both the thermal and the epicadmium fluxes.

After irradiation the actinium was purified by ion exchange and mounted on thin films for counting. The Ac^{228} content of each source was then determined from measurements of the change in its absolute β-disintegration rate with time. The rise in absolute α-disintegration rate of the same source with time gave a measure of its Ac^{227} content. From these data and the known fluxes the effective cross section for Ac^{227} for pile neutrons, its thermal capture cross section, and its resonance capture integral were calculated.

EXPERIMENTAL METHODS

(*a*) *Preparation of Pure Actinium-227*

A sample of Ac^{227} which had been only partially separated from neutron-irradiated Ra^{226} and contained large quantities of water-soluble salts as additional impurities was received from the Commercial Products Division (Ottawa) of Atomic Energy of Canada Ltd. The actinium was freed from salts by repeated coprecipitation with ferric hydroxide, the iron was removed by anion exchange, and the actinium was separated from the products of its decay and from Ra^{226} by cation exchange (see section on chemical purification). The actinium was finally obtained in 2 ml of 6 *M* nitric acid and this solution was used as a stock for all irradiations.

Aliquots taken from the stock solution were evaporated to dryness on platinum disks and the spectra of the α- and β-particles they emitted were examined. An α-pulse analysis carried out 4 hours after the final separation showed that α-particles from Ac^{227} accounted for about half the total α-particle activity. Separate and growing peaks were identified due to the α-particles from Th^{227}, Ra^{223}, Em^{219}, Po^{215}, and Bi^{211} and accounted for the remainder of the α-particle activity. No evidence of the presence of α-particles from Ra^{226} could be found.

Another source was counted in an internal proportional counter whose anode potential was adjusted for β-particle counting, and the counting rate of the source was determined both uncovered and covered with thin aluminum foils of different thicknesses. The resulting absorption curve showed that most of the uncovered activity was due to the β-particles from Ac^{227} (stopped by 4 mg/cm^2 aluminum corresponding to a maximum energy of 46 kev) and the remainder was almost entirely due to α-particles. All these facts are consistent with the sources being initially radiochemically pure Ac^{227}.

(*b*) *Irradiations*

Fifty-microliter aliquots (approximately 3×10^{-9} g Ac^{227}) of the stock solutions were pipetted into small silica ampoules. Some of these were sealed directly, but those to be irradiated under cadmium and one other were taken to dryness and were then sealed except for a capillary vent. Cobalt monitors were attached and the samples were irradiated for between 5400 ± 2 seconds and 5417 ± 2 seconds as described by Cabell (3).

(*c*) *Chemical Purification of Irradiated Actinium*

Cation and anion exchange chromatography were used to purify the irradiated actinium.

Each cation column consisted of 1.00 g (dry weight) of 200–400 mesh Dowex 50 (hydrogen form) contained in a glass tube 10 cm long and 6 mm in diameter sealed onto a reservoir 10 cm long and 3 cm in diameter. Both column and reservoir were jacketed at 60°. Before they were loaded, the columns were prepared by washing with water.

Each anion column contained 0.25 g of 200–400 mesh Dowex 1 (chloride form) in a tube 6 cm long and 6 mm in diameter sealed onto a reservoir 5 cm long and 1.5 cm in diameter. The anion columns, which were operated at room temperature, were washed with 5 ml of 10 *M* hydrochloric acid before loading.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The irradiated actinium sample was dissolved in 5 ml of 2 *M* hydrochloric acid and the solution was warmed to 80° before it was fed to a cation exchange column without application of pressure. When the feed had passed, the column was eluted successively with 5 ml of hot 2 *M* hydrochloric acid (to remove bismuth, lead, and francium) and 20 ml of hot 3 *M* nitric acid (to remove radium). Finally the column was eluted with 25 ml of hot 6 *M* nitric acid; the first 5 ml of eluate was rejected and the remainder, which contained the purified actinium, was collected in a centrifuge tube. The Th^{227} daughter of the actinium was left on the column.

The progress of this separation is illustrated in Fig. 1 (each peak was identified by separate experiments using only one of the five components each time).

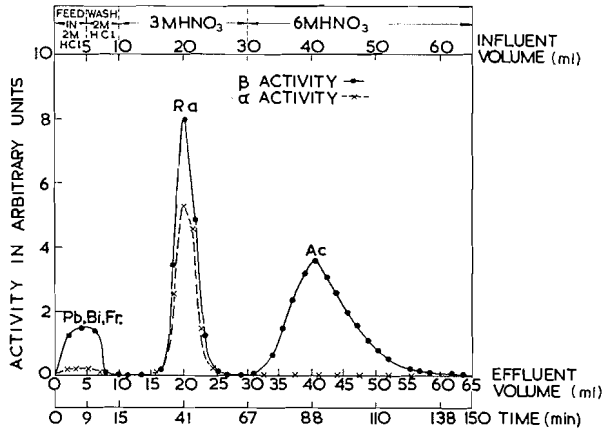

FIG. 1. The separation of Ac^{227} from its daughters by cation exchange chromatography.

Three drops of a ferric nitrate solution (10 mg iron per ml) were added to the eluate obtained from the cation column; the solution was neutralized with ammonia, cooled to room temperature, and the ferric hydroxide precipitate, which carries the actinium, was collected by centrifuging. The precipitate was dissolved in 2 drops of concentrated hydrochloric acid, diluted to 20 ml, and the iron was precipitated again with ammonia. This solution–precipitation cycle was then repeated.

The precipitate was next dissolved in 1 ml of concentrated hydrochloric acid and fed to an anion exchange column at the rate of 0.2 ml/min to remove the iron carrier. After the feed had passed, the column was eluted with 1 ml of 10 *M* hydrochloric acid and the total eluate was collected in a small platinum crucible and evaporated to dryness under an infrared lamp. The crucible was then heated in a furnace at 700° for 5 minutes, cooled, and 2 ml concentrated nitric acid was added and the solution was again evaporated to dryness under an infrared lamp. Finally the residue, which was invisible to the naked eye, was dissolved in 1 ml concentrated nitric acid and the resulting solution was used for making sources on thin films for counting.

(d) Absolute Disintegration-rate Determinations

(1) Determination of Ac^{227}

Ac^{227} decays largely by the emission of β-particles of maximum energy 46 kev (α-particle emission is $1.25 \pm 0.02\%$, Peterson and Ghiorso (5)) and initially attempts were made to determine this isotope by absolute β-disintegration-rate determinations. A series of gold-coated VYNS films of known thickness were prepared and a source of freshly purified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Ac^{227} was mounted on a film 36 $\mu g/cm^2$ thick. This was β-counted in a 4π counter and then another film was made to adhere to the back of the source before counting again. Additional films were then added, with counting after each addition, until a final total thickness of 260 $\mu g/cm^2$ had been built up. Over this range, 36 to 260 $\mu g/cm^2$, there was a loss of 12% in the measured β-disintegration rate. Since this method of determination is so sensitive to the thickness of the source mount and extrapolation from 36 $\mu g/cm^2$ to zero thickness is uncertain, it was not investigated further.

The measurement of the α-disintegration rates of sources of the α-active daughters of Ac^{227} is not subject to the same difficulties as a second and similar experiment showed. A source of initially pure Ac^{227} which had been prepared 22 days previously was investigated by the same procedure. It was found that over a source mount thickness varied from 37 to 252 $\mu g/cm^2$ there was no change in α-disintegration rate outside the statistical error of each count, i.e. $\pm 0.3\%$.

Since the half-lives of Th^{227} and Ra^{223} are very much greater than those of the other α-particle-emitting daughters of Ac^{227}, for some purposes the sequence of decay by α-particle emission only may be simplified to:

$$Ac^{227} \xrightarrow[\lambda_1]{\beta} Th^{227} \xrightarrow[\lambda_2]{\alpha} Ra^{223} \xrightarrow[\lambda_3]{4\alpha} Pb^{207}\ \text{(stable)}$$

where λ_1, λ_2, and λ_3 are the decay constants of Ac^{227}, Th^{227}, and Ra^{223} respectively. It can be shown that, with this simplification, the α-activity of an initially pure source containing N_0 atoms of Ac^{227} at time t hours after its preparation is given by the expression:

$$[1] \qquad \frac{-d\alpha}{dt} = \frac{N_0\lambda_1\lambda_2}{(\lambda_2-\lambda_1)}\left(e^{-\lambda_1 t}-e^{-\lambda_2 t}+\frac{4\lambda_3(e^{-\lambda_1 t}-e^{-\lambda_3 t})}{(\lambda_3-\lambda_1)}+\frac{4\lambda_3(e^{-\lambda_3 t}-e^{-\lambda_2 t})}{(\lambda_3-\lambda_2)}\right).$$

Since

$$\lambda_1 = (3.66\pm 0.07)\times 10^{-6}\ \text{hours}^{-1}\ \text{(Tobailem (6))},$$
$$\lambda_2 = (1.590\pm 0.007)\times 10^{-3}\ \text{hours}^{-1},$$

and

$$\lambda_3 = (2.472\pm 0.011)\times 10^{-3}\ \text{hours}^{-1}\ \text{(Hagee, Curtis, and Grove (7))},$$

substitution in expression [1] gives:

$$[2] \quad (-d\alpha/dt)\,.\,1/N_0 = 3.670\times 10^{-6}[e^{-\lambda_1 t}-e^{-\lambda_2 t}+4.006(e^{-\lambda_1 t}-e^{-\lambda_3 t})+11.21(e^{-\lambda_3 t}-e^{-\lambda_2 t})]$$

where $-d\alpha/dt$ is expressed in disintegrations per hour.

Expression [2] may be used to calculate N_0 provided there is no loss of Em^{219} ($t_{\frac{1}{2}} = 3.92$ seconds) from the source. The possibility of this was studied in separate experiments using "weightless" sources in a 4π proportional counter. One source was sealed in the counter for several days after which it was α-counted, then removed, and the α-background of the counter was followed for the next 8 hours. The background decayed with a half-life of 35 minutes, showing the presence of Bi^{211} (daughter of Pb^{211}). In a second experiment a high gas flow was passed through the counter into a second and larger counter whose rise in α-counting rate was measured. From these and similar experiments it was concluded that up to 2% of the Em^{219} content of a thin source could diffuse into the counting gas. It was found that any error introduced into the determination of total α-disintegration rate by this effect could be reduced to negligible proportions ($< 0.5\%$) by sealing the source in the counter for at least three hours before measurement and by using a minimum gas flow during the measurement.

The possibility of loss of Ra^{223} (and consequently of subsequent decay products) by recoil from the source on emission of an α-particle by Th^{227} must also be considered. Since the recoil energy is 108 kev, the range of Ra^{223} in gold will be of the order 5 $\mu g/cm^2$ and recoils in the direction of the source mount will be successfully trapped, but for a source only 1 atom thick losses of 50% may be expected due to recoil in the opposite direction. In fact it is not possible to make truly "weightless" sources by the method employed in this work, since even the purest reagents inevitably contain traces of non-volatile impurities. The true thickness of the source is seldom known in 4π counting and, in fact, is the largest factor contributing to uncertainty in the technique (see later). In the present work it was known that the recoil effect had no influence on the results. Counting for experiments 3 and 4 of Table II was carried out using sources completely enclosed by gold-coated VYNS films and the results obtained agree with those using uncovered sources. The technique of covering the sources with another thin film was not used except in this one case, since it is clearly unnecessary and additional absorbers should be avoided wherever possible.

Observing these precautions it was found that α-activity measurements made for four or five consecutive days commencing 6 days after preparation of a source gave values for N_0 which agreed with a coefficient of variation of 0.4% to 1.0%. Table I shows the results obtained with one such source.

TABLE I

Determination of Ac^{227} by measurement of its α-particle-emitting daughters

Hours from initial count	α-Count per hour corrected for initial count	$N_0 \times 10^{-10}$
137.1	105920	9.079
159.5	128390	9.098
182.3	151970	9.095
205.8	175800	9.025
231.9	205110	9.050
		Average 9.069 ± 0.032

It is interesting to compare the results obtained by these two possible methods of determining Ac^{227}, i.e. by 4π counting the β-particles emitted and by measurement of the rise in α-particle activity. The former method has been found to give results 23% to 45% lower than the latter for samples prepared from different purifications. These figures emphasize the very large errors which may be expected due to self-absorption when attempts are made to 4π count very weak β-particles even though apparently "weightless" sources are employed.

(*2*) *Determination of* Ac^{228}

The curved line ABC of Fig. 2 shows a decay curve obtained from a purified sample of neutron-irradiated Ac^{227} measured in a 4π proportional counter with its anode potential adjusted for β-particle counting. The shape of the falling portion of the curve, AB, is largely determined by the decay of the β-active Ac^{228} component of the source. By point B most of the Ac^{228} has decayed and the recorded count is largely due to the β-active Ac^{227} component (it has been shown in the previous section that this count cannot be used for the quantitative determination of Ac^{227}).

In addition to the β-particles from Ac^{227} the counter also records pulses arising from α- and β-particles emitted by Th^{227} and its radioactive daughters, and it is the growth of

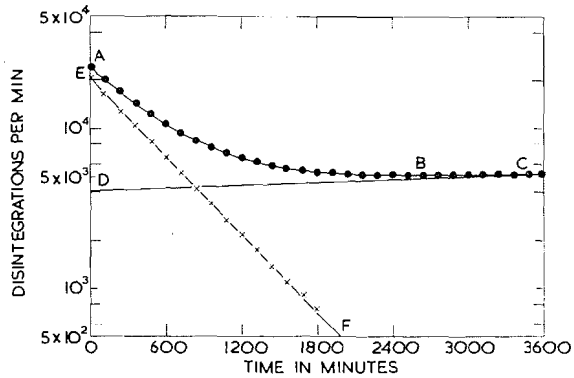

FIG. 2. Decay of neutron-irradiated Ac^{227}.

these which accounts for the upward inclination of the portion of the curve BC. This increase in counting rate follows a form similar to that given in brackets in expression [2], and information obtained by counting after 3 or 4 days (by which time the Ac^{228} will have decayed to about 10^{-5} of its initial amount) was used to correct the portion of the curve AB for these components (line CD). In this way the Ac^{228} contribution alone was obtained and is plotted as points which lie about the line EF which is drawn with a half-life of 6.13 hours, the published value for Ac^{228} (Hahn and Erbacher (8)).

The β-particles emitted by Ac^{228} are mostly highly energetic but 13% have energies below 450 kev (Strominger, Hollander, and Seaborg (9)); sources were therefore examined for possible source mount losses by the technique described above for Ac^{227} particles. It was found that over a source mount thickness varied from 36 to 266 $\mu g/cm^2$ counting rate losses of mixtures of Ac^{227} and Ac^{228} could be ascribed entirely to losses in counting the Ac^{227} component. Using mounts approximately 50 $\mu g/cm^2$ thick losses in counting Ac^{228} would not exceed 0.2% due to this source of error.

A more serious source of error in the absolute disintegration-rate determination of Ac^{228} lies in the possibility of self-absorption in the source itself. Cobble (10) has reported that in certain cases up to 10% losses may occur from apparently "weightless" sources due to this cause and we have shown that for Ac^{227} the losses are even greater. With 450-kev β-particles errors of this magnitude are most unlikely. Since the abundance of the β-particles under consideration is only 13% of the total, we have concluded that the self-absorption losses in determining Ac^{228} in "weightless" sources is much less than one per cent.

(3) Counting Procedure

An important feature of the counting procedure used lay in the fact that after irradiation and purification of the actinium, a single aliquot could be used to determine both the amount of Ac^{227} in that aliquot and also the amount of Ac^{228} which it had yielded on irradiation. Consequently, provided sufficient actinium was purified that adequate counting rates could be obtained, the chemical yield of the purification process was unimportant.

When a batch of irradiated Ac^{227} had been purified, three or four aliquots (sufficient to give between 100 and 1000 β-particle counts/second but whose volume did not need to be known) were mounted on films of approximately 50 $\mu g/cm^2$ thickness and as soon as possible each was counted for α-particles and then, at a higher applied potential, for β-particles in a 4π counter. The progress of β-decay was then followed for 6 or 7 days and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the absolute β-disintegration rate of the Ac^{228} component during each initial count was determined as described above. The decay of this component was also determined to confirm its identity and purity. From the corrected initial count the absolute β-disintegration rate which the Ac^{228} in each source would have had at the end of the irradiation was calculated using 0.1131 ± 0.0005 hours^{-1} (Hahn and Erbacher (8)) for its decay constant.

The α-particle activities of the same sources were measured again 6 days after their preparation and also on each of the 5 succeeding days after this. Increases in α-particle activity over the initial counts made when the sources were first prepared were used to calculate values of N_0 from the expression:

$$[3] \quad [(d\alpha_0/dt)-(d\alpha/dt)]\cdot 1/N_0 = 3.670\times 10^{-6}[1.013(e^{-\lambda_1 t}-e^{-\lambda_2 t})+4.006(e^{-\lambda_1 t}-e^{-\lambda_3 t}) +11.21(e^{-\lambda_3 t}-e^{-\lambda_2 t})]$$

where $-d\alpha_0/dt$ is the initial counting rate.

Expression [3] differs from expression [2] by a small factor on the right-hand side which arises as follows. The initial α-counts are due to the α-particles emitted in the decay of Ac^{227} to Fr^{223} (plus small activities due to α-active daughters produced during the short time between actinium purification and source counting) and thence to Ra^{223}. Subsequent corrected α-particle counts do not take into account the fact that although all Ac^{227} atoms which disintegrate decay eventually to Ra^{223}, only $98.75 \pm 0.02\%$ (Peterson and Ghiorso (5)) of them decay via Th^{227}. The factor $(e^{-\lambda_1 t}-e^{-\lambda_2 t})$, which expresses the Th^{227} contribution to the total α-particle activity, must therefore be corrected accordingly.

Use of expression [3] rather than [2] for calculations has the merit that a short time may be allowed to elapse between actinium purification and counting without prejudicing the result. This is an advantage when several sources from the same purification have to be counted and, moreover, when it is not possible to determine exactly when the actinium was free from daughters.

For each source the values for N_0 determined on 5 successive days by using expression [3] were averaged and the ratio $(R_{\beta,\,N_0})$ was determined for each film where

$$[4] \quad R_{\beta,\,N_0} = \frac{\text{absolute disintegration rate of the } Ac^{228} \text{ in the source at the end of the irradiation}}{\text{number of atoms of } Ac^{227} \text{ in the source}}.$$

Standard deviations for the three or four separate determinations of $R_{\beta,\,N_0}$ for any one irradiation were calculated and additional uncertainties of 1% and 1.9% were allowed for possible errors in β-disintegration-rate determinations and for errors in the half-lives used in calculating N_0. Distinguishing the results for unshielded and shielded samples by the subscripts 1 and 2 respectively, errors in $(R_{\beta,\,N_0})_1$ varied between 2.6% and 4.2% and errors in $(R_{\beta,\,N_0})_2$ between 5% and 16%.

(4) Measurements with Cobalt Monitors

These have been described by Cabell (3) and by Cabell, Eastwood, and Campion (4).

RESULTS

The results were calculated in terms of the convention advocated by Westcott, Walker, and Alexander (11); application of this convention to the type of experiment described in this paper has been described by Eastwood *et al.* (12).

The measured rate of reaction of a detector, R, is expressed as

$$[5] \quad R = \hat{\sigma}.(nv_0)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

where (nv_0) is the conventional flux, i.e. n is the total neutron density in neutrons/cm^3 and v_0 is 2200 m/sec, and $\hat{\sigma}$, the effective cross section, is defined by expression [5]. It is assumed that the neutron spectrum is the sum of two components; an epithermal dE/E flux distribution cut off at a suitable lower limit of energy and a Maxwellian distribution of thermal neutrons at a temperature $T°$ K. The two components overlap in energy since no upper limit is imposed on the Maxwellian component.

It is possible to express $\hat{\sigma}$ as

$$\hat{\sigma} = \sigma_0(g+rs) \quad [6]$$

where r is a measure of the relative density of the epithermal component of the neutron spectrum and g and s are functions of the temperature T which describe the departure of the detector from the $1/v$ law; for true $1/v$ behavior $g = 1$ and $s = 0$.

Values of s and g for a number of elements and isotopes for which differential and resonance integral data are well known have been tabulated by Westcott (13) for a number of temperatures. Amongst these is cobalt.

Since the neutron temperatures are not known in the experiments described here, s is replaced by a temperature-independent term, s_0, such that $s_0 = s\sqrt{(T_0/T)}$. Substitution in equation [6] then gives

$$\hat{\sigma} = \sigma_0\{g+r\sqrt{(T/T_0)}s_0\}. \quad [7]$$

For the cobalt monitors $\sigma_0 = 36.5$ barns, $g = 1$, $r\sqrt{(T/T_0)}$ can be obtained from $(R_{Cd})_{Co}$, the cadmium ratio for Co^{59}, and $s_0 = 0.953$ (Westcott (13)). Therefore, $\hat{\sigma}$ for cobalt can be calculated and substituted in equation [5] to obtain the total flux (nv_0).

Given (nv_0) equation [5] is used to obtain $\hat{\sigma}$ for Ac^{227} and, *if the assumption is made that $g = 1$ for actinium, i.e. that actinium is a $1/v$ absorber in the thermal region*, σ_0 for actinium may then be obtained from equation [7].

The resonance integral for actinium, $(R.I.)_{Ac}$, is given by:

$$(R.I.)_{Ac} = (R.I.)_{Co}\frac{(R_{Cd}-1)_{Co}}{(R_{Cd}-1)_{Ac}}\cdot\frac{(\sigma_0)_{Ac}}{(\sigma_0)_{Co}}. \quad [8]$$

We have used 48.6 barns for the resonance integral of Co^{59}.

The results obtained are recorded in Table II. It is not to be expected that $\hat{\sigma}(Ac^{227})$ will be constant since the experiments extended over a period of months during which the neutron spectrum in the irradiation position (and hence R_{Cd}) changed. An average value of 839 barns was obtained for $\hat{\sigma}(Ac^{227})$.

The four values of $\sigma_0(Ac^{227})$ recorded in Table II were each weighted in proportion to the reciprocal of the square of its error and gave an average value of 814 ± 13 barns. Similar treatment of the four results for $(R.I.)_{Ac}$ gave an average value of 1177 ± 19 barns.

CONCLUSIONS

The thermal capture cross section of Ac^{227} obtained in this work (814 ± 13 barns) is considerably larger than any figure previously obtained. It is not possible to explain why this figure differs from those quoted by Hughes and Schwartz (1) (510 ± 40 barns by a pile oscillator method and 520 ± 50 barns by an activation method) since these authors refer to unpublished work. Timma and Russell (2) give details of their work which led to 493 ± 53 barns, using an oscillator method, and, although no obvious flaw is apparent in their procedure, the possibility of neutron attenuation within the sample does not

appear to have been considered. A major uncertainty in using a macro quantity of a rare and highly radioactive material as the sample under investigation might be expected to lie in the chemical purity of the sample, but although Timma and Russell quote no spectrographic or other analyses for the sample they used, they determined its Ac^{227} content by two independent methods (gravimetrically and calorimetrically) with good agreement.

The procedure described here relies entirely on 4π counting methods for the determination of numbers of atoms. The half-lives involved are known with good precision and agreement between published data and those realized during the experiments was excellent. With the present state of our knowledge of 4π counting the major uncertainty lies in the possibility of self-absorption in the source itself. In the experiments described the sources used were invisible to the naked eye and adequate allowance was made for the possibility of self-absorption, taking into account the fact that only relatively energetic particles were of interest. Should these allowances, in fact, be inadequate it is much more likely that the β-counting rather than the α-counting would be in error and consequently the resulting cross section would be higher rather than lower than that quoted here and would make the discrepancy with previous values even greater.

PREPARATION AND INFRARED SPECTRA OF DIVINYL SULPHIDE, 2-METHYL-1,3-THIOXOLANE, AND 1,4-THIOXANE[1]

K. K. Georgieff and A. Dupré

ABSTRACT

Dehydration of thiodiglycol at 195°–230° with potassium hydroxide produced a 36% yield of divinyl sulphide, 9–10% of 2-methyl-1,3-thioxolane, 7–8% of 1,4-thioxane, and 3.5% of vinyl 2-hydroxyethyl sulphide. Physical properties and infrared spectra are reported. Divinyl sulphide of high purity for polymer work was obtained by distillation in a Podbielniak column. Precautions that must be observed in the preparation, distillation, and storage are given.

INTRODUCTION

To prepare some divinyl sulphide of high purity for polymer and spectroscopic studies, an examination of the possible methods was made. Dehydrochlorination of mustard gas (2,2′-dichlorodiethyl sulphide) gives reasonable yields (1, 2, 3, 4, 5), but this material is very hazardous to handle, and is not readily available commercially. Dehydrobromination of 2,2′-dibromodiethyl sulphide is less dangerous (6) but this material also is unavailable. Dehydration of thiodiglycol with anhydrous potassium sulphate (7) gives some divinyl sulphide, but also a large proportion of by-products.

$$(CH_2OH.CH_2)_2S \rightarrow (CH_2{=}CH)_2S + 2H_2O$$

Dehydration of thiodiglycol with potassium hydroxide, which has been described more recently by Doumani (8), appeared more promising since no mention of by-products other than 2-hydroxyethyl vinyl sulphide was made. Furthermore, since thiodiglycol is commercially available, investigation of this latter method appeared justified.

Doumani added thiodiglycol slowly to potassium hydroxide and continuously distilled off the divinyl sulphide and water. In this investigation, all of both reagents were added at the beginning and were stirred, but whether this difference in procedure materially affected the yield of divinyl sulphide is not known, since Doumani failed to publish such data. No systematic investigation to determine optimum yield conditions was made, but some precautions which are necessary due to excessive foaming of the thiodiglycol and the ease of polymerization of divinyl sulphide are described in the experimental section.

EXPERIMENTAL

Samples of thiodiglycol were kindly supplied by the Defence Research Laboratories, Shirley Bay, Ontario, and Carbide and Carbon Chemicals Corp., and were used without prior purification. Foaming during the reaction is a problem but may be largely overcome if the following precautions are observed: an oversize reaction flask fitted with a stirrer should be used and the temperature of reaction should be raised very slowly. Also, if it is desired to prepare a second batch, the flask must be thoroughly cleaned before a new charge is added, since even small amounts of residue cause uncontrollable foaming.

The reaction was carried out as follows: into a 500-ml round-bottom flask fitted with an Ace "Tru-bore" stirrer and a distillation column head with a water-cooled condenser were placed 75 ml of thiodiglycol and 75 g of potassium hydroxide pellets (85%). To minimize polymerization, the entire apparatus was evacuated and filled with nitrogen.

The stirrer was started after adjusting the blade so as to just clear the pellets, and the flask was immersed in a bath of Arochlor 1252. The bath temperature was raised slowly and reaction started at 195°. The organic vapors and water were condensed and drawn off as soon as they formed. Reaction was complete at 230°. The product, which was kept at −50° during the course of the reaction, was allowed to warm up to room temperature and the organic layer separated from the water. The aqueous layer was not further worked up even though it contained several per cent of product. The organic layer was dried with Linde Molecular Sieves No. 4A, stabilized with 1% para-tertiary butylcatechol and 2% copper resinate, and fractionated at a pressure of 105–156 mm Hg (abs.) in a Podbielniak column which had previously been flushed with nitrogen. The distillate receivers were kept at −50° during the distillation.

Since divinyl sulphide polymerizes rapidly at room temperature in the presence of air, the contents of each Podbielniak receiver was redistilled as soon as possible into a closed tube fitted with a stopcock and semiball joint using the high vacuum, low temperature technique (9, 10). By storing the samples in the above tubes at −78° in the complete absence of permanent gases, especially oxygen, it was possible to keep over 90% of the material in a monomeric state for over a year without the use of any stabilizer. Traces of certain impurities markedly decrease the rate of polymerization. For example, purified divinyl sulphide recovered from raw acetylene produced from calcium carbide, which probably still contained minute traces of divinylacetylene, did not polymerize at all under the above conditions in over a year.

Preparation of 2-Methyl-1,3-thioxolane from 2-Mercaptoethanol and Acetaldehyde (11)

Redistilled 2-mercaptoethanol (31.2 g) (obtained from Fisher Scientific Co.) and 17.7 g of freshly distilled acetaldehyde dissolved in 100 ml of cold benzene were charged into a 250-ml, stirred, round-bottom flask, fitted with a distillation column head with a brine-cooled condenser. Some heat was generated on mixing the reagents. Then 8 ml of 0.7 *N* anhydrous hydrogen chloride in ether was added from a dropping funnel over a period of 5 minutes. Slight cooling was required to maintain a temperature of 35–38°. The charge was then heated slowly to the reflux point and maintained there for 4 to 5 hours until the theoretical amount of water formed and was drawn off. The crude product was cooled and extracted with several 10-ml portions of aqueous 10% potassium carbonate solution. The benzene was separated by distillation through a short column at atmospheric pressure and the 2-methyl-1,3-thioxolane was fractionated in a Podbielniak column at 53 mm Hg (abs.). Yields were 77–80% on acetaldehyde and somewhat higher on mercaptoethanol.

Infrared spectra were obtained with a Perkin–Elmer, Model 12-C, single beam spectrometer with a rock salt prism.

RESULTS

The dehydration of thiodiglycol with potassium hydroxide produced a much more complex reaction product than previously indicated (8). After the mixture was separated into several main fractions by distillation in a Podbielniak column, the fractions were further resolved by gas chromatography. The various components so obtained were then identified by their mass, infrared, and ultraviolet spectra. The yield of divinyl sulphide was about 36%. Its spectra and rate of polymerization indicated that the mid-distillation cut was of high purity. Its infrared spectra in the gas and liquid phases are given in Fig. 1.

All three major by-products showed parent peaks of 104 in the mass spectrometer.

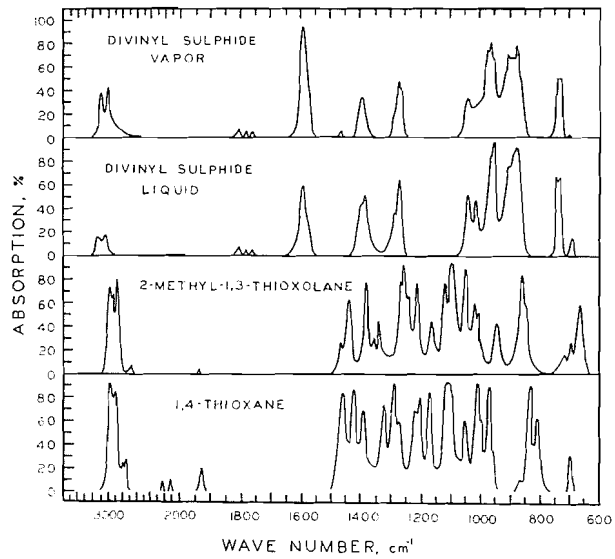

FIG. 1. Infrared spectra. Divinyl sulphide vapor, 34.4 mm pressure in 10-cm cell. Peaks: 3080, 3010, 1806, 1781, 1755, 1592, 1465, 1388, 1286sh, 1272, 1261sh, 1039, 969, 958, 953sh, 914sh, 908, 888, 876, 858sh, 746sh, 738, 733, 696 cm^{-1}.

Divinyl sulphide liquid, 10% by volume in CCl_4 or CS_2 in 0.14-mm cell. Peaks: 3110, 3040, 2970sh, 1588, 1391sh, 1383, 1279, 1265, 1041, 1016, 960sh, 951, 901, 883sh, 874, 736, 729, 685 cm^{-1}.

2-Methyl-1,3-thioxolane, 10% by volume in CCl_4 or CS_2 in 0.128-mm cell. Peaks: 2980, 2940, 2890, 2680, 1934, 1468, 1439, 1380, 1356, 1340, 1267, 1256, 1240, 1212, 1162, 1121, 1095, 1049, 1017, 1007, 996sh, 941, 872sh, 857, 846sh, 712, 691, 661 cm^{-1}.

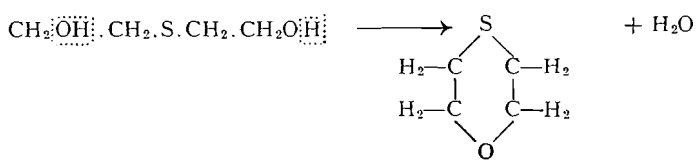
1,4-Thioxane, 100% in 0.029-mm cell. Peaks: 2960, 2900, 2800, 2750, 2220, 2110, 1925, 1459, 1420, 1388, 1323, 1286, 1272, 1216, 1203, 1172, 1105, 1050, 1006, 993sh, 969, 956sh, 865, 828, 809, 693 cm^{-1}.

The highest boiling one appeared to be vinyl 2-hydroxyethyl sulphide in accordance with the findings of Doumani (8), but in point of quantity it was the smallest. The yield was about 3.5%.

$$(CH_2OH.CH_2)_2S \rightarrow CH_2OH.CH_2.S.CH{=}CH_2 + H_2O$$

Infrared bands at 3500 cm^{-1} and at about 1100 indicated the presence of hydroxyl and ones at 1634 and 945 indicated unsaturation.

The second highest boiling by-product was identified as 1,4-thioxane (*p*-oxathiane). Physical properties, infrared and mass spectra, were identical with those of an authentic sample (purchased from Robinson Brothers Ltd., Great Britain). It also formed by splitting of 1 mole of water from thiodiglycol but in this case, elements were removed from both hydroxyl groups, followed by cyclization.

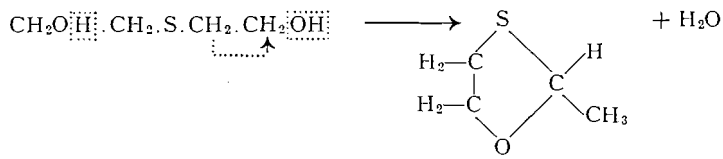


Its formation was not surprising since it was previously obtained from thiodiglycol using potassium sulphate (7) or sulphuric acid (12) as dehydrating agents. The yield was 7–8%. Its infrared spectrum is given in Fig. 1.

The major and third highest boiling by-product was unexpected since its formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

from thiodiglycol does not appear to have been previously reported. It too formed by splitting of 1 mole of water. Its mass spectrum showed a parent peak of 104 and large peaks at 15 and 89 which suggested a methyl group. Its infrared spectrum (cf. Fig. 1) failed to give any indication of unsaturation or a hydroxyl group. Since a straight chain compound would require one element of unsaturation, a cyclic compound seemed probable. Since it boiled about 27° below 1,4-thioxane, a five-membered ring instead of a six appeared possible. From the above data and since its boiling point was identical with that reported by Copenhaver (13, 14), it appeared that our compound might be 2-methyl-1,3-thioxolane (2-methyl-1,3-oxathiolane).



This was confirmed by preparing an authentic sample by the reaction of 2-mercaptoethanol with acetaldehyde in the same manner as Kipnis and Ornfelt (11) prepared 2-isopropyl-1,3-thioxolane from 2-mercaptoethanol and isobutyraldehyde. Physical properties, mass and infrared spectra were identical with those of the compound obtained from the dehydration of thiodiglycol. Its yield from thiodiglycol was 9–10%. The compound appeared to be quite stable at 0° for a period of at least one year.

The lowest boiling by-product obtained was methyl vinyl sulphide. It composed 7–8% of the total volatile product. Identification was made by its boiling point, infrared spectrum (15, 16), and mass spectrum. It is probable that it was formed, in part or in whole, by the dehydration of 2-hydroxyethyl methyl sulphide, which appeared to be a likely impurity in the thiodiglycol. Good mass spectra could not be obtained due to their high boiling points, but on distillation of a few drops from a small charge of the original thiodiglycol in a Podbielniak column, very much larger mass peaks of 74, 61, 47, and 15 were obtained with the distillate than with the residue. This is an indication that some 2-hydroxyethyl methyl sulphide was originally present. Two other by-products were obtained in trace quantities. They had mass parent peaks of 100 and 118 but could not be identified.

Some of the physical properties of the compounds obtained are given below.

TABLE I

Compound	B.p.*	n_D^{20}	d_4^{20}
1,4-Thioxane	67° at 44 mm (abs.)	1.5080	1.105
2-Methyl-1,3-thioxolane	58° at 53 mm (abs.) 130.55° (corr.) at 752 mm	1.4867	1.069
Divinyl sulphide	42.5° at 150 mm	1.5076	
Methyl vinyl sulphide	28° at 155 mm		

*All boiling points are uncorrected except when otherwise stated.

SELF-ABSORPTION IN SOURCES PREPARED FOR 4π BETA COUNTING[1]

JANET S. MERRITT, J. G. V. TAYLOR, AND P. J. CAMPION

ABSTRACT

Using the $4\pi\beta$-γ coincidence method the self-absorption of $4\pi\beta$ counting sources prepared by a number of source preparation techniques has been measured for the negatron emitters Cs^{134} (86-kev branch only), Nb^{95}, Hg^{203}, Co^{60}, Sc^{46}, Rb^{86}, Au^{198}, Na^{24}, and the positron branch of Cu^{64}. The self-absorption varied from a few tenths of one per cent to about ten per cent for sources with a mean superficial density of 2 $\mu g/cm^2$ for most of the nuclides studied. Subsidiary experiments were carried out to indicate the variation of self-absorption with source superficial density.

INTRODUCTION

The comparative simplicity of $4\pi\beta$ counting has led to its general use for absolute disintegration rate measurements. It is well known that the chief corrections are those required for absorption in the source and mount. The latter has been extensively discussed (1, 2, 3) and is small for all but the softest beta emitters if thin source mounts are used. Self-absorption cannot be so readily determined, and this is the principal uncertainty in $4\pi\beta$ counting. Hawkings *et al.* (4) progressively diluted a stock solution, and observed the activity (expressed in terms of the original solution) as a function of the dilution factor. At sufficiently high dilutions a constant activity was observed, which was taken to indicate that self-absorption had been eliminated. This procedure has been criticized (5) on the grounds that diluting a stock solution may not decrease the size of the crystals forming an active deposit but merely increase the distance between them. Pate and Yaffe (5) have described a distillation technique for preparing uniformly thin sources and have used this method to set up self-absorption curves for several isotopes (6). Seliger and Schwebel (7) have estimated the self-absorption of a number of isotopes from electron microscope measurements of the crystal sizes. The $4\pi\beta$-γ coincidence method has been used by Gunnink *et al.* (8) to study self-absorption in thin sources prepared by conventional techniques. Assuming that the observed inefficiencies are entirely due to self-absorption they have obtained a curve of per cent loss in 4π counting against maximum beta particle energy. These authors are careful to point out that these losses are "best" averages, and that the value for any one source may deviate considerably from the mean.

In this laboratory a $4\pi\beta$-γ coincidence counting system consisting of a $4\pi\beta$ proportional counter sandwiched between two 3 in. $\times$ 3 in. sodium iodide crystals (9) has been used to investigate the relative merits of various source preparation techniques. The results of six such techniques applied to several isotopes of widely differing maximum beta particle energy are reported here.

EXPERIMENTAL

In their simplest form the equations relating the observed counting rates in a coincidence determination to the absolute disintegration rate, N_0, are:

$$N_\beta = N_0\epsilon_\beta$$
$$N_\gamma = N_0\epsilon_\gamma$$
$$N_c = N_0\epsilon_\beta\epsilon_\gamma$$

[1]*Manuscript received March 11, 1959.*
Contribution from the Physics Division, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 796.

where N_β, N_γ, and N_c are the observed rates in the beta, gamma, and coincidence scalers respectively, and ϵ_β and ϵ_γ are the efficiencies for the beta and gamma detectors. Hence it follows that

$$\epsilon_\beta = N_c/N_\gamma.$$

In practice these equations require several small corrections, the largest of which are due to dead time, accidental coincidences, and backgrounds (9). Since the counter has been shown to have 100% of 4π geometry (9), the inefficiency in the beta detector is due to self-absorption, source mount absorption, and the possibility that the counter–amplifier system may not detect one ion pair.

The following negatron emitters Cs^{134} (86-kev branch only), Nb^{95}, Hg^{203}, Co^{60}, Sc^{46}, Rb^{86}, Au^{198}, Na^{24}, and the positron branch of Cu^{64} were used in this study. Aliquots were deposited on VYNS plastic films (superficial density 5 $\mu g/cm^2$) stretched across aluminum rings 1.5 in. outside diameter, 1.0 in. inside diameter, and 0.022 in. thick. The underside of the plastic film was coated with 15 $\mu g/cm^2$ of gold. After a sample was deposited, a similar gold-coated film was placed over the source so that both gold surfaces were outermost. Provided that the source is not exceptionally thick this second film adheres well to the source material and the first film without forming cavities. The resistance between the center of a film and the mount ring on the coated and uncoated side is about 0.2 and 1.5 meg respectively, while the resistance of a film having no gold on either side is greater than 600 meg. This sandwich technique ensures that no active material can flake off the source, and also provides a more durable source mount for very little increase in total mount thickness compared with a single film coated on both sides.

The correction for absorption in the source mount was determined by observing the efficiency as a function of the number of pairs of gold-coated films added to the sandwich, and extrapolating the resultant "absorption curve" to zero film thickness. The corrections are listed in Table I, those for Cs^{134}, Nb^{95}, Co^{60}, and Na^{24} were measured as described above, while the remainder were found by interpolation.

A small correction required for the threshold detection energy of the counter–amplifier system was estimated as follows. Pulses due to K X rays from Ca^{41}, Cr^{51}, and Fe^{55} observed at the output of the first stage of the amplifier showed that the system was linear in the range 3.3 to 5.9 kev. Comparison of these pulses with the amplitudes of suitably shaped signals fed to the amplifier input from a pulse generator which just failed to register in the beta scaler gave a threshold detection energy of 0.35 ± 0.1 kev when the counter was operated near the center of the plateau. Assuming that self-absorption does not appreciably distort the spectrum, corrections for undetected particles below this threshold energy were calculated using theoretical beta spectral shapes. The corrections for this effect are shown in Table I.

The determination of the efficiency for the 86-kev beta branch in Cs^{134} presented some difficulty owing to the complex nature of the Cs^{134} disintegration scheme. The results for this branch were determined by accepting pulses in the γ-channel corresponding to the sum peak at 1.97 Mev only. In order to increase the efficiency for detecting this peak the outputs of both crystals were added linearly before discrimination, giving a gamma efficiency of 0.03% (as compared with 10 to 15% for the other nuclides). The statistical uncertainty of the efficiency measurement of any one source is estimated to be $\pm 2\%$ for Cs^{134}, while for all the remaining nuclides the corresponding value is $\pm 0.2\%$. The values obtained for the positron branch in Cu^{64} were determined by accepting pulses corresponding to the 0.511-Mev photo peak in the gamma detectors. A correction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of about 0.3% was necessary for the contribution of the 1.34-Mev gamma ray lying under this peak.

To obtain an indication of the variation of self-absorption with source thickness the beta counting efficiency was measured as a function of the carrier concentration for Au^{198}, Rb^{86}, and Nb^{95}. The results are given in Fig. 1 where the crosshatched area represents the spread in self-absorption which was found.

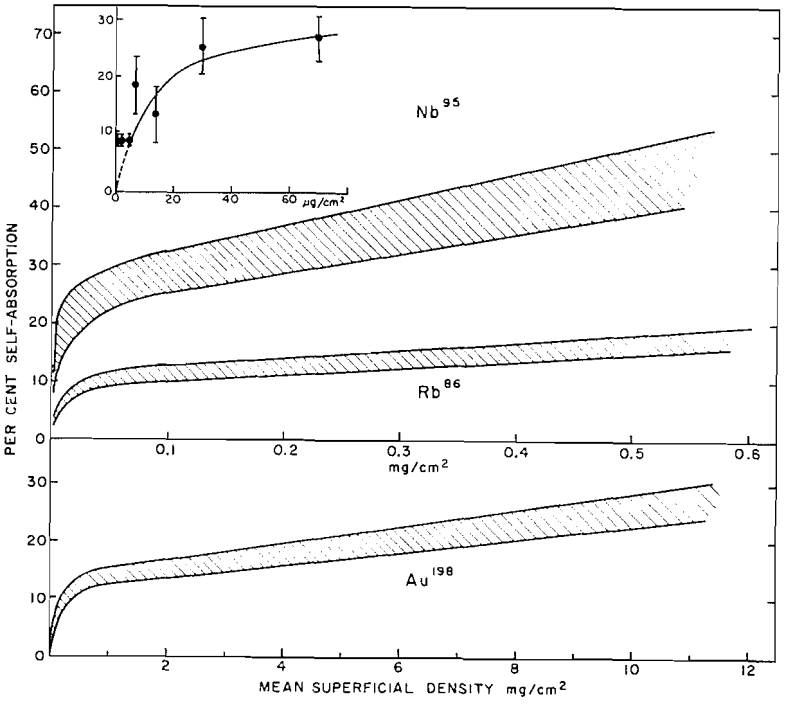

FIG. 1. Per cent self-absorption as a function of the mean superficial density for Au^{198}, Rb^{86}, and Nb^{95}. The Au^{198} and Rb^{86} sources were prepared using the colloidal silica and insulin treatments respectively, while both methods were used in obtaining the curve for Nb^{95}. The inset shows the variation of self-absorption at low mean superficial densities for Nb^{95}.

In order to compare the self-absorption of sources prepared by different methods and with different isotopes, an attempt was made to maintain a mean superficial density of 2 $\mu g/cm^2$, but variations in the area of the deposits may have caused deviations of 50% in this value. In Table I we list the self-absorption, corrected for source mount absorption and threshold detection energy, for a number of isotopes and source preparation techniques. The quoted errors are standard deviations for about five sources. Brief descriptions of, and comments on, the techniques follow according to the column headings of Table I.

(*a*) *Simple evaporation method.*—Aliquots are dried under an infrared lamp and yield a roughly circular deposit of about 1 cm^2. Microscopic inspection shows that this method often results in clumping of the source material, usually around the edge of the deposit, cf. Pate and Yaffe (5). The large errors in this column show the poor reproducibility of the method, especially for the lower energy beta emitters.

(*b*) *Precipitation method.*—A drop of distilled water is added to a source which has been dried as in (*a*). The source is then redried in an atmosphere of ammonia provided by rinsing a beaker with concentrated ammonium hydroxide solution and inverting it

Na^{24}	1.39	0.04	0.01	1.0±0.5			0.8±0.3	0.2±0.2	

over the source. These sources appear more uniform and exhibit higher counting efficiencies than similar sources prepared by method (*a*). The ammonia treatment is limited to elements which form insoluble hydroxides, but the technique has been extended by the use of hydrogen sulphide in the preparation of precipitated Hg^{203} sources.

(*c*) *Insulin treatment.*—Insulin solution used as a wetting agent improves the uniformity of evaporated sources and hence their efficiencies, particularly when the solids content is high. Although the usual practice is to remove (prior to depositing the activity) most of the insulin solution from the source mount the solids in the remainder are often considerably more than those contained in many high specific activity solutions, and hence the presence of these solids partially offsets the beneficial properties of the insulin. The sources employed in these studies contained about 2 μg of such residual solids from the insulin. Hence the mean superficial density of sources listed in column (*c*) of Table I is about 4 $\mu g/cm^2$.

(*d*) *Colloidal silica treatment.**—Aliquots are delivered into a small amount of silica sol on a source mount and dried as in (*a*). A freshly prepared $1:10^4$ aqueous dilution of "Ludox" SM (du Pont) has been found convenient. A study of beta efficiencies as a function of the amount of "Ludox" showed that about 10 to 20 μl of the diluted sol (about 0.2 to 0.4 μg residual silica) is optimum for most isotopes. Although high ionic concentrations should be avoided to prevent gelation of the silica, "Ludox" has been successfully used with solutions as acidic as 0.5 *N*.

(*e*) *Spray method.*—The source preparation technique of Carswell and Milsted (11) has been used to prepare almost invisible sources on gold-coated VYNS mounts.† The activity is dissolved in acetone, which is then introduced into a fine glass capillary ($\sim$ 0.005 in. at the tip). When about 3 kv d-c. potential is applied between the source mount and the tip of the capillary a fine spray is ejected. Conditions are adjusted so that the droplets forming the spray evaporate before they reach the source mount. Although the method is presently not quantitative, the yields can be made better than 90% and the convenience of the method together with the low self-absorption obtained suggests its use for the technique proposed by Seliger (12) for the standardization of beta emitters having no γ-ray in their decay scheme. A thin source is prepared from high specific activity material, and counted. The deposit is then completely dissolved,

**This method was developed by W. F. Merritt, who used it to prepare* S^{35} *sources (10).*

†*We are indebted to Drs. Fraser and Milton of this laboratory for the use of their equipment, which is a modification of that described by Carswell and Milsted.*

For personal use only.

carrier added, and the solution made up to volume to form a standardized stock solution. This can then be used to calibrate other similar solutions by direct comparison.

(*f*) *Distillation method.*—Some sources of Co^{60} have been prepared by the distillation method of Pate and Yaffe (5).* These are very uniform deposits which exhibit about the same self-absorption as sprayed sources. For the sources studied the yields were low, but according to (5) the method may be made very nearly 100% quantitative.

DISCUSSION

The self-absorption values obtained by the simple evaporation method and by the use of colloidal silica (columns (*a*) and (*d*), Table I) are shown graphically in Fig. 2,

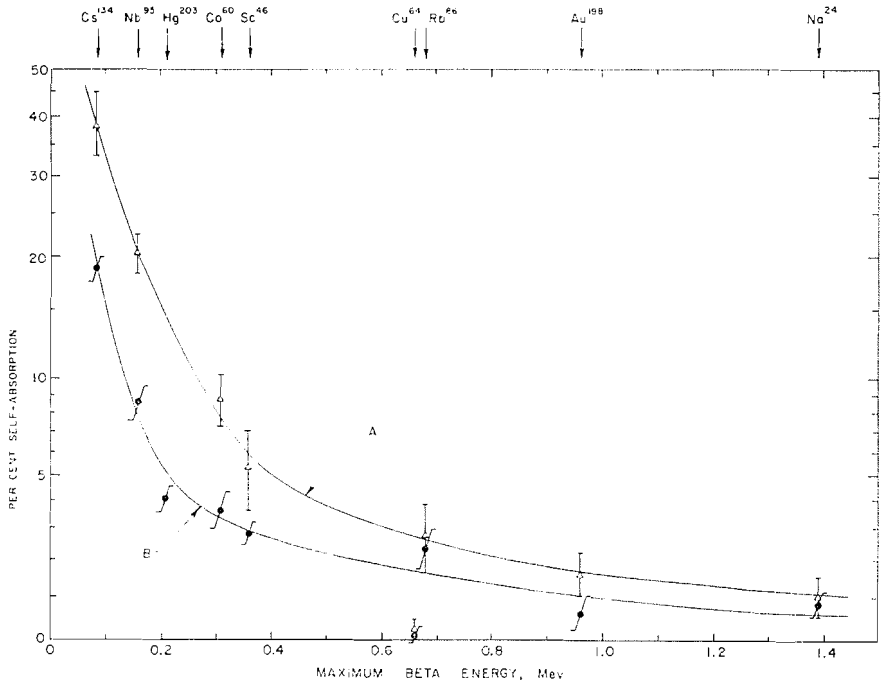

FIG. 2. Per cent self-absorption as a function of beta end point energy for sources of mean superficial density of 2 $\mu g/cm^2$. Curves A and B represent sources prepared by the simple evaporation and colloidal silica methods respectively.

curves A and B respectively. For clarity the results for insulin-treated sources have not been plotted; inspection of Table I shows that they are very similar to those for colloidal silica-treated sources. The results show a comparatively small variation of self-absorption with beta end point energy above about 400 kev, but below this value the absorption rapidly increases. We also note, in agreement with others (8), that the reproducibility in general tends to decrease as the self-absorption increases. On the whole there is good agreement between the self-absorption values obtained by method (*a*) and the experimental results of Gunnink *et al.* (8). Our values are slightly larger than those estimated by Seliger and Schwebel (7), while those obtained for the distilled Co^{60} sources are in agreement with the curve given by Yaffe (6). The use of colloidal silica is seen to be particularly advantageous at low beta end point energies, although no

*We are indebted to Dr. Yaffe and Mr. J. B. Fishman for the preparation of these sources.

For personal use only.

technique that we have investigated to date is capable of reducing self-absorption to negligible proportions. There is one notable deviation from the curves of Fig. 2, viz. the positron branch of Cu^{64}. This may be explained by the fact that owing to the coulomb repulsion effect there are fewer low energy particles in a positron spectrum than in a negatron spectrum having the same end point energy and hence self-absorption effects are smaller.

It should be emphasized that the rapid variation of self-absorption with source thickness (Fig. 1) demands that the source preparation techniques and mean superficial densities be closely similar to those used here if the curves of Fig. 2 are to be used to estimate even approximate self-absorption corrections for $4\pi\beta$ counting. Further, Fig. 1 (inset) and Fig. 8 of (5) show that for sources of smaller mean superficial density it does not necessarily follow that the self-absorption will be significantly less.

NOTES

INDEPENDENCE IN HYDROLYSIS OF CONDENSED PHOSPHATES

M. Joyce Smith

In a series of papers (1) from these laboratories, it was concluded that the hydrolysis of sodium tetrameta-, tetrapoly-, tripoly-, and pyro-phosphate at constant pH and 65.5° C followed first-order kinetics and that hydrolysis of different species in the same dilute solution proceeded independently. A convenient method for making numerical calculations of consecutive reactions was also developed.

When this method was applied to the complete hydrolysis of tetrapolyphosphate near pH 5 using the available rate constants a poor fit was obtained for the curve showing the appearance and disappearance of tripolyphosphate. Either the rate constant for tripolyphosphate at pH 5 or the assumption of independence, or both, might be in error.

Recently an opportunity occurred to investigate the hydrolysis of tetrapolyphosphate using improved chromatographic techniques (2) and carrying out the whole experiment in a reasonably short time without change of personnel.

The results were:

(1) a closer quantitative confirmation of first-order kinetics;
(2) a higher value for the rate constant for tripolyphosphate at pH 5 (6.70×10^{-4} vs. 2.89×10^{-4});
(3) much improved agreement with the theory of consecutive reactions (see Fig. 1); and
(4) confirmation of first-order kinetics by the addition of pyrophosphate and orthophosphate during hydrolysis of tripolyphosphate without effect on the rate constant.

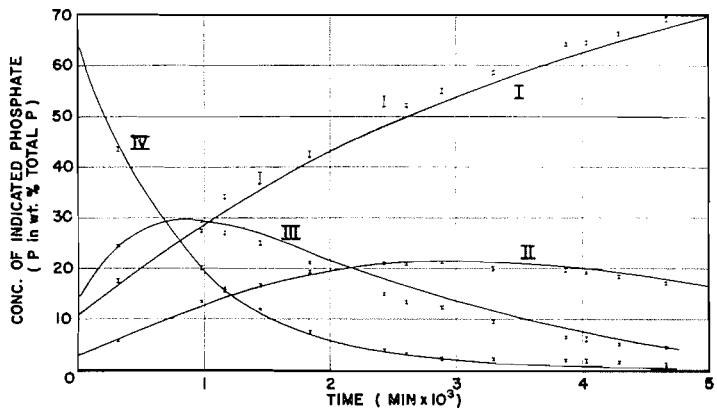

Fig. 1. The course of the reaction degrading tetrapolyphosphate to orthophosphate at 65.5° C and pH = 5.0. Full lines show the proportions of the constituents of the reaction mixture as calculated from the theory of consecutive reactions (1 *d*), individual points show the chromatographically determined values, in duplicate. I, orthophosphate; II, pyrophosphate; III, tripolyphosphate; IV, tetrapolyphosphate.

Since one experiment in the earlier work had given a rate constant of 6.2×10^{-4} at pH 5 for tripolyphosphate, the possibility that it might change drastically in the neigh-

borhood of pH 5 was considered. However, several experiments in the neighborhood of pH 5 showed this not to be the case.

The revised rate constants are given in Table I.

2,4-DIAMINO-2-METHYLPENTANE DIISOCYANATE AND ITS METHYL URETHANE

K. H. KOSSMANN

2,4-Diamino-2-methylpentane is easily prepared from acetone and ammonia via 2,2,4,4-pentamethyl-2,3,4,5-tetrahydropyrimidine ("Acetonine") (1, 2).

While investigating methods of preparation of the diamine it was found desirable to prepare the diisocyanate of diamino-methylpentane and its methylurethane. The procedure used was similar to one given for hexamethylenediamine (3) with the exception that the dihydrochloride was not isolated.

EXPERIMENTAL

A. 2,4-Diamino-2-methylpentane diisocyanate 58 g ($\frac{1}{2}$ mole) of 2,4-diamino-2-methyl-

pentane was dissolved in 500 cc of *sec*-amylbenzene in a 1-liter, 3-necked flask fitted with stirrer, gas inlet, and gas outlet.

Dry HCl gas was bubbled through at 20–25° C, with stirring, until precipitation of the dihydrochloride was complete. The charge was heated with constant stirring to 180–185° C. Phosgene was then introduced, as a gas, for about 16 hours, after which time all the dihydrochloride had disappeared. After filtering, the reaction product was distilled at 10 mm Hg. Diisocyanate (30 g) was obtained, which represented a 35.7% yield. Methylpentanediamine diisocyanate boiled at 90–92° C at 10 mm Hg. Its refractive index at 20° C was 1.4445 (1.4449), its density at 20.5° C was 1.019.

B. The methylurethane of methylpentanediamine diisocyanate was prepared by dissolving 2 g of the diamine in 10 cc of methanol. The mixture warmed up. When it had been cooled the urethane crystallized and was recrystallized from methanol. Its melting point was 81° C.

A SIMPLE THERMOSTATED PROBE ASSEMBLY FOR HIGH RESOLUTION NUCLEAR MAGNETIC RESONANCE SPECTRA

S. BROWNSTEIN

The observation of high resolution nuclear magnetic resonance spectra at a variety of temperatures is desirable to determine rates and activation energies for intramolecular motions (2, 3). The problem of constructing a thermostated probe assembly is complicated by the necessity of spinning the sample rapidly, not using magnetic materials, and having only a small space available. Nevertheless two such probes have been described in the literature (1, 4). Both of these assemblies have the disadvantage of requiring highly skilled glass-blowing techniques, and one of these (4) requires winding of a special receiver coil. In the assembly described here only a simple modification of the commercially available receiver coil unit is required. The apparatus may be easily dismantled and therefore can be used at a variety of frequencies by merely exchanging the receiver coil unit.

A plastic sleeve, tapered at the upper end, is cemented to the base of the probe insert. This mechanically strengthens it and serves as a seal to the thermostated compartment. A slot is cut below the receiving coil, and the insert is lengthened by sealing on an additional length of glass tubing. The resultant probe insert is shown in Fig. 1.

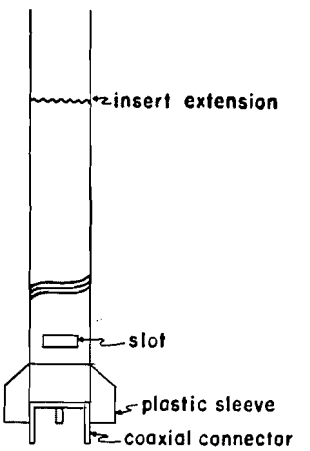

FIG. 1. Modified probe insert.

A cylindrical vacuum jacket, through which a side arm leads, is placed around the insert, fitting against the plastic sleeve at the lower end and supported by a tapered Teflon plug at the upper end. This fits tightly into the probe assembly, with the aid of a Teflon gasket, and is tuned in the usual manner. An aluminum housing, sitting on a cork gasket, with a slot for the glass side arm is screwed to the housing of the probe assembly. An extension of the housing fits snugly against the Teflon plug so that the thermostating air may leave only through the side arm in the aluminum housing. A commercially available sample spinner screws onto the top of the aluminum housing (5). Figure 2 shows the completed assembly with arrows indicating the path of the thermostated air.

The thermostated air was carried to the glass side arm by a Teflon tube wrapped in glass wool and aluminum foil. The temperature was measured by a copper constantan

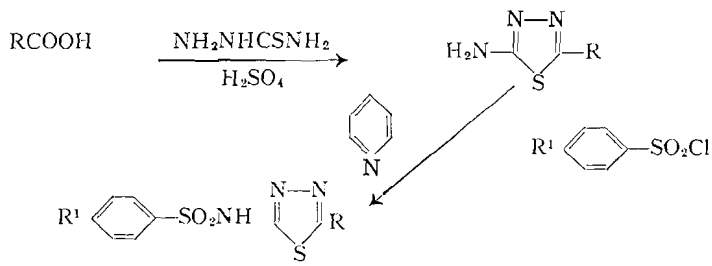
SOME HYPOGLYCEMIC THIADIAZOLES

Francis L. Chubb and Jacqueline Nissenbaum

In 1942 Janbon (1) first noticed that 2-sulphanilamido-5-isopropyl-1,3,4-thiadiazole caused hypoglycemia. Bovet and Dubost (2) as well as Loubatières (3) studied the relationship between structure and activity in this series. The present work was undertaken in an effort to prepare some new hypoglycemic thiadiazoles.

A series of 2-arylsulphonamido-5-alkyl-1,3,4-thiadiazoles (Table II) was synthesized according to the following reaction scheme.



The pharmacology of these compounds will be reported elsewhere.

EXPERIMENTAL

2-Amino-5-alkyl-1,3,4-thiadiazoles (Table I)

A well-stirred mixture of 0.3 mole of fatty acid, 31.5 ml of concentrated sulphuric acid, and 0.25 mole of thiosemicarbazide was slowly heated to 80–90° and maintained at that temperature for 7 hours. After the reaction mixture was cooled, it was poured into ice water and made basic with concentrated ammonia. The crude product, which precipitated upon addition of the ammonia, was filtered and washed with water. It was recrystallized from alcohol–water.

thermocouple, B and S gauge 20, inserted through the side arm to 1/4 in. from the receiving coil. This assembly has been operated from −60° to 120° C with resolution equal to that obtained in instruments without a thermostated assembly. Figure 3 shows a trace obtained for the aldehydic proton of acetaldehyde. The resolution is at least one part in 10^8. Since the receiver coil may be tuned without disassembling the apparatus, it is used for routine investigations as well as variable temperature studies.

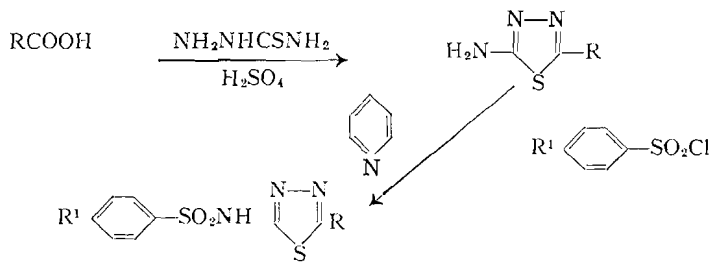
SOME HYPOGLYCEMIC THIADIAZOLES

Francis L. Chubb and Jacqueline Nissenbaum

In 1942 Janbon (1) first noticed that 2-sulphanilamido-5-isopropyl-1,3,4-thiadiazole caused hypoglycemia. Bovet and Dubost (2) as well as Loubatières (3) studied the relationship between structure and activity in this series. The present work was undertaken in an effort to prepare some new hypoglycemic thiadiazoles.

A series of 2-arylsulphonamido-5-alkyl-1,3,4-thiadiazoles (Table II) was synthesized according to the following reaction scheme.



The pharmacology of these compounds will be reported elsewhere.

EXPERIMENTAL

2-Amino-5-alkyl-1,3,4-thiadiazoles (Table I)

A well-stirred mixture of 0.3 mole of fatty acid, 31.5 ml of concentrated sulphuric acid, and 0.25 mole of thiosemicarbazide was slowly heated to 80–90° and maintained at that temperature for 7 hours. After the reaction mixture was cooled, it was poured into ice water and made basic with concentrated ammonia. The crude product, which precipitated upon addition of the ammonia, was filtered and washed with water. It was recrystallized from alcohol–water.

2-Arylsulphonamido-5-alkyl-1,3,4-thiadiazoles (*4*) (*Table II*)

A solution of 0.06 mole of the arylsulphonyl chloride in 25 ml pyridine was slowly added with stirring to a solution of 0.06 mole of 2-amino-5-alkyl-1,3,4-thiadiazole in 25 ml pyridine. The resulting solution, after being allowed to stand overnight at room temperature, was slowly added to an excess of 6 *N* hydrochloric acid. The crude product separated, usually as a solid but sometimes as a yellow gum which crystallized on standing. It was dissolved in dilute sodium hydroxide, treated with charcoal, and reprecipitated with hydrochloric acid. The 2-arylsulphonamido-5-alkyl-1,3,4-thiadiazole was recrystallized from alcohol–water.

Microanalyses were performed by Dr. Carl Tiedcke, Teaneck, N.J., U.S.A.

NOTE ON THE PHOTOOXIDATION OF TETRAMETHYLRUBRENE*

ROBIN M. HOCHSTRASSER

Badger's group (1) first noticed that tetramethylrubrene (5,6,11,12-tetra-*p*-tolylnaphthacene) crystals change from their normal deep red to a colorless form on exposure to sunlight. This is not a widely observable phenomenon in as much as substances which are photochemically active when dissolved in a suitable solvent do not normally undergo the same reaction in the pure crystalline form. Rubrene (5,6,11,12-tetraphenylnaphthacene) was found to exhibit the same type of decoloration on exposure to ultraviolet irradiation (3), but in this case specially prepared thin films on a large area substrate were necessary. In each case the product is a transannular peroxide.

It is the purpose of this note to report the results of some experiments on the photooxidation of tetramethylrubrene crystals. The experiments were done at 25° C in cells with plane quartz windows. The light source was a 1-kw AH6 water-cooled mercury arc. The apparatus was as previously described by Hochstrasser and Ritchie (3), and differential pressure measurements could be made to within 0.002 mm Hg at total pressures below 25 mm Hg. The oxidation was followed by noting the changes of oxygen pressure in a constant volume system as the crystals were illuminated with near monochromatic light. The small crystals were scratched on to the surface of a quartz disk (in the absence of absorbable light) and the disk was then carefully sealed on to one end of a cylindrical cell. The cell was then evacuated, oxygen allowed in to a known pressure in the dark, and when stability was maintained the crystals were illuminated and the decrease in pressure determined as a function of time. Experiments involving intermittent illumination and irradiation with light at two wavelengths were performed.

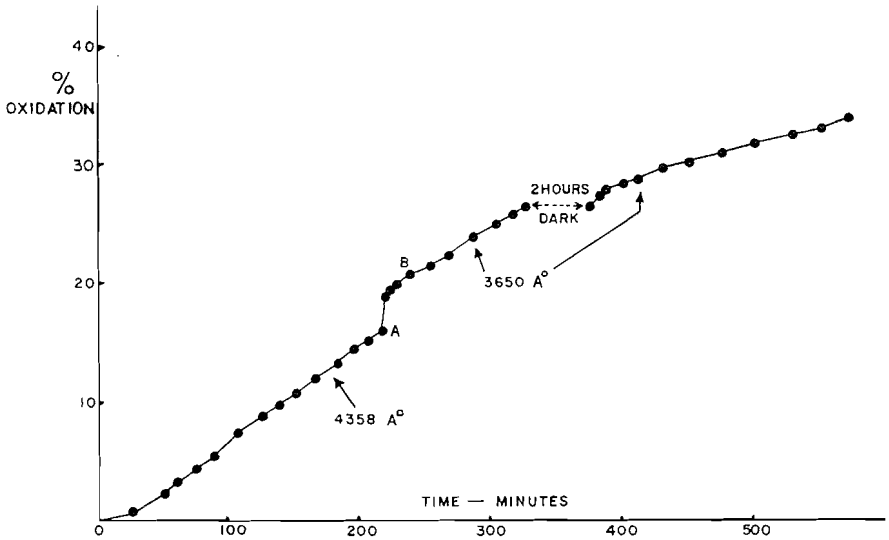

FIG. 1. Photooxidation of tetramethylrubrene crystals (10^{-6} mole of crystal; quanta at 3650 Å approximately double 4358 Å; O_2 pressure 25 mm).

A typical result is shown on Fig. 1 where the extent of the oxidation is plotted against time of irradiation. At A the illumination was discontinued and the crystals left in contact with oxygen for 30 minutes, then reirradiated. The magnitude of the increased rate from A to B was a function of the time of dark contact with oxygen. These results indicate that the photooxidation of tetramethylrubrene is diffusion-controlled. The effects observed when the intensity or the wavelength of the exciting light was changed were again indicative of a diffusional rate-determining step. The absolute rates of oxidation were not reproducible with different crystalline deposits, but the initial rate constants were all of the order of 10^{-10} mole second^{-1} and the quantum yields were approximately 10^{-4} depending on the oxygen pressure. The peroxide is in thermal equilibrium with oxygen but the dissociation is occurring at a negligible rate at this temperature.

Such a system is interesting in as much as not many similar cases are known and certainly not in relation to the combination of molecular oxygen with an aromatic hydrocarbon. As has already been pointed out, crystals of rubrene do not oxidize at a measurable rate even in an atmosphere of oxygen. During the formation of the transannular peroxide a drastic structural change must occur as shown in Fig. 2. Microscopic examination of partly oxidized crystals shows that the oxidation is occurring at the crystal surface.

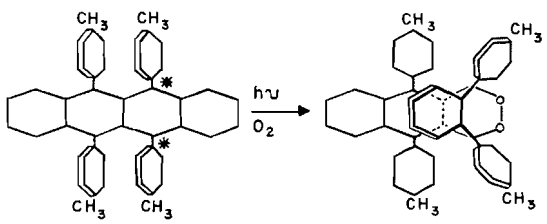

FIG. 2. Schematic representation of the photooxidation of tetramethylrubrene.

It is reasonably well established that oxidations of this type occur via the triplet state of the molecule attained after intersystem-crossing from the first excited singlet state (4). In a molecular crystal intersystem-crossing will manifest itself as localization of excitation energy within the crystal. This arises from the theory of molecular crystals (2) which shows that the singlet levels of the isolated molecule will be split in the crystal into a broad band ($\sim 3000\ cm^{-1}$), while the triplet splitting will be very small by virtue of the fact that the transition moment integral between the ground singlet and first triplet is negligibly small. In order that the reaction with oxygen can occur, this energy must be transported to the surface of the crystal, where there is an oxygen molecule available. It is the availability of oxygen which is the limiting factor in this case. To accomplish photooxidation, the oxygen must first traverse the peroxide layer. Here the rate of diffusion is measurable, and the observation of a diffusion-controlling step suggests that one reason why other aromatic hydrocarbons containing the basic anthracenic structure do not apparently react with oxygen to any great extent is the imperviousness of the peroxide layer to oxygen. With a bulky molecule such as tetramethylrubrene or even rubrene under special conditions this layer becomes permeable. The discovery of an effect such as this opens up a wide field which should yield much information regarding the transport of electronic excitation energy in molecular crystals. In the near future it is proposed to commence a detailed rotating sector and intensity study of the photooxidation of tetramethylrubrene single crystals.

The author expresses his thanks to Professor G. M. Badger for a sample of tetramethylrubrene.

STUDY OF THE RADIOLYSIS OF BROMAL HYDRATE SOLUTIONS USING C^{14}-LABELLED BROMAL[1]

H. HEUSINGER, R. J. WOODS, AND J. W. T. SPINKS

ABSTRACT

Bromal labelled with C^{14} in the carbonyl group has been used to show that small amounts of carbon dioxide and carboxylic acids are produced in the radiolysis of aqueous bromal solutions. *G* values for the production of CO_2 and carboxylic acid are about 7.5% and 15% of those for HBr production, respectively. The observed yield of carboxylic acid is in agreement with that found by titration.

INTRODUCTION

The decomposition of aqueous bromal hydrate solutions by cobalt-60 gamma rays has already been studied with special reference to the formation of hydrogen bromide (1). Some of the major products of the radiolysis were determined, but it proved difficult to separate those products which were formed in smaller amounts and the quantitative determination of these was not attempted. This suggested the use of labelled bromal, which would facilitate the separation of products using carrier techniques. The determination of the relative activities would give directly the ratio of the products formed.

EXPERIMENTAL

Preparation of C^{14}-Labelled Bromal Hydrate

1-C^{14}-Ethanol[2] (0.1 mc) diluted with 4 g inactive ethanol was oxidized with hot, aqueous dichromate solution (2) and the acetaldehyde produced collected in a bulb cooled in a solid carbon dioxide – methanol bath. The bulb was removed from the cooling bath and equipped with an efficient reflux condenser, through which a drop of dilute sulphuric acid was added. The acetaldehyde became hot and polymerized. The polymer was brominated (3), and the products separated by fractional distillation under reduced pressure. The bromal fraction, b.p. 85–87° C/38 mm, was dissolved in 10 ml acetone, and 3 ml water added. Bromal hydrate (5.5 g, 9×10^3 disintegrations/min mg), m.p. 53.5° C, crystallized as the acetone evaporated. An additional small quantity of bromal was obtained by brominating the low boiling fractions further.

Irradiation of Bromal Hydrate Solutions

Solutions (2 or 3 ml) were irradiated in glass test tubes equipped with gas inlet and outlet tubes and supported in lucite blocks arranged concentrically about a 90-curie Co^{60} source, permitting dose rates of up to 1510 roentgens per minute. Dose rates were measured by determining the ferric ion formed when solutions of ferrous ammonium sulphate were irradiated (4), assuming a *G* value of 15.5 for the formation of ferric ions and a conversion factor of 1 r = 0.975 rad (5).

[1]*Manuscript received January 19, 1959.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*Merck and Co., Montreal, Quebec.*

Gaseous and volatile products were removed by passing a stream of oxygen or hydrogen through the solution either during the irradiation or afterwards. Carbon dioxide was subsequently absorbed from the gas stream by sodium hydroxide solution. In one experiment the oxygen leaving the irradiation tube was passed through a heated platinum catalyst, to oxidize volatile organic compounds to carbon dioxide, before being passed through the sodium hydroxide solution.

Hydrobromic acid and the "total acid" were determined in irradiated solutions of inactive bromal hydrate by titration with silver nitrate solution (eosin) and sodium hydroxide solution (bromophenol blue), respectively.

Counting

In order to get directly comparable values for the radioactivity present in the starting material and the products, all were counted as barium carbonate. The carbonate was counted in a gas-flow proportional counter as infinitely thick samples.

Bromal hydrate, and products other than carbon dioxide, were oxidized to carbon dioxide by warming with an aqueous solution of potassium persulphate containing silver nitrate as a catalyst (6). The carbon dioxide was absorbed in sodium hydroxide solution, carrier sodium carbonate added, and a solution containing ammonium and barium chlorides added to precipitate barium carbonate.

Determination of Carboxylic Acids Formed by Irradiation

To 2 ml of irradiated bromal hydrate solution were added 50 mg inactive bromal hydrate and 40 mg glacial acetic acid, and the solution stirred with 2 g barium carbonate. The neutral solution was filtered, extracted with ether, acidified, and again extracted with ether. Acidic materials were extracted from the ethereal solution with dilute sodium hydroxide solution, a stream of air passed through the alkaline extract to remove dissolved ether, and the organic acids oxidized with persulphate as described above.

RESULTS

The amount of carbon dioxide formed was plotted against the dose of radiation received, as shown in Fig. 1, and the slope of the line measured. Results obtained in this manner,

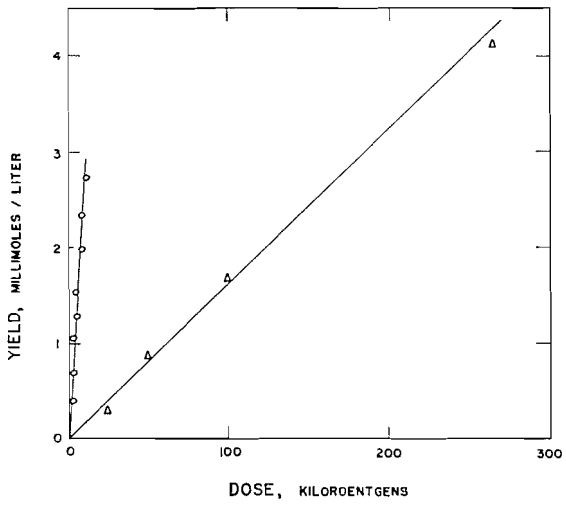

FIG. 1. Production of hydrobromic acid and carbon dioxide on irradiation of 0.2 molar bromal hydrate solution. Dose rate, 216 r/min; ○, HBr; △, CO_2.

expressed as G values (1), are given in Table I. Yields of hydrobromic acid, determined by titration are given for comparison. In one experiment the gases from the irradiated solution were passed over a catalyst with oxygen; since this did not increase the yield of carbon dioxide it was assumed that carbon monoxide and other volatile compounds containing the aldehyde–carbon from bromal were absent.

Table II gives yields of hydrobromic acid and the total acid which were determined by titration of irradiated solutions of inactive bromal hydrate. The ratio $G_{\text{total acid}}/G_{\text{HBr}}$ appears to be constant with a value of about 1.16, and to be independent of concentration of bromal hydrate, dose rate, and the presence or absence of oxygen (the "oxygen-depleted" solutions in Table II contained only the oxygen diffusing into the solution from the air above it, oxygen originally present having been used up), although all of these factors have a considerable effect upon the yield of acid. The ratio of $G_{\text{HBr+carboxylic acid}}/G_{\text{HBr}}$ found using labelled bromal (1.15 cf. Table I) agrees well.

TABLE I

Radiolysis products from 0.2 molar aqueous bromal solutions

Gas-saturating soln. during irradiation	Dose rate (r/min)	G_{HBr}	G_{CO_2}	$G_{\text{carboxylic acid}}$	$(G_{\text{CO}_2}/G_{\text{HBr}})\times 100$
Oxygen	216	245	16.2	—	6.6
Oxygen	460	160	12.6	—	7.9
Oxygen	1510	96	7.2	—	7.5
Hydrogen	1510	17.5	0.44	—	2.5
Air (depleted in O_2 during latter stages of irradiation)	460	33.5*	3.5*, †	5.0*	10.4

* Values determined after a single dose of about 100 kr.

† Not changed by oxidation of exit gases.

TABLE II

Hydrobromic acid and total acid produced by radiolysis of aqueous bromal hydrate solutions

Gas-saturating soln. during irradiation	Dose rate (r/min)	Molarity	G_{HBr}	$G_{\text{total acid}}$	$G_{\text{total acid}}/G_{\text{HBr}}$
Oxygen	20	2.0	985	1070	1.09

Air (O_2-depleted)	1100	0.1	14	18	1.29

DISCUSSION

It has already been shown (1) that the radiolysis of aerated, aqueous solutions of bromal hydrate gives hydrobromic acid in such amounts that a chain reaction, initiated by the primary radicals produced by the radiation–water interaction, must be postulated to account for it. Dibromoacetaldehyde, together with a smaller quantity of dibromoacetic acid, was also found among the products of the reaction, although the yields of each could only be estimated approximately. Oxygen was found to be necessary for the highest yields of hydrobromic acid, and was used up during the reaction. The yield fell markedly if the oxygen present in solution was used up or was displaced with nitrogen. About one mole of oxygen was used up for every 3 or 4 moles of hydrobromic acid produced.

For personal use only.

Both the mechanism of the chain reaction and the fate of the oxygen which is consumed are uncertain. The present study was initiated to examine the possibility that carbon–carbon bond fission was a step in the chain reaction that would account for the uptake of oxygen.

Probable chain-initiating reactions between the primary radicals and bromal hydrate are:

$$R\cdot + Br_3C.CH(OH)_2 \rightarrow RBr + Br_2\dot{C}.CH(OH)_2, \quad [1]$$

$$\rightarrow RH + Br_3C.\dot{C}(OH)_2, \quad [2]$$

$$\rightarrow ROH + Br_3C.\dot{C}H(OH), \quad [3]$$

where R· is a hydrogen atom or a hydroxyl radical. Oxygen, if present, could react with the organic radicals to give peroxy radicals which, since stable peroxides have not been detected after irradiation, must subsequently break down. The peroxy radical from reaction [1] would probably break down, the over-all reaction being represented by,

$$Br_2C.CH(OH)_2 + O_2 \rightarrow 2HBr + 2CO_2 + HO_2\cdot. \quad [4]$$
$$\dot{O}_2$$

In this case both carbon atoms appear as carbon dioxide. Peroxy radicals from reactions [2] and [3] would be liable to break down to give the relatively stable tribromomethyl radical, $Br_3C\cdot$, carbon dioxide from the carbonyl carbon atom, and either hydrogen peroxide or water.

Since the amount of carbon dioxide found is only about 7% of the amount of hydrobromic acid it is evident that the fission reactions suggested above, although they may account for the carbon dioxide produced and for part of the oxygen consumed, are not steps in the chain reaction. Furthermore, the carbon dioxide/hydrobromic acid ratio does not vary with dose rate as would be expected if the carbon dioxide were formed in a chain-stopping step; the yield of hydrobromic acid is inversely proportional to the square root of the dose rate (1). Thus, carbon dioxide must be formed by a side reaction which is not part of the chain reaction producing hydrobromic acid. The lower yield of carbon dioxide in the absence of oxygen is in line with the reactions suggested above.

The yield of carboxylic acid also bears a constant ratio to the amount of hydrobromic acid formed and is independent of dose rate, but the yield of acid is too small for it to be formed directly during the chain reaction. The ratio is the same in the presence or absence of oxygen and the acid may result from rearrangement of a proportion of the radicals concerned in the chain reaction. The only carboxylic acid isolated was dibromoacetic acid, suggesting that the rearrangement might be,

$$Br_3C.\dot{C}(OH)_2 \rightarrow Br_2\dot{C}.CBr(OH)_2, \quad [5]$$

followed by removal of hydrogen from a solvent or solute molecule and hydrolysis of the acid bromide. The rearrangement of a number of radicals with the migration of a hydrogen atom has been discussed by Semenov (7), and instances in which a chlorine atom migrates have been given by Wiley (8) and Nesmeyanov (9), the examples given by the latter author involving migration of a chlorine atom from a trichloromethyl group to the adjacent carbon atom. Rearrangement to more stable structures of the organic radicals concerned in the radiolysis of bromal should be favored by the relatively long mean lifetime of the radical chains, about 0.1 to 1 second (10).

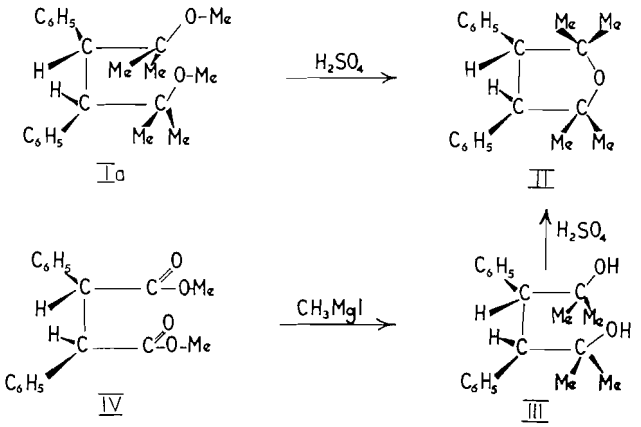
THE CONFORMATIONS OF THE DIASTEREOMERIC 2,5-DIMETHYL-2,5-DIMETHOXY-3,4-DIPHENYLHEXANES[1]

HENRY SAWATZKY, GEORGE K. WHITE, AND GEORGE F WRIGHT

ABSTRACT

The electric dipole moments of six possible rotamers comprising the two diastereomeric forms of 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane have been calculated vectorially. Comparison of these values with the experimental determination of polarization in benzene and carbon tetrachloride shows that only two of the rotamers of the *dd,ll* form and only one of the *meso* form are present in significant amount. The moment of the *dd,ll* diastereomer decreases with increasing temperature but that of the *meso* form is almost invariant. It is probable that all six central linkages in these diastereomers are hindered from free rotation.

The two diastereomers (I*a* and I*b*) of 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane may be obtained by homopolar reduction of 1-chloromercuri-1-phenyl-2-methoxy-2-methylpropane (1). One of these diastereomers (I*a*) was reported (1) as a non-crystallizable oil, but we have now succeeded, after chromatographic removal of impurities, in the isolation of I*a*, as a low-melting solid.



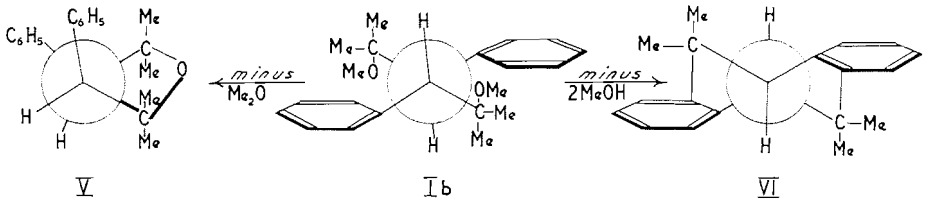
Ia II IV III

The configuration of I*a* has been established (2) by its conversion in concentrated sulphuric acid to the related diastereomer of 2,2,5,5-tetramethyl-3,4-diphenyltetrahydrofuran, II. The configuration of this cyclic ether was established as *dd,ll* because it could be prepared from the diol III, which was obtained from methyl Grignard reagent and *dd,ll*-dimethyl-2,3-diphenylsuccinate, IV (3).

As might be expected in view of the steric convenience in conversion of I*a* or III to II, the other diastereomeric (*meso*) 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane, I*b*, does not form a cyclic ether, V, with ease. It does undergo condensations of the Friedel–Crafts type so that the methoxyisopropyl group on one of the central ("pivot") carbon atoms reacts with the ortho position of a phenyl group on the other "pivot" atom to form 5,5,10,10-tetramethyl-4*b*,5,9*b*,10-tetrahydroindeno[2,1-*a*]indene, VI.

The difference in types of reaction and products formed from I*a* and I*b* would suggest a strong steric influence. Moreover, the specific reactivity with respect to condensing agents (1, 2) shows that the geometry of the diastereomers must be important. For

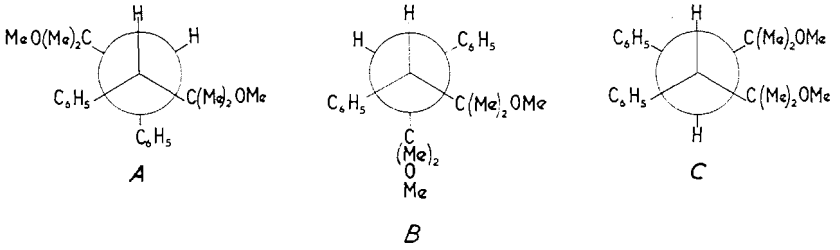
[1]*Manuscript received January 20, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.



V Ib VI

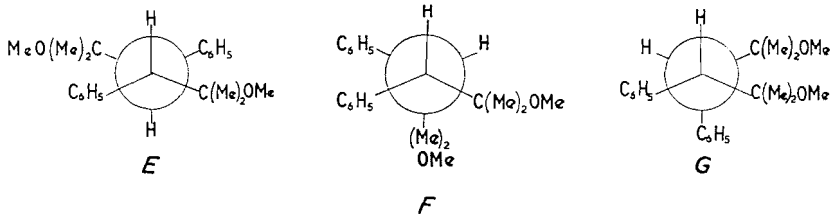
these reasons we have determined the electric moments of I*a* and I*b* in two solvents and at various temperatures.

The geometry of these diastereomers may be expressed roughly by the rotameric forms (4) in which each would exist if there were restriction toward rotation at the pivot bond. Each diastereomer may be shown as three rotamers which for I*a* are A, B, and C. The three rotamers of the *meso* diastereomer, I*b*, are shown as E, F, and G,



A B C

although it should be noted that F and G are enantiomerically different but geometrically identical. Thus F and G represent one *meso* rotamer while E represents the other.



E F G

One realizes that none of these rotamers would have an electric moment equal to zero (even E) because of rotational motion at the isopropylidene and the oxygen linkages. Therefore it is necessary to know the expected moments for different extents of fixity at these linkages before a comparison can be made with experiment. For this purpose we have symbolized the structure of I*a*–I*b* in Fig. 1. In this diagram the carbons are

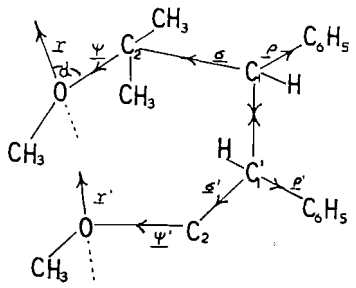


FIG. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

taken as tetrahedral (109°28′) while the oxygen angles are assumed to be 108°. The moment (b) of the phenyl group is chosen as 0.37 Debye while that (a) of the methoxy group is 1.31 D (the observed moment of dimethyl ether). If the unit vectors are defined as shown, σ, ϱ, ψ, τ, σ', ϱ', ψ', and τ', the resultant moments of these vectors (assuming hydrogen compensation) for each rotamer are $a\tau+a\tau'+b\varrho+b\varrho'$.

FREE ROTATION ONLY ABOUT THE ETHER LINKAGE

We shall first consider certain fixed positions for σ, ϱ, ψ, σ', ϱ', ψ' while τ and τ' are rotating freely. In this circumstance (5)

$$[1] \quad \mu^2 = a^2[1+1+2\cos^2 54°\,(\psi.\psi')]+ b^2[1+1+2\varrho.\varrho']+2ab[+\cos 54°\,(\psi\varrho+\psi\varrho')+\cos 54°\,(\psi\varrho'+\psi'\varrho)]$$
$$= 3.706+1.186\psi.\psi'+0.274\varrho.\varrho'+0.570\,(\psi+\psi').(\varrho+\varrho').$$

It is convenient to align Fig. 1 so that "the ethane pivot bond" is parallel (001) to the Z-axis. Now, since the cosine of the angle between Z and ϱ is $+1/3$, ϱ may be written:

$$[2] \quad \varrho = \sqrt{8/9}\cos\phi, \sqrt{8/9}\sin\phi, 1/3 \text{ (as shown in Fig. 2),}$$

similarly

$$\sigma = \sqrt{8/9}\cos\theta, \sqrt{8/9}\sin\theta, 1/3$$

where θ and ϕ represent the polar angles in the plane of projection.

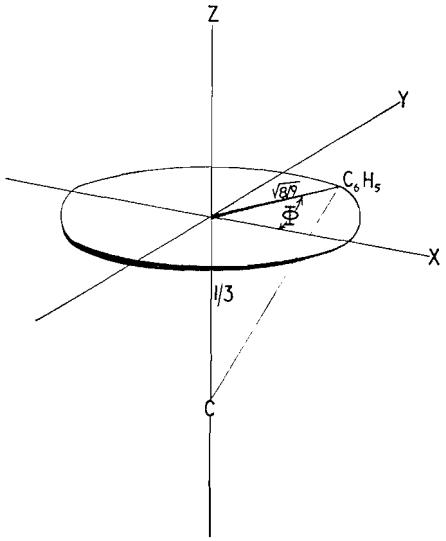

FIG. 2.

Also since $\varrho.\sigma = -1/3$, then $\theta-\phi = \pm 120°$.

We thus need specify only the X-axis in order to get ϱ and σ. This X-axis is best chosen for each isomer according to the symmetry of that particular isomer.

In order to co-ordinatize ψ, it is easiest to take ψ relative to σ in the same manner in which we took σ and ϱ relative to Z.

Since the cosine of the angle between σ and ψ is $-1/3$, ψ may be written as

$$\psi = \sqrt{8/9}\cos\beta\mathbf{k}+\sqrt{8/9}\sin\beta\mathbf{l}+1/3\sigma \text{ (see Fig. 3)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

where $\mathbf{kl}\mathfrak{d}$ form a right-handed triad of unit vectors. Thus $\sqrt{8/9}\cos\beta$ is the projection of ψ on the $\mathbf{k}$-vector of Fig. 3.

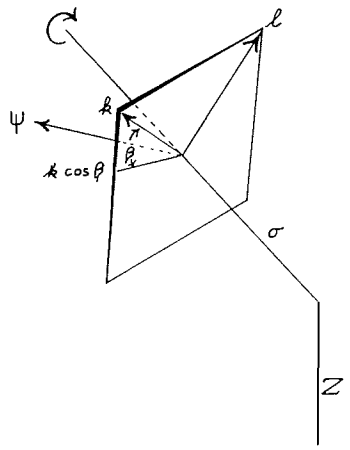

FIG. 3.

Once a particular $\mathbf{l}$ is chosen perpendicular to $\mathfrak{d}$, $\mathbf{k}$ is then fixed and ψ depends only on β. The variation in β corresponds to the rotation of ψ about $\mathfrak{d}$.

Any $\mathbf{l}$ perpendicular to $\mathfrak{d}$ may be chosen, but the following choice simplifies the calculation:

$$\mathbf{l} = (\sin\theta,\ -\cos\theta,\ 0),$$

whence

$$\mathbf{k} = (1/3\cos\theta,\ 1/3\sin\theta,\ -\sqrt{8/9}),$$

i.e. $\mathbf{k}$ is in the (Z, σ) plane, $\mathbf{l}$ is in the (X, Y) plane. Then, as above, if

$$\psi = 1/3\mathfrak{d}+c_2\mathbf{k}+c_3\mathbf{l},$$

substituting,

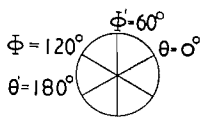
[3] $$\psi = 1/3\sqrt{8/9}\cos\theta\,(1+\cos\beta)+\sqrt{8/9}\sin\theta\sin\beta,\ 1/3\sqrt{8/9}\sin\theta\,(1+\cos\beta) -\sqrt{8/9}\cos\theta\sin\beta,\ 1/9-8/9\cos\beta.$$

A similar derivation can be made for ψ', or it may be determined intuitively from the symmetry of the molecule about its central bond.

Now the moment of each of the rotamers A–G inclusive may be calculated from ψ and ϱ obtained from equations [2] and [3] after the values for $\psi\cdot\psi'$, $\varrho\cdot\varrho'$, and $(\psi+\psi')\cdot(\varrho+\varrho')$ are determined from the geometry of each rotamer; the moment $(\sqrt{\mu^2})$ may then be determined by substitution into equation [1].

Rotamer A

Reference to the graphic formulation of the A rotamer of the *dd,ll* diastereomer shows the relationship where θ refers to the bonding of the methoxyisopropyl group and ϕ refers to the bonding of the phenyl group. Now for the two central carbon atoms, $A'(x, y, z) = A(-x, y, -z)$, i.e. symmetry about the Y-axis.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Then

$$\varrho \cdot \varrho' = -\rho_x^2+\rho_y^2-\rho_z^2(+\rho_y^2-\rho_y^2) = 2\rho_y^2-1,$$

and A,A' refers to all corresponding fixed linkages, in particular ϱ and δ. Similarly

$$\psi \cdot \psi' = 2\psi_y^2-1.$$

So

$$(\varrho+\varrho') \cdot (\psi+\psi') = 4\rho_y\psi_y = -16/9\sqrt{3} \sin \beta$$

since

$$\varrho_y = \sqrt{8/9} \sin \phi = \sqrt{8/9}\sqrt{3/2}$$

and

$$\psi_y = 1/3\sqrt{8/9} \sin \theta (1+\cos \beta)-\sqrt{8/9} \sin \beta \cos \theta = -\sqrt{8/9} \sin \beta,$$

whence

$$\mu^2 = 3.706+1.186(16/9 \sin^2 \beta-1)+(0.274/3)+0.570(-)(16\sqrt{3} \sin \beta/9).$$

Then

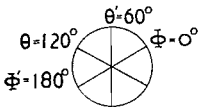
$$d\mu^2/d\beta = 0 = \cos \beta (4.216 \sin \beta-1.755).$$

The maximum for μ is then determined as 2.54 D ($\mu^2 = 6.474$) when $\sin \beta = -1$ ($\beta = 270°$, $\cos \beta = 0$), of course with a smaller maximum when $\beta = 90°$ ($\sin \beta = 1$, $\mu^2 = 2.964$). The minimum for μ at $\sin \beta = 1.755/4.216$ ($\beta = 24°36'$ or $155°24'$) is then 1.50 D since $\mu^2 = 2.246$.

Rotamer B

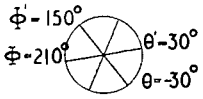
In like manner rotamer B may be evaluated since it differs from rotamer A only in the sense that

$$\varrho_y = \sqrt{8/9} \sin \phi = 0.$$



Rotamer C

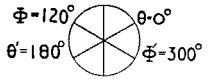
Symmetrical about X-axis, i.e. $A'(x', y', z') = A(x, -y, -z)$.



$$\varrho_x = -\sqrt{8/9}.\sqrt{3}/2$$
$$\psi_x = 1/3\sqrt{8/9}.\sqrt{3}/2(1+\cos \beta-\sqrt{3} \sin \beta)$$

Rotamer E

This rotamer, one conformation of the *meso* diastereomer, will be shown to have a moment that is independent of the angle β. Inspection shows that the z co-ordinate of A' = minus the z co-ordinate of A, that is $A'(x', y', z') = A(-x, -y, -z)$.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

So

$$\psi' = -\psi,$$
$$\varrho.\varrho' = -1,$$
$$\psi.\psi' = -1,$$

and

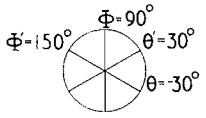
$$(\psi+\psi')(\varrho+\varrho') = 0.$$

Then

$$\mu^2 = 3.706+1.186(-)+0.274(-) = 2.246.$$

Rotamers F and G

The other rotamers of the *meso* isomer are the enantiomorphous F and G in which $A'(\theta', z) = A(\theta+60, -z)$.



Then

$$\varrho = (\sqrt{8/9}\cos\phi,\ \sqrt{8/9}\sin\phi,\ 1/3)$$
$$\varrho' = \sqrt{8/9}\cos\phi',\ \sqrt{8/9}\sin\phi',\ -1/3$$

and

$$\psi = 1/3\sqrt{8/9}\cos\theta\,(1+\cos\beta)+\sqrt{8/9}\sin\theta\sin\beta,$$
$$1/3\sqrt{8/9}\sin\theta\,(1+\cos\beta)-\sqrt{8/9}\cos\theta\sin\beta, 1/9-8/9\cos\beta.$$

Since

$$\psi = \psi(-30, z) \text{ and } \psi' = \psi(30, -z),$$
$$\psi' = [\sqrt{3}/6\sqrt{8/9}(1+\cos\beta)+1/2\sqrt{8/9}\sin\beta,\ 1/6\sqrt{8/9}(1+\cos\beta)-\sqrt{3}/2\sin\beta,$$
$$-1/9+8/9\cos\beta]$$

so

$$\varrho+\varrho' = -\sqrt{3}/2\sqrt{8/9},\ 3/2\sqrt{8/9},\ 0$$

and

$$\psi+\psi' = \sqrt{3}\sqrt{8/9}\,[1/3(1+\cos\beta),\ -\sin\beta,\ 0]$$
$$\psi.\psi' = 1/27(13+8\cos\beta-32\cos^2\beta)$$
$$\varrho.\varrho' = 1/3.$$

Then

$$d\mu^2/d\beta = 0.098\sin\beta+2.812\cos\beta\sin\beta-1.316\cos\beta = 0$$
$$\sin\beta = 0.468+0.035\tan\beta,$$

whence $\beta = 29°12'$ or $86°18'$ as well as $153°12'$ or $271°24'$ and the maxima and minima may be chosen from these values.

FREE ROTATION ABOUT ALL BONDS EXCEPT THE PIVOT BOND

In this condition ψ and ψ' (Fig. 1) are presumed to rotate as freely as τ and τ'. Then,

$$\mu^2 = a^2(1+1+2\cos^2(180-\alpha)\cos^2(180-C)(\mathfrak{o}.\mathfrak{o}')+b^2(1+1+2\varrho.\varrho') +2ab[\cos(180-\alpha)\cos(180-C)(\mathfrak{o}.\varrho+\mathfrak{o}.\varrho'+\mathfrak{o}'.\varrho+\mathfrak{o}'.\varrho')]$$

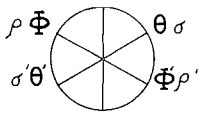
where $\cos C = \mathfrak{o}.\varrho = \mathfrak{o}'\varrho' = -1/3$, i.e. cos of the tetrahedral angle and $\alpha = 180° - 1/2$. The ether angle $= 126°$, whence

$$\mu^2 = 2a^2+2b^2+2ab\cos 54°(+1/3)(-2/3)+a^2.2/9(\mathfrak{o}.\mathfrak{o}')\cos^2 54° +b^2\,2\varrho.\varrho'+2ab\cos 54°.1/3(\mathfrak{o}.\varrho'+\mathfrak{o}'.\varrho).$$

Assuming as before that $a = 1.31$ and $b = 0.37$

$$[4] \qquad \mu^2 = 3.579+0.132(\mathfrak{o}.\mathfrak{o}')+0.274\varrho.\varrho'+0.190(\mathfrak{o}.\varrho'+\mathfrak{o}'.\varrho).$$

This condition of free rotation may be diagrammed as follows:



Earlier we specified:

$$\varrho = \sqrt{8/9}\cos\phi,\ \sqrt{8/9}\sin\phi,\ +1/3$$
$$\mathfrak{o} = \sqrt{8/9}\cos\theta,\ \sqrt{8/9}\sin\theta,\ +1/3$$

so ϱ' and $\mathfrak{o}'$ will differ only by the co-ordinate $-1/3$. Then

$$\varrho.\varrho' = 8/9\cos(\phi'-\phi)-1/9$$
$$\mathfrak{o}.\mathfrak{o}' = \{8\cos(\theta'-\theta)-1\}/9$$
$$\mathfrak{o}.\varrho'+\mathfrak{o}'.\varrho = 8/9\,(\cos\theta'-\phi)+\cos(\phi-\theta)-2/9.$$

When the values of θ and ϕ for the five rotamers comprising the two diastereomers are substituted in these equations, the $\sigma.\rho$ values thus obtained may be used in equation [4].

TABLE II

Moments of the rotamers when all but the pivot bonds are freely rotating

	dd,ll			*meso*	
Rotamer	A	B	C	E	F, G
$\varrho.\varrho'$	1/3	−1	1/3	−1	1/3
$\mathfrak{o}.\mathfrak{o}'$	−1	1/3	1/3	−1	1/3
$\mathfrak{o}.\varrho'+\mathfrak{o}'.\varrho$	2/3	2/3	−2	2/3	−2/3
μ^2	3.665	3.476	3.334	3.300	3.588
μ, Debye	1.91	1.86	1.83	1.82	1.89

For a comparison with these calculated moments benzene and carbon tetrachloride solutions of the diastereomers I*a* and I*b* were examined according to techniques described previously (6). Because of the low melting point (45–46°) of the *dd,ll* diastereomer we were unable to measure its distortion polarization by the pelleted solid tech-

nique (7, 8), but the density (1.121) and the dielectric constant (2.460) of the *meso* isomer (pelleted solid) at 23° afforded a P_{e+a} value of 95.5 cc. This experimental value is lower than the electronic polarization (99.9 cc) calculated from additive bond refractions. Since the discrepancy does not alter the moment values appreciably the latter value (99.9 cc) has been subtracted from the total polarization in calculation of the moments recorded in Table III.

TABLE III

Electrical polarizations of the *dd,ll* (I*a*) and *meso* (I*b*) diastereomers of 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane in benzene (C_6H_6) and in carbon tetrachloride (CCl_4)

Diastereomer	Solvent	Temp., °C	$d\epsilon/d\omega$	$d\bar{V}/d\omega$	P_{total}, cc	Moment, Debyes

	Same	27	1.35	0.169	178	1.95
	Same	40	0.97	0.176	156	1.69
	CCl_4	20	2.70	0.328	184	1.99
	Same	27	2.36	0.332	173	1.89
	Same	40	2.14	0.333	168	1.83
meso	C_6H_6	20	0.69	0.147	139	1.36
	Same	30	0.67	0.175	136	1.33
	Same	40	0.63	0.177	135	1.33
	CCl_4	20	1.52	0.324	143	1.44
	Same	30	1.40	0.334	140	1.40

According to the data of Table III the diastereomers I*a* and I*b* behave differently from the simple 1,2-disubstituted ethanes and their homologues (Ref. 5, page 355) except for the similarity that moments are apparently higher in benzene than in carbon tetrachloride. But, by contrast, the polarization increases as with rising temperature of 1,2-dichloroethane, its analogues and homologues, whereas the polarizations of I*a* and I*b* decrease with increasing temperature. Moreover, this latter behavior is in contrast with the temperature invariance observed for simple tetrasubstituted ethanes.

The contrast may be attributed to potential energy barriers in I*a* and I*b* which are so complex that they may be described as "group entanglement". In consideration first of the *dd,ll* diastereomer I*a* it may be seen by comparison of Tables II and III that free rotation is excluded by the fact that in this circumstance the moments of rotamers A, B, and C would be almost identical. This expected invariance with respect to temperature does not correspond with the 0.42-D decrease in benzene or the 0.16-D decrease in carbon tetrachloride solution over a 20° temperature rise.

Thus some hindrance to free rotation in the *dd,ll* diastereomer must exist, but the data of Table I are not definitive for an exact assignment. It is probable that rotamer A makes some contribution; indeed it is required to account between its maximum and minimum in respect of isopropylidene conformation for the observed moment (2.11 D) in benzene at 20°. Likewise the maxima and minima of rotamer B at the specified β-angles can account for the entire range of I*a* moment from 20 to 40°. On the other hand the maximum of rotamer C is less than the minimum observed moment in carbon tetrachloride. Therefore one may say that the amount of rotamer C is minimal but no decision can be made in respect of the relative amounts of A and B.

The situation is clearer when one considers the *meso* diastereomer. Certainly the calculated moments of Table II preclude any possibility of free rotation. When rotation restriction at the isopropylidene linkage is considered it may be seen from Table I that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the presence of rotamer F, G in appreciable amount is unlikely. Because of the maxima and minima the effect of this enantiomeric rotamer ought to be observed as change in moment with respect to temperature. In fact the moment is almost invariant either in benzene or carbon tetrachloride. This situation fits rotamer E, in which the moment is independent of isopropylidene conformation.

While rotamer E seems to describe the *meso* diastereomer I*b* entirely it will be seen that the observed moments (1.33–1.44 D) are lower than have been calculated (Table I) for restriction at the isopropylidene linkage. The only explanation apparent for this discrepancy is that of rotational restriction at the methoxy linkage. Thus it would seem that free rotation is absent in any part of this diastereomer and this circumstance probably applies to the other diastereomer as well. It is in this sense that the term "group entanglement" has been used above.

Of course these arguments may be considered to be trivial; certainly one may draw the conclusions intuitively by inspection of the rotameric formulae A–G. Moreover, these conclusions might have been predicted from the chemical reactions of the diastereomers. However, the present data may be useful in discernment of the intimate mechanisms of the chemical reactions. Certainly it is apparent that the presently popular mechanisms in terms of ionic species appear to be shallow representations of the geometric complexity of diastereomers such as the 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexanes. Of course, the symmetrically staggered conformations of formulae A–G also fail to represent entirely the deformations caused by steric effects.

We are grateful to Mr. C. C. Meredith for suggestions which were adopted in improvement of the measuring equipment.

EXPERIMENTAL

dd,ll-2,5-Dimethyl-2,5-dimethoxy-3,4-diphenylhexane (I*b*)

The oil (b.p. 203–205° at 13 mm) previously designated as this diastereomer was purified by passage in hexane solution through a column containing neutral alumina activated at 200° C. The eluate was separated so as to segregate the least ultraviolet fluorescent part. Solvent evaporation left an oil which was dissolved (10 ml per g) in 95% ethanol at 25° and slowly chilled to −78°. Although oil usually separated, eventually crystals, m.p. 41–41.5°, were obtained. Subsequent crystallizations by seeding ethanol, or ethanol–water mixtures at room temperature or below, gave a material melting at 45.6° to 46.3°.

Dielectric Constants of Solutions

The measurements were made by use of an apparatus which has previously been described (9). However, the precision of temperature control has been improved to ±0.04° by alterations in the thermostatting system. Water is circulated through the test cell (Fig. 4) by means of a 1/3-hp centrifugal pump from and to a "slave" bath equipped for controlled heating and cooling by means of a Wheelco Model 7431 recording regulator. Into the test cell at B is fitted a removable 200K thermistor (Western Electric 14A, bottom wet with ethylene glycol), which is held in a connector plug C that may be transferred to a "master" thermostat at entry point F (Fig. 5), which is threaded to accommodate D (Fig. 4). When this thermistor is plugged into G (Fig. 5), which is connected parallel with H (Fig. 4), it is connected with T1 (Fig. 6). The permanent

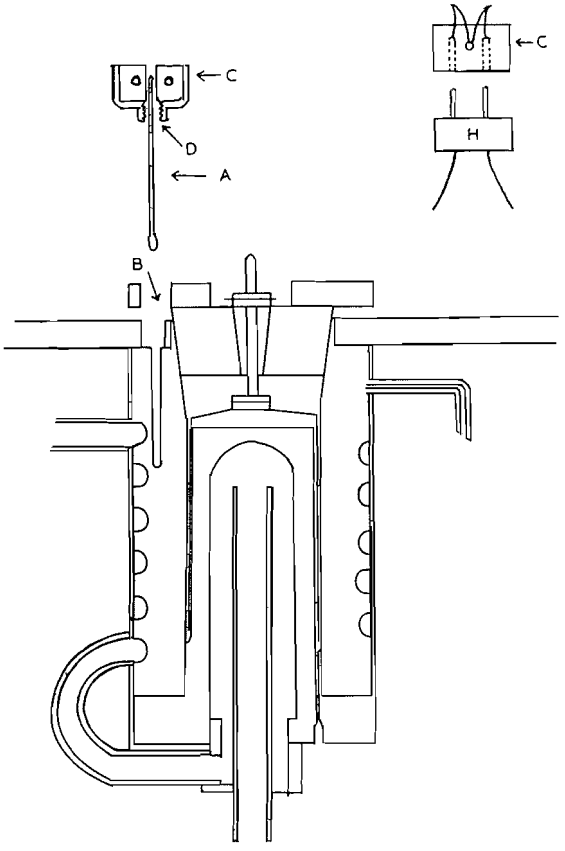

FIG. 4.

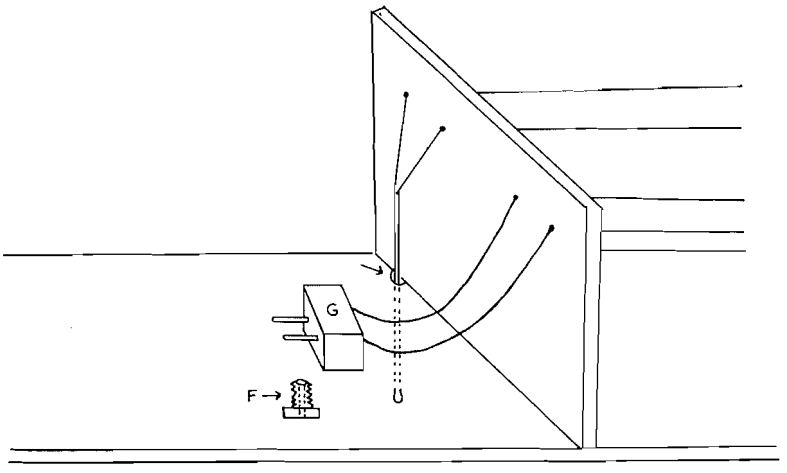

FIG. 5.

thermistor (Fig. 5) in the "master" bath is connected at T2 (Fig. 6) so that the Wheatstone bridge, across which is a 6-v dry cell pack connected via S2, may be balanced by R4 and R5 at the temperature of the master bath.

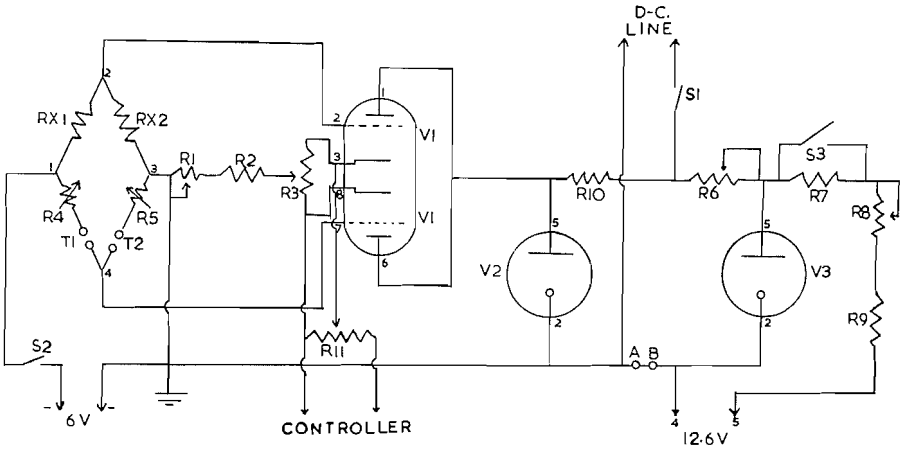

FIG. 6.

When the movable thermistor is returned to B any imbalance in the bridge causes a potential difference at the grids of the twin triode V1–V1 to which a common gas tube regulated d-c. plate supply is available as well as a regulated filament voltage (points 4 and 5, Fig. 6). The amplified imbalance signal, adjusted for scale by R1 and R3 and for sensitivity by R11, is transferred to the "slave" bath regulator (recorder) circuit.

The components of the bridge circuit (Fig. 6) with its voltage-regulated supply are as follows:

R1	0.5 kΩ	R7	1 kΩ	V1–V1	12AT7
R2	0.75 kΩ	R8	0.25 kΩ 10w	V2	VR75
R3	2 kΩ	R9	0.25 kΩ 10w	V3	VR75
R4	25 kΩ	R10	1.5 kΩ 10w	d-c. Line	110 v
R5	25 kΩ	R11	3 kΩ	S3	Push button starter
R6	0.25 kΩ 10w	RX1	100 kΩ		
		RX2	100 kΩ		

The voltage supply regulation is adjusted to 12.6 v by means of R8, and then R6 is adjusted until the current across the otherwise bridged terminals A and B (Fig. 6) is 167–168 ma. The bridge amplifier is adjusted, after a jumper is placed between terminals 2 and 4 of the bridge, by setting R1 to maximum, R11 to minimum resistance; then adjust R3 and R11 until the regulator recorder is in its operating range at sufficient sensitivity. When R11 is returned to minimum resistance R1 is now adjusted so that the potential at either of the 12AT7 grids is 6 v. Again sensitivity is increased via R11, R3 is readjusted to the regulator scale, and the jumper between 2 and 4 is removed.

The specific volumes of solutions between 0.002 and 0.008 weight fraction were determined in the master bath and the dielectric constants were determined at 0.5 mc in

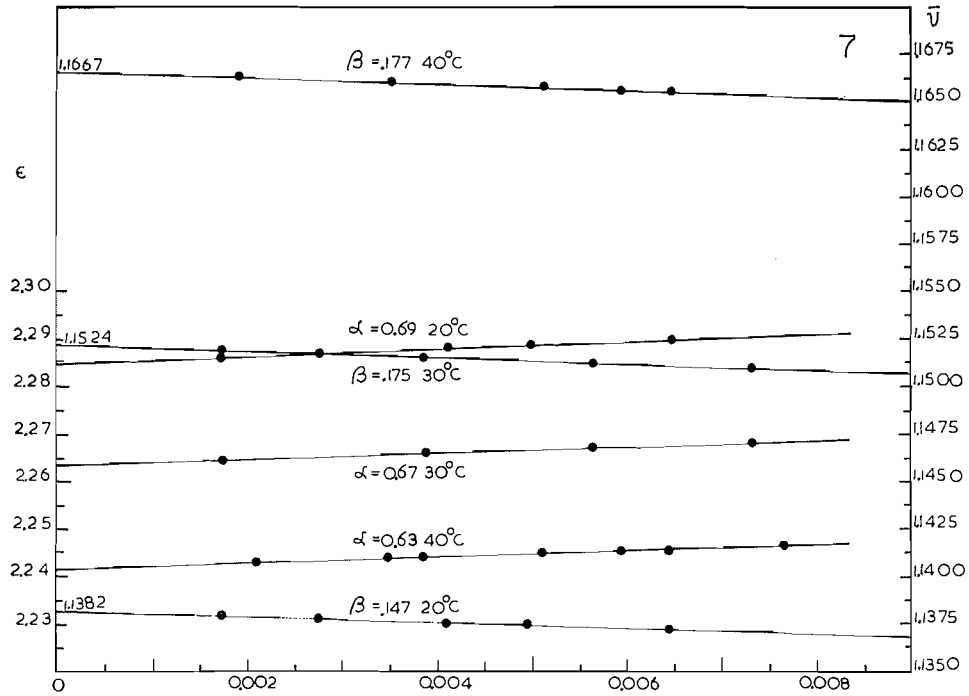

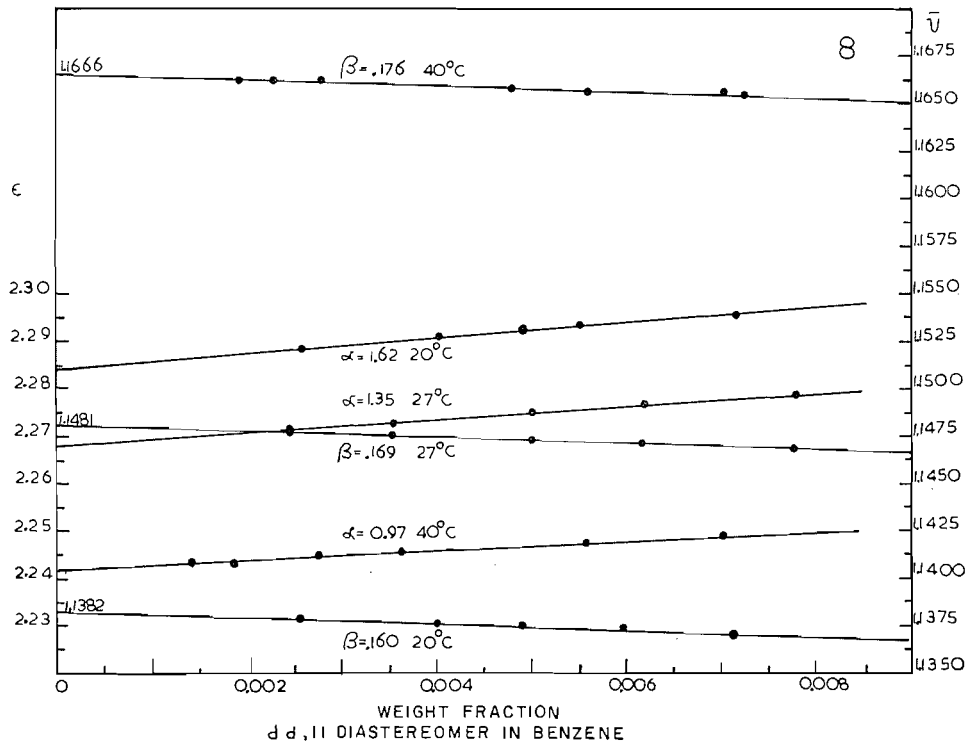

FIGS. 7 AND 8.

benzene and in carbon tetrachloride, the constants of which have been reported recently (6). Typical plots from which $d\bar{V}/d\omega(\beta)$ and $d\epsilon/d\omega(\alpha)$ were obtained are shown in Fig. 7 and Fig. 8. The determinations in carbon tetrachloride were carried out on weight fractions between .001 and .005 and are of comparable precision.

Infrared Spectra

Solutions were examined by the double beam technique (IR4) and frequencies of the absorption peaks are reported as wave numbers, cm^{-1}, for which the molecular extinction coefficients "ϵ" are listed. Benzene solutions were used for the 300–900 cm^{-1} spectral range, while for the 900 and up range carbon disulphide and carbon tetrachloride solutions were used.

The spectra for the benzene solutions are as follows:

meso Diastereomer		*dd,ll* Diastereomer

THE INFRARED SPECTRA OF MALONATES AND OXALATES: TEMPERATURE EFFECT[1]

R. A. ABRAMOVITCH

ABSTRACT

The infrared spectra of a number of malonates and oxalates (as liquid films) were examined at various temperatures and narrower slit widths than had previously been used. The absorption in the 5.8 μ region is very complex, at least four bands being observed in each case. Small but definite temperature effects were recorded for both types of esters. At somewhat wider slit widths only two bands were observed, these occasionally having indistinct shoulders. The spectra of some of the compounds were also measured in both carbon tetrachloride and acetonitrile solutions (two bands observed in each case) and the ratios of the intensities of the two bands compared. A possible explanation of the effects observed is that at least two rotational isomers can exist for each compound and that vibrational coupling of the carbonyl stretching frequencies can occur in each of the rotational isomers.

The infrared spectra of a number of malonic ester derivatives were shown to exhibit two carbonyl stretching bands both in the pure liquid state and in solution (1) (these measurements were carried out on a Grubb–Parsons double-beam spectrometer, type S4, with a sodium chloride prism and at a slit schedule of 1.5 mm). The splitting of the carbonyl band was shown not to be due to either enolization and conjugate chelation or to association. Two further possibilities were considered at that time, these being vibrational coupling and rotational isomerism, but no decision could be reached on the basis of the evidence available. To determine whether, in the absence of rotational isomerism, vibrational coupling was possible the spectra of some cyclic malonates were studied (2). Two carbonyl stretching bands were again observed and since there was no evidence of enolization in these compounds the two bands were attributed to vibrational coupling of the two β-carbonyl groups. This did not, however, eliminate the possibility that in the open chain compounds the two bands could be due to rotational isomerism.

It therefore became necessary to examine the temperature dependence (if any) of the two carbonyl peaks in the case of the open chain compounds. If rotational isomerism did in fact occur, the ratio of the intensities of the two bands should change on raising the temperature, as one of the rotational isomers became favored with respect to the other (3, 4). While this work was in progress Simon and Seyferth (5) reported the spectra of a number of oxalate esters in which two strong carbonyl stretching peaks were observed in every compound examined. It was decided, therefore, to extend our study to the oxalates as well to try and distinguish between rotational isomerism and vibrational coupling. Bellamy and Williams (6) observed a change in the ratios of the intensities of the carbonyl bands due to both rotational isomers of chloroacetone, ω-chloroacetophenone, and related compounds on passing from a solution in acetonitrile to one in carbon tetrachloride, the solvent of high dielectric constant favoring the more polar rotational isomers. The spectra of a few malonates and of diethyl oxalate were measured in both acetonitrile and in carbon tetrachloride to determine whether any such change in the ratio of the intensities did occur.

EXPERIMENTAL

Most of the malonates were commercially available and were purified just before use by repeated fractional distillations. Diethyl methylmalonate was obtained by heating

[1]*Manuscript received February 27, 1959.*
Contribution from the Chemistry Department, University of Saskatchewan, Saskatoon, Saskatchewan.

diethyl methyloxaloacetate (7). Diethyl and dimethyl oxalate were purified by standard methods. Carbon tetrachloride and acetonitrile were AnalaR grade and were redistilled twice just before use.

A Perkin–Elmer model 21 double-beam spectrophotometer with sodium chloride optics was used for the infrared measurements. For the studies of the temperature effect the spectral range from 1800 to 1700 cm^{-1} only was studied. For this purpose a Perkin–Elmer heated cell holder and horizontal cell attachment were used. The compounds were studied as liquid films. Because of evaporation each compound had to be studied at a different "high" temperature at which evaporation was not appreciable. This was checked by running spectra over the same range until a temperature was reached at which no changes in the intensities of the bands occurred in two or more consecutive runs at that temperature. The spectra of the liquids were again recorded after the liquids were cooled to room temperature and the compounds allowed to reach equilibrium for about 15 minutes. The spectra were the same as before heating. Best resolution was observed when only a very thin film of liquid was used (maximum absorption 35–40%) and all spectra were run at speed 4. At higher speeds the resolution was much poorer. Somewhat narrower slit widths ($S' = 6.8\ cm^{-1}$) were used than those usually used for ordinary qualitative runs ($S' = 7.9\ cm^{-1}$), and increased resolution was thus obtained resulting in more bands being observed. A comparison of the number of bands observed at the two slit schedules is given in the discussion. The computed spectral slit width S' was obtained from the mechanical slit width at 1697 cm^{-1} using Williams' equation (8 *a*). The values of the refractive indexes of rock salt used in the calculation of the prism dispersion were those given in Landolt-Börnstein.

The solution spectra were run in compensated 0.028-mm cells, with $S' = 7.9\ cm^{-1}$ at 1697 cm^{-1}.

The standard abbreviations are used: (s) = strong, (m) = medium, (w) = weak, (vw) = very weak, (sh) = shoulder, (br) = broad.

RESULTS AND DISCUSSION

Malonate Esters

The following diethyl malonate derivatives were studied: the dihydrogen-, methyl-, ethyl-, diethyl-, *n*-butyl-, ethylphenyl-, bromo-, and dibromo-malonic esters. All except diethyl methylmalonate had been studied by us before (1) using the Grubb–Parsons S4 spectrophotometer with a slit schedule of 1.5 mm. In nearly all cases two bands had been observed though it was noted that in many examples a weak shoulder was present at 1700–1712 cm^{-1}. In the present study the spectra were first measured over the whole range (2.5–15 μ) with a computed spectral slit width $S' = 7.9\ cm^{-1}$: no bands were observed, overtones or combinations of which would give rise to peaks in the 1770–1700 cm^{-1} region. Two strong bands were observed in all cases in the carbonyl region as reported previously (1), though the position of these differed slightly from those given in the first paper. In some cases, indistinct shoulders were also observed. The shifts in the band maxima are attributed to different resolutions of the two instruments since it is now shown that the two bands observed are really compounded of at least four overlapping strong bands. The spectra were then examined using the heated cell and horizontal attachment at a computed spectral slit width $S' = 6.8\ cm^{-1}$. The results obtained are summarized in Table I.

In all examples the intensity increases or decreases are only small. In the spectrum of diethyl ethylmalonate, raising the temperature to 85° caused the 1753 cm^{-1} shoulder

(d) = Slight decrease in intensity at the higher temperature.
(c) = Approximately constant intensity.

to increase in intensity somewhat and the 1740 cm^{-1} shoulder to decrease slightly in intensity resulting in both these bands becoming merged into one very broad flat maximum. In the case of diethyl *n*-butylmalonate, raising the temperature to 75° resulted in an increase in the intensity of the 1750 cm^{-1} shoulder with respect to the 1732 cm^{-1} shoulder. The latter did not change in intensity but was merged in with the 1725 cm^{-1} band, resulting in a broad flat maximum. Barely discernible shoulders at 1750 and 1712 cm^{-1} were observed in the spectrum of diethyl ethylphenylmalonate at 30° and $S' = 7.9$ cm^{-1}. In the case of diethyl bromomalonate, raising the temperature to 82° caused the 1761 cm^{-1} shoulder to become a resolved maximum while the 1742 cm^{-1} band became a shoulder on the low frequency side of the 1761 cm^{-1} band.

It is clear that open chain malonate esters exhibit four or more bands in the carbonyl stretching region but that due to considerable overlap only two broad maxima can be observed at the slit schedules used in routine qualitative runs (1). This very complex

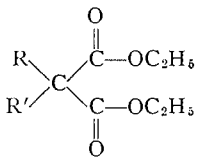
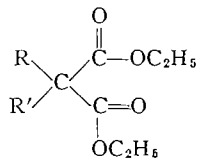
system of bands cannot arise through overlap with overtone or combination bands since there are no strong absorptions up to 15 μ which could give rise to them. The slight temperature dependence indicates that rotational isomerism does, in fact, occur. Here, unlike in the case of the α-halogenoketones (4, 6) where the more polar *cis*-configuration is stabilized both by steric repulsion and by some form of dipolar interaction between the halogen and the carbonyl group, the two polar groups are β- to each other and



(I)



(II)

dipolar effects of the above type would be small. The stabilities of the two rotational isomers would then be governed mainly by steric considerations and, in the case of solutions, by solvent–solute interactions. A consideration of models indicates that steric interactions are similar in both forms I and II so that these should be of comparable stability. Rotational isomers other than the two represented here could, in theory, also exist. It was shown (2) that, in the absence of rotational isomerism, vibrational coupling can occur between two carbonyl groups β- to each other; vibrational coupling could occur then also in the case of the open chain malonates *in each of the rotational isomers*, thus giving rise to at least four bands which would be close together and would overlap considerably. This is actually observed. A study of the temperature effect data indicates that with increasing temperature two of the bands rise somewhat whereas two of them fall, the 1712 cm^{-1} band remaining almost constant. This suggests the possibility that two of the bands are due to one rotational isomer and two to the other (the splitting in each case being due to vibrational coupling) and one of these is slightly more stable at the higher temperature than the other one is, as would be expected if the energy difference between the two forms were small. Due to the complexity of the spectra it doesn't seem possible to attribute any specific bands to any one of the possible rotational isomers at this time.

The spectra of diethyl *n*-butylmalonate and diethyl bromomalonate were also measured in carbon tetrachloride and in acetonitrile. Only two sharp bands were observed. Shifts in the positions of these bands in the two solvents were recorded:

TABLE II

	CCl_4	CH_3CN
Diethyl *n*-butylmalonate	1760, 1743	1754, 1737
Diethyl bromomalonate	1778, 1755	1765, 1749

When taking into account the slight variations in $\Delta\nu_{\frac{1}{2}}$ in the different solvents, the relative intensities of the two bands were very close to each other in both solvents. Though the data are inconclusive the two bands could presumably correspond to two rotational isomers if it is assumed that in the case of the malonates the polarity of the solvent has no effect on the stability of the rotational isomers. It is difficult to see, however, why no vibrational coupling would be observed. Such frequency shifts as are observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

here on passing from a less to a more polar solvent are well known (8 *b*). An alternative explanation, which involves vibrational coupling, is that each compound is present as a single rotational isomer in each solvent, e.g. form (I) in acetonitrile and form (II) in carbon tetrachloride. This would explain the appearance of only two bands. On the other hand (and this seems more likely), if both rotational isomers are present in solution then the higher of the two bands arising from coupling in one rotational form overlaps with the corresponding one from the other form, as also do the two lower bands.

The dipole moments of some malonate derivatives were measured by Phalnikar (9), who also calculated the expected dipole moments assuming the absence of rotation of the carbethoxyl group about the C—C axis (as for formula I). The calculated values were somewhat high (e.g. diethyl malonate: μ_{calc} 2.72, μ_{obs} 2.54) but that author suggested that this could perhaps be due to induced moments. The moment of diethyl malonate was later measured by Jatkar and Phansalkar (10), who obtained a lower value (2.10 D in benzene solution) by using a new equation instead of the Onsager one. The moment of diethyl malonate as a pure liquid increased from 2.17 D at 31° to 2.29 D at 120° (10), which is consistent with our suggestion that rotational isomers exist but that the energy difference between them is probably small. Further, it is interesting to note that the moment decreased somewhat on going from the pure liquid to a benzene solution. Jatkar and Phansalkar explained the observed moment by assuming free rotation of the two esterified carboxyl groups. Rough calculations indicate that approximately equal amounts of forms (I) and (II) would give rise to a value for the dipole moment of diethyl malonate close to that reported by the above authors. Complete free rotation of the carbethoxyl groups is unlikely in view of the results of dipole moment measurements on monocarboxylic esters (11).

Oxalate Esters

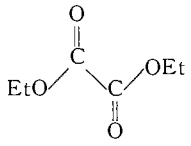
The infrared spectra of dimethyl and diethyl oxalate were examined for temperature dependence in the same way as for the malonates and with similar results. At 30° and $S' = 6.8$ cm^{-1}, diethyl oxalate exhibited the following bands: 1775 (sh), 1760 (sh), 1742, 1733 cm^{-1} (sh), all strong broad bands. At 71°, the 1775 cm^{-1} shoulder increased in intensity, the 1760 cm^{-1} shoulder became a broad rounded maximum at 1756 cm^{-1}, the 1742 cm^{-1} maximum decreased slightly in intensity becoming a shoulder, and the 1733 cm^{-1} shoulder also decreased in intensity. The band observed at 1760 cm^{-1} at 30° is the same as that observed at 1756 cm^{-1} at the higher temperature, but due to considerable overlap with the 1742 cm^{-1} band is not resolved from it. As the latter decreases in intensity the 1756 cm^{-1} band becomes more distinct. Similar observations apply to dimethyl oxalate. These results contrast sharply with those of Miyazawa and Kurantani (12), who only reported a single C=O stretching frequency at 1730 cm^{-1} for dimethyl oxalate, and with those of Simon and Seyferth (5), who reported two bands at 1740 and 1765 cm^{-1} (liquid film) for diethyl oxalate. At 30° and with $S' = 7.9$ cm^{-1} three bands were observed at 1767, 1752 (sh on 1744 band), and 1744 cm^{-1}.

In solution, two bands only were observed: in CCl_4 at 1780 and 1755 cm^{-1}; in acetonitrile at 1774 at 1753 cm^{-1}. In this case, whereas the intensity of the 1755–1753 cm^{-1} band remains approximately the same in both solvents ($\Delta\nu_{\frac{1}{2}}$ practically unchanged), the intensity of the 1780–1774 cm^{-1} band increases considerably on passing from the carbon tetrachloride to the acetonitrile solution, which is in contrast to the results obtained with the malonate esters.

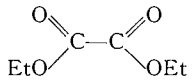
Though the temperature dependence results may be explained on the same basis as were the ones for the malonate esters, i.e. rotational isomerism between (III) and (IV)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

and vibrational coupling of the two α-carbonyl groups in each rotational isomer, it is difficult to explain the solvent effect along those lines. That coupling is possible between two carbonyl groups alpha to each other is seen from the examples of cyclic α-diketones



(III)



(IV)

(in which no enolization is possible) studied by Leonard and Little (13). The situation in the case of the oxalates is akin to that in the α-chloroketones and α-chloroesters studied by Bellamy and co-workers (4, 6) as far as dipole–dipole interaction goes without, however, the steric repulsion in the *trans*-form (III) which makes the *cis*-form in the α-chloroketones the more stable of the two isomers. One would, therefore, expect (III) to be the predominant molecular species under normal conditions. Both the temperature dependence and the solvent effect indicate that it is not the only species present by any means and that its rotational isomer may be of comparable stability. Some weak intramolecular associative-type interaction in the pure liquid state may also be operative. This might explain the large shift in frequency on passing from the pure liquid state to the solution in the non-polar carbon tetrachloride, and would imply the existence of rotational isomers but no vibrational coupling. (The concentration independence and lack of solvent effect of the infrared spectra of the malonates does not necessarily eliminate such a type of interaction in the pure liquid state.) Again, from the dipole moment of diethyl oxalate (2.06 D in benzene solution), Jatkar and Phansalkar (10) concluded that free rotation of the two ester groups occurs. The moment of the pure liquid was appreciably higher than that of the ester in benzene solution and increased, though less markedly than in the case of diethyl malonate, on raising the temperature, from 2.23 D at 24.8° to 2.27 D at 99°. No definite conclusions about the oxalates may be drawn from the present results, except that contrary to Bellamy's suggestion (14) interaction between adjacent carbonyl groups may be appreciable.

ACKNOWLEDGMENTS

The author wishes to thank the National Research Council for a grant in aid of this research. Thanks are also due to Mr. E. C. Bailey for assistance with the adjustment of the horizontal cell attachment and to Mr. M. J. Kinnear for the purification of the samples used in this study.

SURFACE ELECTRICAL CONDUCTANCE AND ELECTROKINETIC POTENTIALS IN NETWORKS OF FIBROUS MATERIALS[1]

C. E. MOSSMAN[2] AND S. G. MASON

ABSTRACT

Stream-current, permeability, and conductance measurements were made on cylindrical pads of randomly oriented Dacron, glass, Nylon, and Orlon fibers over a range of electrolyte and solid concentrations. Values of the specific surface conductivity were computed from the conductance data, using equations which were derived from a capillary network theory.

The measured conductance values were independent of pad concentration, increased with increasing electrolyte concentration, and were higher than values calculated from electrical double-layer theory using the measured values of ζ-potential. A number of plausible reasons for the discrepancies are advanced.

INTRODUCTION

When a non-conducting solid is brought into contact with a dilute electrolyte, there is generally an increase in electrical conductivity. This increase, which is most marked with solids of high surface area, is usually associated with the electrical double layer at the solid/liquid interface and is referred to as surface conductance. It is usually considered to be closely related to the conventional electrokinetic effects such as electro-osmosis and electrophoresis.

The present investigation was undertaken to obtain surface conductance data for pads of randomly oriented fibers, as an extension of previous studies (1, 2, 3) of the electrokinetic properties of fibrous materials. To avoid complications, non-swelling fibers (Dacron, glass, Nylon, and Orlon) were used. Values of the ζ-potential were obtained simultaneously by the stream-current method (1, 3).

Previous experimental work on surface conductance has been carried out using glass capillaries (4, 5, 6, 7), glass and other particles (8, 9, 10, 11), and cellulose fibers (12, 13). Wide discrepancies are apparent among the results of different workers and in only a few cases were ζ-potentials measured for the same system. Most of the investigations have yielded surface conductivity values considerably higher than those predicted by the theory outlined below.

THEORETICAL PART

Classical Theory

The surface conductivity is most conveniently defined by considering a non-conducting cylindrical capillary tube filled with an electrolyte. The bulk liquid and the interface are assumed to act as conductors in parallel with a total conductance given by

$$[1] \qquad \frac{1}{R'} = \frac{\pi r^2 \kappa}{L'} + \frac{2\pi r \kappa_s}{L'} = \frac{1}{L'}[a\kappa + f\kappa_s],$$

where R' is the total resistance, and r, f, a, L' are the radius, perimeter, cross-sectional area, and length of the capillary, κ is the specific (volume) conductivity (mho/cm) of the liquid, and κ_s the surface conductivity (mho) of the solid/liquid interface.

A theoretical expression, based on classical diffuse double-layer theory for a plane interface, for κ_s in a capillary has been obtained by several workers (14, 15). In the derivation, it is assumed that the double-layer thickness is much smaller than the capillary radius, and that the potential $\psi(x)$ varies in the double layer from ζ at the surface, where shear motion starts, to zero in the interior of the capillary. It is also assumed that the electrolytes behave as ideal solutions, implying that the results will be strictly valid only at infinite dilution.

The surface conductance is considered to be made up of two parts: (1) an electroosmotic contribution, a result of the mass displacement of the free charge in the double layer; and (2) a term proportional to the mobility of the ions, arising from the fact that the double layer contains more counter ions than the bulk liquid.

The complete theoretical expression for a 1–1 electrolyte may be written

$$\kappa_s = \left(\frac{DnkT}{2\pi}\right)^{\frac{1}{2}}[O+I'] \qquad [2a]$$

where the electroosmotic term

$$O = \frac{kTD}{\pi\eta e}\left[\cosh\left(\frac{e\zeta}{2kT}\right)-1\right] \qquad [2b]$$

and the excess ion mobility term

$$I' = v_+\left[\exp\left(-\frac{e\zeta}{2kT}\right)-1\right]+v_-\left[\exp\left(\frac{e\zeta}{2kT}\right)-1\right] \qquad [2c]$$

where the symbols have the meanings assigned in the List of Symbols (see p. 1163).

It should be noted that, for a given solvent, O is a function of ζ, and I' a function of ζ and the ion mobilities. It is also seen from eq. [2c] that the mobility of the counter ion, i.e. the ion of charge opposite to that of the surface, is the more important in determining I'. Thus when $\zeta > 0$, the right-hand side of eq. [2c] is determined largely by the term containing v_-, and when $\zeta < 0$ by that containing v_+. Similar but more complicated equations can be derived for Z_+-Z_- electrolytes. It follows from eqs. [2] that κ_s depends both on the bulk ion concentration (n) and on the ζ-potential.

Equation [2a] is equivalent to an expression for surface conductivity derived by Bikerman (14). Bikerman assumed that when measurements are made with alternating current there should be no electroosmosis, so that the ion-mobility term is sufficient to describe the surface conductance. However, none of the measurements of the effect of frequency upon κ_s support this assumption (6, 8), and a subsequent theoretical analysis by Rosenhead and Miller (16) has shown that the electroosmotic contribution would become negligible only at frequencies higher than 10 Mc per second.

It is often assumed (12, 17) that at high ionic strengths (κ_s/κ) $\rightarrow$ 0, i.e. that the surface conductance contribution to the total becomes negligible. The validity of this assumption can be demonstrated from the theory by assuming that when ionic strength is varied, the surface charge density, q, remains constant. Under these conditions, the following relation holds (18):

$$\sinh\left(\frac{e\zeta}{2kT}\right) = q\sqrt{\left(\frac{\pi}{2DnkT}\right)} = \frac{1}{\sqrt{n}} \times \text{(constant)}. \qquad [3]$$

Assuming further that the electrolyte is ideal and that

$$\kappa = \lambda n \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

and combining eqs. [2*a*] and [4] and reducing, it follows that

$$\frac{\kappa_s}{\kappa} = \frac{1}{\lambda n}\left[\beta\sqrt{n}(O+I')\right]$$

where β is a constant. It follows from eq. [3] that as $n \rightarrow \infty$, $\sinh(e\zeta/2kT) \rightarrow 0$, as a result of which it readily follows that $(O+I') \rightarrow 0$, and hence $(\kappa_s/\kappa) \rightarrow 0$.

κ_s in Porous Media

To obtain κ_s values from the experimental conductance data for pads of fibers, it is necessary to obtain an equation allowing for the complex internal pore structure of the pad. The development given here is similar to that used by Sullivan and Hertel (19) and Goring and Mason (1) for describing viscous and electrokinetic flow in uniformly packed pads of solid particles, starting with the analogues of eq. [1] for straight cylindrical capillaries.

For a single channel inclined at an angle θ to the axis of a pad of thickness L, $L = L' \cos\theta$. Since the total conductance is given by the sum of the individual conductances, it follows from eq. [1] that:

$$\frac{1}{R} = \sum\left[\frac{a\kappa}{L'} + \frac{f\kappa_s}{L'}\right] \qquad [5]$$

where the summation is carried out over all the pores.

The term $\sum \frac{a}{L'}$ may be written as $\sum \frac{a\cos\theta}{L}$ where $\sum a\cos\theta = \xi$, the geometrical "pore factor" (1). Assuming that the distribution functions of pore size and pore orientations are independent of one another, it follows (1) that $\xi = A\epsilon\,\overline{\cos^2\theta}$, where A is the pad cross-sectional area and ϵ is the void fraction. Since $\epsilon = 1-\alpha c$, where c is the solid mass per volume concentration of the pad and α is the specific volume of the fiber, then:

$$\sum \frac{a}{L'} = \frac{A(1-\alpha c)\,\overline{\cos^2\theta}}{L}. \qquad [6]$$

By similar reasoning,

$$\sum \frac{f}{L'} = \frac{1}{L^2}\cdot\overline{\cos^2\theta}\cdot\sum(fL') \qquad [7]$$

where $\sum(fL')$ represents the total surface area of the pad. Also, since $\sum(fL') = \sigma.c.A.L$, where σ is the specific surface per unit mass of material in the pad, the total pad conductance can be written:

$$\frac{1}{R} = \frac{A}{L}\,\overline{\cos^2\theta}\,[(1-\alpha c)\kappa + \sigma c\kappa_s]. \qquad [8]$$

In this equation A, L, and c are obtainable from the dimensions and weight of the pad, κ and R by direct electrical measurement, and σ and α from a liquid permeability measurement on the pad *in situ*.

Thus to calculate κ_s directly from eq. [8], the pore orientation factor $\overline{\cos^2\theta} = \Omega$ must be known. It has been shown empirically (3) that for ionic conductance in fibrous pads

$$\Omega_c = 0.955\,\epsilon. \qquad [9]$$

Eq. [8] can thus be written

$$\kappa_s = \frac{1-\alpha c}{\sigma c R}\left[\frac{1.048\,L}{A(1-\alpha c)^2} - \kappa R\right]. \qquad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Alternately, eq. [8] may be written in terms of the pad cell constant, C ($= \kappa R$):

$$\frac{1}{C} = \frac{A}{L}\,\Omega_c\left[(1-\alpha c)+\sigma c\,\frac{\kappa_s}{\kappa}\right]. \qquad [11]$$

Let C_0 be the pad cell constant at high ionic strengths when $(\kappa_s/\kappa) = 0$; it follows from eq. [11] that

$$\frac{1}{C_0} = \frac{A}{L}\,\Omega_c(1-\alpha c). \qquad [12]$$

By combining eqs. [11] and [12], Ω_c can be eliminated and κ_s computed directly without knowledge of Ω_c:

$$\kappa_s = \kappa\left(\frac{1-\alpha c}{\sigma c}\right)\left(\frac{C_0-C}{C}\right), \qquad [13a]$$

$$= \frac{(1-\alpha c)}{\sigma c R}\,(C_0-\kappa R). \qquad [13b]$$

If the two methods are to give identical values of κ_s, it follows from a comparison of the eqs. [10] and [13*b*] that

$$\left(\frac{L}{C_0}\right)^{\frac{1}{3}} = (0.955\,A)^{\frac{1}{3}}\,(1-\alpha c). \qquad [14]$$

By definition κ_s should be independent of the pad concentration c.

EXPERIMENTAL PART

Materials

The following fibrous materials were used:

1. Nylon: 3 denier delustered.
2. Orlon: continuous filament.
3. Dacron: 1.5 denier staple.
4. Glass fiber: 0.5 μ diam. staple from Glass Fibers Inc., Toledo, Ohio.

All fibers were first chopped into short lengths in a Wiley mill and were then run through a Bauer–McNett classifier, the fractions between the 65- and 150-mesh screens being retained for use.

The solutions used in the experiments were prepared by dilution of stock solutions of HCl, KCl, $CaCl_2$, and $ThCl_4$, their exact normality being determined conductimetrically. Distilled water having a specific conductivity of 1.4×10^{-6} mho/cm was used.

In one series of measurements solutions of KCl in 20% (by volume) ethanol/water were used as electrolytes.

Apparatus

The high-compression cell described previously (2) was used for the permeability, stream-current, and conductance measurements. This arrangement permitted comparison of κ_s values computed from the experimental data (using either eq. [10] or [13]) with those predicted by eq. [2] using ζ-values measured on the same system by the stream-current method.

Reversible Ag–AgCl electrodes were used in the electrical measurements. These were chloridized less heavily than before to reduce the electrical resistance of the chloride layer. Electrodes prepared by anodizing silver electrodes at 1 ma/cm^2 for 15 minutes in 0.1 N HCl were quite stable, showing a slight residual potential and a small polarization effect only at high electrolyte concentrations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Pad Formation

Approximately 9 g of fiber was used to form each pad. The fibers were first washed repeatedly in distilled water and then soaked overnight in 4 l. of a 10-l. batch of the electrolyte to be used.

Pad formation and deaeration procedures were identical with those previously described (1, 3). The oven-dry weight of each pad was determined at the end of each experiment, and, together with the measured pad length L and the cross-sectional area A (5.00 cm^2), was used to calculate the pad concentration c.

Surface Conductance Measurements

A complete measurement consisted of measuring R, the resistance of the pad, over a series of pad lengths L at each electrolyte concentration. The specific bulk conductivity κ of each solution was determined using a calibrated conductivity cell placed in the system in series with the high-compression cell. The correction for the specific conductivity of the distilled water was negligible except in very dilute solutions. L was measured to 0.001 cm with a travelling microscope. After compressing the pad in a series of steps, it was possible to expand it to almost its original length for measurements at the next electrolyte concentration by releasing the pressure in the electrodes and streaming some of the electrolyte solution through the cell.

No solution was streamed through the pad during the resistance measurements, although separate experiments revealed no perceptible difference caused by slow streaming of the solution under constant pressure. However, if the solution were streamed rapidly through the system, there was a risk of the equilibrium being disturbed by changes in temperature.

Resistances were measured with a Jones Conductivity Bridge using a Hewlitt–Packard audio-oscillator as a source of 1000 c.p.s. alternating current and a cathode-ray oscilloscope as null-point detector. It was established that the resistances measured at this frequency were the same as the d-c. values, so that there was no low-frequency dispersion effect which was previously observed (20, 21) with fibers swollen by the liquid medium.

Stream-current and Permeability Measurements

By measuring the stream-current function ($I\eta L/pD$) over a range of pad concentrations, ζ was calculated at each electrolyte concentration from the semiempirical equation (ref. 3) expressing the variation of stream current with c:

$$[15] \qquad \left[\frac{I\eta L}{pD}\right]^{2/5} = \left[\frac{Ab\zeta}{4\pi}\right]^{2/5}(1-\alpha c),$$

using the intercept method, and assuming $b = 1$. Typical rectilinear plots of stream-current data are shown in Fig. 1.

Permeability measurements were made on several pads of each material to obtain values of α and the specific surface σ. The rectilinear form of the Kozeny–Carman equation (ref. 3)

$$[16] \qquad (Kc^2)^{1/3} = \frac{(1-\alpha c)}{(5.55\,\sigma^2)^{1/3}},$$

where K is the measured permeability coefficient, was used for this purpose.

RESULTS

Measurement of κ_s

Representative plots of the variation of the pad cell constant C with electrolyte

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

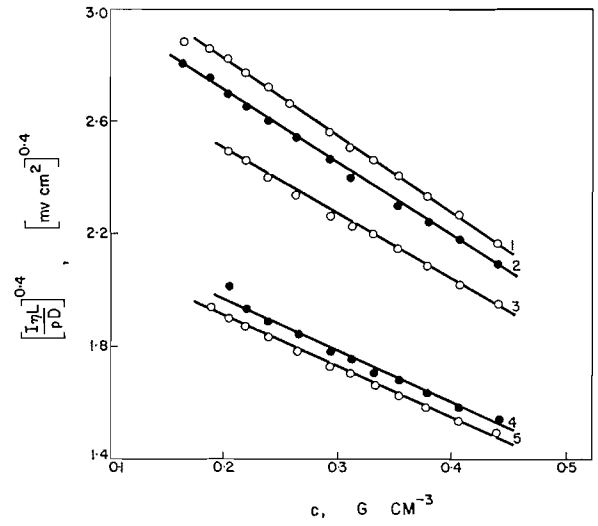

FIG. 1. Rectilinear stream-current – pad concentration plots for Dacron in 7.08×10^{-5}, 1.32×10^{-4}, 3.63×10^{-4}, 2.44×10^{-3}, 3.50×10^{-3} M $CaCl_2$ (lines 1 to 5 respectively).

concentration are shown in Fig. 2 for three concentrations of the same pad; in each case C increased with increasing ionic strength until the plateau value C_0 was reached. For the data illustrated in Fig. 2, the surface conductance represented a maximum of about 30% of the total conductance.

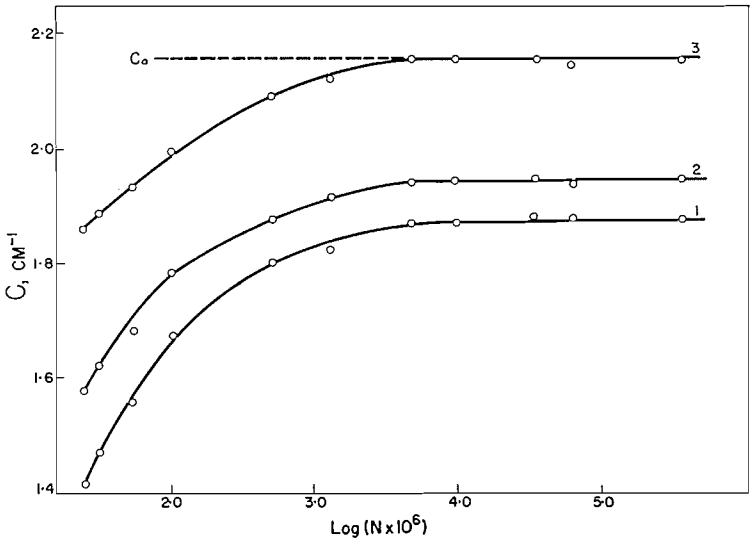

FIG. 2. Pad cell constant versus electrolyte concentration for a pad of Dacron–KCl, at pad concentrations of 0.453, 0.362, and 0.279 g/cc (curves 1 to 3 respectively). As expected from earlier considerations (3), C_0 decreased with increasing pad concentration over this range of void fractions.

Values of κ_s could be calculated from the experimental data using either eq. [10] or [13]. As already pointed out, however, the equations will yield identical results if eq. [14] is satisfied, as was established previously (3). Further confirmation of eq. [14] has been provided by the present data, as is illustrated by the typical linear plots of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

$(L/C_0)^{1/2}$ vs. c shown in Fig. 3. Extrapolation of the lines yields c-intercepts which give α values in excellent agreement with those provided by the rectilinear plots of stream-current and permeability data using eqs. [15] and [16]. An exception was glass, which could not be compressed to values of ϵ sufficiently low (< 0.8) for eqs. [15] and [16] to

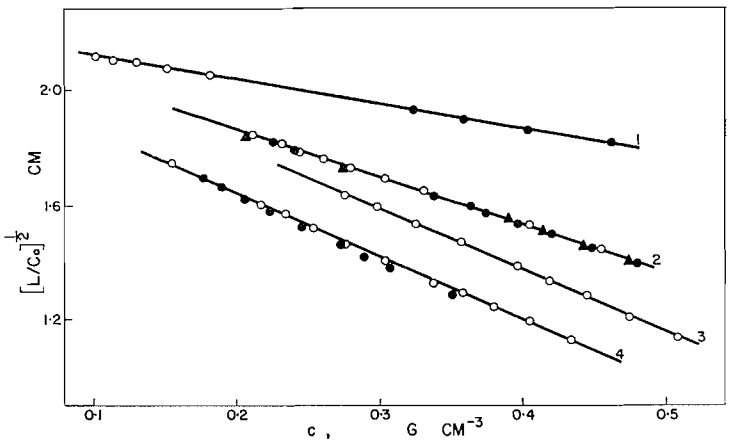

FIG. 3. Rectilinear plots of $(L/C_0)^{1/2}$ versus c for glass, Dacron, Nylon, and Orlon at high concentrations of KCl when $(\kappa_s/\kappa) = 0$ (curves 1 to 4 respectively).

be completely valid. Nevertheless, the conductance plot (Fig. 2) remained linear to void fractions as high as 0.96; the value of α for the glass fiber obtained from Fig. 3 by the intercept method was 0.39 cc/g, which is in good agreement with the specific volume of 0.40 cc/g. Thus eqs. [9] and [14] apply over a much wider range of void fractions than eqs. [15] and [16] (3). The values of σ and α used to compute κ_s are summarized in Table I.

TABLE I

Glass	0.39*	32,000†

*From conductivity plot only. Other α's from permeability, stream current, and conductivity.
†Estimated.

Equation [13] was generally used to calculate κ_s, since it was found to yield less scatter, and because it involved no assumptions as to the variation of Ω with ϵ.

At a given electrolyte concentration, κ_s should be independent of the pad concentration c. This condition was generally fulfilled and is illustrated by the typical plots shown in Fig. 4. However, because of the decreased sensitivity of the method at high electrolyte concentrations when C approached C_0, the scatter in κ_s tended to increase. In reporting κ_s, the mean value over a range of pad concentrations was calculated.

Variation of κ_s with Electrolyte Concentration

The increase in κ_s with increasing electrolyte concentration for Dacron–KCl is shown in Fig. 5 for four different pads; it is seen that the results were reproducible. Similar

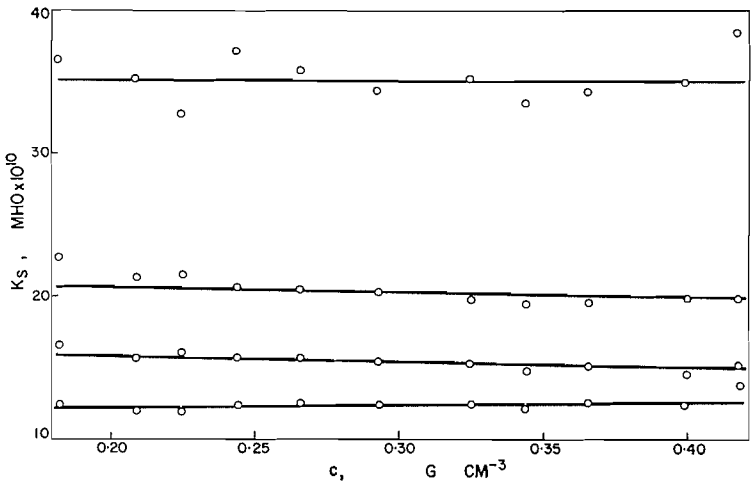

FIG. 4. Experimental values of κ_s at various pad concentrations for Orlon and 5.1×10^{-5}, 8.5×10^{-5}, 1.3×10^{-4}, and 9.6×10^{-4} N KCl (lowest to uppermost curves respectively). Note increasing scatter at higher electrolyte concentrations.

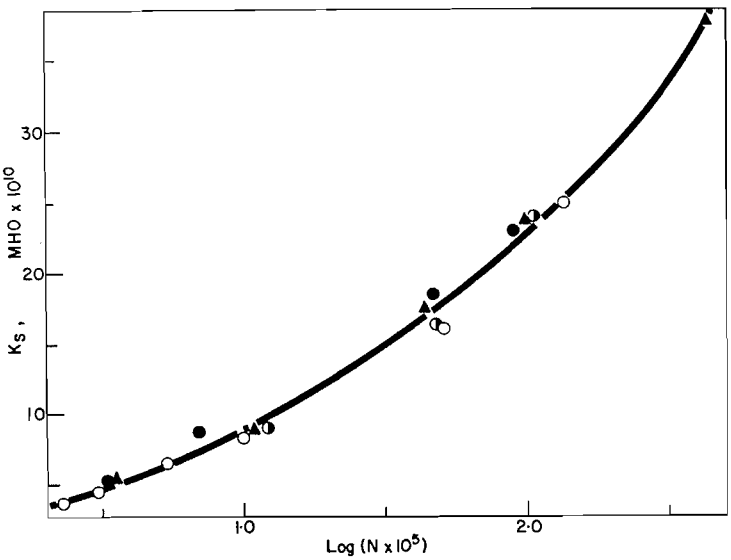

FIG. 5. Reproducibility of κ_s for five different pads of Dacron at various concentrations of KCl.

results were obtained for Dacron–HCl, Dacron–$ThCl_4$, Dacron–KCl (in 20% ethanol), Orlon–KCl, Nylon–KCl, and glass–KCl. In the system Dacron–$CaCl_2$, κ_s increased to a plateau value.

A summary of the data, including measured values of ζ and values of κ_s calculated from eq. [2] using the measured values of ζ and the literature values of the other parameters, is given in Table II. It is interesting to note that at low concentrations of KCl, ζ passed through a maximum and then decreased with increasing electrolyte concentration; this effect was almost negligible in measurements with HCl, while no maximum was observed with $CaCl_2$. This type of behavior has been observed before with various solid systems (23, 24, 25).

In the KCl systems, for which $v_{K^+} = v_{Cl^-}$ *approximately*, calculations show that the excess ion contribution I' is about twice O. With HCl, I' is approximately $10\times O$ as the result of the high mobility of H^+.

When comparisons can be made, the κ_s values are in fair agreement with results reported by other workers. For example, Hirschler (9) obtained a value of 3.49×10^{-8} mho for glass spheres in 10^{-3} N KCl, while McBain *et al.* (4) reported a value of 4.3×10^{-8} mho for a glass surface in contact with the same concentration of KCl.

According to eq. [2], $\kappa_s = 0$ when $\zeta = 0$. Experiments were undertaken using multivalent cations such as Ce^{3+}, Al^{3+}, and Th^{4+} (as chlorides) in an attempt to pass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

continuously from the normally negative ζ-potential to the positive value. Unfortunately, in each case charge reversal occurred at too low an electrolyte concentration to permit satisfactory conductance measurements near $\zeta = 0$. Previous workers (13, 26) showed that κ_s of cellulose and glass passed through a minimum at the point of charge reversal by Th^{4+}. In the present experiments Dacron became positively charged at 3×10^{-7} M $ThCl_4$; as with the negatively charged systems, κ_s increased with increasing electrolyte concentration.

Without exception the κ_s values from the experimental data were higher than the corresponding theoretical values, the discrepancy becoming more marked as the electrolyte concentration was increased. This is in accord with the experience of other workers, although they are somewhat greater than those recently found by Street (11) using kaolinite suspensions.

DISCUSSION

There are a number of plausible reasons for the discrepancies between measured and theoretical values of κ_s. Without going into the reasons in detail, we may summarize them as follows:

1. The value of σ may be too low, thus yielding incorrectly high "experimental" values of κ_s. The specific surface measured by the liquid permeability method is more properly designated the "hydrodynamic surface" (27), since it measures the area of the envelope of the "hydrodynamic volume". Because of surface roughness and other irregularities in which liquid may be immobilized the correct surface area to be used in eqs. [10] and [13] may be considerably higher than given by eq. [16]. It may be significant that Street used B.E.T. surface areas (based on nitrogen adsorption) in his measurements on kaolinite and which yielded somewhat better agreement of κ_s with theory than reported here (11).

2. In calculating κ_s from the experimental data it is assumed that the appropriate pore orientation factor is Ω_c, the factor for bulk conductance. The correct factor may instead be $\Omega_\zeta = (1-\alpha c)^{3/2}$, the factor for electrokinetic flow (3). Analysis shows that if this is so, the κ_s values of eqs. [10] and [13] would be increased by the factor $0.955/b\sqrt{\epsilon}$, which varies with c. Since $b < 1$ but is otherwise unknown (see below) it is not possible to estimate the magnitude of the effect except that the true κ_s would be increased. Thus there is some doubt of the validity of the capillary network equations, e.g. eq. [5], as has been discussed elsewhere (3).

3. The values of ζ used to calculate κ_s from eq. [2] are those calculated from the stream-current measurements using eq. [15] and assuming that $b = 1$. It has been pointed out, however, that probably $b < 1$ (3), so that the ζ-values used are probably too low. If the experimental values of κ_s listed in Table II are inserted into eq. [2] to calculate values of ζ necessary for the theory to hold, it is found that they are 2 to 10 times the values of ζ given in the same table, corresponding to values of b varying from 1/10 to 1/2. Since b must be constant, this cannot be the whole explanation.

4. In addition to invalidating eq. [16] for calculating σ as mentioned above, surface roughness may require modification of eq. [2]. If electrokinetic flow in the inner portion of the diffuse layer is hindered by irregularities in the surface, it is evident that $\zeta < \psi_0$, where ψ_0 is the potential at the surface. While the electroosmotic flow may be hindered, the excess ion contribution may be unaffected by surface roughness. Equation [2] should then become

$$\kappa_s = \left(\frac{DnkT}{2\pi}\right)^{\frac{1}{2}} [O(\zeta)+I'(\psi_0)] \qquad [17]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

thus yielding greater values of κ_s. Table II shows a number of values of ψ_0 calculated by means of eq. [17] using values of ζ and κ_s from the same table. The values do not show any marked variation with electrolyte concentration. On this basis it is possible to estimate the magnitude of the surface roughness.

In classical double-layer theory the potential at any point in the double layer of a 1–1 electrolyte is expressed as a function of distance x from the solid surface as follows:

$$[18] \qquad \frac{x}{\delta} = \log_e \frac{[\exp(e\psi/2kT)+1][\exp(e\psi_0/2kT)-1]}{[\exp(e\psi/2kT)-1][\exp(e\psi_0/2kT)+1]}.$$

Here δ is the effective thickness of the double layer ($= (3.03\times10^{-8}$ cm$)/\sqrt{}$(ionic strength) for aqueous solutions at 25° C). By substituting $\zeta = \psi$ in eq. [18] it is possible to calculate $x(\zeta)$ the distance from the solid surface where $\psi = \psi_0$ to the electrokinetic slipping plane where $\psi = \zeta$. Thus $x(\zeta)$ is the thickness of the hydrodynamically immobilized layer. Values are included in Table II where they may be compared with δ. Bikerman (28) and Eversole and Lahr (29) estimate values of 10^{-6} to 10^{-7} cm as the magnitude of surface irregularities for "smooth" surfaces, which is the same order as $x(\zeta)$. The fact that $x(\zeta)$ is not constant for a given solid (e.g. Dacron) in the presence of various electrolytes indicates that this explanation, although reasonable, cannot account completely for the discrepancies.

Other possible reasons are (i) deviations from the ideal ion conductance eq. [4] at the high counter ion concentrations in the inner part of the double layer, (ii) the effect of adsorbed (i.e. Stern layer (30)) ions, and (iii) immobilization of the water by dielectric saturation in that part of the double layer where the electrical field strength is high (in excess of 10^5 volts/cm (31)); the effect of this on ψ_0 and κ_s is strictly analogous to that of immobilization by surface asperities as considered above.

It must be concluded that the theory of surface conductance has not been established. Evidently more precise and less equivocal measurements on better defined and smooth solids are required for clarification of the phenomena. In the light of the tentative explanations which have been advanced above, however, it is possible that additional studies of surface conductance may throw valuable light on the structure of the electrical double layer.

LIST OF SYMBOLS

a, A = cross-sectional area of capillary and pad (cm^2),
b = proportionality constant in stream-current equation,
c = pad concentration (g cm^{-3}),
C, C_0 = pad cell constant (cm^{-1}) with and without surface conductance contribution,
D = dielectric constant of solvent,
e = electronic charge,
f = perimeter of pore,
I = stream current (μa),
I' = ion-mobility term in surface conductance equation (cm$^{3/2}$ g$^{-1/2}$),
K = permeability coefficient (cm^2),
k = Boltzmann constant (ergs deg^{-1}),
L', L = length of capillary, pad (cm),
n = electrolyte concentration (ions cm^{-3}),
O = electroosmotic term in surface conductance equation (cm$^{3/2}$ g$^{-1/2}$),
p = applied pressure (dynes cm^{-2}),
q = surface charge density (e.s.u. cm^{-2}),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

r = radius of capillary (cm),
R', R = electrical resistance of capillary and pad (ohms),
T = absolute temperature (deg),
v_+, v_- = ion mobilities (g^{-1} $cm^{3/2}$),
x = distance from solid surface (cm),
α = specific volume of fiber (cm^3 g^{-1}),
δ = equivalent thickness of double layer (cm),
$\epsilon = 1-\alpha c$ = void fraction of pad,
σ = specific surface of fiber (cm^2 g^{-1}),
η = viscosity of liquid (poises),
θ = pore orientation with respect to axis of pad,
ψ = electrical potential in double layer (mv),
ζ = zeta-potential,
κ = specific bulk conductivity of electrolyte (mho cm^{-1}),
κ_s = specific surface conductivity (mho),
λ = equivalent conductance (mho cm^2 per ion),
Ω_c, Ω_ζ = pore orientation factors for ion conductance and electrokinetic flow.

DISPROPORTIONATION AND RECOMBINATION OF CYANISOPROPYL RADICALS

REARRANGEMENT OF DIMETHYLKETENECYANISOPROPYLIMINE TO TETRAMETHYLSUCCINODINITRILE[1]

M. TALÂT-ERBEN AND A. N. ISFENDIYAROĞLU

ABSTRACT

Evidence is presented that the ketenimine intermediate formed in the thermal decomposition of azo-bis-isobutyronitrile (AIBN) rearranges quantitatively to tetramethylsuccinodinitrile (TMSDN), mainly by a molecular mechanism. Interpretation of experimental data on the basis of a reaction scheme consistent with the nature of the main products and the features of the kinetics of the decomposition permits estimation, by means of a simple diagram, of the extent of disproportionation, as well as that of the normal and abnormal recombination of cyanisopropyl radicals. The result obtained for the latter is in good agreement with that determined previously by an alternative method. The analysis does not exclude absolutely the possibility of side reactions in which the azo-compound partly decomposes by a molecular process, and the intermediate decomposes into free radicals. However, it is concluded that these side reactions, if any, must be of minor importance.

INTRODUCTION

A recent work by the present authors (7) has shown that as much as 55% of the initial recombination of cyanisopropyl radicals is to dimethylketenecyanisopropylimine, an unstable intermediate detected by Talât-Erben and Bywater (6). On the other hand, Bickel and Waters (3) have isolated amounts of the normal dimer, TMSDN, which correspond to an 84% radical recombination. These two results would be compatible only if part of the dinitrile is a transformation product of the intermediate. There are other observations which support this conclusion: The oily fraction, isolated by Talât-Erben and Bywater (6), which contained the ketenimine in a high concentration, slowly deposited TMSDN crystals when left standing, and in an attempt to purify the oil by chromatography, using aluminum oxide as absorbent, these authors obtained a high yield of dinitrile, and none of ketenimine. Moreover, the slope of the experimental curve reported by Bevington (1) for the formation of TMSDN as a function of conversion is not constant during decomposition as would be expected for a product forming solely at the expense of the free radicals; instead, the curve presents a marked convexity towards the conversion axis, which must indicate that a noticeable fraction of the dinitrile is produced from a precursor other than the free radicals.* Therefore, it would be of interest to reconsider the reaction scheme proposed in reference (6), in which the stable products of decomposition of the intermediate would now have to be specified as TMSDN. The reaction scheme under consideration is the following:

[1]
$$\begin{aligned} &R{-}N{=}N{-}R \rightarrow 2R\cdot + N_2 && (k_1)\\ &R\cdot + R\cdot \rightarrow \text{TMSDN} && (k_2)\\ &R\cdot + R\cdot \rightarrow \text{Intermediate} && (k_3)\\ &\text{Intermediate} \rightarrow \text{TMSDN} && (k_4)\\ &R\cdot + R\cdot \rightarrow \text{ISBN} + \text{MAN}. && (k_4) \end{aligned}$$

[1]*Manuscript received March 4, 1959.*
Contribution from the Faculty of Mining Engineering, Technical University of Istanbul, Istanbul, Turkey.
**It is interesting to note that Bevington (1), who ignored the intermediate, considering the shape of this curve, came to the conclusion that the percentage of free radical disproportionation decreases as the decomposition proceeds. However, it will be seen that disproportionation, and recombination as well, remain constant in the whole course of the reaction; the apparent decrease of the former (or the apparent increase of the latter) can be accounted for by the intermediate rearranging to the dinitrile, as suggested quite properly by Walling (8).*

The rate constant for the decay of intermediate has been taken equal to the rate constant of decomposition of the azo-compound in accordance with the features of the kinetics (6). The radical disproportionation products, isobutyronitrile and methacrylonitrile, are denoted as ISBN and MAN respectively.

Integration of the rate equations using the steady-state hypothesis and proper boundary conditions gives for the intermediate the same relations as those of reference (6). In addition, the following relation is obtained between the concentration D of the dinitrile and the time:

$$[2] \qquad 1-\frac{D}{A_0-A} = \frac{k_4}{k_2+k_3+k_4}+\frac{k_3}{k_2+k_3+k_4}\cdot\frac{k_1t}{e^{k_1t}-1}$$

where A_0 and A are the initial concentration and the concentration at any time of azo-compound, respectively. It is seen that if the expressions $k_1t/(\exp k_1t-1)$ and $1-D/(A_0-A)$ are taken as the abscissa and ordinates, respectively, the experimental points will define a straight line, whose slope and ordinate at the origin will be numerically equal to the extent of the abnormal recombination and that of disproportionation, respectively.

Bevington (1) has measured the amounts of TMSDN formed at various stages of the decomposition of 1 mg of AIBN at 60° C, using C^{14}-labelled azo-compound. Bevington's results may be used to check [2] for this particular temperature. Inspection of [2] shows that the slope and the ordinate at the origin of the straight line are exclusive functions of rate constants of free radical recombination reactions; it follows that these geometrical elements must be temperature-independent, owing to the very low activation energies associated with reactions of this kind. To check this, measurements have been carried out at a different temperature, namely 80° C, under the experimental conditions described below.

EXPERIMENTAL

The azo-compound* (Westville Laboratories, Monroe, Connecticut) was recrystallized from benzene; m.p. 102° C decomp. The thermal decomposition was carried out at 80° in toluene (C.P.), in a thermostat controlled to about 0.1°, under a stream of purified nitrogen, with continual shaking. Azo-compound (1.6 to 1.8 g) was decomposed in 50 cc of toluene. At the end of a definite reaction time the solution was cooled quickly to stop the reaction, and transferred quantitatively into a separatory funnel. Fifty cubic centimeters of 1 N HCl were added, and the two phases were stirred vigorously for at least 20 minutes in order to hydrolyze the ketenimine present in, and remove its hydrolytic products from, the toluene solution. This operation of removal of the ketenimine was repeated at least three times with fresh portions of HCl. Then, the toluene layer was taken quantitatively in a weighed crystallization dish, and the solvent evaporated to constant weight under an air current provided by the fan of a fume hood, the window of which was kept low enough to maintain an efficient air flow. Under these conditions the residue must consist of a mixture of the undecomposed AIBN and TMSDN formed, ignoring minor amounts of 2,3,5-trimethyl-2,3,5-tricyanohexane identified by Bickel and Waters (3). ISBN and MAN (both low boiling point liquids) escape along with toluene. The sublimation of TMSDN was studied by using an authentic sample of this compound. It was found that a 4-hour prolongation of the drying period, under the same conditions, caused only about 1% loss of weight. The undecomposed amount of AIBN was calculated,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

using the value 1.55×10^{-4} sec^{-1} for the rate constant of decomposition at 80° (6). This was subtracted from the weight of the residue to obtain that of TMSDN formed at the particular reaction time.

RESULTS AND DISCUSSION

Experiments were performed at 80° with reaction times of 60, 90, 120, 150, 240, and 900 minutes. The amounts of TMSDN found are given in Fig. 1 (circles), where Bevington's (1) data (squares) at 60° are also quoted. Both sets of points fall nearly on the same curve, as the equation

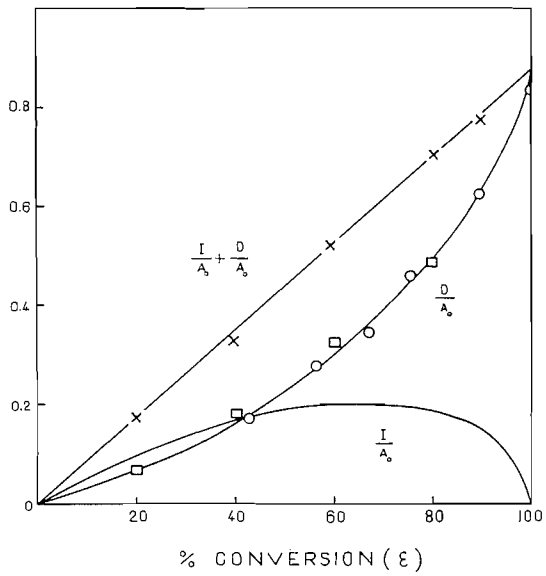

FIG. 1. Moles of TMSDN (upper curve) and ketenimine intermediate (lower curve), present at various stages of the decomposition of 1 mole of AIBN. Circles: Data at 80°; squares: Bevington's (1) results at 60°. The fact that the ordinates of the two curves add up to give a straight line signifies that the intermediate decays quantitatively to TMSDN, and that this decay is almost exclusively a molecular process.

$$[3] \qquad \frac{D}{A_0} = \frac{k_2+k_3}{k_2+k_3+k_4}\epsilon + \frac{k_3}{k_2+k_3+k_4}(1-\epsilon)\ln(1-\epsilon)$$

requires (ϵ is the extent of decomposition). In Fig. 1 the curve for the intermediate, reported in reference (7), whose equation in terms of ϵ is:

$$[4] \qquad \frac{I}{A_0} = -\frac{k_3}{k_2+k_3+k_4}(1-\epsilon)\ln(1-\epsilon),$$

has also been given.

It is seen that the curve $(D/A_0)+(I/A_0)$ versus ϵ must be a straight line if scheme [1] applies. The sums of the ordinates of the two experimental curves at $\epsilon = 0.20$, 0.40, 0.60, 0.80, and 0.90 are also indicated on the same diagram (points marked ×); it is seen that they lie along a straight line, quite satisfactorily. This would be the case only *if* the intermediate decays quantitatively to TMSDN. In fact, it is only in this case that the absolute value of I/A_0 and that of the second term on the right-hand side of [3] are equal, and eliminate each other leaving only the linear term in ϵ. This is simply a requirement of the material conservation. The ordinate of the straight line at $\epsilon = 1$, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

must measure the total fraction of recombination, is found to be 0.84, in excellent agreement with Bickel and Waters (3). Furthermore, the intersection of the two curves, which occurs at $\epsilon = 0.42$, gives for the ratio k_2/k_3 the value 0.50, which means that the extent of the abnormal recombination of the radicals is twice their normal recombination; this unexpected result can also be seen on Fig. 2. The sum and the ratio of the extent of the two recombinations being now known, their individual values can be calculated as 0.28 and 0.56; the former is in good agreement with the value obtained by an alternative method without making use of the curve for the intermediate (Fig. 2).

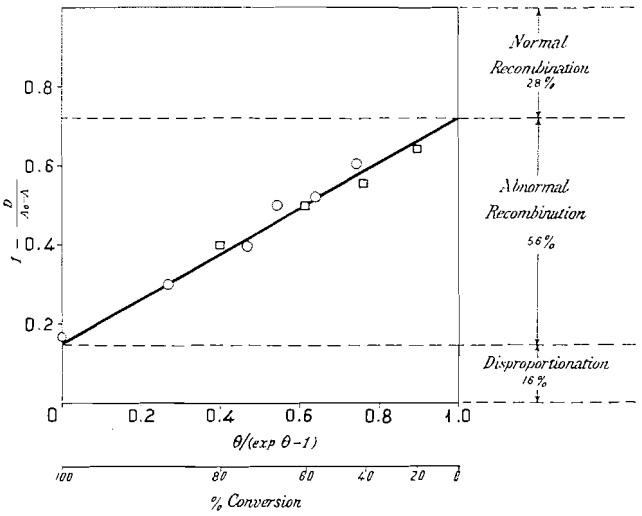

FIG. 2. Graphical estimation of the extent of the normal and abnormal recombination, and dispro portionation. The quantity $1-D/(A_0-A)$ may be called the "apparent" extent of disproportionation; it decreases during decomposition, the true one, $k_4/(k_2+k_3+k_4)$, remaining constant.

As it has already been pointed out, another implication of our reaction scheme is that a plot of $1-D/(A_0-A)$ versus $k_1t/(\exp k_1t-1)$ has to be a straight line, irrespective of the constant temperature at which the amounts D and A are measured. This is shown to be the case in Fig. 2, using again both Bevington's (1) data at 60° and the results of the present work at 80°. It is seen that the slope of the best line gives for the extent of the abnormal recombination the value 0.56, which is in good agreement with that of reference (7).

We have worked out a number of reaction schemes resulting from suitable modifications applied to the one under consideration, in such a way as to make it possible to check some conclusions reached by various authors. For example, Roy *et al.* (5) suggest that the path through the ketenimine intermediate does not involve free radicals. A simple calculation shows that in this case the slope of the straight line of Fig. 2 will be equal to the fraction of AIBN which decomposes molecularly; but, the existing data on the catalyst efficiency of AIBN in styrene and methyl methacrylate polymerization, namely 60% between 30° and 80° (see Tobolsky, A. V. Ann. Rev. Phys. Chem. **7**, 175 (1956), and references given therein), set a limit of 0.40 for the highest possible value of the slope, which would be clearly distinguishable from the observed value of 0.56. This excludes a reaction scheme in which the intermediate is assumed to have a non-radical precursor, although such a scheme would exhibit kinetic features similar to those of the mechanism under consideration. On the other hand, Bevington's (2) conclusion that part of the azo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

compound decomposes by a molecular mechanism would be inconsistent with the properties of the diagrams presented herein, unless the extent of such a decomposition is negligible. In the same way, it can be shown that a reaction scheme in which it is postulated that at least a fraction of the ketenimine intermediate regenerates cyanisopropyl free radicals, as claimed by Hammond (4), cannot be maintained, unless this fraction is negligibly small. In fact, let P denote disproportionation products, I intermediate, D dimer, ϵ extent of decomposition. The equation $A_0\epsilon = I+D+P$ is true for any mechanism involving an intermediate by any path of formation and decomposition. Now, if the intermediate, which is formed in large quantities, decays to form free radicals, P/A_0 and hence $(I/A_0)+(D/A_0)$ cannot be linear in ϵ. Thus, a free radical successor for the intermediate should also be excluded.

NOTE ADDED IN PROOF

Dr. S. Bywater has kindly drawn our attention to a recent work by Keys, R. T. and Hammond, G. S. Dissertation Abstr. February, 1934 (1959), in which the authors use the ketenimine as initiator in the polymerization of styrene. This may at first sight seem contradictory to the conclusion reached in the present paper that the ketenimine decays molecularly. However, their results indicate that the catalyst efficiency of this compound changes with monomer concentration, and they advance the explanation that "the monomer may complex with the radicals from the decomposition of the initiator thereby to decrease the importance of cage effects". This means that the smaller the monomer concentration the larger the cage effects. Then, in the limiting case of the complete *absence* of monomer, which is the case in our experiments, the "cage effect" (one could rather say "the intramolecular recombination of the two radicals" instead) is predominant. Thus, in the decay of intermediate in a non-reactive solvent there is no noticeable formation of "free" radicals, so that the process exhibits the characteristics of an almost exclusively molecular decomposition.

THE PHASE DIAGRAM OF THE SYSTEM Na_3AlF_6–Na_2SO_4 AND THE DISSOCIATION OF THE CRYOLITE ANION IN MOLTEN SODIUM SULPHATE[1, 2]

KAI GRJOTHEIM, TOR HALVORSEN, AND SIGMUND URNES[3]

ABSTRACT

The binary system Na_3AlF_6–Na_2SO_4 has been investigated. A eutectic point was found at 91 mole % Na_2SO_4. On the Na_3AlF_6 side of the diagram extensive solid solution was found. No solid solution was observed on the Na_2SO_4 side, either by thermal analysis or by Debye–Scherrer diagrams. The freezing point depression of Na_2SO_4 caused by additions of Na_3AlF_6 has been used to evaluate the dissociation scheme of the cryolite anion in a sodium sulphate melt. The calculations favor the following scheme:

$$AlF_6^{3-} = AlF_4^- + 2F^-.$$

INTRODUCTION

Current interest (1, 2) in the structure of molten cryolite has led to the examination of some binary systems containing cryolite. Assuming ideal ionic mixtures, the phase diagrams of these systems may be used for calculations of the dissociation of the cryolite anion. For this purpose, systems without solid solutions but with ions sufficiently similar to justify the assumption of ideal ionic mixtures (3) were chosen.

The first system to be studied was Na_2SO_4–Na_3AlF_6.

EXPERIMENTAL

The experimental techniques involved in the present study have been described in previous papers from this Institute (1, 4, 5, 6, 7).

The investigation was mainly undertaken by careful recording of cooling curves. However, for the determination of the solidus curve the method of Flood and Seltveit (4) was used. By this method, a very small amount is added of a third, radioactive component which is soluble in the liquid, but insoluble in the solid phase. For these experiments Cs^{134} in the form of the chloride was used as a tracer.

The reagents used were sodium sulphate from Merck (Darmstadt, Germany) chemically pure quality, and hand-picked crystals of cryolite from Ivigtut, Greenland.

Some of the experimental data are given in Table I, and the phase diagram is shown in Fig. 1. The eutectic mixture contains 91 mole % Na_2SO_4. The maximum amount of Na_2SO_4 that can be taken in solid solution by Na_3AlF_6 is 80 mole %.

No solution of Na_3AlF_6 in solid Na_2SO_4 was detected, either by thermal analysis or by Debye–Scherrer diagrams made on the samples.

ON THE DISSOCIATION OF CRYOLITE

Structural Models for the Melt and Method of Calculation

Structural interpretations of the liquidus line in systems without solid solubility seem in many cases to give information of considerable value (2).

Investigations by different methods of several binary salt systems with sodium sulphate have by now fairly well established that pure molten sodium sulphate is composed of sodium cations and anions of the sulphate group (6). A review of structural models with corresponding dissociation schemes for pure molten cryolite is given in a previous paper (2).

In the following, the correctness of the most probable of these models will be tested by comparing the calorimetrically determined heat of fusion of sodium sulphate with the heats of fusion that can be evaluated according to the different models from the freezing point depression data of sodium sulphate caused by cryolite additions.

The following two dissociation schemes for the cryolite anion will be considered:

$$AlF_6^{3-} = AlF_4^- + 2F^-$$

$$AlF_6^{3-} = Al^{3+} + 6F^-.$$

The first one will be quantitatively treated here both for complete and part dissociation. The last one has only been considered for the complete dissociation.

The equations used in the calculations are well known in classical physical chemistry, but they will be briefly reviewed.

The liquidus line on the sulphate side of the phase diagram gives the composition of the liquid phase which is in equilibrium with pure solid sodium sulphate at the temperature T. The partial free energy of sodium sulphate in the liquid, referred to pure liquid sodium sulphate at the same temperature as the standard state, is given by the following equation:

$$[1] \qquad \overline{\Delta F}_{Na_2SO_4} = \overline{\Delta H}_{Na_2SO_4} - T\overline{\Delta S}_{Na_2SO_4} = -\Delta H_f[1-(T/T_0)]$$

where T_0 is the melting point of pure sodium sulphate and ΔH_f is the heat of fusion. (In obtaining these equations the difference in the specific heat between the solid and liquid sodium sulphate is as usual (8) neglected, because of its small influence.)

In this case we are dealing with mixtures high in sodium sulphate, so we will neglect the energy term in the free energy equation. Equation [1] is thus reduced to

$$[2] \qquad T\overline{\Delta S}_{Na_2SO_4} = \Delta H_f[1-(T/T_0)].$$

In the following we will use Temkin's model (3) of fused salts to evaluate the expression for $\overline{\Delta S}_{Na_2SO_4}$.

The Temkin model can be summarized as follows:

1. The entropy of mixing is entirely configurational.
2. There are two sets of positions in the salt melts, one for the cations and one for the anions.
3. The cations and the anions are randomly distributed over all the cation and anion positions regardless of the magnitude of the charges.

According to this, the partial entropy of sodium sulphate is given by:

$$[3] \qquad \overline{\Delta S}_{Na_2SO_4} = -R \ln (N^2_{Na^+} \cdot N_{SO_4^{2-}})$$

where N_{Na^+} and $N_{SO_4^{2-}}$ are the cation and anion fractions. These ionic fractions will depend on what structural models are chosen for the cryolite anion in the molten mixture.

Plotting $\ln (N^2_{Na^+} \cdot N_{SO_4^{2-}})$ as a function of $1/T$ should give a straight line in the region where $\overline{\Delta H}_{Na_2SO_4}$ can be neglected. The slope of this line should correspond to the calorimetrically determined heat of fusion of sodium sulphate (9). In this way a means is provided to distinguish between different structural models.

RESULTS

If the cryolite anion does not dissociate in the sulphate melt, the ionic fractions of sodium sulphate will be:

$$N_{Na^+} = 1$$

$$N_{SO_4^{2-}} = n_{Na_2SO_4}/(n_{Na_2SO_4}+n_{Na_3AlF_6})$$

where $n_{Na_2SO_4}$ and $n_{Na_3AlF_6}$ are the molar amounts of sodium sulphate and cryolite in the melt.

Plotting for this model $\ln (N^2_{Na^+} \cdot N_{SO_4^{2-}}) = \ln N_{SO_4^{2-}}$ against $1/T$ gives a heat of fusion around 1900 cal/mole as shown by the dashed line in Fig. 2.

Assuming that the cryolite anion dissociates completely into AlF_4^- ions and fluoride ions, we get these expressions for the ionic fractions:

$$N_{Na^+} = 1$$

$$N_{SO_4^{2-}} = n_{Na_2SO_4}/(n_{Na_2SO_4}+3n_{Na_3AlF_6}).$$

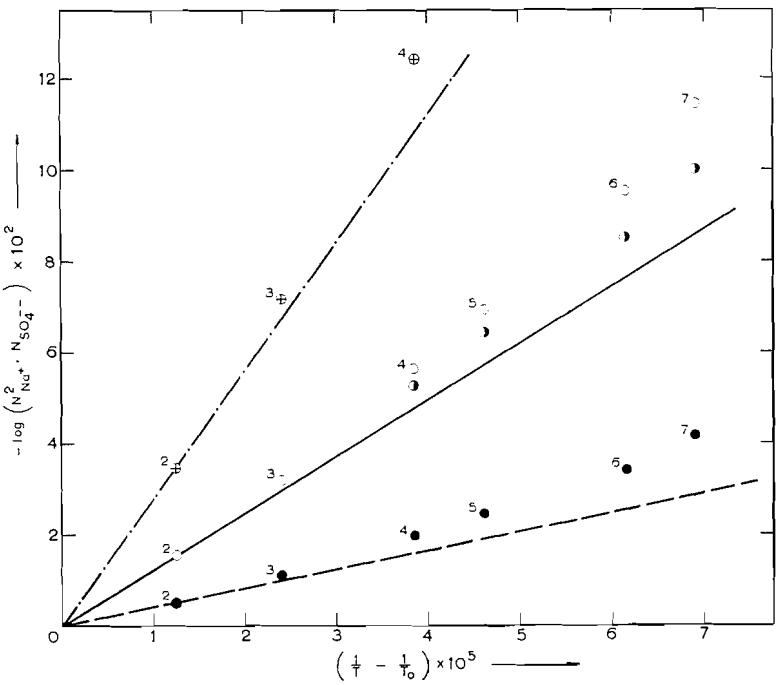

FIG. 2. $-\text{Log}\ (N^2_{Na^+} \cdot N_{SO_4^{2-}})$ versus $1/T$ on the sodium sulphate side of the system Na_3AlF_6–Na_2SO_4, $(N^2_{Na^+} \cdot N_{SO_4^{2-}})$ is calculated according to four different models of the melt. ● Temkin ionic mixture of the ions Na^+, SO_4^{2-}, and AlF_6^{3-}. ○ Temkin ionic mixture of the ions Na^+, SO_4^{2-}, AlF_4^-, and F^-. ◑ Same as above, except AlF_6^{3-} is only partly dissociated into $AlF_4^- + 2F^-$ (with the dissociation constant $K = 0.06$). ⊕ Temkin ionic mixture of the ions Na^+, Al^{3+}, SO_4^{2-}, and F^-. Full line corresponds to the calorimetrical determined heat of melting for sodium sulphate of 5670 cal/mole, dashed line corresponds to 1900 cal/mole, and dashed-dotted line to about 13,000 cal/mole.

A plot (full line in Fig. 2) of $\ln N_{SO_4^{2-}}$ against $1/T$ gives in this case a curve with a limiting slope corresponding to the calorimetrically determined heat of fusion 5670 cal/mole (9).

For comparison, the ionic fractions of Na^+ and SO_4^{2-} are also calculated for an assumed complete dissociation of the cryolite anion into Al^{3+} and $6F^-$ ions. In this case we have:

$$N_{Na^+} = (2n_{Na_2SO_4} + 3n_{Na_3AlF_6})/(2n_{Na_2SO_4} + 4n_{Na_3AlF_6})$$

$$N_{SO_4^{2-}} = n_{Na_2SO_4}/(n_{Na_2SO_4} + 6n_{Na_3AlF_6}).$$

A plot of $\ln (N^2_{Na^+} \cdot N_{SO_4^{2-}})$ against $1/T$ gives in this case a curve (dashed-dotted line in Fig. 2) with a limiting slope corresponding to a heat of fusion around 13,000 cal/mole. (The ionic fractions calculated according to the different models are listed in Table II.)

The results are clearly in favor of the dissociation scheme:

$$AlF_6^{3-} = AlF_4^- + 2F^-.$$

Therefore, a calculation was undertaken using the dissociation constant $K = 0.06$ previously found for this scheme (1, 2). As seen from Fig. 2 this assumption brings the experimental points at higher concentrations closer to the straight line. When a dissociation constant equal to 0.02 is used the points will fall close around the line which corresponds to the heat of fusion of sodium sulphate.

Discussion of Other Experimental Data for this System

A few freezing point depression measurements were undertaken in sodium sulphate by a simultaneous addition of small amounts of both cryolite and sodium fluoride. To get the points on the straight line corresponding to the calorimetric heat of fusion of sodium sulphate it was necessary, for this mixture, to use a dissociation constant $K = 0.04$, to be compared with 0.06 above.

The complete dissociation of AlF_6^{3-} into $6F^-$ ions and one Al^{3+} ion in sulphate melt can be also ruled out from some other experimental evidence. This reaction scheme leads to free Al^{3+} ion. However, at the actual temperatures Al^{3+} will be a stronger acid than SO_3. The following reaction will therefore take place:

$$2Al^{3+} + 3SO_4^{2-} = Al_2O_3 + 3SO_3(g).$$

Thus addition of $Al_2(SO_4)_3$ or $KAl(SO_4)_2$ to sodium sulphate melts leads to SO_3 evolution corresponding to the reaction just mentioned.

If aluminum fluoride is added to a sodium sulphate melt, there will not be sufficient fluoride to form any stable AlF_4^- complex and we should thus expect a reaction between Al^{3+} and the sulphate ion. To test this the following experiments were carried out. In a platinum crucible, Na_2SO_4, with small additions of AlF_3, was heated to melting. The whole system was kept just above the melting point of sodium sulphate in an inactive atmosphere for about half an hour. The heating resulted in a loss of weight corresponding to about one mole of SO_3 given off for each two moles of AlF_3. However, if NaF is added to the charge before the run, a little in excess of the composition $NaAlF_4$, no loss in weight is observed, neither does any addition of cryolite to sodium sulphate give any loss of weight by melting.

CONCLUSIONS

Cryoscopic data for the liquid mixtures of $NaCl$–Na_2SO_4 and $NaBr$–Na_2SO_4 (4) indicate that these systems are essentially ideal over a wide concentration range. Careful measurements of e.m.f. between oxygen electrodes in the system Na_2SO_4–Na_2CO_3 (10) have shown the ideality of that system. It is, thus, fair to assume that a liquid mixture containing the ionic species Na^+, F^-, AlF_4^-, AlF_6^{3-}, and SO_4^{2-} should also show ideal behavior. In that case it may be concluded from this study of the system Na_2SO_4–Na_3AlF_6 that cryolite anion dissociates in sodium sulphate melt according to the scheme

$$AlF_6^{3-} = AlF_4^- + 2F^-,$$

with a dissociation constant of the same order as previously found by similar calculations for the cryolite anion in the system NaF–AlF_3. The surprisingly good agreement may indicate that the AlF_4^- ion is fairly stable at these temperatures.

REACTIONS OF TITANIUM HALIDES WITH ORGANOMETALLIC COMPOUNDS

I. STOICHIOMETRY OF THE REACTIONS BETWEEN TITANIUM TETRACHLORIDE AND SOME ORGANOMETALLIC COMPOUNDS[1]

ALBERTO MALATESTA[2]

ABSTRACT

The over-all stoichiometry of the reactions involving titanium tetrachloride and various organometallic compounds has been determined. While titanium tetrachloride reacts with aluminum ethyldichloride and lead tetraethyl according to a 1:1 stoichiometry for any ratio investigated, the reaction between aluminum triethyl and titanium tetrachloride proceeds according to different paths when the ratio of the reagents is changed. Equations describing the reactions between aluminum triethyl and titanium tetrachloride, where the stoichiometries are respectively 1:1, 1:2, 1:3, are derived. Although a certain amount of hydrogen has been isolated after hydrolysis of the products of these reactions, no definite evidence is found for the presence of Ti(II).

In all the experiments (except those in which an Al/Ti ratio greater than unity was used) substantial amounts of ethyl chloride and ethylene have been found, together with the main gaseous components, ethane and butane. A higher alkane was also isolated from the solid products of the reaction and is equal to the quantity of ethane liberated.

INTRODUCTION

The reaction of organometallic compounds with titanium derivatives has been under investigation for a long time (1) in an attempt to prepare compounds containing titanium–carbon bonds. Gilman and Jones (2), reacting phenylmagnesium bromide with tetrabutyl titanate in ether at about 8° C, succeeded in demonstrating the formation of a Ti–C bond by a test with Michler's ketone which developed slowly but ultimately became strong in color. The colors appearing in the reaction mixture, attributable to titanous compounds, led to the conclusion that the phenyl–titanium bond decomposes spontaneously giving phenyl radicals and Ti(III). In the case of a reaction mixture of methylmagnesium bromide and tetrabutyl titanate, the formation of Ti(III) and methane was observed to proceed at the same rate. Herman and Nelson (3), using phenyl lithium and isopropyltitanate in ether at 8–15° C, succeeded in preparing a compound whose analysis led to the formulation $C_6H_5Ti(OC_3H_7)_3 \cdot LiOC_3H_7 \cdot LiBr \cdot (C_2H_5)_2O$. This compound was reacted further with an excess of titanium tetrachloride, and phenyltitanium triisopropoxide was isolated with a yield of 53%. This compound is very stable, it melts at 88–90° C and shows no darkening after 1 year of storage at 10° C. On being heated at 100–120° C it decomposes giving a violet compound. In a second paper the same authors (4) report some information on the stability of titanium–carbon bonds as a function of the alkyl or aryl groups involved in the organometallic bond, of the number of these groups attached to the titanium atom, and of the nature of the other groups bonded to the metal atom. Using phenylmagnesium bromide and titanium tetrabutylate in different ratios, they found that a different organotitanium compound is formed for each ratio used. They based their conclusions on the rate of spontaneous decomposition of solutions of the organometallic compounds. Although no clear-cut evidence is given, the formation of highly unstable polyphenyltitanium compounds is favored when higher ratios are used, while more stable mono-substituted phenyltitanium compounds are formed at lower ratios. Ti(II) was found at higher ratios (from hydrogen evolved upon

[1]*Manuscript received March 19, 1959.*
[2]*Present address: Dunlop Research Centre, Toronto 8, Ontario.*

hydrolysis of the products of the reaction) suggesting that diphenyltitanium may be present as a relatively stable organometallic compound. Summers and Uloth (5), reacting bis-(cyclopentadienyl)-titanium halides with several lithium aryls, succeeded in preparing relatively stable compounds containing two titanium–carbon bonds.

The present series of experiments was carried out in order to determine the over-all stoichiometry involved in the alkylation reaction of titanium tetrachloride with various organometallic compounds.

EXPERIMENTAL

Materials

$AlEt_3$ (Ethyl Corp.) was vacuum-distilled through a short Vigreux column and stored at room temperature. The purity of the product was checked by gravimetric analysis with 8-hydroxyquinoline (6 *b*) and potentiometrically (7) in order to determine the amount of aluminum triethyl, aluminum diethyl monohydride, and aluminum alkoxide derivatives. The aluminum triethyl used in this investigation was 99.8% pure. No aluminum hydride derivatives were found and the only impurities present were aluminum alkoxide compounds.

$AlEtCl_2$ was prepared according to the procedure of Grosse and Mavity (8), distilled through a Vigreux column, and stored at room temperature. Gravimetric analysis gave a purity of 99.9%.

$TiCl_4$ (Fisher) was purified according to the procedure of Gilchrist (9).

$PbEt_4$ (Ethyl Corp.) was dehydrated with anhydrous magnesium sulphate, filtered, and stored in a dark bottle under nitrogen. The purity of the product was determined iodometrically (6 *a*) and was 99.2%.

Prepurified nitrogen (Mathieson) was used as an inert gas to prevent contamination of the reaction materials. Before use the gas was passed through alumina activated at 250° C and calcium hydride.

Procedure

The organometallic compounds and titanium tetrachloride react together with gas evolution. A specially designed reaction vessel of known volume connected to a mercury manometer (made with a calibrated capillary tubing) and by a high-vacuum stopcock to a vacuum system was used to study the reaction (Fig. 1).

The apparatus was heated for at least 12 hours at 100° C in vacuum and then assembled in nitrogen atmosphere. Before assembling the apparatus, two glass ampoules, each containing a weighed amount of reactants, were introduced through the female joint. This was then closed with a male ground-glass joint fitted with a long glass rod. By small vertical movements of the rod it was possible to break the two ampoules. Before breaking the ampoules the system was evacuated to 10^{-3} mm of Hg and then cooled at $-35°$ C. After the ampoules were broken the temperature of the vessel was slowly raised to 0° C and maintained there in order to insure a smooth reaction. After a few minutes the vessel was introduced into a thermostat and kept at $35\pm0.1°$ C until the reaction was complete. The end of the reaction was indicated by stabilization of the level in the mercury manometer. From a knowledge of the final pressure (obtained from the difference between the reading of the mercury manometer and the barometric pressure, less the vapor pressure of the reagent present in excess),[3] the number of moles of gas liberated during

[3]*The vapor pressure values of the reagents were determined at 35±0.1° C in the apparatus used for the investigation here reported. In this way it was also possible to ascertain that while lead tetraethyl and aluminum ethyldichloride are stable under vacuum, aluminum triethyl split off ethylene. At 35±0.1° C, the moles of ethylene liberated per mole of aluminum triethyl are* 5.61×10^{-4}.

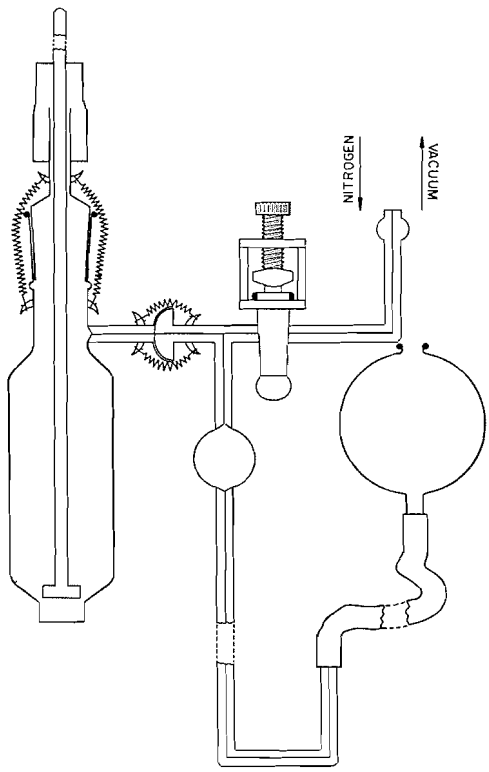

FIG. 1. Reaction vessel.

the reaction was calculated. Since the amount of gas formed is dependent on the amount of the organotitanium derivative produced in the alkylation reaction of titanium tetrachloride,[4] the moles of the organometallic compound reacted with titanium tetrachloride were then calculated from the moles of gas liberated after the determination of its composition by mass spectrometry. After the removal of the gas sample for the analysis, the vessel was frozen at $-35°$ C and the gas was pumped off. When the original pressure (10^{-3} mm of Hg) was restored, carefully degassed water was introduced.

The temperature of the system was raised to 0° C, and, after the hydrolysis was complete, the gas was again analyzed by mass spectrometry. Atmospheric pressure was then restored with nitrogen and the Ti(III) was determined with Fe(III) in the presence of ammonium thiocyanate as an indicator (4). At the end of each experiment a waxy substance was found in the vessel. This substance, soluble in organic solvents, had a molecular weight (determined by the cryoscopic method in benzene) which varied between 750 and 1000 and was characterized by I.R. spectroscopy as a high alkane (4).

A few reactions were duplicated in the apparatus described using a pressure of 545 mm of Hg, or the atmospheric pressure instead of the pressure of 10^{-3} mm of Hg. Since no appreciable differences have been found in quantity and composition of the gas liberated in these experiments and in comparable experiments conducted at 10^{-3} mm of Hg, it is

[4]*C. F. Feldman, L. C. Arnold, and D. W. McDonald, in a paper presented at the 131st National Meeting of the American Chemical Society, Miami, Florida, April 1957, reported that with the aluminum triisobutyl – titanium tetrachloride system at a ratio* Al/Ti *1.2:1, the reduction of* Ti(IV) *to* Ti(III) *according to the reactions* $AlR_3 + TiCl_4 \rightarrow AlR_2Cl + TiCl_3R$ *and* $TiCl_3R \rightarrow TiCl_3 + R\cdot$ *was more than 90% complete in 20 minutes. See also reference 2.*

concluded that the evolution of the gas observed in the reactions between organometallic compounds and titanium tetrachloride is not influenced by the pressure at which the experiments were conducted.

The ampoules were made with capillary tips at one end, and had a predetermined volume. They were filled according to the following procedure: the organometallic compounds and the titanium tetrachloride were stored in separate specially designed glass containers (Fig. 2) each with a side arm through which prepurified nitrogen could

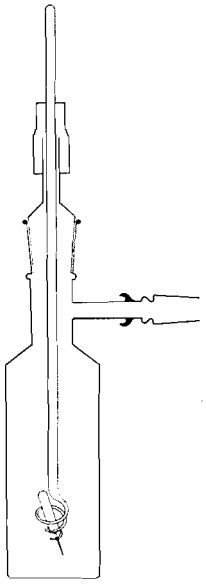

FIG. 2. Container for the sampling of the reagents.

be introduced when necessary. The container was closed with a male joint fitted with a glass rod. The end of the rod introduced into the container was formed as a thin spiral on which the glass ampoules could be conveniently placed with the tip down. All the ampoules were previously heated in vacuum for at least 24 hours and filled with nitrogen. The apparatus, containing the substance and the ampoule, was evacuated, and upon complete evacuation the tip of the ampoule was inserted below the liquid level, by pushing down the glass rod. Nitrogen was admitted slowly thus filling the ampoule with liquid. On exposure to air the ampoules containing both the organometallic compounds and the titanium tetrachloride became sealed by reaction of the air with the compound present in the capillary tip. The ampoules containing lead tetraethyl were sealed with a microflame. All the ampoules used in this investigation were filled at the same time. The analysis for the purity of each compound was actually performed using the product sampled at the start, in the middle, and at the end of the operation, in order to verify that the sampling procedure did not change the purity of the reagents. Analyses were also made at the end of the investigation in order to check that the purity of the material had not changed during that time.

EXPERIMENTAL RESULTS

Reaction of $AlEtCl_2$ *and* $TiCl_4$

Aluminum ethyldichloride and titanium tetrachloride react quite smoothly with the formation of a reddish-brownish precipitate. A qualitative evaluation of the rate of gas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

evolution shows that, whatever the ratio between the organometallic compound and titanium tetrachloride there is no considerable difference in the rate. The gases evolved during the reaction are mainly ethane and butane. Substantial amounts of ethylene and ethyl chloride are also liberated and traces of higher alkanes. The absolute molar amount of each gas liberated per mole of aluminum ethyldichloride used is plotted against the molar ratio of aluminum ethyldichloride and titanium tetrachloride in Fig. 3.

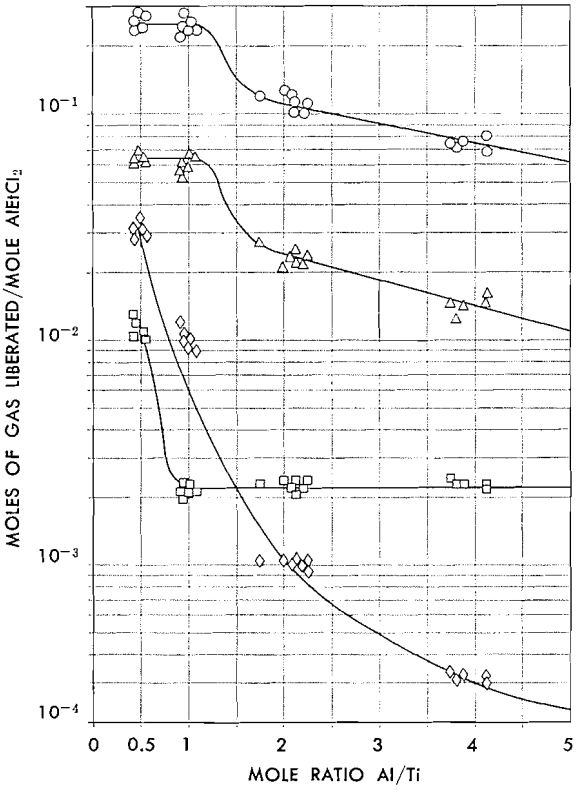

FIG. 3. Reaction of $AlEtCl_2$ with $TiCl_4$. Molar amounts of ethane, butane, ethylene, and ethyl chloride liberated per mole of $AlEtCl_2$ used vs. the molar ratio of $AlEtCl_2$ and $TiCl_4$.
○ Ethane □ Ethylene
△ Butane ◇ Ethyl chloride

An interesting result is the presence of ethyl chloride in the gas evolved during the reaction. The amount of this component is very close to the amount of butane evolved, especially at ratios Al/Ti below 1. The presence of ethyl chloride demonstrates that part of the alkylated form of titanium is decomposed according to the equation [1] proposed by Friedlander and Oita (10).

$$TiCl_3R \rightarrow TiCl_2 + RCl \qquad [1]$$

Titanium dichloride obtained from this reaction reacts with the excess of titanium tetrachloride present for every ratio, according to the reaction [2] which is completely

$$TiCl_2 + TiCl_4 \rightleftharpoons 2TiCl_3 \qquad [2]$$

shifted to the right at room temperature (11). The presence of ethylene, already ascertained by Gilman (12) in similar reactions, and of the waxy polymer, already mentioned,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

throws light on the fate of the ethyl radicals split from the alkylated product. The sum of the moles of ethylene found in the gas and of the polymer found in the reaction vessel is equal, within experimental error, to the amount of ethane liberated.[5] After decomposition with water, the analysis of the gas reveals no hydrogen for any ratio of Al/Ti, thus ruling out the possibility of having Ti(II) as a product of the reaction. The gases produced during the hydrolysis are mainly ethane and a small amount of butane. The acid solution containing the titanium was analyzed for Ti(III) content.

In Table I are reported the amounts of the reagents used, the amount of the reagents reacted, the per cent of Ti(IV) reduced, and the average valence of the metal in the product of the reaction.

Reaction of $PbEt_4$ *and* $TiCl_4$

These two compounds react as smoothly as aluminum ethyldichloride and titanium tetrachloride, with the formation of a brownish-blackish precipitate. In this case an approximate evaluation of the rate of gas evolution shows that no large difference exists in the rate of the reaction between the two reagents for any ratio studied and that the gases evolved during the reaction are mainly ethane and butane with substantial amounts of ethylene and ethyl chloride and traces of higher alkanes. In Fig. 4 the absolute amount of each gas liberated per mole of lead tetraethyl used is plotted against the ratio

[5]*An exhaustive discussion on the relationship between the mechanism of the decomposition of the organometallic compounds of the transition metals and their stability is reported by Cotton, F. A. Chem. Revs.* **55**, *551 (1955).*

$PbEt_4/TiCl_4$. It is possible to conclude that ethyl chloride also results in this case from a reaction of the same type as in equation [1]. After hydrolysis, the analysis of the gas shows no hydrogen for any ratio of Pb/Ti. The gases present after decomposition are mainly ethane and a trace of butane. The solution containing the titanium was titrated with Fe(III) and the amount of Ti(III) was determined. After the titration the solution was filtered and the solid collected was dissolved in hot *n*-heptane. From the solution a white powder was recovered. This substance was purified by crystallization from *n*-heptane and analyzed for chlorine. The compound was identified as $PbEt_3Cl$. (Anal. Calc. for $PbEt_3Cl$: Cl, 10.71. Found: Cl, 10.69.)

In Table II are reported the quantities of reagents used, the amount of the reagents reacted, the per cent of titanium tetrachloride reduced, and the average valence of the metal in the product of the reaction.

Reaction of $AlEt_3$ *and* $TiCl_4$

Aluminum triethyl and titanium tetrachloride react very fast even at low temperature with the formation of blackish-brown precipitate depending on the ratio of Al/Ti used. An approximate evaluation of the rate in this case was quite difficult because the reaction is completed in a few minutes. It is also doubtful at what temperature the alkylation reaction was actually conducted although the standard technique already described was used. In spite of these difficulties the results were reproducible enough to be interpreted.

1.10	2.41	0.56	1.34	1.05	0.78	55.4	3.44

In this case also the gases formed during the alkylation reaction were mainly ethane and butane and traces of higher alkanes, but if the ratio Al/Ti was kept above the value 1, ethylene and ethyl chloride were not found. These two components appear in substantial amount when ratios of Al/Ti less than unity are used.

In Fig. 5 the absolute amount of each gas liberated per mole of aluminum triethyl used is plotted against the ratio $AlEt_3/TiCl_4$.

After hydrolysis, analysis of the gas showed that ethane was the principal component, and that a small amount of butane was also present. Hydrogen was also found in small amounts only for ratios of Al/Ti greater than unity. In Table III are reported the quantity of reagents used, the amount of the reagents reacted, and the per cent of titanium tetrachloride reduced. The amount of $TiCl_2$, which can be calculated from the hydrogen evolved on hydrolysis, is not reported here because no other direct evidence of its presence in the alkylated material is available. While it is possible to have compounds of Ti(II) as direct products of the alkylation reaction, it is also possible that such products could be formed by thermal effects from higher valence compounds during the hydrolysis itself. This possibility is discussed later. Nevertheless, the moles of titanium dichloride calculated from the hydrogen evolved represented only a small per cent (about 5%) of the initial amount of $TiCl_4$ used for all the ratios of Al/Ti above 1.81.

DISCUSSION

The alkylation of titanium tetrachloride with various organometallic compounds reported is a well-defined reaction, at least with organometallic compounds of low activity such as aluminum ethyldichloride and lead tetraethyl. With these compounds the stoichiometry of the reaction follows reaction [3] for any ratio investigated. The

$$MR_x + TiCl_4 \rightarrow MR_{x-1}Cl + TiCl_3R \qquad [3]$$

formation of a specific compound as a product of the alkylation is demonstrated by a constant rate of gas evolution during the reaction and by the almost constant composition of the gas obtained for any ratio of the reagents used. For the reaction between

aluminum triethyl and titanium tetrachloride, it is not possible to derive a constant stoichiometric relationship for the various ratios used. However, it appears that for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

an Al/Ti ratio greater than 3 the reaction goes according to reaction [4], while for Al/Ti ratios below 0.5 reaction [5] is followed. Since it is possible to observe a continuous

$$AlEt_3 + TiCl_4 \rightarrow AlEt_2Cl + TiCl_3R \quad [4]$$

$$AlEt_3 + 3TiCl_4 \rightarrow AlCl_3 + 3TiCl_3R \quad [5]$$

variation in the ratios of reacted aluminum triethyl and titanium tetrachloride from 1 to 0.35, it is difficult to determine boundary lines dividing the regions where the reactions [4], [5], and [6] occur.

$$AlEt_3 + 2TiCl_4 \rightarrow AlEtCl_2 + 2TiCl_3R \quad [6]$$

The reactions [4] and [6] do not account for the further reduction of titanium to the bivalent state.

The formation of Ti(II), which probably becomes apparent only upon hydrolysis, can occur according to the reactions [7] and [7′]

$$TiCl_3 + AlEt_3 \rightarrow TiCl_2R + AlEt_2Cl \quad [7]$$

$$TiCl_2R \rightarrow TiCl_2 + R\cdot \quad [7']$$

or according to the reactions [8] and [8′].

$$TiCl_4 + 2AlEt_3 \rightarrow TiCl_2R_2 + 2AlEt_2Cl \quad [8]$$

$$TiCl_2R_2 \rightarrow TiCl_2 + 2R\cdot \quad [8']$$

While both reactions may be responsible for the formation of Ti(II), it is probably true that the course of reaction [7] is hindered by its heterogeneity. Reaction [8], with the production of Ti(IV) alkyl derivatives (which are the only stable organometallic compounds of titanium isolated (4, 5)), is more likely responsible for the formation of Ti(II). Since no titanium metal has been found after hydrolysis of the alkylated material, and since titanium can form di-, tri-, and tetra-substituted derivatives as well as complex anions (using its empty *d*-orbitals), all the alkylation reactions which produce those organotitanium compounds which give titanium metal directly or by disproportionation on hydrolysis can be eliminated. It is reasonable to assume, at this point, that the alkylation of titanium tetrachloride proceeds only through the reaction schemes from [3] to [8]. Among all the possible organotitanium compounds only TiR_2Cl_2 and $TiRCl_3$ are likely to be present as tetra-substituted derivatives, while the only one likely to be present as a tri-substituted derivative is $TiRCl_2$.

Saltman and co-workers (13) found that with a Al/Ti ratio of 0.33 (in the case of a reaction of aluminum triisobutyl and titanium tetrachloride) the amount of solid obtained from the reaction per mole of $TiCl_4$ consumed is very similar in weight and composition to a mixture of 1 mole of $AlCl_3$ and 3 moles of $TiCl_3$. This result calls for a stoichiometry as in equation [5], which was derived using a completely different experimental procedure.

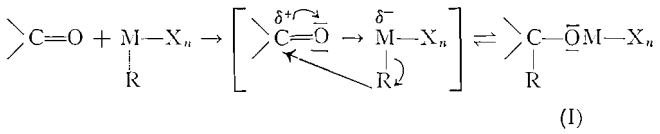
The possibility of having titanium as a complex anion has been suggested by Summers and Uloth (5) in order to explain the solubility of bis-(cyclopentadienyl)-titaniumdiphenyl in ether when an excess of phenyl lithium is added, according to the equilibrium equation [9], with the formation of dark orange-brown or nearly black solutions.

$$Ph_2[(C_5H_5)_2Ti] + PhLi \rightleftharpoons Ph_3[(C_5H_5)_2Ti]^- Li^+ \quad [9]$$

This possibility is reported here in order to discuss the observations of Friedlander and Oita (10) that the product of the reaction of aluminum triethyl with titanium tetrachloride for ratio values equal or less than unity gave negative tests with Michler's

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

ketone, indicating that all the alkyl compound either reacted with titanium tetrachloride or was held in an inactive complex. For a ratio Al/Ti greater than 2.5, strong positive Michler's ketone tests were observed thus indicating the presence of an excess of aluminum alkyl while between ratios 2.5 and 1, weakly positive test results were obtained, indicating the formation of new carbon–metal bonds or the formation of a complex which modified the properties of the aluminum alkyls. The mechanism of the reaction of Michler's ketone with a carbon–metal bond (14) consists of co-ordination of the oxygen of the carbonyl group with the metal, followed by migration of the group R with its electrons according to equation [10].



[10]

(I)

It is possible that if the color test (based on the hydrolysis of (I) and a chromatic reaction of the tertiary alcohol (15)) is negative, the co-ordination of the carbonyl does not occur. In presence of titanium derivatives this could only be explained by the fact that the empty *d*-orbitals of the metal are already occupied. The presence in the system of anions of the type suggested by Summers and Uloth (5) can explain why the Michler's ketone test failed to give positive results.

THE ALKALOIDS OF INULA ROYLEANA[1]

O. E. Edwards and M. N. Rodger[2]

ABSTRACT

Royline and inuline, previously isolated from *Inula royleana*, have again been isolated from this source, and shown to be lycoctonine and anthranoyl-lycoctonine respectively. The presence of a third known alkaloid, methyl-lycaconitine has also been established. This is the first recorded occurrence of lycoctonine and its derivatives outside the family Ranunculaceae.

Inula royleana DC. Prod., a perennial plant of the family Compositae, with reputed medicinal value, is found in the lower reaches of the Himalayas. Its extractives had been previously examined by two groups of workers. In 1944 Chopra, Kohli, and Handa (1) isolated an alkaloid, m.p. 120–121° $[\alpha]_D$ −42.5° to which they gave the name royline, and assigned the empirical formula $C_{21}H_{33}O_6N$. These workers were unable to isolate any crystalline derivatives of this base other than an aurichloride, m.p. 142° (decomp.) for which no analysis was given. Chatterjee and Talapatra (2) later examined this plant and isolated the same alkaloid. They changed its name to royline and altered the empirical formula to $C_{21}H_{35-37}O_6N$. In addition, these workers found another alkaloid, m.p. 165° (decomp.) $[\alpha]_D$ +44.3°, which they called inuline. This analyzed correctly for $C_{16}H_{23}O_4N$, and gave a crystalline chloroplatinate which analyzed for $C_{32}H_{46}O_8N_2 . H_2PtCl_6$.

We have re-examined the roots of *Inula royleana*, and have isolated and characterized three alkaloids, two of which correspond to those encountered by the Indian workers.

The dried root gave a phenomenal yield of alkaloid (*ca.* 5%), most of which was extracted by methylene chloride when a solution of its salt was adjusted to pH 8. This material was a complex mixture which was not readily separated by chromatography on alumina. After solvent precipitation of the darker colored components, the bases were separated by countercurrent distribution between benzene and buffer of pH 5. Royline remained in the early tubes, while inuline moved rapidly with the benzene phase, and both alkaloids were obtained pure after 180 transfers.

Inuline, when submitted to paper chromatography and paper electrophoresis proved to be homogeneous. The base formed a highly crystalline perchlorate, m.p. 206° (decomp.) which analyzed for $C_{32}H_{46}O_8N_2 . HClO_4$. On alkaline hydrolysis of the alkaloid two fragments were isolated—a base, $C_{25}H_{43}O_8N$, and a fluorescent amino acid $C_7H_7O_2N$. The latter fragment was identified as anthranilic acid by direct comparison with an authentic specimen. The basic fragment was similarly identified as the monohydrate of the known alkaloid lycoctonine. Inuline is therefore anthranoyl-lycoctonine. In accord with this, inuline and anthranoyl-lycoctonine[3] showed no depression of melting point on admixture, and their infrared spectra were identical. The corresponding perchlorates also proved to be identical. We were able to confirm that our material corresponded to that obtained by the earlier workers (I.R., melting point, mixed melting point, and rotation) using a sample kindly supplied by Mrs. A. Chatterjee whom we cordially thank.

Royline was also shown to be homogeneous by paper chromatography. Comparison of the base and its perchlorate with lycoctonine and its perchlorate proved the identity of the two alkaloids. We were again able to confirm that the material in our hands was the same as that examined by the earlier workers using a sample supplied by Mrs. A. Chatterjee. This sample had a rotation identical with that of lycoctonine, hence the reported negative rotation (1) for royline is in error.

The bulk of the alkaloids from the roots was separated manually in large funnels (12 transfers) using the above solvent system, but moving the lower phases.

The contents of the first three funnels were rich in inuline. The contents of the later funnels would not crystallize. The material from funnels 7–9 was redistributed (100 transfers) between benzene and buffer of pH 5. The major peak (tubes 34 to 79) was still non-crystalline, hence was redistributed between benzene and buffer of pH 4 (100 transfers). The material corresponding to the main peak (tubes 11 to 45) proved to be homogeneous. It could not be obtained crystalline, but it gave a crystalline hydriodide, m.p. 201° (decomp.). The base on hydrolysis gave lycoctonine and 1-methylsuccinyl-anthranilic acid. This suggested that it was methyl-lycaconitine, and comparison of the hydriodide with a sample kindly supplied by Professor R. C. Cookson, whom we cordially thank, established the identity (I.R., melting point, mixed melting point). Methyl-lycaconitine had previously been isolated by Goodson (3) and by Cookson, Page, and Trevett (4). These workers were also unable to induce the base to crystallize.

In addition to the major component found in the distribution at pH 4 there were four minor components, one moving more slowly than methyl-lycaconitine, and the remaining three moving more rapidly. These bases have not as yet been crystallized but each has a distinctive infrared spectrum, especially over the carbonyl and aromatic absorption regions.

The aqueous mother liquor from which the main basic fraction had been extracted was made strongly alkaline, and extracted with chloroform. The base obtained was largely lycoctonine (royline).

Alkaline hydrolysis of the material precipitated by the initial benzene–hexane separation of the weak bases (see experimental) gave a further yield of lycoctonine, and this fraction may well consist largely of oxidation and decomposition products formed from methyl-lycaconitine during drying of the root and subsequent operations.

Inula royleana now becomes the richest known source of lycoctonine. Now that the alkaloids isolated by the previous workers have proved to be lycoctonine and anthranoyl-lycoctonine we suggest that the names "royline" and "inuline" be deleted from the chemical literature.

Lycoctonine and its derivatives have been found in *Aconitum lycoctonum* and all the *Delphinium* species which have been carefully examined; but their presence in *Inula royleana* is the first recorded occurrence of these alkaloids outside the family Ranunculaceae. It seems remarkable to us that not only should an alkaloid as complex as lycoctonine be synthesized by a plant belonging to an entirely different family from the previously known sources, but that it should be esterified with the same complex acid.

EXPERIMENTAL

Melting points were taken in an open tube unless marked (K), in which case they were taken on the Kofler block. Infrared spectra were taken as "Nujol" mulls on a Perkin–Elmer model 21 spectrophotometer.

Isolation and Separation of the Alkaloids

Inula royleana was obtained from an Indian source by the S. B. Penick Co. through the good offices of Dr. H. R. Schmidt. The finely ground dry roots (25 lb) were extracted exhaustively with methanol at room temperature, and the methanolic extract taken to dryness under reduced pressure. The material so obtained was dissolved in dilute sulphuric acid and the neutral and acidic material removed by extraction with methylene chloride.

The methylene chloride solution was back-washed with dilute sulphuric acid. The combined aqueous layers were taken to pH 8 using sodium carbonate and again extracted with methylene chloride. This extract was evaporated under reduced pressure to give a dark brown gum (498 g) ("weak bases").

The pH of the aqueous layer was raised to 11 and the solution extracted with chloroform. The chloroform was removed under reduced pressure to yield a dark brown gum (70 g) ("strong bases").

A portion of the crude weak base (25 g) was dissolved in the minimum quantity of benzene and an equal volume of hexane added. The dark gum which precipitated was laid aside. The mother liquors were evaporated under reduced pressure, and the material obtained (15 g) separated into its components in a Craig apparatus for countercurrent distribution. Four tubes were loaded with a benzene solution of the alkaloids (40 ml; 10 ml per tube) and the material was moved through 180 tubes against citric acid – phosphate buffer of pH 5. The contents of the last 29 tubes yielded 4.4 g of pure inuline, while the material identified as royline (2.2 g) was left in the early benzene layers. Both alkaloids crystallized from aqueous methanol as needles, and were shown to be homogeneous by paper chromatography. The homogeneity of inuline was also checked by paper electrophoresis.

A preliminary examination of the "strong base" fraction indicated that this consisted largely of royline. The weak bases insoluble in benzene–hexane, on alkaline hydrolysis gave a 45% yield of lycoctonine.

Inuline

The base had m.p. 145–154° (decomp.) undepressed on admixture with anthranoyl-lycoctonine, and $[\alpha]_D$ +51° ($CHCl_3$). Comparison (melting point, mixed melting point, I.R., rotation) of the base with a sample of inuline supplied by Mrs. A. Chatterjee confirmed their identity. The infrared spectrum of inuline was identical with that of anthranoyl-lycoctonine. The perchlorate of the base crystallized from ethanol as needles m.p. 206° (decomp.) undepressed on admixture with the perchlorate from anthranoyl-lycoctonine. Found: C, 55.91; H, 7.01. Calc. for $C_{32}H_{46}O_8N_2.HClO_4$: C, 55.94; H, 6.85.

Hydrolysis of Inuline

Inuline (220 mg) was refluxed for 45 minutes with 1% ethanolic potassium hydroxide. The solution was cooled and extracted with chloroform, and the chloroform solution on evaporation under reduced pressure afforded lycoctonine, crystallizing from aqueous methanol as needles, m.p. 115–123° (decomp.), undepressed on admixture with an authentic sample of lycoctonine. The infrared spectra of the two samples were also identical. Found: C, 61.77; H, 8.74; N, 2.93. Calc. for $C_{25}H_{43}O_8N$: C, 61.83; H, 8.93; N, 2.88.

On neutralization of the hydrolysis mother liquors and extraction with chloroform, anthranilic acid was obtained, identical with an authentic specimen (melting point, mixed melting point, I.R., and U.V.). Found: C, 61.62; H, 4.98; N, 9.97. Calc. for $C_7H_7O_2N$: C, 61.31; H, 5.15; N, 10.21.

Royline

The base had m.p. 115–123° (decomp.) undepressed on admixture with lycoctonine hydrate, and $[\alpha]_D$ +47 (EtOH). Comparison of the base with a sample of royline supplied by Mrs. A. Chatterjee (melting point, mixed melting point, I.R., rotation) confirmed their identity. The infrared spectrum of royline was identical with that of lycoctonine hydrate.

The perchlorate of the base crystallized from ethanol as needles, m.p. 215° (decomp.) undepressed on admixture with the perchlorate from lycoctonine.

Methyl-lycaconitine

The main bulk of the "weak bases" (*ca.* 400 g) was dissolved in benzene and the less soluble components precipitated by hexane. The remaining solution was evaporated to dryness, leaving 155 g of pale yellow alkaloid. This was taken up in benzene and separated manually in large funnels (12 transfers), the moving phase being in this case the buffer solution of pH 5. The contents of funnels 1–3 (55 g) proved to be largely inuline and yielded 37 g of crystalline base. Funnels 7–9 contained 21 g of alkaloid which was separated by a further 100 transfers on the Craig countercurrent apparatus using the same solvent system. Fractions 85–98 from this separation afforded 3.6 g of inuline, and fractions 1–12 gave 0.5 g of royline. Funnels 4–6 from the manual separation contained 41 g of alkaloid which could not be crystallized, hence this was distributed between benzene and buffer pH 5 in the countercurrent apparatus (100 transfers). The bulk of the alkaloid was found in fractions 34–79, and this material (14 g) was redistributed between benzene and buffer pH 4 in the Craig countercurrent apparatus (100 transfers). Five components were thus separated. The major component (tubes 11–45, 6.6 g) could not be crystallized, but gave a crystalline hydriodide, m.p. 199–201° (K), undepressed on admixture with an authentic specimen of methyl-lycaconitine hydriodide. The infrared spectra of the hydriodide of the base and of methyl-lycaconitine hydriodide were identical.

Hydrolysis of Methyl-lycaconitine

The base (404 mg) was refluxed for 45 minutes with 1% ethanolic potassium hydroxide. On cooling of the reaction mixture and extraction with chloroform, lycoctonine was obtained, and was recrystallized from aqueous ethanol as needles (256 mg) m.p. 115–123° (decomp.) undepressed on admixture with an authentic sample of lycoctonine. The infrared spectrum of the material obtained was identical with that of lycoctonine.

On acidification and further extraction of the hydrolysis mother liquors with chloroform, 1-methylsuccinyl-anthranilic acid was obtained (81 mg) which recrystallized from acetone–hexane as needles, m.p. 150–154° (K) with sintering at 146°, $[\alpha]_D$ −6° (EtOH). Found: C, 56.89; H, 5.02. Calc. for $C_{12}H_{13}O_5N$: C, 57.37; H, 5.22. (Goodson (3) reports a melting point of 155° with sintering at 147° $[\alpha]_D$ −7° (EtOH).)

ACKNOWLEDGMENTS

The authors wish to thank Mr. A. Knoll for technical assistance, Mr. H. Seguin for the microanalyses, and Mr. R. Lauzon for the infrared spectral determinations. We gratefully acknowledge the co-operation of Dr. A. Chatterjee, University of Calcutta, in informing us of their observations, and providing us with reference samples.

ACTIVATION ENERGIES OF SEMICONDUCTORS WITH THE ZINC BLENDE STRUCTURE[1]

W. B. PEARSON

ABSTRACT

Difficulties of determining the binding energies and effective charges on the atoms are the main reason why no systematic explanation of the variation of the size of the energy gap among members of the simplest family of semiconductors—those with the zinc blende structure—has ever been given. It is shown that by the choice of suitable atomic parameters for discussing the activation energies of these compounds these difficulties may be avoided, and the variation of the size of the energy gap between one compound and another can be systematically accounted for. In the treatment which develops no particular distinction need be made between the III–V, II–VI, and I–VII compounds, and it is concluded that the anomalously high or low activation energies, which certain compounds appear to have, are just the result of the relative sizes of the cations and anions in influencing the polarization of the bonds.

INTRODUCTION

Energy band calculations of semiconductors involve so much labor and difficulties that they do not provide a ready means of determining activation energies from the properties of the component atoms of the semiconductor. More intuitive chemical approaches have also made singularly little progress and it has not so far been possible, for instance, even to give a self-consistent discussion of the variation of activation energy among the compounds of the simplest family of semiconductors—those with the zinc blende type of structure. Welker (11) has shown essentially that the activation energy of a semiconductor depends on the binding energy and on the effective charges on the atoms. However, Folberth (3) has pointed out that consideration of Welker's rules alone is insufficient to explain the relative variation of activation energy among the III–V compounds with the zinc blende structure. The size of the energy gap depends both on the binding energy and on the extent of the modulation of the crystalline field in the compound semiconductor. Folberth postulates a linear relationship between the degree of modulation and the polarization of the chemical bonds, and establishes the relative size of the modulation of the crystalline field in a number of III–V compounds from calculated values of the polarization. Nevertheless, this work does not lead to an understanding of the variation of the activation energies of *all* compounds with the zinc blende structure since he deals only with the III–V compounds and then ignores some of these without comment.

Another method of approach has been developed by Goodman (4) in discussing the relative variation of electron mobilities in some semiconductors with the zinc blende structure. He determined the "ionic contribution" to the activation energy for the compounds from a linear relationship between the square root of the size of the energy gap and the reciprocal of the square of the interatomic distance, which he established for the truly homopolar Group IV semiconductors with the diamond structure. However, it does not seem possible to develop this approach further to describe the variation of the activation energies of these compounds, and the reason appears to be that no account is taken of the relative atomic sizes of the component atoms which are also significant.

DISCUSSION

The two main difficulties in developing a chemical discussion of the activation energies of compounds with the zinc blende structure along lines suggested by the work of Welker and Folberth are the determination of the binding energy and the effective charges on the atoms. Although some information of the latter may be gained by calculation from experimental data (cf. Wolff (2), Picus *et al.* (10), and Ehrenreich (1)) or perhaps by the arguments used by Pauling (cf. 8), there is no comprehensive knowledge of these charges which can be drawn on at present. Faced with these difficulties it seems that some progress may be made by indirect means, by comparing for these compounds atomic parameters to which the binding energy and effective charges are related, without ever considering the quantities explicitly.[2] For instance, Mooser and Pearson (6) have recently given a classification of normal valence compounds with simple atomic ratios in terms of two parameters: $\bar{n}$, the average principal quantum number of the valence electrons of the component atoms, and Δx, the difference of the electronegativities of the component atoms. These two parameters, which respectively describe the loss of directional character of covalent bonds in the compounds as the metallic character and as the ionic character increase, give a sharp separation of the compounds into groups with different structures and co-ordinations. Together or severally they bear a loose relationship to the binding energy and to the atomic size which is important in the modulation of the crystalline field in compounds of the zinc blende type. However, Δx alone is not sufficient to take account of the effective charges on the atoms of such compounds which depend on the polarization of the bonds, and this in turn depends on the relative sizes of the cation and anion. For reasons which are discussed more fully below we take the ratio of the cationic and anionic radii r_c/r_a as a measure of the polarization.

Several interesting facts appear when we examine the observed activation energy, ΔE_{obs}, of compounds with the zinc blende structure and of the Group IV elements with the diamond structure as a function of $\bar{n}$, Δx, and r_c/r_a. In each of the three isoelectronic series of substances shown in Table I we can investigate the variation of ΔE_{obs} as a

TABLE I

*Values taken from Gordy and Thomas' (5) recently reviewed values of electronegativity.

†Based on Pauling and Huggins' tetrahedral radii (see e.g. Wells (12)).

‡A value of ΔE_{obs} = 5.0 ev for a hypothetical compound MgS with the zinc blende structure is consistent with the activation energies of the other members of the series with $\bar{n}$ = 3. MgS actually has the rock salt type of structure.

[2]*Since there are only bonds of one type in the zinc blende structure, it is reasonable not to have to consider the binding energy explicitly. This would not, however, be the case in, say, the chalcopyrites where bonds of two types occur and the energy gap would essentially depend on the weaker of the two bonds.*

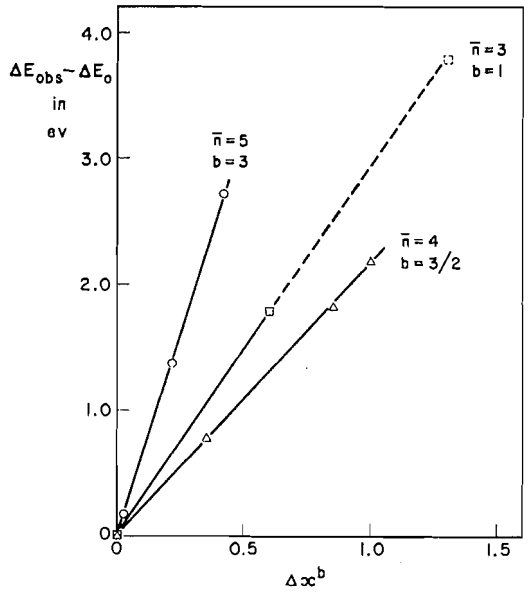

FIG. 1. Plots of $\Delta E_{obs} - \Delta E_0$ against Δx^b for three isoelectronic series of compounds. See text and Tables I and II.

function of Δx at a constant $\bar{n}$ value and at an r_c/r_a value which is approximately constant (taking Pauling's (7) single bond radii), or regularly increasing (taking tetrahedral radii, Pauling and Huggins (9)). We find (Fig. 1) that relationships of the type

$$\Delta E_{obs} = \Delta E_0 + c.\Delta x^b$$

hold in each of these series when ΔE_0 is the activation energy of the isoelectronic Group IV element and c and b are constants having the values depending on $\bar{n}$ given in Table II.

TABLE II

$\bar{n}$	ΔE_0 in ev	c	b
3	1.21	2.97	1
4	0.75	2.19	1.5
5	0.082	6.4	3

An approximately linear function of the average interatomic distance (lattice spacing) of substances in each of the three isoelectronic series is represented by b.

The form of these relationships for the isoelectronic series of substances indicates that no distinction need be made between the III–V, II–VI, and I–VII compounds if suitable parameters are chosen to discuss their activation energies, so that questions of whether a formal transference of one, two, or three valence electrons from anion to cation takes place in these compounds are avoided. As far as we are aware it has only previously been possible to obtain relationships between activation energies and atomic or bulk properties of compounds with the zinc blende structure which are of one type, e.g. the III–V or the II–VI compounds.

Using the above relationship for $\bar{n}$ values of 3, 4, and 5, we can derive the activation energy contours on an $\bar{n}$ vs. Δx plot shown in Fig. 2 so that the observed activation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

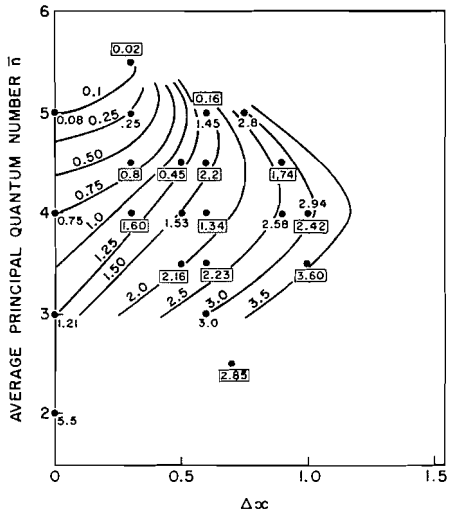

FIG. 2. Isoactivation energy contours on a $\bar{n}$ vs. Δx plot. These have been derived for the three isoelectronic series of compounds using the data in Fig. 1 and the unenclosed numbers are the observed activation energies for these compounds. The numbers enclosed in rectangles are the observed activation energies of the remaining compounds with the zinc blende structure.

energies of the remaining compounds with the zinc blende structure can be compared with the predicted values, ΔE_{pred}. As such a diagram only allows us to take account of $\bar{n}$ and Δx values, we would expect the observed and predicted activation energies of compounds to agree only if their r_c/r_a values were the same as those of the appropriate compounds of the isoelectronic series for which the contours were derived.[3] As Table III shows, this is indeed the case. The activation energies of AlAs, GaP, and ZnS with $\bar{n} = 3.5$ (and HgTe) are correctly predicted to within an average of 3% as their r_c/r_a values differ little from those interpolated from the isoelectronic series of compounds (i.e. $\Delta(r_c/r_a)$ in Table III). On the other hand the predicted and observed activation energies of compounds with $\bar{n} = 4.5$ and the remaining compounds with $\bar{n} = 4$ and $\bar{n} = 5$ differ widely, and this divergence systematically accompanies the difference between their r_c/r_a values and those of the isoelectronic series of compounds ($\Delta(r_c/r_a)$ in Table III). These compounds all contain one component atom from the fifth or sixth periods, the other coming from a lower period. The value of ΔE_{pred} is always *too small* when the *anion* comes from the fifth period and *too large* when the cation comes from the fifth or sixth periods. Now there is a much larger difference in atomic size between elements in the fourth and fifth periods, than between elements in the third and fourth,

[3]*In order to make this comparison with substances having fractional values of $\bar{n}$, we interpolate values as follows, say for $\bar{n} = 4.5$:*

$$(r_c/r_a)_{\bar{n}=4.5} = \{(r_c/r_a)_{\bar{n}=4} + (r_c/r_a)_{\bar{n}=5}\}/2.$$

In order to compare the r_c/r_a values of compounds in the isoelectronic series with r_c/r_a values of the remaining compounds we define

$$\Delta(r_c/r_a) = (r_c/r_a)_{\text{isoelectronic compound}} - (r_c/r_a)_{\text{other compound}}$$

comparing together III–V or II–VI compounds with the same $\bar{n}$, or interpolated $\bar{n}$, values. Thus for example

$$\Delta(r_c/r_a)_{CdS} = (r_c/r_a)_{ZnSe} - (r_c/r_a)_{CdS}.$$

The reason for this is that r_c/r_a for tetrahedral radii is an approximately linear function of the atomic number of the anion or cation in a series of isoelectronic compounds going from the Group IV element to the I–VII compound.

or fifth and sixth, periods. In all of these compounds, therefore, with $\bar{n}$ having values of 4, 4.5, or 5, the values of r_c/r_a are appreciably larger or smaller, depending on whether the cation or the anion comes from the fifth period, than the values estimated from compounds of the three isoelectronic series upon which the $\bar{n}$ vs. Δx relationship for ΔE_{obs} was based. We would therefore expect that the polarization of the bonds and hence the effective atomic charges in these compounds would differ considerably from those in corresponding compounds of the isoelectronic series.

Let us consider the polarization of, say, a III–V compound with the zinc blende structure; the basic assumption in considering the chemical bonding is that an electron is transferred from the five-valent atom to the three-valent atom so that each atom has four valence electrons and forms four shared electron pair bonds. The formal charges on the atoms are then $:\dot{\underset{\cdot\cdot}{\text{III}}}^{-}\ :\dot{\underset{\cdot\cdot}{\text{V}}}^{+}:$. Polarization of the bonds in this structure involves the movement of the electron pairs from the center of the bonds towards the five-valent atom, thus reducing the formal charges on the atoms. Therefore the greater the polarization, the smaller the effective charges on the atoms (provided of course that the polarization is not so strong as to reverse the charges on the atoms), and hence the smaller is the activation energy of the compound. The polarization depends on the relative sizes of the anions and cations and also on the principal quantum number of their valence electrons and on the electronegativity difference. The larger the cation and the smaller the anion, the greater is the polarization of the bonds in these compounds and we therefore take the ratio of the cationic to anionic radii, r_c/r_a, as a measure of the polarization.

As shown in Table III, HgSe, InAs, CdSe, InP, and CdS, with r_c/r_a values considerably greater than those of compounds in the corresponding isoelectronic series, all have activation energies lower than those predicted, because a negative $\Delta r_c/r_a$ value means a greater polarization of the bonds, smaller effective charges on the atoms, and hence lower activation energies. The converse is true for GaSb, ZnTe, AlSb, and BAs, which have positive $\Delta r_c/r_a$ values and hence higher activation energies.

CONCLUSION

We are thus led to the conclusion that the variation of the activation energy in compounds of the zinc blende type (with $\bar{n}$ values from 3 to 5.5) is perfectly systematic and it can be accounted for by the use of three atomic properties, $\bar{n}$, Δx, and r_c/r_a. The treatment does not require that any particular distinction be made between the III–V, II–VI, and I–VII families of compounds. The apparently anomalously large or small activation energies of some compounds such as ZnTe and InAs, which have previously led to difficulties of interpretation, are shown to be the result of excessively small or excessively large polarization of the bonds when either the anion or the cation alone comes from the fifth or sixth periods. The discussion, however, fails to reach a satisfying quantitative conclusion since we have been unable to calculate the activation energies of all compounds with the zinc blende structure from the values of $\bar{n}$, Δx, and r_c/r_a alone. Relationships giving the sign and magnitude of $(\Delta E_{pred} - \Delta E_{obs})$ in terms of $\Delta(r_c/r_a)$ do exist, but they depend on the $\bar{n}$ value of the compounds.

Our investigation suggests that the observed activation energy of SiC is lower than expected and this could be accounted for by polarization of the bonds, but there is little value in entering into a discussion of SiC, or in attempting to predict the activation energy of the compound BP, until the activation energy of cubic BN with $\bar{n} = 2$ is known, since this would only involve uncertain extrapolations.

ACKNOWLEDGMENTS

I am very grateful to Drs. D. K. C. MacDonald and E. Mooser for many stimulating discussions about theories, interpretations, and activation energies.

NOTE ADDED IN PROOF

This correlation of the activation energies of compounds with the zinc blende structure is based on examination of compounds lying along a non-planar section in $\bar{n}$–Δx–r_c/r_a space for which activation energy contours can be constructed. All compounds lying above this section, that is having greater r_c/r_a values, have activation energies smaller than those expected for a compound with the same $\bar{n}$ and Δx values which lies in the section, and the converse is true for compounds with smaller r_c/r_a values which lie below the section. Compounds with r_c/r_a values lying in the section have their activation energies correctly predicted. This is in complete accord with the expected polarization of the bonds in these substances, provided that it is assumed that the cations still possess small effective negative charges and the anions positive charges (i.e. that the polarization is not so strong as to reverse the formal charges on the covalently bonded atoms). On the other hand the percentage ionic character of the bonds in these compounds determined from infrared measurements (Picus *et al.* (10)) and microcleavage studies (Wolff (2)) suggests that the cations are positively charged and the anions are negatively charged.

THE BIOGENESIS OF ALKALOIDS

XXIII. THE ROLE OF PROLINE AND ORNITHINE IN THE BIOGENESIS OF STACHYDRINE[1]

A. V. Robertson[2] and Léo Marion

ABSTRACT

When methionine-Me-^{14}C, pyridoxine, and folic acid were fed to growing alfalfa, the stachydrine isolated from the plant was radioactive. This observation supports the assumption that stachydrine arises from proline by methylation since pyridoxine has been shown to induce the formation of proline from ornithine in the plant. However, the administration of labelled ornithine, pyridoxine, folic acid, and methionine to alfalfa failed to produce the radioactive alkaloid. Similar experiments were performed in which methionine-Me-^{14}C and folic acid, methionine-Me-^{14}C and pyridoxine, and finally methionine-Me-^{14}C alone were fed to alfalfa, and in each case the stachydrine isolated from the plant was radioactive, while the homostachydrine remained inactive. Feeding proline-carboxyl-^{14}C to alfalfa failed to produce radioactive stachydrine. It must be concluded that in alfalfa which is 2 to 3 weeks old, stachydrine is actively synthesized although homostachydrine is not. The implications of these observations are discussed.

The biogenesis of stachydrine in alfalfa (*Medicago sativa* L. Grimm) has been studied in this laboratory for some time (1, 2, 3). In these studies the assumption has always been made that stachydrine was formed in the plant by methylation of proline, and that the latter has for its precursor ornithine. Indeed, in higher plants, it has been shown that ornithine is the precursor of the disubstituted N-methylpyrrolidine ring of hyoscyamine (4) and of the monosubstituted N-methylpyrrolidine ring of nicotine (5, 6). Leete, Marion, and Spenser (1) administered ornithine-2-^{14}C to 2-week-old alfalfa seedlings, but found that the stachydrine isolated from the plants a week later was not radioactive. In further experiments this result was confirmed, and it was established that the proline in the plant was not active either although glutamic acid, aspartic acid, and glycine were (2). Even in 12-week-old alfalfa, stachydrine and proline were not actively synthesized from ornithine (2). When, however, ornithine-2-^{14}C together with pyridoxine was administered to 7-day-old seedlings, the proline isolated from the plants 12 days later was radioactive although the stachydrine was not (2). Feeding glutamic acid-2-^{14}C and pyridoxine to 2-week-old alfalfa seedlings also produced radioactive proline, but again the stachydrine was inactive (3). The effect of feeding radioactive glutamic acid without pyridoxine has not been examined. To test the possibility that stachydrine formation might not occur until a later stage of growth, ornithine-2-^{14}C was fed to flowering alfalfa plants, 9 months old, but the stachydrine subsequently isolated was not radioactive (7).

From the foregoing results it was concluded that although the conversion of glutamic acid and ornithine to proline occurs in the presence of pyridoxine the methylation of proline to stachydrine does not take place in alfalfa at an age of 2–3 weeks. In an attempt to stimulate the plant methylation processes, alfalfa seedlings were treated with ornithine-2-^{14}C, pyridoxine, and methionine, but the stachydrine obtained showed no radioactivity (7). In a further effort to enhance the probability of methylation, Wiehler and Marion (3) found that after feeding methionine-Me-^{14}C, pyridoxine, and folic acid, the stachydrine was radioactive. On the assumption that proline was the precursor of stachydrine, they concluded that the young plants were deficient in folic acid and that the artificial appli-

[1]*Manuscript received March 16, 1959.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 5226.
[2]*National Research Council of Canada Postdoctorate Fellow.*

cation of this compound had induced the biosynthesis of stachydrine. However, if the substance being methylated to produce stachydrine is not proline, other interpretations are possible, and the purpose of the present work was to examine this possibility. Nevertheless it is definitely established that although proline is a normal constituent of alfalfa, no interconversion with ornithine takes place in plants 2–3 weeks old unless pyridoxine is added; interconversion between glutamic acid and proline also occurs in the presence of pyridoxine.

If folic acid is really a necessary co-factor for the biological methylation of proline then administration of ornithine-2-^{14}C with pyridoxine and folic acid should produce radioactive stachydrine. This experiment was performed on plants 2 weeks old, and inactive methionine and ornithine were added as well to boost the concentration of these amino acids. The purified mixture of stachydrine and homostachydrine hydrochlorides (8) isolated after a week was not radioactive. The result was surprising and it suggested that the presence of folic acid was incidental to the formation of radioactive stachydrine from Me-labelled methionine. A small scale repetition of the experiment of Wiehler and Marion using radioactive methionine, pyridoxine, and folic acid confirmed their result. Similar experiments were then performed on 2-week-old alfalfa by feeding methionine-Me-^{14}C and folic acid, methionine-Me-^{14}C and pyridoxine, and finally methionine-Me-^{14}C alone. In all of these experiments the betaine fraction was radioactive, and paper chromatographic assay showed the whole of the activity was present in the stachydrine and that the homostachydrine was inactive. These results lend further support to the suggestion made in Part XXI of this series of studies (9) that homostachydrine is not formed until a later stage of development and that translocation of this alkaloid stored in the seeds is the reason for its isolation from alfalfa seedlings. From the facts described it seems that at least a partial synthesis of stachydrine is actively going on in the plant during the first 3 weeks of growth in the absence of pyridoxine and folic acid, and also that proline might not be involved in the chain of precursors. As a check on the role of proline in stachydrine biogenesis, proline-carboxyl-^{14}C was fed to alfalfa on the 17th day of growth and after 2 days the plants were harvested. The crystalline mixture of stachydrine and homostachydrine hydrochlorides was not radioactive.

To sum up, and assuming that ornithine-2-^{14}C in conjunction with pyridoxine is equivalent to proline-2-^{14}C, the radioactivity of ring-labelled or carboxyl-labelled proline is not incorporated in stachydrine at a plant age when experiments with methionine-Me-^{14}C indicate that the synthesis of the alkaloid is taking place. At first glance these results indicate that proline is not a precursor of stachydrine, but this conclusion is difficult to accept on general chemical and biogenetic grounds. Assuming, however, that the alkaloid is in fact derived from the expected amino acids, there are three hypotheses which are not eliminated on the basis of the present evidence. Firstly stachydrine may be ultimately derived from the expected amino acid precursors, but the stages of the synthesis occur at different times so that the final step is a methylation of an intermediate which is so far undetected in alfalfa, and which is preformed from proline and stored in some suitable form. Secondly there may be a specific reversible equilibrium between preformed stachydrine (the alkaloid having been formed from the amino acid at a different period of growth) and administered methionine or some intermediate to which methionine-methyl may be transferred, leading to methyl exchange, such as

2-S-adenosylmethionine-Me* + stachydrine-Me $\rightleftharpoons$ 2-S-adenosylmethionine-Me + stachydrine-Me*.

Thirdly[3] the site of stachydrine synthesis may be highly localized and possibly not

[3]*We are grateful to Dr. I. D. Spenser, McMaster University, for suggesting this third possibility.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

all amino acids can enter this site preformed. For instance, yeast cells readily assimilate methionine, but do not apparently take up proline (10). Methionine (or at least its methyl group) can obviously penetrate the site of stachydrine synthesis, and it could be assumed that proline, glutamate, and ornithine cannot, and must be formed *in situ* to be utilized. This would explain the finding that radio-proline, when fed, did not give rise to stachydrine, and that proline, isolated after administration in the presence of pyridoxine of radio-ornithine or radio-glutamate, was labelled, whereas stachydrine was not.

The second of these assumptions involving a methylation equilibrium is not too probable, because processes involving only the betaine methyl groups are unlikely since homostachydrine is not affected. In the first hypothesis N-methyl proline (hygric acid) should be involved, and the results of feeding carboxyl-labelled hygric acid are being examined. It seems that either the first or third hypothesis is more probable than the assumption that proline might not be a precursor of stachydrine.

EXPERIMENTAL

The alfalfa seedlings were grown and the alkaloids were isolated as described previously (9).

Radioactive Ornithine Experiment

Alfalfa seeds (300 g) were germinated on glass wool in 10 trays (20×30 cm). On the 16th day, DL-ornithine-2-^{14}C-monohydrochloride (208.5 mg, total activity 5×10^7 d.p.m., purchased from Tracerlab Inc.), DL-methionine (100 mg), folic acid (2 mg), and pyridoxine hydrochloride (2 mg) were administered in nutrient solution. These materials were fed again in the same quantities on the 21st day and the plants were harvested the next day. The alcoholic extract of the dried plants contained 3% of the radioactivity administered, and 0.465 g of betaine hydrochlorides was obtained. After purification via the mercuric chloride complex and recrystallization, the mixture of stachydrine and homostachydrine hydrochlorides was radioinactive.

Radioactive Methionine Experiments

For each of these four experiments, 30 g of seeds were germinated in one tray. On the 16th day, the plants were fed the following compounds in aqueous solution:

Experiment 1.—Methionine-Me-^{14}C (25 mg, total activity 3.05×10^7 d.p.m.), pyridoxine hydrochloride (1 mg), folic acid (0.5 mg).

Experiment 2.—Methionine-Me-^{14}C as for 1, folic acid (0.5 mg).

Experiment 3.—Methionine-Me-^{14}C as for 1, pyridoxine hydrochloride (0.5 mg).

Experiment 4.—Methionine-Me-^{14}C as for 1.

After 1 day only 1–2% of the radioactivity remained in the nutrient solutions and only 0.1–0.3% after 2 days, so the plants were harvested on the 18th day. The alcoholic extract contained 11–13% of the activity administered. The alkaloid fractions were purified by means of a mercuric chloride precipitation but the mixture of betaines was very difficult to crystallize because of inorganic and other impurities which could not be removed on this small scale. The alkaloid mixtures had activities of about 400 d.p.m./mg, and paper chromatographic assay (3) in butanol – hydrochloric acid and ethanol–ammonia (9) showed that the stachydrine contained all the radioactivity in each case. The crude choline reineckate from each experiment was radioactive and averaged about 500 d.p.m./mg.

Radioactive Proline Experiment

Alfalfa seeds (250 g) were grown in 10 trays. On the 17th day, proline-carboxyl-^{14}C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

(9.2 mg, total activity 6.4×10^7 d.p.m., purchased from Volk Radiochemical Co.) was fed, as usual. A small part of this activity (3.5%) remained in the nutrient solution after 1 day, and less than 2% after 2 days. The plants were harvested on the 19th day. The alcoholic extract contained 1.8% of the radioactivity administered. Sixty-eight per cent of the activity in the extract was present in the protein fraction, and the remaining activity stayed in the filtrate after precipitating the betaine reineckates. The pure crystalline mixture of stachydrine and homostachydrine hydrochlorides (0.283 g) was not radioactive, nor was the crystalline asparagine (2.53 g) or choline chloride (0.46 g).

DEGRADATIVE STUDIES ON λ-CARRAGEENIN[1]

K. MORGAN[2] AND A. N. O'NEILL[3]

ABSTRACT

λ-Carrageenin was subjected to partial acetolysis. Chromatography of the deacetylated products on charcoal led to the isolation of D-galactose, 3-*O*-α-D-galactopyranosyl-D-galactose (A), and a crystalline trisaccharide (B) tentatively identified as *O*-α-D-galactopyranosyl-(1 → 3)-*O*-α-D-galactopyranosyl-(1 → 3)-D-galactose. Periodate oxidation of the polysaccharide indicated the presence of more than one type of linkage in the polymer.

The name carrageenin (1, 2) was first applied to the polysaccharide which can be extracted with hot water from certain red seaweeds, where it occurs as an intercellular constituent. The main source of carrageenin is the alga *Chondrus crispus*, but similar material has been isolated from *C. ocellatus* (3) and *Gigartina stellata* (4).

In 1953, Smith and Cook (5) reported the separation of two major discrete polysaccharide components from carrageenin. This was achieved by fractionation with potassium chloride which, when added to a dilute solution of carrageenin, causes one component to gel. This gel fraction, which constitutes approximately forty per cent of unfractionated carrageenin, has been designated κ-carrageenin. It has been shown (6) to be composed of residues of 3,6-anhydro-D-galactose and sulphated D-galactose in approximately equimolar amounts. The other major polysaccharide component is insensitive to potassium ion, and can be recovered from the mother liquor by ethanol precipitation (5, 7, 8); this fraction has been termed λ-carrageenin. In addition to κ- and λ-carrageenin, minor amounts of other polysaccharides occur in carrageenin preparations as indicated by the detection of small amounts of L-galactose, glucose, and xylose in hydrolyzates (8).

Although the structure of λ-carrageenin has not been extensively investigated, results from X-ray analysis (9) and periodate oxidation (8) of the polysaccharide, together with data from methylation of unfractionated carrageenin (4, 10, 11, 12), suggest that it consists essentially of a sulphated galactan in which D-galactose residues are linked glycosidically through positions 1 and 3, and bear sulphate half-ester groups on position 4. The purpose of the present work was to obtain definitive evidence for the fundamental structural linkage in λ-carrageenin.

The polysaccharide was isolated from commercial carrageenin by fractionation with potassium chloride (5, 7, 8). Analytical figures for three separate preparations are shown in Table I. Acid hydrolyzates of the preparations were shown chromatographically to contain galactose and a trace of xylose only.

Since sulphated polysaccharides do not lend themselves easily to examination by exhaustive methylation, a method involving partial degradation was indicated. This was accomplished most satisfactorily by acetolysis, in which degradation of the polymer was accompanied by rapid desulphation to give a good yield of neutral oligosaccharide acetates.

λ-Carrageenin was treated with a mixture of acetic anhydride and acetic acid containing sulphuric acid (6%) at 25° C for 71 hours, and the sulphate-free product was deacetylated

with methanolic sodium methoxide. The reducing power of the solution corresponded to an apparent degree of conversion into galactose of 45%. The deacetylated acetolyzate was adsorbed on a column of charcoal–Celite. Elution with water yielded D-galactose, characterized as its β-penta-acetate, and a small amount of xylose, detected chromatographically. The oligo- and higher saccharides were recovered by elution of the column with aqueous ethanol (50% v/v). Hydrolysis of a small portion, followed by chromatographic examination, indicated that the oligosaccharides present were composed of galactose residues only.

The oligosaccharides were separated on a charcoal–Celite column by stepwise elution with aqueous ethanol (13) (see Fig. 1). One disaccharide (A), one trisaccharide (B), and

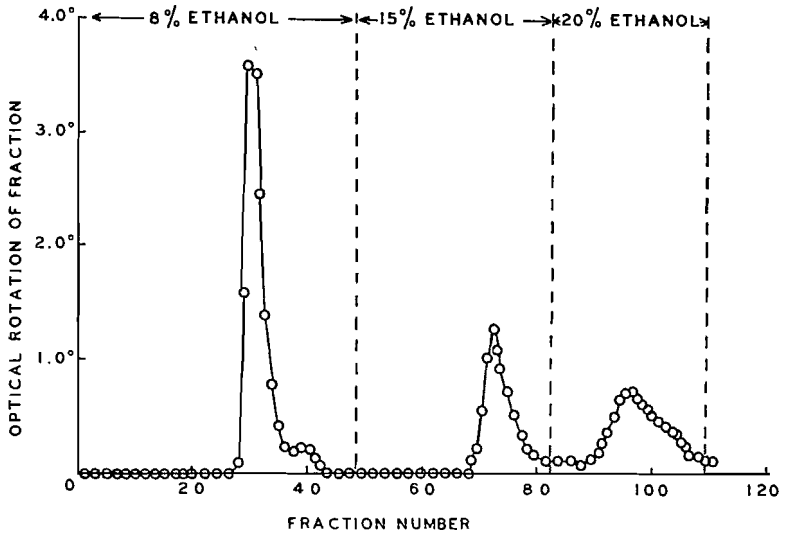

FIG. 1. Charcoal fractionation of oligosaccharide mixture from a deacetylated acetolyzate of λ-carrageenin.

an impure tetrasaccharide fraction (C) were isolated. These travelled on chromatograms at the relative rates expected for a polymer-homologous series (14). A fraction (D) containing the higher saccharides was also recovered from the column. The physical properties of the di- and tri-saccharides and their derivatives are recorded in Table II.

The disaccharide (A) was not obtained crystalline but afforded crystalline β-octa-*O*-acetyl and phenylosazone derivatives. On paper chromatograms and ionophoretograms

it was located as a single discrete spot and moved at markedly different rates from those of 4-*O*- and 6-*O*-α-D-galactopyranosyl-D-galactose. Its high specific optical rotation (+155°, water) indicated that it was α-linked, and distinguished it from 3-*O*-β-D-galactopyranosyl-D-galactose, which has $[\alpha]_D$ +63° (15). Hydrolysis of the methylated disaccharide yielded 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose, characterized as their crystalline aniline derivatives. Periodate oxidation (25) of the disaccharide (1 mole) under unbuffered conditions led to an initial rapid uptake of 4.2 moles of oxidant and the production of 2.2 moles of formic acid (see Fig. 2). The disaccharide is thus identified as 3-*O*-α-D-galactopyranosyl-D-galactose.

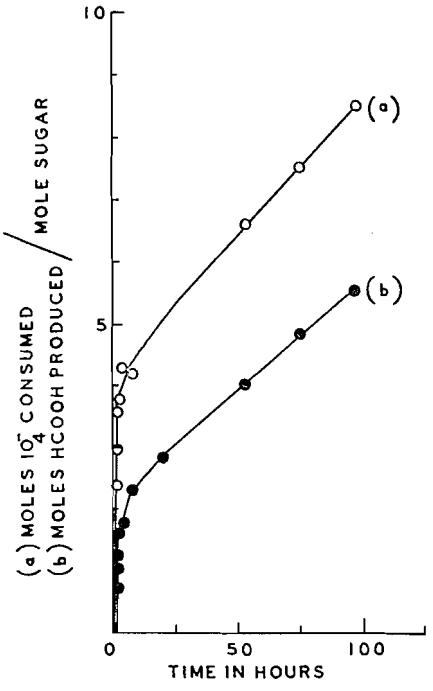

FIG. 2. Oxidation of disaccharide in 0.004 *M* solution with 0.125 *M* sodium metaperiodate at 25° C.

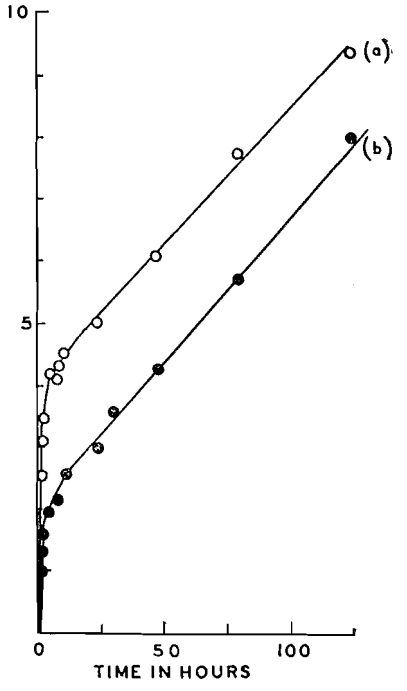

FIG. 3. Oxidation of trisaccharide in 0.003 *M* solution with 0.125 *M* sodium metaperiodate at 25° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The trisaccharide (B) crystallized, and gave a crystalline β-hendeca-*O*-acetyl derivative. Partial hydrolysis of the trisaccharide yielded galactose and one disaccharide only. The latter was chromatographically and ionophoretically indistinguishable from (A). Its specific optical rotation (+146°, water) suggested that both galactosidic linkages were in the α-configuration. Periodate oxidation (25) of the trisaccharide gave results similar to those obtained for the disaccharide as shown in Fig. 3, thereby indicating that both glycosidic linkages are (1 → 3). The trisaccharide is therefore suggested to be *O*-α-D-galactopyranosyl-(1 → 3)-*O*-α-D-galactopyranosyl-(1 → 3)-D-galactose.

Portions of fractions (C) and (D) were partially hydrolyzed. Chromatographic and ionophoretic examinations of the hydrolyzates indicated the presence of one disaccharide and one trisaccharide, the mobilities of which were identical with those of (A) and (B), respectively.

Oxidation of the three separate preparations of λ-carrageenin in 0.05 *M* sodium metaperiodate resulted in each case in the uptake of 0.15 mole of periodate and the production of 0.05 mole of formic acid per anhydrogalactose residue.

DISCUSSION

The foregoing results corroborate the evidence of Smith *et al.* (8) that the λ-carrageenin molecule is composed mainly, if not exclusively, of D-galactopyranose residues. Also, their conclusion that the xylose found in carrageenin hydrolyzates arises from a contaminating xylan is supported by the fact that the total oligo- and higher saccharide fraction isolated in the present work was free from xylose residues. The analyses of λ-carrageenin preparations for galactose and sulphate (Table I) show that a large proportion of the galactose residues are disulphated.

The structural evidence presented here shows that the λ-carrageenin molecule is composed mainly of α-1:3 galactosidic linkages, and also suggests that the di-, tri-, and tetra-saccharides, (A), (B), and (C), are members of a homologous series composed uniformly of α-(1 → 3)-linked-D-galactopyranose residues. The substantial yield of these sugars, and the failure to detect the presence of other di- and tri-saccharides in the deacetylated acetolyzate, indicate a paucity in the polymer of other types of linkages. That other linkages are present, however, is clear from the fact that λ-carrageenin is susceptible to periodate ion. The periodate uptake and the yield of formic acid observed in the present work correspond to the presence, for every 20 D-galactose residues, of one residue bearing three contiguous, unsubstituted hydroxyl groups, and of a second residue bearing two such hydroxyl groups. Methylation data for unfractionated carrageenin (4, 10, 11, 12) indicate the presence of some 1 → 6 linkages in the polysaccharide mixture. In the λ-carrageenin molecule, therefore, two such linkages may be present for every 20 residues. Whether these linkages occur in linear chains of galactose residues, or constitute branch points, remains quite obscure, as also does the distribution of the half-ester sulphate groups.

EXPERIMENTAL

Chromatograms were developed on Whatman No. 1 filter paper with the following solvent systems: (*a*) 1-butanol–ethanol–water (4:1:1); (*b*) 1-butanol–pyridine–water (6:4:3); (*c*) 1-propanol – ethyl acetate – water (6:1:3); and (*d*) 1-butanol – acetic acid – water (4:1:5; upper phase). Sugars were located by spraying with benzidine (16), silver nitrate (17), or aniline hydrogen phthalate (18) reagents, and their mobilities are quoted relative to galactose (R_{Gal}).

For personal use only.

Electrophoresis was carried out using Whatman No. 1 paper, supported horizontally, and a borate buffer (pH 10) (19). A potential difference of 500–600 v was applied, corresponding to a current of *ca.* 20–25 ma. Sugar spots were detected with the benzidine spray reagent (16).

Melting points were determined with a Kofler micro melting point apparatus. Solutions were concentrated under reduced pressure at 40–45° C. Polysaccharide samples were analyzed for galactose by complete hydrolysis and then determination of the reducing sugar by the Somogyi method (20). Sulphate determinations were made on completely hydrolyzed polysaccharide samples by precipitation with barium chloride.

Preparation of λ-Carrageenin

An aqueous solution of commercial carrageenin[4] was treated with potassium chloride, and the resulting gel removed as previously described (7, 8). The λ-carrageenin was precipitated from the mother liquor by addition of ethanol to a final concentration of 38–40% (v/v), and was collected in a Sharples centrifuge. After the precipitate was washed with aqueous ethanol (50% v/v), followed by ethanol, and then ether, a white fibrous polysaccharide (λ-1) was obtained. The yield from 65 g of commercial carrageenin was 20 g. A further quantity (λ-2; 30 g) was prepared in the same way.

A portion (3 g) of λ-1 was dissolved in aqueous potassium chloride (0.25 *M*; 1.75 l.) at 65° C. The solution was cooled to 20° C and centrifuged at 15,000 r.p.m. for 30 minutes, when a small amount of gel separated. Addition of aqueous "Cetavlon" (20% w/v; 25 ml) to the centrifugate yielded a precipitate (21) which was separated by centrifugation, washed with water, and dissolved in aqueous potassium chloride (2 *M*; 1 l.). Ethanol (1 l.) was added, and the precipitated material was collected (centrifuge) and washed with aqueous ethanol (60% v/v). The precipitate was then dissolved in water (750 ml) and the solution dialyzed against aqueous potassium acetate (0.0025 *M*) until free from chloride ion. From the impermeate a purified sample of λ-carrageenin (λ-IP; 2.25 g) was recovered in the usual way.

Analytical figures for preparations λ-1, λ-2, and λ-IP are given in Table I. In each case, samples hydrolyzed with 0.1 *N* hydrochloric acid at 100° C for 24 hours yielded galactose and a trace of xylose only, detected chromatographically.

Partial Acetolysis of λ-Carrageenin

A sample of λ-carrageenin (λ-1 + λ-2; 45 g), dried *in vacuo* at 60° C for 24 hours, was added slowly during 30 minutes to a rapidly stirred mixture of acetic anhydride (250 ml), glacial acetic acid (180 ml), and concentrated sulphuric acid (25 ml) at 0–5° C. After the mixture was shaken at 25° C for 71 hours the small amount of insoluble material which remained was removed by filtration. The filtrate was poured into ice-cold water (2.5 l.), which was then made neutral to Congo red with solid sodium bicarbonate. The precipitated material was separated by filtration, washed with water, and dried to a white, amorphous powder (29.5 g). The filtrate was extracted by shaking with chloroform (3×500 ml), and the combined chloroform extracts dried and concentrated to a yellow syrup (10.2 g). The two products contained no detectable sulphate, and were combined. The total product (39.5 g) was dissolved in methanol (410 ml), and a solution of sodium methoxide (0.5% sodium in methanol) (135 ml) was added. The mixture was kept at 5° C for 20 hours, and water was then added until the precipitated sugars just redissolved. The solution was neutralized with Amberlite resin IR-120, filtered, and concentrated to a syrup (22.0 g). The reducing power of the product corresponded to an apparent degree

[4]*Product of the Seaplant Chemical Corporation, New Bedford, Mass., U.S.A.*

of conversion into galactose of 45%. Chromatographic examination indicated the presence of galactose and a trace of xylose, together with three oligosaccharide components (A, B, and C) which had R_{Gal} values in solvent *d* of 0.56, 0.33, and 0.20, respectively. Some higher saccharides were also present.

Fractionation of the Deacetylated Acetolyzate

The above product (22 g) was adsorbed on a column of charcoal–Celite (1:1 w/w; adsorbent, 90×4.8 cm), and the monosaccharide components removed by elution with water (1 l.). The oligo- and higher saccharides were recovered by elution of the column with aqueous ethanol (50% v/v; 5 l.); the eluate was concentrated to a syrup (18.3 g), a portion of which, when hydrolyzed in 0.1 *N* hydrochloric acid at 100° C for 24 hours and examined chromatographically, revealed the presence of galactose only.

The oligo- and higher saccharide mixture was readsorbed on a column of charcoal–Celite (1:1 w/w; adsorbent, 68×8.0 cm), which was then eluted stepwise with increasing concentrations of ethanol in water (13). Fractions (150 ml) were collected under reduced pressure as described by Whelan *et al.* (22). The course of the elution was followed polarimetrically (see Fig. 1). Appropriate fractions were combined, concentrated to dryness, and examined chromatographically.

Elution of the column with 8% (v/v) aqueous ethanol displaced component A (3.75 g in 2.5 l.). Aqueous ethanol (15% v/v; 2.5 l.) then displaced component B (2.15 g), and fraction C (2.15 g) was eluted with 20% (v/v) aqueous ethanol (2.5 l.). The higher saccharides, D (6.0 g), were then eluted with 50% (v/v) aqueous ethanol (5 l.).

Examination of the Fractions

(*i*) *Monosaccharide Components*

Concentration of the aqueous eluate from the first charcoal–Celite column afforded a syrup (3.8 g) which was shown chromatographically to contain galactose and a trace of xylose. A portion (1 g) was acetylated with acetic anhydride and sodium acetate (23), and yielded β-D-galactopyranose penta-acetate, m.p. 142° C, $[\alpha]_D^{25}$ +23.7° (*c*, 0.6, chloroform).

(*ii*) *Component A*

The amorphous powder, $[\alpha]_D^{25}$ +155° (*c*, 0.3, water), had R_{Gal} 0.56 (solvent *b*). Authentic specimens of 4-*O*- and 6-*O*-α-D-galactopyranosyl-D-galactose had R_{Gal} 0.50 and 0.35, respectively, in the same solvent, and had ionophoretic mobilities different from that of A. The molecular weight of the sugar, determined iodometrically (24), was 330.

Oxidation of the disaccharide (71.6 mg) in sodium metaperiodate (0.125 *M*; 50 ml) is illustrated in Fig. 2. Both periodate uptake and formic acid liberation were followed iodometrically (25). Extrapolation of the overoxidation curves indicated that in the initial rapid oxidation, the disaccharide (1 mole) consumed 4.2 moles of periodate and yielded 2.2 moles of formic acid.

Acetylation of the disaccharide (23) (800 mg) yielded a crystalline β-octa-acetate (800 mg) which, after recrystallization from ethanol, had m.p. 157.5–158.5° C and $[\alpha]_D^{25}$ +110.2° (*c*, 0.5, chloroform). Calculated for $C_{28}H_{38}O_{19}$: C, 49.3%; H, 5.6%. Found: C, 49.53%; H, 5.76%.

A solution of the disaccharide (200 mg) in water (2 ml) was heated at 100° C with phenylhydrazine (1.5 ml) and 2 *N* acetic acid (7.5 ml) to yield a crystalline phenylosazone which, after recrystallization from ethanol, had m.p. 227–229° (decomp.) and $[\alpha]_D^{25}$ +114.6° (*c*, 0.2, pyridine).

A solution of the disaccharide (430 mg) in water (3 ml) was stirred at 0° C in an atmosphere of nitrogen; dimethyl sulphate (2 ml) and aqueous sodium hydroxide (30% w/w; 3 ml) were added. After 2 hours the solution was warmed to 25° C, treated with dimethyl sulphate (9 ml) and aqueous sodium hydroxide (30% w/w; 5 ml), added over a period of 45 minutes, and then warmed to 40° C for 1 hour. Methylation in this way was repeated three times. The solution was then heated at 100° C for 2 hours, neutralized with acetic acid, and extracted with chloroform. Evaporation of the extract afforded a syrup, which was further methylated three times with methyl iodide (20 ml) and silver oxide (4 g). The product crystallized, and after two recrystallizations from *n*-hexane (yield 143 mg) it had m.p. 110–115° C, $[\alpha]_D^{25}$ +95.5° (*c*, 0.7, chloroform). Found: OMe, 53.9%. Calculated for $C_{20}H_{38}O_{11}$: OMe, 54.6%.

The methylated disaccharide (60 mg) was hydrolyzed in 0.25 *N* sulphuric acid (5 ml) at 100° C for 20 hours. The solution was then neutralized with barium carbonate, filtered, and concentrated to a syrup (55 mg). Chromatography of the hydrolyzate indicated the presence of two components, *X* and *Y*, which travelled at rates identical with those of 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose, respectively. They were separated on a sheet of Whatman No. 3 MM paper with benzene–ethanol–water (200:47:15 v/v; upper phase) (26) as the developing solvent.

Component *X* afforded a crystalline aniline derivative which, after recrystallization from ethanol and ethyl acetate, had m.p. 198–199° C, undepressed on admixture with *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine, and $[\alpha]_D^{25}$ −79.6° → −36.4° (24 hours) (*c*, 0.5, acetone).

Component *Y* crystallized, and was recrystallized from ethyl acetate – petroleum ether. It had m.p. 103–105° C. The derived *N*-phenyl-glycosylamine had m.p. 173–174° C, undepressed on admixture with *N*-phenyl-2,4,6-tri-*O*-methyl-D-galactosylamine, and $[\alpha]_D^{25}$ −91° → −41° (24 hours) (*c*, 0.4, acetone). For purposes of comparison, authentic 2,4,6-tri-*O*-methyl-D-galactose was prepared by the method of Bell (27).

(*iii*) *Component B*

The amorphous material had R_{Gal} 0.26 (solvent *b*). It was crystallized from 95% (v/v) aqueous methanol and the product had m.p. 237–239° C (decomp.) and $[\alpha]_D^{25}$ +146° (*c*, 0.5, water). Upon partial hydrolysis in 0.1 *N* hydrochloric acid the trisaccharide yielded galactose and one disaccharide only, detected chromatographically. The latter was chromatographically and ionophoretically indistinguishable from 3-*O*-α-D-galactopyranosyl-D-galactose.

The molecular weight of the sugar was found (24) to be 490. Calculated for $C_{18}H_{32}O_{16}$: C, 42.87%; H, 6.35%. Found: C, 42.38%; H, 6.44%.

Oxidation of the trisaccharide (81 mg) with sodium metaperiodate (0.125 *M*; 50 ml) (25) gave results, illustrated in Fig. 3, similar to those obtained for the disaccharide (see Fig. 2). The trisaccharide (1 mole) consumed 4.02 moles of periodate and yielded 1.93 moles of formic acid.

Acetylation of the trisaccharide (500 mg) (23) afforded a crystalline β-hendeca-acetate (100 mg). After recrystallization from ethanol the product had m.p. 275–277° C and $[\alpha]_D^{25}$ +106.0° (*c*, 0.05, chloroform). Calculated for $C_{40}H_{54}O_{16}$: C, 49.70%; H, 5.60%. Found: C, 49.48%; H, 5.69%.

(*iv*) *Fraction C*

Paper chromatography of this fraction revealed the presence of a small amount of contaminating trisaccharide. Partial hydrolysis of a small portion in 0.1 *N* hydrochloric acid for 1 hour, followed by paper chromatography, showed that galactose, one disac-

charide, and one trisaccharide were present in the hydrolyzate. The chromatographic mobilities of the di- and tri-saccharides corresponded to those of components (A) and (B), respectively.

(*v*) *Fraction D*

This fraction contained the penta- and higher saccharides from the deacetylated acetolyzate. Partial hydrolysis of small portions in 0.1 *N* hydrochloric acid for periods of 1, 2, 3, and 5 hours yielded in each case only one di-, one tri-, and one tetra-saccharide, detected chromatographically. These had R_{Gal} values identical with those of the components (A), (B), and (C), respectively.

Periodate Oxidation of λ-Carrageenin

A sample of λ-carrageenin (637 mg) was oxidized with sodium metaperiodate (0.05 *M*; 250 ml). The reaction solution was stored in the dark at 25° C, and at intervals aliquots were removed for the determination of the periodate uptake and formic acid production. Determinations were made at each time in duplicate.

(*a*) *Periodate Uptake*

An aliquot (10 ml) was transferred to a flask containing 0.05 *N* sodium arsenite (25 ml) and after 15 minutes the excess sodium arsenite was titrated against 0.02 *N* iodine.

Time (hours)	2	4.5	7.5	29	55	103	127	175	217	290	318
Periodate uptake (moles $\times 10^2$)	7.8	9.4	9.4	11.2	11.9	12.7	12.7	14.7	15.0	14.7	15.2

(*b*) *Formic Acid Production*

An aliquot (5 ml) was added to ethylene glycol (0.5 ml) and the solution stored in the dark at 25° C for 30 minutes. Neutral potassium iodide (10% w/v; 2 ml) was then added and the liberated iodine titrated rapidly against 0.005 *N* sodium thiosulphate.

Time (hours)	1.5	5	19	43	74	118	165	193	212
Formic acid produced (moles $\times 10^2$)	1.3	2.0	2.7	2.9	3.4	3.8	5.1	5.1	5.0

ACKNOWLEDGMENTS

Samples of 4-*O*-α-D-galactopyranosyl-D-galactose and 6-*O*-α-D-galactopyranosyl-D-galactose were very kindly provided by Professor E. Pacsu and Professor J. K. N. Jones.

The assistance of Dr. T. J. Painter in the preparation of this paper is gratefully acknowledged.

RADIATION-INDUCED ADDITION OF HBr TO C_2H_4 IN THE GASEOUS STATE[1]

D. A. ARMSTRONG[2] AND J. W. T. SPINKS

ABSTRACT

The gas phase addition of hydrogen bromide to ethylene in a pyrex irradiation cell was induced by the action of Co^{60} γ-rays. Dose rates were calculated by means of the Bragg–Gray cavity principle from saturation ionization currents measured in air in a similar cell. The only product detected was ethyl bromide and the ion pair yield was of the order of 10^5. The rate of addition was followed with an electrically adjusted "spoon gauge" and was studied (*a*) with HBr in great excess, (*b*) with HBr and C_2H_4 in equal concentration, (*c*) with C_2H_4 in great excess. For condition (*a*) the rate showed a first-order dependence on $[C_2H_4]$, an approximate second-order dependence on [HBr], a negative temperature coefficient, and a dose rate exponent of unity. It was concluded that the reaction rate was determined by the same step as for the photobromination reaction and that wall termination predominated. For conditions (*b*) and (*c*) the dose rate exponent was found to be approximately 0.5 indicating a predominance of mutual termination. Definite conclusions with regard to the termination reaction were not possible but the data suggested that certain ion–molecule reactions may precede ion combinations.

Investigations of the fast electron or γ-radiolysis of gaseous systems are usually hindered by the low product yields obtained. However, in systems where there is a free radical chain reaction of appreciable chain length this difficulty should be considerably reduced. Such chain reactions are to be found in the addition of halogens and hydrogen halides to the olefins. Quantum yields of 10^4 or greater have been observed (1, 2) in the photosensitized bromination of ethylene, and although the gas phase addition of hydrogen halides to the olefins has not been investigated in very great detail, the work of Vaughan, Rust, and Evans (3) indicated that an analogous type of chain reaction was probably responsible for the rapid photoaddition of hydrogen bromide to ethylene and propylene. These considerations, together with the relative ease with which hydrogen bromide can be handled, and the fact that its X-radiolysis in the gaseous state has recently been investigated (4), led to the choice of the hydrogen bromide – ethylene reaction as the subject for the present study.

The work of Vaughan, Rust, and Evans was largely confined to the addition of hydrogen bromide to propylene. They found that the photochemical reaction was extremely rapid, provided the wave length of the light used was sufficiently short for dissociation of the hydrogen bromide into a hydrogen and a bromine atom (< 2900 Å). Photosensitization at longer wave lengths could be achieved by the addition of acetone, bromine, and lead tetraethyl (or other substances which gave rise to free radicals on photolysis). In all cases the "abnormal" type addition was observed, the product being almost entirely *n*-propyl bromide. Methyl iodide and iodine inhibited the reaction. Large quantities of oxygen somewhat reduced the rate of addition and gave rise to significant yields of an oxidation product, but, in contrast to the bromination reaction (cf. 1, 2), complete inhibition by oxygen was never observed.

The ethylene reaction proceeded at about the same rate as the propylene reaction, and "the data of certain individual experiments" indicated an approximate proportionality between the rate of ethyl bromide formation and the product of the hydrogen bromide and ethylene concentrations. The effect of oxygen on the ethylene reaction was

[1]*Manuscript received February 25, 1959.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*Present address: University of Alberta, Calgary, Alberta.*

similar to its effect on the propylene reaction. A mechanism for the addition, which involved bromine atoms and bromo-ethyl free radicals, was proposed.

In this study the main characteristics of the radiation-induced addition were examined, and where possible the results have been discussed in the light of data obtained from the photochemical studies already mentioned.

EXPERIMENTAL

The 90-c Co^{60} unit, which was used as the source of radiation in all experiments, has been described (5).

A diagram of the jacketed pyrex irradiation cell is given in Fig. 1. One end of the cell, A, was attached through capillary tubing to a 2-mm-bore vacuum-seated stopcock, C, and a ground joint. The opposite end was similarly connected to a "spoon gauge",

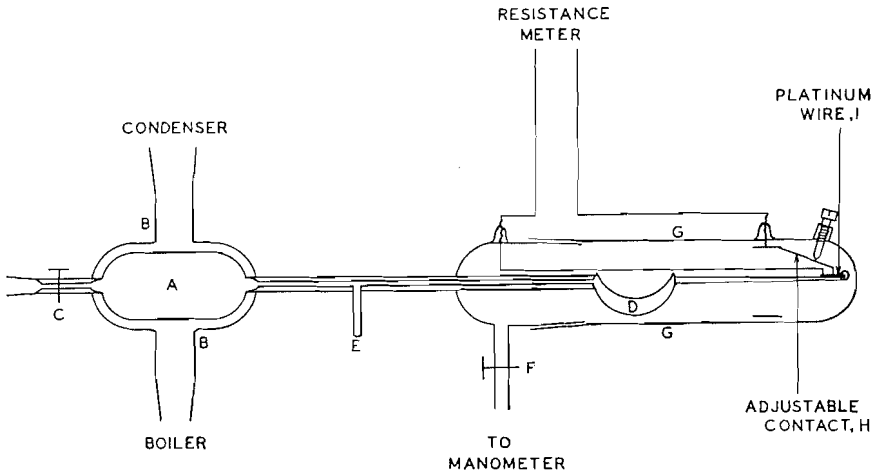

FIG. 1. The apparatus.

D, and a cold trap, E. The volumes of the cell and associated "dead space" were 35.2 and 6.6 ml, respectively. The envelope, G, of the gauge was connected through stopcock, F, and several feet of copper tubing to a mercury manometer located on the exterior wall of the irradiation cave. A resistance meter, also located outside the cave, was wired in series with the electrical contacts, H and I, on the gauge. This device was used as a "null instrument" for equating the envelope pressure and the internal gauge-cell pressure. (In practice it was usually necessary to apply a small correction to the pressure indicated by the external manometer.) Pressure measurements were reproducible to within 0.1 mm and could be made continuously during an irradiation.

The cell was maintained at a constant temperature by surrounding it with a suitable vapor generated in a boiling-flask beneath it. The condensed vapor ran down the outer wall of the jacket, B, thus returning to the boiling-flask without dropping on the walls of the cell. Most experiments were performed at the boiling point of ether. The vapor temperature, indicated by a thermometer located just above the cell, showed minor day-to-day fluctuations of about $\pm 0.1°$ C from the mean value, but was constant over the duration of any one experiment. The thermometer showed the same reading when placed directly in the neck of the boiling-flask.

The cell jacket, stopcock, and gauge envelope were firmly fastened to a metal frame which could be placed in any one of three fixed irradiation positions, approximately

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

3, 9, and 18 cm from the source. As shown in Fig. 2, the stopcock and gauge were shielded from the direct Co^{60} radiation by the source assembly. The dose rate at each irradiation position was measured with a pyrex-walled ionization chamber, of the same dimensions as the irradiation cell, supported in a pyrex jacket on a similar frame. The inner surface of the chamber was silvered to render it conducting, and a polythene cap, which carried the aluminum collecting-electrode, was inserted at the open end. Electrical contact between the grounded portion of the cap and the silvered chamber wall was achieved by the use of "Aquadag" paste. Ion currents were measured with a Townsend balance.

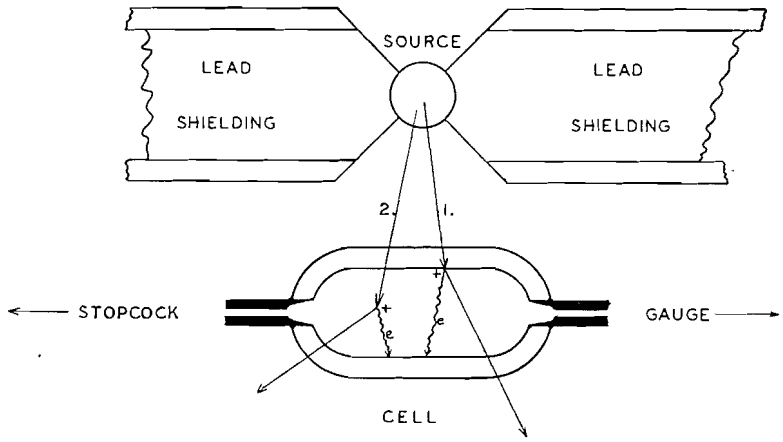

FIG. 2. Schematic diagram of reaction cell and Co^{60} source.

A vacuum line fitted with storage bulbs and a gas-measuring apparatus, to which the irradiation cell could be attached, was used for storing the reactants and preparing the desired mixtures for irradiation. The pumping system consisted of a Cenco Hyvac oil pump and a Todd single stage mercury diffusion pump. Ultimate vacua of about 10^{-5} mm of mercury were obtained with this combination.

Ethylene of 99.5% purity was obtained from a cylinder supplied by the Ohio Chemical and Surgical Equipment Co. of Cleveland. This material was subjected to two or three bulb-to-bulb distillations and then stored. Hydrogen bromide from a cylinder supplied by the Matheson Co. of Ohio was freed from traces of water by passing it over fused calcium bromide. A further purification by bulb-to-bulb distillation was carried out before the gas was stored. A sample of this gas was absorbed in water and titrated with silver nitrate. The bromide analysis showed 100.3% of the theoretical.

Hydrogen bromide was also prepared by warming a mixture of potassium bromide, phosphorus pentoxide, and syrupy phosphoric acid. This gas was purified in the same way. Similar rates of addition were obtained with hydrogen bromide from both sources.

The cell and associated apparatus were evacuated to a pressure of 10^{-4} mm or less before use. A gas mixture of the required composition was synthesized and the cold trap, E, of the irradiation cell was immersed in liquid nitrogen. The gases were then slowly admitted to the cell through stopcock, C. After they had been condensed, the stopcock was closed and the liquid nitrogen removed from E. As the condensed gases evaporated, the pressure in the gauge envelope was increased at a corresponding rate by admitting air through F. After the cell had been set up in the irradiation cave and the vapor bath had attained thermal equilibrium, the initial pressure in the cell was measured on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

external manometer by "zeroing" the spoon gauge. The envelope pressure was then reduced by about 1 mm and the irradiation was started. The time at which the envelope and cell pressures became equal was noted and the envelope pressure was subsequently reduced by a further 1 mm. In this way, successive pressure readings could be taken every 30–40 seconds during an irradiation.

On completion of an experiment, the gas mixture was carefully removed from the cell and gauge, the envelope pressure being reduced at the same rate as the internal cell pressure. As a standard procedure, the cell was filled with an atmosphere of ethylene when it was not in use, and whenever it was necessary to regrease stopcock, C. Air was not admitted to the cell unless it was unavoidable, as it seemed to produce fluctuations in the rate of reaction. Dow-Corning High Vacuum Silicone grease was used wherever possible on the apparatus, as it was more resistant to hydrogen bromide and ethyl bromide than Apiezon grease.

In calculating the reaction rate or concentration of either component in the reaction cell, corrections were made for the gas drawn into the cell from the gauge as the pressure fell. It was assumed that the initial concentrations of ethylene and hydrogen bromide in the gauge and cell were identical and that their relative concentrations in the gauge remained unaltered as the pressure fell. The results were, in general, consistent with this assumption.

Dosimetry

The number of ion pairs formed in the ionization chamber per unit volume per second in air was calculated from the saturation ionization currents for each of the three irradiation positions. These values, corrected to N.T.P. were 18.9_2, 4.7_2, and $1.3_8 \times 10^9$ ion pairs per milliliter per second, respectively.

There are two processes which may contribute to the ionization of the gas in the chamber: (1) ionization by fast electrons ejected from the chamber wall, and (2) ionization by fast electrons formed by the interaction of γ-rays with the electrons of the gas molecules in the chamber. Both processes have been illustrated in Fig. 2. Theoretical estimates, based on γ-ray interaction cross sections, show that with Co^{60} γ-radiation process (2) can only account for about 0.5% of the total ionization in the chamber in air at N.T.P. For dosimetry purposes the ionization can therefore be treated as being exclusively of type (1) and the Bragg–Gray cavity principle (6) can be used to estimate the dose rate in gas mixtures in the irradiation cell, which was similar to the ionization chamber in dimensions and wall thickness (2 mm). The electrons ejected from the wall of the cell will possess energies varying from about 1 Mev down. Their number per unit dose, and energy distribution, will be determined by the wall material* and will be independent of the gas in the cell, provided the conditions of the Bragg–Gray cavity theory hold. In traversing the cell these electrons will lose energy by interactions with the electrons of the gas molecules, giving rise to excitations as well as ionizations. The rate of loss of energy per unit length of fast electron track in the gas (or "stopping power" of the gas) can be calculated from the Bethe or the Block formula (6). For an electron of given energy traversing a medium containing only one element of atomic number Z, the latter formula may be written in the form:

$$-\left(\frac{dE}{dx}\right) = S_A \times [C] = \frac{2\pi r_0^2 m_0 c^2 Z}{\beta^2} \{\Phi - 2 \log_e I\} [C]$$

**It is necessary to assume that the layer of silver on the wall of the ionization chamber does not appreciably alter the electron flux or energy distribution.*

For personal use only.

where the quantities r_0, m_0, c, and β have their usual significance, and Φ is the value of the Block function calculated for the particular fast electron energy. $[C]$ is the number of atoms per unit volume of the medium, and I is their mean ionization–excitation potential. S_A is the stopping power per atom of the element.

Assuming that the Bragg law of additivity of stopping powers holds, values of (dE/dx) can be calculated for hydrogen bromide and ethylene from the individual atomic stopping powers of hydrogen, bromine, and carbon. The following values were obtained for fast electrons of 0.3-Mev energy:

$$-(dE/dx)_{HBr} = 2.1_2\times10^{-22}\times[HBr] \text{ Mev/cm}$$

$$-(dE/dx)_{C_2H_4} = 1.20_7\times10^{-22}\times[C_2H_4] \text{ Mev/cm}$$

$$-(dE/dx)_{air} = 2.7_4\times10^{-3} \text{ Mev/cm at N.T.P.}$$

where the concentrations of ethylene and hydrogen bromide must be expressed in molecules/ml. The values of I used were: $I_H = 13$ ev, $I_C = 67$ ev, and $I_{Br} = 328$ ev (7). For consistency, $-(dE/dx)_{air}$ was also calculated.

According to the Bragg–Gray principle, the number of ion pairs formed in ethylene ($J_{C_2H_4}$) can be calculated from the number found in air (J_{air}) with the aid of the formula:

$$J_{C_2H_4} = J_{air}\times\frac{W_{air}}{W_{C_2H_4}}\times\frac{(dE/dx)_{C_2H_4}}{(dE/dx)_{air}} \text{ ion pairs/ml second}$$

where W is the energy required to create a single ion pair in the particular gas.

The value of the quantity $(dE/dx)_{C_2H_4}/(dE/dx)_{air}$ varies with the electron energy and should be averaged over the entire electron energy spectrum. However, it is unlikely that the ratio of the stopping powers of ethylene and air for 0.3-Mev electrons will be very different from the weighed mean ratio for the electron distribution from Co^{60} radiation in the glass cells used (cf. ref. 9). Hence:

$$J_{C_2H_4} = J_{air}\times5.6_6\times[C_2H_4]\times10^{-20} \text{ ion pairs/ml second.}$$

The values of W were chosen from recent results reported in the literature (8). No experimental value of W_{HBr} has been reported, but a theoretical estimate of 26.5 ev by Platzman has been cited (2). Using this value, one obtains a similar formula for ionization in hydrogen bromide:

$$J_{HBr} = J_{air}\times9.8_5\times[HBr]\times10^{-20} \text{ ion pairs/ml second.}$$

This is probably somewhat less accurate than that for ethylene. A combination of these formulae with the values of J_{air} for radiation positions I, II, and III yields:

position I: $J_{total} = \{[HBr]+0.57_5[C_2H_4]\}\times1.8_6\times10^{-9}$ ion pairs/ml second
position II: $= \{[HBr]+0.57_5[C_2H_4]\}\times4.6_5\times10^{-10}$ ion pairs/ml second
position III: $= \{[HBr]+0.57_5[C_2H_4]\}\times1.3_6\times10^{-10}$ ion pairs/ml second.

It may be noted that a correction should be applied to these formulae to make allowance for energy which is lost from the radiation cell (10) due to the escape of the higher energy δ-rays (or secondary electrons) from the radiation cell. This depends on the gross stopping power of the gas in the cell, and hence on the gas pressure and composition. At the lowest pressures used in these experiments J_{total} might be about 10% lower than calculated by the above formulae. Under conditions where the gross stopping power was equivalent to air at N.T.P., J_{HBr} would be only about 3% less than estimated,

For personal use only.

and $J_{C_2H_4}$ should be almost unaffected. In view of the uncertainty involved in estimating this correction and the approximations already made, the formulae have been used without correction.* They are probably correct to within $\pm 10\%$ when ethylene is the main component.

RESULTS

Two methods were employed in identifying the product of the reaction:

(1) A gas chromatogram of the material produced, from which ethylene and hydrogen bromide had been separated by virtue of their higher vapor pressures, showed only one peak after it was scanned for 33 minutes. The time of appearance (13.5 minutes) and "skewness" of this peak were identical with those of the peak from a commercial sample of ethyl bromide.

(2) A number of experiments were performed in which the hydrogen bromide remaining after irradiation was determined by absorption. It was found that the hydrogen bromide consumed in the irradiation corresponded closely to the over-all pressure decrease. This indicated a mole-for-mole addition of HBr to ethylene, and this conclusion received further support from the observation that the over-all pressure decrease in experiments where the reaction was taken to virtual completion corresponded to complete consumption of the component present in lower concentration.

These results are in accordance with the photochemical work, and because of the long chain length (see below) the species formed in the initiation and termination processes would be present in relatively small amounts and could only be detected by the use of special techniques.

The rate of addition of hydrogen bromide to ethylene was investigated under three distinct sets of conditions: (1) the hydrogen bromide concentration greatly exceeded the ethylene concentration, (2) the hydrogen bromide and ethylene concentrations were approximately equal, (3) the ethylene concentration greatly exceeded the hydrogen bromide concentration.

I. HBr *in Excess*

Over a period of several months the rates of addition were reproducible to within $\pm 10\%$ under any given set of conditions. However, duplicate experiments in the same series usually agreed to within $\pm 5\%$. The pressure decrease versus time curves for two identical experiments have been given in Fig. 3. These were carried out at 33.9° C with hydrogen bromide and ethylene concentrations of 10.5 and 1.5×10^{18} molecules per ml, respectively, at the highest of the three possible dose rates. From the estimated dose rate ($2.1_4 \times 10^{10}$ ion pairs per ml per second) an ion pair yield of about 2×10^5 was calculated.

All experiments showed an induction period of about 60 seconds and there was no obvious relation between its magnitude and the concentration of either component. Experiments in which the irradiation was interrupted usually showed a second induction period (see Fig. 3). The initial induction periods could be attributed to "clean-up" of an inhibiting impurity in the cell at a concentration of the order of 10^{12} molecules/ml (3×10^{-5} mm of Hg pressure). However, the second induction periods cannot be explained in this way.

In some experiments there appeared to be a small postirradiation reaction (of the order of 1 mm), which was complete in a few minutes. It seems likely that this post-

**In any case the majority of experiments were carried out at a gross stopping power in the range 0.8–1.2 times that of air.*

irradiation effect is an inverse Budde–Draper effect and that the induction periods may be partly, but not wholly, due to Budde–Draper effect (cf. (11)). Other effects such as interaction of the radiation with the walls of the radiation cell may also contribute.

The dependence of the rate on ethylene concentration was studied over the range $0.6–2.9\times10^{18}$ molecules/ml of ethylene. In these experiments the initial hydrogen bromide concentration was 10.6×10^{18} molecules/ml and the cell temperature, 33.9° C. Plots of $\log_{10}[C_2H_4]$ versus time have been given in Fig. 4. It would appear that there is a first-order dependence of the rate on ethylene concentration, and values of the first-order rate constant (i.e., rate/$[C_2H_4]$) taken over the first 50% of the reaction, have been summarized in Table I. They showed a tendency to fall off as the ethylene concentration was increased.

The dependence on hydrogen bromide concentration over the range $4–21\times10^{18}$ molecules/ml was investigated at the same temperature. The ethylene concentration was kept within the range $1.4–1.6\times10^{18}$ molecules/ml. Rates of addition, determined from first-order plots for ethylene consumption, have been given in Table I. A log–log plot of the rate versus hydrogen bromide concentration indicated an exponent slightly greater than 2 for [HBr] at this temperature.

Experiments at 54° and 25° C were also performed, using the same ethylene con-

centration as above and two hydrogen bromide concentrations. As shown in Table I, the reaction rate decreased with increasing temperature.

A dose rate exponent of approximately unity was observed for hydrogen bromide and ethylene concentrations of 10.5 and 1.5×10^{18} molecules/ml, respectively, at 33.9° C. A logarithmic plot of rate versus dose rate has been presented in Fig. 5.

II. HBr *and* C_2H_4 *Present in Approximately Equal Concentrations*

Three experiments performed under these conditions were followed to almost 100% addition. The results have been summarized in Table II*a*, where the reaction rates at various stages have been included. The initial concentrations of hydrogen bromide were approximately the same in each experiment (10^{19} molecules/ml), while the concentrations of ethylene were slightly less than, equal to, and slightly greater than the hydrogen bromide concentrations in experiments 1, 2, and 3, respectively. In a fourth experiment, a gas mixture similar in composition to that of experiment 2 was irradiated in position II until a steady rate had been attained and measured. It was then irradiated in position I, and the steady rate again measured. A log–log plot of the two rates against dose rate has been included in Fig. 5. It is apparent that the dose rate exponent has fallen at the higher ethylene concentration and is approaching a value of 0.5.

III. C_2H_4 *Present in Excess*

The data for these experiments have been given in Table II*b*. The dose rate exponent was again determined from a fourth experiment, in which the concentrations were similar to those of experiment 5. This time the gas mixture was irradiated first in position II and then in position III. The rates obtained in these two irradiations, together with the rate from experiment 2, have been plotted in Fig. 5. The gradient of this logarithmic plot indicated a dose rate exponent of about 0.5 under the conditions existing.

DISCUSSION

The Initiation Process

The following reactions, originally suggested by Eyring, Hirschfelder, and Taylor, were found by Zubler, Hamil, and Williams (4) to be consistent with their experimental results on the X-radiolysis of hydrogen bromide:

$$HBr \rightsquigarrow HBr^+ + e \qquad [1]$$

$$e + HBr \rightarrow H + Br^- \qquad [2]$$

$$Br^- + HBr^+ \rightarrow H + 2Br \qquad [3]$$

$$H + HBr \rightarrow H_2 + Br. \qquad [3a]$$

NOTE: In calculating the values of [A′] it was assumed that the contribution of HBr to M could be neglected (cf. ref. (1), results of Section I). $k' = k_{16}/k_{11a}$ at 33.9° from Section I; all experiments at 33.9° C.

These reactions explained the destruction of four molecules of HBr per ion pair formed and indicate that in the present system four initiating radicals (H and Br) would be produced from each HBr^+ ion.

More recent work (12) has shown that ion–molecule reactions are generally rapid. In fact it seems that they will compete with ion combinations under certain conditions. The reaction (cf. ref. 12*a*):

$$HBr^+ + HBr \rightarrow H_2Br^+ + Br \qquad [4]$$

should therefore be considered in addition to those given above especially when HBr is present in high concentrations as in the experiments reported in Section I of this paper. Neutralization of the H_2Br^+ ion by bromide ions might give rise to two or four initiating radicals:

$$Br^- + H_2Br^+ \rightarrow H_2 + 2Br \qquad [5a]$$

$$HBr + H + Br \qquad [5b]$$

$$2H + 2Br. \qquad [5c]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

Since the positive ions are probably surrounded by a cluster of HBr molecules, which would act in essentially the same way as a solvent cage does in liquid phase photolyses, it seems unlikely that these dissociative ion combinations will be 100% efficient in forming radicals unless a considerable amount of energy is released as kinetic energy. While undoubtedly a large amount of energy would be released in reactions [5*a*] and [5*b*], this is not likely to be the case for reaction [5*c*]. Consequently, reaction [4] would probably be followed by reactions [5*a*] or [5*b*], but not by reaction [5*c*]. The number of initiating radicals formed per initial HBr^+ ion would then still be four.

Excited hydrogen bromide molecules formed in the reaction mixture could dissociate to radicals, thus enhancing the number of initiations. However, excited species did not seem to play a major role in the X-ray-induced decomposition of HBr. In this study the results of Section I (HBr in excess) were therefore interpreted on the assumption that four initiating radicals were formed per ion pair and that the number formed through excitations was negligible.

In the experiments of Sections II and III, where the ethylene concentration was high, positive ions would have been formed by the direct ionization of ethylene molecules:

$$C_2H_4 \rightsquigarrow C_2H_4^+ + e \qquad [6]$$

or possibly by ion–molecule reactions (cf. ref. 12*a*) such as:

$$HBr^+ + C_2H_4 \rightarrow HBr + C_2H_4^+ \qquad [7]$$

$$HBr^+ + C_2H_4 \rightarrow C_2H_5^+ + Br \qquad [8a]$$

$$C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3 \qquad [8b]$$

and:

$$C_2H_4^+ + HBr(+M) \rightarrow C_2H_5Br^+(+M). \qquad [9]$$

As the reaction proceeded and the concentration of ethyl bromide increased, it too would have suffered ionization (see ref. 13):

$$C_2H_5Br \rightsquigarrow C_2H_5Br^+ + e. \qquad [10]$$

The electron capture process:

$$e + C_2H_5Br \rightarrow C_2H_5 + Br^- \qquad [11]$$

is a likely one (13*a*, 14) and might have competed with reaction [2] as the hydrogen bromide was consumed.

Neutralization of the positive ions $C_2H_4^+$, $C_2H_5^+$, $C_3H_5^+$, and $C_2H_5Br^+$ by negative bromide ions would undoubtedly furnish a large number of radicals, and although there is no specific information about ion combinations of this type, it is clear that the number of initiating radicals formed might vary from one positive ion to another. The number of initiations per ion pair would therefore be sensitive to the competition between the various ion–molecule reactions cited above, and thus also to the relative concentrations of HBr and C_2H_4. Under the conditions existing in Sections II and III the initiation process is therefore likely to be much more complex than for those of Section I.

Section I

The results in Table I indicated a first-order dependence of the reaction rate on ethylene concentration. However, the value of the rate constant fell as the ethylene concentration increased. This may have been due to the occurrence of reactions [18] and [19] (see below), but since the value of k_I decreased by only 20% for a fourfold change in ethylene concentration, these processes could not have been very significant under the conditions existing in Section I. The linearity of the first-order plots for ethylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

consumption over 90% of the reaction supports this conclusion and also shows that there was no appreciable change in the number of initiating radicals formed per ion pair* as the ethylene was replaced by ethyl bromide.

The following mechanism (in accordance with the bromine atom theory of abnormal addition) was proposed by Vaughan and co-workers for the photoaddition of hydrogen bromide to ethylene:

$$h\nu + HBr \rightarrow H + Br \quad [12]$$

$$Br + C_2H_4 \rightarrow C_2H_4Br \quad [13]$$

$$C_2H_4Br + HBr \rightarrow C_2H_5Br + Br. \quad [14a]$$

It may be observed that reaction [14*a*] is probably some 10 kcal exothermic, while the alternative propagating mechanism would involve the endothermic reaction:

$$C_2H_5 + HBr \rightarrow C_2H_5Br + H$$

and could not therefore account for the rapid addition observed.

This mechanism may be compared with that of Schumacher and co-workers (1) for the bromination of ethylene:

$$h\nu + Br_2 \rightarrow 2Br \quad [15]$$

$$Br + C_2H_4 \rightarrow C_2H_4Br \quad [13]$$

$$C_2H_4Br \rightarrow C_2H_4 + Br \quad [16]$$

$$C_2H_4Br + Br_2 \rightarrow C_2H_4Br_2 + Br. \quad [14b]$$

The same propagating radicals, Br and C_2H_4Br, are involved in both mechanisms, and reaction [16] should obviously be included in the mechanism for the hydrobromination.

In either system, termination may occur by any one of the following processes, or possibly by a combination of them (cf. 15 and 16):

$$Br + \text{wall} \rightarrow \tfrac{1}{2}Br_2 \quad [17]$$

$$Br + Br + M \rightarrow Br_2 + M \quad [18]$$

$$Br + C_2H_4Br \rightarrow C_2H_4Br_2 \quad [19a]$$

or

$$\rightarrow C_2H_4 + Br_2 \quad [19b]$$

$$2C_2H_4Br \rightarrow C_2H_4 + C_2H_4Br_2 \quad [20a]$$

or

$$\rightarrow C_4H_8Br_2. \quad [20b]$$

The process involved will depend largely on the relative concentrations of Br and C_2H_4Br, and application of the principle of stationary states leads to the following relation between the concentrations of these species:

[i] $$[Br]/[C_2H_4Br] = (k_{14a}[HBr]+k_{16})/k_{13}[C_2H_4] \text{ for hydrobromination}$$

[ii] $$= (k_{14b}[Br_2]+k_{16})/k_{13}[C_2H_4] \quad \text{for bromination.}$$

Since only the ratio k_{16}/k_{14b} is known, estimates of the above concentration ratio cannot be made with certainty in either system. However, reactions [17] and [18] were apparently the main modes of termination in the photobromination reaction at 60° C for ethylene pressures less than 8 cm. It may thus be concluded that at least under these conditions (which approach those of Section I in the present study) the bromine atom concentration is appreciably greater than the concentration of bromo-ethyl radicals.

**It is improbable that the value of W for C_2H_5Br will be very different from those of HBr and C_2H_4. Assuming that the Bragg law of additivity of stopping powers holds, there should therefore be no marked change in the number of ion pairs formed in the cell as the reaction proceeds.*

The dose rate exponent of unity in Section I indicated linear termination. Assuming that this was due to reaction [17] the following rate expression may be derived (cf. ref. 2).

$$\text{Rate} = \frac{k(R.J)k_{13}[C_2H_4][HBr]}{\bar{D}\{[HBr]+k_{16}/k_{14a}\}}$$

where k is a constant, $\bar{D}$ the mean diffusion coefficient for bromine atoms in the reaction mixture, J the dose rate in ion pairs per milliliter per second, and R the number of initiations per ion pair (taken as 4). Since both J and $1/\bar{D}$ are directly proportional to the hydrogen bromide pressure, this expression accounts for the observed dependence of the rate on hydrogen bromide concentration, as well as for the first-order dependence on ethylene concentration and the dose rate exponent of unity.

In theory the reaction rate for wall-terminated chain reactions in cylindrical vessels should be proportional to the square of the cell diameter (cf. ref. 17). The above rate expression may therefore be rearranged to:

$$\frac{k'\times d^2\times(J\times R)\times[C_2H_4][HBr]}{\bar{D}\times\text{Rate}} = \frac{[HBr]}{k_{13}}+\frac{k_{16}}{k_{13}k_{14a}}$$

where k' is a second constant having a value of 1/16 in this case and d is the cell diameter. Values of the left-hand side of this expression, denoted as the function F, have been given in Table I and are plotted against the hydrogen bromide concentration in Fig. 6 for the three temperatures studied. The mean diffusion coefficient, $\bar{D}$, was calculated for each individual experiment. The results are consistent with the above rate expression, and the following values of k_{16}/k_{14a} were calculated from the ratio of the intercepts to the slopes of the lines obtained in Fig. 6: 2.0, 4.8, 18.4×10^{18} molecules/ml at 25, 34, and 54° C, respectively. These values of k_{16}/k_{14a} would require an activation energy difference of 14 ± 2 kcal for $E_{16}-E_{14a}$. This seems rather high since Schmitz *et al.* (1) obtained a value of only 6 kcal for $E_{16}-E_{14b}$, and Anderson *et al.* (18) found that $E_{14a}-E_{14b}$ for ethyl radicals was very small. More detailed studies of both systems would be required to establish the reason for this discrepancy, but in view of certain criticisms made by Kistiakowski and Sternberg (2) it seems that the low value for $E_{16}-E_{14b}$ may be in error. With this exception the results of Section I are consistent with the wall termination mechanism and with the work on the photobromination of ethylene. The value of k_{16}/k_{14a} at 34° C has been used in Sections II and III.

A point of interest is the fact that in the bromination reaction at 60° C the reaction rate rose as the pressure of inert gas (CF_2Cl_2) in the reaction cell was increased, and passed through a maximum at 200 mm. Above this pressure the intensity exponent fell from 1.0 to 0.5, and wall termination ceased to predominate. In contrast, no evidence of a maximum was observed in this study up to hydrogen bromide pressures of 600 mm. This difference in behavior of the two systems may be attributed to a poor third-body efficiency of hydrogen bromide and to the larger diameter of the reaction cell used in the previous study (5.9 cm as opposed to 2.6 cm). (By substituting these values of d in the rate equations for the two systems, estimates of the values of k_{13} in the two systems may be made. These agreed within a factor of 2, and were of the order of 4×10^{10} mole ml^{-1} sec^{-1}. Such a value would seem to be reasonable for a radical addition reaction of this type.)

Sections II and III

The results of Sections II and III may be discussed together since the mechanism of termination in each was apparently almost exclusively by mutual interaction of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

chain centers. Relation [i] shows that the chances of mutual termination by reactions [19] or [20] increase with the ethylene concentration. However, according to Schumacher and co-workers ethylene is about five times as efficient a third body for bromine atom combination as Freon, and in view of the results of Section I it seems likely that ethylene will also be more efficient when compared to hydrogen bromide. The probability of reaction [18] occurring would therefore also increase with ethylene concentration.

Termination by reactions [18], [19], and [20] leads to the following three rate expressions, respectively.

$$[A] \qquad \text{Rate} = \frac{k_{13}}{k_{18}^{\frac{1}{2}}}(RJ)^{\frac{1}{2}}\frac{[HBr][C_2H_4]}{[M]^{\frac{1}{2}}\{[HBr]+k_{16}/k_{14a}\}}$$

$$[B] \qquad = \sqrt{\frac{k_{13}k_{14a}}{2k_{19}}}(RJ)^{\frac{1}{2}}\frac{[HBr][C_2H_4]^{\frac{1}{2}}}{\{[HBr]+k_{16}/k_{14a}\}^{\frac{1}{2}}}$$

$$[C] \qquad = (k_{14a}/k_{20}^{\frac{1}{2}})(RJ)^{\frac{1}{2}}[HBr].$$

These expressions may be rearranged to the forms:

$$[A'] \qquad \frac{k_{13}R^{\frac{1}{2}}}{k_{18}^{\frac{1}{2}}} = \frac{\text{Rate}[M]^{\frac{1}{2}}\{[HBr]+k_{16}/k_{14a}\}}{J^{\frac{1}{2}}[HBr]\times[C_2H_4]}$$

$$[B'] \qquad \sqrt{\frac{k_{13}\cdot k_{14a}R}{2k_{19}}} = \frac{\text{Rate}\,\{[HBr]+k_{16}/k_{14a}\}^{\frac{1}{2}}}{J^{\frac{1}{2}}[HBr][C_2H_4]^{\frac{1}{2}}}$$

and

$$[C'] \qquad \frac{k_{14a}R^{\frac{1}{2}}}{k_{20}^{\frac{1}{2}}} = \frac{\text{Rate}}{J^{\frac{1}{2}}[HBr]}.$$

The right-hand sides of expressions [A'] and [B'] have been calculated for various points on the reaction–time curves of each individual experiment and are given in Tables II*a* and *b*.

The initial rates of experiments 1, 2, and 3 gave fairly consistent values of either [A'] or [B'], but over the course of each experiment both the [A'] (experiment 1 excepted) and [B'] values fell by almost 50%. Fluctuations of a similar nature were observed in the values of [C'] which have not been given. It is not possible, therefore, to draw definite conclusions from the present experiments as to which mode of termination predominates at high ethylene pressures, but, whichever this may be, it seems that the variations in [A'], [B'], or [C'] could be explained by a dependence of R on hydrogen bromide pressure. This would account for the similar results of Section III and might be attributed to a competition between ion–molecule reactions as already discussed. More definite conclusions could be drawn if the mechanism of termination at high ethylene pressures were established by independent photochemical experiments.

In conclusion, the similarities between the photoinitiated bromination and the radiation-induced hydrobromination may be summarized: (1) similar chain lengths (10^5), (2) same rate-controlling step at low ethylene pressures ($Br + C_2H_4 \rightleftharpoons C_2H_4Br$), (3) negative temperature coefficient, and (4) similar modes of termination dependent on the third-body efficiency of the gases present and the cell diameter.

NOTE ON THE INTRINSIC VISCOSITY OF POLYSTYRENE IN MIXED SOLVENTS*

J. F. Henderson† and C. A. Winkler

The ability of solvents to dissolve high polymers, especially polystyrene, and the properties of the resulting solutions is a subject that has received much attention (1, 2, 3, 4, 5, 6). The following is a brief account of results obtained from a few experiments which were made in this laboratory.

The intrinsic viscosity of polystyrene dissolved in binary mixtures of methanol with benzene, bromobenzene, and chloroform was determined, and the results are shown in Fig. 1. Although benzene is a better solvent than bromobenzene for polystyrene, more methanol is required to precipitate polystyrene from bromobenzene than from benzene. Both this result and those of earlier investigations (1, 2) indicate that knowledge of the intrinsic viscosity of a polymer in a given solvent does not permit prediction of either the variation of intrinsic viscosity with addition of non-solvent or the amount of non-solvent required to produce precipitation.

The expansion of a polymer molecule from its unperturbed dimensions, and consequently the intrinsic viscosity of the polymer solution, depends upon the relative magnitudes of the heat of dilution and of the entropy of dilution parameters (7). It was decided to investigate solutions of polystyrene in binary mixtures of three different types of solvents, the solvents being characterized by their heat of dilution and entropy of dilution parameters.

Measurements of the intrinsic viscosity of a polystyrene sample dissolved in several mixtures of methyl ethyl ketone and benzene were made, for which solvents the values of κ_1, the heat of dilution parameters, are approximately equal (7). The intrinsic viscosity

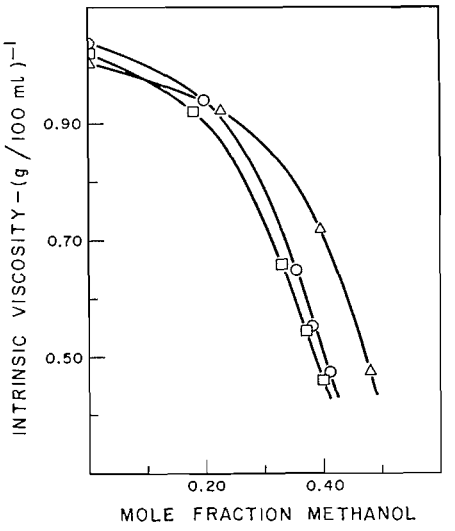

FIG. 1. The intrinsic viscosity of polystyrene ($[\eta]_\theta = 0.43$) in solvent mixtures containing methanol at 24.2° C.

○ Benzene
□ Chloroform
△ Bromobenzene

was very nearly linear in solvent composition and was independent of temperature for all solvent compositions (Fig. 2). On the other hand, the intrinsic viscosity of polystyrene in mixtures of benzene and cyclohexane, for which the entropy parameters, ψ_1, were approximately equal (7), was not linear in solvent composition and in the solvents rich in cyclohexane the intrinsic viscosity was temperature-dependent (Fig. 2) (3). It seems evident, therefore, that the relations between the composition of a mixture of two solvents and the two parameters κ_1 and ψ_1 are different.

The intrinsic viscosity of polystyrene dissolved in mixtures of methyl ethyl ketone and cyclohexane increased to a maximum and then decreased with increasing cyclohexane concentration. In the solvent mixtures rich in cyclohexane the intrinsic viscosity increased with increasing temperature (Fig. 2). These results bear a striking resemblance to those for polystyrene dissolved in mixtures of acetone and methylcyclohexane (5).

The addition of cyclohexane to polystyrene dissolved in methyl ethyl ketone will cause the values of both κ_1 and ψ_1 to increase. To account for the curves in Fig. 2, it is suggested that, in solvent mixtures rich in methyl ethyl ketone, ψ_1 will increase at a greater rate than κ_1 with increasing cyclohexane concentration. However, when the cyclohexane concentration is in excess of a given value, κ_1 will increase at the greater rate with increasing cyclohexane concentration. Hence, the difference $\psi_1 - \kappa_1$, and therefore the intrinsic viscosity, will first increase and then decrease with addition of cyclohexane to the solvent mixture. This suggestion is in accord with the observed behaviors of solutions of polystyrene in benzene – methyl ethyl ketone and in benzene–cyclohexane mixtures.

If different relations exist between the composition of a mixture of two solvents and the two parameters κ_1 and ψ_1, it becomes immediately possible to account at least qualitatively for cosolvency and for the observation, for example, that more methanol is required to precipitate polystyrene from bromobenzene than from benzene. Unfortunately, there is little information about the dimensions of polymer molecules in mixtures of specific types of solvents.

It should be noted that a truly adequate theoretical explanation of these observations would require that solvent mixtures be considered, not as single components as done above, but as two components, and this would require knowledge of the thermodynamic interactions between the polymer and each solvent and between the solvents themselves. This has been done for solutions of polystyrene in benzene–cyclohexane mixtures (8) but not for solutions of polystyrene in benzene – methyl ethyl ketone and cyclohexane – methyl ethyl ketone mixtures since information about solvent–solvent interactions in the latter systems is not available.

HYDROGENOLYSIS OF CARBOHYDRATES

VII. METHYL β-L-ARABOPYRANOSIDE-1-C^{14} [1]

THOMAS FRANCIS[2] AND A. S. PERLIN

ABSTRACT

Methyl β-L-arabopyranoside-1-C^{14} was hydrogenolyzed in the presence of copper chrome oxide catalyst at 250° C, yielding an approximately equimolar mixture of optically inactive *cis*- and *trans*-3,4-dihydroxytetrahydropyran-C^{14}, together with 2,3-dihydroxypentane-C^{14}. The latter was formed by reductive ring-opening of the tetrahydropyrandiols. Ether cleavage of each of the cyclic diols afforded 1,2,3,5-tetrahydroxypentane-C^{14} in which the tracer was distributed about equally between carbons 1 and 5. Carbon-14 in the pentanediol was distributed in a similar manner. The results show that both the 2- and 4-hydroxyl groups of the original pentoside are prone to reductive cleavage, and that *cis*- and *trans*-glycol groups in the cyclic diols are formed by isomerization. They suggest that hydrogenolysis of the methoxyl group takes place initially, accompanied by isomerization, to give a mixture of tetrahydropyrantriols in which the 2- and 4-hydroxyl groups have equivalent reactivity.

In Part V of this series (1) methyl β-L-arabopyranoside (I) was shown to isomerize readily at 180° C in the presence of hydrogen and copper chromium oxide catalyst to a mixture of methyl D- and L-pentosides. This finding offered an explanation of the earlier report (2) that the arabinoside is hydrogenolyzed at 250° to form optically inactive *cis*- and *trans*-3,4-dihydroxytetrahydropyran (dihydro-DL-arabinal and -DL-xylal), rather than the expected L-isomers (II and III, respectively). Clearly, the glycosidic methoxyl group is easily hydrogenolyzed and the 3-hydroxyl group, though isomerized (1), is stable, but it was not possible to decide from these data whether the 2- or 4-hydroxyl group (or both) is cleaved reductively. In the present study this problem has been examined by tracer techniques using methyl β-L-arabopyranoside-1-C^{14}.

The dihydroglycal-C^{14} fraction, isolated as the major product from hydrogenolysis of the labelled L-arabinoside at 250°, comprised an approximately equimolar mixture of *cis*- and *trans*-isomers, in agreement with the earlier finding (2). Acetonation of the mixture afforded the *O*-isopropylidene derivative of the *cis*-diol, and the *trans*-isomer remaining was freed from a small proportion of unacetonated *cis*-diol by selective lead tetraacetate oxidation of the latter. The purified isomers were optically inactive.

Acetolysis of the diols-C^{14} in the presence of boron trifluoride (3) yielded from each the tetraacetate of 1,2,3,5-tetrahydroxypentane (IV). Following deacetylation the tetritols were oxidized with periodate, and the formaldehyde produced was isolated as the dimedon derivative or the 2,4-dinitrophenylhydrazone. Since the formaldehyde was derived either from carbon 1 or carbon 5 of the original methyl L-arabinoside, or from both, its specific activity provided a measure of the percentage survival of the 2- and 4-hydroxyl groups of the glycoside. Thus, if only the 4-hydroxyl group had been hydrogenolyzed all of the carbon-14 should have been located in the formaldehyde, but inactive formaldehyde should have been obtained if the 2-position was attacked exclusively. In fact, the formaldehyde from the *cis*- and *trans*-isomers contained 40–45% of the total activity (Table I), showing clearly that the 2- and 4-hydroxyl groups were cleaved

TABLE I

†Calculated by difference from average of the C_4 values.

reductively almost to the same extent. The results show also, contrary to the original interpretation (2), that the presence of *cis*- and *trans*-1,2-diol groups in the products is not related necessarily to the occurrence of such groups in the methyl L-arabinoside, but to isomerization. Thus, *cis*- and *trans*-glycol groups are located in the tetrahydropyrandiols at positions corresponding to both the 2,3- and 3,4-positions of the glycoside.

The approximately equivalent reactivity of the 2- and 4-hydroxyl groups in methyl L-arabinoside contrasts with hydrogenolysis mainly of the 4-position in methyl α-D-glucopyranoside (4, 5). Possibly hydrogenolysis of the pentoside is initiated at carbon 1 giving rise, also as a result of isomerization (1), to a mixture of 1,5-anhydropentitols (e.g., V). In the latter mixture the 2- and 4-hydroxyl groups would be more nearly equivalent than in the parent glycosides and hence reduced at about the same rate. The survival in each molecule of one of these groups together with the 3-hydroxyl group may be attributed to the resistance of 1,2-diols and the instability of 1,3-diols to hydro-

For personal use only.

genolysis (6). Relatively greater reactivity of the 4-position in methyl D-glucoside possibly is associated with the influence of the primary carbinol group.

About one-third of the hydrogenolysis product consisted of a low-boiling oil which yielded a *p*-nitrobenzoate corresponding to that of a pentanediol. This product was found to be mainly 2,3-dihydroxypentane, for it consumed about one mole of periodate with production of acetaldehyde and propionaldehyde. Previously, methoxypentanediols were reported present in the reaction mixture (2), but, since polyols may give spurious methoxyl values (7), it is likely that the product actually encountered was the pentane-2,3-diol. The diol was produced also by hydrogenolysis of the isolated tetrahydropyrandiols, and hence was a secondary reaction product resulting from reductive cleavage of the cyclic ether group. When the C^{14}-labelled glycoside was used as starting material the propionaldehyde obtained from the pentanediol by periodate cleavage accounted for 58%, and the acetaldehyde 36%, of the tracer (Table I). These data show again that the 2- and 4-positions of the methyl pentoside are both subject to reduction, and correspond closely to the data obtained with the tetrahydropyrandiols.*

Another possible procedure was examined for evaluating the distribution of tracer in the tetrahydropyrandiols. The diols were oxidized with periodate and the resulting dialdehydes reduced to give the corresponding dihydroxy ether (VI). Cleavage of VI was expected to afford ethylene glycol and 1,3-dihydroxypropane, the specific activities of which would indicate the relative proportion of carbon 1 from the L-arabinoside-C^{14} in each fragment. However, the ether linkage of VI proved to be particularly resistant, and the low yield of products obtained made the procedure unattractive for use with the small quantity of radioactive diols available.

EXPERIMENTAL

Methyl β-L-arabopyranoside-1-C^{14}, m.p. 171–173°, was prepared by methanolysis (8) of L-arabinose-1-C^{14}.

Paper chromatography was carried out with Whatman No. 1 paper using *n*-butanol: ethanol:water (40:11:19) as solvent and ammoniacal silver nitrate as the spray reagent (9).

Melting points are corrected.

Radioactive samples were combusted and the specific activity of the carbon dioxide liberated was measured by the procedure of Buchanan and Nakao (10). Reproducibility of the measurements was about ±3%.

Hydrogenolysis of Methyl β-L-Arabopyranoside-1-C^{14}

Methyl β-L-arabopyranoside-1-C^{14} (47.6 mμc/mmole) (6.0 g) in dioxan (100 ml) was shaken for 5 hours at 250° with copper chromium oxide catalyst (1.25 g) in an atmosphere of hydrogen at 2000 p.s.i. The syrupy product (3.2 g) obtained after removing the catalyst and evaporating the solvent was found by paper chromatography to consist of two main components (R_F 0.52 and 0.82). Distillation at 0.3 mm afforded the faster-travelling of these components as an oil (1.0 g), b.p. 51–65° (bath temp.), n_D^{20} 1.4404, and the second as an oil (1.5 g), b.p. 81–90°, n_D 1.4630. The latter product was identified by paper chromatography as 3,4-dihydroxytetrahydropyran and, by plotting its rate of uptake of lead tetraacetate, was found to consist of a 45:55 mixture of *cis*- and *trans*-isomers (cf.

**Cleavage of the ether ring in tetrahydropyran derivatives with boron trifluoride – acetic anhydride has been found in at least one instance to produce positional isomers (3). Formation of* IV *from* II *or* III, *however, did not appear to involve such a side reaction (3). The distribution of tracer in 2,3-dihydroxypentane affords an independent check on the latter acetolysis reaction, by showing that labelling in the tetrahydroxypentane is that expected for normal ring-opening of the cyclic ether.*

ref. 2). Separation of the isomers on chromatograms could not be effected by adding boric acid to the solvent, nor by column chromatography on cellulose using benzene: ethanol:water (500:50:1).

cis-3,4-Dihydroxytetrahydropyran-C^{14}

The higher-boiling oil (1.0 g) was dissolved in acetone (50 ml) containing 1% concentrated sulphuric acid. After 24 hours at room temperature the solution was neutralized with anhydrous potassium carbonate, filtered, and evaporated. The residual syrup was dissolved in water and the solution extracted 3 times with ether. Acetic acid (10 ml, 30%) was added to the extract, the ether evaporated, and the solution heated on the steam bath for 1 hour. Removal of the solvent gave a syrup (R_F 0.51) which was purified by distillation. Weight 0.27 g, $[\alpha]_D^{24}$ 0°±0.1° (*c*, 2, satd. borax). Treatment of the product with *p*-toluenesulphonyl chloride in pyridine gave *cis*-di-*O*-*p*-toluenesulphonyl-3,4-dihydroxytetrahydropyran, m.p. 131–132°; the infrared absorption spectrum was indistinguishable from that of an authentic specimen.

trans-3,4-Dihydroxytetrahydropyran-C^{14}

The water-soluble fraction from the acetonation procedure (0.56 g) appeared, from its rate of lead tetraacetate uptake, to contain about 15% of *cis*-isomer. The latter was preferentially removed by lead tetraacetate oxidation and the product worked up as described earlier (2), affording an oil (0.31 g), R_F 0.57, $[\alpha]_D^{24}$ 0°±0.1° (*c*, 2, satd. borax). The derived tosyl ester had m.p. 159–162°, and gave an infrared absorption spectrum indistinguishable from that of *trans*-di-*O*-*p*-toluenesulphonyl-3,4-dihydroxytetrahydropyran.

1,2,3,5-Tetrahydroxypentane-C^{14}

The tetritol was prepared from the *cis*- and *trans*-diols by acetolysis in the presence of boron trifluoride as described earlier (3), and separated from a small proportion of starting material by column chromatography on cellulose using *n*-butanol. The *trans*-isomer (0.31 g) and the *cis*-isomer (0.27 g) each yielded 0.19 g of tetritol.

Periodate Oxidation of 1,2,3,5-Tetrahydroxypentane-C^{14} *and Isolation of Formaldehyde*

(*a*) Oxidation of the tetritol with periodate and recovery of liberated formaldehyde as the dimedon derivative was carried out according to the procedure of Bell (11). In a typical experiment, the tetritol (0.10 g) derived from *cis*-3,4-dihydroxypyran-C^{14} yielded 0.20 g of formaldehyde dimedon, m.p. and mixed m.p. 192–193°.

(*b*) In a typical experiment, the tetritol (0.09 g) in water (20 ml) was oxidized with periodic acid (0.40 g) for 4 hours. Dowex-1 resin (bicarbonate form) was added until a negative starch–iodide test was obtained, the solution was concentrated, the distillate being trapped in a solution of 2,4-dinitrophenylhydrazine in dilute hydrochloric acid. After it was dried, the recovered hydrazone was purified by chromatography on silicic acid:Supercel (2:1) using Skelly B containing 5% ether (12). Weight 0.09 g, m.p. 166–167°, undepressed by admixture with formaldehyde 2,4-dinitrophenylhydrazone.

2,3-Dihydroxypentane-C^{14}

The low-boiling oil consumed 0.96 mole of periodic acid per mole, producing 0.86 mole of acetaldehyde (estimated colorimetrically (13)), and 0.13 mole of formaldehyde (estimated colorimetrically (14)). On treatment with excess *p*-nitrobenzoyl chloride in hot pyridine it afforded a di-*O*-*p*-nitrobenzoate, m.p. 168–169° after recrystallization

from ethyl acetate. Calc. for $C_{19}H_{18}O_8N_2$: C, 56.71%; H, 4.51%; N, 6.96%. Found: C, 56.80%; H, 4.50%; N, 6.73%.

The oil (0.10 g) in water (25 ml) was treated with periodic acid (0.20 g) for 1.5 hours, the solution was neutralized with Dowex-1 resin, and a solution of 2,4-dinitrophenylhydrazine in dilute hydrochloric acid was added. A precipitate which formed was collected, dried, and chromatographed on silicic acid:Supercel as described above. Two fractions were isolated, the first having m.p. 157°, after recrystallization from ethanol, undepressed by admixture with propionaldehyde 2,4-dinitrophenylhydrazone. Calc. for $C_9H_{10}O_4N_4$: C, 45.38%; H, 4.23%. Found: C, 45.85%; H, 4.01%. The second fraction, recrystallized from ethanol, had m.p. 159–164°. Calc. for $C_8H_8O_4N_4$: C, 42.90%; H, 3.60%. Found: C, 43.30%; H, 3.72%.

2,3-Dihydroxypentane from Hydrogenolysis of 3,4-Dihydroxytetrahydropyran

A mixture of *cis*- and *trans*-3,4-dihydroxytetrahydropyran (4.4 g) was treated for 24 hours under the hydrogenolysis conditions described above. The product (1.5 g), which on chromatographic examination appeared to consist mainly of 2,3-dihydroxypentane, distilled at 45–55°/0.05 mm (bath temp.) to give an oil, having an infrared absorption spectrum indistinguishable from that of 2,3-dihydroxypentane, n_D^{25} 1.4412. The derived *p*-nitrobenzoate had m.p. 165–167°, undepressed by admixture with 2,3-dihydroxypentane di-*p*-nitrobenzoate; the X-ray diffraction patterns of the two diesters were indistinguishable.

Hydroxyethyl-(3-hydroxy)n-propyl Ether (VI)

A mixture of *cis*- and *trans*-3,4-dihydroxytetrahydropyran (2.4 g) in water (40 ml) was treated with periodic acid (4.8 g) for 5 hours. Excess periodate and iodate were removed with Dowex-1 resin (bicarbonate form), the solution was evaporated to half volume and added dropwise to a solution (30 ml) of sodium borohydride (1.5 g). After 18 hours excess Amberlite IR-120 was added, the filtrate was concentrated to dryness, and boric acid removed by repeated (4 times) addition and evaporation of methanol. The product (1.65 g), b.p. 115–125°/0.8 mm (bath temp.), was a viscous oil, n_D^{24} 1.4515, R_F 0.66. It yielded a *p*-nitrobenzoate which solidified when taken up in ether and, after four recrystallizations from methyl ethyl ketone – ether, had m.p. 98–100°. Calc. for $C_{19}H_{18}O_9N_2$: C, 54.55%; H, 4.34%; N, 6.70%. Found: C, 54.73%; H, 4.26%; N, 6.54%.

Cleavage of the Dihydroxy Ether (VI)

(*a*) Treatment of the dihydroxy ether with acetic anhydride – boron trifluoride as described above for 3,4-dihydroxytetrahydropyran yielded only trace amounts of cleavage products.

(*b*) The syrupy ether (0.15 g), in acetic anhydride (2 ml) containing freshly fused zinc chloride (0.15 g), was heated on the steam bath for 12 hours. Cold saturated potassium carbonate was added and the neutral solution extracted three times with chloroform. Evaporation of the chloroform solution yielded a residue which was treated with 0.1 *M* sodium methoxide for 18 hours. The solution was neutralized with Amberlite IR-120 and concentrated, giving a dark syrup (0.074 g). Chromatographic examination indicated that the product consisted of ethylene glycol and 1,3-dihydroxypropane, and a minor, slower-moving component which was not starting material. The spot corresponding to ethylene glycol was absent from the chromatogram when the mixture was treated beforehand with periodic acid, and formaldehyde was produced in the oxidation as shown by isolation of formaldehyde dimedon (6 mg from 30 mg of cleavage product), m.p. and mixed m.p. 186–189°.

ACKNOWLEDGMENTS

The authors express their gratitude to Dr. A. C. Neish for a generous sample of L-arabinose-1-C^{14}. Dr. P. A. J. Gorin contributed valuable suggestions. Carbon-14 assays were carried out by J. Dyck, and microanalyses by T. Mazurek; infrared spectra and X-ray diffraction patterns were prepared by Inez Gaffney and M. Granat.

ADSORPTION OF STERICALLY HINDERED PHENOLS ON CARBON[1]

OWEN H. WHEELER[2] AND ERIC M. LEVY

ABSTRACT

The Freundlich isotherms for the adsorption of some ortho-alkylated phenols on carbon from cyclohexane solution have been determined. The minimum surface area covered by the adsorbed phenols is compared with the area of the molecules themselves. Large alkyl groups ortho to the hydroxyl group greatly reduce the adsorption.

INTRODUCTION

The importance of steric effects in reactions occurring in a homogeneous phase is now well understood (1), but few data are available concerning the effect of steric hindrance in heterogeneous reactions. The kinetic rate-controlling step in such reactions is often the adsorption of the reactants on the surface of an adsorbent, and such a process will be considerably influenced by steric effects.

The adsorption of a series of ortho-alkylated phenols on carbon from cyclohexane solution has been studied. Phenols were chosen since they should be strongly adsorbed and can be easily analyzed. Carbon is a suitable adsorbent since it contains neither strongly acidic nor basic groups, and cyclohexane is a convenient inert solvent which is available in a state of high purity.

The effective surface area of the carbon used was first determined by the standard method (2) of adsorption of nitrogen at liquid air temperature.

The results of the adsorption of the phenols were expressed in the form of the Freundlich isotherm equation ($x/m = k.c^n$, where x is the amount adsorbed by m grams of adsorbent, and c is the equilibrium concentration of the adsorbate) as plots of x/m against c (Fig. 1). In all cases the graphs show limiting values of the amounts of phenol adsorbed, which must correspond to the formation of unimolecular layers.

EXPERIMENTAL

Reagents

Carbon

This was a sample of Darco G-60 adsorbent carbon supplied by the Atlas Powder Company of Canada, Ltd. The manufacturer's analysis was: ash content 2–5%, water solubles 0.1–0.2%, acid solubles 0.5%, pH of water extract 5–6, moisture 5–10%. The loss of weight of a sample dried to constant weight at 145° C corresponded to a moisture content of 5.2%. The sample used was dried under these conditions and stored over phosphorus pentoxide.

Gases

Nitrogen and helium were Canadian Liquid Air Company's pure samples and were dried prior to use.

Phenols

Phenol (Allied Chemical and Dye Corporation, absolute), *p-tert*-butylphenol (Dow Chemical Company), and 2,6-dimethylphenol (Aldrich Chemical Company) were used without further purification. 2,6-Diisopropylphenol (Aldrich) was vacuum-distilled twice.

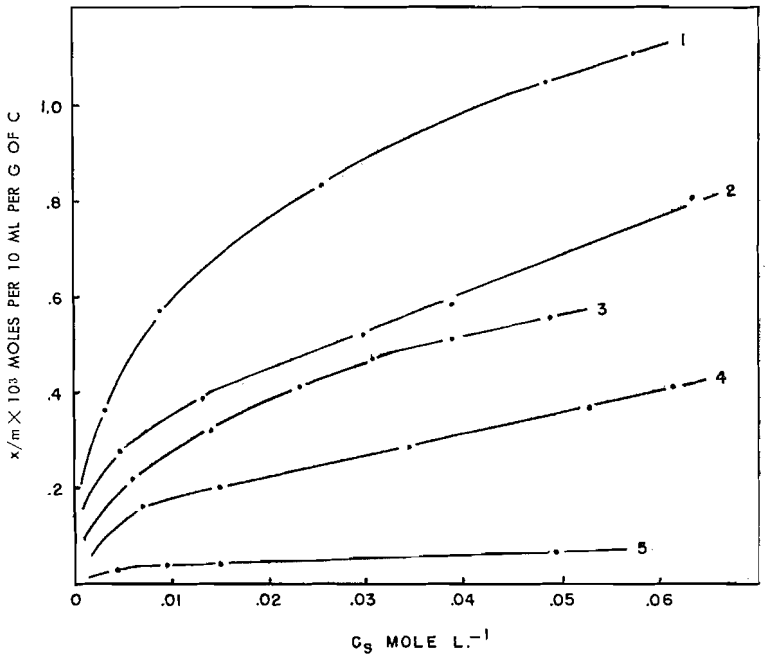

FIG. 1. Adsorption of phenols. 1. Phenol. 2. 2,6-Dimethylphenol. 3. *p-tert*-Butylphenol. 4. 2,6-Diisopropylphenol. 5. 2,6-Di-*tert*-butylphenol.

A yellow-colored impurity persisted in the product. 2,6-Di-*tert*-butylphenol (Aldrich) was recrystallized twice from ethanol.

The physical constants of the phenols are given in Table I.

TABLE I

Physical constants of phenols

	M.p./b.p.[a]	λ_{max}[b]
Phenol	43.0° (41°)	271 (1520), 276 (1450)[c]
p-tert-Butylphenol	97° (100°)	277 (1810)
2,6-Dimethylphenol	49.0° (49.0°)	273 (1450), 276 (1400)[c]
2,6-Diisopropylphenol	107.5°/110 mm, n_D^{20} 1.5124	273 (1700), 276 (1650)[c]
2,6-Di-*tert*-butylphenol	37.0° (39°)	272 (1410), 275 (1340)[c]

Aromatic Hydrocarbons

Benzene, *o*- and *p*-xylene, isopropyl- and *tert*-butyl-benzene, and mesitylene were Eastman-Kodak white label grade and were distilled before use (see Table II for physical constants).

Solvents

Cyclohexane was Fisher or Eastman-Kodak spectro-grade and was used as received. The 95% alcohol was a commercial grade which was free from aromatics as judged from its ultraviolet adsorption.

Physical constants of hydrocarbons

	B.p.[a]	n_D^{25}	λ_{max}[b]
Benzene	80.2° (80.1°)	1.5000	254.5 (186)
o-Xylene	143.5° (144.9°)	1.5030	263 (245)
p-Xylene	138.5° (138.3°)	1.4924	268.5 (243) 274.5 (269)
Isopropylbenzene	152.5° (152.4°)	1.4875	260 (180)
tert-Butylbenzene	170.0° (169.1°)	1.4894	278 (178)
Mesitylene	165.0° (164.7°)	1.4922	255 (193)

[a]Literature values in parentheses. [b]Wavelength of principal maxima in mμ. Molar extinction coefficients in parentheses.

Specific Surface Area of Carbon

The apparatus used was similar to that of Emmett and Brunauer (2) and consisted of an adsorption bulb connected by narrow bore glass tubing to a calibrated gas burette and a mercury manometer, attached to a conventional high vacuum line. The dead space in the adsorption bulb containing the carbon specimen was determined from pressure–volume measurements using helium. A series of pressure–volume experiments were then carried out with pure nitrogen while the adsorption vessel was immersed in liquid air. An adsorption isotherm of residual pressure against volume of nitrogen adsorbed was constructed and gave a limiting value of nitrogen required to form a unimolecular layer at 78° K of 42.0 cm^3 for 0.5424 g of carbon. Using the value of the effective area of nitrogen molecule at −195.8° C of 16.2 $Å^2$ (3), the corresponding specific surface area of the carbon is 1.15×10^3 $meter^2$ per g. This is in agreement with the findings of other workers (3) and Kipling states that "there has recently been a downward trend in surface area values of Darco G from 2123 $meter^2/g$ to 1295 $meter^2/g$" (3).

Adsorption of Phenols on Carbon

Samples of 10 ml of solutions of varying concentrations (0.01 to 0.1 *M*) of the phenols in cyclohexane were shaken with 0.200 g of carbon in 12-ml centrifuge tubes fitted with ground glass stoppers. The shaking was carried out by tumbling the tubes end-over-end at *ca.* 75 r.p.m. with a constant speed motor for ½ hour. It was found that in the case of phenol itself adsorption on the carbon was very rapid for the first 10 minutes and essentially complete after ½ hour. A very slow increase in adsorption took place with a longer time of contact. The suspensions were centrifuged for 5 minutes, and 5-ml portions of the clear solutions were removed with a pipette, care being taken not to disturb the carbon. All these operations were carried out in a constant-temperature room maintained at 20.5±0.5°. The 5-ml aliquots were diluted with 95% ethanol to give solutions of about 4×10^{-4} *M*, and the concentration of unadsorbed phenol was determined by measuring the intensity of ultraviolet absorption at the wavelength of maximal absorption of the phenol (270 to 275 mμ, see Table I). Graphs of the amount of phenol in moles adsorbed per gram of carbon against unadsorbed phenol are given in Fig. 1.

The adsorption of the aromatic hydrocarbons was determined in like manner and the results are expressed graphically in Fig. 2.

Surface Area Occupied by Phenol Molecules

The experimental area of the surface of the adsorbent occupied by one molecule of phenol was calculated (Table III, column 3) from the limiting amount of phenol adsorbed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

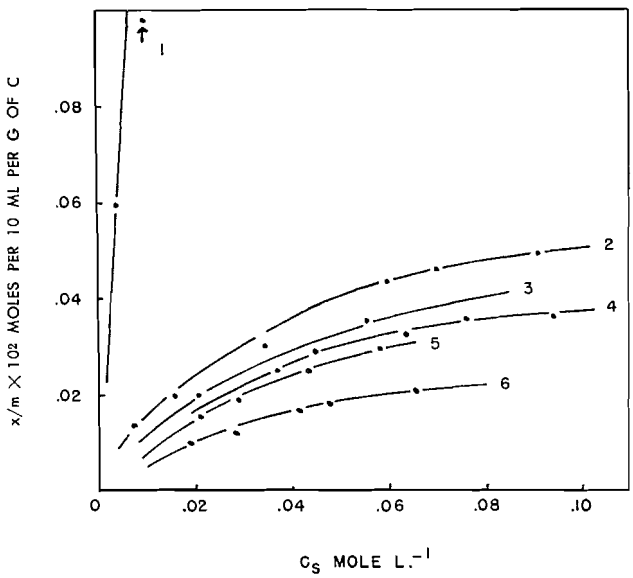

FIG. 2. Adsorption of hydrocarbons. 1. Benzene. 2. Mesitylene. 3. *o*-Xylene. 4. *p*-Xylene. 5. *tert*-Butylbenzene. 6. Isopropylbenzene.

(in moles per 10 ml of solution per gram of carbon) and the known active surface area of the carbon sample.

TABLE III

Surface area occupied by phenol molecules

Phenol	Moles/g 10 ml $\times 10^3$	Exptl. area (A_E)	Calc. area (A_c)	(A_E/A_c)
Phenol	0.97	200	33	6.0
p-tert-Butyl	.52	368	45	8.2
2,6-Dimethyl	.35	550	49	11.2
2,6-Diisopropyl	.175	1090	64	17.0
2,6-Di-*tert*-butyl	.048	3980	64	62.0

The surface area of each phenol molecule in the plane of the benzene ring was calculated (Table III, column 4) using the value of bond distances and the radius of the hydrogen atom given by Pauling (4) and the ring carbon–methyl and carbon–hydroxyl distances of Badger (5). The ratio of the experimental surface area covered by a phenol molecule to the plane surface area of the molecule (assuming "square packing") is given in the last column of Table III.

DISCUSSION

If it is assumed that the phenols are adsorbed with the benzene ring parallel to the surface of the adsorbent, then the fraction of the available surface covered in the case of phenol and *p-tert*-butylphenol is only 1/6 and 1/8, respectively. For the ortho dialkyl-substituted phenols the fraction is 1/11, 1/17, and 1/62 for methyl, isopropyl, and *tert*-butyl groups, respectively. The small fraction of the surface covered even in the case of phenol itself suggests that adsorption of the phenols takes place only at certain "active centers" on the adsorbent. The decreasing adsorption of 2,6-dimethyl and 2,6-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

diisopropylphenol is consistent with the increasing steric shielding of the hydroxyl group and suggests that this group is largely responsible for the adsorption. The greatly decreased adsorption of 2,6-di-*tert*-butylphenol must be due to the large steric size of the *tert*-butyl groups, and the effect of their steric hindrance is also manifest in the physical properties (6) and chemical reactions (7, 8, 9) of this phenol. Carlton and Bradbury (10) have studied the paper chromatographic behavior of these phenols and they found that while alkyl groups in the meta- and para-positions have little effect on the adsorption, in the case of ortho-alkylated phenols the adsorption decreases with increasing size of the substituent. Under their conditions 2,6-di-*tert*-butylphenol was not adsorbed at all. The decreased adsorption of *o*-toluic acid as compared with benzoic acid on carbon (11), and of *o*-cresol and *o*-anisidine as compared to their *p*-analogues on silicic acid (12), has also been observed.

Recently Hallum and Drushel (13) have advanced infrared and polarographic evidence that the surface of carbon black contains free hydroquinone and quinone groups. These could constitute the "active centers" for adsorption of the phenols by hydrogen bonding, and since the hydroquinone and quinone groups do not cover the entire free surface it is understandable that the phenols can cover only part of the available surface area.

Though the principal adsorption force will be hydrogen bonding a further possibility is interaction between the π-electrons of the phenol rings and those of the "aromatic structure" of the graphite surfaces on the carbon particles. Experiments with aromatic hydrocarbons (see Fig. 2) show that although benzene itself is easily adsorbed the effect of alkyl substituents is to greatly reduce adsorption. This is true whether there is one, or more than one, group in ortho- or para-positions or whether the groups are methyl, isopropyl, or *tert*-butyl. Thus, since phenol and *p-tert*-butylphenol are adsorbed to similar extents, π-electron interaction cannot contribute to the forces of adsorption to any large extent. However, there is a small difference between these two phenols, which suggests that adsorption is with the plane of the benzene ring parallel to the surface of the carbon, since if the molecule were perpendicular to the surface no difference would be observed. (The electronic effect of the *p-tert*-butyl groups (donating electronic charge to the ring) (14) will increase the acid strength of the phenol and increase the strength of hydrogen bonding, producing an effect which would be opposite to that observed.)

The steric effect of the ortho alkyl groups in the phenols will decrease their acid strengths by inhibiting resonance with the benzene ring (14), and this in turn will decrease the strength of hydrogen bonding. Thus it appears that the ortho-alkylated phenols are adsorbed weakly, due both to the direct steric effect of the alkyl groups preventing hydrogen bonding and to their indirect effect of weakening this hydrogen bonding.

Spectra of the Phenols

The ultraviolet absorption spectra of the phenols shows some interesting effects. Thus *p-tert*-butylphenol absorbs at a higher wavelength and with a higher intensity than phenol itself. This is attributable to the inductive effect of the *tert*-butyl group increasing the electron density in the ring. The displacement to higher wavelength also results in submergence of the inflection at *ca.* 275 mμ which is present in all the other phenols measured.

In the case of 2,6-dimethyl-, 2,6-diisopropyl-, and 2,6-di-*tert*-butyl-phenol, though the wavelengths of the maxima do not change, the intensities of absorption increase and then decrease with increasing size of the group. This must be due to the opposing effect of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

increasing inductive effect (which will increase the intensity) and increasing steric effect (which will decrease the intensity) (15) on passing from methyl, through isopropyl, to *tert*-butyl.

ACKNOWLEDGMENTS

The authors are indebted to the Atlas Powder Company, Canada, Ltd., Brantford, Ont., and Dow Chemicals, Midland, Mich., for gifts of Darco carbon and *p-tert*-butylphenol, respectively.

THE ISOLATION AND PROPERTIES OF LIGNINS OBTAINED BY THE ACIDOLYSIS OF SPRUCE AND ASPEN WOODS IN DIOXANE–WATER MEDIUM[1]

J. M. Pepper, P. E. T. Baylis,[2] and E. Adler

ABSTRACT

A study has been made of the isolation of a lignin fraction from spruce and aspen wood meals using a low temperature (90–95° C) acidolysis involving a dioxane–water (9:1) solvent medium containing the equivalent of 0.2 *N* hydrochloric acid. The effect of extraction time on the yield of precipitated lignin and ether-soluble material, and on the methoxyl content of these products, was investigated. For both species prolonged extraction times led to greater yields of lignin with lower methoxyl content.

Further acidolysis of isolated spruce lignin led to no significant loss of methoxyl indicating the stability of this group to these reaction conditions. With increasing times of acidolysis of the aspen wood, a slow rise in the carbon–methyl/methoxyl ratio was observed for the isolated lignins. This is in agreement with earlier findings for the spruce lignin. The yields of vanillin and syringaldehyde from aspen lignin on alkaline nitrobenzene oxidation were much less than those from wood meal, and the relative yield of syringaldehyde was higher.

It is suggested that this type of lignin may be only mildly modified during extraction and hence suitable for subsequent chemical investigation. The significance of the findings is discussed.

An attempt has been made to isolate the lignin fraction from both spruce and aspen woods, in yields sufficiently high that the product may be considered representative of the lignin in the wood and yet remain in a form suitable for subsequent extensive chemical investigation. It is well established that rearrangements, which occur during the ethanolysis of wood meal, give rise in both the soluble Hibbert monomers (1) and in the ethanol lignin (2) to an increased percentage of carbon–methyl groupings over that of the original, acetoxy-free, wood meal. This suggested the need for a readily available lignin in which these acid-catalyzed rearrangements could be studied more systematically. The importance of the nature of the extracting solvent in typical alcoholysis reactions has been emphasized by Schuerch (2, 4), who stated, "The low reported yields of lignin alcoholysis products are mainly the result of the slight solubility of the products in the solvent rather than solely the result of polymerization reactions". Other workers (5, 6) have also emphasized the importance of using an aqueous organic solvent system for increased lignin solubility. The well-known alcoholysis procedure for the isolation of lignin suffers primarily from the disadvantage of solvent–lignin interaction. Thus the use of methanol or ethanol was excluded since the ready etherification of various lignin alcoholic groups would yield a product whose analysis for either methoxyl or carbon–methyl respectively would be difficult to interpret.

The use of dioxane in a typical solvolysis reaction has been studied (1), but has led to conflicting reports as to its usefulness. However, dioxane–water appeared to offer many advantages as a solvolysis medium: it has been shown to be a good solvent (5); dioxane is not known to react with lignin to any appreciable extent, and such a system, at reflux, would provide a moderately elevated extraction temperature. The presence of small amounts of a mineral acid (usually hydrochloric acid) are necessary in the lignin solvolysis

reaction. Concentrations of such acid ranging from 0.01 to 3.8% have been reported (1) but no detailed study appears to have been reported on the effect of this variable on yields of isolated lignins. Schuerch (4) reported that in a series of experiments involving the solvolysis of spruce lignin in a chloroform–ethanol system, the decrease in hydrogen chloride concentration from 1.75 to 0.7% substantially lowered the rate of delignification. Konkin and Rogovin (7), in a study of the delignification of wood using ethylene glycol for ½ hour at 180° C, showed that a slight decrease in the amount of lignin dissolved occurred if the hydrogen chloride concentrations were varied from 0.1 to 0.02%. The most commonly used acid concentration is 0.2 *N* (0.7%) and this is used throughout this research.

A. ISOLATION OF LIGNIN FROM SPRUCE WOOD

In a series of preliminary experiments to compare the suitability of various solvent systems, pre-extracted spruce wood meal was suspended in the solvent medium containing 0.2 *N* (by weight) dry hydrogen chloride and refluxed for 4 hours in a nitrogen atmosphere. The solvents chosen were chloroform–methanol (4:1), dioxane–methanol (9:1) as recommended by Schuerch (3), dioxane, and dioxane–water (9:1). The reaction mixture was filtered, and the filtrate, after neutralization with sodium bicarbonate, was concentrated to a small volume. The lignin was precipitated by forcing this concentrate, as a fine stream, under the surface of 1% sodium sulphate solution. The lignin was removed by centrifugation and decantation and the mother liquors were exhaustively extracted with ether. The residual wood meal, the lignin, and the ether-soluble extract* were dried to constant weight and analyzed for methoxyl content. The results are given in Table I.

TABLE I

Preliminary lignin extraction experiments[a]

[c]The wood meal was first refluxed for 4 hours with 0.2 *N* HCl, then filtered and treated as indicated.

The significant alkylation as indicated by the marked increased total methoxyl content in those experiments using methanol supports this well known reaction of lignin. This alkylation reaction has been studied (8) and explained as being due to the etherification of benzyl alcohol groups or the re-etherification of benzyl ether groups. The effect of an acid treatment of the wood meal prior to the chloroform–methanol extraction was limited. There is an indication that some added methylatable hydroxyl groups were liberated but that some condensation occurred to decrease the solubility of the lignin. The advantage of using aqueous dioxane over dioxane alone is indicated by the significantly increased yield and methoxyl content of the isolated lignin. It would appear that,

**It must be pointed out that the small amounts of dioxane introduced during the precipitation process modify the solubility of the extracted substances.*

in the aqueous system, some carbohydrate or other non-methoxyl-containing fragments that appear with the lignin in the pure dioxane extraction have been separated and appear instead in the ether extract giving rise to the relatively lower methoxyl content of this fraction.

Since it had been shown that the dioxane–water (9:1) solvent system was effective for lignin extraction, the effect of the time of reflux was studied. Similar experiments were conducted with the reflux times of 1, 2.5, 4.0, and 8.0 hours. The components of the reaction mixture were obtained and analyzed as before. The results are given in Table II.

TABLE II

Effect of reflux time on isolation of spruce lignin[a]

Time, hours	Residual pulp		Lignin		Ether extract		Total methoxyl recovery, %
	Recovery, %	Methoxyl, %	Weight, g(% K.L.)[b]	Methoxyl, %	Weight, g(% K.L.)[b]	Methoxyl, %

[a]Pre-extracted spruce wood (25 g); dioxane–water (9:1) (200 ml); 0.2 *N* HCl; reflux temperature, 90–94° C, under nitrogen.
[b]Expressed as percentage of Klason lignin.
[c]Included from Table I to indicate order of reproducibility.

There is no evident variation in methoxyl recovery with time of reflux, but the average value of 92.5% appears sufficiently significant to suggest a small but rapid acid-catalyzed loss of methoxyl. This could arise by the hydrolysis of methyl acetal linkages or by the solubilization of methoxyl-bearing components which are not extracted by ether. The lignin extracted by the 1-hour treatment was of a light tan color and its methoxyl content of 16.1% agrees with that reported by Björkman (6) for a sample of spruce milled wood lignin whose methoxyl content of 15.8%, after correction for 1.9% hydrolyzable carbohydrates, becomes 16.1%. A similar 1-hour preparation analyzed for carbon, 64.6; hydrogen, 5.55%; results, which again agree closely with the elemental analysis of other extracted lignins.

The steady decrease, with time of extraction, of the methoxyl content of both the isolated lignin and the corresponding ether extracts may be explained as follows. Either the protolignin is non-homogeneous, at least with respect to its ease of extraction, and the higher percentage methoxyl components are most readily liberated and solubilized (e.g., terminal units), or the isolated "lignin" fraction contains increasingly larger relative amounts of carbohydrate fragments. This latter situation could arise as the result of the direct isolation of such lignin–carbohydrate portions pre-existing in the wood, or as a result of secondary condensations between solubilized lignin and carbohydrate fragments.

It was felt that some information might be obtained regarding the homogeneity of the protolignin if a stepwise isolation were conducted and the lignin products examined at each stage. To this end the residual pulp from the 1-hour extraction procedure (25 g wood meal) was treated under the same experimental conditions for a further $1\frac{1}{2}$ hours and the solubilized lignin and ether extracts obtained. This was repeated again on the second pulp residue. The lignin yields with methoxyl content given in brackets, obtained by the successive extraction periods of 1, 1.5, and 1.5 hours, were 2.25 g (16.1%), 0.684 g

For personal use only.

(14.85%), and 0.514 g (14.5%). The corresponding ether extracts were 0.774 g (14.9%), 0.338 g (8.45%), and 0.21 g (4.62%). There is a considerable decrease in the total available lignin products as compared to those obtained by either the one-step 2.5 hours or the one-step 4.0 hours extraction. The chemical nature of these products isolated by the successive stepwise method varied considerably, indicating a non-homogeneity of the lignin substance. It must be pointed out that each wood residue was dried first in the air then in a vacuum desiccator over phosphorus pentoxide, and it is conceivable that during this time oxidation or condensation occurs which decreases the ease of subsequent isolation.

The ready availability, light tan color, high methoxyl content, and solubility in dioxane–water (9:1) of the lignin isolated by the 1-hour treatment was considered as sufficient indication that this material would prove suitable for extended chemical studies. Thus, studies could be made on the effect of increasing times of acidolysis on the establishment of carbon–methyl groups by rearrangement, and on the liberation of free phenolic hydroxyl groupings. For this purpose solvent-extracted wood meal (300 g) was extracted, as before, for a 1-hour period. The resulting lignin weighed 31.2 g (37.8% of the Klason lignin) and analyzed for 15.53% methoxyl. The ether extract yielded a dark colored oil fraction, 7.92 g (9.6% of the Klason lignin) which was not studied further.

Samples of this dioxane–water lignin were subsequently refluxed further under similar conditions for periods of 3, 11, 23, and 47 hours. The resulting reaction products were studied as before, the lignin recovered by precipitation into 1% sodium sulphate, and the ether-soluble oils extracted from the aqueous filtrate. The results of these treatments are given in Table III.

TABLE III

Acidolysis of isolated dioxane–water lignins[a]

Run	Sample (g)	Reflux (hours)	Lignin recovered		Ether extract		Methoxyl recovery (%)
			Weight (g)	OCH_3 (%)	Weight (g)	OCH_3 (%)

[a]Reaction medium: dioxane–water (9:1) (100 ml); 0.2 *N* HCl.

The consistently high methoxyl content of the recovered lignins indicates the stability of this grouping to these reaction conditions. This fact, together with the close similarity in the amounts of the ether extracts, suggests a rapid release of these lower molecular weight fragments from this lignin. Support is thereby also given to the belief that the decrease in methoxyl content of both the isolated lignin and the ether-soluble extracts, with increasing time of acidolysis of the original wood (see Table II), is a result of the simultaneous isolation of lower methoxyl content portions. A progressive darkening in color of the isolated lignins from run A through D indicates a distinct chemical change which, however, did not result in a change of the methoxyl content. The analytical results showing the increasing content of both carbon–methyl and of free phenolic hydroxyl groups with increased time of acidolysis have been reported and their significance to the chemistry of spruce lignin discussed (9). It is obvious that extensive rearrangements or other structural changes were occurring as a result of the prolonged treatment.

B. ISOLATION OF LIGNIN FROM ASPEN WOOD

The method of lignin isolation described above offered a simple but rapid means of obtaining, in good yields, a light, tan-colored material suitable for further extensive chemical studies. The method was then applied to a typical angiosperm, *Populus tremuloides*. The effects of time of extraction on the yields of the precipitated lignin and the ether-soluble oils along with their respective methoxyl contents are given in Table IV.

TABLE IV

Effect of reflux time on isolation of aspen lignin[a]

[b]Lignin A refers to that fraction obtained from the neutralized filtrate; lignin B to that fraction obtained from $NaHCO_3$ layer.
[c]Unknown mechanical loss during evaporation.

One of the striking features of this extraction of aspen wood meal is the consistently low recovery of methoxyl as compared to that obtained from spruce wood by a similar treatment. Two possible reasons for this poor recovery may be suggested; either a significant proportion of the original methoxyl is present in an acid labile form, e.g., acetal linkage, or it is associated with readily hydrolyzable carbohydrate fractions which remain unrecovered in the aqueous residue. As high as 15% of the methoxyl of aspen wood has been reported (10) to be associated with the holocellulose.

The steady decrease in the methoxyl content of the isolated lignins and of the ether extracts with times of extraction from 0.5 to 48 hours follows a pattern similar to that found for spruce and may be likewise explained. The high (21%) methoxyl content of the lignin isolated after ½-hour or 1-hour treatments is in general agreement with the several values reported by Brauns (1) ranging from 20.4 to 20.9% and slightly higher than the 19.4% reported for native aspen lignin (11). The results presented in Table IV suggest that as a result of extended acidic treatment secondary reactions occur involving the isolated lignin and residual carbohydrate components. The significantly increasing methoxyl content of the pulps after longer than 4 hours' extraction time indicates a recombination of methoxyl-bearing components and pulp residues.

The characteristic reaction of hardwood lignin whereby it may be oxidized by hot alkaline nitrobenzene solution to produce vanillin and syringaldehyde was applied to the isolated lignins recorded in Table IV. These results are given in Table V.

It is very significant that even after only a ½-hour acidolysis treatment, the yields of vanillin and syringaldehyde have been markedly decreased over those obtainable using wood meal alone. No results were obtained respecting the aldehyde yields of the ether extract, but since it represented only 7.5% of the total lignin, the possible aldehyde yields would be less than this value. The combined yields of vanillin and syringaldehyde from the isolated lignin and from the residual pulp of the ½-hour extraction procedure

[b]Solvent-extracted wood meal.
[c]Reported as percentage by weight of the original Klason lignin.

amounted to only 9.49 and 25.3%, as compared to yields of 16.6 and 33.9% respectively obtained from the wood meal itself and calculated as percentage of the Klason lignin. This marked difference suggests a very rapid change in chemical structure, under the conditions of the acidolysis, into a form which no longer is oxidized to the phenolic aldehydes. A strikingly similar result was observed previously by Kavanagh and Pepper (12), who showed that if similar wood meals were subjected to a 2.5-hour pretreatment with 8% sodium hydroxide, then on subsequent oxidation with nitrobenzene yields of vanillin and syringaldehyde were only 9.65 and 22.6% respectively. It seems clear that as a result of either an acid- or base-catalyzed reaction, structural changes in the lignin occur rapidly either prior to, during, or after solution of the lignin fraction.

The methoxyl content of aspen lignin may be considered to arise from the methoxyl groups associated with the guaiacyl and syringyl nuclei of the lignin substance. If a typical guaiacyl-containing unit be represented by $C_{10}H_{12}O_4$ and a typical syringyl-containing unit by $C_{11}H_{14}O_5$, a ratio of these two units of close to 2:1 respectively would be equivalent to a combined methoxyl content of 21% as found for the least modified isolated lignin (see Table IV). As may be seen from Table V the actual ratios of vanillin to syringaldehyde as obtained by the alkaline nitrobenzene oxidations are all (except in the 48-hour experiment) close to 1:3. Since neither vanillin nor syringaldehyde is lost to any appreciable extent by this treatment (12), the inverse ratio and high relative yields of syringaldehyde may be explained as follows. Under the conditions of the reaction a secondary condensation occurs involving the reactive 5-position of the 1-substituted guaiacyl nuclei giving rise to products that no longer can be oxidized to vanillin. No such secondary reaction is possible for the fractions composed of syringyl nuclei.

The increasing carbon–methyl content of the isolated spruce wood lignin with increasing time of subsequent further acidolysis treatment has already been reported (9). The carbon–methyl/methoxyl ratio increased from 0.04 to 0.20 as a result of a 48-hour

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

acidolysis treatment. Similarly, for the lignin isolated from aspen wood the carbon–methyl/methoxyl ratio was shown to increase with increasing times of acidolysis during isolation. After 0.5, 1.0, 2.5, 4.0, 8.0, and 48.0 hours of acidolysis, the average carbon–methyl/methoxyl ratio was 0.13, 0.10, 0.11, 0.15, 0.22, and 0.29 respectively.

These results again indicate the rearrangements that readily occur intramolecularly in isolated lignins. They emphasize too the requirement of short times of extraction in order to obtain a representative lignin fraction. Earlier workers (2) had shown that for maple negligible amounts of carbon–methyl groups existed in the whole wood other than those derivable from the readily hydrolyzable acetate groupings.

The application of this procedure of lignin isolation to both spruce and aspen woods gives rise in good yields to a readily obtained product, which, on preliminary examination, appears to be only moderately changed from protolignin. In comparison it appears that aspen wood lignin is isolated rather more easily than that from spruce wood. It appears too, that there is evidence in the former case for an initial rapid extraction of about two-thirds of the lignin followed by a slower rate of extraction of the remainder. There is no similar inflection in the rate of lignin isolated from spruce. This effect may be associated with the proved dinuclear character of the hard wood lignins as compared to the greater homogeneity of the softwood lignins. This suggested greater ease of cleavage, and subsequent dissolution of fragments with syringyl-type nuclei is supported by the evidence presented regarding the relative yields of aldehydes obtained by oxidation.

EXPERIMENTAL

Preparation and Analysis of Wood Meal

Spruce wood.—Swedish spruce wood meal was extracted continuously with a mixture of ethanol–benzene (1:1) for 53 hours, air-dried, and finally dried to constant weight in a vacuum desiccator over phosphorus pentoxide. Anal: Klason lignin, 27.55%; methoxyl, 4.85%.

Aspen wood.—Native Saskatchewan aspen (*Populus Tremuloides*) sapwood, 20 mesh, was extracted with ethanol–benzene (1:1) for 45 hours, air-dried, and finally dried to constant weight over phosphorus pentoxide. Anal.: Klason lignin, 18.2%; methoxyl, 5.13%.

Solvent.—The dioxane was purified according to the procedure of Fieser (13).

General Procedure for Lignin Isolation

A procedure typical of that used for all acidolysis treatments is as follows. Pre-extracted wood meal (25 g) was placed in a 2-liter, 3-necked flask fitted with a reflux condenser, a nitrogen bubbler, and a dropping funnel. The flask was evacuated at the water aspirator (10–15 minutes), the connection to the pump closed, and the solvent system (200 ml of dioxane–water (9:1) containing 1.46 g dry HCl gas) added slowly from the dropping funnel. The reaction mixture was heated using a heating mantle and refluxed gently for varying periods of time of 0.5, 1.0, 2.5, 4.0, 8.0, and 48 hours under a nitrogen atmosphere. For the experiments using aspen wood the reaction mixture was stirred using a magnetic stirrer. The reaction mixture was allowed to cool, filtered whilst blanketed with nitrogen, and the residue washed on the filter with a further 50 ml of the same solvent. The residual pulp was dried to constant weight and analyzed for methoxyl content.

The filtrate was neutralized with excess sodium bicarbonate and allowed to stand overnight. The liquid layer was concentrated under reduced pressure, using a nitrogen leak, to a thick syrupy consistency, dissolved in ca. 30 ml of the solvent, and forced

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

under pressure (syringe bulb) in a fine stream under the surface of 250 ml of a 1% Na_2SO_4 solution. The precipitated lignin was separated by centrifugation and decantation, washed thoroughly with water, and centrifuged three times more, and finally dried to constant weight in a vacuum desiccator over P_2O_5. In the case of the aspen wood experiments, the sodium bicarbonate sludge layer was dissolved in a large excess of water (60 ml) and acidified with hydrochloric acid. The lignin thus precipitated is referred to as lignin B in Table IV.

Those lignins isolated by the short periods of reflux (0.5–1.0 hours) were light tan-colored powders, but the color darkened as the time of reflux increased. These lignins were all slightly hygroscopic, highly susceptible to static electricity when dry, soluble in pure dioxane or dioxane containing a few per cent water, and soluble in glacial acetic acid and sodium hydroxide but only slightly soluble in ether and carbon tetrachloride.

The alkaline nitrobenzene oxidations were conducted according to the procedure of Stone and Blundell (14).

The carbon–methyl analyses were determined according to the procedure outlined by Smith and Shriner (15).

ACKNOWLEDGMENTS

One of the authors (J.M.P.) wishes to acknowledge the granting to him by the University of Saskatchewan of a year's study leave in Sweden, where the research on spruce was performed. Acknowledgment is also made of the financial assistance provided by the Saskatchewan Research Council for the work on the aspen wood. Thanks are expressed to Miss R. Sins for assistance with the methoxyl and carbon–methyl analyses.

HYDRONIUM ION ABSORPTION IN THE REGION 1.7 μ[1]

W. J. Biermann and J. B. Gilmour

ABSTRACT

Optical absorption of the hydronium ion in the region 1.7 μ was measured in solutions of nitric acid and perchloric acid in the concentration range 0.01 to 4.0 moles per liter. Above 0.1 molar the absorption did not follow Beer's Law, being smaller than predicted from the low concentration behavior. This enhanced transparency is attributed to a "negative absorption" band, associated with the change in solvent structure, found in this spectral region.

INTRODUCTION

In an attempt to establish relationships between the thermochemical properties of aqueous solutions of strong acids and the structures of these solutions, the degree of dissociation of the acid is an indispensable quantity. The limited information presently available has been based, for the most part, on observations of the optical absorption or Raman spectra of undissociated molecules and the anions produced in dissociation (1, 6, 7, 9, 10, 12). The degree of dissociation of a few oxyacids, notably nitric and perchloric acids, seems to be reliably established over a wide concentration range, but these methods are not applicable to binary strong acids.

While casting about for alternate methods of studying the dissociation of strong acids in aqueous solutions, we observed the near infrared absorption spectra of a number of aqueous solutions of strong acids (2). In all cases, these spectra showed a strong absorption band centered in the region of 1.7 μ (5800 cm^{-1}). It appeared reasonable to classify this as an harmonic of a fundamental vibrational frequency of the hydronium ion. Very shortly thereafter, Giguère and Falk (5) reported broad absorption peaks for the hydronium ion at 2900 cm^{-1} and 3300 cm^{-1}.

A study of this absorption band over a range of concentrations was undertaken, primarily to determine the applicability of Beer's Law. If Beer's Law were obeyed, a useful method would be available for the determination of the degree of dissociation of acids in water. Nitric acid and perchloric acid solutions were chosen because the hydronium ion concentrations of these can be calculated with some degree of confidence from existing data.

EXPERIMENTAL

Nitric and perchloric acid solutions were prepared by diluting concentrated reagent grade chemicals with conductivity water. The diluted solutions were analyzed by titration with carbonate-free sodium hydroxide solutions, using bromcresol purple as indicator. The percentages of light transmitted by the diluted solutions were measured on a Beckmann DK-II spectrophotometer, using 1.0-cm Corex cells at room temperature. Conventional procedures were used to insure temperature similarity between the solution and the water-filled reference cell, to correct for inequalities of cell length, and to minimize the chance of gross error by a suitable schedule of repetition of observations.

The experimental results are summarized in Tables I and II, which give the average absorbancy ($\log_{10} I_0/I$) and the wavelength of the maximum of the absorption peak for a range of concentrations of nitric acid and perchloric acid from 0.01 to 4.0 molar. All the absorbancy values were measured at the wavelength of maximum absorption. Figure 1

is a graphical presentation of the absorbancy, plotted against concentration. The solid lines are extensions of the limiting slopes and, since both of these acids are substantially completely dissociated in the concentration range studied, are approximately the loci which would be anticipated if the absorption followed Beer's Law. Figure 2 shows the low concentration absorbancy versus concentration plot, in which Beer's Law is obeyed within the accuracy of observation.

DISCUSSION

That the phenomenon being observed is more complex than a simple absorption of light by H_3O^+ is shown by four types of behavior inconsistent with the simple picture:

1. Absorbancy falls off too rapidly with concentration. If the experimental results are used to compute degrees of dissociation on the assumption that Beer's Law is applicable, these are much lower than the values consistently obtained by other methods.

For personal use only.

2. The wavelength of the peak maximum shifts to a lower value as the concentration increases.

3. Nitric acid appears to be "stronger" than perchloric acid, whereas all other investigations have shown perchloric acid to be the stronger.

4. The limiting value of the extinction coefficient differs between nitric and perchloric acids.

The shift in the peak maximum is a particularly strong indication that the entity being observed does not retain its physical structure throughout the concentration range.

It is quite certain that the H_3O^+ ion, which has three hydrogen atoms available for bonding to oxygen atoms and a positive charge, is connected by hydrogen bonding to the surrounding water molecules. Raman studies by Cross, Burnham, and Leighton (4) have shown that at low temperature water has a fourfold co-ordination structure, but above 26° C the twofold co-ordination structure predominates. The structure of course is a dynamic one; over a long range there would appear to be repetition of units, but nevertheless there is a short range order. Hence, the co-ordination or hydration sphere of the H_3O^+ ion would include not free water molecules but a structure at least similar to that of water itself, and would therefore be subject to any change in the solvent, which would be reflected by a change in the co-ordination sphere of the hydronium ion.

If this picture is close to the true model of a dissociated acid in water, one can expect a change in the nature of the $H_3O^+.nH_2O$ hydrate with concentration. At higher concentrations, hydronium ions would compete for available water units in order to form co-ordination spheres. Once these co-ordination spheres are formed, they would be subject to any change in the structure of the solvent.

It is well known that the association of water is disturbed by an electrolyte. Bernal and Fowler (3) first suggested that electrolyte ions cause a rearrangement of the structure of liquid water. Leighton and Burnham (8) showed that zinc chloride, when dissolved in water, causes a shift in the short frequency component of a main Raman band. Using the X-ray diffraction curves of lithium chloride, sodium chloride, and potassium chloride in aqueous solution at 15° C, Stewart (11) demonstrated that with increasing ionic concentration, the amount of fourfold co-ordination of water is lessened.

The absorbancy values observed above 1 molar are lower than would be anticipated from available dissociation data. Introduction of ions would undoubtedly cause some measure of distortion of the structure of water, probably through orientation of water dipoles, especially in the case of a small ion. The water in an ionic solution might then absorb less light than pure water at the same wavelength. (One can conveniently call this "negative absorption".) The existence of some such negative absorbance mechanism, superimposed on the position absorbance of the hydronium ion, offers a facile explanation for the low absorbancies found for nitric and perchloric acids.

If such a negative absorption is caused by the introduction of hydronium ions, it should also be caused by introduction of any small positively charged ions which are hydrated, such as sodium or lithium ions. Since they will have no positive absorption in this region, solutions containing sodium or lithium ions should be more transparent than water in the spectral region 1.7 μ. Figure 3 shows shapes of curves which resulted when the absorbancies of lithium nitrate, sodium nitrate, and sodium chloride solutions were compared to water. As predicted, all of the solutions gave negative absorption in the region of the absorbance peak of the acids. These solutions were all approximately 1 molar.

It is planned to examine the applicability of Beer's Law to the other two absorption bands reported for the hydronium ion and to examine the "negative absorption" of a series of solutions containing small cations.

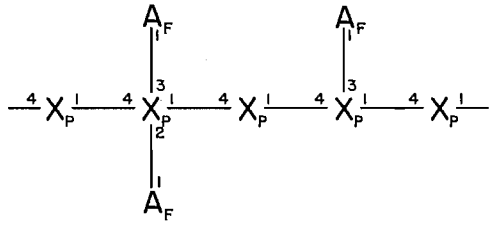
THE ARRANGEMENT OF BRANCHING IN AN ARABINO-XYLAN FROM WHEAT FLOUR[1]

CONSTANCE M. EWALD[2] AND A. S. PERLIN

ABSTRACT

The manner in which L-arabinofuranose branches are arranged along the xylan chain of the pentosans has been examined. The approach used was based on the fact that D-xylose units engaged in branching are resistant to periodate oxidation whereas other sugar residues are readily attacked. Selective degradation of oxidized portions of the polymer with phenylhydrazine or sulphurous acid enabled the isolation of fragments which corresponded to branch points in the original pentosans. D-Xylose and xylobiose were the major products obtained, and xylotriose a minor product. The results indicate that L-arabinose branches of the polysaccharide occur sometimes on isolated D-xylose residues, sometimes on two adjacent D-xylose units, less frequently on three, but not on four, five, etc., consecutive D-xylose residues along the chain.

A water-soluble polysaccharide fraction isolated from wheat flour has been shown to contain a group of closely related pentosans composed of D-xylose and L-arabinose (1, 2). Structure I (A_F = L-arabinofuranosyl; X_P = D-xylopyranosyl) was suggested as an average representation of these pentosans (2), a formulation which has received support in more recent studies (3). Pentosans from a variety of plant sources appear to have a similar type of structure, differing mainly in the relative proportion of the two pentoses or in containing D-glucuronic acid (or a methyl ether of it) as a third component sugar



I

(e.g., 4, 5, 6, 7, 8 and references therein). Major structural features are a linear chain of β-D-xylopyranose units joined by (1 → 4)-linkages, and L-arabinofuranose (or uronic acid) end groups, which, in at least some of the polysaccharides (2, 4, 7), are attached directly by (1 → 2)- or (1 → 3)-linkages to the xylan chain. The available data do not define how the branches in these polysaccharides are arranged, and are consistent with a variety of sequences. Thus, branching may be uniform throughout (II white circles = D-xylopyranosyl; dark circles = L-arabinofuranosyl), in some molecules the incidence of side chains very high (III), or a mixture of arrangements (IV), may be found. The current paper deals with attempts to obtain more definitive information about the mode of branching in the wheat flour pentosans.*

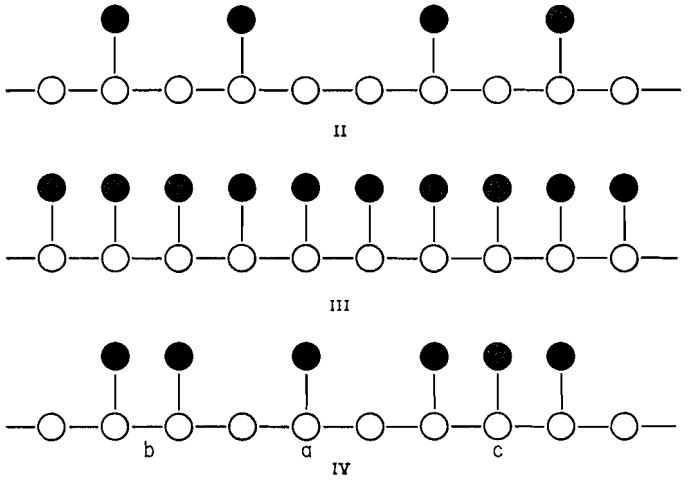
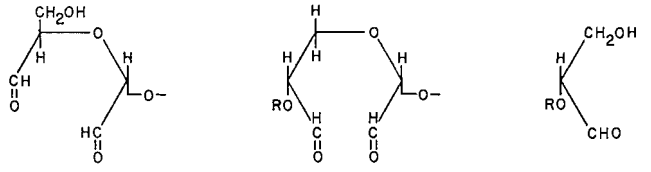
**Detailed information about the arrangement of branching in complex polysaccharides is generally lacking. The chain length of branches in polymers such as glycogen or amylopectin, for example, must be regarded at present as an average value rather than an accurate representation of the size of each branch.*



In devising an approach to this problem the following considerations were made. Treatment of the pentosans with periodate promotes oxidation of the L-arabinose units and D-xylose units which do not constitute branch points. Selective removal of oxidized residues and isolation of unoxidized portions of the molecule as intact fragments should then permit a distinction between II, III, IV, etc. According to this scheme, for example, structure II would afford D-xylose, III a polymeric xylan, and structure IV mono-, di-, and tri-saccharides.

A means for degrading dialdehydes* from periodate oxidation through reaction with phenylhydrazine acetate was developed by Barry (9). The method has been used effectively in examining the fine structure of several polysaccharides which are oxidized partially by periodate (9, 10, 11, 12, 13, 14) facilitating the removal of oxidized portions of the polymers. With a dialdehyde such as V the reagent cleaves the oxygen-bridge and forms glyoxal bis(phenylhydrazone) and triose phenylosazone. It was to be expected, therefore, that the Barry reaction would remove oxidized L-arabinofuranose units (the L-isomer of V) from the oxidized pentosans. Similarly, a dialdehyde (VI) adjacent to a second dialdehyde residue (R) yields osazones of glyoxal and glycerose. However, when R is an unoxidized unit the dialdehyde may yield a hydrazone of VII (R = glycosyl) in addition to glyoxal bis(phenylhydrazone), or the glycosidic bond may be cleaved giving triose phenylosazone and a sugar, the latter being converted in turn to an osazone. These reactions were expected to occur with disruption of the partially oxidized xylan chain.



V VI VII

*The dialdehydes may exist in equilibrium with several cyclic modifications (Michell, J. H. and Purves, C. B. J. Am. Chem. Soc. **64**, 589 (1942)). For a recent discussion of these structural types see Goldstein, I. J., Lewis, B. A., and Smith, F. J. Am. Chem. Soc. **80**, 939 (1958).

Depending on the arrangement of branches in the polymer, it was evident that the Barry degradation could yield a complex mixture of products. As osazones, the unoxidized fragments might be especially difficult to separate and characterize, particularly since they would represent as a maximum only about 30% of the original polysaccharide (2). Alternatively, by avoiding use of excess phenylhydrazine, it was found that only a portion of the liberated sugars are converted into osazones and hence could be examined by conventional sugar techniques. In this modification of Barry's procedure, low molecular weight osazones were readily separated from other components of the reaction mixture, and the water-soluble fraction was treated with benzaldehyde to decompose hydrazones (15) which might have been formed. The aqueous solution then afforded in low yield approximately equal amounts of D-xylose and 4-*O*-β-D-xylopyranosyl-D-xylose (xylobiose) as the major products. Xylotriose (16), characterized tentatively, was a minor product, but oligosaccharides of higher molecular weight were not found.*

With excess phenylhydrazine acetate, the oxidized polysaccharide was degraded extensively to low molecular weight fragments and no product corresponding to a xylan was isolated. This finding made it unlikely, therefore, that a substantial proportion of the L-arabinose units are to be found in a densely packed arrangement as in III. Chromatographic examination of the reaction mixture indicated the presence of xylosazone, xylobiosazone, and only traces of higher molecular weight products, in addition to a very large proportion of glyoxal and glyceraldehyde osazones. A partial separation of these products was achieved by column chromatography on silicic acid – Celite (17).

Another procedure examined briefly as a possible means for selectively degrading the periodate-oxidized pentosans employed graded hydrolysis with sulphurous acid. Periodate dialdehydes are remarkably resistant to hydrolysis with mineral acids (18, 19), but are smoothly hydrolyzed by sulphurous acid (20). Progressive gentle hydrolysis of the oxidized pentosans with a saturated solution of sulphur dioxide produced xylose, xylobiose, and a trace of xylotriose (followed chromatographically in small-scale experiments). A small proportion of arabinose which had escaped, or was resistant to, oxidation by periodate (2) was also found on the chromatograms. The two oligosaccharides were hydrolyzed in turn by continued treatment, but no other oligosaccharides were detected.

The data obtained by use of these different procedures are consistent, and indicate that L-arabinose residues in the wheat flour pentosans are linked to isolated D-xylose units (IV*a*), or to two consecutive D-xylose units (IV*b*); occasionally, branching appears to involve three consecutive D-xylose units (IV*c*). It is possible, however, that the pentosans contain branches arranged in yet other ways which have not been detected by the methods used.

EXPERIMENTAL

Water-soluble wheat flour pentosans were prepared from commercial unbleached flours by the acetylation procedure described earlier (1) or by the method of Simpson (21).

Paper chromatography was carried out on Whatman No. 1 paper. Circular chromatograms (22) were used for osazones, the solvent being toluene–ethanol–water (270:30:1) (12) and variations of this mixture to speed up or slow development.

Pentosan was determined by the orcinol method (23).

Preparation of Periodate-oxidized Pentosans

The pentosans (10 g) were moistened with ethanol, pasted in water, and the solution was adjusted to a volume of 700 ml with water. Sodium periodate (17 g) in water (300 ml)

In a preliminary report of this work (Ewald, C. M. and Perlin A. S. Chem. in Can. **10 (No. 4), 62 (1958)) only D-xylose and xylobiose were listed as relevant degradation products.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

was added and the solution stored at 16° in the dark for 100 hours. Excess periodate was reduced with ethylene glycol, the solution was concentrated *in vacuo* at 40–45° to about one-third volume, and acetic acid added with stirring until a copious precipitate formed. The precipitate, which was insoluble in water, was filtered off and washed with water until it gave a negative starch iodide test, then washed with methanol, and dried. Weight 9.5 g. The dialdehyde content of the product, measured potentiometrically by the hydroxylamine method (24) was 0.67 mole per mole, in good agreement with the measured periodate uptake of 0.65–0.70 mole per mole (2). Pentosan content, 33%.

Partial Degradation of Oxidized Pentosans with Phenylhydrazine Acetate

Oxidized pentosans (7 g) in 45% ethanol (650 ml) were heated on the steam bath together with phenylhydrazine (20 ml) and acetic acid (20 ml) for 1.5 hours. The clear solution obtained was concentrated *in vacuo* at 45–50° to a thick slurry which was taken up in water and extracted exhaustively with ether. Paper chromatographic examination indicated that the ether extract contained osazones mainly of glyoxal and glyceraldehyde and of xylose in low proportion, and that the water extract contained mainly xylose, xylobiose in about equal proportion, and a trace of xylotriose together with dark material which streaked heavily on the paper. Two other trace products detected in the water extract (R_{xylose} 0.7 and 0.4) were eluted from paper chromatograms in one run and found by acid hydrolysis to contain xylose and arabinose.

Benzaldehyde (6 ml) and benzoic acid (0.5 g) in ethanol (150 ml) were added to the water extract (200 ml), the solution was heated on a steam bath for 8 hours and then evaporated at 45° almost to dryness. Water was added, the solution was extracted with chloroform (three times), then exhaustively with ether, and concentrated to dryness. Weight 1.73 g. Extraction of the residue with hot ethanol and evaporation of the ethanol afforded a yellow powder (0.83 g) a portion of which (0.65 g) was transferred to a column (2×20 cm) of coconut charcoal (25). Water (200 ml) eluted a dark brown solution which contained some xylose and xylobiose. Gradient elution (26) of the column with aqueous ethanol up to a concentration of 35% afforded a series of fractions.

The first fraction (0.10 g), $[\alpha]_D^{23}$ +13° (*c*, 2, water), contained mainly D-xylose, which crystallized from methanol–ethanol m.p. 141–143°, undepressed; the X-ray diffraction pattern was indistinguishable from that of D-xylose. The derived (2,5-dichlorophenyl)-hydrazone had m.p. 133–136°, undepressed by admixture with D-xylose(2,5-dichlorophenyl)hydrazone (27).

A second fraction (0.08 g), $[\alpha]_D^{23}$ −21° (*c*, 2.7, water), yielded, on acetylation with hot acetic anhydride – sodium acetate, a product having m.p. 154–156°; a mixed melt and comparison of X-ray diffraction diagrams showed that the product was 4-*O*-β-D-xylopyranosyl-β-D-xylose hexaacetate (16). Calc. for $C_{22}H_{30}O_{15}$: C, 49.44%; H, 5.66%. Found: C, 49.62%; H, 5.91%.

At higher alcohol concentrations, a third product was obtained (0.02 g), $[\alpha]_D^{23}$ −44° (*c*, 2, water). On a paper chromatogram it corresponded to xylotriose but appeared to be admixed with a small proportion of another oligosaccharide(s), for, in addition to xylose, it yielded arabinose as a minor hydrolytic product. Its infrared absorption spectrum was closely similar to that of xylotriose; that of the syrupy derived acetate was indistinguishable from the infrared spectrum of hexa-*O*-acetyl-β-xylotriose. Oligosaccharides of higher molecular weight were not obtained, even by washing the column with 60% ethanol.

The water-soluble material not extracted into hot ethanol was a yellow powder (0.65 g) which contained 57% of pentosan, and hence appeared to be an incompletely degraded

polymeric residue. This material was examined further by partial hydrolysis with sulphurous acid (below).

Treatment of Oxidized Pentosans with Excess Phenylhydrazine Acetate

The procedure of Barry and Mitchell (12) was used. Oxidized pentosans (2.7 g) were taken up in 65% ethanol (115 ml), phenylhydrazine (10 ml) and acetic acid (12 ml) were added, and the mixture heated under reflux for 3.5 hours. Material which deposited on cooling (wt. 1.6 g) was readily soluble in ethanol and, after recrystallization from aqueous ethanol had m.p. 165–167°, undepressed by admixture with glyoxal bis(phenylhydrazone). Calc. for $C_{14}H_{14}N_4$: C, 70.56%; H, 5.92%. Found: C, 70.87%; H, 6.03%.

The filtrate was concentrated giving a syrup, part of which was soluble in hot water. The aqueous solution was extracted exhaustively with ether, phenylhydrazine (3 ml) and acetic acid (3.5 ml) were added, it was then heated on the steam bath for 2.5 hours, and again extracted exhaustively with ether. Evaporation of the water afforded a dark syrup (0.91 g), part of which (0.40 g) was insoluble in 80% ethanol. The insoluble portion contained 43% of pentosan and the soluble material 24% of pentosan, and appeared to be incompletely degraded products.

Paper chromatographic examination of the fraction insoluble in hot water (1.5 g) indicated that it contained osazones of glyoxal and glycerose mainly, xylose, xylobiose, and slower moving components in trace amounts. Attempts to resolve this mixture by countercurrent distribution or chromatography on alumina were unsuccessful. (Two batches of alumina tested were much more retentive than the adsorbent used by Barry and Mitchell (12).) On a column of silicic acid – Celite (2:1) (17),* the compounds corresponding on a chromatogram to glyoxal and triose phenylosazones were eluted with ether, and the addition of ether containing 5% of ethanol then eluted material corresponding on a chromatogram mainly to xylosazone. Removal of the solvent afforded a solid product (0.07 g) which, after two recrystallizations from benzene, had m.p. 164–166° (decomp.), and gave an X-ray diagram indistinguishable from that of D-xylose phenylosazone. Elution with ether containing 15% of ethanol yielded a second fraction (0.09 g) which did not crystallize, but which appeared from its chromatographic mobility and infrared absorption spectrum to be mainly xylobiose phenylosazone. Higher concentrations of alcohol promoted elution of only trace quantities of other materials.

The ether extracts appeared (paper chromatograms) to contain osazones of glyoxal, triose, and xylose, and on concentration, afforded a large proportion of *N*-acetylphenylhydrazine (combined wt. 4.2 g), colorless plates, m.p. 125–127°.

Graded Hydrolysis of Periodate-oxidized Pentosans with Sulphurous Acid

An amount (0.05 g) of oxidized pentosans was suspended in water (2.5 ml) in a pressure flask (200 ml capacity), sulphur dioxide gas introduced to saturation (20), and the flask sealed. Several samples prepared in this way were heated on the steam bath for varying periods; within a few minutes the polysaccharide swelled and then dissolved. After the chosen heating interval the flasks were unsealed, most of the excess sulphur dioxide was removed with a stream of nitrogen, and the solutions were neutralized with Dowex-1 (bicarbonate form). Paper chromatographic examination indicated that most of the arabinose was liberated within 0.5 hour together with small proportions of xylose and xylobiose; at 1.5 hours xylose and xylobiose were the major products, and a trace of xylotriose was present; on further hydrolysis the spots corresponding to xylobiose and xylotriose diminished in intensity.

**The use of this adsorbent was kindly suggested by Dr. Thomas Francis.*

The partially degraded water-soluble polymer remaining from the reaction with phenylhydrazine (above), treated with sulphurous acid under the same conditions, also yielded (chromatographic evidence) xylose and xylobiose as the major products together with minor proportions of xylotriose and arabinose; oligosaccharides of higher molecular weight were not detected on the chromatograms.

ACKNOWLEDGMENTS

The technical assistance of J. Giroux and J. W. L. C. Christ is gratefully acknowledged. Microanalyses were carried out by J. A. Baignee and M. Mazurek; X-ray diagrams and infrared spectra were prepared by T. M. Mallard and Inez Gaffney. The authors express their thanks to Dr. F. J. Simpson for a sample of wheat flour pentosans, to Almonte Flour Mills, Almonte, Ont., for a sample of wheat flour, and to Dr. C. T. Bishop for a specimen of xylotriose.

REACTION OF TRICHLOROACETONITRILE WITH PRIMARY AND SECONDARY AMINES

PART III. STRUCTURE OF AMIDINIUM CATION IN THE LIGHT OF INFRARED STUDY[1, 2]

JOHN C. GRIVAS[3] AND ALFRED TAURINS

ABSTRACT

The infrared spectra of 14 trichloro- and trifluoro-acetamidine hydrochlorides were studied. It was concluded that protonation occurs at the imino nitrogen atom of the N-substituted amidines. Both nitrogens of the amidine grouping, C(=N)N, become electron-deficient due to resonance leading to the single structure (III), regardless of which of the tautomers is present in the equilibrium mixture, and of the number and type of substituents on the amidine nitrogen atoms. These findings predestine to *failure* any attempts to isolate the two amidine tautomers, whenever amidinium salts are involved as intermediates.

INTRODUCTION

The assignment of the $-NH_3^+$, $\rangle NH_2^+$, and $\rangle NH^+$ frequencies presents a difficult problem, which has not yet been solved successfully. The infrared spectra of amine hydrohalides show many bands in the stretching region, which cannot be fully assigned. This complexity is undoubtedly due to the strong hydrogen bonding occurring in the solid phase, whereas the free vibrations are not well known since considerable difficulty is encountered in dissolving these salts in non-polar solvents.

The topic has been reviewed by Bellamy (1), by Witkop (2), and by Heacock and Marion (3). The last investigators identified the NH_2^+ deformation mode between 1620 and 1560 cm^{-1} in a series of secondary amine hydrochlorides.

Stone, Craig, and Thompson (4) were able to arrive at more definite conclusions, comparing the spectra of amine salts with those of their deuterated compounds. Thus, the $\rangle NH_2^+$ asymmetrical stretching frequency was found close to 2920 cm^{-1} and the corresponding symmetrical mode at 2780 to 2825 cm^{-1} for some secondary amine hydrochlorides. They also located the deformation frequency, $\delta(NH_2^+)$, between 1560 and 1600 cm^{-1}, in agreement with the findings of Heacock and Marion. The same authors assigned the stretching vibrations, $\nu(\rangle NH^+)$, to the band between 2330 and 2680 cm^{-1}, shown by tertiary amine hydrochlorides.

More recently Chenon and Sandorfy (5) discussed the complexity of the stretching NH^+ modes and reported the $\delta(NH_3^+)$ frequencies at 1510–1600 cm^{-1}. The strong band which appears in many cases near 2000 cm^{-1} was attributed to a combination mode between the scissoring vibration and a very anharmonic band near 400 cm^{-1}.

To our knowledge, the infrared absorption of the NH^+ vibrations of the amidinium cation has not yet been studied. However, Prevoršek (6) suggested the following structure for some N,N′-disubstituted amidine hydrochlorides, on the basis of their infrared spectra.

EXPERIMENTAL

The infrared spectra were recorded on a Perkin–Elmer model 21 double-beam spectrophotometer equipped with a sodium chloride prism. Fluorolube T-45 mulls were used, since Nujol absorbs strongly at 2800–3000 cm^{-1}. A similar cell unit provided excellent compensation between 4000 and 1350 cm^{-1}. The results are summarized in Tables I, II, and III.

Preparation of Hydrochloride Salts

About 100 mg of freshly purified and dry amidine was dissolved in 20 ml of absolute ether and cooled to 0° C in an ice–salt bath. A stream of dry hydrogen chloride gas was passed through this solution, with continuous stirring by means of a magnetic stirrer, until no precipitation was observed. The white crystalline hydrochlorides were filtered off and dried under vacuum. Although they could not be recrystallized, since they decomposed easily, they were pure and suitable for infrared investigation.

Preparation of Deuterium Chloride Salts of N-*Methyltrifluoroacetamidine-d_2 and* N-*Methyltrichloroacetamidine-d_2*

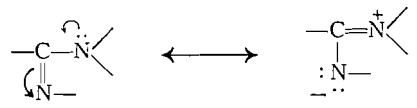
The same procedure as above was followed and gaseous deuterium chloride was used. All the operations were conducted in a dry nitrogen atmosphere.

Deuterated amidines and the free bases were prepared by known methods (7), or by procedures which will be presented in another paper. All unknown parent compounds were analyzed.

RESULTS AND DISCUSSION

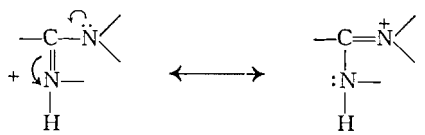
Amidines are monobasic compounds, since they form monosalts with a variety of acids. A literature search revealed that very little is known with respect to the structure of the amidinium cation, which must have an important bearing on the understanding of the chemical behavior of the amidine grouping. Some authors do not draw any distinction between the two nitrogen atoms of amidines.

Theoretical considerations, however, combined with the results of this investigation by the infrared spectroscopy method, may definitely elucidate the course of protonation. Irrespective of the type and number of substituents on the nitrogen atoms, the amidine system is represented by formula (I):



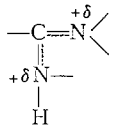
(I*a*) (I*b*)

Such a structure as shown allows for only one charged resonance form having a negative charge on the imino nitrogen and a positive charge on the other. Consequently, the imino group would be expected to accept the proton during the salt formation. Such protonation should yield a resonance hybrid receiving contributions from the two structures shown in formula (II). As a result,



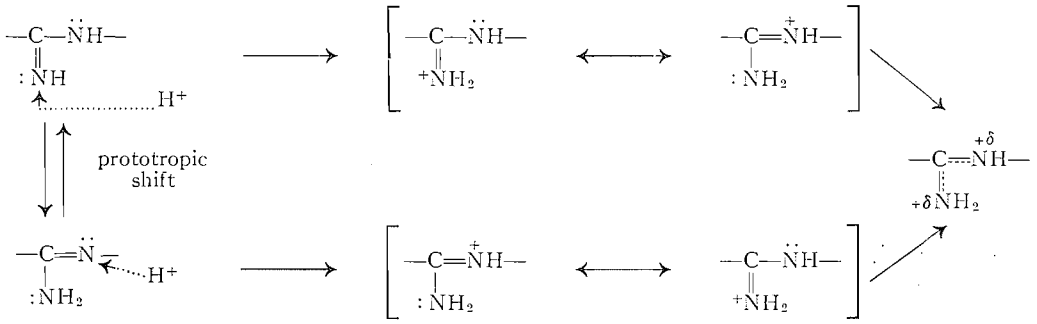
(II)

both nitrogen atoms would become electron-deficient to a degree (III), which should depend on the substituents to some extent. The decreased electron density on nitrogen atoms should prevent any further protonation.



(III)

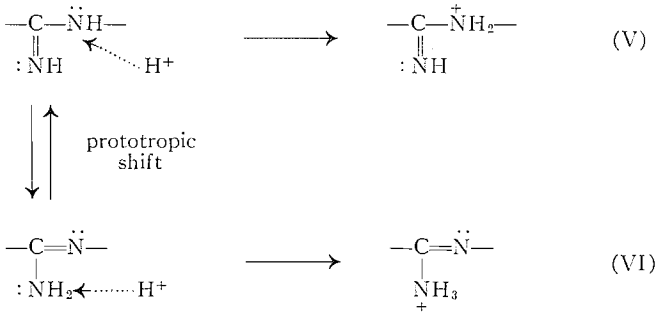
The protonation of both the plausible tautomeric forms of amidines must give one and the same compound (IV) stabilized by resonance, as outlined in the following scheme:



(IV)

This course must be valid in any case, independently of the kind of substitution, and predestines to failure any attempts to isolate the two tautomers, whenever intermediate salt formation occurs. It should be mentioned here that many such unsuccessful attempts have been made, even recently, and in all cases methods leading to salt intermediates were used.

An alternative course of protonation can be written as follows:



(V) (VI)

It is obvious that formulae (V) and (VI) represent two relatively unstable isomers, since resonance stabilization is prevented.

The infrared spectra of the amidine hydrochlorides examined showed characteristically only the stretching vibrations of the $\overset{+}{N}H$ group and the complete absence of any absorption bands of free or bonded NH group (Tables I and II).

*Very broad strong bands.

†Bands have no sharp peaks; positions of absorption maxima represent only approximate values.

A broad and very strong band was shown instead, between 2600 and 3000 cm^{-1}, which possessed two to three well-defined inflections. This absorption includes, of course, the CH stretching vibrations; their separation being impossible with the low dispersion prism used. In addition a broad weak absorption band appeared near 2350 cm^{-1} in all cases.

The striking feature of all the spectra was the complete absence of the strong bands near 2000 cm^{-1} (5) and between 2600 and 2000 cm^{-1}. Furthermore the strongest absorptions occurred at higher frequencies in the corresponding amine hydrochlorides, as was firmly established from a comparison of two amidine hydrochlorides with their deuterated analogues (Table III). Since the greater the positive charge on a nitrogen atom the greater is the displacement of its NH^+ stretching vibrations towards the lower frequencies (1), this observation may definitely demonstrate that only partial positive charges are present in the amidinium cation, which does not agree with structures (V) and (VI).

The stretching $\nu(C=\overset{+}{N})$ vibrations were easily detected since they showed the strongest band between 1600 and 1700 cm^{-1}. Moreover, deuterium chloride salts of two deuterated N-alkylamidines established this assignment, since they displaced all $\delta(\overset{+}{N}H)$ absorptions. This frequency seems to be quite sensitive to small changes, because substitution of the two amino and imino hydrogens by deuterium in N-methyltrifluoro- and N-methyltrichloro-acetamidine salts reduced the absorption frequency by about 20 cm^{-1}, and formula (III) indicates that some distortion of the almost planar configuration of the molecule is likely to occur.

8	$Cl_3C-C(=ND\leftrightarrow DN^+)-NDCH_3$						2260vs

*Also 2420 (s), 2190 (s), and 2110 (s) peaks.

TABLE III*b*

Comparison of ν(NH)/ν(ND) ratios of absorption maxima (cm^{-1}) in the infrared spectra of N-methyltrichloro- and N-methyltrifluoro-acetamidines and their salts

Compound No.	$\frac{\nu(NH)}{\nu(ND)}$	$\frac{\nu(=NH)}{\nu(=ND)}$	$\frac{\nu(NH^+)}{\nu(ND^+)}$
1/2	1.36	1.37	
3/4			1.32
5/6	1.31	1.31	
7/8			1.30

There was no difficulty in the identification of the $\delta(=NH_2^+)$ modes with the N-dialkyl compounds, since only one band was present and suitable for this assignment between 1530 and 1590 cm^{-1}.

Two peaks of medium to strong intensity appeared in the spectra of the N-substituted compounds. Although no decisive conclusions could be drawn, the one existing very close to the amidine II band in the corresponding free bases was attributed to the $\delta(>NH^+)$ of the secondary amino group, and the other to the $\delta(=NH_2^+)$ frequency.

The present study suggests quite clearly that protonation is always initiated at the imino group, and the distribution of the positive charge over the two nitrogens takes place in agreement with this theory.

THE REACTION OF NITROACETONITRILE WITH AROMATIC AMINES[1]

JOHN C. GRIVAS[2] AND ALFRED TAURINS

ABSTRACT

It has been shown by infrared spectroscopic study that the alleged N-aryl-nitroacetamidines are in fact the salts of nitroacetonitrile with aromatic amines.

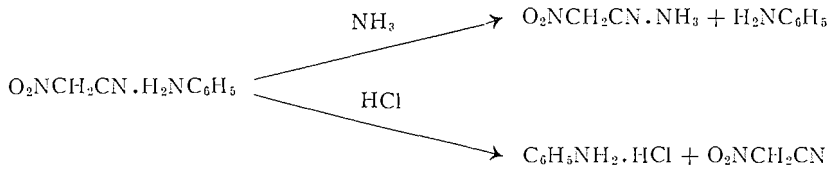
RESULTS AND DISCUSSION

Studies have been made of the reactions of nitroacetonitrile with various amines in an attempt to examine the influence of electronegative groups attached to the α-carbon atom of acetonitrile on the formation of the amidines. The reaction forming alleged N-phenyl-, N-*o*-tolyl-, and N-(2,4-dimethylphenyl)-nitroacetamidine has been reported (1) to occur almost instantaneously in ether at about 0° C.

Early observations were made, showing that ammonia gas decomposed the alleged N-phenylnitroacetamidine in ether solution, to give a precipitate of ammonium salt of nitroacetonitrile while aniline remained in solution. Passing hydrogen chloride gas through a similar solution caused the amidine to decompose into aniline hydrochloride and nitroacetonitrile.

The hydrolysis of these alleged amidines to their starting materials was attributed recently (2) to the formation of a resonance-stabilized carbonium ion, although no other amidines are known to hydrolyze in this way.

It seemed doubtful to us that the amidines of nitroacetonitrile and aromatic amines could be formed so readily, since the reaction between the more electropositive carbon atom of the carbon–nitrogen triple bond of trichloroacetonitrile, with primary aromatic amines, takes place only very slowly at room temperature, even in polar solvents (3). Furthermore, the reported behavior of the reaction products towards ammonia and hydrogen chloride, and their solubilities, could be explained better if they were salts rather than amidines. Since nitroacetonitrile is about as acidic as acetic acid, the reaction of the salts with ammonia and hydrogen chloride could then be represented by the following scheme:



In view of these contradictory facts, we have prepared the three addition compounds in question, and investigated their infrared spectra, together with that of ammonium salt of nitroacetonitrile, $NH_4^+[O_2NCHCN]^-$. The results are summarized in Table I.

The presence of very sharp strong absorption bands in the infrared spectra of the four compounds, due to the (C≡N) vibrations being very close to 2200 cm^{-1}, suggested immediately that no addition occurred across the carbon–nitrogen triple bond. The four

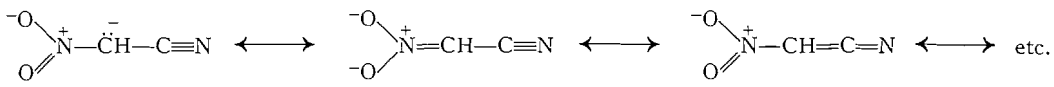
‡Broad bands.

salts absorbed at a frequency even lower than the conjugated aliphatic nitriles (2235–2215 cm^{-1}), as one might expect for a strongly resonating carbanion structure.



On the other hand, the two NH stretching vibrations, characteristic of the N-substituted amidines, which occur between 3300 and 3500 cm^{-1} (4) were completely absent. New wide strong bands appeared in the region 2500–3100 cm^{-1}, corresponding to the (NH_3^+) modes and indicating that the aromatic amines were present in the form of salts.

Finally, resonance within the carbanion ion caused a remarkable frequency shift in the asymmetric stretching vibration of the $-NO_2$ group to the lower part of the absorption range (1500 cm^{-1}), whereas the similar symmetric mode showed absorption at 1320–1345 cm^{-1}.

EXPERIMENTAL

The infrared spectra of the nitroacetonitrile salts were recorded on a Perkin–Elmer Model 21 double beam spectrophotometer. Nujol mulls of the solid compounds were prepared and spread between NaCl plates. A similar cell containing Nujol was used for compensation.

The substances were prepared according to described procedures (1, 2). They were purified in small quantities by careful sublimation at low pressure and, since they were slightly explosive, at a temperature not exceeding 50°.

KINETIC EQUATIONS FOR ENZYME REACTIONS IN THE PRESENCE OF POWERFUL INHIBITORS[1]

RICHARD M. KRUPKA AND KEITH J. LAIDLER

ABSTRACT

Steady-state equations are worked out for the case of a competitive inhibitor that is present in concentrations comparable with that of the enzyme; allowance is made for the inhibitor attached to the enzyme. Two cases are considered: in case 1 the enzyme and inhibitor form a simple addition complex, while in case 2 a molecule is split off. Methods of graphical analysis of rate data are described.

INTRODUCTION

In the development of steady-state equations for enzyme systems (1) the assumption is generally made that the enzyme concentration is much less than the concentrations of substrates, inhibitors, and activators; allowance is therefore not made for the fact that the amounts of these substances that are present in the free state are, owing to complexing with the enzyme, less than the total amounts. This assumption is justified for most systems. However, when very powerful inhibitors such as diisopropyl phosphorofluoridate (DFP) are present their molar concentrations are frequently comparable with those of the enzyme. There is, therefore, need for steady-state equations appropriate to this situation.

Such equations are developed in the present paper, and they are applied to some data obtained in the following paper. Two cases are considered: in the first, the enzyme forms a simple addition compound with the inhibitor, while in the second the complexing is accompanied by the splitting-off of a molecule. In both cases the inhibition is regarded as competitive, since this appears always to be the situation for inhibitors of this type.

STEADY-STATE EQUATIONS

Case 1: The Enzyme and Inhibitor Form a Simple Addition Complex

This case is represented by the equations

$$E+S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \overset{k_2}{\rightarrow} E+\mathrm{P}$$

$$E+I \overset{K_1}{\rightleftarrows} EI.$$

K_1 is the equilibrium constant for the formation of the enzyme–inhibitor complex, and is defined by

$$[1] \qquad K_1 = [\mathrm{EI}]/([\mathrm{E}][\mathrm{I}]).$$

A constant $\bar{K}$, equal to the reciprocal of the conventional Michaelis–Menten constant, is defined by

$$[2] \qquad \bar{K} = [\mathrm{ES}]/([\mathrm{E}][\mathrm{S}]) = k_1/(k_{-1}+k_2).$$

[1]*Manuscript received February 27, 1959.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The total concentrations of enzyme and inhibitor are given by

[3] $$[E]_0 = [E]+[ES]+[EI]$$

[4] $$[I]_0 = [I]+[EI].$$

The rate in the absence of inhibitor is given by

[5] $$v_0 = (k_2\bar{K}[E]_0[S])/(1+\bar{K}[S])$$

while the general rate is given by

[6] $$v = k_2[ES] = k_2\bar{K}[E][S].$$

From [5] and [6] it follows that

[7] $$[E] = \frac{v}{v_0}\frac{[E]_0}{1+\bar{K}[S]}$$

and

[8] $$[ES] = \frac{v}{v_0}\frac{[E]_0\bar{K}[S]}{1+\bar{K}[S]}.$$

From [3] and [4] it follows that

[9] $$[EI] = (K_I[E][I]_0)/(1+K_I[E])$$

and using [7],

[10] $$[EI] = \frac{vK_I[E]_0[I]_0}{v_0(1+\bar{K}[S])+vK_I[E]_0}.$$

Introduction of the expressions [7], [8], and [10] into eq. [3] gives rise to

[11] $$[E]_0 = \frac{v}{v_0}[E]_0+\frac{vK_I[E]_0[I]_0}{v_0(1+\bar{K}[S])+vK_I[E]_0}.$$

This rearranges to

[12] $$[I]_0+\left(\frac{v}{v_0}-1\right)[E]_0 = \left(\frac{v_0}{v}-1\right)\frac{1+\bar{K}[S]}{K_I}.$$

Experimental results for this type of system may therefore be analyzed by plotting

$$[I]_0+\left(\frac{v}{v_0}-1\right)[E]_0$$

against $(v_0/v-1)$ for a given substrate concentration; from the slope of the line K_I can then be calculated provided that $\bar{K}$ is known from separate studies in the absence of inhibitor. An example of this type of plot is shown below.

Case 2: Complexing Associated with the Splitting-off of a Molecule

This case is represented by

$$E+S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow{k_2} E+P$$

$$E+I \overset{K_I}{\rightleftarrows} X+Y$$

where X is the complex and Y the molecule split off. The concentrations of X and Y must always be identical, and will be written as [X].

Equations [1] to [4] are now replaced by

$$[13] \qquad K_1 = [X]^2/([E][I])$$

$$[14] \qquad \bar{K} = [ES]/([E][S])$$

$$[15] \qquad [E]_0 = [E]+[ES]+[X]$$

$$[16] \qquad [I]_0 = [I]+[X].$$

From [13] and [16] it follows that

$$[17] \qquad [X]^2+K_1[E][X]-K_1[E][I]_0 = 0.$$

From [7] and [8]

$$[18] \qquad [E]+[ES] = (v/v_0)[E]_0$$

so that using [15]

$$[19] \qquad [X] = [E]_0\left(1-\frac{v}{v_0}\right).$$

Introduction of [7] and [19] into [17] gives

$$[20] \qquad [E]_0^2\left(1-\frac{v}{v_0}\right)^2+K_1\frac{v}{v_0}\frac{[E]_0^2}{1+\bar{K}[S]}\left(1-\frac{v}{v_0}\right)-K_1\frac{v}{v_0}\frac{[E]_0[I]_0}{1+\bar{K}[S]} = 0,$$

which reduces to

$$[21] \qquad 1-\frac{v}{v_0} = \frac{K_1}{1+\bar{K}[S]}\left[\frac{[I]_0}{[E]_0\{(v_0/v)-1\}}-\frac{v}{v_0}\right].$$

The value of K_1 could now be determined from a plot of $1-v/v_0$ against

$$\frac{[I]_0}{[E]_0\{(v_0/v)-1\}}-\frac{v}{v_0}.$$

APPLICATION TO EXPERIMENTAL DATA

In the work described in the following paper rates have been measured for the α-chymotrypsin-catalyzed hydrolysis of hydrocinnamic ester, over a range of pH values and of concentrations of DFP. Figure 1 shows a case 1 plot for the rates obtained at pH 8.1; the experimental details are given in the following paper. The plot is seen to be satisfactorily linear when the degree of inhibition ($v_0/v-1$) is small. At high inhibitor concentrations, however, there are very significant deviations from linearity, in the sense that the inhibition is much greater than would be predicted from the behavior at low inhibitor concentrations. This effect is attributed tentatively to the formation of a second complex of the type EI_2, as found with other enzyme–substrate systems (for example, urease (2), carboxypeptidase (3), acetylcholinesterase (4); cf. also ref. 1, pp. 71–77, 260–263).

The slope of the linear portion of the curve is 1.93×10^{-6}, and from this, since [S] = 1.17×10^{-3} and $\bar{K}$ = 2500, a value of 2.04×10^{6} is calculated for K_1. It is of interest that use of the simple conventional inhibition equation

$$[22] \qquad v/v_0 = (1+\bar{K}[S])/(1+\bar{K}[S]+K_1[I])$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

leads to a K_i value of 1.2×10^6, which is much less than the true value. The equations developed in the present paper will always give higher K_i values than the simple formula, which overestimates the concentrations of inhibitor present free in the solution.

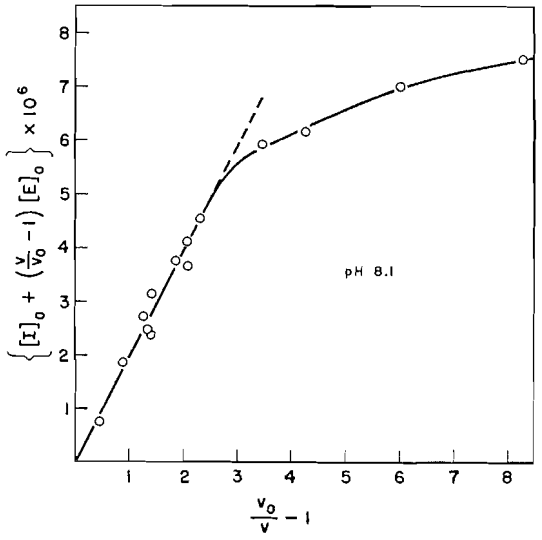

FIG. 1. A plot showing that the mechanism of case 1 is applicable at low inhibitor concentrations.

A plot of the data according to the case 2 mechanism did not give a straight line even at low inhibitor concentrations, and it is concluded that this situation is not applicable. Although the reaction of DFP with the enzyme is accompanied by the liberation of HF (5), it may be that the fluoride ions remain attached to the protein so that equation [1] applies rather than equation [13].

KINETICS OF THE INHIBITION OF α-CHYMOTRYPSIN BY METHANOL AND DFP[1]

BERNARD R. STEIN[2] AND KEITH J. LAIDLER

ABSTRACT

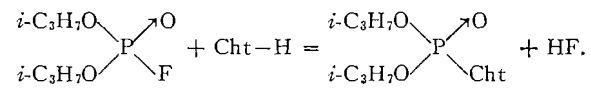
A study has been made of the kinetics of the α-chymotrypsin-catalyzed hydrolysis of methyl hydrocinnamate in the presence of various concentrations of methanol, of eserine, and of diisopropyl phosphorofluoridate (DFP). In 20% methanol the pH optimum, using a substrate concentration of 1.20×10^{-3} *M*, is 7.8; in pure water it is 8.3; and at intermediate pH's the optimum varies between these values. No inhibition was observed with eserine. In aqueous solution the character of the inhibition by DFP differs from that in alcohol solutions; the inhibition is of the competitive type, and the inhibition constant varies with pH in essentially the same manner as does the rate of the reaction. This result suggests that DFP interacts with the same active groups on the enzyme as are responsible for the hydrolysis of the substrate. A specific mechanism for inhibition is suggested.

INTRODUCTION

Studies of the influence of inhibitors on the rates of enzyme reactions have contributed considerably to an understanding of the mechanisms of enzyme action. In a recent paper (1) the kinetics of the α-chymotrypsin-catalyzed hydrolysis of methyl hydrocinnamate have been studied in the presence of hydrocinnamic acid, and it has been concluded that this inhibitor interacts with the enzyme at its active center, and that this active center contains a negatively charged group in addition to the acidic and basic groups actually responsible for the hydrolysis of the substrate.

In the present investigation this general line of attack on the chymotrypsin system has been extended to a study of the inhibition of the enzyme by methanol and by diisopropyl phosphorofluoridate (DFP). The main purpose of the work with methanol was to relate previous kinetic studies in 20% methanol–water mixtures with those that we are at present carrying out in pure aqueous solutions. Since 20% methanol solutions are far from physiological, and since (as shown below in the case of inhibition by DFP) the behavior is sometimes quite different in the two media, it seemed to be of interest to carry out kinetic studies in pure water and to relate the results to those obtained in the presence of alcohol.

The inhibition of α-chymotrypsin by DFP has been very thoroughly investigated (2, 3, 4, 5, 6, 7, 8, 9) but always, it would appear, using solvents containing propanol or other alcohols. Under the conditions previously employed the DFP reacts stoichiometrically with the enzyme, with the release of hydrogen fluoride, in accordance with the following equation:



In previous studies this reaction has appeared to proceed essentially to completion, although the inhibitor can be displaced from the enzyme by the action of electrophilic reagents such as hydroxylamine (10, 11, 12, 13, 14, 15, 16).

In our experiments in pure aqueous solutions we have found definite evidence for reversibility; the DFP indeed acts as a competitive inhibitor. The behavior has been

[1]*Manuscript received February 27, 1959.*

[2]*Present address: Army Research Office, Arlington, Virginia, U.S.A.*

investigated over a range of inhibitor concentrations and pH values, and conclusions drawn about the nature of the interaction between the DFP molecule and the active center of the enzyme.

EXPERIMENTAL

Materials

The enzyme and ester were as described in the previous paper (1), and the methanol was purified by distillation. The DFP was a pure sample supplied by the Defence Research Chemical Laboratories, Shirley Bay, Ontario.

Kinetic Procedure

The rate measurements were carried out using a pH-stat, manufactured by the Ole Dich Company of Copenhagen, together with a radiometer automatic titrator. Calomel and glass electrodes in the reaction mixture together with the titrator allowed the pH to be recorded, and when the pH fell below the designated value the pH-stat injected 0.02 *M* sodium hydroxide from a syringe micropipette into the reaction system. The pH-stat contains a rotating drum on which a record is made of alkali added vs. time; since the alkali is added in increments of about 10^{-4} cc, the record is extremely smooth and allows rates to be measured with great accuracy. All rates quoted are initial rates.

The reaction vessel was a small glass cell maintained at constant temperature (20.0° C) by circulation of thermostatically controlled water through an outer jacket. Fifteen milliliters of reaction mixture was employed in each case, and stirring was done magnetically. Various enzyme concentrations were employed, mostly in the region of 3×10^{-6} *M*. Owing to the limited solubility of the substrate in pure water, runs could not be done at concentrations higher than about 3×10^{-3} *M*; most were done at about 1.2×10^{-3} *M*. To avoid changes in ionic strength all runs were carried out at a sodium chloride concentration of 0.1 *M*. The total volume of sodium hydroxide solution added during a run never exceeded 3% of the total volume, and was usually less than this; the correction required is therefore very small.

RESULTS

Inhibition by Methanol

The work of Laidler and Barnard (17) showed that in 20% methanol there is a well-defined pH optimum at 7.8. In the present study runs were made at methanol concentrations varying from zero to 12%, and at pH values ranging from 7.5 to 8.5. The results are shown in Table I and Fig. 1, in which are included the rates measured by Laidler and Barnard (17) in 20% methanol–water mixtures.

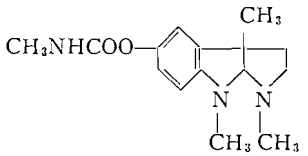
Lack of Inhibition by Eserine

Since eserine (physostygmine), which has the structure



is a very powerful inhibitor for cholinesterase, a study has been made of its action on chymotrypsin. Rate measurements have been made, using the same conditions as above, at pH values varying from 7.5 to 8.7 and at eserine:enzyme molar ratios of up to 40. There was no inhibition under any of the conditions employed.

Inhibition by DFP

In the majority of our experiments with DFP the procedure was to add the aqueous solution of the inhibitor to the enzyme solution which had previously been brought to the required pH by addition of sodium hydroxide; this addition was carried out slowly with the vessel connected to the pH-stat, so that no change in pH occurred, and the mixture was then allowed to stand, with stirring, for 10 minutes. The substrate was then added slowly and the reaction followed with the recorder.

Table II shows some typical results using this procedure. It is to be noted that even when the inhibitor was considerably in excess of the enzyme the inhibition is not complete; this was the case even when the inhibitor–enzyme ratio was as high as 4:1. This result is in marked contrast to that obtained by Jansen and co-workers (2), who used a propanol–water mixture as solvent and acetyl tyrosine ethyl ester as substrate. They found that when the molar ratio of DFP to enzyme was greater than unity there was

practically 100% inhibition. This observation was confirmed by us using their experimental conditions, but using pure water as solvent the inhibition was much less strong, as shown in Table II. We tentatively attribute this difference to the fact that the alcohol interacts with the HF formed and in this way displaces the equilibrium.

The interaction between DFP and chymotrypsin is thus reversible under our conditions. Experiments were also carried out to determine whether the behavior was competitive or non-competitive with respect to the substrate. This was done by determining the degree of inhibition at various substrate concentrations; the degree of inhibition was found to be reduced by increasing the substrate concentration, so that it is concluded that the behavior is competitive.

The above work was done by measuring initial rates. Further evidence that the inhibition is reversible and competitive under our reaction conditions was provided by studies of the time course of the reactions. Experiments were carried out in which the DFP and substrate were mixed first, after which the enzyme was added. It was found that the greater the substrate:inhibitor ratio the less was the falling-off of the rate as the reaction proceeded. It follows that the substrate competes with the inhibitor and can displace it from the enzyme surface.

Measurements were then carried out with a view to determining the association constant K_I between the enzyme and the inhibitor. In this series of experiments the enzyme and inhibitor were mixed first, after which substrate was added and initial rates measured using the pH-stat.

As discussed in the preceding paper, the inhibition by DFP can, at low inhibitor concentrations, be interpreted in terms of the mechanism

$$E+S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow{k_2} E+P$$

$$E+I \overset{K_I}{\rightleftarrows} EI.$$

Allowance must be made for the inhibitor that becomes bound to the enzyme, and the resulting kinetic equation is [12] of the preceding paper.

The data have been analyzed in terms of this equation, and plots similar to that of the preceding paper were obtained at all pH values. The resulting K_I values are shown in Table III. The variation of K_I with pH is shown in Fig. 2, which also shows the variation of rate with pH at a substrate concentration of 1.20×10^{-3} M.

DISCUSSION

The influence of methanol on the kinetics of the α-chymotrypsin – hydrocinnamic ester system was treated by Barnard and Laidler (18) as a dielectric constant effect. This may well be the case under the conditions of the previous experiments, in which the methanol concentration varied from 15 to 25%. However, the very marked inhibition brought about by small amounts of methanol, as found in the present work, is too great to be explained as a solvent effect, and is probably due to a specific interaction between the enzyme and the methanol. The methanol may well interfere with hydrogen bonding at the active center and in this way affect markedly the interaction between the enzyme and the substrate. The small shift in pH optimum is understandable on the same basis.

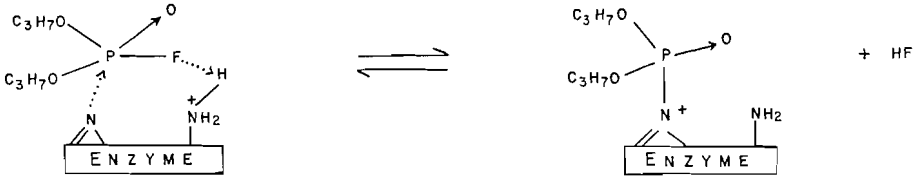
The complete lack of inhibition by eserine indicates that the negatively charged group on the chymotrypsin molecule (indicated by the work with hydrocinnamic acid (1)) is not able to interact with a positively charged group on the eserine molecule. This anionic site on chymotrypsin therefore differs in character from that on the cholinesterase molecule, which is markedly inhibited by eserine.

The most significant result of the present investigation is that the inhibitor constant K_i varies with pH in approximately the same manner as does the reaction rate itself. It follows from this that the reaction between the enzyme and DFP is of a similar nature to that between the enzyme and the substrate.

Previous work, including studies of the pH dependence of the rate (17, 19, 20, 21),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

has suggested that the hydrolytic action of the enzyme involves a simultaneous nucleophilic attack by an imidazole nitrogen atom and an electrophilic attack by a protonated ω-amino ion. It is postulated that a similar process occurs when the enzyme forms a complex with the DFP molecule, and the reaction may be represented as



This proposal relates to the reversible binding of the inhibitor. The irreversible inhibition may be due to the transfer of the $(C_3H_7O)_2PO$- group from the imidazole ring to a neighboring serine residue.

NOTE ON THE DETECTION OF AN APPARENT PHASE TRANSITION OF ADSORBED WATER ON POROUS VYCOR GLASS BY MEASUREMENTS OF DIMENSIONAL CHANGES[1]

C. HODGSON[2] AND R. MCINTOSH

ABSTRACT

A new technique is described for detecting possible phase transitions of adsorbates. The method involves the measurement of length changes of the solid, but only solids for which the surface-to-volume ratio is large could be used with the present form of instrument because of its moderate sensitivity. Using this measurement an apparent phase transition for water adsorbed on porous Vycor glass has been detected at approximately −22° C.

The detection of phase changes occurring in adsorbates on solids has been attempted in a variety of ways. Among these are the dependence of equilibrium pressure on temperature, the anomalies of carefully determined cooling curves, and dilatometric techniques (1, 2, 3). The experimental evidence is not always readily acceptable because of the methods employed.

Recently Puri, Singh, and Myer (4) reported the experimental detection of the formation of the "solid" phase for a variety of adsorbate–adsorbent systems by means of measurements of equilibrium pressures. These authors compared their data with predicted freezing point depressions based upon the Kelvin theory of capillary condensation and the assumption that the adsorbed "solid" would have the same equilibrium vapor pressure as that of bulk solid. This implies that the adsorbed "solid" is not under any negative pressure due to concave menisci, which could well be valid, and also that the adsorbed "solid" has the properties of bulk solid, which is unlikely. The validity of the latter assumption could be directly established by a measurement of equilibrium pressure over the adsorbate.

In view of the earlier work from this laboratory (5, 6), the contraction of the adsorbent system due to concave menisci seems reasonably well established. If the effects of menisci could be appreciably changed by forming the solid phase a marked expansion of the system might be expected. It should be noted that the change of molar volume of the adsorbate could also produce an effect. Discrimination between these two causes should be possible using an adsorbate for which the solid molar volume is less than that for liquid, e.g. benzene. A further reason to employ such an adsorbate is given below.

An expansion on lowering temperature, and a contraction through the same range of temperature when the system is rewarmed, have now been established for water adsorbed on porous Vycor glass (see Fig. 1). The phenomenon may exist for water contents below the beginning of the hysteresis loop, but experimental precision in determining length changes makes this speculation. However, because the extent of the anomaly increases markedly for water contents above the inception of the hysteresis loop the effect is probably associated with water condensed in the pores.

The Kelvin theory as applied by Puri, Singh, and Myer (4) does not rationalize our experimental observations since (*a*) the transition should be sharp as all the liquid menisci have the same radius of curvature for a given relative pressure, and (*b*) the transition temperature should depend upon the relative pressure corresponding to the adsorbate content.

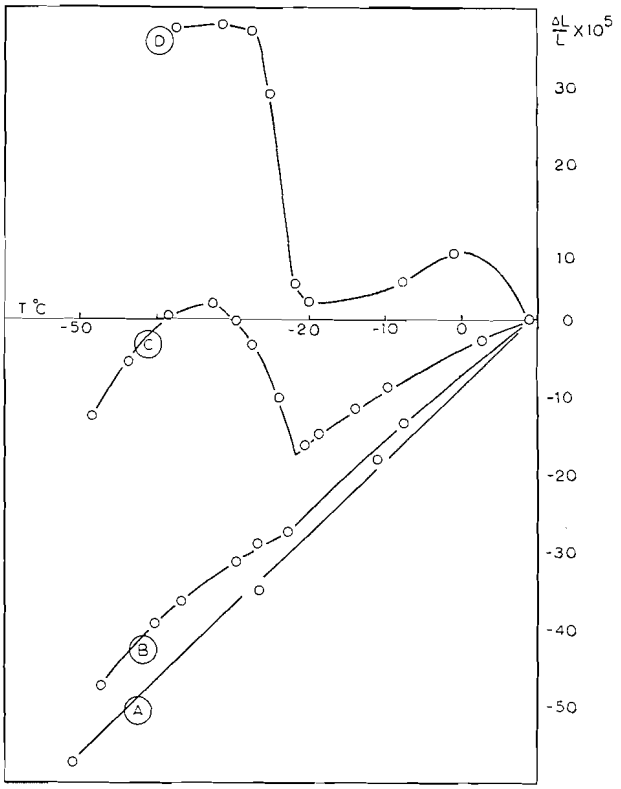

FIG. 1. Plot of fractional length change against decreasing temperature for water contents of:
A, 0.0221 g per g. C, 0.175 g per g.
B, 0.138 g per g. D, 0.195 g per g (desorption branch).

Curve "A" in Fig. 1 for a water content of 0.0221 g water per g glass, i.e. well below the beginning of the hysteresis loop, is approximately linear; curve "B" for a water content on the lower part of the adsorption branch of the hysteresis loop begins to show a slight anomaly at −22° C; while curves "C" and "D" show large anomalies. In the cases "C" and "D" the water contents are high on the adsorption and desorption branches respectively, but the evidence of transition again appears at −22° C in both cases. An unexplained hysteresis on reversing the direction of temperature change has been observed, but has been omitted from the figure.

For a given quantity adsorbed, the transition temperature of the adsorbed matter, relative to that of bulk material, depends upon the relative displacements of the molar free energy versus temperature curves of the adsorbed phases from those of the bulk. The assumption of concave menisci for the adsorbed "liquid" predicts a lowering of its curve relative to that for bulk liquid. The same assumption might be made in dealing with the "solid" phase except for the difficulty of obtaining the value of the surface free energy of the "solid". As pointed out above, the molar free energy of the adsorbed "solid" would be expected to be lower than that of the bulk solid but we have been unable to determine the low pressures with sufficient accuracy to establish the relative values. However, the known compressibility of Vycor-adsorbate systems (7), the negative pressure generated by the liquid menisci, and the measured expansion of about 20 μ in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the transition range (see system "C") combine to suggest that the effect of concave menisci has not been completely eliminated after the transition to "solid".

Whether or not effects due to menisci must be assumed for the "solid" adsorbate can be demonstrated. Hysteresis is caused, in the general view, by the shapes of the voids and the radius of curvature of menisci appropriate to the adsorption or desorption conditions. Thus hysteresis should vanish from an isotherm determined at a temperature where "solid" adsorbate is the stable form, provided that effects due to menisci do not exist for the "solid" phase. The equilibrium pressures for water are too low to make this test conveniently, but it might be possible using benzene. The necessary experiments are now being begun.

Full details of the experiments with water and an expanded discussion of the thermodynamic theory will be published at a later date.

The authors would like to express their thanks to Dr. M. H. Panckhurst for many helpful discussions. Grateful acknowledgment is also made to the National Research Council and to the Advisory Committee on Research, University of Toronto, for financial support of this work.

ULTRAVIOLET IRRADIATION OF PYRIMIDINE DERIVATIVES

III. INFLUENCE OF HYDROGEN CYANIDE ON THE PHOTOLYSIS[1]

A. M. Moore

ABSTRACT

The presence of HCN in concentrations up to 0.05 *M* in aqueous, buffered solutions of uracil, uridine, and 1,3-dimethyluracil has been shown to divert the normal course of the photochemical hydration reactions of these compounds as a result of photochemically induced combination between HCN and the pyrimidine derivative. A simple calculation indicates that HCN is more efficient than water in reacting with activated uracil molecules by a factor of about 10^3. The possible general significance of such nucleophilic addition reactions in the photochemistry of nucleic acids is discussed.

INTRODUCTION

Evidence has been accumulating during the past 5 years (reviewed in 11) to indicate that the principal initial photochemical reaction of aqueous solutions of uracil and cytosine, their nucleosides, and nucleotides consists of the addition of a molecule of water to the 5,6 double bond of the pyrimidine ring. The studies that have been reported in this connection have been made with dilute solutions of the pyrimidine compounds in water or in buffer. Although it is interesting to speculate from such evidence about the possible biological significance of the photochemical hydration reaction, it is important to remember that our knowledge of such reactions is very limited and that, in any case, the analogy between the simple aqueous systems that have been studied and the situation involved in the irradiation of complex nucleic acid molecules in vivo leaves something to be desired.

The present paper reports the results of a study of the influence of hydrogen cyanide, in low concentration, upon the course of the photochemical hydration of uracil and certain of its derivatives. The rather large effect observed makes it clear that the course of the hydration reaction may be greatly modified by the presence of other components of the solution.

The choice of hydrogen cyanide for these experiments was, of course, made not on physiological but on chemical grounds. The addition of hydrogen cyanide and other weak acids to conjugated mono-olefinic carbonyl compounds—in which class we may include uracil and its derivatives—has been extensively studied (cf. for example, ref. 3). Furthermore, the ready availability of carbon-14-labelled cyanide makes it a convenient tool for such study.

METHODS

General

Irradiations were carried out with the apparatus previously described (8) using low-pressure mercury arcs (wavelength mainly 2537 Å) as light source. The spectroscopic changes were determined on samples withdrawn after various irradiation times with either a Beckman DU or DK2 spectrophotometer.

The solutions which were irradiated contained the pyrimidine compounds (10^{-4} *M*), phosphate buffer (0.5 *M*, pH 7.0), various concentrations of HCN added from a stock solution of KCN (0.5 *M*) which was titrated to pH 7.0 with HCl just before use, and KCl,

[1]*Manuscript received April 16, 1959.*
Contribution from the Biology Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.
Issued as A.E.C.L. No. 831.

added as required, so that all solutions had the same total chloride concentration (0.05 *N*).

The uracil and uridine used in these experiments were obtained commercially. The former was recrystallized twice from water and dried at room temperature *in vacuo*. The 1,3-dimethyluracil was prepared from this purified uracil by the method of Davidson and Baudisch (2) and was purified by recrystallization from 95% ethanol, (m.p. 122° C; $\epsilon = 8600$ at 2660 Å). The KCN and KCl were reagent grade.

C^{14}-Labelled Compounds

The $HC^{14}N$ was prepared by the method of McCarter (4) starting with $BaC^{14}O_3$ provided by Atomic Energy of Canada Ltd. As the final stage of purification it was distilled into 0.1 *N* KOH in which form it was stored until required.

The uracil-2-C^{14} was the same preparation as that previously reported (6).

EXPERIMENTAL AND RESULTS

Effect of HCN *on the Irradiation of Uracil*

Solutions of uracil were irradiated in the presence of HCN in concentrations ranging from zero to 0.05 *M*. The results (Fig. 1) show that the presence of HCN accelerated the photochemical destruction of uracil in a striking manner. Unirradiated controls showed no change in spectrum on standing in the presence of 0.05 *M* HCN for periods up to 30 minutes.

It has been reported (13) that, without HCN, about 50% of the uracil destroyed by irradiation with filtered 2537 Å light may be regenerated by heating or by acid treatment. In our own experiments, using the unfiltered light from low-pressure mercury arcs, 42–43% of the loss in optical density (2600 Å) produced by irradiation was restored by heating (100° C; 5 minutes; pH 1), and this proportion was independent of the extent of decomposition for optical density decreases of 51 to 86%. On the other hand, after irradiation (6 minutes) in the presence of 0.05 *M* HCN until the optical density had decreased by 67%, the restoration on heating amounted to only 6.5%.

Effect of HCN *on the Irradiation of 1,3-Dimethyluracil*

The quantum yield for the photodecomposition of 1,3-dimethyluracil in simple aqueous solution is about twice as large as that for uracil (see 11), and the photodecomposition curves are correspondingly steeper. No effect of HCN on the rate of reaction was observed. However, after irradiation until the optical density had fallen to 8–9% of its initial value, it was found that the extent of recovery that ensued upon heating decreased as the concentration of HCN was increased. Thus, for HCN concentrations of 0, 0.005, 0.01, and 0.05 *M* the recoveries were 100, 93, 91, and 70% respectively. Without irradiation no effect of HCN (0.05 *M*) on the spectrum of 1,3-dimethyluracil was detectable.

Effect of HCN *on the Irradiation of Uridine*

Uridine, like uracil, was decomposed more rapidly in the presence of HCN (0.05 *M*) than in simple aqueous solution (Fig. 2). A sample which had been irradiated for 5 minutes in the presence of 0.05 *M* HCN was subsequently heated to promote regeneration of the uridine. The spectrum, after this treatment, indicated that partial recovery had occurred. The final optical density at 2610 Å was only about 38.9% of the density before irradiation. By contrast, uridine irradiated in the absence of cyanide gave 97.5% recovery on heating. This latter finding agrees with the observation of Rapport and Canzanelli (10) of virtually 100% regeneration of uridine after irradiation in water for short times.

Test for Spontaneous Reaction of Uridine with HCN

A solution 10^{-2} M with respect to uridine and 0.05 M with respect to HCN (pH 7) was allowed to stand at room temperature in a glass-stoppered flask. Samples were withdrawn at 0, 6, and 24 hours, diluted 1:100 with water, and their spectra determined. After 24 hours at room temperature a final sample was heated at 70° C for 20 minutes before dilution and examination. The absorption spectrum showed no significant change in any of these samples.

Irradiation of Uracil and Uridine in Presence of $HC^{14}N$

Although an effect of HCN on the course of irradiation was evident in the foregoing experiments, it was not certain that it involved actual combination between cyanide and pyrimidine. In order to settle this point three experiments were performed with labelled reagents. In one, uracil-2-C^{14} was irradiated along with ordinary cyanide; in the second, ordinary uracil was irradiated along with $HC^{14}N$; in the third, ordinary uridine was irradiated with $HC^{14}N$. The products of all three experiments were chromatographed together on paper using *n*-propanol:water, 70:30 by volume, as solvent, and the materials on the chromatogram were located both by autoradiography and by contact printing with ultraviolet (2537 Å) light (5) (Fig. 3).

In the experiments with labelled uracil and ordinary cyanide, three radioactive spots (R_f, 0.24, 0.50, and 0.62) were found in addition to uracil itself (R_f 0.58). Ordinary uracil and labelled cyanide gave four prominent radioactive spots. Three of these (R_f 0.24, 0.50, and 0.62) evidently corresponded to the same products as were obtained with labelled uracil. The other spot (R_f 0.36) was presumably due to a substance derived only from the $HC^{14}N$ since it was absent when the labelling was reversed.

The result of the experiments with uridine tends to support this conclusion. Here again there were four main radioactive spots. One spot corresponded in position to the R_f 0.36 component of the uracil–$HC^{14}N$ lane; the other three spots (R_f 0.19, 0.49, and 0.59) appear to be the analogues of the spots at R_f 0.24, 0.50, and 0.62 observed with uracil, the slightly lower R_f values corresponding to the fact that uridine itself has a slightly lower R_f than uracil, 0.51 compared with 0.58 in this experiment.

The individual lanes of these chromatograms were also counted in a gas flow proportional counter designed for counting chromatograms. Typical results are given in Fig. 4. The two components with R_f 0.24 and 0.62, respectively, in the uracil–HCN lanes were

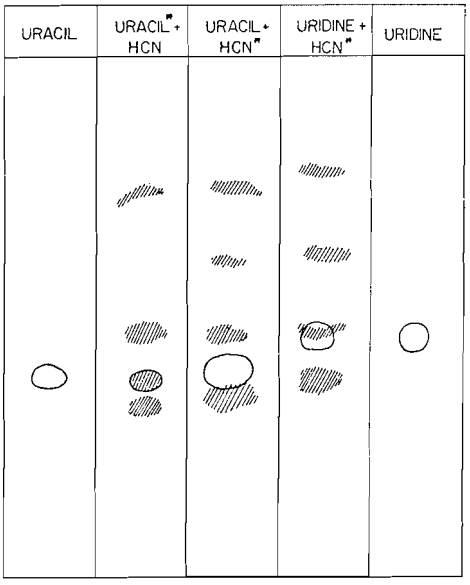

FIG. 3. Paper chromatogram of products of irradiation of pyrimidines in presence of HCN. C^{14}-Labelled reagents are indicated by asterisks in the column headings. Ultraviolet-(2537 Å)-absorbing spots are outlined; radioactive spots, located by autoradiography, are indicated by diagonal shading.

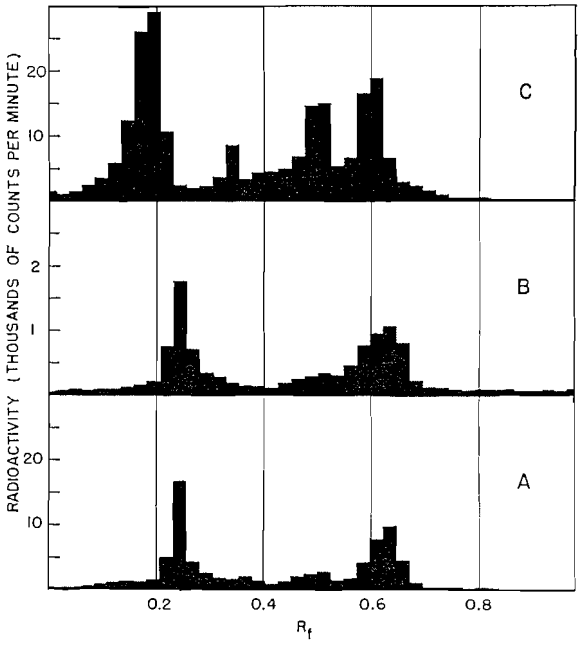

FIG. 4. Reaction products formed on irradiating pyrimidines (0.01 *M*) with HCN (0.05 *M*). 50-μl samples were chromatographed on paper(*n*-propanol:water 70:30 v/v)and the lanes were counted separately with a gas flow proportional counter. (A) Ordinary uracil and labelled HCN irradiated 6 hours. (B) Labelled uracil and ordinary HCN irradiated 4 hours. (C) Uridine and labelled HCN irradiated 3 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

approximately equal in amount and together accounted for 80 to 90% of the activity on the lanes in different runs, while the component with R_f 0.50 accounted for about 10% of the activity. In the uridine–HCN experiments the component of R_f 0.19 amounted to about 42% of the total activity and those with R_f 0.49 and 0.59 each contributed about 25% of the total activity.

The products of the uracil–HCN experiments were also chromatographed using *n*-butanol saturated with water as developing solvent. Irrespective of which component carried the C^{14} initially, the chromatograms exhibited three prominent radioactive components of R_f 0, 0.27, and 0.37. An additional minor component of R_f 0.11 was present in the experiments in which the HCN was labelled.

DISCUSSION

The experiments described in the foregoing pages show that when HCN is present during the irradiation of uracil, 1,3-dimethyluracil, or uridine, the activated pyrimidine reacts preferentially with it. This is made clearly evident by the extent to which the presence of the HCN reduces the yield of "reversible" product in all three cases, by the net increase in the rate of photochemical destruction of uracil and uridine, and by the chromatographic analysis of the products of irradiation using C^{14}-labelled reagents. It was also shown that the reactions with HCN were photochemical, not spontaneous.

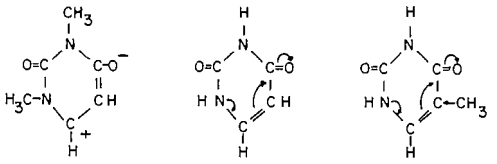
The fact that 0.05 *M* HCN largely suppresses the formation of the "reversible" product in the case of uracil suggests that HCN is particularly efficient in competing with water for the excited uracil molecules. This matter is considered in detail in the appendix to this paper in which it is estimated that the specific reaction rate of excited uracil molecules with HCN is greater than that with water by a factor of about 10^3.

The chromatographic experiments using C^{14} demonstrated that there were multiple products. Uracil and uridine each yielded three principal products of reaction with HCN, which account for about 90% of the total reaction in each case. The most likely product in the reaction with uridine would be the nitrile of 5,6-dihydroorotidine. Other possibilities include the isonitrile and its hydrolysis products. At present the evidence does not permit a decision regarding the identity of the observed products but it may be noted that the disappearance of the ultraviolet absorption maximum (ca. 2600 Å) suggests reactions that eliminate the 5,6 double bond of the pyrimidine ring.

These results with cyanide fit into a general scheme according to which nucleophilic addition may be considered the primary photochemical reaction of the uracil derivatives. Mulliken (9) and Braude (1) have developed the concept that the first electronic excited state of compounds such as the aromatic ketones may be represented as a zwitterion with the negative charge on the oxygen and the positive charge on a carbon at the opposite end of the conjugated chain. Wang (14) has applied this concept to the pyrimidines, suggesting that the absorption of an ultraviolet quantum by a molecule of 1,3-dimethyluracil, in water solution, converts it to the structure I, which then undergoes a typical nucleophilic addition reaction with water.

The original state of polarization of the pyrimidine ring would be expected to have a considerable effect on the probability of attaining such a structure. For example, comparing uracil (II) with thymine (III) the hyperconjugating effect of the methyl group at position 5 would be expected to oppose the development of a positive charge on the carbon at position 6 thereby making thymine less susceptible than uracil to nucleophilic addition at the 5,6 double bond. In fact, thymine is much more resistant than uracil to photodecomposition and does not appear to undergo the 5,6 hydration reaction (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.



I II III

Extending the concept one would predict that other nucleophilic agents might be induced to participate in the photochemical reactions of the pyrimidines. The results of the present experiments support this prediction. Observations have also been reported (7, 11) to indicate that ethanol, like water, undergoes reversible addition to the 5,6 double bond of 1,3-dimethyluracil and uracil under the influence of ultraviolet light.

There is thus a growing body of evidence supporting the view that photoinduced nucleophilic addition may be a general reaction of the substituted uracils. Not all additions of this sort will be as easily reversed as in the case of water; indeed the addition of cyanide appears to be irreversible. In considering the fate of pyrimidines irradiated in vivo we may expect to encounter other examples of a similar nature. Such reactions might be significant when pyrimidines are irradiated as constituents of nucleic acid molecules, where they are ideally situated to undergo reactions with neighboring pyrimidines or purines especially in structures like the Watson–Crick model of deoxyribonucleic acid (15).

APPENDIX

The absorption of ultraviolet light by a uracil molecule raises it into an excited state. Its excitation energy may then be dissipated by both physical and chemical processes. The principal physical process is likely to be the transfer of vibrational energy to the solvent water molecules during collisions. Fluorescence has not been observed and is, in any case, unlikely because the lifetime of excited molecules with respect to radiation is generally long compared with the interval between collisions with the solvent molecules. The chemical processes, on the other hand, are known to be of two kinds: one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

leading to a labile product that is capable of regenerating uracil, and another (or possibly more than one) leading to irreversible destruction of uracil. These two processes have roughly equal quantum yields (13).

The net effect of the physical and chemical processes of energy dissipation together with a fixed rate of energy input will be the establishment of an equilibrium concentration of excited molecules $[u^*]$ which will vary with time during irradiation. It will be convenient to refer to its initial value as $[u^*]_0$.

We may thus summarize the processes of energy dissipation:

[1] $$u^* + H_2O \xrightarrow{k_1} u.HOH \text{ (reversible chemical reaction)},$$

[2] $$u^* \xrightarrow{k_2} X \text{ (irreversible chemical reaction)},$$

[3] $$u^* + H_2O \rightarrow u + H_2O^* \text{ (physical deactivation by collision)}.$$

Equation [2] may represent several reactions, in which case k_2 will be the weighted mean rate constant for all the irreversible chemical processes. Reactions [1] and [2] are the only processes leading to a decrease in the concentration of uracil. Thus the total initial rate of disappearance of uracil will be $k_1.[u^*]_0[H_2O] + k_2[u^*]_0$ or, since the rates of reactions [1] and [2] are known to be roughly equal, we may represent the total initial rate approximately as $2k_1.[u^*]_0[H_2O]$.

In the presence of HCN we will have additional chemical reactions which may be lumped together as:

[4] $$u^* + HCN \xrightarrow{k_4} u.HCN \text{ (irreversible chemical reaction)}$$

where k_4 represents the weighted mean rate constant for the various reactions of u^* and HCN. We may neglect any effect of HCN on the purely physical processes of energy transfer for the concentrations of HCN employed in these experiments and, since this is still the principal mode of deactivation, the chemical quantum yields being of the order 0.01 mole per einstein, we may assume that $[u^*]_0$ will be essentially unchanged by the addition of the HCN. The initial rate of disappearance of uracil in the presence of HCN will therefore be $k_4[u^*]_0[HCN] + 2k_1.[u^*]_0[H_2O]$.

The ratio of the initial rates with and without HCN is:

$$\frac{k_4[u^*]_0[HCN]+2[k_1][u^*]_0[H_2O]}{2k_1[u^*]_0[H_2O]} = 1 + \frac{k_4[HCN]}{2k_1[H_2O]}.$$

In the experimental section the initial rate of disappearance of uracil during irradiation in the presence of 0.05 M HCN was found to be about 2.4 times the rate without HCN (Fig. 1), i.e.,

$$(k_4[0.05])/(2k_1[55.5]) = 1.4,$$

whence

$$k_4/k_1 = \text{ca. } 3100.$$

Even making allowance for the approximations involved in this derivation it appears that k_4 is larger than k_1 by a factor of the order of 10^3. This could explain the fact that the formation of the "reversible" product, 6-hydroxyhydrouracil, is almost completely suppressed in the presence of 0.05 M HCN.

CONDUCTANCE IN THE RANGE OF MEDIUM CONCENTRATION[1]

A. N. Campbell and R. J. Friesen

ABSTRACT

Equivalent conductances, densities, and viscosities of aqueous solutions of ammonium nitrate, of silver nitrate, and of lithium nitrate were determined at 25° C and at 35° C at concentrations ranging from 0.01 *N* to 1.0 *N*.

Experimental equivalent conductances have been compared with those calculated by the Wishaw–Stokes and Falkenhagen–Leist equations. Suitable choice of one parameter, the distance of closest approach, permits reproduction of the experimental data with an error of less than 0.5%. A study of the deviations of the calculated from the experimental conductances reveals that the distance of closest approach (so-called) varies appreciably with concentration and temperature.

In previous papers from this laboratory, we have reported our experimental results on conductances, densities, and viscosities of concentrated solutions (1). More recently, we have ventured into the field of extreme dilution (2). In the concentrated region, we have always compared our experimental results for equivalent conductance with the values calculated by means of the equations of Wishaw and Stokes (3) and of Falkenhagen and Leist (4); it is therefore not necessary to reproduce here these often-quoted equations. In the region of high concentration, the agreement between observed and calculated results is far from exact, and this is to be expected since neither of the above equations makes any assumptions other than those of the Debye–Hückel–Onsager treatment, and it is hardly to be expected that this relatively simple treatment would account for the behavior of the (presumably) complicated concentrated solutions.

We therefore decided to determine, with a high degree of accuracy, the conductances, densities, and viscosities, in a range of concentration varying from 0.01 *N* to 1.0 *N*, of those electrolytes with which much of our previous work has been done, viz. ammonium nitrate, silver nitrate, and lithium nitrate. The presumption was that agreement between calculated and observed conductances would be much better if the above equations have even approximate validity. We worked at the two temperatures, 25° C and 35° C. Our technique has been described frequently and need not be repeated here. The conductances of ammonium nitrate were corrected for hydrolysis by the method of Campbell and Bock (2); in the most dilute solution the correction amounts to 0.11 mho.

EXPERIMENTAL RESULTS

The experimental results are given in Tables I to VI. Three fundamental properties (density, specific conductance, and relative viscosity) and two derived properties (equivalent normality or molarity and equivalent conductance) are given for each solution.

DISCUSSION OF RESULTS

The densities are accurate to 0.002%, weight per cent concentration to 0.01%, and hence equivalent concentration to 0.015%. The accuracy of specific conductance measurements depends principally on the knowledge of the cell constant and this is known within 0.02%. Hence, equivalent conductances are within ±0.05% of their true values.

If $\mathring{a}$, the distance of closest approach in angstroms, is treated as the unknown in the equations of Falkenhagen–Leist and Wishaw–Stokes, it is possible to solve for this quantity, and to plot it as a function of concentration. This has been done in Figs. 1, 2, and 3, which are typical of many similar diagrams. In Fig. 1, $\mathring{a}$ of the Falkenhagen–Leist

NOTE: Column

I Rounded concentration, moles per liter.
II Experimental equivalent conductance.
III Experimental equivalent conductance multiplied by relative viscosity.
IV Calculated equivalent conductance, Falkenhagen equation, $\mathring{a}$ = 3.00 Å.
V Same as IV, except $\mathring{a}$ = 4.00 Å.

equation, for ammonium nitrate at 25° C, is plotted against log c; one curve refers to equivalent conductance without viscosity correction, the other to conductance multiplied by relative viscosity. In Fig. 2, the $\mathring{a}$ of the Wishaw–Stokes equation, for silver nitrate at 25° C, is plotted against log c. In Fig. 3, the Falkenhagen–Leist $\mathring{a}$, for lithium nitrate, is plotted against log c. It is apparent that $\mathring{a}$ is far from constant; often it appears to pass through a maximum. Theoretically, $\mathring{a}$ should be independent of concentration and even, perhaps, of temperature. In fairness, however, it should be pointed out that this method of treatment forces $\mathring{a}$ to absorb not only all the imperfections in the conductance equations but any experimental error as well.

Considering the Falkenhagen–Leist equation only, it appears that $\mathring{a}$ determinations in dilute solutions show greater scatter than in concentrated solutions. The reason for this is that $\mathring{a}$ appears only in the linear and quadratic divisors $(1+Ka)$ and $(1+1/2\sqrt{2}Ka+1/6K^2a^2)$, both of which approach unity with dilution. The more dilute the solution, the greater the uncertainty in the determination of $\mathring{a}$ from conductance.

Curves similar to Figs. 1, 2, and 3, for the higher temperature (35° C), show that above 0.1 N there is no doubt that two different $\mathring{a}$ values are necessary to reproduce the experimental results at the two temperatures.

Despite the apparent variations in $\mathring{a}$, however, if a suitable "best" value of $\mathring{a}$ is chosen, it is possible to reproduce the values of equivalent conductance, between 0.01 N and 1.0 N, within 0.5 mho, using either the Falkenhagen–Leist or the Wishaw–Stokes equation. This is shown in Tables IV, V, and VI, which are self-explanatory. Although it might seem that, on theoretical grounds, the Wishaw–Stokes equation is less acceptable than that of Falkenhagen–Leist, the agreement between calculation and experiment is better with the former equation: this we have observed before.

LIGHT ABSORPTION STUDIES

PART XIV. THE ULTRAVIOLET ABSORPTION SPECTRA OF PHENOLS[1]

J. C. Dearden and W. F. Forbes

ABSTRACT

A spectral analysis of benzene derivatives is extended to substituted phenols. The discussion emphasizes hydrogen bonding and steric effects which occur in phenols. Some of the phenolic absorption bands are ascribed to locally excited states.

INTRODUCTION

The effect of the hydroxy group on the electronic spectra of benzene derivatives is of interest for a number of reasons. First, phenols are known to give rise to various forms of hydrogen bonding, and hence the investigation of spectral effects which may be ascribed to hydrogen bonding affords further information concerning the nature of the hydrogen bond. Next, compounds which may be regarded as substituted phenols, for example flavones, frequently occur as natural products, and hence an understanding of phenolic spectra assists in the identification and quantitative estimation of such naturally occurring compounds. Lastly, previous papers in this series have attempted to analyze the spectra of benzene derivatives in terms of mesomeric and steric interactions, and it is therefore of interest to test these hypotheses on the observed spectra of phenols.

The ultraviolet spectra of a number of phenols have previously been investigated by other workers (1, 2, 3, 4, 5), but whenever convenient we have redetermined the spectra in order to ensure near-identical conditions.

THE SPECTRUM OF PHENOL

Phenols generally exhibit two absorption bands in the spectral region under investigation, that is, between 200 and 360 mμ. The band at longer wavelength is referred to as the *C*-band, and the band at shorter wavelength as the *B*-band. This assignment corresponds to the assignment for anilines and is based on similar reasoning (cf. ref. 6). The data for phenol are listed in Table I.

The bands are somewhat altered with change of solvent, and it has been shown by Coggeshall and Lang (3) that some of these spectral changes do not depend on *stable* hydrogen-bonded complexes, although there is evidence that some of the observed spectral changes are caused by some type of hydrogen bonding (5). Various forms of intermolecular hydrogen bonding are certainly possible, involving both the hydrogen atom of the hydroxy group and the oxygen atom. The wavelength displacement between the spectra in the vapor phase and in cyclohexane solution must also result from some solute–solvent interaction; but the latter interaction is unlikely to be associated with hydrogen bonding because similar displacements are observed for phenols and anilines (cf. ref. 6). In more concentrated solutions of phenol in cyclohexane, yet other spectral effects occur, presumably caused by intermolecular hydrogen bonding between phenol molecules (see ref. 4).

The fine structure of the *C*-band for phenol or anisole in cyclohexane or similar inert media is fairly characteristic of these chromophores, and can often be recognized in substituted, including sterically hindered, phenols (see also later section). The fine structure disappears if the phenolic species no longer contributes appreciably to the

observed spectrum; as for example in the *C*-band of *m*-nitro- or *m*-amino-phenol, where the compound absorbs preferentially as nitrobenzene or aniline (see Table II). The fine structure of the *C*-band also disappears for intramolecularly hydrogen-bonded molecules such as salicylaldehyde (see Table II), but the fine structure *is* noticeable for a number of orthosubstituted phenols even in ethanolic solution (see Table III). The most probable explanation seems to be that this fine structure is caused by vibrational sublevels and that a hydrogen bond may obscure this fine structure. Hence, the fine structure is frequently reduced if the phenol is associated with a solvent molecule by means of an intermolecular hydrogen bond (see Table I) or if the phenol molecule is intramolecularly hydrogen-bonded, but the fine structure does become evident if steric interactions hinder the formation of a hydrogen bond (see section on orthosubstituted phenols).

In sodium hydroxide solution the phenolic spectrum is radically altered, and the spectrum is assumed to correspond to the phenolate ion. For phenol in basic medium, compared with cyclohexane solution, a wavelength displacement of 24 mμ is observed for the *B*-band and a displacement of 16 mμ is observed for the *C*-band (see Table I). As expected, similar wavelength displacements are not observed for the spectrum of anisole (see ref. 7).

THE SPECTRA OF PARASUBSTITUTED PHENOLS

The spectra of substituted phenols are listed in Table II.

Table II lends support to the naming of the *B*-bands, that is, as bands corresponding to the so-called *B*-bands in benzene, acetophenone, nitrobenzene, benzoic acid, and

benzaldehyde, although the excited state of phenol may represent a locally excited state (see below). This follows because the gradual displacement of the band for a series of compounds such as phenols indicates that the main absorption band in phenol (and incidentally aniline) is of similar nature for the compounds listed in Table II. Further, as shown in Parts XI and XII (10, 11), this same band, for example in *p*-hydroxyacetophenone, can likewise be related to the *B*-band in acetophenone. This confirms the suggestion that *all* the above-mentioned absorption bands may be described as *B*-bands.*

The *B*-band in phenol is shown to be displaced to longer wavelength on parasubstitution. If the parasubstituent is electron-withdrawing, this displacement is greater, *qualitatively* related to the electron-withdrawing effect of the substituent, and the usual high-intensity band corresponding to an extended conjugated system is obtained. The wavelength displacements with respect to phenol in cyclohexane are parallel to the displacements in the aniline series (6). The *quantitative* relation observed between spectra of parasubstituted nitrobenzenes, acetophenones, and benzaldehydes (10, 11) is, however, absent for the displacements observed between parasubstituted anisoles and phenols, since in the latter example the straight line plot of the wavelength displacements does not pass through the origin (see following paper).

As will also be shown in the following paper and elsewhere, this difference can be rationalized by assuming that the *B*-band in phenol involves transitions which should be associated to an appreciable extent with locally excited states of type I. In support of this hypothesis the following may be cited: (i) the *B*-band of phenol at 210 mμ in

I

II

cyclohexane is displaced by about 7 mμ from the corresponding band in benzene, a wavelength displacement similar to that associated with the short-range interaction of the hydroxy group (see section on metasubstituted phenols); (ii) if phenol is assumed to absorb at longer wavelength, because hypothetical structures of type II contribute more appreciably to the electronic excited state, the above-mentioned relationship between wavelength displacements in parasubstituted anisoles and phenols becomes more nearly quantitative (see following paper); (iii) steric effects in the *B*-band of phenol are different from those which would be anticipated for a band associated with transitions to excited states of type II (see section on orthosubstituted phenols); (iv) the anomalous nature of the wavelength displacements for phenols has previously been noted by Doub and Vandenbelt (8); and (v) the bathochromic wavelength displacement obtained for the spectra of metasubstituted phenols compared with the spectrum of phenol when the metasubstituent is electron-withdrawing can be explained since an electron-withdrawing substituent has been assumed to facilitate resonance forms of type II (see ref. 6) and this therefore can account for the anomalous *bathochromic* wavelength displacement (see the discussion of the spectra of metasubstituted phenols).

**Alternatively, it has been proposed that the B-band of compounds like, for example, nitrobenzene should be related to the C-band of benzene, that is to the band occurring in benzene at ca. 250 mμ. Wepster (12), in the course of a discussion on steric effects, suggests that this latter argument is supported because for sterically hindered nitrobenzenes the absorption band in hexane remains near 250 mμ, that is, near the C-band absorption of benzene. Our interpretation is to regard this band in substituted nitrobenzenes as a nitrobenzene B-band, since the latter band also occurs near 250 mμ. We believe that our argument receives support from the absorption maxima of sterically hindered p-nitroanilines in ethanol. These maxima are all reported to occur near 380 mμ (12), that is, near the maximal absorption of p-nitroaniline, and the maxima for these examples do not therefore revert to a maximum near 250 mμ.*

It may be noted that this hypothesis assumes that the absorption of parasubstituted phenols such as *p*-cresol, hydroquinone, or *p*-bromophenol may still involve locally excited states of type I with both substituents exerting only a secondary effect. However, in compounds of this type, structures involving appreciable resonance interaction with at least one substituent seem more probable because the second substituent facilitates additional electronic interaction. The relevant structures may be represented by resonance forms of types III and IV, and consideration of structure IV also suggests that structure

III IV V

V cannot be ruled out. The actual contributing structures will depend on the relative over-all electronegativities of the two substituents in the ground and excited states. For phenols in basic media, a different type of resonance interaction presumably occurs in the excited state because of the replacement of the phenol group by the phenolate ion. Since this resonance interaction will be reflected in the maximal wavelengths it follows that the mesomeric interaction between the hydroxy group and the benzene ring is less than the mesomeric interaction between the amino group and the benzene ring. Extending the argument one step further, the maximal absorptions suggest an order of mesomeric interaction $PhO^- > PhNH_2 > PhOH > PhNH_3^+$.

The *C*-band shows the expected changes if the parasubstituent is electron-withdrawing, namely, with increase of mesomeric interaction the *C*-band usually becomes progressively less pronounced (see Table II and Ref. 13). If the parasubstituent is electron-donating, the fine structure of the *C*-band is frequently enhanced, the effect being most pronounced for the spectra of *p*-methyl- and *p*-fluoro-phenol in cyclohexane. It is worth noting that the fine structure of the *C*-band in these latter compounds is considerably more pronounced than for the corresponding meta isomers (see Table II). This is surprising since increased molecular symmetry is generally assumed to simplify the absorption spectra, and one would therefore have expected the fine structure of the *C*-band to be less pronounced in the para isomer than in the meta isomer.

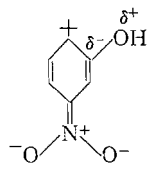
THE SPECTRA OF METASUBSTITUTED PHENOLS

In metadisubstituted benzene derivatives direct resonance interaction is ruled out by definition, and hence we would expect two *B*-bands corresponding to the two monosubstituted benzene derivatives (cf. refs. 6, 10, 11). Both these bands may be modified because of the other substituent, either by means of secondary short-range electronic interactions (cf. ref. 7), or possibly because of the buttressing effect (cf. refs. 14, 15). It is, of course, possible that one of the two *B*-bands may be obscured, either because of overlap by the other *B*-band or because of *A*-band absorption (cf. ref. 13), and these factors may also prevent a reliable band assignment for some examples. On the other hand, characteristic properties like the fine structure of the phenolic *C*-band assist in the band assignments.

These generalizations are illustrated for phenols in Table II. If the non-phenolic substituent is electron-withdrawing, it is found that the non-phenolic *B*-bands are normally displaced to longer wavelength on account of the secondary interaction of the hydroxy group, and this displacement is of the order of 7 mμ for a number of compounds (cf. ref. 7). This wavelength displacement of *ca.* 7 mμ suggests that the hydroxy group tends

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

to facilitate the absorption of the non-phenolic chromophore. The hypothesis may be illustrated by structures of type VI, by analogy with similar structures used in previous arguments (cf. ref. 10). In basic media the secondary interaction is considerably increased, because of the replacement of the hydroxy group by the O^--entity, and bathochromic wavelength displacements of up to 25 mμ (for *m*-nitrophenol compared with nitrobenzene) are observed.



VI

As has previously been noted by Lemon (2, cf. also ref. 7),* the effect of alkali on the spectra of hydroxybenzaldehydes and hydroxyacetophenones is greatest in the para isomers.

Our data also show that for the *B*-bands the displacement in the para isomers in basic media is much more pronounced. For example, the phenolic *B*-band of *m*-nitrophenol on passing from neutral to alkaline solution shows a wavelength displacement of 23.5 mμ (see Table II), comparable with the displacement of 24 mμ for phenol (see Table I). In the para isomer, presumably because appreciable primary resonance interaction occurs, the displacement of the *B*-band, caused by the addition of alkali, is *ca.* 90 mμ (see Table II). These observations may be of some practical importance. For example, if the *B*-band of an acetyl-substituted phenol on changing the solvent from neutral to basic medium does not show a bathochromic wavelength displacement greater than *ca.* 25 mμ, it may be assumed that no uninhibited, direct mesomeric interaction occurs between the hydroxy and acetyl groups.

The effect of the second substituent on the *phenolic B*-band is also illustrated for some of the compounds listed in Table II. Unfortunately, the relevant absorption band frequently occurs at too short a wavelength to be identified with certainty. However, for a few compounds the band assignment presents little difficulty, as for example, in *m*-nitrophenol where the phenolic absorption is appreciably displaced to longer wavelength (see Table II). This latter displacement has previously been ascribed to the nitrosubstituent facilitating the phenolic absorption (10). This bathochromic displacement for the phenolic *B*-band in compounds like *m*-nitrophenol may be related to the changes in the integrated absorption intensities for the infrared hydroxyl absorption in phenols, since the integrated absorption intensity for compounds like *m*-nitrophenol is greater than for phenol (17, 18), and since increased integrated absorption intensities, like bathochromic wavelength displacements in the *B*-band, may be related to increased mesomeric interactions.

It should be noted that when the metasubstituent is electron-withdrawing, the phenolic *B*-band appears sometimes to be moved to longer wavelength (see Table II), whereas the anilinic *B*-band under these conditions is moved to shorter wavelength (see ref. 6). More-

**Lemon arrives at this conclusion, although for the ortho and meta isomers he considers what we believe to be the C-band, whereas for the para isomers he considers the B-band. Another example of what we believe is an incorrect assignment is provided by the reported data for the intense o-hydroxyacetophenone band near 315–330 mμ, which has been described as a B-band (K-band, see ref. 16), whereas we would regard it as a displaced C-band.*

over, these wavelength displacements are parallel in the corresponding infrared bands. For example, in *m*-nitroaniline compared with aniline (19), the NH_2 stretching vibration is moved to higher frequency, that is to shorter wavelength, whereas the OH stretching vibration in *m*-nitrophenol compared with phenol is moved to lower frequency. These anomalous wavelength displacements for phenols can be explained by assuming that the *B*-band of phenol occurs at unusually *short* wavelength because of the contribution of locally excited states of type I (see section on parasubstituted phenols). In this way, the above-mentioned comparisons involving phenol are rendered invalid, in the sense that metasubstituted phenols compared with hypothetical phenol molecules containing more similar contributions of locally excited states than aniline may still afford the anticipated hypsochromic wavelength displacement.

If the above assignments are accepted, examination of the relative intensities of the two *B*-bands suggests that the phenolic *B*-band absorption usually occurs preferentially. For example, in *m*-nitrophenol, compared with the two monosubstituted parent compounds, the nitrobenzene *B*-band absorption decreases, whereas the phenolic absorption increases in intensity. A similar relative intensity increase is observed for the aniline *B*-band in *m*-nitroaniline (6), although the relative increase in the intensity of the phenolic *B*-band is less than for the anilinic *B*-band. These observations may be rationalized by a converse of the mechanism postulated to account for the increased extinction coefficient in associated benzoic acid molecules (see ref. 20). There it was shown that an electron-withdrawing substituent, in the absence of direct resonance interaction, gives rise to an increased maximal extinction coefficient. Likewise, in metasubstituted anilines or phenols the nitro group may be assumed to increase the probability of the phenolic or anilinic transition, and conversely, the *m*-hydroxy and the *m*-amino substituents may be assumed to have the effect of relatively *weakening* the nitrobenzene absorption, the effects being more pronounced for the meta-amino substituent, which donates electrons more effectively.

Some of the *C*-bands in metasubstituted phenols show the expected changes. For example, if the metasubstituent is electron-withdrawing the *C*-bands are enhanced compared with the *C*-bands in para isomers (cf. ref. 13).

THE SPECTRA OF ORTHOSUBSTITUTED PHENOLS

The *B*-bands of the ortho isomers frequently resemble the *B*-bands of the meta isomers. For example, for *o*-nitrophenol in 0.1 *N* NaOH where intramolecular hydrogen bonding is ruled out, the nitrobenzene band at 282 mμ, $\epsilon = 4300$, is similar to the nitrobenzene *B*-band in the meta isomer which occurs at 291 mμ, $\epsilon = 4500$ (9). The phenolic *B*-band is considerably reduced in intensity and occurs in the ortho isomer as an inflection at 250 mμ, $\epsilon = 5000$, whereas in the meta isomer it occurs at 251.5 mμ, $\epsilon = 11{,}000$ (9, and see Table II). For *o*-nitrophenol in basic solution there is therefore no evidence for appreciable resonance interaction. Similar spectral effects are observed in other examples listed in Table II, and the examples of 2,4- or 2,4,6-substituted nitrobenzenes when an ortho-alkyl substituent does not contribute to the direct resonance interaction, have previously been mentioned in this paper in the discussion of parasubstituted phenols. Effects of this type may also be noted in the *B*-bands of a number of parasubstituted phenols in neutral solution when, on introduction of two *t*-butyl groups in the ortho-positions, no appreciable wavelength displacement is observed, but a decreased extinction coefficient indicative of steric interactions is obtained (21).

This absence of resonance interaction may be ascribed to steric interactions, and steric interactions are also indicated by a number of other physical properties, such as the decreased intermolecular hydrogen bond formation in sterically hindered phenols (3, 15, 22, cf. also 23), and more generally by the failure of sterically hindered phenols to exhibit normal phenolic properties (cf. for example, ref. 21). These observed steric effects may be associated, at least partly, with the two unshared electron pairs on the oxygen atom, since a steric effect caused entirely by the more distant hydrogen atom of the hydroxy group would not account satisfactorily for the observed steric effects (cf. ref. 24, p. 360). The *B*-band in orthosubstituted phenols does not normally undergo a pronounced wavelength displacement even if the orthosubstituents are bulky as in diortho-*t*-butylphenol (see Table III). The absence of this spectral effect, characteristic of steric inhibition of resonance in many other conjugated systems, has already received an explanation (see section on parasubstituted phenols, which tentatively ascribes the

phenolic absorption to transitions involving locally excited states). Steric interactions are, however, indicated in the ultraviolet spectra by the *absence* of the usual wavelength displacements between solutions in cyclohexane and ethanol. That is, whereas between solutions of phenol in cyclohexane and ethanol a wavelength displacement of 8 mμ is observed in the *B*-band (see Table I), no such displacement is observed for solutions of strongly sterically hindered phenols (see Table III for the spectra of various orthosubstituted phenols in cyclohexane and ethanol). Our explanation, following the suggestion of Coggeshall and Lang (3), is to ascribe a reduced wavelength displacement to steric interactions inhibiting solvent–solute interactions between phenol and solvent molecules.

Yet another spectral effect which may be associated with steric interactions is the progressive *increase* in extinction coefficient of the *C*-band for the spectra of orthosubstituted phenols in alkaline solution with increased size of the orthosubstituent (cf. ref. 13). The relevant *C*-band data are listed in Table IV, and Table IV also shows that the *B*-bands are not appreciably affected under these conditions.

*Solution contains *ca.* 1% ethanol.

Next, in neutral solution, there is evidence for intramolecular hydrogen bonding, and the spectral effects ascribed to hydrogen bonding are more pronounced for orthosubstituted phenols than for the corresponding anilines (cf. ref. 6). The evidence is obtained by comparing the *B*-bands of a number of orthosubstituted phenols with the *B*-bands of the meta isomers, where the former *B*-bands show a bathochromic wavelength displacement accompanied by an increased absorption intensity.

Since these spectral changes are much more pronounced in orthosubstituted phenols than in the corresponding anisoles (see following paper) it is assumed that the spectral changes must be caused, at least partly, by intramolecular hydrogen bonding. Evidence for an intramolecular hydrogen bond in, for example, *o*-nitrophenol is also provided by the appreciably displaced hydroxyl band in the infrared region at 3240 cm^{-1} for *o*-nitrophenol compared with the band at 3590 cm^{-1} for the meta and para isomers (25, 26, cf. also refs. 27, 28, 29). Further evidence is provided by the C–H bending frequency at 748 cm^{-1} for *o*-nitrophenol (30).

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP500 spectrophotometer. For each compound at least two independent sets of observations were made. Some of the spectra have previously been described in this series.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12

The phenols were mostly commercial materials, purified by distillation or recrystallization until their boiling points or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) or commercially available absolute ethanol. The spectra of the aminophenols and dihydroxybenzenes were determined as quickly as possible to prevent oxidation. With this end in mind, the air in the flasks containing these solutions was also replaced by nitrogen.

ACKNOWLEDGMENTS

The authors are greatly indebted to Miss Florence Jackman for very competent technical assistance in the determination of some of the spectral data. They also wish to thank the Fisheries Research Board of Canada for financial support, since the major part of this work was carried out under a contract between the Fisheries Research Board of Canada and Memorial University of Newfoundland. The authors further acknowledge the general assistance of the National Research Council in support of these studies.

LIGHT ABSORPTION STUDIES

PART XV. THE ULTRAVIOLET ABSORPTION SPECTRA OF ANISOLES[1]

J. C. Dearden and W. F. Forbes

ABSTRACT

Anisoles, compared with phenols, possess similar spectral properties, except that properties determined mainly by the hydrogen atom of the hydroxy group are modified. In this way, comparison of the ultraviolet absorption spectra of phenols and anisoles permits, for example, the study of the spectral effects of hydrogen bonding and the study of steric interactions involving the hydroxy and methoxy groups.

INTRODUCTION

In previous parts of this series (1) it was found that ultraviolet *B*-band spectra can often be interpreted by assuming that the *B*-bands of ultraviolet spectra are determined predominantly by mesomeric and steric interactions. Phenolic spectra, which were examined in the previous paper (1*a*), were found to be of interest since they provide good examples of secondary interactions such as intramolecular hydrogen bonding. The phenolic *B*-band is also of interest, since it is believed to be determined by so-called locally excited states; that is, in the absence of appreciable direct mesomeric interaction between the hydroxy group and the benzene ring, the benzene ring is assumed to determine the observed absorption band with the hydroxy group exerting only a secondary influence. The anisole spectra provide an evident extension of this investigation, and we have therefore determined, or redetermined, a number of the relevant anisole spectra.

THE SPECTRUM OF ANISOLE

Table I lists the main absorption maxima of anisole in the region 210–330 mμ.

Anisole in cyclohexane absorbs maximally at 220 mμ, that is, at longer wavelength than the corresponding absorption of phenol at 210 mμ (1*a*). We deduce from this that the methoxy group does not merely exert a "secondary" interaction on the benzene ring, as has been postulated for the spectrum of phenol, since such a secondary interaction would cause a wavelength displacement of only *ca.* 7 mμ relative to benzene (see ref. 1*a* and section on metasubstituted anisoles). This in turn suggests that some additional mesomeric interaction occurs between the methoxy group and the benzene ring or, in other words, that the transitions leading to the *B*-band in anisole involve a smaller proportion of locally excited states compared with the transitions leading to the *B*-band in phenol.

The important question arises why locally excited states should preferentially contribute to this absorption in phenol. One possible explanation is that in phenol the O—H bond is aligned approximately parallel to the plane of the benzene ring (I*a*), whereas in anisole, partly for steric reasons, the O—CH_3 bond is directed out of the plane of the benzene ring as in I*b*. To satisfy this explanation, it must further be assumed that this direction of the O—CH_3 bond as in I*b* favors the overlap of the unshared electrons of the oxygen atom with the π-electrons of the benzene ring, and that in this way additional resonance interaction is possible. This explanation is consistent with the observation that the spectrum of phenol in ether or ethanol solution, which presumably involves the attachment of a solvent molecule to the phenolic hydrogen atom and hence causes an

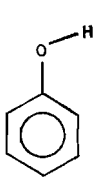
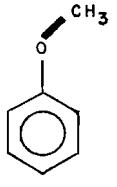
increase in the effective size of the hydroxy group, shows maximal absorption at or near 218 mμ (1*a*), namely much like that of anisole in most solvents (see Table I). This therefore may imply that under these conditions structures such as I*a*, partly for steric reasons, tend to change into structures of type I*b* which facilitate orbital overlap and which tend to give rise to a maximal absorption near 218 mμ.*



I*a*



I*b*

The *C*-band fine structure, which is observed in cyclohexane solution for the spectra of both anisole and phenol, is evident, though to a lesser extent, for anisole in aqueous and alcoholic solution. It almost disappears for phenol in the latter solvents (1*a*). This reduced fine structure in the *C*-bands of both anisoles and phenols is ascribed to solute–solvent interactions (cf. ref. 1*a*). A striking difference between the spectra of phenol and anisole is the different behavior of both *B*- and *C*-band maxima on changing the

**For a full discussion concerning the conformation of the methoxy group, with particular emphasis on the tendency of the methoxy group to be coplanar with the benzene ring, see Wheland, G. W. Resonance in organic chemistry. John Wiley & Sons, Inc., New York. 1955. pp. 238–243.*

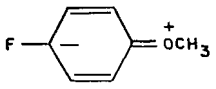
solvent from neutral to basic; the phenolic bands are appreciably displaced to longer wavelength (1*a*), while addition of alkali to an aqueous solution of anisole only slightly displaces the *B*-band (by 4 mμ), and does not displace the *C*-band (see Table I).

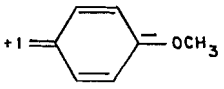
THE SPECTRA OF PARASUBSTITUTED ANISOLES

As in previous parts (1), the spectra of paradisubstituted benzene derivatives may be classified into spectra of compounds when both substituents are electron-donating, or electron-withdrawing, and into spectra of compounds when one substituent is electron-donating and the other electron-withdrawing. For the former group, the spectrum of the disubstituted benzene compound usually resembles the spectrum of the monosubstituted parent compound, that is, the transition involves locally excited states with the second substituent exerting only a secondary influence on the spectrum. If in the former group, in addition, the two substituents are dissimilar, the spectrum of the monosubstituted compound will involve the substituent which interacts preferentially with the benzene ring. These generalizations are illustrated by the data in Table II.

The earlier *B*-band spectra of parasubstituted anisoles listed in Table II usually show the anisole-type spectrum. Exceptions are provided when the methoxy substituent does not preferentially interact with the benzene ring. For example, for *p*-aminoanisole, and incidentally for the meta and ortho isomers also, in non-acidic media an aniline-type *B*-band is obtained, and for *p*-iodoanisole an iodobenzene-type spectrum is obtained. This may be illustrated by assuming structures of type II or III to be involved preferentially in the transitions leading to the spectra of *p*-fluoro- and *p*-iodo-anisole.*



II



III

If the parasubstituent is electron-withdrawing (see lower part of Table II) the anticipated appreciable wavelength displacements, accompanied by intensity increases, are observed in the *B*-band. These wavelength displacements are shown in Fig. 1 to be parallel to the wavelength displacements obtained for phenols. The electron-withdrawing substituent may be visualized as facilitating the formation of resonance forms of type IV.

**The second substituent will in this way exert only a secondary effect on the B-band. Thus the location of the B-band remains essentially unaltered between p-fluoroanisole and anisole. Fluorobenzene, by contrast, shows the following, quite different, B-band absorption in cyclohexane solution, that is, λ_{max} 204 mμ, ε = 6600. Iodobenzene, on the other hand, shows a B-band reasonably similar to that of p-iodoanisole, that is: λ_{infl} 223 mμ, ε = 9400; λ_{max} 227 mμ, ε = 12,700; and λ_{max} 232 mμ, ε = 12,000 (see also Table II). Moreover, the bathochromic B-band wavelength displacements reported by Schubert et al. (3) on determining the B-bands in the vapor phase and in cyclohexane solution are 2.8 and 4.6 mμ for p-fluoroanisole and anisole respectively, while there is a hypsochromic wavelength displacement of 2 mμ for fluorobenzene. Therefore in only one of the two examples will the "second" substituent be a halogen atom, and it follows from this that care must be taken in deducing the order of electron release for the halogen atoms from the spectra of para-halogen-substituted anisoles (cf. refs. 3, 4).*

It may also be noted that the C-band spectral changes do not entirely bear out this analysis, since the C-band changes suggest a different pattern for p-fluoroanisole and the other three para-halogen-substituted anisoles. However, although we are not strictly concerned with C-band changes at this time, it may be observed that the location of the C-band maxima are closer to the location of the C-band maxima in anisole than to the location of these maxima in fluorobenzene (λ_{max} 246.5 mμ, ε = 350; λ_{max} 252 mμ, ε = 750; λ_{max} 258 mμ, ε = 1100; and λ_{max} 264 mμ, ε = 1050), and the C-band fine structure in p-fluoroanisole is also obtained for para-alkyl-substituted anisoles and cannot therefore be associated specifically with the fluoro substituent. In addition, the iodobenzene C-band fine structure (λ_{infl} 246 mμ, ε = 590; λ_{max} 251 mμ, ε = 670; λ_{max} 255.5 mμ, ε = 710; and λ_{max} 261 mμ, ε = 620) is similar to that in p-iodoanisole (see Table II).

*B-Band assignment doubtful. †In aqueous solution. ‡In 0.1 N HCl. §In n-hexane solution. ‖These values should replace those previously reported (see ref. 1*c*). ¶Ref. 2.

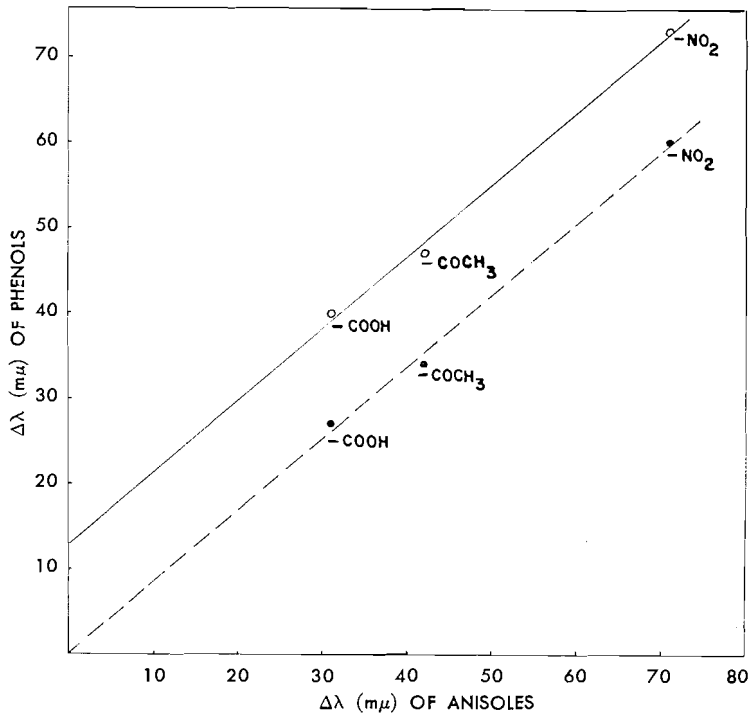

FIG. 1. Wavelength displacements ($\Delta\lambda$) of the *B*-band obtained in neutral inert solution on introducing an electron-withdrawing parasubstituent in anisole and phenol. (Values from this study, and ref. 1*a*.) The dotted line shows the plot if the phenolic absorption at 223 mμ is used as the reference compound (see text). ○ $\Delta\lambda$ for phenols taken as (λ_{max} −210). ● $\Delta\lambda$ for phenols taken as (λ_{max} −223).

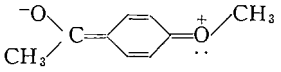
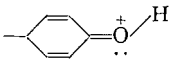
The appreciable wavelength displacements for parasubstituted phenols are calculated with reference to a hypothetical absorbing species absorbing maximally at 223 mμ, and



IV



V

involving in its transitions structures of type V to an appreciable extent. If, on the other hand, the phenolic absorption in cyclohexane at 210 mμ is assumed to involve preferentially electronic excited states of type V and is taken as the reference point, then the straight line, as shown in Fig. 1, does not pass through the origin. The data thus lend support to the suggestion made in the previous paper concerning the supposed absence of appreciable mesomeric interaction for phenol in cyclohexane solution (see section on the spectrum of anisole and ref. 1*a*).

The *C*-bands of para- and meta-substituted anisoles undergo the previously noted general changes (1*e*). Moreover, the *C*-band spectral changes are similar for para- and meta-substituted phenols and anisoles (see previous paper).

THE SPECTRA OF METASUBSTITUTED ANISOLES

The *B*-bands of meta- and ortho-substituted anisoles are again classified into *B*-bands associated with the anisole chromophore, and into *B*-bands associated with the other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

monosubstituted benzene chromophore (cf. refs. 1*a*, *b*, *c*, *d*). The two types of *B*-bands are in this way observed in a number of meta- and ortho-substituted anisoles.*

Using this classification, it may first be noted that the "secondary effect" of the methoxy group on the *B*-band associated with the non-anisole, monosubstituted benzene chromophoric system is as anticipated. That is, the non-anisole *B*-bands are generally bathochromically displaced by *ca.* 7 mμ for compounds where the second substituent is electron-withdrawing (see Table II and cf. ref. 6), and it is thus assumed that the overall effect of the methoxy group facilitates the formation of electronic excited states.

The effect of the second substituent on the anisole *B*-band is very similar to the effect of the same substituent on the phenolic *B*-band. Both the phenol and anisole *B*-bands are frequently displaced to longer wavelength if the second substituent is electron-withdrawing, and the displaced *B*-bands are sometimes more intense than for the parent compounds, namely phenol or anisole. For compounds of this type the observed intensities of the *B*-bands also suggest that the anisole *B*-band absorption occurs preferentially (see Table II). This again supports the previously noted generalization that, in the absence of direct primary resonance interaction, an electron-withdrawing substituent tends to cause an intensity increase (see refs. 1*a*, 1*d*, 7).

THE SPECTRA OF ORTHOSUBSTITUTED ANISOLES

Comparing the *B*-bands of orthosubstituted phenols and anisoles it is found that frequently only the *B*-band of the phenol is appreciably intensified and displaced to longer wavelength. Other secondary interactions may evidently contribute to these observed spectral changes but the data certainly provide qualitative evidence for intramolecular hydrogen bonding, since the above-mentioned spectral changes are most pronounced if a strong intramolecular hydrogen bond is expected. Qualitative evidence for intramolecular hydrogen bonding may also be obtained by comparing the spectra of ortho isomers with those of the meta isomers; for intramolecularly hydrogen-bonded phenols the bathochromic wavelength displacement and intensity increase in both *B*- and *C*-bands are greater between the ortho- and meta-substituted phenols than between the corresponding anisoles. A fuller discussion of semiquantitative methods, which may be used to estimate the strength of the intramolecular hydrogen bond in orthosubstituted phenols and related compounds, will be presented in a separate communication.

Steric effects have, by implication, been noted in the section on the spectrum of anisole since it has been tentatively assumed that, partly for steric reasons, the methoxy group in anisole is directed out of the plane of the benzene ring. It follows that an orthosubstituent would not be expected readily to cause an appreciable wavelength displacement or intensity decrease, since the methoxy group is already dislodged from the plane of the benzene ring. In fact, even for bulky orthosubstituents, the maximal *B*-band absorption still occurs close to 220 mμ (see Table III). It should be noted, however, that for compounds such as 2,6-dimethylanisole or *tert*-butoxybenzene appreciable spectral changes can be discerned in the *C*-band (see Table III and ref. 8). For example, the *C*-band of 2,6-dimethylanisole as shown in Table III is considerably less intense than the *C*-band

**Only one B-band is usually observed for the para isomer, although a band that may, incorrectly, be assumed to be a second B-band occurs in compounds like p-nitroanisole at λ_{max} 227 mμ, ε = 7000 (in water). However, this absorption band, which also occurs in p-nitrophenol at λ_{max} 227 mμ, ε = 7000 (in water), is not a B-band, since in basic solution this band of p-nitrophenol still occurs at λ_{max} 226 mμ, ε = 6500 (in N NaOH) (5). If the absorption band were a B-band, addition of alkali would appreciably displace the band to longer wavelength (1a) and because this is not so, the absorption bands near 227 mμ in p-nitrophenol and p-nitroanisole are both assumed to be A-bands.*

in 3,5-dimethylanisole. The latter compound in cyclohexane solution absorbs as follows: λ_{max} 219–220 mμ, ϵ = 7250 (*B*-band); λ_{infl} *ca.* 264 mμ, ϵ = 900; λ_{infl} *ca.* 268 mμ, ϵ = 1250; λ_{max} 271 mμ, ϵ = 1450; λ_{infl} *ca.* 274 mμ, ϵ = 1250; and λ_{max} 278 mμ, ϵ = 1700. 2,5-Dimethylanisole also absorbs similarly, thus: λ_{max} 219 mμ, ϵ = 7200 (*B*-band); λ_{infl} *ca.* 266 mμ, ϵ = 1400; λ_{infl} *ca.* 270 mμ, ϵ = 1900; λ_{max} 273 mμ, ϵ = 2100; and λ_{max} 278.5 mμ, ϵ = 2150.

Table III lists the spectra of some orthosubstituted anisoles. The data show that changing the solvent from cyclohexane to ethanol has practically no effect on the observed *B*- and *C*-bands of many of these compounds. This absence of solvent effect has previously been noted for orthosubstituted phenols. Both phenol and anisole data are therefore consistent with the explanation put forward in the previous paper, that a large orthosubstituent prevents solvent–solute interaction between the unshared electron pair of the oxygen atom and the ethanol molecules.

The frequent similarity of the spectra of the ortho and meta isomers, which has been observed for phenols (1*a*), is also observed for the anisole analogues. However, there are some significant differences. Thus, the intensity decreases which may be caused partly by steric interactions are frequently more pronounced for anisoles. For example, comparing the nitrobenzene *B*-bands of the meta and ortho isomers of nitrophenol and nitroanisole, it is found that the decrease of the ϵ_{max} values in the ortho isomers is more pronounced for *o*-nitroanisole. Unfortunately, this example does not lend itself to unambiguous analysis since in neutral solution intramolecular hydrogen bonding affects the *B*-band of *o*-nitrophenol, while in basic solution the effective size of the methoxy group is compared with that of the O^- group rather than with the effective size of the hydroxy group. However, it seems certain that a steric factor contributes to the relatively low ϵ_{max} value of *o*-nitroanisole in various solvents (see Table II). Supporting evidence for the

For personal use only.

ability of the methoxy group to cause steric inhibition of resonance is further provided by the spectrum of 2,6-dimethoxynitrobenzene in cyclohexane solution (λ_{max} 276 mμ, ϵ = 1700) which shows a yet more pronounced decrease in intensity for the nitrobenzene *B*-band. Further, for ortho-halogen-substituted phenols and anisoles, the ϵ_{max} values of the ortho-fluoro and ortho-chloro compounds are *smaller* for the phenols than for the anisoles, but for the ortho-bromo compound, that is, for a larger orthosubstituent, the ϵ_{max} value of the orthosubstituted phenol is *greater* than that of the anisole (see Table II and ref. 1*a* for the relevant *B*-bands; for evidence of steric interactions because of the methoxy group, see also refs. 9, 10).

In orthosubstituted anisoles there is also evidence that large steric interactions contribute to more pronounced spectral changes. For example, in 2,6-dimethylanisole a hypsochromic wavelength displacement, indicative of steric interaction, is obtained in the *B*-band, and the *C*-band is very considerably reduced in intensity (see Table III). It may finally be noted that in many hindered phenols and anisoles, that is, in compounds where *C*-band fine structure is evident in both cyclohexane and ethanol solutions, a relative decrease in intensity occurs for the long wavelength peak of the *C*-band in ethanol solution (see, for example, in Table III the *C*-bands of *o-tert*-butylanisole in cyclohexane and ethanol solution).

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using Unicam SP 500 spectrophotometers. For each compound at least two independent sets of observations were made. Some of the spectra have previously been described in this series and elsewhere. Whenever possible, the anisole spectra were determined under conditions identical with those under which the phenolic spectra had been determined. Frequently, but not always, our data were in good agreement with recent values reported by other workers (cf. refs. 4, 5, 11, 12, 13).

The anisoles were mostly commercial materials, purified by distillation or recrystallization until their boiling points or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) or commercially available absolute ethanol.

ACKNOWLEDGMENTS

The authors are greatly indebted to Mr. D. L. Coffen for very competent technical assistance in the preparation of some of the compounds.

They also wish to thank the Fisheries Research Board of Canada for financial support, since the major part of this work was carried out under a contract between the Fisheries Research Board of Canada and the Memorial University of Newfoundland. The authors further acknowledge the general assistance of the National Research Council in support of these studies.

PHOTOCHEMICAL SEPARATION OF MERCURY ISOTOPES

IV. THE REACTION OF $Hg^{202}6(^3P_1)$ ATOMS, PHOTOEXCITED IN NATURAL MERCURY VAPOR, WITH METHYL CHLORIDE AND ISOPROPYL CHLORIDE[1, 2]

K. R. OSBORN[3] AND H. E. GUNNING[4]

ABSTRACT

A detailed investigation has been made of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in natural mercury vapor (Hg^N), with methyl chloride, at room temperature. Data are also reported on the reaction with isopropyl chloride as substrate. Hg^{202} enrichment in the calomel product is taken as evidence of its formation in the primary quenching reaction.

Under static conditions the methyl chloride reaction was found to form calomel with the natural Hg^{202} abundance (29.8%). With increasing flow rate a progressive increase in Hg^{202} abundance was observed. Maximum enrichments were found at fast flow rates, low substrate pressures, and high values for the absorbed light intensity (I_A). The most highly enriched calomel obtained in this study contained 50.4% Hg^{202}. With increasing I_A, a corresponding increase in flow rate was required to achieve maximum Hg^{202} enrichment. The addition of propylene or butene-1 to the methyl chloride stream was found to result in a slight decrease in Hg^{202} abundance over that for the pure substrate.

The isotopically specific aspects of the reaction are explained in terms of the sequence:

$$RCl + Hg^{202}6(^3P_1) \rightarrow Hg^{202}Cl + R \quad [1]$$

$$RCl + Hg^{202}6(^3P_1) \rightarrow R + Cl + Hg^{202}6(^1S_0) \quad [2]$$

$$Cl + Hg^N + M \rightarrow Hg^NCl + M \quad [3]$$

where M represents a third body, including the wall. The decrease in enrichment observed at high substrate pressures is shown to be due to Lorentz-broadening effects on the hyperfine absorption contours of Hg^N. The failure to obtain enrichment under static conditions is explained by the depletion in Hg^{202} of the Hg^N in the cell through reaction [1].

The investigation shows that there are two primary processes operative in the mercury-$6(^3P_1)$-photosensitized decomposition of alkyl chlorides, in one of which calomel is formed. These processes presumably involve a common short-lived intermediate R—Cl—Hg.

INTRODUCTION

In the investigation reported in this paper, the technique of mono-isotopic mercury-$6(^3P_1)$-photosensitization, in natural mercury vapor (Hg^N), developed in a previous study in this series (1), has been used to study the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^N, with two alkyl chlorides. The effect of reaction parameters on the Hg^{202} content of the calomel product of the methyl chloride reaction has been investigated in some detail. Preliminary experiments with isopropyl chloride as substrate are also given for comparative purposes. As in the earlier investigation with hydrogen chloride (2), Hg^{202} enrichment in the calomel product is taken as evidence of formation of the product in the primary quenching process.

In an investigation of the reaction of flowing hydrogen chloride with $Hg^{202}6(^3P_1)$ atoms in Hg^N, McDonald, McDowell, and Gunning (2) found that the calomel product contained a maximum of 44% Hg^{202}, under conditions of fast flow and low substrate pressure. This Hg^{202} abundance corresponds to an enrichment of 48% over the natural Hg^{202} abundance of 29.8%. In the presence of unsaturated addends, such as butadiene-1,3, the Hg^{202} enrichment was found to increase to a maximum of 98%.

The $Hg^N6(^3P_1)$-photosensitized decomposition of methyl chloride has been investigated by Masson and Steacie (3) over the pressure range 10–640 mm at temperatures from 72 to 328° C. These authors concluded that the calomel product, under the afore-mentioned conditions, arises from the secondary reaction of unexcited Hg^N with CH_2Cl radicals. By photosensitization of a single isotopic species, as in the present study, fairly unequivocal evidence can be obtained on the importance of primary formation of mercury compounds in alkyl chloride reactions. The present investigation was undertaken, therefore, to gain further insight into the nature of the primary process in the mercury-$6(^3P_1)$-photosensitized decomposition of calomel-forming substrates.

EXPERIMENTAL

The high-vacuum flow system was so arranged that reproducible gas flow rates could be achieved for compounds which were either gases (CH_3Cl) or liquids ($(CH_3)_2CHCl$) at room temperature. The pressure of the flowing gas was measured with a manometer upstream from the reaction cell. Flow rates were determined by calibrated capillary flow meters situated on the entrance and exit sides of the reaction cell.

The methyl chloride was taken directly from a cylinder. To obtain a fixed pressure of isopropyl chloride vapor, the temperature of the liquid was held constant in a modified Ward still (4). The flow rate was controlled with a Warrick–Fugassi valve (5). Efficient saturation of the gases with Hg^N was accomplished by allowing the gases to pass through an operating "umbrella-type" mercury diffusion pump. The exit condenser of the pump was temperature-regulated to ± 0.5° C by circulating water from a thermostat through its jacket.

The reaction cells used were rectangular in shape, with faces 2.5 cm × 8.0 cm and an internal path length of 0.1 cm. They were made of Vycor 7910 glass, and attached to the system by offset arms, terminating in 12/5 spherical joints.

The Hg^{202} source and photometric apparatus have been previously described (2). The reaction cell was located 5 cm from the source. A rectangular slit was used to confine the beam within the cell faces. A portion of the transmitted radiation was focussed on a Westinghouse WL-775 photocell by means of a quartz lens.

A special procedure was employed in the determination of the relative mean absorbed light intensity during a run. The relative intensity of the source could be obtained at any time by rotating the cell through 90° out of the light path. Before attaching the cell to the system, the transmission of the cleaned, Hg^N-free, cell was first measured in the absorbiometric analysis apparatus (6). With the cell in position, and the Hg^N-saturated gas flowing through the system, the transmission was again measured. From these data, together with the calibration curve obtained on the analysis system (6), the fraction of light absorbed by the Hg^N in the cell, and the Hg^N concentration, could be calculated. During the reaction, the determination of absorbed intensity was complicated by the accumulation of the calomel product on the faces of the reaction cell. Preliminary experiments showed that the transmitted intensity was reduced by calomel deposition to approximately one-half of the initial value in the first 5–10 minutes of irradiation. At this half-time point, the cell was rotated out of the light beam, and the faces were heated with a Bunsen burner until the calomel had sublimed away. After it was cooled, the cell was again moved into the light beam. It was consistently observed in this procedure that subsequent calomel deposition occurred largely in the area to which the original calomel product had been sublimed. Thus the transmitted intensity did not decrease as rapidly in the latter part of the run, as in the initial period. Usually

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

the transmitted intensity was again reduced to one-half after 30 to 60 minutes of further irradiation. The run was terminated at this point by rotating the cell out of the light path. The method of recovering the isotopic mercury from the calomel, and the procedure for isotopic analysis, have been previously described (1, 6). Before the reaction cell was used again, it was cleaned with hot aqua regia, rinsed, and dried at 120° C. In order to obtain reproducible enrichment data, it was found necessary, also, to heat the cell to a dull red heat prior to each run.

The methyl chloride, propylene, and butene-1 used were Matheson C.P. grade, with minimum purity of 99%. The isopropyl chloride used had a boiling range of 34–36° C. It was purified by several trap-to-trap distillations before use.

RESULTS

A preliminary series of runs was first made on the methyl chloride reaction. The Hg^{202} abundance in the calomel product was studied as a function of flow rate, at a fixed pressure of 7 mm. The incident intensity, I_0, was maintained essentially constant in this series. It should be noted that throughout this paper intensity will be expressed in terms of scale divisions on the 5×10^{-10} ampere scale of the Beckmann Ultrohmeter, used for monitoring the photocell output (6). Since the relative positions of all optical components were held constant in this investigation, the intensity values given are directly proportional to the absolute intensities.

The data are presented in Table I, and shown graphically in Fig. 1. It will be noted that two "saturation temperatures" were used. By this term is meant the temperature of the water circulating through the exit arm of the mercury saturator. From Fig. 1, it can be seen that the Hg^{202} abundance increases directly with the flow rate. With the saturator temperature at 9° C the abundance appears to maximize at 42.7% Hg^{202}. Considerably higher abundances were found with the saturator temperature at 20° C. At a flow rate of 22.5 liter $minute^{-1}$, an abundance of 50.4% Hg^{202} was obtained at the higher saturator temperature. It should also be pointed out, at this time, that no enrichment was found under static conditions. In Fig. 1, it can be seen that the Hg^{202} abundance approaches the natural value of 29.8% as the flow rate goes to zero.

Under the conditions of constant I_0, saturator temperature, and substrate pressure obtaining in the first series, variations were observed in the intensity absorbed by the

mercury vapor. In subsequent runs, therefore, the effect of this parameter was studied in some detail.

To evaluate the intensity, I_A, absorbed by the mercury in the reaction cell, the ratio of transmitted to incident intensity was determined for the evacuated cell ($\bar{T}_C$) and also for the cell under reaction conditions ($\bar{T}_R$). The two faces of the cell were assumed to be identical, and the fraction of light transmitted by the incident face, by the filter-product rule, was taken as the square root of $\bar{T}_C$. With I_0 as the mean incident intensity of the lamp during the reaction, I_A was calculated from the equation

$$I_A = \bar{T}_C^{\frac{1}{2}}(1-\bar{T}_R/\bar{T}_C)I_0 = \bar{T}_C^{\frac{1}{2}}.A.I_0.$$

Values of A were determined at the beginning of the run, and also following sublimation of the calomel at the half-time point, in most of the runs.

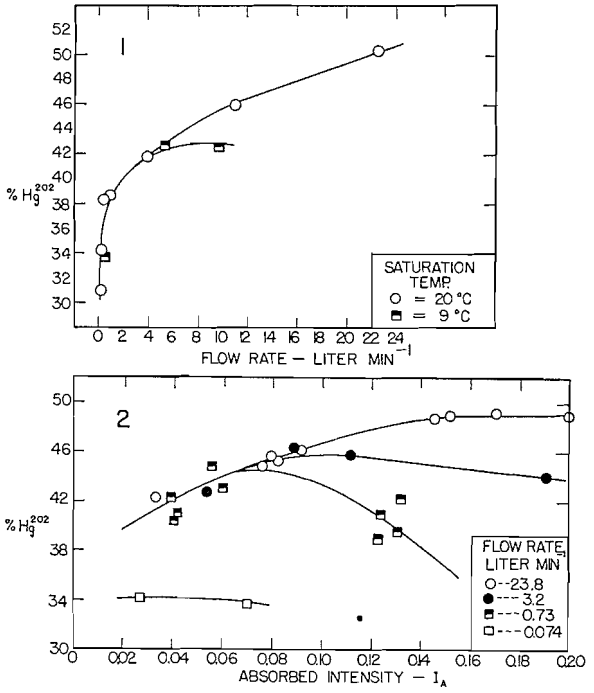

FIG. 1. The effect of flow rate on the abundance of Hg^{202} in the calomel product of the methyl chloride reaction, at two saturation temperatures.

FIG. 2. The effect of I_A on the abundance of Hg^{202} in the calomel product of the methyl chloride reaction, at four flow rates.

In Table II, the Hg^{202} abundance is shown as a function of I_A, for mean flow rates of 0.074, 0.73, 3.2, and 23.8 liter minute^{-1}. In the graphical representation of the data in Fig. 2 it would appear that the Hg^{202} abundance passes through a maximum then decreases with increasing absorbed intensity, except at the highest flow rate used, i.e. 23.8 liter minute^{-1}. In other words, for each absorbed intensity there is a minimum value of the flow rate which must be achieved in order to obtain maximum isotopic enrichment. These minimal flow rate values increase with increasing absorbed intensity. With the flow rate sufficiently high to eliminate any enrichment-depressing effect of this parameter, the Hg^{202} abundance clearly increases with increasing absorbed intensity.

It should be emphasized that the I_A values are initial absorbed intensities averaged from the readings taken at the beginning of the run and after sublimation of the calomel at the half-time point. The average intensity of radiation absorbed during the run would be about three-fourths of the reported I_A values.

The variation-in-intensity technique, described above, was used to study the effect of varying I_A on the Hg^{202} abundance, for several substrate pressures, at a constant flow rate of 2.7 ± 0.7 liter $minute^{-1}$. The data for substrate pressures of 0.27, 136, and 314 mm are shown in Table III. From Table II, data are available for the same flow rate at a substrate pressure of 7.2 mm. At the lowest pressures of 0.27 and 7.2 mm, the I_A values had to be corrected for incomplete quenching. Since the absorption path was only 0.1 cm, and the pressure of Hg^{202} was small, imprisonment of the hyperfine component was assumed to be negligible. The Stern–Volmer relation (7) should therefore be valid under these conditions. To make the correction the values of I_A, derived from the absorption data, were multiplied by $Z\tau/(1+Z\tau)$, where Z is the number of collisions per second of one Hg^{202} atom with the methyl chloride, and τ is the lifetime in seconds of the $Hg^{202}6(^3P_1)$ state. The Z values were calculated from Maxwell's collision frequency equation, with the collision cross section taken as the quenching cross section of methyl chloride for $Hg^N6(^3P_1)$ atoms. This value has been found by Darwent and Phibbs (8) to be 24×10^{-16} cm^2. The question of the magnitude of the lifetime, τ, of the $Hg^{202}6(^3P_1)$

state has been discussed in an earlier paper in this series (1). For the lifetime of the $6(^3P_1)$ state of the even-mass mercury isotopes, Lennuier and Cojan (9) obtained 1.12×10^{-7} seconds. This value was used in the present calculations. The correction factors for incomplete quenching applied at the pressures of 0.27 and 7.2 mm were 0.19 and 0.88 respectively. It should be noted that the I_A values given in Table II are uncorrected for incomplete quenching.

The Hg^{202} abundance vs. I_A curves, corrected for incomplete quenching, are shown for the four pressures, 0.27, 7.2, 136, and 314 mm in Fig. 3. The enrichment-depressing effect of high substrate pressure is clearly shown at 314 mm. The values obtained in the 0.27–136 mm range all appear to fall on the same curve within the experimental error.

At low methyl chloride pressures, collisional transfer of energy between $Hg^{202}6(^3P_1)$ and Hg^N atoms could conceivably become important. From resonance radiation imprisonment measurements, Holstein, Alpert, and McCoubrey (10) have estimated that the mean quenching cross section of Hg^N is 10^{-13} cm^2. Knowing the quenching cross sections

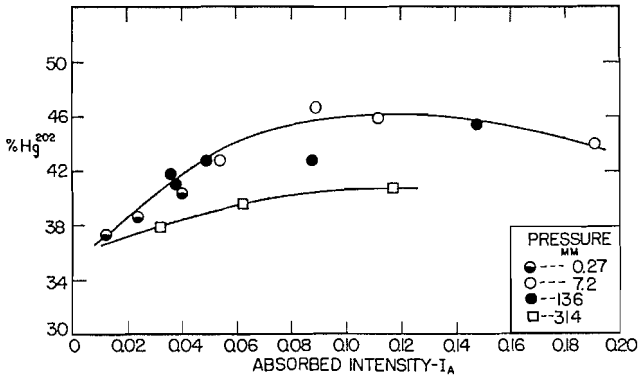

FIG. 3. The effect of I_A at constant flow rate on the abundance of Hg^{202} in the calomel product of the methyl chloride reaction at four substrate pressures.

of Hg^N and methyl chloride, it is possible to obtain the relative quenching of $Hg^{202}6(^3P_1)$ by Hg^N and methyl chloride from the collision frequency equation. At the lowest substrate pressure used, i.e. 0.27 mm, and with a mercury vapor pressure corresponding to equilibrium at 21° C, it was calculated that 99% of the $Hg^{202}6(^3P_1)$ atoms were quenched by methyl chloride. Quenching by Hg^N atoms was therefore considered negligible in the present investigation.

In all of the experiments reported in this paper on the effect of various reaction parameters on the Hg^{202} abundance, a consistent procedure was used in treating the reaction cell between experiments. Following the removal of the calomel product by solution in boiling concentrated hydrochloric acid, the cell was cleaned in aqua regia, to remove any traces of calomel or mercury, rinsed in distilled water, dried at 120° C, and heated to a dull red with a gas–oxygen flame. The flaming served to burn off any polymeric material formed on the cell during reaction. With repeated use it was observed that the transmission of the cleaned, Hg^N-free, cell slowly decreased. To improve the transmission, the cell was immersed in concentrated hydrofluoric acid for 30 minutes, rinsed, dried, and flamed. The transmission, following this treatment, was considerably higher. However, the Hg^{202} content of the calomels formed in succeeding experiments was found to be lower than before the treatment.

In order to determine whether surface factors influenced the Hg^{202} abundance, a series of 10 consecutive runs were performed, on the same cell, and under essentially the same reaction conditions. The runs differed only in the method of cell treatment between successive experiments. The data are summarized in Table IV.

It is apparent from the data that the aqua regia treatment, followed by flaming, is necessary to obtain maximum enrichments reproducibly. Furthermore, it appears that

the "recovery" of the cell surface from other treatments is not immediate. In the last five runs in Table IV it can be seen that the untreated cell does not yield high values for the enrichment until two runs have been performed using the aqua regia method.

The possibility of isotopic degradation in the calomel product by gas-phase exchange reactions between $Hg^{202}Cl$ and Hg^{N} has been considered in an earlier study in this series (2) on the reaction of $Hg^{202}6(^3P_1)$ atoms with hydrogen chloride – butadiene mixtures. It was found that repeated sublimation of the calomel product did not alter the Hg^{202} abundance, compared to that for unsublimed calomel.

In this investigation, exchange between Hg^{N} vapor and isotopically enriched solid calomel was examined. A deposit of enriched calomel was first laid down in the cell under the following reaction conditions: 6.87 mm pressure of methyl chloride, at a flow rate of 0.7 liter minute^{-1}, a saturation temperature of 20° C, and an absorbed intensity of 0.159. The lamp was then turned off, and the Hg^{N}-saturated methyl chloride was allowed to flow through the cell for an additional 30 minutes. The Hg^{202} abundance was found to be 40.8%, the value to be expected under the conditions of the experiment. This experiment would suggest that exchange between gaseous Hg^{N} and isotopically enriched solid calomel is not significant under the conditions of this investigation.

The reaction between photoexcited Hg^{202} atoms and solid calomel is another exchange reaction which could be influential in determining the Hg^{202} abundance. This possibility was investigated by depositing a layer of $Hg^{N}{}_2Cl_2$ by irradiating the Hg^{N}-saturated stream of methyl chloride with an electrodeless discharge source containing Hg^{N}. The deposit was sublimed from the cell face and the system was evacuated. A stream of nitrogen, presaturated with Hg^{N}, was then allowed to flow through the system, under irradiation with the Hg^{202} source. After 30 minutes the run was stopped and the mercury from the calomel was analyzed. An Hg^{202} content of 29.7% was found, corresponding to the natural abundance. This experiment would suggest that neither $Hg^{202}6(^3P_1)$ atoms nor $Hg^{202}6(^3P_0)$ atoms can displace the mercury atoms in solid calomel.
