The effect on the Hg^{202} enrichment of adding unsaturated hydrocarbons to the methyl chloride stream was studied using propylene and butene-1 as addends. The data are summarized in Table V. In this table the I_A values given were determined as described above. The numbers are proportional to the absorbed intensity for the Hg^{N}-saturated gas mixture. The fraction of I_A partitioned in competitive quenching to methyl chloride is designated in Table V as $I_A(CH_3Cl)$. To obtain $I_A(CH_3Cl)$, the I_A values were multiplied by the relative quenching factor $[Z(CH_3Cl)/Z(G)]/[1+Z(CH_3Cl)/Z(G)]$: where $Z(CH_3Cl)$ and $Z(G)$ represent respectively the number of collisions between Hg^{202} and methyl chloride and between Hg^{202} and the added gas. For calculating the collision frequency ratio, quenching cross sections of 31 and 33.5×10^{-16} cm^2 were used respectively for propylene and butene-1 (11). In addition to the correction of I_A for competitive quenching, the fraction of light escaping by resonance fluorescence was also considered.

From Table V, it can be seen that the addition of propylene and butene-1 has a slightly depressing effect on the Hg^{202} content in comparison with the value for the pure substrate, under comparable conditions. From the four runs with varying concentrations of butene-1, it would appear that the enrichment-depressing effect of this addend decreases with increasing concentration.

As a preliminary study on the effect of the alkyl side chain on the isotopically specific reaction, a series of 19 runs was done with isopropyl chloride as substrate. Reaction pressure was varied from 0.16 to 308 mm, and the flow rate from 0.0007 to 11.20 liter minute^{-1}.

TABLE V

The effect of added gases on the Hg^{202} content of the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms, photoexcited in Hg^N, with methyl chloride at a flow rate of 20.5 ± 1.5 liter $minute^{-1}$

Added gas	P (Total), mm	P (CH_3Cl), mm	P, mm	% added gas	I_A	I_A (CH_3Cl)	Hg^{202} abundance, atom %
Propylene	4.89	3.46	1.43	28.3	0.175	0.093	42.2
Propylene	4.90	3.53	1.37	28.0	0.175	0.095	44.2
Butene-1	5.51	3.47	2.04	37.0	0.202	0.110	42.0
Butene-1	4.63	3.06	1.57	33.8	0.233	0.113	41.4
Butene-1	4.69	4.28	0.41	8.7	0.222	0.149	40.4
Butene-1	4.76	4.35	0.41	8.6	0.133	0.099	38.5
None	4.63	4.63	0	0	0.130	0.130	44.0

As with methyl chloride, maximum enrichments were obtained at low pressures and high flow rates. The highest Hg^{202} abundance was 44.1%, for a pressure of 6.42 mm and a flow rate of 8.0 liter $minute^{-1}$. This point fits on the curve for methyl chloride, shown in Fig. 1, for the same saturation temperature of 20° C.

DISCUSSION

In a previous paper (2) in this series, on the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^N, with hydrogen chloride, it was pointed out that there are two factors which must be considered before the significance of reaction parameters in the kinetics can be properly assessed. These factors are (*a*) the Lorentz-broadening effects of substrate pressure on the hyperfine absorption contours, and (*b*) the depletion in Hg^{202} of the Hg^N present in the reaction zone through isotopically specific processes. These factors will first be discussed.

By analogy with the hydrogen chloride reaction (2), the formation of a calomel product, enriched in Hg^{202}, in the reaction of methyl chloride with $Hg6(^3P_1)$ atoms, in Hg^N, could be ascribed to the sequence:

$$CH_3Cl + Hg^{202}6(^3P_1) \rightarrow CH_3 + Hg^{202}Cl \quad [1]$$

$$CH_3Cl + Hg^{202}6(^3P_1) \rightarrow CH_3 + Cl + Hg^{202}6(^1S_0) \quad [2]$$

$$Hg^N + Cl + M \rightarrow Hg^NCl + M \quad [3]$$

where M represents a third body in the gas phase, or the wall.

The Lorentz-broadening effects of methyl chloride on the five absorption contours of the 2537 Å line of Hg^N have been discussed in some detail in a previous paper (1). Quantitative estimates were there made of the fraction of Hg^{202} resonance radiation absorbed by Hg^N with increasing methyl chloride pressure. From these data, and the Hg^{202} abundances in the present investigation, an approximate calculation can be made of the magnitude of the Lorentz effect in the methyl chloride reaction. On the basis of the three-step mechanism above, the ratio, R, of the rates of $Hg^{202}Cl$ to Hg^NCl formation is related to the fractional Hg^{202} abundance, α, in the calomel product by the equation:

$$R = (\alpha - 0.298)/(1-\alpha),$$

where 0.298 is the α value for natural mercury. The calculation can only be made for low I_A values, under which conditions Hg^{202} depletion of the Hg^N in the irradiated zone should be negligible, as required by reaction [3]. From Fig. 3 it can be seen that at substrate pressures less than 136 mm, there is no appreciable pressure effect on the Hg^{202} enrichments, since the abundance values all lie on the same curve within the

For personal use only.

experimental error. From this curve the value of $\alpha = 0.44$, for $I_A = 0.06$; whence, from the above equation, $R = 0.25_4$. From reference 1 the fraction of incident Hg^{202} radiation absorbed by Hg^{202} atoms, at a methyl chloride pressure of 314 mm, is 0.70. The apparent R value at this substrate pressure will therefore be $(0.70)(0.25_4) = 0.17_8$. Substituting this value in the above equation an α value of 0.40 is obtained. From Fig. 3, the experimental value is 0.395, for $I_A = 0.06$ and $P = 314$ mm.

From the above calculation, the Lorentz effect would appear sufficient to account for the decrease in Hg^{202} abundance at high substrate pressures. This subject will be dealt with in greater detail in forthcoming papers from this program.

From Fig. 2, it would appear that the Hg^{202} abundances, at a fixed flow rate, increase with increasing I_A to a maximum value and then fall off. The maximum value becomes progressively greater with increasing flow rate. This behavior can be adequately explained in terms of a localized depletion of the Hg^{202} content of the Hg^N in the reaction zone through reaction [1]. Under such conditions reaction [3] takes place with mercury containing less than the normal abundance (29.8%) of Hg^{202}. The net Hg^{202} enrichment found in the recovered calomel will thereby be reduced. This depletion effect would be minimized at high flow rates and low I_A values. The extreme case of Hg^{202} depletion would of course occur under static conditions. Here a calomel containing the normal Hg^{202} abundance was recovered. The static behavior points up the fact that the photochemical reaction is very much faster than the rate of evaporation of the liquid Hg^N present in the reaction cell. All of the Hg^N present must be consumed in primary and secondary calomel-forming reactions in order for Hg^NCl to be recovered.

Since the relative mean absorbed intensities (I_A) were determined under reaction conditions, the net decrease in the Hg^{202} content of the Hg^N with decreasing flow rate can be calculated. In Table II, the three sets of runs at flow rates of 23.8, 0.73, and 0.074 liter minute^{-1} were performed consecutively with the same reaction cell. For each set the A values were averaged and the corresponding mean concentrations of Hg^{202} were obtained from the calibration curve of the absorbiometric analysis unit (6). The results of the calculations are shown in Table VI, with the mean Hg^{202} concentrations

TABLE VI

The effect of flow rate on the concentration of Hg^{202} atoms in the reaction zone, in the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with methyl chloride

Flow rate, liter minute^{-1}	Average absorption	N^{202}, atoms cm$^{-3}\times10^{-13}$	Equilibrium temp., ° C
23.8	0.335	1.45	21.2
0.73	0.231	0.93	16.1
0.074	0.128	0.52	9.8

(N^{202}) given as the number of Hg^{202} atoms per cc. The progressive decline in the N^{202} values with decreasing flow rate is clearly evident. In the last column of Table VI the equilibrium temperatures of liquid Hg^N are given corresponding to the vapor concentrations of Hg^N indicated by the N^{202} values. At the highest flow rate (23.8 liter minute^{-1}), the equilibrium temperature corresponds, within the experimental error, to the temperature of the exit condenser of the mercury saturator. However, at the lowest flow rate (0.074 liter minute^{-1}) the equilibrium temperature is 11.4° C below the saturator temperature. These calculations show up clearly the Hg^{202}-depleting effect of reaction [1] on the Hg^N in the light zone. It should further be noted that these results prove the efficiency

of the method used for saturating the gas stream with Hg^N. This is evident from the fact that the equilibrium temperature is the same as the saturation temperature at the highest flow rate employed.

From the preceding considerations, it seems reasonable to conclude that the Hg^{202} abundances in the methyl chloride reaction are invariant in both substrate pressure and volume flow rate when the actual data are corrected for Lorentz-broadening of the hyperfine absorption contours and depletion of Hg^{202} in the Hg^N present during reaction.

The specific nature of the primary processes occurring in the reaction of methyl chloride with $Hg^{202}6(^3P_1)$ atoms was the focus of interest in this study. Pertinent to this, the quenching cross section of methane for $Hg^N6(^3P_1)$ atoms is only 0.08×10^{-16} cm^2 (7), whereas that of methyl chloride is 24×10^{-16} cm^2 (8). The substitution of chlorine in the methane molecule results therefore in well over a 300-fold increase in quenching cross section. From these data alone one would expect that chemical quenching would occur almost exclusively at the C—Cl bond in methyl chloride. In their study of the methyl chloride reaction with $Hg^N6(^3P_1)$ atoms, at elevated temperatures, Masson and Steacie (3) came to this conclusion on the basis of the nature and quantum yields of the products formed. The results of the present work substantiate this conclusion and show further that at least part of the calomel product recovered originates in the primary quenching reaction. It should be emphasized that this study indicates primary calomel formation in the room temperature reaction. It would be expected that increasing reaction temperature would favor reaction [2] over reaction [1]. Hence our results are not necessarily in disagreement with the conclusions of Masson and Steacie (3) that the primary process is exclusively reaction [2] at elevated temperatures.

From the fact that the calomel recovered is not pure $Hg^{202}Cl$, it would appear necessary to postulate the two primary processes, [1] and [2], to allow for secondary Hg^NCl as well as primary $Hg^{202}Cl$ formation. That calomel is forming by secondary reactions is clearly indicated by the effect of flow rate and intensity, discussed above, on the Hg^{202} abundance. Further evidence for reaction [2] has recently been obtained in further studies on the methyl chloride reaction (12). It has been found that hydrogen chloride is an important product of the reaction at room temperature. The presence of this product can be most readily explained by the reaction:

$$Cl + CH_3Cl \rightarrow HCl + CH_2Cl. \qquad [4]$$

This step has been previously postulated by Masson and Steacie (3) to explain HCl formation in the reaction at higher temperatures. It is likely that the two primary processes involve a common intermediate, since reaction parameters do not appear to influence the ratio of the rates of the two processes.

To this point it has been implied that secondary Hg^NCl formation arises by direct reaction of Cl atoms with Hg^N in the presence of a third body, as shown in reaction [3]. For their higher temperature conditions, Masson and Steacie (3) concluded that calomel formed by the reaction:

$$CH_2Cl + Hg^N \rightarrow Hg^NCl + CH_2. \qquad [5]$$

In the present investigation, CH_2Cl radicals will be available not only through reaction [4] but also from abstraction reactions of methyl radicals, formed in [1] and [2], with the substrate (13):

$$CH_3 + CH_3Cl \rightarrow CH_4 + CH_2Cl. \qquad [6]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

It would be expected that these radicals would be consumed mainly through recombination (3):

$$2CH_2Cl \rightarrow C_2H_4Cl_2. \qquad [7]$$

With increasing I_A, there would be a localized build-up in Cl atom concentration, favoring reactions [3] and [4]. This should result in no net change in the Hg^{202} abundances, since $Hg^{202}Cl$ is simultaneously being formed in reaction [1]. However, if $Hg^{N}Cl$ is also being formed by [5], and since any increase in I_A will enhance the steady-state concentration of CH_2Cl radicals, the rate of $Hg^{N}Cl$ formation will increase more rapidly than that for $Hg^{202}Cl$ formation, with a resulting decrease in the Hg^{202} content of the recovered calomel. This is contrary to our findings, since actually an increase in Hg^{202} content was observed with increasing I_A. It appears therefore unlikely that reaction [5] is significant under our reaction conditions. It should further be noted that a similar intensity effect was found in the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^{N} with hydrogen chloride – butadiene mixtures (2).

It is possible that the reason for the positive intensity effect should be sought in the nature of reaction [3]. With increasing I_A, the localized enhancement of Cl atom concentration may result in a decreased efficiency in reaction [3] through its third-body restriction. Any reduction in the efficiency of [3] would result in a net increase in the Hg^{202} content of the recovered calomel.

From Table V it can be seen that the addition of propylene or butene-1 to the methyl chloride stream results either in no change or a slight decrease in the Hg^{202} content of the recovered calomel. While it is likely that these addends are slightly more efficient than methyl chloride in removing Cl atoms, any beneficial effect of this type in suppressing $Hg^{N}Cl$ formation will be compensated by a decreased I_A partitioned to the methyl chloride through competitive quenching effects from the added olefins.

The influence of cell-cleaning techniques on the Hg^{202} abundance is summarized in Table IV. The behavior suggests that isotope exchange reactions in product recovery may be playing a role in determining the Hg^{202} abundance found in the mercury recovered from the calomel product. Thus the physical condition of the cell surface may determine the extent to which Hg^{N} adsorbs upon it. In the recovery of Hg^{202}-enriched mercury from the calomel the importance of isotopic degradation through exchange reactions between Hg^{202} ions and Hg^{N} will be determined by the quantity of Hg^{N} adsorbed on the calomel product. This problem has been discussed in an earlier publication (14). The importance of exchange reactions in investigations of this type is currently being studied in the laboratories of one of us (HEG).

From the preliminary study of the isopropyl chloride reaction there is no evidence that an increase in the carbon chain length has any influence on the enrichment process.

CONCLUSIONS

As a result of this investigation it can be concluded that $Hg6(^3P_1)$ atoms react with alkyl chlorides through two primary modes:

$$RCl + Hg6(^3P_1) \rightarrow HgCl + R$$

$$RCl + Hg6(^3P_1) \rightarrow R + Cl + Hg6(^1S_0).$$

Through the technique of initiating the photosensitized decomposition with $Hg^{202}6(^3P_1)$ atoms in Hg^{N}, it has been possible to show that the calomel product is formed partially in the primary quenching reaction, and partially by secondary reactions of the type:

$$Cl + Hg + M \rightarrow HgCl + M.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The two primary modes of decomposition presumably involve the same short-lived intermediate in which the mercury atom is associated with the chlorine of the alkyl chloride. For alkyl halides in general the scission of the intermediate R—X—Hg into HgX and R would presumably be favored with increasing bond strength of the HgX. For this reason studies are now in progress in the laboratories of one of us (HEG) on the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with alkyl fluorides. Here it is conceivable that higher Hg^{202} enrichments would be obtained because of the greater stability of HgF compared to HgCl.

ACKNOWLEDGMENTS

THE MECHANISMS OF OXYMERCURATION[1]

M. J. Abercrombie, Alan Rodgman, K. R. Bharucha, and George F Wright

ABSTRACT

The oxymercuration of norbornenes has been found to be acid-catalyzed, and to give oxymercurials which have a higher dipole moment and greater stability toward deoxymercuration than do their diastereomers in which the configuration of the mercuri linkage has been inverted. Since these properties can be correlated with those of the oxymercurials from norbornenedicarboxylic acids (partly published heretofore and elaborated in the present report) the configurations of which are known, it follows that the configurations of the oxymercurials from norbornene are ↑↓ (*trans*). But these configurations must be opposite to those of the oxymercurials from cyclohexene, cyclopentene, α-terpineol, and the geoisomeric stilbenes, the formations of which are not acid-catalyzed and the dipole moments of which are lower than those of the diastereomers inverted with respect to the mercuri linkage. The configuration of these oxymercurials must be ↓↓ (*cis*) and the mechanism of their formation must be different from the acid-catalyzed oxymercuration of norbornene. The mechanism for *cis* (↓↓) addition has previously been suggested as non-ionic. Calculation of the electric moments of these ↓↓ diastereomers shows that hindrance to group rotation must prevail. It is reasonable to attribute the relative ease with which they may be deoxymercurated to this hindrance.

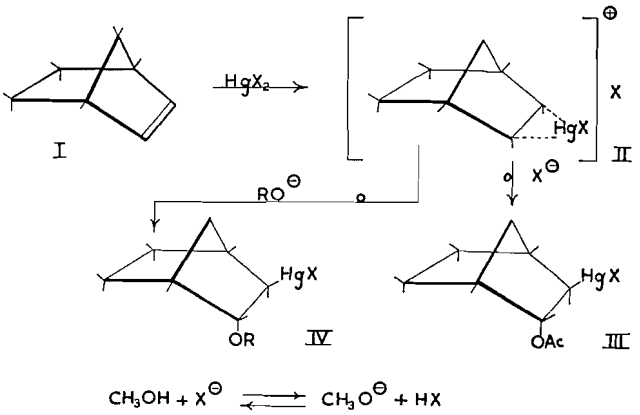
For some years there has been a difference of opinion in respect of the mechanism whereby the elements of hydroxy- or alkoxy-mercuric salts add to alkenes. This controversy is of interest beyond that of the oxymercurials because oxymercuration may provide an insight of alkene reactions not provided by less definitive reactions of these hydrocarbons. Thus it has been observed that oxymercuration is generally entirely stereospecific, with simple second-order kinetics in which a *cis*-geometric isomer is oxymercurated at a faster rate than is its *trans*-modification. However, none of these characteristics define the mechanism of reaction.

In 1935 the reaction was specified as an addition of molecular hydroxy- or alkoxymercuric acetate to the carbon–carbon double bond (1), and this belief that the added groups were in contiguous (so-called *cis*) configuration was reiterated in 1947 (2). Meanwhile, the alternative postulation has been made (3) that an ionized alkane–mercurinium salt is first formed from an ionizable mercuric salt and an alkene. The cation of this salt is subsequently attacked by a nucleophilic hydroxide or alkoxide ion, with inversion, to produce the oxymercurial in which the added groups are in the non-contiguous (so-called *trans*) relationship to one another. This mechanism is portrayed here for the oxymercuration of 1,4-methylene-Δ^2-cyclohexene (norbornene, I).

It might be predicted from this mechanism that the reaction would be favored by a system in which the ionization of mercuric salts would be enhanced. Moreover, the prevalence of the two possible products, 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric salt (IV) versus 3-↓-acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric salt (III), ought to depend upon the relative activities of the anions $X^{\ominus}$ (usually acetate) and $OCH_3^{\ominus}$ in the system.

The oxymercuration of norbornene, I, has been found to conform with these predictions. A quantitative yield of III is formed rapidly when I is treated with mercuric acetate (X = OAc) in acetic acid. More specifically, a 0.34 molar solution of mercuric acetate in 2,5-dioxahexane converts 1 equivalent of norbornene into nearly pure 3-↓-acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric salt (III, X = Cl after treatment with aqueous sodium chloride, m.p. 126–128°) in 98% yield during 30 minutes. Neither rate

[1]*Manuscript received March 31, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.



nor yield is diminished by inclusion of either 1 or 0.1 equivalent of boron fluoride etherate, although 0.1 equivalent of pyridine decreases the yield to 62% and 1 equivalent to 24% during 30 minutes. The effect of pyridine may be expected because of its tendency to coordinate with mercuric salts.

The configuration of this oxymercurial has been studied. The position of the acetoxy group in III (X = Cl) has been proved by saponification to be 3-↓-hydroxy-1,4-↑↑-methylene-2-↑-cyclohexylmercuric chloride (IV, R = H). This substance may be reduced by use of hydrazine hydrate in large excess to 3-↓-hydroxy-1,4-↑↑-methylenecyclohexane, identical with that obtained by Alder, Stein, and Rickert (4, 5) and configurationally established by Alder and Windemuth (6). The position of the chloromercuri group seems to be *trans* (↑) with respect to the acetoxy substituent according to the comparatively high dipole moment (3.6 Debye) which III (X = Cl) displays in dioxane. Therefore, the oxymercuration seems to have occurred via the alkane–mercurinium salt, II.

The same mode of reaction seems to occur when an equivalent of methanol is included with the mercuric acetate and norbornene in 2,5-dioxahexane but the product is IV (R = CH_3), as might be expected if methoxide ion were strongly nucleophilic in this medium. The configuration of 3-↓-methoxy-1,4-↑↑-methylene-2-↑-cyclohexylmercuric chloride (IV) corresponds with that of III because the 3-↓-hydroxy analogue to which III has been converted may be methylated in good yield (7) to the methoxy analogue, IV.

In protonic media the oxymercuration of norbornene is less simple. In water a mixture of III and IV (R = H, X = Cl after sodium chloride treatment) is obtained from which pure IV may be obtained by saponification. In methanolic solution, 0.00025 molar in I, and mercuric acetate a 97% yield of a mixture comprising 65% of IV (R = CH_3) and 35% of III is obtained. This behavior, not usual in the preparation of oxymercurials, would seem to be due to competition in nucleophilic attack of an intermediate like II by alkoxide and acetate ions. The following experiments substantiate this belief.

In Table I, items 1 to 4, is shown a series of experiments in which the molarity of norbornene and mercuric acetate in methanol has been lowered by dilution with this solvent. The products from these 90-minute experiments have been analyzed by melting point – composition diagram and by acetyl determinations.

It may be seen that upon increased dilution the yield is first increased and then essentially is constant. Of greater significance is the increasing amount of methoxymercurial (IV) instead of acetate (III) in the product. Item 11 shows that this tendency is independent of the absolute quantity of mercuric acetate in the system, although item 12, like

TABLE I

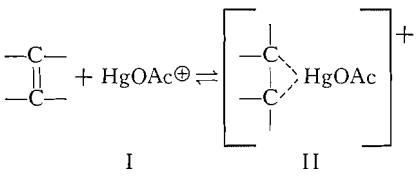
Oxymercuration of norbornene by mercuric acetate in methanol during 90 minutes followed by dilution into aqueous sodium chloride (X = Cl)

Item	Molarity of I and $Hg(OAc)_2$ in MeOH $\times 10^3$	Excess equiv. $Hg(OAc)_2$	Equiv. NaOAc	Equiv. HOAc	Total yield, %	% IV in total
1	0.5				86	61
2	0.25				97	66
3	0.1				93	73
4	0.07				95	86
5	0.25			1	85	80
6	0.25			5	69	73
7	0.25			20	69	67
8	0.25		1		73	21
9	0.25		2		60	15
10	0.25		10		81	10
11	0.04	9			99	90
12	0.12	3			90	60

item 1, shows that a high ratio of mercuric acetate to norbornene tends to decrease the formation of IV in favor of III. These behaviors might be expected if formation of methoxide ion were a consequence of equation [i] to which the reaction of equation [i] furnished little acetate because of limited dissociation.

Consideration of equations [i]–[vii] permits explanation of the results shown in Table I.

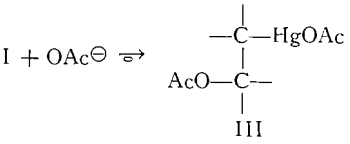
$$Hg(OAc)_2 \rightleftharpoons HgOAc^{\oplus} + OAc^{\ominus} \qquad [i]$$



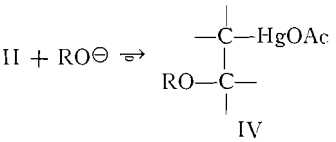
I II [ii]

$$HOAc \rightleftharpoons H^{\oplus} + OAc^{\ominus} \qquad [iii]$$

$$ROH + OAc^{\ominus} \rightleftharpoons RO^{\ominus} + HOAc \qquad [iv]$$



III [v]



IV [vi]

$$Hg(OAc)_2 + ROH \rightleftharpoons RO-HgOAc + HOAc \qquad [vii]$$

$$HgO + 2HOAc \rightarrow Hg(OAc)_2 + H_2O \qquad [viii]$$

The reaction involving norbornene (I), mercuric acetate, and methanol may be adequately described by these equations. Dilution of the solution of reactants with methanol as indicated in items 1–4, Table I, would result in increased formation of methoxide ion and reduction of acetate ion by equation [iv]; thus favoring the formation of IV as described by equation [vi] at the expense of formation of III by equation [v]. Reduction of acetate ion would result in increased formation of the acetoxymercurinium ion (equa-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

tion [i]). Thus increased dilution of the reactants with methanol would favor increased ionization of the mercuric acetate and would result in an increased yield of III plus IV in 90 minutes.

An equilibrium shift of the reaction described by equation [i] ought to be enhanced more by the ionization of acetic acid than by mercuric acetate. This expectation is realized in item 5 and to a certain extent in item 6, by comparison with item 2, but item 7 shows when addition of acetic acid reaches the 20-equivalent level the presence of acetate ion starts to favor the formation of III to the detriment of IV.

Inclusion of varying amounts of acetic acid (items 5–7, Table I) should reduce the over-all per cent yield in 90 minutes. The reason for this reduction is readily found by interpretation of equations [i]–[vii]. The increase in the ratio of III:IV produced by addition of acetic acid (and thus increased acetate ion) is explicable by consideration of the ratio, acetate:methoxide ion.

Inclusion of sodium acetate, a salt highly ionized in methanol compared with acetic acid, should further enhance the effect observed with added acetic acid. Addition of 10 equivalents of sodium acetate (item 10) increases the amount of the acetoxymercurial III to 90% of the total product.

According to these evidences of ionic participation it would follow that conditions in which basic mercuric salts would be prevalent ought to decrease the rate of reaction. This condition has been devised by inclusion of mercuric oxide into the methanolic system 0.25 molar in norbornene and mercuric acetate. In this experiment, the reaction shown in equation [viii] would be operative together with the reactions described by equations [i]–[vii]. After 4 hours the total yield is only 70% but the acetic acid liberated from this amount of oxymercuration has by this time dissolved the suspended mercuric oxide. Subsequently the yield rises to 90%. Of interest is the observation that the 90% yield contains at least 10% more of the methoxymercurial than is obtained from the reaction system in which no mercuric oxide is present.

This evidence that methoxymercuration of norbornene is retarded in a basic or neutral environment would indicate that this reaction would be favored in acidic media. The data of Table II substantiate this prediction.

The addition of only 0.02 equivalent of sulphuric acid increases the amount of methoxymercurial, IV, relative to the acetate, III, from 67 to 85%. While the addition of larger amounts of sulphuric acid tends slightly to decrease the total yield (deoxymercuration), the percentage of IV in this total actually is increased. It would appear that the bisulphate ion, itself not sufficiently nucleophilic to undergo neutralizing addition to an alkane–mercurinium salt, removes acetate ion from the system according to equation [ix]. The behavior of methoxyfluoboric acid

$$Hg(OAc)_2 + H^{\oplus} + HSO_4^{\ominus} \leftrightarrows HgOAc^{\oplus} + HSO_4^{\ominus} + HOAc \qquad [ix]$$

and *p*-toluenesulphonic acid probably are similar. In this connection it may be observed that hydrochloric acid does not increase the yield of IV, undoubtedly because it is converted to mercuric chloride which is largely unionized.

It may be seen from the table that odd electron donors such as benzoquinone, hydroquinone, and *tert*-butylhydroperoxide are entirely ineffective. To be sure stannous chloride and ferrous sulphate are both effective for augmentation of IV over the acetate, III, but they may be functioning in formation of complex anions. The augmentation by the ferrous salt is of especial interest if the present findings are contrasted to an earlier report of the preparation of 3-methoxymethylenecyclohexylmercuric chloride (8) in which

Pyridine	0.10	95	58	55
	1.00	89	37	30
Trimethylamine	0.10	90	24	21

a good yield in high purity seemingly was obtained with a system comprised only of norbornene, mercuric acetate, and methanol. In view of our findings with this system, we presume that a contaminant such as ferrous salt must have been present in Rowland's system since otherwise he could not have obtained the high yield of methoxymercurial which he reported. Rather he should have obtained a mixture of III and IV.

In addition to the substances which accelerate the methoxymercuration over the formation of 3-↓-acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric salt (III), it may be seen from Table II that tertiary amines like pyridine and trimethylamine strongly retard methoxymercuration in favor of the formation of III. This must be due to the augmentation of acetate ion from the acetic acid formed in the system. Of course these nitrogen-containing electron-donors have been known previously to retard methoxymercuration, and earlier in this report it was shown that pyridine retarded the formation of III in 2,5-dioxahexane. Probably these latter effects are inconsequential to the argument of Table II. It may be seen that the presence of the amines did not appreciably diminish the total yield in methanol. Actually, the effect of either acids or bases on the rate of norbornene oxymercuration has not been evaluated in the present study because the reaction, even without addends, is very fast. Although 90 minutes has been allowed in these studies in order that all reactions would be standardized with respect to time, it is known that the 0.25 molar reaction in methanol at 20° C is complete within 45 seconds.

One may ask how this evidence for an ionic mechanism of oxymercuration may be correlated with previous experience of the general reaction. For example, it has been shown (9) that acetic acid retards one oxymercuration while the removal of acetic acid by evaporation from another, typical, reaction increases the rate (10). Moreover the evidence for ↑↑ (*cis*) addition is strong in respect of general oxymercuration (11), except for an X-ray diffraction study (12) which may be questioned in view of recent opinions about the flexibility of the cyclohexane ring. In view of these experiences the present results might seem to be anomalous.

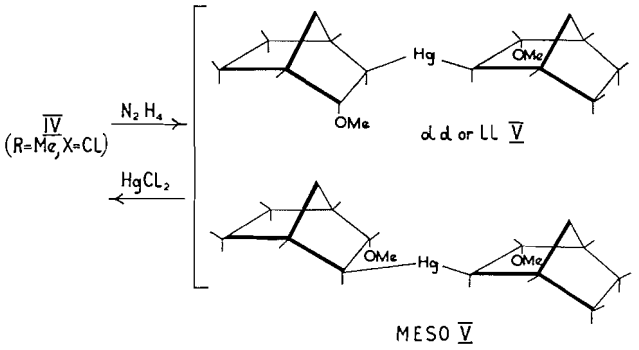
An explanation has been sought, and found, in the chemical and physical properties of the norbornene methoxymercurials. First, the stability of the product designated as 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride (IV, R = Me, X = Cl) is unusually high. This stability is apparent also in the products obtained when IV is treated with excess hydrazine hydrate. For the first time this reaction has yielded methoxyalkyl bis-mercurials; both diastereomers have been obtained as solids which were separable by fractional crystallization. Either diastereomer can be reconverted to the original chloromercurial, IV, so that the reconversion of the bis-mercurial is stereospecific. We consider the higher melting (108°) bis-mercurial to be the meso isomer, V; also it has the higher dipole moment (2.17 D in benzene).

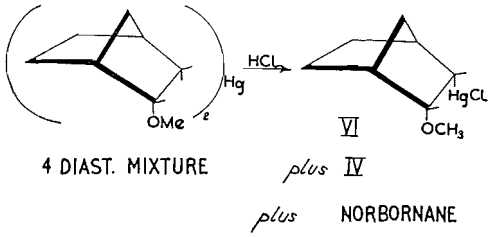
A second evidence of the stability of IV has been observed by the diastereomeric equilibration of IV (↓↑) with its isomer (↓↓, VI) with a small amount of hydrazine hydrate. This reaction has been shown (13) to give diastereomeric mixtures of 2-oxycyclohexyl and 2-oxycyclopentyl mercurials. The more stable diastereomer in the mixture may be isolated by treatment with methanolic hydrogen chloride which deoxymercurates the other diastereomer. The recovered diastereomer, which has been designated as β, has always heretofore been that one *not* obtained by oxymercuration of the alkene.



In contrast, the diastereomer recovered by partial deoxymercuration of the mixture of IV and VI is IV, the product of oxymercuration, in good yield. In order to isolate VI (at best, in small amount) an arduous fractional crystallization of the IV–VI mixture is required. This separation may be facilitated slightly by first converting the IV–VI mixture into a bis-mercurial mixture containing all four diastereomers, of which V represents a pair. This is accomplished by treatment of the IV–VI mixture with excess of hydrazine hydrate. When the four-diastereomer mixture is treated cautiously with less than the stoichiometric amount of methanolic hydrogen chloride for the reaction, the amount of VI in the mixture of IV and VI has been enhanced. Probably steric effects have altered the relative rates of diastereomeric scission.

The properties of VI do not resemble those of the previously known cyclic β-chloromercurials. It has been pointed out above that VI is more easily deoxymercurated than is IV, and this contrast to other cyclic α=β pairs is confirmed by the observation that the dipole moment of VI is found to be lower than that of IV. It would seem from these properties that the configurations of the norbornene oxymercurials are opposite to those of other oxymercurials such as are prepared from terpineol (14), cyclopentene (13), and cyclohexene (13, 15).

According to this definition of the configurations those assigned by Winstein, Traylor, and Garner (15) must be incorrect.



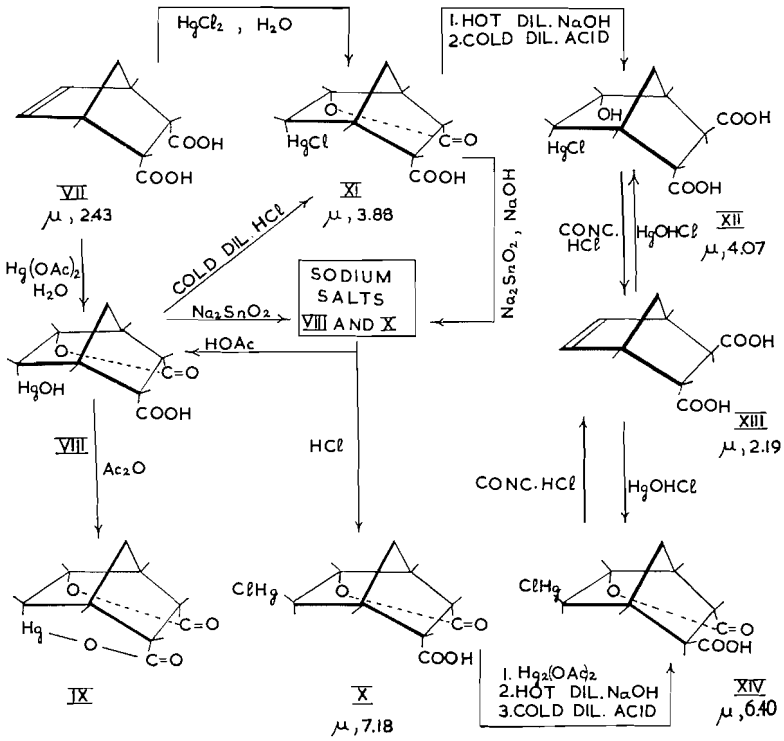
In contrast to the oxymercurations of cyclopentene and cyclohexene it may be said that the oxymercuration of norbornene is abnormal. This unusual behavior may not be unexpected in view of the dipole moments observed (Table III) for norbornane and norbornene, which would indicate a displacement of the electronic fields in these substances. Moreover, it has been shown previously (16, 17) that bromination of the norbornene-2,3-dicarboxylic acids does not follow the common ↑↓ addition of bromine to the double bond. During the remainder of this report it will be shown that some of these dicarboxylic acids also are abnormal in respect of oxymercuration.

During our previous work (11) with 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid (endo-norbornene-2,3-dicarboxylic acid, VII) we did not discern any abnormality when we established the *cis* (↓↓) configuration for the product (VIII) obtained by treatment of VII with aqueous mercuric acetate. Although the compound shown graphically as VIII could, alternatively, be 5-↓-hydroxy-anhydro-[6-↓-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, the choice of which transannular bridge is open is configurationally unimportant. Either form would be expected to undergo dehydration upon treatment with acetic anhydride to give 5-↓-hydroxy-anhydro-[6-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, γ-lactone (IX). The configuration of IX (and therefore of VIII) must be ↓↓ in respect of the oxy- and mercuri-linkages because its molecular weight has been determined cryoscopically as 381. The calculated molecular weight of IX is 382, so a polyester structure is not involved. The configuration of VIII and IX must therefore be ↓↓ as well.

It may be expected that the chloromercurial XI derived from VIII by acidification with hydrochloric acid also will have the ↓↓ configuration. But XI may be obtained directly by treatment of the unsaturated acid, VII, with mercuric chloride in water. This observation by Mr. J. H. Robson marks the first instance of oxymercuration in which participation of a basic mercuric salt cannot be postulated. Indeed, the near-quantitative yield is only lowered by 15% when 2 equivalents of hydrogen chloride are included with the mercuric chloride, although the otherwise very rapid reaction is retarded by this extra acid. The behavior is strongly suggestive of an ionic reaction which will be discussed later in this report.

When either VIII or IX is treated with aqueous sodium stannite the expected precipitation of metallic mercury occurs, and this presumably homopolar reaction (18) yields a diastereomeric mixture. Careful acidification with acetic acid precipitates VIII, perhaps in the anhydromercurial form mentioned above. After removal of VIII the filtrate may be acidified further by use of hydrochloric acid to yield the diastereomeric 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (X). This compound may be deoxymercurated (by treatment with concentrated hydrochloric acid) to the same 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-di-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.



carboxylic acid, γ-lactone, obtained (more easily) by similar deoxymercuration of XI. The latter also yields, with sodium stannite, a mixture from which X may be isolated but the yield is lower, probably because of the presence of chloride ion.

When XI is boiled with aqueous sodium hydroxide it is converted (evidently via lactone hydrolysis) by prototropic rearrangement into 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XII). The alteration in the rearranged substance is proved by deoxymercuration to 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid by means of hydrochloric acid. Further proof is obtained when XII is treated with sodium amalgam, which effects replacement of chloromercuri by hydrogen. The product (which shows no tendency toward spontaneous lactonization) evidently is 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid.

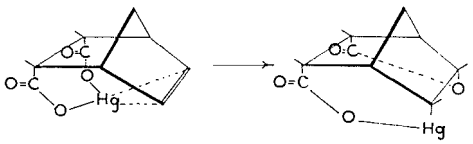
The prototropic rearrangement of XI→ XII is replicated by the conversion X → XIV, although the absence of chloride ion is essential to the latter conversion. The chloride was precipitated as calomel. The 2-carboxyl group seems to be rearranged, since XIV is the lactone of what must be 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid. Confirmation of this structure assignment follows deoxymercuration of XIV with concentrated hydrochloric acid, which yields 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↑-dicarboxylic acid (XIII). Moreover, replacement of the chloromercuri group (with sodium amalgam) by hydrogen leads to the known 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (19).

The oxymercurial from norbornene has been assigned the ↑↓ configuration and that from 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid (VII) the ↓↓ configuration (XI), yet both reactions seem to proceed by the same (ionic) mechanism. It might then be expected that a reaction would exist in which both ↓↓ and ↑↓ configurations would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

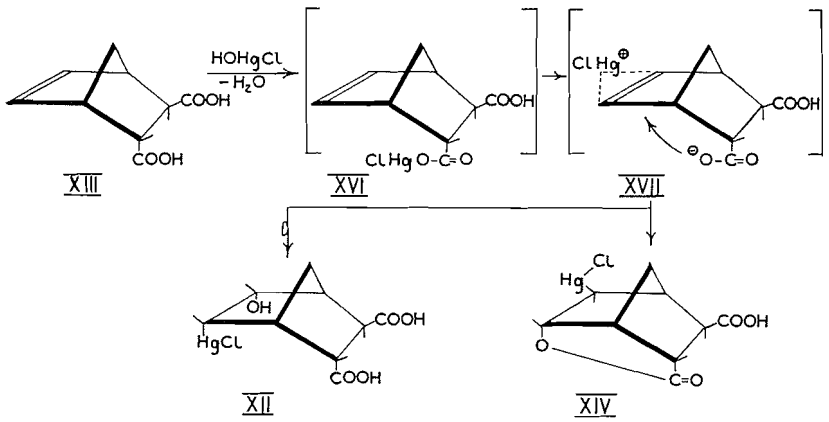
appear in the product. This expectation is realized in the treatment of 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↑↓-dicarboxylic acid (XIII) with basic mercuric chloride in water, since both XII and XIV are obtained as products with the former predominating.

From these examples, it seems reasonable to assume that the norbornenes are oxymercurated uniquely via a π complex with mercuric salts which once was specified for alkenes in terms of an alkene–mercurinium ion (3). The favored neutralization of such an intermediate seems to occur from that region of the norbornane cage farthest from the methylene bridge. The mercuri group will then be situated in that region of the cage where the methylene bridge is predominant, unless it is attracted by an anionic group such as carboxyl in an available (↓) position. The simplest instance where both neutralizing anion and mercuri-attracting anion are two ↓↓ carboxyl groups is exemplified by the π-co-ordinated mercuric salt, XV, which is transformed to IX.



XV IX

When only one ↓ carboxyl group is available, as in 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid (XIII), it seems to play either of the two roles alternatively. Thus it may neutralize the cation XVII formed via the intermediate XVI to yield XIV, or it may attract the mercuri group while hydroxyl ion is the neutralizing species, in which case XII is formed. One might expect in these circumstances that some of the 5-↑-OH diastereomer would be formed despite a preferential anionic approach to the cage. We have not found this diastereomer, but we cannot affirm its absence in view of the difficulties of separation. We shall now present evidence that such anionic neutralization does occur.



XIII XVI XVII XII XIV

This evidence is afforded by oxymercuration of dimethyl 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate (XVIII). Previously, the hydroxymercuration of this substance was reported (11) and the product was specified as 5-↓-hydroxy-6-↓-chloromercuri-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, γ-lactone (XXII). It is now known that XXII from this reaction is contaminated with 5-↑-hydroxy-6-↓-

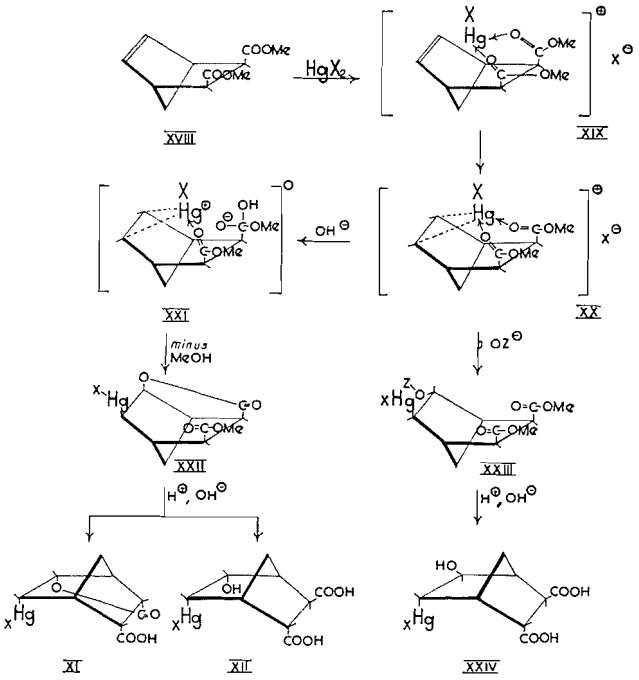
For personal use only.

chloromercuri-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, perhaps as its methyl ester, XXIII, though neither has been isolated. However, the presence of this mono- or di-ester impurity is shown by saponification of the entire product. The main product of this saponification is 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (XI), as well as some of the 2-↓-3-↑-dicarboxylic acid (XII) arising by prototropic rearrangement of XI. The remainder is isolated as 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XXIV), the chemistry of which is discussed below. Thus the dimethyl ester of VII is shown to oxymercurate both ↓↓ and ↓↑, the former being predominant.

When dimethyl 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate (XVIII) is treated with mercuric acetate in acetic acid, the reaction is very rapid. The main product, almost pure, is dimethyl 5-↑-acetoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylate (XXIII, Z = CH_3CO) plus a small quantity of 5-↓-hydroxy-6-↓-chloromercuri-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, γ-lactone (XXII, X = Cl). When XXIII (Z = CH_3CO) is hydrolyzed, a prototropic rearrangement of one carboxyl group occurs to yield XXIV. This shift is indicated because

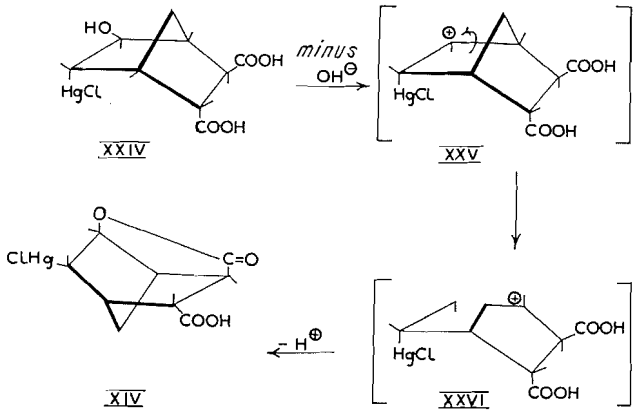


deoxymercuration of XXIV with hydrochloric acid yields 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid (XIII). However, XXII (X = Cl), which may be prepared in excellent yield by mercuration of XVIII with an aqueous solution of mercuric acetate, and XXIII (Z = Me, X = Cl) prepared by methoxymercuration of XVIII, both deoxymercurate with hydrochloric acid to yield 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone. Of course, this does not indicate which carboxyl group in XXIII has diastereomerically shifted. Indeed, XXIV could be either 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑- or 2-↑-3-↓-dicarboxylic acid, but a pyrolytic reaction seems to supply this information.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

The 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XXIV) exists in two forms which evidently are polymorphs since the distortion polarizations and the infrared spectra (900–300 cm^{-1}) are practically identical although the melting points and X-ray diffraction patterns are different. The lower melting of these polymorphs tends slowly to resolidify slightly above its melting point of 194°. If it is maintained at 194–200° for 15 minutes the recognizable product is 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (XIV). This inversion of the methylene bridge seems to be characteristic of the configuration of XXIV (since XII did not rearrange in this manner) and probably is a consequence of the 5-↑-hydroxy configuration. The rearrangement may be described in terms of the intermediates XXV and XXVI, and is typical of dehydration which otherwise would establish a bridgehead unsaturation.

In order to eliminate the possibility that the oxymercuration position assignments were incorrect, and that XXIV and XII differed only in the configuration of the chloromercuri group, the acid XXIV has been treated with sodium amalgam. The product has been designated as 5-↑-hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid; certainly it is not identical with the acid of like composition which has been obtained by reduction of XII. It would seem that XXIV and XII differ in the configuration of the hydroxyl group.



The configurations of the oxymercurials derived from dimethyl 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate seem to be established and the mode of their formations may be suggested. The mechanism may be described essentially as was that of the corresponding acid. If the ester (XVIII) co-ordinates with mercuric acetate (X = OAc) a near-ionic form, XIX, may occur. Within the electropositive portion further co-ordination with the π bond (XX) will be a prelude to further reaction. If the reaction occurs in water, hydroxyl ion may be expected to perform the first step of an ester hydrolysis, i.e. to add to the carbomethoxyl group and form the externally neutral dipole, XXI. This internal mercurinium salt, by loss of methanol, would then culminate in the principal product, XXII. If some hydroxyl ion (or the ever-present acetate ion X) were to attack rearward of the mercurinium linkage (OH or OAc = OZ) then the product of inversion (XXIII) is expected and, in small amount, is obtained. In absence of the hydrolytic reaction, that is, when the reaction medium is acetic acid, XXIII, the product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

of inversion, is obtained in 93% yield, and XXII in small amount (0.5%). This attack by acetate from the region of the cage where the methylene bridge predominates is contrary to that observed with norbornene. This opposite behavior is attributed in the present mechanism to the complexity of the ion, XX.

In connection with the ionic mechanism which has been postulated for the norbornenedicarboxylic acids and their derivatives it may be recalled that inclusion of boron fluoride etherate during the oxymercuration of norbornene largely excluded the acetoxy derivative, III, in favor of the methoxy derivative, IV (R = Me). This behavior is expected when acetate and methoxide ions are competing in an ionic process because of the preferential stabilization of methoxide ion by the Lewis acid, BF_3. It is of interest that the oxymercuration of the ester, XVIII, in methanol leads to XXIII in which Z is almost entirely aceto. However, a mixture is formed in which Z is partly methyl when boron fluoride is included with the methanol. Since the measured dipole moment of this methoxy derivative is of the same magnitude as that of XXIII (Z = CH_3CO), we presume that the configuration is identical. The mechanism of reaction thus seems to be the same as that postulated for oxymercuration of norbornene.

It will be noted in the preceding paragraph that configurational identity has been claimed on the basis of dipole moments. Also configurational relationships must be established between the mercurials from norbornenedicarboxylic acids (the configuration of which has been established by definitive physical and chemical criteria) and the mercurials from norbornene. Therefore the basis for the relationship according to the moment values of Table III must be established.

It must be understood that the moment values per se do not establish configurations but only relate known to unknown configurations. Moreover the moment values must only be considered of qualitative significance. Of course the actual values, all determined at 20° in dioxane (the only non-polar solvent in which all the mercurials are soluble), are reliable within 0.1 D. However, the vectorial assignments and the group moments must be chosen somewhat arbitrarily; indeed another set might have been chosen which would designate configurations opposite to those specified in this report. Nevertheless, like much physical interpretation based on factual logic and non-factual assumptions, the moment calculations are at least self-consistent. As such they suffice to relate the configurations assigned in this report.

Among the group moment assignments which must be made for the calculation is that of the chloromercuri group. A linear (20) and later an angular (21, 22) (+)C—Hg—Cl(−) has been proposed. The angularity must be revised anew in view of evidence (23) that the C—Hg moment is not negligible. Indeed, the measured polarizations of mercuracyclohexane and mercuracycloheptane (0.86 and 0.90 D respectively) show that the bond moment of C—Hg is 1.31 D, negative with respect to carbon, if the C—Hg—C angle is 140°. Then despite uncertainty of mercurial bond angles (23) one may assign to a typical mercurial, *n*-propylmercuric chloride (3.70 D), a C—Hg—Cl bond angle of about 80° if the Hg—Cl moment is 3.2 D. The latter value has been chosen in consideration of the increasing dipole moment of alkylmercuric halides with ascent of the homologous series (23). Essentially these assignments designate mercury as the positive end of the angular alkanemercuric chloride dipole.

A structural assignment must also be made for the gamma–lactone linkage. This assignment has not been made previously, perhaps because the reported values, 3.8 (24) to 4.1 D (25), for γ-butyrolactone are abnormally high by contrast with non-cyclic

5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-methylene-cyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (X)	16.10	0.585	1143.4		56.4	7.18
Same, except -6-↓-chloromercuri- (XI)	4.85	0.600	373.0		56.4	3.88
5-↓-Hydroxy-6-↓-chloromercuri-2-↓-carbomethoxy-1,4-↑↑-cyclohexane-3-↓-carboxylic acid, γ-lactone (XXII)	4.50	0.545	366.6		61.1	3.81
Dimethyl 5-↑-methoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylate (XXIII, Z = Me, X = Cl)	5.80	0.537	508.2		74.2	4.54

little-constrained esters. It seems reasonable to explain this high value as an alteration of bond moments in the —C—O—(C=O)—C linkage from [0.7, 0.7, 2.3, 0.4] to [0.8, 0.5, 2.8, 0.4], after which the moment for γ-butyrolactone is calculated as 4.0 D.

However, the moments of the 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (μ = 4.85 D), and the 2,3-↑↓-diastereomer (μ = 5.06 D) markedly exceed that of γ-butyrolactone. Part of this abnormality may be ascribed to the norbornane ring since a moment of 0.43 D has been observed (Table III) for this hydro-

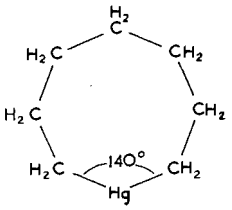
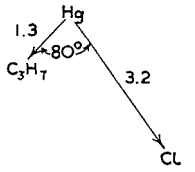
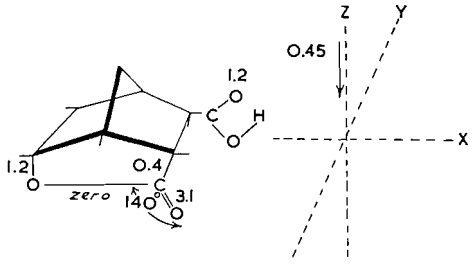
For personal use only.





carbon. The carboxyl group will also contribute, but neither contribution suffices to explain the high moment which has been observed, especially for the 2,3-↑↓-diastereomer. However, it is probable that the additional constraint imposed by the norbornane cage accentuates the alteration in bond moment which has been suggested for γ-butyrolactone.



XXVII

These considerations have suggested the model XXVII in which the alcohol bond is extended to 1.2 D and the carbonyl bond is extended to 3.1 D, while the ester bond is decreased to zero. This condition represents a resonance hybridization of the O—C=O linkage. Moreover the constraint imposed by non-planarity of the γ-lactone ring has distorted the cyclohexane ring so that the ↓ linkages are inclined 18° toward the center of the cage, thus forcing the equatorial ↑ linkage into a plane containing atom 2, 3, 5, and 6. These linkages are assumed to be spread 30° outward from the *X*-axis.

The moment of the free carboxyl group has been estimated as 1.2 D by calculation from the observed moments of 1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid (μ = 2.78 D) and 1,4-↑↑-methylenecyclohexane-2,3-↑↓-dicarboxylic acid (μ = 2.49 D) after subtraction of the norbornane cage moment (0.45 D). In order to simplify subsequent calculations the moment of the carboxyl groups (either ↑ or ↓) has been assumed to be symmetrical about the C—COOH bond. That is to say that the hydroxyl group in the carboxyl is in *cis* relationship to the carbonyl group.

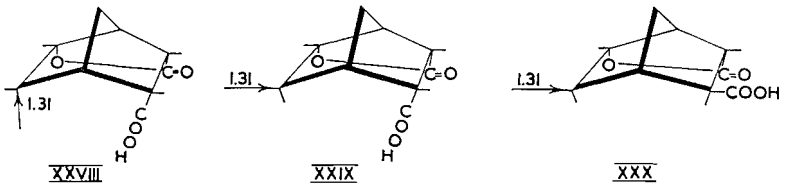
In these circumstances the moment summation with respect to the co-ordinate axes is found to be 4.86 D for 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, and 5.04 D for the 2,3-↑↓-diastereomer. If the C—Hg group moment assigned previously (1.31 D, C ← Hg) is added to each of these γ-lactones in the appropriate sense the following R—Hg moments arise from the calculation.

Calculation of the moment of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, from XXVIII may be made as follows:

$$\mu = [(3.79)^2+(3.22)^2-2(3.79)(3.22)\cos 41°\cos 13°\sin 10°]^{\frac{1}{2}} = 4.6 \text{ D}.$$

It is not surprising that this value, based on harmonic rotation at a rate exceeding 500 kc/second, is appreciably higher than the observed moment (3.88 D) since free rotation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.



$\mu_{R\text{-}Hg}$ = 3.79 D where $\tan\mu_Y/\mu_Z = \tan 11°$ and $\tan\mu_X/\mu_Z = \tan 43°$

$\mu_{R\text{-}Hg}$ = 5.87 D where $\tan\mu_Y/\mu_X = \tan 23°$ and $\tan\mu_Z/\mu_X = \tan 43°$

$\mu_{R\text{-}Hg}$ = 6.31 D where $\tan\mu_Y/\mu_X = \tan 18°$ and $\tan\mu_Z/\mu_X = \tan 27°$

would be most improbable. Calculation at position 6 for the quadrant directions of Hg → Cl shows that when this vector points toward the 2-position the moment would be 6.2 D; away from position 2, 2.3 D; toward position 5, 5.0 D; and away from position 5, 4.3 D. Therefore the observed moment is about what would be expected if rotation were hindered within the realm of the norbornane cage, thus minimizing the 6.2 D and the 5.0 D conformations.

The moment calculation from XXIX for 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (X), assuming free rotation, is 7.0 D. While this is lower than the observed moment (7.18 D) the slight discrepancy is not unexpected in view of possible hindrance when Hg → Cl is directed toward C_5. This conformation detracts slightly from the total because of the angle of 120° which the Hg—C bond makes with the C_5—C_6 bond. Consequently, the observed moment may be expected to be slightly higher than that calculated for harmonic free rotation.

However, a greater discrepancy exists between observed moment (6.4 D) and that calculated (7.50 D) from the partial structure, XXX, for 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (XIV). Several explanations are possible to account for this discrepancy. First, the assumption that the carboxyl group is bound so that its group moment is linear may apply to the ↓ position where it is "bound" by the lactone resonance but not to the ↑ (actually equatorial) position. Thus it may contribute, together with the chloromercuri group, three rotators in the structure. The equation for a single rotator would then not apply. More likely is the possibility that this heavy molecule exists as a carboxylic acid dimer which is stable even in very dilute solution because of the non-hindered equatorial carboxyl group. This hydrogen-bridging would effectively lower the moment. Some evidence for this bridging is found in the fact that the moment in dioxane increases from 6.40 D at 25° to about 6.6 D at 70°.

However, it is advisable to consider only qualitatively any moment value in which more than two rotators are involved. For this reason there are numerous entries in Table III for which no calculations are attempted. However, a typical example may be chosen in the observed moment of 3-↓-acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride (3.6 D, III). When the accepted value (1.80 D) for the acetoxy group (26) in its *cis* conformation is used with a calculated moment angle of 121° the over-all molecular moment where two rotators are inclined at 120° is 4.0 D. However, the discrepancy may be made to disappear and then to reappear in a moment value lower than that observed by alteration in the rotations at the ether linkage and the carbonyl linkage in the acetoxy

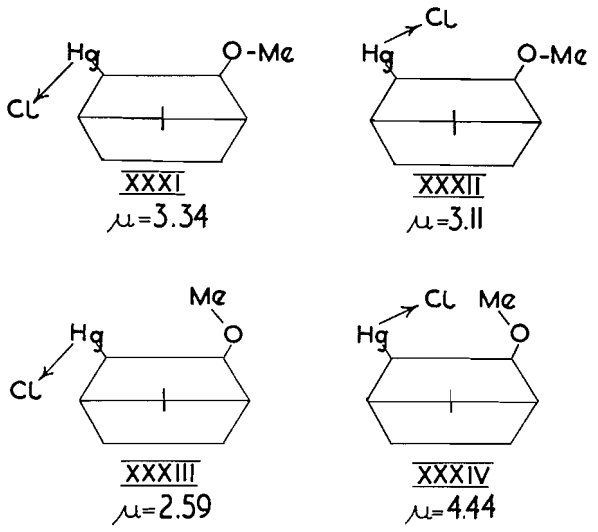
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

group. Since the anharmonicity of these rotators is unknown, the calculation is of little significance.

The moment calculation for 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride (IV) is more propitious because only two rotators are involved. The rotation is assumed to be harmonic. One rotator is C—Hg—Cl with a group moment of 3.67 D and moment angle 79° from C—Hg. The other rotator is a combined norbornane plus methoxyl moment (μ_0 = 1.30+0.43 cos 55° = 1.59 D). The rotator axes are separated by 65°. The resultant is 4.12 D, slightly low by comparison with the observed moment of 4.22 D. This discrepancy may be attributed to anharmonicity such as was postulated for the 2,3-↓↓-dicarboxy analogue (X) because of slight steric hindrance.

When μ for 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↓-mercuric chloride (VI) is calculated on the same free-rotatory basis as is the diastereomer, IV, the value, 3.4 D, is considerably higher than has been measured (2.88 D). However, a consideration of the quadrant conformations shows that XXXIV surely is excluded on the basis of hindrance between chloromercuri and methoxy. Probably XXXII is excluded for the same reason. The average calculated moment due to XXXI and XXXIII is 2.86 D, in agreement with the observed value.

The reasonable adjustments which have been made in calculation are required to bring the norbornane oxymercurials of unknown configuration into correlation with the known configuration of the norbornane dicarboxylic acid mercurials. However, these adjustments have a further significance because those diastereomers (↓↓) in which hindrance is assumed to exist are also the ones which are most easily deoxymercurated.



The mechanism of deoxymercuration has been suggested variously as due to polar (27) and steric effects (28), and both probably are operative. Certainly the extreme resistance of alkylmercuric halides and the moderate resistance of arylmercuric halides toward demercuration, in contrast to comparatively easy deoxymercuration, shows that polarity of substituents is significant. The static aspects of steric effect have been shown by experiment to be profound. Additionally, and related both to polarity and geometry, are the internal degrees of freedom. The acceptance of the deoxymercurating agent either

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

by co-ordination with the oxy group (polar mechanism) or in concerted cyclic transition states (steric (28)) must be related to molecular flexibility. The rigidity imparted by the norbornane cage makes it possible to correlate the moment values with the ease of deoxymercuration and thus to justify the behavior of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (XI), and the simpler mercurial, VI, which is configurationally related to it.

In summary, the calculations show that since the dipole moment of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (XI, the configuration of which is known), is lower than that of 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (X), the moment of the norbornene methoxymercurial (which is higher than that of the diastereomer to which it may be rearranged) designates it as 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride. The addition of the elements of methoxymercuric salts to norbornene thus occurs in the ↓↑ (so-called *trans*) manner. In part, this is true for oxymercuration of all norbornenes except 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid (VII). The oxymercuration of all norbornenes seems to be acid-catalyzed. This catalysis as well as the ultimate configuration indicates that oxymercuration of norbornenes occurs by an ionic mechanism which may be expressed in terms of a cationic intermediate such as the alkene–mercurinium ion postulated by Lucas, Hepner, and Winstein (3).

But the oxymercuration of cyclohexene, for which this postulate was made, is neither acid-catalyzed nor does the product resemble the oxymercurial from norbornene in respect of moment magnitude and resistance toward deoxymercuration. The same dissimilarity applies to the oxymercurials of cyclopentene, α-terpineol, and also of the stilbenes if conformational aspects are taken into consideration. Although the postulation of Lucas, Hepner, and Winstein seems to apply to a bicyclic alkene in which electron field distortion is probable, this postulation is unrealistic in respect of the conformationally restricted type of alkene for which it was promulgated. The latter type seems to be oxymercurated by a molecular mechanism which causes ↓↓ (so-called *cis*) addition. However, ↑↓ oxymercuration might be found to occur among α,β-unsaturated carbonyl compounds.

The authors wish to thank the National Research Council for funds in support of this research, and also Dr. Henry Richmond for aid in some of the moment calculations.

EXPERIMENTAL

Physical Constants

Melting points have been corrected against reliable standards (29). X-Ray diffraction patterns have been made with Cu K_α (Ni-filtered) radiation and are expressed as relative intensities $[I/I_1]$ for d spacings in Å. Temperature composition diagrams have been determined (1° per minute) by the method of Rheinboldt and Kirscheim (30). Electrical polarizations in dioxane solutions were made with the apparatus and method described previously (31), and no value of $\Delta\epsilon/\omega_2$ or $\Delta\bar{V}/\omega_2$ was accepted unless the extrapolation matched the ϵ and $\bar{V}$ for pure dioxane. Distortion polarizations were determined from compressed pellets and/or additive group refractions.

Purification of Reagents

The norbornene (1,4-↑↑-methylene-Δ^2-cyclohexene, 100 g) was shaken twice at 50° with 200 ml of 5% aqueous ferrous sulphate in a separatory funnel under nitrogen, then twice with 50-ml portions of water. After it was dried under nitrogen with magnesium sulphate the norbornene was distilled under nitrogen at 95–97°, then fractionated under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

nitrogen in a 100-plate column, reflux ratio 1:35, b.p. 97–98°, m.p. 45–47°. The mercuric acetate was crystallized from acetic acid (2.5 ml per g) and was washed with anhydrous ether until the odor of acetic acid no longer could be detected.

3-↓-Hydroxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric Chloride (IV, R = H, X = Cl)

A system consisting of 0.94 g (0.01 mole) of norbornene with 3.18 g (0.01 mole) of mercuric acetate and 0.2 ml of concentrated nitric acid in 35 ml of water was allowed to react 1 day and then was treated with aqueous sodium chloride. The product (88%) melted at 124–128° and was purified for analysis (see Table IV) by crystallization from 1:1 ethanol–water. When the nitric acid was not included the crude melting point was 119–125° and treatment with alkali was required to saponify the acetate which was present as an impurity. The other derivatives of Table IV were prepared by treatment with the appropriate sodium halide.

3-↓-Acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric Acetate (III, X = OAc)

To 6.36 g (0.02 mole) of mercuric acetate suspended in 30 ml of 2,5-dioxahexane was added 1.88 g (0.02 mole) of norbornene. After 5.5 hours the insoluble substance was filtered off and washed with 30 ml of dioxahexane, 6.55 g (79%), m.p. 98–100°. The substance was obtained in 84% yield by use of acetic anhydride as the reaction medium (32). Calc. for $C_{11}H_{16}HgO_4$: Hg, 48.7. Found: Hg, 49.3.

4-↓-Acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric Chloride (III, X = Cl)

(*a*) *By Acetylation*

To 2 ml of anhydrous pyridine was added 0.5 g (0.0014 mole) of 3-↓-hydroxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride. To this solution was added 1 ml (0.0065 mole) of acetic anhydride. After 2 days at room temperature the system was poured into 20 ml of cold 5% aqueous sodium chloride. The slowly solidifying product (0.56 g, 98%) melted at 122–124°. After two crystallizations from acetone the melting point (130°) of the product was not depressed by a sample prepared according to procedure (*b*). The substance was found by flotation in thallium formate – malonate at 5° to have a density of 2.37.

(*b*) *By Salt Exchange*

The compound may be obtained in 8% yield by dilution of the mother liquors from the acetate (see above) with aqueous sodium chloride. Alternatively, 1.04 g (0.0025 mole) of 3-↓-acetoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric acetate was shaken with 25 ml of 5% aqueous sodium chloride for 2 hours, converting it to 0.87 g (88%) of the chloromercurial, m.p. 124–128°. Crystallization from acetone (7 ml per g) raised this melting point to 130.8–131.8° (0.63 g).

The X-ray diffraction pattern was determined: [10] 14.40; [7] 4.77, 4.27, 3.86, 3.53, 2.79; [6] 5.71, 2.41; [5] 5.27, 3.12, 2.47; [4] 8.58, 5.90, 4.00, 3.62, 3.06, 2.98, 2.90, 2.51, 2.25; [3] 3.41, 3.25, 2.66, 2.62, 2.35, 2.31, 2.14; [2] 4.13, 2.19, 2.10, 1.96, 1.93, 1.86, 1.81, 1.77; [1] 7.02, 3.34, 2.27, 2.06, 2.00, 1.72, 1.64, 1.36, 1.24, 1.34; [0.5] 4.95, 2.85. Calc. for $C_9H_{13}ClHgO_2$: C, 27.8; H, 3.34; Hg, 51.6. Found: C, 28.0; H, 3.47; Hg, 52.0.

(*c*) *From Norbornene*

To 5 ml of anhydrous peroxide-free 2,5-dioxahexane was added 0.4 g (0.0017 mole) of mercuric acetate with or without a catalyst. To this suspension was added 0.11 g (0.0017 mole) of norbornene and the system was agitated for 4.5 hours, then filtered into 15 ml of 5% aqueous sodium chloride. After 1.5 hours, filtration with water-washing gave 0.65 g (98%), m.p. 126–128°, when no catalyst was added. Addition of boron fluoride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

etherate depressed the melting point but not the yield. Addition of 0.00017 mole of pyridine depressed both (62%, m.p. 122–155°) while 0.0017 mole of this retarder depressed both to 24%, m.p. 121–125°. Under the latter conditions a prolonged reaction time (11 hours) increased this low yield to 41%, m.p. 122–124°. The catalytic effect of an equivalent of methanol was found to be negative since a yield of 70%, m.p. 120–125°, was obtained. None of these products gave a melting point depression upon admixture with the purified product of procedures (*a*) and (*b*). Reaction in glacial acetic acid (15 ml) was more rapid than in dioxahexane. The clear solution, after 30 minutes, was drowned in 30 ml of 5% aqueous sodium chloride giving a quantitative yield, m.p. 127–129°. Two crystallizations from acetone (6 ml per g) raised this melting point to 130°.

3-↓-Methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric Chloride (IV, R = Me, X = Cl)

(*a*) *By Methylation*

From a 250-ml claisen flask containing 80 ml of sulphur-free toluene was distilled 15 ml to remove water. Then 0.59 g (0.015 atom) of potassium and 10 ml of sodium-dried *tert*-butyl alcohol was added. When solution was complete the excess of *tert*-butyl alcohol was distilled off. Then 1.8 g (0.005 mole) of 3-↓-hydroxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride was dissolved in the stirred system. After 90 minutes the whole was partially vacuum-distilled to remove *tert*-butyl alcohol. To the remainder was added 1.89 g (0.015 mole) of pure dimethyl sulphate. After the solution was stirred for 90 minutes 40 ml of 10% aqueous sodium hydroxide was added. The remaining toluene was vacuum-distilled off after 15 minutes. The residue, diluted with 90 ml of 1.5% aqueous sodium chloride, was treated exhaustively with gaseous carbon dioxide. The precipitate, 1.4 g (77%), m.p. 119–122°, was crystallized from absolute ethanol, m.p. 121–123°. A mixture melting point with the methoxymercurial prepared according to procedure (*b*) or by Rowland's procedure (8) was not lowered. The density, determined by flotation at 5° in an aqueous thallium formate – malonate solution, was 2.41. Oxidation with alkaline permanganate was difficult and much unchanged mercurial was recovered. However, a 10% yield of 1,3-↓↓-cyclopentanedicarboxylic acid, m.p. 119°, was obtained.

(*b*) *By Standard Oxymercuration*

To 10 ml of absolute methanol containing the catalyst (see Table II) was added 0.23 g (0.0025 mole) of norbornene. To the homogeneous solution was added with shaking 0.80 g (0.0025 mole) of mercuric acetate. The homogeneous reaction continued for 90 minutes; then the system was chilled to 5° and this temperature was maintained while 20 ml of 5% aqueous sodium chloride was added. The system kept at 5° during 2 hours was filtered, washed with water, and vacuum-dried. The typical yield with 0.5 equivalent of boron fluoride was 0.85 g (95%), m.p. 115–118°, or with 0.2 equivalent of ferrous sulphate was 95%, m.p. 108–114°. The product was analyzed as described below or was crystallized from hot carbon tetrachloride (1 ml per g), m.p. 120–121°. Melting point ranges were determined in the Rheinboldt apparatus, the temperature–composition diagram having been determined from known mixtures of methoxy- and acetoxy-mercurials which were together dissolved in chloroform and evaporated. The acetyl content of the known mixtures and the products were determined by the method of Friedrich (33).

(*c*) *From Mercuric Chloride*

A mixture of 0.94 g (0.01 mole) of norbornene and 2.71 g (0.01 mole) of mercuric chloride in 25 ml of methanol was maintained for 10 hours and then chilled to −60° and filtered to remove 0.67 g, m.p. 89.5–91.5°, which contained 0.30 g of benzene-insoluble mercuric chloride. The filtrate was diluted to a volume of 45 ml and was filtered quickly, 0.49 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

m.p. 121–122°. The total yield (0.86 g, 24%) was crystallized from 2:1 hexane–benzene, m.p. 122–123°. A mixture melting point with the pure products of procedures (*a*) and (*b*) was not lowered.

(*d*) *By Mercuric Acetate plus Mercuric Oxide*

Suspensions of 10 ml of absolute methanol, 0.80 g (0.0025 mole) of mercuric acetate, and 0.10 g (0.0005 mole) of alkali-free yellow mercuric oxide were stirred under reflux in nitrogen for 8 hours. Each was then stirred for various periods of time after 0.23 g (0.0025 mole) of norbornene was added, then was chilled and treated with 20 ml of 5% aqueous sodium chloride and chilled to 5° overnight. The yield after 15 minutes and also after 4 hours was 70%, m.p. 92–101°, but after 12 hours it was 90%, m.p. 92–106°, indicating a retarded formation of methoxymercurial. The marked acceleration after 4 hours undoubtedly is related to the disappearance of suspended material after this time interval.

TABLE IV

Preparation and properties of 2-↓-alkoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric halides (IV) from equimolar amounts of norbornene (1) and mercuric acetate in the protonic medium (ROH), then treated with alkali halides (MX)

2,2′-↑↑-Mercuri-bis-3-↓-methoxy-1,4-↑↑-methylenecyclohexane (V, *dd,ll and* V, *dl,ld*)

To 100 ml of 85% hydrazine hydrate chilled to −70° was added 27 g (0.0075 mole) of 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride. The temperature was allowed to rise slowly to that of the ice bath into which the system was transferred. After 20 minutes a pink color was observed which changed to blue-black. After 12 hours at 25° the whole was heated on the steam bath for 3 hours, then chilled for 12 hours.

The aqueous layer and the metallic mercury were decanted from the white solid (12 g, 70%, m.p. 70–110°) which was heated with 100 ml more of hydrazine hydrate on the steam bath for 11 hours. Chilling yielded 4.3 g (25%) of crude product, m.p. 62–66°, softening at 55°. The same color change and the same yield, but with lower melting point (56.2–57.5°), may be obtained if 1 mole of mercurial in 5 moles of 2.5% aqueous alkali is treated with 0.5 mole of stannous chloride dihydrate during 24 hours.

This mixture of two diastereomers may be separated by 'triangular' crystallization utilizing methanol in which the higher melting isomer is relatively insoluble and methanol–water from which the lower melting isomer may be crystallized. Finally the higher melting isomer was crystallized from acetone, m.p. 107.5–108°. The lower melting isomer finally was crystallized from methanol, m.p. 66–66.5°. The ratio of high to low was found to be 6 to 1. Calc. for $C_{16}H_{26}O_2Hg$: C, 42.7; H, 5.76. Found (high): C, 42.8; H, 5.73. Found (low): C, 42.7; H, 5.67. The X-ray pattern for the high melting diastereomer was [10] 10.64, 10.00, 5.82, 5.60; [6] 4.21, 3.87, 3.77, 3.47, 3.26; [4] 2.74, 2.65, 2.22, while that of the low melting isomer was [10] 11.33, 5.34, 4.79; [9] 7.76, 7.53, 3.90; [8] 3.61, 3.46; [6] 3.09, 3.02, 2.68, 2.59, 2.36, 2.40; [3] 2.15, 2.10.

When either the high or low melting isomer was refluxed for 3 hours with 2 equivalents of mercuric acetate in methanol, and then was treated with sodium chloride, the crude chloromercurials melted at 120–122°. A mixture melting point with 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride was not lowered. In each instance about 10% of bis-mercurial was recovered unchanged. The same chloromercurial, m.p. 121–122°, was obtained when either isomer was treated with methanolic hydrochloric acid for 5 minutes. Either isomer could be heated to 115° for 40 minutes without change.

An unsuccessful attempt was made to synthesize the bis-mercuri diastereomers by converting 0.9 g (0.0025 mole) of 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride either to the organomercuric acetate by 0.41 g of silver acetate or to the organomercuric hydroxide by treatment with silver oxide, both in methanol, followed by treatment with norbornene (0.47 g, 0.005 mole) and 12 mg of boron fluoride etherate. After 1 day the original mercurials were recovered unchanged.

1,4-↑↑-Methylenecyclohexan-↓-yl Phenylurethane

To 1.40 g (0.004 mole) of 3-↓-hydroxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride in 18 ml of methanol was added a solution of 0.32 g (0.008 mole) of sodium hydroxide in 1 ml of distilled water. This solution was refluxed 6 hours with 0.47 ml (0.008 mole) of 85% hydrazine hydrate; 0.70 g (87%) of the mercury was filtered off as the metal.

The filtrate, diluted with 75 ml of water, was ethyl ether-extracted (75 ml) and the extract was evaporated to 5 ml. The solid which crystallized, m.p. 151–152°, 0.28 g (62%), was 2-hydroxy-1,4-↑↑-methylenecyclohexane (no mercury). A mixture melting point with an authentic sample of 2-↓-hydroxy-1,4-↑↑-methylenecyclohexane (34) gave no depression. A 0.01-g (0.0009 mole) portion of the alcohol was treated with 1 equivalent of phenyl isocyanate in 3 ml of hexane for 1 day. The urethane, 0.15 g (60%), melted at 158–159° before and 160–161° after crystallization from benzene, mixture melting point not lowered.

3-↓-Methoxy-1,4-↑↑-methylenecyclohexyl-2-↓-mercuric Chloride (VI)

To 25.2 g (0.07 mole) of 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride (IV, R = Me, X = Cl) in 750 ml of water plus 5.60 g (0.14 mole) of sodium hydroxide was added 0.3 g of 100% hydrazine hydrate. After 6 hours the cooled system was ether-

extracted (30 ml) and the aqueous, metallic, and non-aqueous phases were separated. The aqueous phase was acidified with acetic acid to yield a variable amount of original mercurial admixed with bis-mercurial and product, m.p. 78–95°, mixture melting point with original mercurial 80–110°, maximum amount 12.1 g (48%).

The non-aqueous phase was evaporated leaving an oil, 4.80 g, which was dissolved in 35 ml of hot methanol. Then 2 ml of concentrated hydrochloric acid was added to the slightly warm solution. After 30 minutes at room temperature water was added to turbidity. The system was extracted by chloroform and this extract was vacuum-evaporated leaving 1.80 g of semisolid which was crystallized from carbon tetrachloride (11 ml per g), 1.5 g, m.p. 113–114°, 6% yield. Crystallization from absolute ethanol (30 ml per g) raised this melting point to 117.7–118.5°, recovery 45%. A mixture melting point with the original mercurial was lowered to 80–85°. Diffraction pattern: [10] 11.62; [8] 5.14, 4.14, 3.37, 3.14; [6] 6.91, 6.28, 5.21; [5] 3.09; [4] 3.87, 3.46, 2.15, 2.10. Calc. for $C_6H_{13}ClHgO$: C, 26.6; H, 3.63; Hg, 55.6. Found: C, 26.7; H, 3.74; Hg, 55.0.

In a variation the concentrate from the non-aqueous extract of the reaction system was shaken for 15 minutes with 150 ml of 10% hydrochloric acid. The gummy solid was dissolved in 125 ml of absolute ethanol, and 2 ml of 5% aqueous sodium chloride was added. After 30 minutes a precipitate appeared (m.p. 110–112°, yield 12%), which was purified to m.p. 117.5–118.5° as described above.

A mixture of this ↓↓-diastereomer and the ↑↓-diastereomer from which it was formed (0.1 g of each in 10 ml of methanol) was treated with 0.2 ml of hydrochloric acid for 40 minutes. Addition of sodium hydroxide precipitated mercuric oxide which was filtered off. The filtrate, upon acidification with acetic acid, precipitated 0.06 g (30%), m.p. 112–117°. Crystallization from absolute ethanol raised this melting point to 120–122°. A mixture melting point with the ↓↓-diastereomer was lowered to 95° while no depression was observed upon admixture with the ↑↓-diastereomer.

2-↓-Methoxy-1,4-↑↑-methylenecyclohexane

A suspension of 11 g (0.03 mole) of 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride in 50 ml of water was shaken slowly and 100 g (0.1 atom) of 2% sodium amalgam was added. After 12 hours the system was steam-distilled and the non-aqueous phase of the distillate was dried with magnesium sulphate and distilled, b.p. 59–62°, at 30 mm, 1.90 g (50%), n_D^{20} 1.4574. It was redistilled, b.p. 154–155°, at 750 mm, n_D^{20} 1.4572. This product could not be frozen at −80° C. The same product was obtained by reduction of 3-↓-methoxy-1,4-↑↑-methylenecyclohexyl-2-↑-mercuric chloride with an excess of hydrazine hydrate and by methylation of 2-↓-hydroxy-1,4-↑↑-methylenecyclohexane in diethyl ether by use of sodamide and methyl iodide. Calc. for $C_8H_{14}O$: C, 76.1; H, 11.25; OCH_3, 24.6. Found: C, 76.1; H, 11.17; OCH_3, 25.1.

5-↓-Hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone, μ = 3.88 D (XI)

A solution of 1.82 g (0.01 mole) of 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid in 50 ml of water at 80° was agitated while 2.70 g (0.01 mole) of mercuric chloride dissolved rapidly. The product appeared within 6 seconds and was filtered off when the system was cool, m.p. 202°, 3.97 g (95%). By crystallization via solution in dimethylformamide and gradual precipitation with chloroform (the first slight precipitate being discarded) it melted at 225–226° when inserted about 10° below this melting point. The X-ray diffraction pattern was [10] 4.55; [9] 4.74; [8] 4.00; [7] 6.13, 6.57, 7.25; [5] 2.78; [4] 3.50; [3] 2.57; [2] 2.88, 2.98; [1] 5.51, 3.06; [0.5] 4.16, 3.43.

A repetition of this experiment in which 2 ml (0.02 mole) of concentrated hydrochloric acid was included showed that the reaction was retarded both with respect to time of appearance of product and disappearance of inorganic mercury. However, the ultimate yield was 2.68 g (89%). The delay was still longer (20 minutes) before the first precipitate appeared when 4 ml (0.04 mole) of hydrochloric acid was included and the final yield after 1 day was 75%. Conversely the inclusion of 4 ml (0.01 mole) of 10% aqueous sodium hydroxide in the system reduced the time for appearance of product to 3 seconds; the ultimate yield was 93%.

5-↓-Hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic Acid, $\mu = 4.07$ (XII)

(*a*) *By Isomerization of* XI ($\mu = 3.88$ *D*)

A solution of 41.7 g (0.10 mole) of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylene-2,3-↓↓-dicarboxylic acid ($\mu = 3.88$) in 400 ml (1.0 mole) of 10% aqueous sodium hydroxide was refluxed for 2 hours, then cooled slowly, finally chilled and acidified by acetic acid to pH 5. The precipitate, 12.65 g of impure diastereomer, $\mu = 3.88$, melted at about 200°. The filtrate was made basic to pH 7.5, then was vacuum-evaporated to a 100-ml volume, and then was acidified cold to pH 2 with hydrochloric acid. The 15-g crop, m.p. about 190°, was dissolved in 50 ml of dimethylformamide, filtered, and treated with 80 ml of chloroform. After a precipitate (10 g, m.p. 206°) was filtered off, the filtrate was vacuum-evaporated. The residue was crystallized from 250 ml of boiling water to give 5 g (12%), m.p. 219–219.5°, strongly depressed by admixture with the diastereomer: μ, 3.88. Recrystallization from dimethylformamide–chloroform or from boiling water raised this melting point to 223–223.5° (sample inserted at 215°). Calc. for $C_9H_{11}O_5HgCl$: C, 24.8; H, 2.54. Found: C, 25.0; H, 2.75. The X-ray diffraction pattern was found to be [10] 12.10; [9] 5.12; [8] 3.56; [7] 3.07; [6] 4.67; [5] 6.23; [4] 6.65, 3.97; [3] 10.9, 5.94. The substance largely survived treatment with concentrated hydrochloric acid for 5 minutes but during 50 minutes it was converted to 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↑↓-dicarboxylic acid (XIII), m.p. 184–185°, not depressed by mixture melting point with an authentic sample.

When the mercurial, $\mu = 4.07$, was dissolved in cold alkali and potentiometrically titrated with standard hydrochloric acid it showed by three inflections (corresponding with 3 equivalents) that the substance was not a lactone. Treatment with acetic anhydride failed to convert this hydroxydicarboxylic acid to a γ-lactone.

(*b*) *By Oxymercuration of* XIII

A solution of 76.7 g (0.38 mole) of 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid (XIII) in 3 liters of boiling water was treated with 103 g (0.38 mole) of mercuric chloride. The precipitating system was cooled to 25°, and then 300 ml (0.75 mole) of 10% aqueous sodium hydroxide was added (pH 5). After 8 hours the system was acidified to pH 2. The precipitate was filtered off, washed with methanol and ether, and then vacuum-dried, 145 g, m.p. 211–212°. This crude product was extracted with 1300 ml of boiling water leaving 132 g, m.p. 222–223°. A hot solution in dioxane (10 ml per g) precipitated about 70%, m.p. 217°. The remaining 30% was obtained from the filtrate by addition of an equal volume of diethyl ether and was nearly pure XII, m.p. 218–219°. The process should be repeated with the 70%, m.p. 217°, which yields less pure XII, m.p. 213–214°. All of the crops of XII (estimated total yield, 25%) may be purified by crystallization from boiling water (10 ml per g), m.p. 220–221°.

The aqueous filtrates and the initial precipitates from dioxane crystallizations are rich in XIV. After the latter had been removed as is described below the final aqueous filtrates yielded about 20 g of unchanged norbornenedicarboxylic acid, XIII.

5-↓-Hydroxy-6-↓-hydroxymercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic Acid

A solution of 2.15 g (0.005 mole) of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XII) in 4 ml (0.01 mole) of 10% aqueous sodium hydroxide was shaken with 0.8 g (0.055 mole) of silver oxide for 2 hours, then filtered by suction to remove a mixture of silver oxide and chloride from which 0.70 g (98%) of the chloride was isolated by washing the mixture with nitric acid.

The filtrate from the mixture was acidified to pH 5.6 with acetic acid; the precipitate which appeared momentarily redissolved. When no precipitate appeared after 12 hours the system was further acidified to pH 5 with 10% aqueous acetic acid. The precipitate was filtered off and dissolved in 30 ml of 1% aqueous sodium hydroxide. The solution was clarified by means of Norite, then was filtered, and the filtrate was acidified with acetic acid. After 36 hours at 4° the precipitate was filtered off, 0.70 g (34%), m.p. 198°. Resolution in alkali with Norite treatment gave a solution from which no precipitate appeared upon saturation with carbon dioxide gas. Acidification by acetic acid to pH 5.2 gave a gelatinous precipitate (0.55 g), which was dissolved in alkali, treated with Norite, filtered, and acidified by use of acetic acid, m.p. 200.5–201°. Calc. for $C_9H_{12}O_6Hg$: C, 25.9; H, 2.90. Found: C, 25.8; H, 3.13.

When this substance was dissolved in dilute alkali, and then dilute hydrochloric acid was added, the melting point (221°) of the precipitate was not depressed by admixture with 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XII).

5-↓-Hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic Acid

A solution of 1.08 g (0.0025 mole) of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XII) in 4 ml (0.005 mole) of 5% aqueous sodium hydroxide was chilled to 4°, and 6.5 g (0.01 atom Na) of sodium amalgam was added at once. Next day the system was filtered and the chilled filtrate was acidified with concentrated hydrochloric acid. The crystalline precipitate (0.24 g) melted at 210–211°, decomp. The chilled filtrate after 5 days yielded 0.12 g, m.p. 209–210° (total 72%). The whole was crystallized from 1.5 ml of hot water and also from hot ethyl acetate, m.p. 210–211°, decomp. A mixture melting point with 5-↑-hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid was lowered to 192°. Calc. for $C_9H_{12}O_5$: C, 54.1; H, 6.04. Found: C, 54.1; H, 6.14. The X-ray diffraction pattern is [10] 5.30; [9] 4.38, 4.79; [8] 3.38; [6] 5.68, 3.65; [5] 4.23; [4] 5.98; [3] 3.79, 2.70, 3.22; [2] 2.79, 2.97; [1] 2.16, 2.00, 2.50.

5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-cyclohexane-2-↑-3-↓-dicarboxylic Acid, γ-Lactone, μ = 6.40 (XIV)

(*a*) *By Oxymercuration*

After the product obtained by treatment of 0.38 mole of 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid was extracted to remove XII there remained impure crops (m.p. 208–213°) from dioxane crystallizations, and also filtrates from aqueous extractions and crystallizations. The latter were vacuum-evaporated and the whole was dissolved in hot water (10 ml per g), cooled, and filtered. Evaporation of the filtrates to 1/2–1/3 volume gave precipitates of XIV melting at 228–236°. These crops represent a

total isolable yield of about 40% of theoretical. The final purification was effected by crystallization from hot dioxane (23 ml per g), m.p. 237–238°. Calc. for $C_9H_9ClHgO_4$: C, 25.7; H, 2.18. Found: C, 25.3; H, 2.43. The X-ray diffraction pattern was [10] 13.5; [9] 8.97; [8] 7.29; [7] 10.45; [4] 3.66; [3] 4.27; [2] 6.19, 5.04; [1] 3.01. Treatment for 1 hour with twice its weight of concentrated hydrochloric acid converted the mercurial into 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid, m.p. 186–187°, authenticated by mixture melting point.

When a solution of 150 mg of this mercurial (μ = 6.40 D) and 150 mg of 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (μ = 4.07 D) in 80 ml of dioxane was treated with 0.5 ml of concentrated hydrochloric acid for 3 hours the vacuum-evaporated system could be extracted with chloroform to yield only one mercurial, which, crystallized from water, melted at 230°, 60 mg, with powder diagram identical with that shown above for the compound, μ = 6.40 D. The chloroform-insoluble portion yielded 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid, m.p. 186–187°, with X-ray powder diagram [10] 4.99; [5] 4.34; [4] 3.92; [2] 4.61, 4.51, 3.44, 3.19; [1] 6.43, 5.62, 3.01, 2.95, 2.68. This pattern is in contrast to that determined for 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid, m.p. 179–180°, which is [10] 6.10; [9] 4.44; [8] 4.23; [5] 4.95; [3] 3.86, 3.25; [2] 2.79, 2.73; [1] 5.47, 5.18, 5.06, 3.49, 2.39. The reader is cautioned about the subtle difference between this latter pattern and that of the product of platinum-catalyzed reduction, 1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, m.p. 161–161.5°: [10] 6.25; [9] 4.45; [8] 4.32; [5] 5.05; [3] 3.91, 3.35, 3.27, 2.79, 2.48; [2] 5.23; [1] 5.62, 5.45, 3.82, 2.93, 2.72.

A solution of 0.86 g (0.002 mole) of 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone, in 4 ml (0.005 mole) of 5% aqueous sodium hydroxide was chilled and treated at once with 5.2 g (0.008 atom Na) of 3.5% sodium amalgam. After 7 hours the system was filtered and the chilled filtrate was acidified strongly with concentrated hydrochloric acid. The crystals, 0.25 g, m.p. 127–128° (70%), were recrystallized from benzene (50 ml per g), m.p. 132–133.5°. A mixture melting point with 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone, was not depressed.

(*b*) *By Isomerization*

A mixture of 1.82 g (0.0032 mole) of 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (X, μ = 7.18), and 0.82 g (0.0032 mole) of mercurous acetate in 25 ml of methanol was refluxed for 8 hours. Then it was diluted with water and made slightly alkaline. Darco was added and the dirty yellow precipitate was filtered off. The filtrate was acidified by addition of acetic acid to yield 1.00 g of chloride-free precipitate of indistinct melting point.

This precipitate was refluxed 3 hours in 20 ml of 4% aqueous sodium hydroxide, then chilled and acidified to pH 5.0 by addition of acetic acid. After 12 hours 0.48 g of infusible precipitate was filtered off. The filtrate upon acidification to pH 2 with dilute hydrochloric acid yielded 0.22 g, m.p. 233–235°, not depressed by admixture with the mercurial, μ = 6.40, prepared by oxymercuration, but was depressed by the mercurials X (μ = 7.18) and XII (μ = 4.07).

The infusible precipitate, 0.48 g, was dissolved in 10% aqueous sodium chloride and then was acidified with 12% hydrochloric acid. The precipitate, m.p. 211–213°, was crystallized from water, m.p. 223–224°, not depressed by admixture with the reagent mercurial, X.

5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone, μ = 7.18 D (X)

To a solution of 1.13 g (0.005 mole) of stannous chloride dihydrate in 50 ml (0.02 mole) of 1.6% aqueous sodium hydroxide was added 4.00 g (0.01 mole) of 5-↓-hydroxy-anhydro-[6-↓-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid (11) and then 2.7 cc (0.0068 mole) more of aqueous 10% sodium hydroxide; final pH was 8. After 1 hour the black precipitate was filtered off. The cold filtrate was strongly and quickly acidified with 12% hydrochloric acid in order to redissolve the precipitated tin salts; then a granular precipitate appeared. After 12 hours the precipitate was filtered off and washed with water, 1.95 g (47%), m.p. 204–205°. Crystallization from methanol (0.6 g per ml, Darco) raised this melting point to 225.5–226°. Mixture melting points with the mercurials of moments of 3.88, 4.07, and 6.40 D all were depressed. X-Ray diffraction pattern is [10] 6.70; [7] 12.10; [5] 6.15, 5.02, 4.88, 4.00, 3.62, 3.14; [4] 3.32, 2.74, 5.32, 4.38; [1] 4.58, 4.22, 3.07. Calc. for $C_9H_9ClHgO_4$: C, 25.7; H, 2.17. Found: C, 26.2; H, 2.31.

When 0.10 g of this product and of the diastereomeric mercurial, μ = 3.88 D, were mixed and treated with 0.5 ml of concentrated hydrochloric acid for 5 minutes the diluate with an equal volume of water yielded 6 mg with X-ray diffraction pattern corresponding with the product, μ = 7.18 D. When the latter was treated alone with 1.4 times its weight of concentrated hydrochloric acid for 45 minutes at least 30% of it survived, m.p. 216–217°, not depressed by admixture with the pure reagent, μ = 7.18 D. However, a reaction period of 12 hours yielded only 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, m.p. 202°, not depressed by admixture with the authentic lactone (35). The lactone was characterized further by methylation as described below.

5-↓-Hydroxy-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic Acid, γ-Lactone

A solution of 7.28 g (0.04 mole) of 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, m.p. 201–202°, in 32 ml (0.08 mole) of 10% aqueous sodium hydroxide was heated to boiling for several minutes, then cooled to 25°, and 6.72 g (0.08 mole) of sodium bicarbonate was added in 50 ml of water. Then 15.2 ml (0.16 mole) of dimethyl sulphate was added and the system was stirred for 2 days. The whole was then exhaustively extracted with chloroform. The evaporated extracts were crystallized from water, 4.79 g, 61%, m.p. 76–77°. This product was crystallized from benzene – commercial hexane (1:1, 40 ml per g), m.p. 81–82°. X-Ray diagram was [10] 5.38; [8] 4.73; [6] 6.53; [5] 3.99, 3.50, 3.39; [3] 3.81, 2.85; [2] 5.94, 4.38, 3.27; [1] 7.59, 4.94, 2.27. Calc. for $C_{10}H_{12}O_4$: C, 61.3; H, 6.17. Found: C, 61.3; H, 6.23.

5-↓-Hydroxy-2-↑-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic Acid, γ-Lactone

When 1.96 g (0.01 mole) of 5-↓-hydroxy-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, γ-lactone, m.p. 81–82°, was treated for 45 minutes with a solution of 0.23 g (0.01 atom) of sodium in 15 ml of methanol and then with 0.95 ml (0.01 mole) of dimethyl sulphate a rise in temperature was observed at the last step. After 1 hour the solvent was removed under vacuum and replaced with water. The product (1.46 g, 70%, m.p. 67–68°) was crystallized from boiling ethyl ether (1.2 ml per g), m.p. 68.3–68.8°. X-Ray diagram: [10] 5.15; [9] 4.59; [5] 5.64; [3] 6.60, 4.23; [2] 3.83, 3.46, 2.87; [1] 3.68, 2.58, 2.11. This substance was recovered unchanged after 6 hours with 1 equivalent of 10% aqueous mercuric acetate. When the substance was saponified during 1 hour with 10% aqueous alkali at 80° or was hydrolyzed by concentrated hydro-

For personal use only.

chloric acid during 1 minute it yielded 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone, m.p. 132.8–133°, authentic according to mixture melting point and elemental analysis. Calc. for $C_{10}H_{12}O_4$: C, 61.3; H, 6.17. Found: C, 61.8; H, 6.32.

1,4-↑↑-Methylene-Δ⁵-cyclohexene-2,3-↑↓-dicarboxylic Acid (XIII)

When prepared by sodium methoxide saponification of dimethyl 1,4-↑↑-methylene-Δ⁵-cyclohexene-2,3-↓↓-dicarboxylate (35) the compound melted at 186.5° after crystallization from hot acetonitrile (25 ml per g). The powder diagram is reported above.

Dimethyl 5-↑-Acetoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylate (XXIII, Z = CH_3CO, X = Cl)

(*a*) *In 2,5-Dioxahexane*

To a solution of dimethyl 1,4-↑↑-methylene-Δ⁵-cyclohexene-2,3-↓↓-dicarboxylate (m.p. 37°, 1.05 g, 0.0047 mole) in 10 ml of anhydrous 2,5-dioxahexane was added 1.45 g (0.0046 mole) of mercuric acetate. After 74 hours of agitation the system (in which all of the solid had dissolved) was poured into 40 ml of 2.5% aqueous sodium chloride. The oil soon crystallized, 1.925 g (83%), m.p. 153–158°. Four crystallizations from methanol raised the melting point to 177°. Diffraction pattern was [10] 5.64; [9] 6.41; [8] 11.47, 6.96; [7] 4.80, 3.88; [6] 3.23; [4] 4.50, 3.66; [3] 4.17, 3.48. Calc. for $C_{13}H_{17}ClHgO_6$: C, 30.9; H, 3.38; OCH_3, 12.3. Found: C, 30.6; H, 3.54; OCH_3, 12.1.

(*b*) *In Methanol*

To 2.10 g (0.01 mole) of the dimethyl ester in 35 ml of anhydrous methanol was added 3.18 g (0.01 mole) of mercuric acetate. The salt dissolved during 25 minutes. After 8 hours the system was filtered into 100 ml of 5% aqueous sodium chloride. The precipitate (4.57 g, 95%, m.p. 163–165°) was crystallized from absolute methanol (25 ml per g), m.p. 171–172°.

(*c*) *In Acetic Acid*

A solution of 10.5 g (0.047 mole) of the ester used in procedure (*a*) and 14.5 g (0.046 mole) of mercuric acetate in 50 ml of glacial acetic acid was let stand for 12 hours, then was poured into 350 ml of 3% aqueous sodium chloride. The precipitate was filtered off after 1 hour, washed with water and with methanol, and vacuum-dried, 22.1 g (93%), m.p. 173–174°. Crystallization from methanol (55 ml per g) raised this melting point to 177–177.2° (11.4 g). Subsequent crops, m.p. 175–168°, obtained by chilling and by concentration of the mother liquor finally left a filtrate which was vacuum-evaporated. The residue was twice purified by solution in warm dimethylformamide (12 ml per g), filtration of the slight precipitate appearing at 25°, and then dilution with an equal volume of chloroform. The product (0.13 g, 0.5%), m.p. 229–229.5°, was found to be 5-↓-hydroxy-6-↓-chloromercuri-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic acid, γ-lactone (XXII, X = Cl) (11). Identification was made by mixture melting point after it was found that the substance prepared from the ester and mercuric acetate in water also melted at 229° (rather than 223.5°) after sufficient purification. The two products gave the same X-ray powder pattern.

When 3 g of the dimethyl 5-↑-acetoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylate was reduced by 2 g of lithium aluminum hydride in tetrahydrofuran (slow addition followed by reflux) with hydrolysis by aqueous ammonium chloride, the product, m.p. 78-84°, weight 0.85 g, upon crystallization from commercial pentane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

melted at 81.5–83°. It reacts rapidly with alkaline permanganate to yield a product which may be 2,3-dimethylol-1,4-↑↑-methylene-Δ^5-cyclohexene.

5-↑-Hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic Acid (XXIV)

A solution of 5.15 g (0.01 mole) of dimethyl 5-↑-acetoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylate in 36 ml (0.09 mole) of 10% aqueous sodium hydroxide was maintained at room temperature for 15 hours, then chilled and acidified cautiously to pH 2 with concentrated hydrochloric acid. The precipitation which commenced after 15 minutes was complete after 1 day at 4°. Filtration gave 2.59 g (60%), m.p. 183–184° (inserted at 160°). Quick crystallization from boiling water (10 ml per g) raised this melting point to 184–184.5°. The X-ray diffraction pattern was [10] 4.21, 5.05; [9] 5.79; [8] 5.60; [7] 3.44; [6] 3.26, 3.14; [5] 3.03; [3] 2.39; [2] 2.74; [1] 2.66, 3.91. The infrared band spectrum of polyethylene wax pellets (6000 p.s.i. at 23°) containing 5% is reported in wave numbers [cm^{-1}] at specified per cent transmissions: [316] 46; [352] 82; [388] 85; [410–17] 88; [428] 76; [451] 83; [553] 73; [648] 50; [678] 68; [794] 68; [884] 53. The density of the solid at 23° was 2.420 and the extrapolated dielectric constant of pellets was 3.917, so P_{e+a} is 88.5 cc. Calc. for $C_9H_{11}ClHgO_5$: C, 24.9; H, 2.56. Found: C, 25.0; H, 2.70.

When this substance was dissolved and boiled in water (7–8 ml per g) for 15 minutes the crystals which separated upon cooling melted first at 216–217° and then after an identical crystallization at 221–222°. The X-ray diffraction pattern was [10] 9.65; [9] 5.80; [8] 3.64; [7] 7.22; [6] 4.21, 4.25; [5] 4.56, 4.83, 5.26; [4] 3.22, 3.07; [3] 3.35, 3.50; [2] 2.94; [1] 2.82. The infrared band spectrum (5% in polyethylene wax compressed at 6000 p.s.i.) was recorded in [cm^{-1}] at indicated per cent transmissions: [316.8] 42; [351] 75; [390] 76; [414] 76; [429] 66; [453] 71; [550] 58; [649] 42; [675] 54; [696–702] 55; [791] 42; [841] 40; [881] 35. The density of the solid substance at 23° was 2.453 and the dielectric constants of pellets of various thicknesses were extrapolated to zero thickness for $\epsilon = 4.019$, whence P_{e+a} is 88.9 cc. Calc. for $C_9H_{11}ClHgO_5$: C, 24.9; H, 2.56. Found: C, 24.7; H, 2.53.

The melting point was not depressed when the substance was quickly crystallized from water or other solvents, but when it was dissolved in alkali and then reprecipitated by addition of hydrochloric acid the modification, m.p. 184–185°, reappeared. The latter could again be converted to the 221–222° variety by 15-minute reflux in boiling water. The high melting variety decomposed completely when heated under vacuum at its melting point and did not yield any of compound XIV. The filtrate from the original acidified reaction system was found to yield at least 0.59 g of 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↑-dicarboxylic acid, m.p. 187°. Treatment of the mercurial with concentrated hydrochloric acid also gave this product, authenticated by mixture melting point.

It was observed that the low melting 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid at its melting point tended oftentimes to resolidify after melting. This property was utilized by heating 0.2 g, m.p. 184–185°, in a test tube under continuous water aspirator vacuum by immersion into a paraffin bath heated from 185° to 193° during 15 minutes. After cooling to 25° the residue was extracted with 10 ml of hot acetone. This extract was treated with commercial hexane to incipient turbidity. After several hours the system was filtered to remove a slight precipitate. Then the filtrate was vacuum-evaporated to leave a syrup which solidified when moistened with methanol. The solid product, 0.08 g (24%), melted at 232–232.5°, and was found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

by mixture melting point to be identical with 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (m.p. 234°). The X-ray diffraction pattern also was identical with that of XIV.

5-↑-Hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic Acid

A solution comprised of 129.6 g (0.3 mole) of 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid in 480 ml (0.6 mole) of 5% aqueous sodium hydroxide was prepared during 2 hours of stirring. Then 442 g (0.66 atom Na) of 3.5% sodium amalgam was added with stirring during 2 hours, the temperature being maintained at 33°. Five hours later the system was filtered, chilled, strongly acidified by addition of 75 ml of concentrated hydrochloric acid, and continuously extracted with diethyl ether. The first 14-hour extract contained 7.9 g of unchanged mercurial as ether-insoluble material. Subsequently the extraction was continued for 40 hours longer.

The total extract (except for unchanged mercurial) was evaporated, dissolved in 200 ml of ethyl acetate, and then placed on a chromatographic column, 70 mm O.D. by 150 cm long of 100–170-mesh silica gel which had been deactivated by washing with U.S.P. chloroform. The column was first eluted with 4 liters of chloroform and the eluate was discarded. Likewise the first 2 liters of eluate were discarded after 2 liters of 1:1 chloroform – ethyl acetate (purified) and then pure ethyl acetate was used for elution. The next 1.5 liters yielded about 10 g of 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid, m.p. 182–183°. The subsequent eluant (5 liters) yielded a semisolid upon evaporation which was crystallized from hot ethyl acetate to yield 55 g, m.p. 155–160° (90%). Recrystallization from ethyl acetate raised this melting point to 184.5°. The crystallization is accomplished by solution in 10–20 ml of solvent per gram after which 40% of the solvent is distilled off. The rate of crystal growth usually requires 4 to 5 days. Calc. for $C_9H_{12}O_5$: C, 54.1; H, 6.08. Found: C, 53.9; H, 6.04. The X-ray diffraction pattern was [10] 4.21, 5.05; [9] 5.79; [8] 5.60; [7] 3.44; [6] 3.26, 3.14; [5] 3.03; 3] 2.39; [2] 2.74; [1] 2.66, 3.91.

5-↓-Hydroxy-6-↓-chloromercuri-2-↓-carbomethoxy-1,4-↑↑-methylenecyclohexane-3-↓-carboxylic Acid, γ-Lactone (XXII, X = Cl)

A solution of 7.95 g (0.025 mole) of mercuric acetate in 80 ml of water was shaken with 5.25 g (0.025 mole) of molten dimethyl 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate (m.p. 37.5–38°) until the oil dissolved (8 minutes). Thirty minutes later the system was shaken vigorously while a solution of 1.5 g of sodium chloride in 5 ml of water was added slowly. The crude precipitate, methanol-washed and vacuum-dried, weighed 10.2 g, m.p. 201–203° (95%). This product was dissolved in 35 ml of dimethylformamide at 100°. The precipitate formed upon cooling weighed 6.45 g, m.p. 229–229.5° (60%). A methoxyl analysis showed 7.31% OCH_3, calc. 7.19%. The strongest lines of the X-ray diffraction pattern are [10] 9.30; [9] 4.61; [8] 3.61; [7] 2.92; [6] 5.81; [5] 6.55, 2.43; [4] 2.04. Recrystallization from dimethylformamide raised the melting point to 230.5–231°.

When this ester lactone (0.5 g) was dissolved in 1 ml of concentrated hydrochloric acid and the solution, after 12 hours, was diluted with water and let stand 1 week, crystals were obtained. The product, 0.115 g, m.p. 195–196°, was crystallized from hot water, m.p. 201°. A mixture melting point with 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, was not lowered.

Saponification of the pure ester lactone was effected by maintaining a solution of 2.57 g (0.005 mole) in 18 ml (0.045 mole) of 10% aqueous sodium hydroxide for about 12 hours after which the system was boiled for ½ hour. Acidification with 12% hydrochloric

For personal use only.

acid gave 1.96 g, m.p. 181°. Extraction with 40 ml of boiling water left 0.70 g, m.p. 219–220°, which was not lowered by admixture with XI. The cooled filtrate gave 0.68 g, m.p. 196–197°, from which successive crops of XI could be obtained. The final crop, 0.33 g, melted at 209–210° and was impure 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XII) of X-ray diffraction pattern [10] 5.14; [8] 12.02; [7] 3.55, 3.94; [5] 3.07; [4] 4.30; [3] 4.47, 6.25; [2] 5.92, 6.73; [1] 10.84, 3.74.

A by-product was also found to be formed in the oxymercuration. When the dimethylformamide contained in the mother liquors from crystallization of the 10.2 g portion (above) was evaporated the residue upon quick crystallization from boiling water melted at 181°. After another quick crystallization it melted at 187–188° and resolidified to melt again at 214°. These properties identify it as 5-↑-hydroxy-6-↓-chloromercuri-1,4-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (XXIV). Further proof was obtained by heating 0.2 g under vacuum from 195 to 204° during 20 minutes. An acetone extract of the cooled residue, evaporated and treated with methanol, gave 0.05 g of 5-↓-hydroxy-6-↑-chloromercuri-1,4-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (XIV), m.p. 232–233°, with partial X-ray diagram [10] 7.13; [9] 5.65; [7] 2.35; [6] 3.50; [5] 2.84; [4] 4.05.

Dimethyl 5-↑-Methoxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylate (XXIII, Z = Me, X = Cl)

To a solution of dimethyl 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate (1.05 g, 0.0047 mole) in anhydrous methanol containing 0.5 g (0.0035 mole) of boron fluoride etherate was added 1.58 g (0.005 mole) of mercuric acetate. After 4 minutes the salt dissolved, and after 10 minutes the whole was poured into 50 ml of 5% aqueous sodium chloride. After 2 days at 4° the precipitate was filtered, water-washed, and dried, 1.78 g, m.p. 97–121°. This mixture of acetoxy- and methoxy-mercurials was fractionally crystallized from ethyl acetate – isooctane solutions to give impure acetoxymercurial (X-ray diffraction pattern) and pure dimethyl chloromercurimethoxymethylenecyclohexanedicarboxylate, 0.5 g (10%), m.p. 130–131°. X-Ray diffraction pattern is [10] 6.96; [9] 3.97; [8] 5.34; [7] 3.42, 3.08; [6] 4.62; [5] 5.94, 4.27; [4] 2.91. A longer reaction time (36 hours) gave a lower weight yield (1.55 g) of higher (107–114°) melting point. Calc. for $C_{12}H_{17}ClHgO_5$: C, 30.2; H, 3.56; OCH_3, 19.5. Found: C, 30.4; H, 3.64; OCH_3, 19.1.

When XXIII was treated with concentrated hydrochloric acid, and after 1 hour, the system was evaporated to 20% of the original volume crystals of 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, appeared, m.p. 198°. Crystallization from water raised this melting point to 201–202° and a mixture melting point with an authentic sample was not lowered.

5-↑-Methoxy-1,4-↑↑-methylene-2,3-↑↑-[1′-↑-hydroxy-Δ^2-propene-1′,3′-ylene]-cyclohexane

A solution of 5-↑-methoxy-1,4-↑↑-methylene-2,3-↑↑-propenylenecyclohexane (prepared in 92% yield by use of sodamide rather than sodium (36)) in 200 ml of pure acetic anhydride was added dropwise to a stirred ice-cooled suspension of selenium dioxide (67.2 g, 0.6 mole) in 25 ml of water. Following then a comparable procedure (37), an acetate, b.p. 147° (12 mm), was obtained, n_D^{20} 1.4974, 87 g, 65%, % C, 71.0, % H, 8.40. Hydrolysis by the prescribed method gave an 83% yield of the methoxy alcohol, b.p. 148° (11 mm), n_D^{20} 1.5145. Calc. for $C_{11}H_{16}O_2$: C, 73.3; H, 8.88; Found: C, 73.8; H, 8.78.

5-↑-Methoxy-1,4-↑↑-methylene-2,3-↑↑-propenonylenecyclohexane

Following the recommended procedure (37) upon the methoxy alcohol described above an 83% yield was obtained, b.p. 147° (11 mm), n_D^{20} 1.5188, λ_{max} 225 mμ, E_{max} 8,650. Calc. for $C_{11}H_{14}O_2$: C, 74.1; H, 7.85. Found: C, 73.7; H, 7.70.

5-↑-Methoxy-1,4-↑↑-methylenecyclohexane-2,3-↑↑-dicarboxylic Acid

To a stirred solution of the unsaturated ketone (1.5 g) in 30 ml of acetone plus 1 ml of water was added 8 g of potassium permanganate during 10 minutes (37); the system boiled. After 2 hours of stirring 10 ml of water was added, followed by 20 ml of methanol. After 30 minutes the permanganate was reduced so the manganese dioxide was filtered off and washed with acetone and water. The residue from the vacuum-evaporated filtrate was dissolved in 10 ml of water and the solution acidified to pH 4 was saturated with sodium chloride and thoroughly extracted by ethyl ether. The extracts, evaporated, left 1.1 g of sticky solid which was crystallized from benzene–methanol and from water to give 0.68 g, m.p. 149–152°. Crystallization from methanol – ethyl acetate gave 0.37 g, m.p. 166–167°. Calc. for $C_{10}H_{14}O_5$: C, 56.0; H, 6.58. Found: C, 56.4; H, 6.73. X-Ray diffraction pattern is [10] 4.99; [9] 5.73; [8] 3.91; [7] 4.26; [6] 5.45.

Stability of Mercurials Toward Concentrated Hydrochloric Acid

After 1 year a suspension of 0.2 g of butylmercuric chloride in 2 ml of concentrated hydrochloric acid at room temperature was filtered to recover 0.19 g of the mercurial. The filtrate was evaporated to a volume of 1 ml and then was made basic with aqueous sodium hydroxide. No mercuric oxide was precipitated. The result was unaltered by inclusion of 0.01 g of mercurous chloride into the system.

A suspension of 0.1 g of cyclopentylmercuric chloride in 2 ml of concentrated hydrochloric acid and 1 ml of dioxane was refluxed for 1 day. The mercurial was all recovered unchanged, m.p. 112°. The inclusion of 0.01 g of mercuric chloride did not alter this result.

A mixture of 0.200 g each of β-2-chloromercuricineole and of phenylmercuric chloride in 2 ml of methanol was treated with 2 ml of concentrated hydrochloric acid. The system, which became warm, was cooled to room temperature and was stirred for 30 minutes. After dilution with water the solid phase was filtered off, 0.175 g, m.p. 255–256°, which was proved by mixture melting point to be phenylmercuric chloride. Addition of alkali to the filtrate gave 0.258 mmole of mercuric oxide.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS

V. THE HYDROLYSIS OF ACETIC ANHYDRIDE[1]

J. KOSKIKALLIO,[2] D. POULI,[3] AND E. WHALLEY

ABSTRACT

The spontaneous and the acid-catalyzed hydrolyses of acetic anhydride have been measured as a function of temperature over the range 0 to 40° C, as a function of pressure over the range 0 to 3 kb at 0° C, and as a function of solvent over the range 0 to 70.3% w/w acetone–water at 0° C. The results are discussed with reference to the mechanisms of the hydrolyses. The volume and entropy of activation of the acid-catalyzed hydrolysis are $-17.1 \pm \sim 1.3$ cm^3 mole^{-1} and ~ -20 cal deg^{-1} mole^{-1}, showing that the mechanism

$$Ac_2\overset{+}{O}H \rightarrow AcOH + Ac^+,$$

suggested because the rate was proportional to Hammett's h_0, is not correct. It follows that the Zucker–Hammett hypothesis is invalid for this reaction, as we have shown previously for other reactions, and hence that it does not provide a valid method of distinguishing between the A-1 and A-2 mechanisms.

1. INTRODUCTION

The acid-catalyzed hydrolysis of acetic anhydride has been studied by Kilpatrick (1) and by Gold and Hilton (2, 3). It is usually accepted that the first step in the hydrolysis is the equilibrium transfer of a proton to the anhydride. The second step is most likely either a unimolecular decomposition of the conjugate acid (A-1 mechanism) or a bimolecular addition of or substitution by a water molecule (A-2 mechanism). Gold and Hilton (2) measured the rate constants in concentrated acids and found that the first-order constants were much more nearly proportional to Hammett's acidity function h_0 than to hydrogen-ion concentration. They deduced from this that the mechanism is most likely A-1. However, we have shown in previous papers (4, 5) that some reactions that follow h_0 rather than hydrogen-ion concentration are actually A-2, and so the conclusion of Gold and Hilton is doubtful. We have also shown (4, 5, 6, 7) that the pressure coefficient of an acid-catalyzed reaction can help to elucidate mechanism, and in this paper we report a study of the effect of pressure on the acid-catalyzed hydrolysis of acetic anhydride. There are many possible mechanisms. First, there are two possible locations of the proton in the conjugate acid, the carbonyl oxygen and the ether oxygen. Both forms can react by an A-1 decomposition, an A-2 substitution by water, or an A-2 addition of water, which may be either slow, or fast and followed by a slow step. Consequently, unique conclusions are not to be expected. In order to accumulate useful information the effects of temperature and solvent composition have also been studied.

In order to follow the acid-catalyzed reaction it is necessary to study the spontaneous reaction, and similar measurements have been made for this reaction.

2. EXPERIMENTAL METHODS

Reagent-grade acetic anhydride and acetone, and technical-grade aniline distilled in the presence of zinc and solid sodium hydroxide, were used. The acetone–water solvent mixtures were made up by volume at 25° C.

The high-pressure technique was essentially that described in Part II (7). The apparatus has been somewhat improved by using heavier-walled capillary tube to connect the syringe to the valve, so reducing the number of breakages of the tube, and by measuring the pressures at 1000 b and higher by means of a 3-kb Heise Bourdon gauge of accuracy about 0.1%. Runs at 1 b were done in stoppered flasks.

Initial concentrations of acetic anhydride were 0.1–0.2 *M*. For reactions that were acid-catalyzed the acetic anhydride was dissolved in standard acid. Both reactant and solvent were heated or cooled to the temperature of the experiment before mixing. Analysis was done by pipetting 1 to 5 ml of solution (chosen to give a final titer of about 50 ml of barium hydroxide) into 0.3 *M* aqueous aniline. Acetic anhydride reacts quantitatively and rapidly with aniline to give acetanilide and acetic acid; the acetic acid was titrated, together with the acid catalyst and the acetic acid already produced by hydrolysis, with standard barium hydroxide. The difference between the titer and that of a fully hydrolyzed sample is proportional to the anhydride concentration. The half-lives were, at the higher temperatures, rather short, and the pipettes used for taking samples were cooled or heated to the temperature of the experiment; the sample was blown in about 2 seconds from the pipette to the aniline solution, and the time at which this occurred was the time corresponding to the sample. The smallest half-life for the high-pressure experiments was about $1\frac{1}{2}$ hours, so the sampling introduced only a very small error.

The reactions were kinetically of first order up to 75% of complete reaction. The first-order rate constant k is the sum of spontaneous and acid-catalyzed terms, thus

$$k = k_0 + k_a c_{H^+},$$

where k_0 is the first-order constant for the spontaneous reaction, k_a the second-order constant for the acid-catalyzed reaction, and c_{H^+} is the concentration of hydrogen ion. The spontaneous and acid-catalyzed rate constants were calculated from measurements in pure solvent and in acidified solvent respectively. It was calculated from the final values of k_0 and k_a and the dissociation constants of acetic acid in the solvents used, assuming these to be the same as in water–dioxane mixtures (8) of the same dielectric constant as the water–acetone mixtures, that catalysis by hydrogen ions derived from the acetic acid produced in the hydrolysis is negligible. This is verified by the linear first-order plots.

The 0° C bath was maintained by ice; in order to reduce corrosion of the high-pressure equipment small amounts of sodium dihydrogen phosphate were added to the bath, so its temperature was not exactly 0° C. Small corrections ($< 2\%$) were made to convert the rate constants to 0° exactly using the Arrhenius equation.

The reproducibility of the rate constants was about $1\frac{1}{2}\%$, and the accuracy is probably about 2%.

3. RESULTS

Spontaneous Hydrolysis

The rate constants for the spontaneous hydrolysis are given as a function of temperature, pressure, and composition, in Table I. The only direct comparison with other measurements that can be made is for pure water at 0° C and 1 atm. Under these conditions Kilpatrick (1) found $k_0 = 432 \times 10^{-6}$ sec^{-1}, and Gold (9) found 460×10^{-6} sec^{-1}, in satisfactory agreement with the mean of our values, 468×10^{-6} sec^{-1}. Other results of Gold cannot be compared directly with ours because they were not measured at common

TABLE I

Rate constants for the spontaneous hydrolysis of acetic anhydride

conditions. Consequently, we have interpolated graphically Gold's rate constants at constant temperature to 44.1% w/w acetone by plotting log k_0 vs. concentration of acetone. The interpolated values are compared with ours on an Arrhenius plot in Fig. 1. The agreement is satisfactory, though Gold's values are somewhat lower than ours.

The Arrhenius energy E_A of the equation

$$\ln k_0 = A\, e^{-E_A/RT},$$

where A is a constant, R is the gas constant, and T is the temperature, decreases with increasing temperature, as found by Gold (9). Our values of E_A calculated from rate constants at adjacent temperatures are given in Table I; they agree well with those of Gold for other acetone concentrations. The entropy of activation $\Delta S^{\ddagger}$ calculated from the equation

$$A = (ekT/h)\, e^{\Delta S^{\ddagger}/R}$$

where k is Boltzmann's constant and h is Planck's constant, is also given; it also decreases as the temperature increases.

The rate constants at constant pressure are plotted on a van't Hoff plot in Fig. 2. The volume of activation at 0° C and 1 b was obtained from the graphically measured slope of the curve at 1 b. It is

$$\Delta V^{\ddagger} = -22.0 \pm \sim 1.5 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 0°\text{ C, 1 b.}$$

Acid-catalyzed Hydrolysis

The rate constants for the acid-catalyzed hydrolysis are given as a function of temperature, pressure, and solvent composition, in Table II. The acid concentrations are those at the temperature of the experiment and the pressure of 1 atm calculated from concentrations at room temperature using the data of Thomas and McAllister (10) on the volumes of acetone–water mixtures at various temperatures; because the compression of acetone–water mixtures is not known it is not possible to give rate constants under pressure, but only values of $k/c_{H^+}{}^0 = k_A\rho_p/\rho_{1\,b}$, where ρ_p and $\rho_{1\,b}$ are the densities of the solution at the temperature of the experiment and at pressures p and 1 b respectively.

TABLE III

Arrhenius energies and entropies of activation for the spontaneous and acid-catalyzed hydrolyses of acetic anhydride

Temp. range, ° C	Spontaneous hydrolysis		Acid-catalyzed hydrolysis	
	E_A / kcal mole^{-1}	$\Delta S^{\ddagger}$ / cal deg^{-1} mole^{-1}	E_A / kcal mole^{-1}	$\Delta S^{\ddagger}$ / cal deg^{-1} mole^{-1}
0–19.37	11.95	−37.6	15.34	−21.1
19.37–29.61	10.56	−42.3	16.19	−18.2
29.61–39.86	9.68	−45.2	16.31	−17.8

The Arrhenius energy and the entropy of activation both increase with temperature as shown by the data in Table III, in which E_A and $\Delta S^{\ddagger}$ [$= R \ln (A/\text{l. mole}^{-1})(h/ekT)$] calculated from adjacent temperatures are given. The changes are less marked than those for the spontaneous hydrolysis, but seem reasonably certain.

The values of log $k/c_{H^+}{}^0$ as a function of pressure at 0° C are shown in a van't Hoff plot in Fig. 2. The slope of the curve at 0° C and 1 b as measured graphically is

$$RTd \ln (k/c_{H^+}{}^0)/dp = -\Delta V^{\ddagger} + \chi RT = +18.5 \pm \sim 1 \text{ cm}^3 \text{ mole}^{-1}$$

where χ is the compressibility of the pure solvent.

The compression of acetone–water mixtures has been measured only at 1000 atm and 25° C (11) and 30° C (12). The compressibility of acetone has not been measured at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

0° C, but it appears from the compilation of McGowan (13) that it will be close to 120×10^{-6} atm^{-1} at 0° C and 1 atm. Newitt and Weale (11) point out that the compression of acetone–water mixtures at 25° C and 1000 atm is roughly linear in the mole fraction. Using this assumption and the compressibility of water at 0° C given by McGowan we find $\chi RT = 1.4$ cm^3 mole^{-1} at 0° C and 1 b. Consequently, for the acid-catalyzed hydrolysis

$$\Delta V^{\ddagger} = -17.1\pm\sim1.3 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 0° \text{ C, 1 b}$$

the uncertainty having been increased to allow for the uncertainty in the compressibility.

4. DISCUSSION

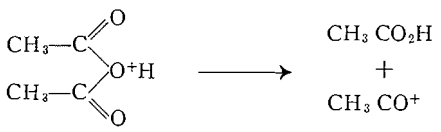
Spontaneous Hydrolysis

The volume of activation, $-22.0\pm\sim1$ cm^3 mole^{-1} at 0° C and 1 b, is very similar to that for the spontaneous hydrolysis of ethylene oxide (14). The mechanism is likely (9) to be the attack of a water molecule on a molecule of acetic anhydride, and a considerable separation of charges occurs. The low volume of activation confirms this; the volume lost due to the formation of a partial valence bond between water and acetic anhydride is expected to contribute only about -5 to -10 cm^3 mole^{-1} to the volume of activation (14), and the remaining part of $\Delta V^{\ddagger}$, -16 to -11 cm^3 mole^{-1}, is presumably due mainly to electrostriction of the solvent.

Acid-catalyzed Hydrolysis

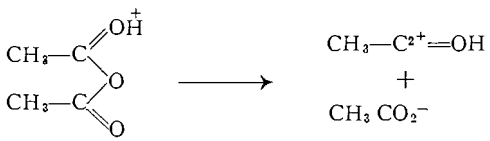
There are many possible mechanisms for the acid-catalyzed hydrolysis of acetic anhydride. The proton can be on either the carbonyl oxygen or the ether oxygen. Either form can react by the A-1 or the A-2 mechanism. The A-2 mechanism can take on several forms according as the incoming water molecule substitutes or adds, and, if it adds, according as the slow step is the formation or decomposition of the adduct.

Gold and Hilton (3) have shown that the rate of hydrolysis in concentrated aqueous acids is nearly proportional to Hammett's acidity function h_0, and is not proportional to c_{H^+}. They assumed that the Zucker–Hammett hypothesis, that rates of A-1 reactions are proportional to h_0 and those of A-2 reactions are proportional to c_{H^+}, holds, and deduced that the slow step is



[4.1]

in which the proton is on the ether oxygen in the reactive conjugate acid. If the slow step were reaction [4.1], then according to arguments developed in Part I of this series (6) and confirmed experimentally for the A-1 hydrolyses of formals, acetals, and ethyl orthoformate in Part II (7), both the volume and entropy of activation would be positive. In fact, both are negative, $\Delta S^{\ddagger}$ being ~-20 cal deg^{-1} mole^{-1} and $\Delta V^{\ddagger}$ being -17.1 cm^3 mole^{-1}. The slow step is not, therefore, reaction [4.1]. The A-1 reaction



[4.2]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

is consistent with the experimental $\Delta V^{\ddagger}$ and $\Delta S^{\ddagger}$ because, due to electrostriction of the solvent, the greatly increased polarity in the transition state would make both the volume and the entropy less than that of the conjugate acid. Thus an A-1 mechanism is possible, but only if a separation of charges occurs in the transition state. The justification of the Zucker–Hammett hypothesis requires that this does not occur, and so it ought not to apply to reaction [4.2]. Consequently, we conclude that the hydrolysis of acetic anhydride is another reaction for which the Zucker–Hammett hypothesis is invalid. We have shown previously that the hydrolyses of ethylene oxide (4) and of diethyl ether (5) do not follow the Zucker–Hammett hypothesis, and Taft, Deno, and Skell (15) refer to other evidence that refutes it. There can be no doubt that the Zucker–Hammett hypothesis does not reliably distinguish between A-1 and A-2 reactions.

The acid-catalyzed hydrolysis of acetic anhydride is formally similar to the acid-catalyzed hydrolysis of aliphatic esters, acetic anhydride being considered as acetyl acetate. It is instructive, therefore, to compare the various quantities of activation of the two hydrolyses. The volume of activation for the hydrolysis of methyl acetate in 44.1% w/w acetone–water is -13.3 cm^3 mole^{-1} at 35° C (16), similar to that for acetic anhydride. The entropy of activation for the hydrolysis of ethyl acetate in 56% w/w acetone–water is, from the data in ref. (17), -26.1 cal deg^{-1} mole^{-1}, again very similar to that for the hydrolysis of acetic anhydride. Unfortunately for a simple explanation of these similarities, the solvent effects are quite different. The logarithm of the ratio of rate constants in 20.8% w/w and 70.3% w/w acetone–water is -0.825 at 0° C for acetic anhydride, while for ethyl acetate it is, from the data in ref. (17), -0.330 at 35° C and for methyl propionate it is, from the data in ref. (18), -0.354 at 25° C. For comparison, the logarithm of the ratio of the *second-order* rate constants for the spontaneous hydrolysis of acetic anhydride is, from our results, -1.284. As we discussed above, the transition state for the spontaneous hydrolysis is probably very polar. The simple conclusion from the volumes and entropies of activation is that the transition state for the hydrolysis of acetic anhydride is similar to that for the hydrolysis of aliphatic esters; the simple conclusion from the solvent effects is that the transition state for the hydrolysis of acetic anhydride is considerably more polar. The resolution of these apparently contradictory conclusions will await more experimental data.

THE LUMINESCENCE OF COMPLEX MOLECULES IN RELATION TO THE INTERNAL CONVERSION OF EXCITATION ENERGY. PART I[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

The relative fluorescence yields of a variety of double molecules have been measured as a function of the wavelength of exciting light. In some cases the yield from the second excited state is lower than from the first. This effect is attributed to either photodecomposition or to the enhancement of intramolecular energy transfer processes which can compete with the internal conversion between the excited singlet states. The experiments on bianthrone have suggested a method of elucidating the mechanism of the photochromic isomerization of this compound.

INTRODUCTION

The fluorescence of the vast majority of aromatic compounds arises from the radiative transition – first excited singlet to ground (singlet) state. On excitation to higher electronic states this same luminescence is observed and usually with unchanged yield. This implies that the rate of internal conversion to the radiating level is fast compared to the rate of intersystem crossing between upper excited states of different multiplicity. It has been suggested (3) that the fall-off in fluorescence yield of dibromoanthracene excited with light below 3000 Å is due to heavy atom-induced intersystem crossing to the second triplet level. This indicates comparable rates for these competing processes. Preliminary studies have indicated that a variety of molecules which are apparently quite stable photochemically have luminescence efficiencies which are anomolous in terms of the above rule.

In this work the relative luminescence yields of a series of double molecules have been measured as a function of the exciting wavelength. A double molecule is one consisting of two identical parts coupled through a conjugating linkage.

EXPERIMENTAL

The fluorescence measurements were made by illuminating the samples contained in a Vycor tube or silica cell with the beam from a hydrogen lamp and Beckman D.U. monochromater. The luminescence was detected over a 20° region centering at 70° to the main beam by means of an end-on-type photomultiplier with S11 response. The incident radiation was filtered out by 1.5 cm of a saturated solution of sodium nitrite in water. By using suitable Corning filters, the cutoff could be extended to longer wavelengths. This combination provided good cutoff at 3950 Å. The relative quantal output of the hydrogen lamp was known at each wavelength from 2500–3800 Å in terms of the luminescence of pure anthracene, which is known to be constant over this region (3, 4). The range was extended to 4100 Å by calibrating the lamp output against the luminescence intensity from a totally (99%) absorbing solution of tetracene. The fluorescence yield of tetracene is independent of the exciting light wavelength in this region of its absorption. The hydrogen lamp becomes less continuous above 3700 Å but good reproducibility could be obtained by opening up the monochromater slit for this range of excitation. All the solutions which were studied absorbed at least 99% of the incident light throughout the exposed pathlength. The solvents were ethyl alcohol or petroleum ether. The low temperature experiments were performed in a quartz Dewar with an optically clear

[1]*Manuscript received March 16, 1959.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C.

base. Rigid glasses were either alcohol, ether–alcohol, or E.P.A., depending on solubility of the compound. The same results were obtained from cracked and optically clear rigid glasses. Luminescence measurements may be radically affected by small amounts of impurities. The criterion for purity in this work was taken to be reproducibility after two further purifications by different methods. These methods involved recrystallization, sublimation, and chromotography. III, VI, VII, VIII, IX, and X were synthesized by Dr. Y. Matsunaga. IV and V were synthesized according to the method of A. Willemart (12). They were purified on alumina. I and II were Delta chemicals samples with fluorescent impurities. The fluorescence spectrum of each substance was examined on a Cary Recording Spectrometer. In no case did the spectrum of the purified material change when the wavelength of the exciting light was altered.

RESULTS AND DISCUSSION

Plots of the relative luminescence yields against exciting wavelength are shown on Figs. 1–3. Some of the curves show slight variations of the order of 3% which cannot be taken as real under the present experimental conditions.

(*A*) *1,1-Binaphthyl* (I); *2,2-Binaphthyl* (II); *α,α-Di-β-naphthol* (III)

These substances have long absorption tails and there is an unusually large separation of absorption and fluorescence, indicating substantial distortion in the excited state. The fluorescence yields of (I), (II), and (III) crystals at 25° C and −183° C were independent of exciting light. Alcoholic solutions and rigid glasses of (I) and (III) also retained constant yields of emission over the range 2500 Å–3500 Å.

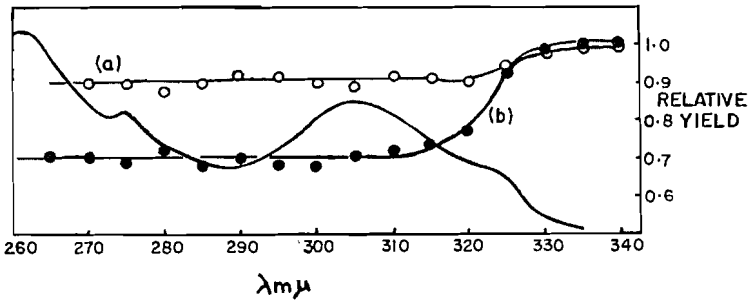

FIG. 1. The variation of the fluorescence yield of 2,2-binaphthyl with wavelength of exciting light. (*a*) crystal (*b*) alcohol solution or rigid alcohol glass. Smooth curve is the approximate absorption spectrum of 2,2-binaphthyl with log (extinction) as abscissa.

The results for (II) are given in Fig. 1. The fluorescence yield is constant to about 3275 Å, and below this exciting wavelength the luminescence falls off by about 30%. This is the type of effect that would be observed if an impurity was emitting above 3200 Å. Commercial (II) is green and even after many recrystallizations the color is greenish, although no impurities can be detected by absorption in a 10-cm path. After purification on alumina, one can obtain with difficulty colorless crystals with a bluish tinge. Such phenomena are reminiscent of the effects of very small quantities of tetracene in anthracene where energy transfer is highly efficient (1). The appearance of the blue fluorescence was accepted as a criterion of purity in this case. The absorption spectrum of (II) differs from (I) in the same manner as that of biphenyl differs from benzene. Free rotation of one ring relative to the other is sterically allowed and conjugative

For personal use only.

interaction may occur, resulting in a red shift of the spectrum (5). It is feasible that the double molecule (II) has two closely lying electronic states at low energies. Such a splitting could arise through a weak interaction between the ring systems and if this is the case electric dipole transitions to one of these states may be more or less forbidden than transitions to the other state, depending on the degree of interaction (7, 9). The results indicate that there is an enhancement of the fluorescence when the excitation is in the long wavelength tail, that is, in the region of the 0–0 transition. It is possible that population of the upper state vibrational levels which are always below the crossing line of the singlet and triplet energy surfaces can occur in this case. In any case this system deserves detailed individual study and will be discussed in a future part of this series.

(*B*) *9,10-Di-α-naphthylanthracene* (IV); *9,10-Di-β-naphthylanthracene* (V); *9,9'-Dianthryl* (VI); *9,9'-Dianthran-10,10-diol* (VII)

The quantum yields of these compounds are independent of the wavelength of exciting light from 2600 to 3900 Å. This conclusion applies to crystals at 25° C and −183° C, alcoholic solutions at 25° C, and to rigid alcohol glasses. The actual quantum yields of luminescence from all but VII were higher than that of anthracene.

(*C*) *trans-Stilbene* (VIII); *p-Dimethoxystilbene* (IX); *Di-α-ethoxynaphthostilbene* (X); *α,β-Bis (9,9'-anthronylidene)-ethane* (XI)

No fluorescence could be detected from XI crystals below 6000 Å.

The luminescence yields in Fig. 2 relate to alcoholic solutions of X and XI and crystals of IX at −183°. There is little difference between rigid glass and viscous solution except in relation to the absolute fluorescence yield which is always greater in the glass. It

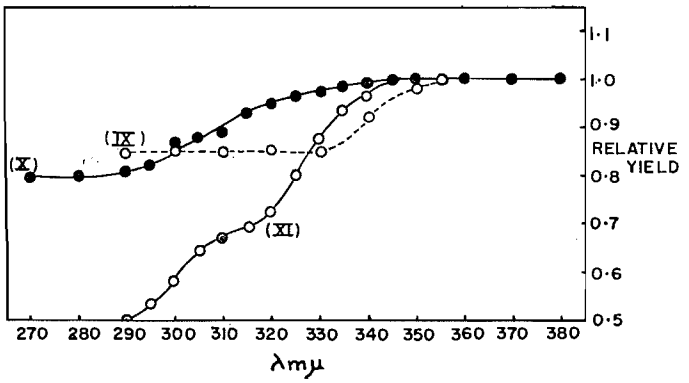

FIG. 2. Fluorescence yields as functions of the wavelength of exciting light for IX, X, and XI.

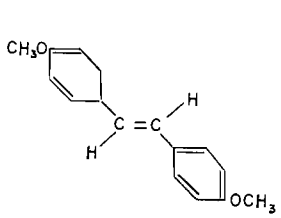
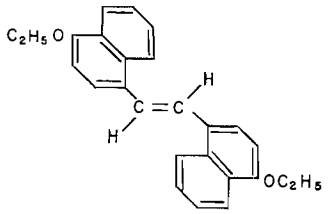
can be seen that double molecules of this type exhibit a marked wavelength dependence, which may be due either to photochemical reaction in upper excited states or to an intramolecular energy transfer process which is much more efficient in the upper excited state than in the fluorescent state. With the exception of XI, which is in any case too complex a molecule to permit a detailed study, it is felt that the fall-off in fluorescence yield may be caused by a lowering of the potential energy barrier to rotation about the ethylenic double bond in the upper excited states. The different results obtained with VIII on the one hand and with IX and X on the other would be attributed to the double bond character of the ethylenic link in each of these types. The naphthalenic groups will certainly be out of plane even in the trans form and consequently there will be less

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

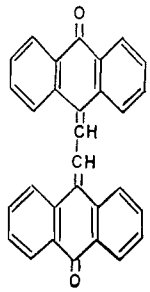
conjugative interaction through the central double bond. If the time spent in an upper excited state is of the order of 10^{-12} seconds then the frequency of twist must be of the same order as a few hundred vibration frequencies if the fall-off in yield is due to this process. This corresponds to a considerable lowering of the barrier. The phosphorescence contribution to the total luminescence curve in Fig. 2 must be negligible under these experimental conditions as the same curve was obtained in solution at room temperature and in rigid glasses at liquid nitrogen temperature. In all cases no permanent changes in the absorption spectrum could be detected which would have indicated a photoprocess occurring with a significant quantum yield. Some experiments were done using completely oxygen-free solutions and no differences were obvious. In the case of *trans*-stilbene the fluorescence yield was constant throughout the absorbing region. The fluorescence yield was also measured as a function of temperature for crystalline VIII and no discontinuities were observed.



IX



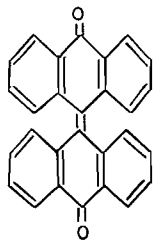
X



XI

(*D*) *Bianthrone* (XII)

This substance is photochromic (6), thermochromic (11), and photochemically reactive (12). The bianthrone used in this work was recrystallized twice from dichloroethane, sublimed *in vacuo*, then chromatographed twice on alumina. Even under these conditions a fluorescent impurity was shown to be present. (XII) did not fluoresce in solution at 25°, i.e. the apparatus would detect very low light levels corresponding to fluorescence yields of the order of 10^{-3}. In ether–isopentane glass at −183° C the fluorescence yield varied with exciting energy in the manner shown in Fig. 3 along with the absorption spectrum of bianthrone.



XII

The fluorescence yield is constant throughout the first absorption band but falls off to about 50% of this value below 3400 Å. During irradiation in the low energy band the so-called colored form of bianthrone is being produced, and the constancy of the luminescence yield indicates that the process of photochromism is also independent of

For personal use only.

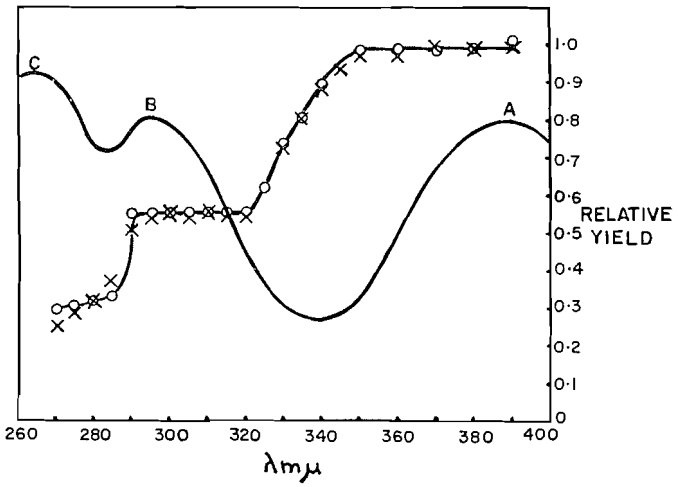

FIG. 3. The fluorescence of bianthrone as a function of the wavelength of exciting light.
○ In ether–isopentane glass.
× After U.V. irradiation in non-rigid medium.
— Absorption spectrum of bianthrone. The absorption at A corresponds to a $n \rightarrow \pi^*$ transition while B and C are probably $\pi \rightarrow \pi^*$.

the excitation energy over this region; such considerations will apply if only the formation of the photochromic isomer is in competition with fluorescence. The similarity of the fluorescence curves for bianthrone in ether–isopentane and the pre-irradiated sample—which is green due to reversion to photochromic isomer—indicates that the same fluorescence is being observed in each case. The actual yield was diminished slightly owing to reabsorption by the long wavelength band of the colored form. The absorption band at 2950 Å is due to a higher electronic transition, and either an internal conversion process, *other* than the rearrangement of the electronic excitation of this state into the vibrational modes of the fluorescent state, is occurring *or* the probability of photodecomposition is enhanced by exciting the molecule to this state. Here again the barrier to isomerism may be very slight in the higher levels of excitation. This is tantamount to an increased probability of intersystem crossing in the upper state as it is likely that the photochromic isomer is the molecule in its lowest triplet state. Hirshberg and Fischer (6) point out that no photochemical reactions other than photochromism occur at low temperatures.

CONCLUSIONS

As a rule the fluorescence yield is independent of the wavelength of the exciting light. Some double molecules have provided striking exceptions to this rule. The exceptions have arisen in the first place when there is slight conjugative interaction between two aromatic ring systems; e.g., 1,1′-binaphthyl exhibits normal behavior while 2,2′-binaphthyl is exceptional. Secondly, exceptions also arise when the molecule can be photochemically isomerized, e.g., naphthostilbene and bianthrone respectively.

It is likely that the configurations of the latter type of molecule in the excited states will differ markedly from those in the ground state. In particular the relative orientation of the ring systems may change considerably. This consideration is supported by the large separation of emission and absorption for the compounds studied here.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/04/12
For personal use only.

That some of the phenomena reported here may be due in part to an enhancement of the rate of intercombination between states of different multiplicity may only be considered as an interesting conjecture at this stage. It is likely that deformation of a π-molecular orbital, such as in the case of the trinitrobenzene complexes of aromatic hydrocarbons (10), could result in a considerable increase in the rate of intersystem crossing. With molecules such as naphthostilbene and bianthrone this rate may be unusually great in the upper excited states if there is a reasonable distortion. Such a distortion would necessarily increase the $\pi-\sigma$ interactions in the molecule and it is known that the main contribution to the spin orbital coupling in these molecules arises from interactions of this type (8).

It has been the purpose of the first part of this paper to present the results of fluorescence studies on a variety of double molecules. It is apparent that a detailed study of the photochemistry of some of these systems will be necessary before more certain conclusions can be reached. Subsequent parts of this series will describe such studies as well as results on the phosphorescence of these and similar molecules and new results on the phosphorescence and fluorescence of N-heteroaromatics and their derivatives.

ACKNOWLEDGMENTS

This research was supported by a grant from the National Research Council of Canada. Thanks are due to Dr. Y. Matsunaga for gifts of the compounds as indicated in the text, and to Dr. C. Reid for many helpful discussions.

THE LOW TEMPERATURE PREPARATION OF ANHYDROUS TITANIUM IV BROMIDE AND ANHYDROUS TITANIUM IV IODIDE FROM BENZENE SOLUTIONS

KARL H. GAYER AND GERALD TENNENHOUSE

A recent series of experiments required supplies of anhydrous titanium IV bromide and anhydrous titanium IV iodide. The usual methods for preparing titanium IV bromide by passing either bromine vapor or hydrogen bromide gas over a heated mixture of titanium dioxide and carbon or titanium metal were found to be too time-consuming for frequent use. Consequently the following method was devised.

EXPERIMENTAL

Preparation of Titanium Tetrabromide

The following experimental procedures, which required an inert atmosphere, were carried out in a dry box in which the air had been dried over P_2O_5. Hydrogen bromide gas, flowing at approximately 350 cubic centimeters per minute, was dried by being passed through a porous tower of phosphorus pentoxide. This dry gas was directed into the reaction vessel.

A solution of titanium IV chloride was made by adding 35 g of redistilled titanium IV chloride to 71 g of reagent grade benzene in a 250-ml two-necked flask. The flask was maintained at 0° C by means of a salt–ice bath. Hydrogen bromide gas was bubbled into this solution. After 20 minutes of gassing the solution had turned from colorless to yellow to red. After 1 hour, the gassing was stopped and the solution permitted to rise in temperature to 25° over a period of 3 hours. The benzene was distilled off. This was followed by the titanium IV bromide. The portion boiling between 229° and 232° was collected. The product obtained in 80% yield based on $TiCl_4$ was found to melt at 39° C and boil at 231° C. The literature (1, 2) lists the melting point and boiling point as 39° C and 230° C respectively. The compound was analyzed gravimetrically for both titanium and bromide. The following are mean values of three determinations:

Calculated values for	Ti = 13.03%	Br = 86.97%
Experimental values for	Ti = 13.17%	Br = 86.81%

The anhydrous product is an orange-red solid at room temperature, which sublimes readily and is extremely hygroscopic, fuming strongly in air. It is soluble in acetone and ether. It could not, however, be crystallized from these solvents. Furthermore, the product is soluble without reaction in benzene and carbon tetrachloride.

Preparation of Anhydrous Hydrogen Iodide

Anhydrous hydrogen iodide free of elementary iodine was prepared by distilling a mixture of 80 g of reagent potassium iodide in 400 ml 85% phosphoric acid. The resulting product, slightly contaminated with water and iodine, was purified by passing it over an intimate mixture of red phosphorus and iodine, then through a condenser maintained at 0° C to remove iodine, and finally over phosphorus pentoxide.

Preparation of Titanium Tetraiodide

The hydrogen iodide prepared above was bubbled (at approximately 400 cc per minute) into a round-bottom flask containing 35 g of redistilled titanium IV chloride and 88 g

of reagent grade benzene. The flask was kept at 0° C by means of an ice–salt bath. After 5 minutes, the solution had turned dark. The addition of hydrogen iodide was continued for 1 hour. After the mixture had been left to stand for 30 minutes at 0° C, it was freed of excess hydrogen iodide by vigorous gassing with dry nitrogen. The mixture was kept overnight at 0° C after which the titanium iodide was filtered off. The product was recrystallized, then dried under reduced pressure of 25 mm Hg, and sealed in a bent glass tube about 30 cm in length. Finally, the product was sublimed by immersing one end of the tube in an ice–salt bath while gently heating the other end. The purple solid collected in the cold part of the tube. A 70% yield, based on $TiCl_4$ was obtained. Analysis: The titanium was precipitated as the oxide, ignited, and weighed. The iodide was determined by preliminary oxidation with KIO_3, followed by titration with standard $Na_2S_2O_3$ solution. The following are mean values of three determinations:

Calculated values for	Ti = 8.62%	I = 91.38%
Experimental values for	Ti = 8.49%	I = 91.46%

The product is extremely hygroscopic, fuming strongly in air. It is readily soluble in water, forming a brown-colored solution. On standing for several weeks out of contact with the air, the brown solution becomes colorless. The product is soluble without reaction in benzene and carbon tetrachloride.

A NEW SYNTHESIS OF 5-HYDROXYTRYPTOPHAN*

GERASSIMOS FRANGATOS AND FRANCIS L. CHUBB

The biological significance of 5-hydroxytryptophan has been established. It is an important metabolite of tryptophan and is a precursor of serotonin (5-hydroxytryptamine) (1). In recent years serotonin has been the subject of an extensive study by many workers due to its potential importance in the function of the autonomic and central nervous system (2).

The first synthesis of 5-hydroxytryptophan was reported by Ek and Witkop (3), and is an application of the gramine synthesis developed by Snyder and Smith (4). A second synthesis of 5-hydroxytryptophan, which is also an application of the gramine synthesis, has recently been reported by Koo, Avakian, and Martin (5). The synthesis herein reported is an application of the convenient tryptophan synthesis of Warner and Moe (6). This method eliminates the difficult and tedious preparation of 5-benzyloxyindole.

The *p*-benzyloxyphenylhydrazone of γ,γ-dicarbethoxy-γ-acetamido-butyraldehyde (I) was prepared, and cyclized, without isolation, to form ethyl β-(5-benzyloxyindolyl-3)-α-carbethoxy-α-acetamidopropionate (II). This was identical with material prepared

A NEW SYNTHESIS OF 5-HYDROXYTRYPTOPHAN*

GERASSIMOS FRANGATOS AND FRANCIS L. CHUBB

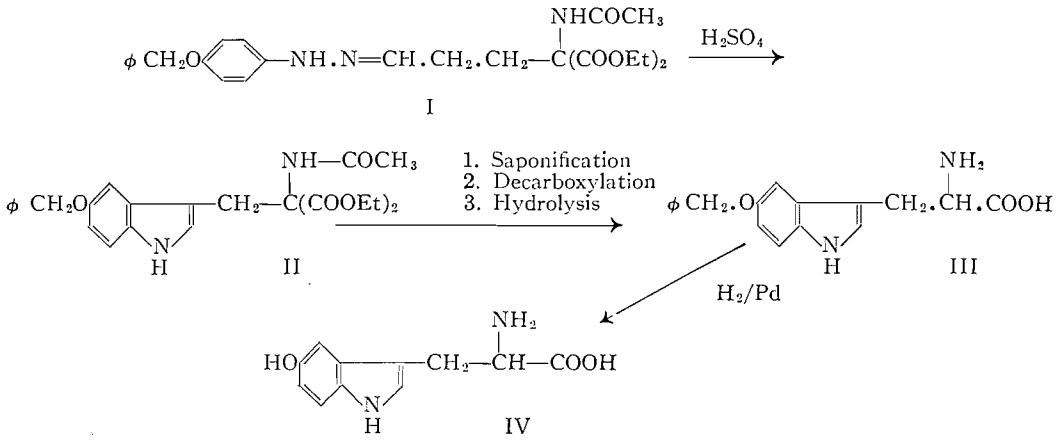
The biological significance of 5-hydroxytryptophan has been established. It is an important metabolite of tryptophan and is a precursor of serotonin (5-hydroxytryptamine) (1). In recent years serotonin has been the subject of an extensive study by many workers due to its potential importance in the function of the autonomic and central nervous system (2).

The first synthesis of 5-hydroxytryptophan was reported by Ek and Witkop (3), and is an application of the gramine synthesis developed by Snyder and Smith (4). A second synthesis of 5-hydroxytryptophan, which is also an application of the gramine synthesis, has recently been reported by Koo, Avakian, and Martin (5). The synthesis herein reported is an application of the convenient tryptophan synthesis of Warner and Moe (6). This method eliminates the difficult and tedious preparation of 5-benzyloxyindole.

The *p*-benzyloxyphenylhydrazone of γ,γ-dicarbethoxy-γ-acetamido-butyraldehyde (I) was prepared, and cyclized, without isolation, to form ethyl β-(5-benzyloxyindolyl-3)-α-carbethoxy-α-acetamidopropionate (II). This was identical with material prepared

**Based on a paper presented at the 41st Annual Conference of the Chemical Institute of Canada, Toronto, May 26–28, 1958.*

from the reaction of ethyl acetamidomalonate with 5-benzyloxygramine. Saponification and partial decarboxylation of II, followed by hydrolysis of the acetamido group, gave 5-benzyloxytryptophan (III). 5-Hydroxytryptophan (IV) was obtained by hydrogenolysis of III.



EXPERIMENTAL

Ethyl β-(5-Benzyloxyindolyl-3)-α-carbethoxy-α-acetamidopropionate (II)

A mixture of 85 g of ethyl acetamidomalonate (4), 0.4 g of sodium methoxide, and 200 ml of absolute ethanol was cooled to 0° with stirring. A thin slurry formed and then 31 ml of acrolein was added during 1.5 hours, keeping the temperature at 0–3°. The stirring was continued for 2 hours at 0–3°. Then 85 g of *p*-benzyloxyphenylhydrazine (7) and 10 ml of glacial acetic acid were added with vigorous stirring. The reaction mixture was heated to 50°, with stirring, and maintained at that temperature until the hydrazine went into solution. The resulting dark solution of II was kept at room temperature overnight. It was then transferred to a three-necked flask and water was added to bring the total volume to 1.5 liters. After 70 ml of concentrated sulphuric acid was added, the mixture was stirred vigorously and refluxed for 3 hours. The ethyl β-(5-benzyloxyindolyl-3)-α-carbethoxy-α-acetamidopropionate soon crystallized. The reaction mixture was cooled and filtered to yield 160 g of crude product. Three recrystallizations from toluene followed by one from aqueous ethanol gave 135 g (75.5%) of pure II, m.p. 169°, undepressed on admixture with an authentic sample prepared according to ref. 5. Anal. Calculated for $C_{25}H_{28}N_2O_6$: C, 66.36; H, 6.24; N, 6.19. Found: C, 66.60; H, 6.28; N, 6.08.

5-Benzyloxytryptophan (III)

The ester II (50 g) was saponified, decarboxylated, and deacetylated according to the procedure of Koo, Avakian, and Martin (5). The intermediate dicarboxylic acid was not purified before decarboxylation and deacetylation to form 5-benzyloxytryptophan (III).

The crude III was purified according to the following procedure. 5-Benzyloxytryptophan (20 g) was warmed with 100 ml of water and 1 liter of ethanol. If solution was not complete then 1% sodium hydroxide was added dropwise until the material all dissolved. After treatment with charcoal and filtration, the solution was cooled and adjusted to pH 6.6 with acetic acid. The 5-benzyloxytryptophan began to crystallize

immediately. In case it separated as a gel, warming and stirring converted it to the crystalline form. A total of 29 g (88.5%) of III, m.p. 276–280° was obtained.

5-Hydroxytryptophan (IV)

5-Hydroxytryptophan was prepared by catalytic hydrogenolysis of III according to the procedure of Koo, Avakian, and Martin (5).

THE EFFECT OF AMINES AND PHENOLS ON THE GAS-PHASE OXIDATION OF *n*-BUTANE AND ISOBUTANE*

K. U. INGOLD AND I. E. PUDDINGTON

In recent years the antiknock efficiency of a large number of fuel additives has been measured. Among the more powerful fuel additives are amines both aliphatic and aromatic (1, 2, 3, 4), and aromatic compounds in general (2, 5).

From an examination of the high and low temperature oxidation of diisopropyl ether, Chamberlain and Walsh (6, 7) concluded that inhibition of this reaction by aromatic compounds and, therefore, the antiknock ability of aromatic compounds, was due primarily to the electronic properties of the ring, nitrogen, and other side groups merely modifying the properties of the ring. However, it has since been shown by using deuterated amine antiknocks that, in the internal combustion engine, aromatic amines owe their antiknock efficiency to their ability to destroy chain-propagating radicals ($X^{\cdot}$) by the reaction (3)

$$X^{\cdot} + ArNHR \rightarrow XH + Ar\dot{N}R \qquad [1]$$

where $Ar\dot{N}R$ is a less reactive radical than $X^{\cdot}$. The effect of deuterated antiknocks on the low temperature oxidation of hydrocarbons has, however, not been previously studied.

The present work involved a brief investigation of the effect of aniline and aniline N—D_2 on the low temperature oxidation of two simple paraffins, viz. *n*-butane and isobutane. The effect of a few other amines and phenols was also examined with a view to comparing inhibitor efficiencies in gas- and liquid-phase (8) hydrocarbon oxidations.

The oxidation was studied in a conventional apparatus, except that the progress of the reaction was measured by means of a diaphragm manometer to avoid contamination of the reaction vessel with mercury. The butane (70 mm) and oxygen (280 mm) were premixed before being admitted to the cylindrical Pyrex reaction vessel (15 cm long, 4 cm diameter). The oxidation of *n*-butane was studied at 275° C and isobutane in the range 275°–310° C. The pressure–time curves for both butanes are S-shaped, and although the

THE EFFECT OF AMINES AND PHENOLS ON THE GAS-PHASE OXIDATION OF *n*-BUTANE AND ISOBUTANE*

K. U. INGOLD AND I. E. PUDDINGTON

In recent years the antiknock efficiency of a large number of fuel additives has been measured. Among the more powerful fuel additives are amines both aliphatic and aromatic (1, 2, 3, 4), and aromatic compounds in general (2, 5).

From an examination of the high and low temperature oxidation of diisopropyl ether, Chamberlain and Walsh (6, 7) concluded that inhibition of this reaction by aromatic compounds and, therefore, the antiknock ability of aromatic compounds, was due primarily to the electronic properties of the ring, nitrogen, and other side groups merely modifying the properties of the ring. However, it has since been shown by using deuterated amine antiknocks that, in the internal combustion engine, aromatic amines owe their antiknock efficiency to their ability to destroy chain-propagating radicals ($X^{\cdot}$) by the reaction (3)

$$X^{\cdot} + ArNHR \rightarrow XH + Ar\dot{N}R \qquad [1]$$

where $Ar\dot{N}R$ is a less reactive radical than $X^{\cdot}$. The effect of deuterated antiknocks on the low temperature oxidation of hydrocarbons has, however, not been previously studied.

The present work involved a brief investigation of the effect of aniline and aniline N—D_2 on the low temperature oxidation of two simple paraffins, viz. *n*-butane and isobutane. The effect of a few other amines and phenols was also examined with a view to comparing inhibitor efficiencies in gas- and liquid-phase (8) hydrocarbon oxidations.

The oxidation was studied in a conventional apparatus, except that the progress of the reaction was measured by means of a diaphragm manometer to avoid contamination of the reaction vessel with mercury. The butane (70 mm) and oxygen (280 mm) were premixed before being admitted to the cylindrical Pyrex reaction vessel (15 cm long, 4 cm diameter). The oxidation of *n*-butane was studied at 275° C and isobutane in the range 275°–310° C. The pressure–time curves for both butanes are S-shaped, and although the

rate of pressure increase is at first very small, there is no initial decrease in pressure at these temperatures. The onset of a pressure increase has been shown (9) to mark a transition from a surface-inhibited reaction to an autocatalytic reaction in which effects resulting from chain-branching predominate and surface effects are much less important. For this reason, the amines and phenols were added not only at the start of the reaction ($\Delta p = 0$) where their effect might be due to their action on the surface, but were also added during the course of the reaction after a definite pressure increase had occurred and the induction period was over.

Since most of the additives had rather low vapor pressures at room temperature, they were stored in traps separated from the reaction vessel by metal valves; both traps and valves could be heated to 100° C. Helium at 1 atmosphere pressure was admitted to the traps and after residence for at least half an hour was used to carry the additive into the reaction vessel. Induction periods (defined as the time required for a pressure increase of 1.0 mm) are summarized in the table, all values being averages of at least two experiments.

TABLE

Effect of amines and phenols on the induction period of *n*-butane and isobutane
(Butane 70 mm, oxygen 280 mm, helium 180 mm)

Additive	Additive pressure (mm)	Added at Δp (mm)	*n*-Butane (275° C) induction period (seconds)	Isobutane (310° C) induction period (seconds)
None	—	—	140	400
He	—	0	125	140
He + aniline	9.0	0	1620	3900
He + aniline N—D_2	9.0	0	1090	2350
He + phenol	9.0	0	210	270
He + *o*-toluidine	4.5	0	750	1100
He + N-methylaniline	4.5	0	700	1200
He + *p*-cresol	3.5	0	160	185
He + piperidine	9.0	0	440	30
He + pyrrole	9.0	0	650	150
He + ammonia	9.0	0	165	110
He	—	2.7	20	10
He + aniline	9.0	2.7	110	250
He + aniline N—D_2	9.0	2.7	100	200
He	—	4.5	16	5
He + aniline	9.0	4.5	64	160
He + phenol	9.0	4.5	36	9
He + *o*-toluidine	4.5	4.5	55	40
He + N-methylaniline	4.5	4.5	60	40
He + *p*-cresol	3.5	4.5	22	7
He + piperidine	9.0	4.5	90	5
He + pyrrole	9.0	4.5	84	15
He + ammonia	9.0	4.5	30	5

Analysis of the reactants at the end of the induction period showed that the addition of aniline at the start of the reaction decreases the rate of butane consumption during the induction period. Aniline is, therefore, a true inhibitor for the oxidation of both butanes.

The reduced inhibiting effect of aniline N—D_2 compared with aniline shows that the rate-controlling step of at least a part of the inhibition must involve rupture of the N—D or N—H bond. This result is in agreement with the results of Brown *et al.* (3) on the antiknock efficiency of N-methylaniline and N-deutero-methylaniline. Although the conclusions of Walsh (7) that aromatic compounds inhibit by virtue of the electronic properties of the ring are not invalidated, this factor would seem to be of little importance with aromatic amines.

Since the isotope effect exists when aniline is added, both at the start of the reaction and during its course when surface effects are at a minimum, inhibition probably occurs to a fairly large extent in the gas phase. The reduction in the isotope effect when aniline is added during the reaction suggests that some exchange may occur, probably on the walls between the deuterated aniline and the various oxygenated products. The isotope effect is somewhat less than when aniline is used to inhibit liquid phase oxidations (8).

The results obtained with aniline, phenol, N-methylaniline, and *p*-cresol, all of which have also been studied in the liquid phase (8), show that the range of inhibitor efficiencies is smaller in the gas than in the liquid phase. By analogy with the results obtained with aniline these additives also probably inhibit by way of reaction [1].

Pyrrole and piperidine were studied to see if there was any correlation between the base strength of amines and their inhibiting efficiency. These two compounds have similar inhibiting power on the oxidation of diethyl ether (10) yet pyrrole is an extremely weak base while piperidine is a strong base. Both amines inhibit the *n*-butane oxidation. At 310° C pyrrole has only a small inhibiting effect on isobutane, while piperidine behaves as a strong catalyst. The catalytic action of piperidine occurs at temperatures as low as 275° C where, judging by the results with *n*-butane, the piperidine itself is probably not decomposed or oxidized appreciably. At low temperatures pyrrole also becomes a catalyst, although a rather weak one. For example, at 297° C the induction period for isobutane with helium alone is 1400 seconds, for pyrrole 1000 seconds, and for piperidine 100 seconds. The catalysis by both amines is not likely to be due to their decomposition, since such catalysis would be expected to increase with temperature. Ammonia, also, acts as an inhibitor with *n*-butane and as a catalyst with isobutane. The difference in behavior of these three compounds with the two butanes suggests that different intermediates are involved in the oxidation of the butanes. Inhibition of the *n*-butane oxidation may be due to reaction [1]. The catalysis observed with isobutane suggests that a catalyzed decomposition of the chain-branching intermediate is of considerable importance.

THE THERMODYNAMIC PROPERTIES OF THE SYSTEM CELLULOSE – WATER VAPOR[1]

JOHN L. MORRISON[2] AND MATTHEW A. DZIECIUCH[3]

ABSTRACT

The heats of wetting by water of cotton cellulose containing various amounts of adsorbed and desorbed water were measured. These measurements together with those of the water vapor sorption isotherm were used to calculate the integral and differential enthalpies, free energies, and entropies of adsorption. Irreversible effects were avoided by vacuum-drying all samples at room temperature. The differential enthalpy values suggest hydrogen bonding. The differential entropies are explained in terms of changes in both the adsorbate and adsorbent.

The surface area of the cellulose is calculated by applying the Brunauer–Emmett–Teller and Harkins–Jura equations to the adsorption isotherm. The changes in the differential enthalpies and entropies of adsorption follow the same sequence as the changes in film formation given by the surface area calculations.

No hysteresis was observed in the heats of wetting of adsorbed and desorbed samples. It is concluded that the hysteresis of the sorption isotherm is an entropy phenomenon. This supports Barkas' explanation of hysteresis in terms of plastic deformation of a gel.

INTRODUCTION

Measurement of the amounts, the vapor pressures, and the energies involved when water vapor is added to and removed from fibrous natural polymers have made it possible to calculate in detail the thermodynamic properties of the systems silk fibroin – water vapor and wool keratin – water vapor (1, 2, 3). The present report includes the same kind of measurements on the system cellulose – water vapor.

Wahba also made similar measurements on the cellulose – water vapor system (4). However, we believe that Wahba's drying procedures introduce an irreversible effect. A similar but larger effect is shown in the work of Argue and Maass (5), who made the first detailed measurements of the heats of wetting of cellulose by water.

Babbitt (6) made a comprehensive analysis of the adsorption isotherm of the cellulose – water vapor system and was the first to apply the Brunauer, Emmett, and Teller adsorption isotherm equation (7) to this system. In the present work, surface area measurements have assisted us in interpreting the thermodynamic properties.

EXPERIMENTAL

Calorimetric measurement of the heats of wetting by liquid water of cellulose equilibrated with various amounts of adsorbed and desorbed water vapor is the basis of the

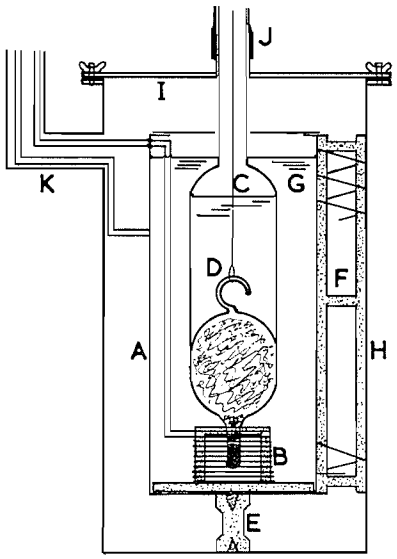

FIG. 1. The adiabatic calorimeter.

enthalpy calculations. Measurement of the adsorption and desorption isotherms is the basis of the corresponding free energy calculations. The entropies of sorption then follow from the well-known equation connecting the three thermodynamic functions.

Calorimeter

The adiabatic calorimeter (Fig. 1) was a simplified version of one by Howard and Culbertson (8). An inner cylindrical copper can, A, 2 inches in diameter by 5.5 inches long, was secured on a small lucite pedestal E inside an outer concentric copper jacket H with an air gap of 0.75 inch. A thermel F of 21 pairs of copper–constantan junctions supported on a light lucite frame was placed between the concentric walls. A 100-ohm manganin wire, non-inductively wound on a lucite frame, served as a calibration heater coil B and was placed in the bottom of the inner can.

The flanged lid I of the outer can had a central brass tube to act as a bearing for the glass reaction cell D. A side tube K from the outer can carried the wiring of the thermels and heater. The complete assembly rested in a well-stirred crock containing water. A rubber tube J was clamped to the lid-bearing to prevent leakage of water from the crock into the calorimeter.

Adiabatic control, sensed by the thermel and a sensitive galvanometer, was obtained manually by hot and cold water streams. Temperature changes were measured by a pair of thermistors (Stantel Type F, Standard Telephone and Cables, Ltd., England, total resistance about 3500 Ω at 25° C) immersed in the outer water bath and connected to a wheatstone bridge reading to 0.1 Ω. (Simultaneously, for some experiments, the resistance was measured by a Sargent Recorder, Model S-72150.) Electrical duplication of the heat changes was obtained with a circuit (9) which included an electronic voltage stabilizer to give a constant voltage (5 to 10 v). Between particular heat of wetting experiments, the outer crock was maintained at constant temperature by a thermoregulator and heater assembly, and at least 20 hours was allowed for the calorimeter and reaction cell to come to thermal equilibrium. All experiments were started at about 24.5° C.

A double compartment glass reaction cell D was used for contacting the cellulose and liquid water (Fig. 1). The cellulose in the lower compartment was sealed under vacuum. This ensured complete wetting when the breaking of the glass septum by pulling on a looped wire C allowed the water in the upper compartment to enter the lower one. The glass tube of the reaction cell passes through the calorimeter lid and is suspended by a coupling to a reciprocating stirring device. The main parts of the reaction cell are suspended in a heat transfer fluid G (light grade vacuum pump oil) in the inner can. After a sample has been prepared, the vacuum seal which is finally made at the lower end of the reaction cell is pinched into a paddle shape to act as a stirrer. This stirrer is suspended just inside the electrical heater B, thus securing dissipation of the heat evolved by the heater and by the wetting process. A new glass cell is required for each experiment.

Adsorption Apparatus

The sorption isotherm of cellulose and water vapor was determined with a vacuum apparatus similar to that used by Wiig and Juhola (10) for charcoal. About 8 g cellulose were placed in a detachable cylindrical glass bulb fitted with a vacuum stopcock and ground glass joint. The bulb had a central glass tube with several perforations to hasten equilibration. The vapor pressure was measured with an oil (Apiezon B) manometer and cathetometer, and the amount of water in the sample was obtained by detaching and weighing the assembly. Special precautions were taken in experiments near saturation vapor pressure because the top surface of the water bath thermostat had a slightly lower temperature than the bulk of the thermostat. A small heating coil was clasped around the tubes of the adsorption cell and the water reservoir to prevent condensation. The manometer was maintained at a temperature slightly above that of the thermostat. The isotherm was measured at 24.6° C.

Preparation of Cellulose

Standard cellulose was prepared from absorbent cotton (Johnson and Johnson Red Chain) by the same method as that of Argue and Maass (5), with the exception that *the cellulose was never allowed to dry above room temperature.*

All of the samples of cellulose, both for the calorimetry and for the sorption isotherm, were evacuated at room temperature for a minimum of 24 hours by means of a system including a mercury diffusion pump, magnesium perchlorate drying tube, a glass trap in dry ice – acetone mixture, and a rotary oil vacuum pump. "Stick" vacuums were consistently obtained as shown by the McLeod gauge. It was found that evacuation for 2 or 3 days neither reduced the moisture content nor produced a higher heat of wetting than for samples evacuated for 24 hours.

Samples for heat of wetting experiments (about 1 g) were placed in the lower compartment of the reaction cell; a small plug of Pyrex glass wool was inserted to prevent singeing of the cellulose. A vacuum stopcock and a male ground glass joint were sealed to the lower compartment, and the assembly was evacuated to constant weight. The dry weight of the cellulose was obtained by weighing the assembly after removing the grease (Apiezon L) from the ground glass joint with ether. All other joints and all stopcocks were greased with Dow Corning High Vacuum Silicone Grease, but Apiezon L is more easily removed because of its yellow color and hydrocarbon nature.

Samples were prepared with various adsorbed and desorbed water contents by contacting water vapor in an otherwise evacuated line. In each case at least 24 hours (11) were allowed for the final equilibration *after* the addition or removal of water. Also, at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

least 24 hours were allowed for saturation with water vapor *before* the water was partially removed for the desorption experiments. Thus, at least 48 hours were required to prepare adsorption samples and 72 hours to prepare desorption samples for the calorimeter.

The correction for the heat of bulb-breaking (12) when water entered the evacuated bulb containing cellulose was calculated to be about 0.2 cal for each cell. A blank run on an empty cell gave a value of about 0.15 cal, so that this was subtracted from the heat of wetting of each sample. It happens that this correction does not affect any of the thermodynamic functions except the net enthalpy ΔH at saturation.

RESULTS AND CALCULATIONS

Drying Temperatures and the Heats of Wetting

The heats of wetting of standard cellulose with varying water contents, both adsorbed and desorbed, are given in Table I and Fig. 2. It would appear that within the experimental error, there is no hysteresis between the "adsorbed" and "desorbed" heats of wetting.

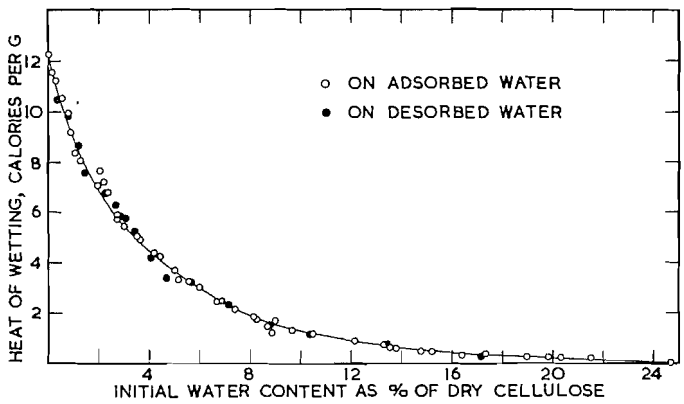

FIG. 2. The heats of wetting by water of cotton cellulose containing various amounts of adsorbed and desorbed water.

There is more scatter in the heats of wetting of samples below 3% water content than above. We believe that this is due to difficulty in removing the last traces of water from the cellulose rather than to errors in the calorimetry.

The heats of wetting obtained here are significantly higher than those obtained by Argue and Maass (5) and Wahba (4). For example, our value for dry cellulose was 12.33 cal/g whereas theirs were 10.16 and 10.72 respectively.

Argue and Maass heated their samples in air at 100° C, while Wahba heated his cellulose *in vacuo* at 65° C. In contrast, our samples were never permitted to go above room temperature. Kouris, Ruck, and Mason (13) also found that drying cellulosic material (a purified sulphite pulp) at elevated temperatures lowers the heat of wetting significantly compared with drying at room temperature.

There is some evidence that the cellulose–water system undergoes a change around 40° to 50° C. For example, Collins (14) found a parallel break in the curves of the cross-sectional area changes *and* the regain when plotted against temperature, with a complete change in direction occurring in the range 40° to 50° C.

Wahba and Nashed (15), on the basis of the experimental determination of adsorption isotherms at different temperatures, found that the isosteric heats of adsorption decreased markedly above an optimum temperature of from 40° to 50° C for "unstabilized" cellulose. They attribute this change to the development of new adsorbing centers above the optimum temperature.

The absence of hysteresis in the heats of wetting probably was found because the samples were dried at room temperature. Wahba and Nashed (16) found some hysteresis when they dried cellulose at 65° C and Argue and Maass (5) found even more when they dried it at 100° C.

The scatter in the heat of wetting values at very low moisture contents may arise from a high energy of activation for the transfer of water out of and into the cellulose fibers. Thus, room temperature drying increases the difficulty of obtaining reproducible drying. If we had used smaller samples, and evacuated them for longer times, the scatter probably would be reduced. Above the moisture content of the monolayer value (later), the scatter is much smaller in spite of the smaller amount of heat to be measured. It follows quite reasonably that the energy of activation for the removal of the upper layers is much less than for the first layer of sorbed water.

Thermodynamic Calculations

The heat of wetting data are used to calculate the integral and differential net enthalpies of sorption ΔH and $\overline{\Delta H}$ in calories per 100 g cellulose (above the heat of condensation of water vapor to liquid).

The adsorption isotherm (Table II and Fig. 3) is used to calculate the integral and differential free energies of adsorption, following the method of Dole and McLaren (17), see also (1, 2), which is similar to that of Wahba (4).

Finally, the integral and differential net entropies of adsorption are calculated from the enthalpies and free energies by the equations

$$\Delta S = (\Delta H - \Delta F)/T \quad \text{and} \quad \overline{\Delta S} = (\overline{\Delta H} - \overline{\Delta F})/T.$$

The various thermodynamic data are given in Table III and the differential properties are plotted in Fig. 4.

Adsorption Areas

equation to a large number of protein – water vapor adsorption isotherms (19). In both cases the B.E.T. equation fitted the lower part of the adsorption isotherm.

Dunford and Morrison (20) have shown that the Harkins–Jura (H.J.) equation (21) applied to the upper part of Bull's isotherms and, by using Liang's correlation (22), they found the *same* monolayer content for both the B.E.T. and H.J. equations.

Applying these equations to the present isotherm, we obtain monolayer contents of 3.19 and 3.29 g water per 100 g cellulose for the B.E.T. and H.J. equations, respectively. The relative pressures over which these equations apply are 0.075 to 0.30 *and* 0.68 to

DISCUSSION

Isotherm Equations and Areas

The application of theoretical adsorption equations to water vapor – natural polymer systems such as the present one helps us to interpret the thermodynamic data. The finding that at least two different equations, the B.E.T. and the H.J. equations, are required to account for the major part of the adsorption isotherm suggests either or both of two interpretations, (*a*) that a phase change occurs in the state of the adsorbed film (21) or (*b*) that a new phase appears as the relative pressure increases.

We note here that the B.E.T. equation is based on an immobile film with adsorption on definite sites, while the H.J. equation is based on a mobile condensed film.

Following the suggestion of Dunford and Morrison (20) with respect to the adsorption of water vapor by proteins, we consider that the adsorption of water vapor by cellulose from the dry state to saturation takes place as follows: a monolayer of immobilized water molecules is completed well before a relative pressure of 0.5 is reached, while further adsorption occurs *above* this monolayer; no surface is developed beyond that occupied by the monolayer; some multilayers, also immobile, are built up until the onset of a condensed film occurs at a relative pressure of about 0.6. Since the H.J. equation is based on *monolayer* film formation, it is suggested that the condensed film may appear as a new phase above an underlying "iceberg" phase of immobilized water (23).

The interpretation given here is in part confirmed by the observations of Hermans and co-workers (24). When the density of cotton cellulose is plotted against water content, a very well-defined maximum occurs at about 3.1% water content. This corresponds in their terms to the "formation of the first hydrate", and in our terms to the completion of a monolayer of immobilized water. Subsequently, there is evidence from their data of additional hydration up to 10 to 12% water content, succeeded by a density of sorbed water indistinguishable from that of liquid water.

A Comparison of Cellulose and the Fibrous Proteins

When the differential entropy and enthalpy curves (Fig. 4) of the cellulose – water vapor system are compared with those for silk fibroin and wool keratin (1, 2, 3), it is seen that the curves of the cellulose system are not as *definite* in their features. Whereas the breaks in the $\overline{\Delta H}$ and $\overline{\Delta S}$ curves of the two protein systems are very definite, and these breaks coincide very well with the B.E.T. and H.J. equation ranges, the same features in the corresponding cellulose curves are much less definite. For example, the beginning and end of the B.E.T. ranges of the two proteins coincide with the minimum and maximum respectively of the breaks in the $\overline{\Delta S}$ curves. In contrast, the B.E.T. range for cellulose begins earlier and it ends before the second break in the $\overline{\Delta S}$ curve.

It is possible that in the case of the proteins, the first monolayer is largely completed before the second and higher layers begin to form. In contrast, Babbitt has suggested for cellulose "that condensation begins in the second layer long before the first is completed" (6).

There is much evidence to suggest that cellulose is a much less reproducible material than the fibrous proteins. In our experience with the three fibers, the proteins are much less sensitive to high temperature drying than cellulose. Wool keratin can be dried in vacuum up to 80° C without affecting its heat of wetting (25), and it shows no hysteresis in its heat of wetting curve (2). Probably silk fibroin could also be heated nearly to this temperature without changing its adsorption properties, because on drying at 100° C it shows only a small hysteresis in its heat of wetting curve (1). Moreover, this

hysteresis is in the opposite direction to that observed for cellulose (5). Hutton and Gartside (26) have shown after very careful experiments that silk fibroins of Japanese, Chinese, and Italian origin gave exactly the same sorption isotherms.

In contrast, as already noted, cellulose is very sensitive to its mode of drying (see also Brown and co-workers (27)) and other features of its past history.

Perhaps the most important evidence for the contrast between protein fibers and cellulose is given by Mellon, Korn, and Hoover (28). They found that complete solution and reprecipitation of fibroin and keratin did not essentially alter their sorption isotherms. On the other hand, it is well known that solution and reprecipitation of cellulose always result in very large increases in the amount of water adsorbed.

Differential Enthalpy and Hydrogen Bonding

Although less definite than the fibrous proteins, nevertheless cellulose reveals the same kinds of breaks in its differential enthalpy and entropy curves. The enthalpy $\overline{\Delta H}$ decreases rapidly and levels off somewhat at -1.4 kcal per mole water adsorbed. This is comparable to the first layer heat value, -1.44, which Babbitt obtained for cellulose from one of the constants in the B.E.T. equation (6). It is also similar to the value obtained in this laboratory for mercerized cotton cellulose (29).

The value, -1.4, is significantly lower than the corresponding one, -2.4, which was obtained for both fibroin and keratin (1, 2, 3). As in the latter cases, we consider that the value -1.4 corresponds to a single hydrogen bond between water molecules and cellulose. Since the $\overline{\Delta H}$ values are net ones above the heat of condensation to liquid water, the hydrogen bond values would be $-4.5+(-1.4) = -5.9$ kcal per mole water, which is reasonable (30).

The high initial values of $\overline{\Delta H}$ may be due in part to the formation of two or more hydrogen bonds (15) per adsorbed water molecule; also, there may be a contribution from the release of tensions within the excessively dried cellulose. After the break in the region of monolayer formation, $\overline{\Delta H}$ decreases continuously up to saturation vapor pressure when it is indistinguishable from that of condensation on liquid water.

Entropy Changes

The differential entropy of adsorption for the cellulose – water vapor system is given in Fig. 4. The entropy curve exhibits a minimum similar to that of the fibrous proteins (3). Kelsey and Clarke (31) have a break in their $\overline{\Delta S}$ curve for a wood – water vapor system at about 8% to 9% water content. Since their wood adsorbed about 1.65 times as much water as pure cellulose, their observation is consistent with our maximum at a moisture content of 5.4%.

The explanation of the entropy curve is based on the assumption that both the adsorbate and adsorbent are contributing to $\overline{\Delta S}$ and $\overline{\Delta H}$. It is considered that after the *minimum* in $\overline{\Delta S}$ ($n = 0.25$) the contribution of the adsorbent is negligible on the *adsorption* side.

Pure adsorption, being an ordering process, contributes negative entropy ($-\overline{\Delta S}$ = +value). On the other hand, the disorganization of a highly dried gel (cellulose, fibroin, etc.) by water, contributes positive entropy ($-\overline{\Delta S}$ = −value). The high initial values of $-\overline{\Delta S}$ are probably due to adsorption of water, while the very rapid decrease to a minimum may be due in part to the disordering of the dried gel and in part to the replacement of two or more hydrogen bonds per water molecule by one per molecule. Then $-\overline{\Delta S}$ recovers up to a maximum. Here it is suggested that the disordering of the gel is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

largely completed and the ordering due to adsorption asserts itself sufficiently to give a net recovery in $-\overline{\Delta S}$.

Adsorption into the second layer is less ordering than into the first so that $-\overline{\Delta S}$ continues to fall off after the maximum.

There is only a suggestion of a second break in the $-\overline{\Delta S}$ curve at $n = 0.70$, which corresponds to the pronounced break in the fibroin and keratin curves (1, 2, 3). A revision of a former explanation (3) is given here for the second and final break. It has already been suggested that well before the final break is reached, the contribution of the adsorbent to $-\overline{\Delta S}$ is negligible. The final break is considered to be a recovery in $-\overline{\Delta S}$ *after* the onset of a mobile film.

The transition from an immobile to a mobile film, *or* the appearance of a new mobile film above the immobile one, probably is marked by the beginning of the H.J. range, and is a disordering effect ($-\overline{\Delta S} = -$value). Thus, the net $-\overline{\Delta S}$ decreases more rapidly than if such a transition did not occur. But, after it has occurred, further adsorption (an ordering effect) continues and there is some recovery in $-\overline{\Delta S}$. Finally, the entropy changes become indistinguishable from condensation on liquid water.

Hysteresis

The adsorption–desorption isotherm for the cellulose – water vapor system exhibits a well-known hysteresis. Everett and Whitton (32) have discussed the validity of calculating thermodynamic properties of systems which exhibit such a permanent hysteresis. They have shown that these systems are thermodynamically stable, and differ from more familiar thermodynamic systems in having at least one other (an internal) variable.

It has been found that there is no hysteresis in the enthalpies of adsorption and desorption of water vapor on cellulose (also wool keratin and probably silk fibroin). Since the sorption curves determine the free energy functions, it follows that hysteresis in these systems is an entropy phenomenon.

The absence of hysteresis in the enthalpy seems to rule out the suggestion that hysteresis in the sorption isotherm involves the uncovering of new, more active sites on the desorption branch. Thus, Wahba and Nashed (15) suggest that the water molecules are more tightly held on the desorption side so that the vapor pressure is lower than on the adsorption side for the same amount of water sorbed.

If the hysteresis in the sorption isotherm is an entropy phenomenon, we would look for a difference in the arrangements (ordering) of the system on the two sides of the hysteresis loop rather than a difference in the bonding energies (enthalpies). It is difficult to conceive of the water alone having a different arrangement on the two sides of the loop, without the cellulose also being different. In fact, it is more usual that the adsorbent determines the arrangement of the adsorbate than the opposite. The general observation that the hysteresis of the water sorption isotherms of these fibrous systems is an entropy phenomenon supports Barkas' explanation of these hystereses (33).

Barkas explains hysteresis in terms of plastic deformation of a gel on the desorption of water vapor. This sets up internal stresses which affect the vapor pressure in a way analogous to the effect of an external hydrostatic pressure on the vapor pressure of a liquid. Thus, the vapor pressure on the desorption side is decreased by increased stresses on that side of the hysteresis loop.

We are suggesting that on the adsorption side of the hysteresis, the stresses of a completely dried gel have been largely removed in the low vapor pressure region of water uptake and that beyond about a monolayer, the isotherm is essentially stress-free up to saturation. Otherwise, it is difficult to understand the fit of the B.E.T. and H.J. equations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

to the lower and upper parts of the adsorption isotherms with the same area being found for both equations. Attempts to fit these equations to the desorption side have been unsatisfactory. In the case of cellulose, the points do not lie on a 'good' straight line; and when the 'best' one is drawn, the H.J. monolayer area is at least 10% higher than the B.E.T. area.

Barkas predicted that there should be a hysteresis in the volume of the gel on the two sides of the loop. He found such to be the case for the wood – water vapor system (34). However, he calculated that in the case of *solid* filaments the volume hysteresis would be too small to observe experimentally. Hermans and his co-workers (24) confirmed this in the case of solid filaments of regenerated cellulose.

However, Collins (14), in some work apparently overlooked by Barkas, observed a definite hysteresis in the diameter of cotton cellulose fibers which have been treated with 15% NaOH to smooth them. Here, the same result as Barkas found for wood was observed in that the volume on the desorption side was greater than on the adsorption side.

Correspondingly, the differential entropy curve of desorption lies below that of adsorption. Since these are negative entropies, the desorption side has a higher positive entropy and is, therefore, more disordered than the adsorption side. This observation is consistent with the volume hysteresis.

A calculation based on Collins' measurements and on Urquhart and Williams' sorption isotherm for cellulose treated with 15% NaOH (35) shows, for example, that at 8% water content, the cross-sectional area changes are 9.7% on the adsorption side and 11% on the desorption. At 13% water content, the cross-section changes are 15.3% and 17.3% respectively.

Recently, Chakravarty (36) observed a similar hysteresis in the cross-sectional areas of single jute fibers at different relative humidities. However, Chakravarty found that there was no measurable hysteresis below a relative humidity of 25%, which corresponds to about one monolayer content for cellulose. This observation when taken together with Hermans and his co-workers' observations on isotropic solid filaments suggests that hysteresis may be largely an interfibrillar phenomenon rather than one within any single microfibril.

In conclusion, our work emphasizes the importance of measuring and reporting both the adsorption and desorption isotherms of systems which exhibit hysteresis. Unfortunately, this has not been done in many cases reported in the literature. For example, Bull in his classical work (19) measured the adsorption isotherms of about 18 protein materials. In the case of five of these (silk, wool, collagen, gelatin, and lyophilized egg albumin) he stated that "equilibrium was approached from both the wet and dry side of the equilibrium point". He found that "there is some hysteresis between a relative pressure of 0.15 and 0.65 while above and below these humidities the agreement is very good. In reporting the adsorption curves for the above five proteins, an average of the adsorption and desorption curves has been given." Here, Bull has assumed that hysteresis is a transient phenomenon; moreover, in calculating the "average of the adsorption and desorption curves", he does not indicate which of the two averages he used, the average at equal relative vapor pressure or at equal water content.

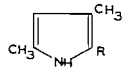
ADDITION OF PHENYL ISOTHIOCYANATE TO PYRROLES[1]

E. BULLOCK[2] AND R. J. ABRAHAM[2]

ABSTRACT

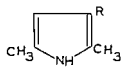
Pyrrole and alkyl pyrroles react spontaneously with phenyl isothiocyanate to produce C-substituted derivatives. The structures of the products are confirmed by physical methods. The reaction is catalyzed by organic bases.

Alkyl pyrroles react with phenyl isocyanate; the speed of reaction varies widely, depending on the substituents on the pyrrole ring. Where the pyrrole has a free α-position, the product is considered to be the α-anilide, e.g., I*a*. Reaction with α, α'-disubstituted pyrroles is slow and is thought to yield β-anilides, e.g. II*a* (1).



I

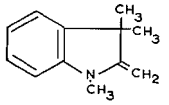
(*a*) R = CO.NH.Ph
(*b*) R = CS.NH.Ph



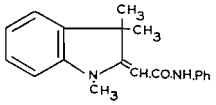
II

(*a*) R = CO.NH.Ph
(*b*) R = CS.NH.Ph

Generally, phenyl isocyanate reacts only sluggishly with "active" carbon atoms (e.g. with acetoacetic ester (2)) though the formation of IV from Fischer's Base (III) is rapid (3).



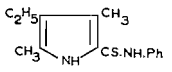
III



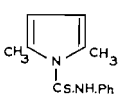
IV

Phenyl isothiocyanate is less reactive than the oxygen analogue towards water (4), amines (5), and acetoacetic ester, though it reacts readily with sodioethyl acetoacetate (11). The reaction with pyrroles is often rapid and the products are easily isolated (no competing side reaction with water). The thioanilides are converted to the corresponding anilides by alkaline peroxide.

In the ultraviolet, I*b* has a single absorption band of high intensity, while II*b* has two weaker bands at shorter wavelengths. This corresponds well with the difference in absorption of the α-(VII*a*) and β-(VII*b*) carboxylic acids (7).



V



VI

[2]*National Research Council Postdoctorate Fellow.*

N.M.R. spectra were recorded on several of these derivatives. The cryptopyrrole adduct shows no signal due to pyrrole C—H protons (8) and is therefore the α-thioanilide V (Fig. 1*a*). This compound is very similar (e.g. in infrared and ultraviolet spectra) to I*b*, which must therefore belong to the α-series, a fact confirmed by the proton resonance (Fig. 1*b*).

The nuclear magnetic resonance spectrum of II*b* confirms the structure since, apart from the single β-proton signal (Fig. 1*c*) the presence of two different sets of $-CH_3$ protons (Fig. 1*d*) rules out the symmetrical N-substituted compound (VI).

There is a qualitative relationship between the degree of alkyl substitution on the pyrrole nucleus and the rate of reaction with isothiocyanate in the α-series (Table I). The work on the anilides (1) shows a similar trend.

TABLE I

Reaction rates of substituted pyrroles

	Reaction (heating time)	Derivative	Yield (%)
Pyrrole	7 hours	α	3
α-Methyl	40 minutes	α	88
2,4-Dimethyl	10 minutes	α	90
2,4-Dimethyl-3-ethyl	2 minutes	α	100 (approx.)
2,3,4-Trimethyl	1 minute	α	100
2,3-Dimethyl	15 minutes	α	95
3,4-Dimethyl	5 minutes	α	73
2,5-Dimethyl	12 hours	β	7
2,3,5-Trimethyl	$1\frac{1}{2}$ hours	β	45

The reaction is base-catalyzed and solvent-sensitive. In several cases dissolution of the reactants (10%) in NN-dimethyl formamide (cf. 9) gives almost quantitative yields of thioanilides after 12 hours at room temperature and is the most convenient method of preparation; similar solutions in heptane yield no isolable product after 7 days.

Addition of triethylamine to mixtures of phenyl isothiocyanate with pyrrole, 2,4-, and 2,5-dimethyl pyrrole causes a marked increase in reaction rate and in the yield of the anilide.

The reaction with 2,3,5-trimethylpyrrole is interesting since it is faster than that of pyrrole and is comparable with α-methyl pyrrole. Thus, despite the steric effect of two adjacent methyl groups this β-position approaches the α-position of the simpler compound in reactivity.

Unlike the oxygen analogue, phenyl isothiocyanate failed to react with tetramethyl pyrrole (cf. 13) under vigorous conditions.

The variation of reaction rate with substitution may be due to two effects: (*a*) a general increase in the reactivity of the pyrrole ring with alkyl substitution and (*b*) the similarly increasing basicity of the pyrroles.

The close similarity of the reactions of isothiocyanates and isocyanates suggests that the mechanisms are analogous. The base catalysis observed for the pyrrole reaction indicates that as in the "normal" reaction with amines formation of a reactive complex (10) probably involving the pyrrole nitrogen atom is an intermediate step.

EXPERIMENTAL

Melting points are uncorrected.

Pyrryl carbanilides were prepared for comparison purposes according to Treibs and Ott (1).

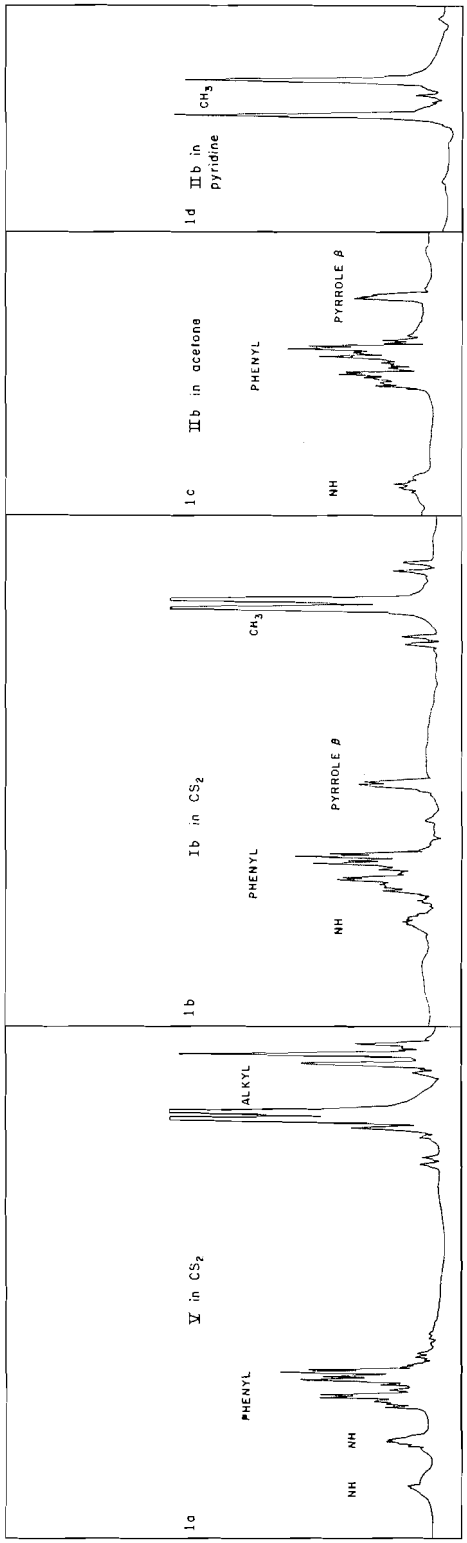

FIG. 1. N.M.R. spectra of pyrryl thiocarbanilides.

General Procedure for Isothiocyanate Reactions

The pyrrole was treated with approximately 10% excess of phenyl isothiocyanate and the mixture heated on the steam bath, the conditions being given for individual compounds in Table I. When the reaction mixture became very viscous, cold heptane was added; the product usually solidified when scratched with a glass rod. The solid was filtered and washed with heptane, then crystallized from a small volume of ether to which heptane was carefully added.

Pyrrole-2-thiocarbanilide

The reaction was far from complete after 7 hours and isolation of the product was made difficult by the presence of the reactants. The product was soluble in many organic solvents but was finally crystallized from heptane to yellow plates, m.p. 96–97° (3%). Calc. for $C_{11}H_{10}N_2S$: C, 65.31; H, 4.98; N, 13.85. Found: C, 64.96; H, 4.86; N, 13.92.

2-Methylpyrrole-5-thiocarbanilide

The thioanilide crystallized to thick yellow needles (88%), m.p. 109.5–111°. Calc. for $C_{12}H_{12}N_2S$: C, 66.62; H, 5.59; N, 12.95. Found: C, 66.46; H, 5.41; N, 12.65.

2,4-Dimethylpyrrole-5-thiocarbanilide

The product (90%) was crystallized to long yellow needles, m.p. 112–115°. Calc. for $C_{13}N_{14}N_2S$: C, 67.79; H, 6.13; N, 12.17. Found: C, 67.73; H, 5.76; N, 11.95. Ultraviolet spectrum: λ_{max} 344, λ_{infl} 218 mμ; log ϵ_{max} 4.38, log ϵ_{infl} 4.12 (95% ethanol). Infrared spectrum (nujol mull): 3380, 3340, 1603, 1500, 1482, 1448, 1427, 1375, 1355, 1315, 1288, 1235, 1207, 1155, 1027, 1008, 986, 945, 892, 820, 802, 744, 695, 680, 642 cm^{-1}.

2,5-Dimethylpyrrole-3-thiocarbanilide

The reactants were heated on the steam bath for 12 hours after which time the reaction mixture was black. The product was isolated by sublimation (0.5 mm, 150°) from the black solid obtained on addition of heptane to the reaction mixture, as small white needles, m.p. 194° (7%). Calc. for $C_{13}H_{14}N_2S$: C, 67.79; H, 6.13; N, 12.17. Found: C, 67.96; H, 5.77; N, 12.13. Ultraviolet spectrum: λ_{max} 319–325, 263, 217 mμ; log ϵ_{max} 4.09, 4.09, 4.32 (95% ethanol). Infrared spectrum (nujol mull): 3170, 1595, 1527, 1493, 1372, 1337, 1315, 1304, 1285, 1219, 1199, 1127, 1067, 1025, 1002, 966, 910, 790, 755, 712, 700, 682, 653 cm^{-1}.

In $CHCl_3$ solution, the NH band resolves to two peaks at 3380, 3440 cm^{-1}.

2,3-Dimethylpyrrole-5-thiocarbanilide.—2,3-Dimethylpyrrole-5-thiocarbanilide was isolated as thick yellow needles (95%), m.p. 144–145°. Calc. for $C_{13}H_{14}N_2S$: C, 67.79; H, 6.13; N, 12.17. Found: C, 68.13; H, 6.00; H, 12.15.

3,4-Dimethylpyrrole-2-thiocarbanilide.—3,4-Dimethylpyrrole-2-thiocarbanilide was obtained as yellow needles (73%), m.p. 118–119.5. Calc. for $C_{13}H_{14}N_2S$: C, 67.79; H, 6.13; N, 12.17. Found: C, 67.75; H, 6.06; N, 12.01.

2,4-Dimethyl-3-ethylpyrrole-5-thiocarbanilide

An almost quantitative yield of the product was isolated as thick yellow needles, m.p. 98–99°. Calc. for $C_{15}H_{18}N_2S$: C, 69.72; H, 7.02; N, 10.84. Found: C, 69.93; H, 6.87; N, 10.91.

2,3,4-Trimethylpyrrole-5-thiocarbanilide.—2,3,4-Trimethylpyrrole-5-thiocarbanilide was obtained in quantitative yield, m.p. 123–124°. Calc. for $C_{14}H_{16}N_2S$: C, 68.34; H, 6.60; N, 11.21. Found: C, 68.74; H, 6.49; N, 11.11.

For personal use only.

2,3,5-Trimethylpyrrole-4-thiocarbanilide.—2,3,5-Trimethylpyrrole-4-thiocarbanilide was formed in good yield when the reactants were heated alone (or with triethylamine) for 1½ hours on the steam bath. Shorter reaction times yielded a product which was difficult to purify owing to the presence of starting material. Addition of heptane gave a dark gummy solid which when washed with ether yielded a yellow powder which was crystallized from chloroform–heptane as yellow prisms, m.p. 195–196° (45%). Calc. for $C_{14}H_{16}N_2S$: C, 68.34; H, 6.60; N, 11.21. Found: C, 68.12; H, 6.47; N, 11.37. Ultraviolet spectrum: λ_{max} 313 (broad), λ_{infl} 292 mμ; log ϵ_{max} 4.16, log ϵ_{infl} 4.10 (95% ethanol).

2,3,4,5-Tetramethylpyrrole.—2,3,4,5-Tetramethylpyrrole yielded no derivative under the following conditions: heating for 1 minute, 1 hour, 3 hours, heating for 3 hours then 24 hours at room temperature, standing for 48 hours at room temperature.

Oxidation of Thioanilides to Anilides (6)

Thioanilide (0.2 g) was dissolved in ethanol–water (10:1) in which 1 pellet of sodium hydroxide was dissolved. Hydrogen peroxide solution (100 vol., 1 ml) was added to the cold solution dropwise with shaking, and crystalline material appeared in the mixture soon after the addition of all the peroxide. After 30 minutes the product was isolated by pouring the reaction mixture into water (100 ml) and crystallized from chloroform–heptane.

(*i*) 2-Methylpyrrole-5-thiocarbanilide yielded 0.11 g of the corresponding anilide, m.p. 174–176° alone or mixed with authentic material (lit. 173° (1)).

(*ii*) 2,4-Dimethylpyrrole-5-carbanilide (0.15 g), m.p. 161° (lit. (1) 163°), was isolated.

(*iii*) Cryptopyrrole-5-thiocarbanilide yielded the corresponding anilide (0.06 g), m.p. 128–129° alone or mixed with authentic material (lit. (1) 137° for sublimed material or 131° (12)).

Comparison of Catalyzed and Uncatalyzed Reactions

The pyrrole (1 ml) was mixed with phenyl isothiocyanate (1 ml, 1.13 g) in each of two vessels to one of which triethylamine (3 drops) was added. The reactions were stopped by the addition of heptane (50 ml) and the product filtered off.

In the pyrrole case a black solid was produced in the catalyzed reaction from which two products, one white unidentified, the other the yellow thioanilide, were isolated and separated by fractional crystallization. In the other cases the crude solid was dried and weighed for comparison (a single recrystallization of these materials yielded products of good melting point).

Compound	Heating time	Uncatalyzed	Catalyzed
Pyrrole	6 hours	0.025 g 1.5%	0.17 g 10%
2,4-Dimethylpyrrole	2 minutes	1.40 g 73%	1.66 g 86%
2,5-Dimethylpyrrole	2½ hours	0 0	0.21 g 11%

ACKNOWLEDGMENTS

Analyses are by Mr. H. Seguin and the infrared spectra were recorded by Mr. R. Lauzon.

MOLTEN SALTS

THE DENSITY AND ELECTRICAL CONDUCTIVITY OF THE SYSTEMS: $AgNO_3$–$Ba(NO_3)_2$, –$Ca(NO_3)_2$, AND –$Mg(NO_3)_2$ [1]

J. W. Murphy and F. E. W. Wetmore

ABSTRACT

The density and electrical conductivity of the systems $AgNO_3$–$Ba(NO_3)_2$, –$Ca(NO_3)_2$, and –$Mg(NO_3)_2$ have been determined from 210 to 320° and from 0 to 20 equiv. %. The addition of magnesium nitrate causes the greatest shrinkage of the equivalent volume and reduction of the conductivity, barium nitrate the least.

The low conductivity of the binary melts is explained in terms of a mechanism involving restricted jumps and variation of the energy barrier with temperature and kind of ion added.

To date there have been few systematic studies of the density and electrical conductivity of binary salt melts comprising other than uni-univalent salts. This report concerns melts of silver nitrate with additions of barium, calcium, and magnesium nitrates.

EXPERIMENTAL

Materials

The silver nitrate was of reagent grade with a limit of 0.02% impurity, dried by oven-heating and finally by fusion. Barium nitrate of reagent grade was dried in an oven in which the temperature was slowly raised to a point just short of fusion. Calcium nitrate was prepared from reagent tetrahydrate by holding it at 300° for more than a day and heating it to 450° for an hour before use. Magnesium nitrate was prepared from reagent hexahydrate by vacuum-exsiccation from 50° slowly up to 150° (1); the weight of the charge was determined periodically. The salts were stored under dry air. Dryness of the melts was assured by the fact that their properties (density, conductivity, and freezing point) were not altered by longer periods of drying or by being held at high temperatures for several days during the runs; it is also significant that on heating the melts through more than 100° and returning them to the original temperature, the properties were not changed.

Apparatus

The apparatus used for the determination of density and conductivity differed from that used by Spooner (2) in only a few respects. The furnace was fitted with top and bottom plate heaters, which improved the homogeneity of the temperature of the melt. The silica conductivity cell was similar to that used by Lorenz and Kalmus (3), open at the bottom and having the lower electrode in the main body of the melt; the position of this electrode was found to be not critical.

Calibration with potassium chloride solution (4) showed the cell constant to be 801.93 cm^{-1} at 25°; appropriate correction was made for the expansion of the silica at higher temperatures. The bridge circuit was similar to that recommended by Jones and Josephs (5); both ratio arms were 1000 ohms. The signal leaving the bridge could be sent through a wide-band (400 to 10,000 c.p.s.) filter or through one sharply peaked. The amplitude and phase angle of the signal were observed on a cathode ray tube.

[1]*Manuscript received April 20, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

Procedure

Preliminary determinations of the apparent resistance of the melts with frequencies from 400 to 10,000 c.p.s. showed that it varied inversely as the square root of the frequency. The small polarization, not exceeding 0.05%, was thereafter conveniently determined by measuring the apparent resistance at two frequencies, 1000 and 4000 c.p.s.

Both conductivity and density measurements were made at intervals of about 12°, first with rising temperature and then with falling. The results fell on one smooth curve. Melts containing 1, 2, 3, 4, 5, 10, and 20 equiv. % of calcium and magnesium nitrate were studied; the dictate of solubility limited the addition of barium nitrate to 5 equiv. %.

RESULTS

From the measured buoyancies and resistances were derived equations of density and specific conductivity as functions of temperature. From these equations the equivalent volume and equivalent conductivity were calculated for intervals of 10°. The deviations of the original data from the equations indicated that the equivalent volumes of Table I are precise within 0.04%, the conductivities of Table II within 0.1%.

The equivalent volume of a melt, whether unary or binary, is the volume of 1 equivalent of nitrate ion with its associated equivalent of cation. Calculation of the shrinkage to be expected from simple replacement of silver ion by an equivalent amount of divalent ion (one-half as many) can be based on the reported (6) radii of the ions. The absolute values must depend on the assumption of the volume to be ascribed to an ion, varying, for example, from an extreme of $4.2\,r^3$ (spherical) to the other extreme of $8\,r^3$ (cubic). The relative shrinkages do not depend on this assumption; they are 1.0:2.0:2.5 for Ba:Ca:Mg. The actual shrinkages shown in Table I are $2.5N_2$, $5.5N_2$, and $7.3N_2$, corresponding to 1.0:2.2:2.9. In the melt, compared with the condition for which the radii were determined, the magnesium ion is most closely bound to the nitrate ions, the barium ion least.

TABLE I

Equivalent volume (cm^3 g-equiv.$^{-1}$) of the systems $AgNO_3$–$M(NO_3)_2$

Temp., °C	Equiv. %, divalent nitrate

Flood, Forland, and Grjotheim (7) suggested that the addition of divalent salt to univalent salt with a common ion could create vacancies in the melt. The shrinkages found here are of a magnitude which indicates the possibility of only small formation of vacancies, if any.

If ideality in conductivity is defined as the absence of effect of the presence of one ion on the mobility of another, then $\Lambda = N_1\Lambda_1^0 + N_2\Lambda_2^0$, in which N_i is the equivalent fraction of component i and Λ_i^0 is the equivalent conductivity of pure component i, is the condition of ideality. Since the melting points of the divalent nitrates lie well above the decomposition temperature of silver nitrate, comparison of real with ideal behavior is restricted to melts containing a high proportion of silver nitrate.

TABLE II

Equivalent conductivity (ohms cm^{-2} g-equiv.$^{-1}$) of the systems $AgNO_3$–$M(NO_3)_2$

Temp., °C	Equiv. %, divalent nitrate					
	0	3	5	10	20	M

		47.17	45.61	41.56	33.92	Mg

Table II and the solid curves of Fig. 1 show the real behavior; the broken line indicates the ideal contribution of silver nitrate alone, $N_1\Lambda_1^0$. The conductivity of the melt is much less than that of silver nitrate diluted by a non-conducting substance; assumption of lack of conductivity on the part of the divalent nitrate will therefore not alone explain the low conductivity.

Van Artsdalen and Yaffe (8) pointed out that shrinkage of the equivalent volume (quasi-lattice) would increase the electrostatic energy barrier for the conducting species. At 260° a melt containing 20 equiv. % magnesium nitrate, for example, shows a conductivity 20% less than $N_1\Lambda_1^0$. The volume is only 3% less than that of silver nitrate, corresponding to 1% reduction in interionic spacing and 2% increase in coulomb force. This increase in the energy barrier can account for about one-third of the observed decrease.

The suggestion of Van Artsdalen and Yaffe can be extended by supposing that silver ion is the important carrier of charge and that it moves by jumping from one cation site to another, but not to a site occupied by a cation closely bound to its anion neighbors. In comparison with pure silver nitrate there would be in the binary melt only N_1 as many silver ions and only some N_1 as many sites to which jumps are possible. The contribution of silver nitrate, without allowance for an increase in the energy barrier,

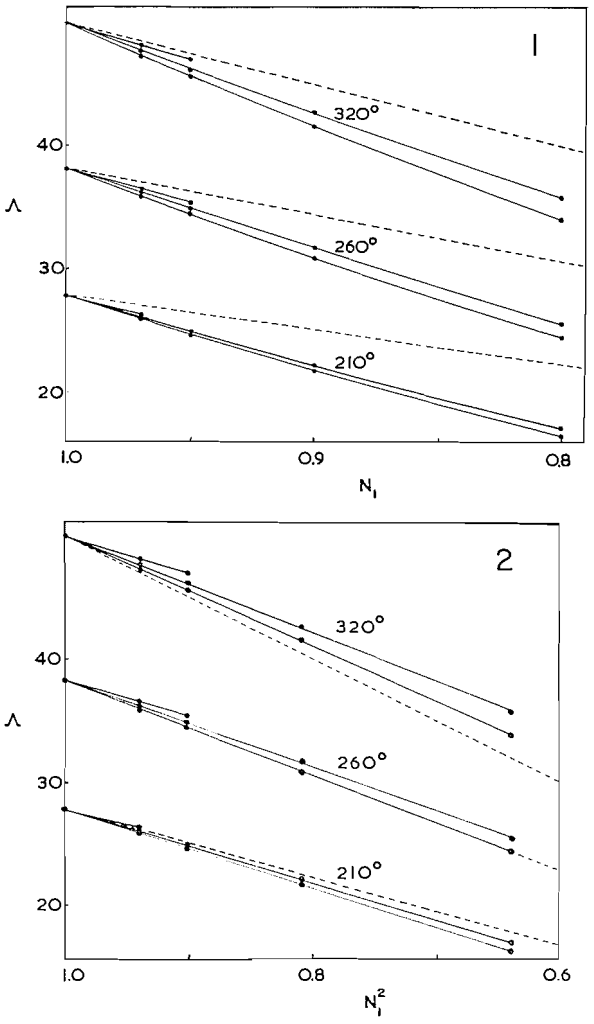

FIG. 1. The equivalent conductivity of silver nitrate with addition of divalent nitrate. The broken line shows the value of $N_1\Lambda_1^0$. In descending order the three solid curves in each group refer to barium, calcium, and magnesium nitrate, respectively.

FIG. 2. The equivalent conductivity of silver nitrate with addition of divalent nitrate. The broken line shows the value of $N_1^2\Lambda_1^0$. In descending order the three solid lines in each group refer to barium, calcium, and magnesium nitrate, respectively.

would be approximately $N_1^2\Lambda_1^0$. The solid lines of Fig. 2 show that Λ is essentially linear in N_1^2, but not exactly equal to $N_1^2\Lambda_1^0$. The deviations with change of temperature and divalent ion are in qualitative agreement with the views expressed above. The energy of activation of the conduction process decreases with rising temperature (2), and it can be seen from the expression $\Lambda = A.\exp(-E/RT)$ that the increase in the energy barrier with shrinkage of the quasi-lattice will be most pronounced at low temperature. The fall of conductivity should be greatest for addition of magnesium ion, least for barium ion. Both of these expectations are borne out.

THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF TRIARYL CARBONIUM IONS[1]

R. B. MOODIE,[2] T. M. CONNOR,[3] AND ROSS STEWART

ABSTRACT

The N.M.R. spectra of the triphenylmethyl cation and several of its derivatives substituted with methyl, methoxyl, and *tert*-butyl groups in the meta or para position have been obtained in trifluoroacetic acid – trifluoroacetic anhydride solution. The ring protons and substituent protons are all shifted to lower fields, i.e. are less shielded in the carbonium ions than in the neutral compounds of similar structure. The chemical shifts for the substituent protons are greater for para than for meta substituents and for mono- rather than tri-substituted ions. With each ion only a single peak was observed for the substituent protons but the ring protons were, in some cases, well resolved. The theoretical implications of these results are discussed.

INTRODUCTION

Triaryl carbinols are known to ionize in strongly acid solution to give carbonium ions.

$$Ar_3COH + 2H^+ \rightleftharpoons Ar_3C^+ + H_3O^+$$

The stability of these ions depends mainly on the extent of resonance interaction between the central electron-deficient carbon atom and the aromatic rings. Substituents which can aid this charge dispersal are known to have very large stabilizing effects on the carbonium ion. Thus the equilibrium constant for the ionization of tri-*p*-anisylcarbinol is larger by a factor of 3×10^7 than that of unsubstituted triphenylcarbinol (1). The effect of substituents in the meta position is much smaller since direct resonance interaction is not possible.

There are in addition two steric factors which are known to influence this electronic interaction. They are, first, the effect of bulky ring substituents such as *tert*-butyl in inhibiting solvation of the rings (2), and second, the steric interaction at the ortho positions. This latter effect precludes the formation of the electronically favored planar structure. The actual structure is open to question and it has been suggested that only one or two of the rings are conjugated with the central carbon atom (3). There is evidence, however, that favors, at least for the symmetrically substituted ions, a symmetrical "propeller" structure in which the π orbitals of each ring overlap to the same extent with the central carbon atom's p orbital (4, 5).

This paper reports a study of the nuclear magnetic resonance spectra of some substituted triarylmethyl cations in which the frequency of the aromatic and substituent proton resonances gives information about the distribution of the positive charge. The only previously reported N.M.R. spectra of carbonium ions are those of some protonated aromatic hydrocarbons (6) and the tropylium cation (7).

In order to compare the chemical shifts with those of neutral compounds containing similar groups, we sought a solvent which was sufficiently acidic to cause complete ionization of the triarylcarbinols, which would dissolve such compounds as toluene and anisole, and which was free from proton resonances in the region to be studied. A solution of trifluoroacetic acid in trifluoroacetic anhydride was found to be a suitable solvent system.

EXPERIMENTAL

The nuclear magnetic resonance spectra were recorded on a Varian 4300 spectrometer at 40 Mc, using an external water marker. In some cases the aromatic proton resonances were also examined at 60 Mc. Shifts were measured using conventional side band and interpolation techniques. Since all the solutions were dilute and the volume susceptibilities of the triarylmethyl cations are expected to be similar, the bulk susceptibility corrections are negligible so that the measured shifts can be compared directly. In each case the sample consisted of a 10% solution of the carbinol in a solvent of 1.5 *M* trifluoroacetic acid in trifluoroacetic anhydride sealed off *in vacuo*. The diamagnetic properties of the solvent were not appreciably changed over the range 1.5 to 3 *M* acid since the position of the proton resonances of toluene did not change.

The visible spectra of 3×10^{-4} *M* triphenylcarbinol (λ_{max} 410 mμ, ϵ 43,500, λ_{max} 425 mμ, ϵ 42,200) and of 1.5×10^{-4} *M* tri-*p*-anisyl carbinol (λ_{max} 478 mμ, ϵ 87,000) in the trifluoroacetic acid – trifluoroacetic anhydride solvent were measured with a Cary Model 14 recording spectrophotometer using cells of 0.1-cm path length. The spectrum appeared to be unchanged in more concentrated solutions (ca. 4×10^{-2} *M*) using cells of 10^{-3}-cm path length, but the volatility of the solvent precluded any precise determination with these cells.

The absorption maxima and extinction coefficients are very similar to those of the carbonium ions in sulphuric acid solution (triphenylmethyl cation: λ_{max} 404 mμ, ϵ 40,000, λ_{max} 431 mμ, ϵ 40,000 (2), tri-*p*-anisylmethyl cation: λ_{max} 483 mμ, ϵ 91,000 (8)). It was assumed that complete ionization also occurred in the slightly more concentrated solutions used for the N.M.R. spectral measurements. The N.M.R. spectra would, however, not necessarily reveal the presence of a small amount of the unionized triarylmethyl trifluoroacetate since in the equilibrium below,

$$CF_3CO_2CAr_3 \rightleftharpoons Ar_3C^+ + CF_3CO_2^-,$$

the rate of interconversion of the ionized and unionized forms may be too fast for separate substituent proton resonances to be observed.

The N.M.R. and visible spectra of *m*-methoxyphenyl diphenylcarbinol and tri-*m*-methoxyphenylcarbinol in this solvent were found to be quite different from the other carbinols studied. There seems to us to be some doubt as to the nature of the colored species formed in this solvent and their spectra are not further discussed here.

Preparation of Carbinols

The carbinols in Table I were prepared from the indicated starting materials by conventional Grignard syntheses.

[a]These melting points refer to *p-tert*-butylphenyl diphenylchloromethane which was prepared and used directly for the N.M.R. measurements.

Compounds IV and V gave poor yields and were purified by alumina chromatography. Compounds III and VI were purified by conversion to the triarylchloromethane and after several recrystallizations reconversion to the carbinol, as described by Gomberg (15). We are indebted to Mr. L. J. Muenster for the preparation of compound III.

RESULTS AND DISCUSSION

Table II records the chemical shifts of the aromatic and substituent protons measured from an external water marker at 40 Mc. In the case of the aromatic protons, these measurements were made to the largest peak except in the case of the tri-*p*-anisylmethyl cation where the measurement is to the center of the symmetrical quartet.

TABLE II

Chemical shifts of aromatic and substituent protons in cycles per second

Compound from which cation was derived	Aromatic shift (to main peak)	Substituent shift
Triphenylcarbinol	−101.0	—
p-Tolyl diphenylcarbinol (I)	− 98.0	+102.5
Di-*p*-tolyl phenylcarbinol (II)	− 94.75	+104.5
Tri-*p*-tolylcarbinol (III)	− 93.5	+105.5
m-Tolyl diphenylcarbinol (IV)	− 95.5	+112.5
Tri-*m*-tolylcarbinol (V)	− 89.0	+112.5
p-Anisyl diphenylcarbinol (VI)	− 96.0	+ 42.0
Tri-*p*-anisylcarbinol (VII)	− 87.5	+ 47.0
p-tert-Butylphenyl diphenylchloromethane (X)	−101.0	+151.0
Compound		
tert-Butylbenzene	− 76.0	+161.5
Anisole	− 68.0	+ 59.5
Toluene	− 69.0	+124.0

The Substituent Protons

In no cases were multiple substituent proton peaks observed. This is expected for the symmetrical propeller form but is also consistent with the one-ring-conjugated form if one assumes that the interconversion of isomers is too rapid to be detected by N.M.R. No splitting of the substituent proton resonances of the tri-*p*-anisylmethyl and tri-*p*-tolylmethyl cations was observed when the solutions were cooled to −80°.

Greater shielding of the substituent protons is observed in the carbonium ions sub-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

stituted in all three para positions compared with those with only one para substituent. In the latter case greater stability would be expected for a structure in which the substituted ring occupies a position of greater conjugation with the central carbon than the other two rings. This effect should be less marked with metasubstituted compounds, where the direct resonance interaction with the substituent is not possible, and in fact no difference was observed in the shielding of the substituent protons for the *m*-tolyl diphenylmethyl and tri-*m*-tolylmethyl cations.

The greater shift between toluene and the tri-*p*-tolylmethyl cation (18.5 c/s) than between anisole and the tri-*p*-anisylmethyl cation (12.5 c/s), in spite of the greater contribution to stability that a methoxy substituent makes, shows the importance of hyperconjugative structures in the former case.

A considerable loss of shielding is also observed going from *tert*-butylbenzene to the *p-tert*-butylphenyl diphenylmethyl cation (10.5 c/s). However, it is not possible to say whether this is purely an inductive effect or involves carbon–carbon hyperconjugation.

The Ring Protons

The effect of the substituents is to increase the shielding of the ring protons as can be seen by comparison with the triphenylmethyl cation (Table II). In the monosubstituted compounds this effect in the substituted ring is partly offset by the presumed greater conjugation it has with the central carbon atom. The result is that the signals from substituted and unsubstituted rings overlap.

The fine structure of the aromatic peaks is shown in Figs. 1–6. Figures 1 and 2 show the spectra of the triphenylmethyl cation at 40 Mc and at 60 Mc respectively and give us some information regarding the distribution of positive charge within the rings.

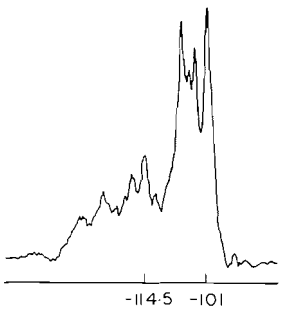

FIG. 1. Spectrum of aromatic protons of the triphenylmethyl cation at 40 Mc.

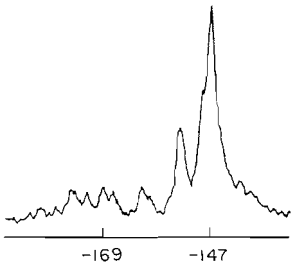

FIG. 2. Spectrum of aromatic protons of the triphenylmethyl cation at 60 Mc.

Resonance theory predicts that the meta protons should be more shielded than either the ortho or para protons in a carbonium ion. (This argument does not apply to molecules like nitrobenzene, for which it has been shown by Corio and Dailey (17) that the ortho hydrogens are least shielded with the meta and para proton peaks superimposed at higher field. The proximity of the latter is reasonable since the Hammett substituent constants (18) for meta and para nitro groups are close, i.e. resonance is of minor importance in nitrobenzene.) The complexity of the triphenylmethyl cation spectrum is due to coupling between aromatic protons and prevents complete identification of the proton signals. The group of peaks at low field however (below 157 c/s), can be assigned to the para protons since they occupy the theoretical value of one fifth of the area of the curve. The meta and ortho proton peaks overlap at higher field. (This agrees with

For personal use only.

S.C.M.O. calculations of π electron densities (19).) This is similar to the N.M.R. spectrum of protonated pentamethylbenzene in which the para substituent is the least shielded (6).

A factor which we will call ortho electrostatic interaction may be important in determining the charge distribution in triarylmethyl cations. The propeller form of the ion will be of lowest energy when the three rings are folded close to one another to enable maximum overlap to occur with the central p orbital. The ortho carbons are very close in this form, however, and electrostatic repulsion between these partially positively charged atoms may be expected to render the para positions relatively more positive.

FIG. 3. Spectrum of aromatic protons of p-tolyl diphenylmethyl cation at 60 Mc.

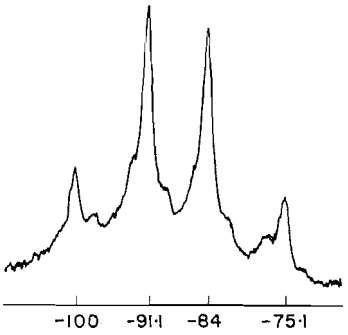

FIG. 4. Spectrum of aromatic protons of tri-p-anisylmethyl cation at 40 Mc.

The spectrum of the mono-para methyl ion (Fig. 3) resembles that of the unsubstituted triphenylmethyl cation with the single peak due to the substituted ring superimposed on the main peak. The peaks at low field are probably due to the para protons in the unsubstituted rings since the area under the peaks below -154 c/s is approximately one seventh of the area under the whole aromatic proton spectrum.

The spectrum of the tri-p-anisylmethyl cation at 40 Mc shows a well-resolved quartet (Fig. 4) due to coupling between ortho and meta positions. Assuming negligible cross ring coupling this quartet may be considered as a superposition of two AB cases in the notation of Bernstein, Pople, and Schneider (20). Using their theory one may calculate the absolute values of the spin-coupling constant, J, and chemical shift, δ, between the ortho and meta protons. J is given directly by the separation of the right- or left-hand pair of lines, which is 8.9 c/s, and the separation of the inner pair of lines (7.1 c/s) is given by $2C-J$ where $C = \frac{1}{2}[\delta^2+J^2]^{\frac{1}{2}}$. This gives a value of $\delta = 13.3$ c/s. Values of J, the ortho coupling constant, found by other authors range from 8.2 c/s to 8.6 c/s (20, 21). This value may also be compared with the value of 8.0 ± 0.5 c/s found for

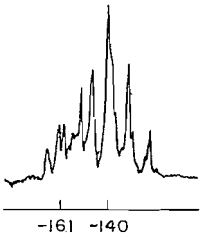

FIG. 5. Spectrum of aromatic protons of *p*-anisyl diphenylmethyl cation at 60 Mc.

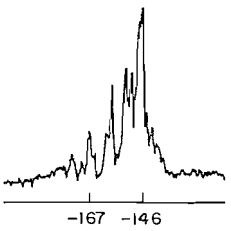

FIG. 6. Spectrum of aromatic protons of *p-tert*-butylphenyl diphenylmethyl cation at 60 Mc.

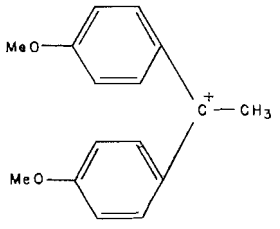
protonated dianisylethylene in sulphuric acid. In the case of the tri-*p*-tolyl ion, this quartet is not resolved even at 60 Mc, and the aromatic protons give rise to only a single sharp peak.

The spectra of the aromatic protons of the *p*-anisyl diphenylmethyl and *p-tert*-butylphenyl diphenylmethyl cations were recorded at 60 Mc as shown in Figs. 5 and 6. A well-resolved fine structure was observed but no definite assignments could be made.

The meta-methyl-substituted ions illustrate an interesting point. Table II shows that a meta methyl substituent shields the ring protons to a greater extent than does a para methyl substituent. This is because the electron-donating properties of the methyl group function to donate negative charge to the electron-deficient ring but, because of its meta location, it is unable to interact directly by resonance with the central electron-deficient carbon atom.

Di-p-anisylethylene in Sulphuric Acid

The N.M.R. spectrum of 1,1-di-*p*-anisylethylene in sulphuric acid was recorded in connection with other work and its similarity to that of the triarylmethyl cations warrants its being discussed briefly here. The spectrum of the resulting carbonium ion is shown in Fig. 7. Thanks are due to Mr. A. L. Gatzke for the preparation of this compound.



II

Like the tri-*p*-anisylmethyl cation there is a well-resolved quartet due to the coupled ortho and meta protons, the chemical shift between the two halves of the quartet being 32 c/s. The methoxy protons and the methyl protons are at higher field but the high degree of positive charge in the latter, which are in a hyperconjugating position, is reflected in the large shift to low field (−85 c/s) from the cyclohexane marker.

It is of interest to note that the N.M.R. and visible spectra of this compound in trifluoroacetic acid – anhydride solvent is quite different to that in sulphuric acid. Anomalous visible spectra in carboxylic acid solvents for this compound have previously been observed by other workers (8, 22, 23).

THE SYSTEM Li^+–Na^+–K^+–SO_4^{--} AND WATER, AT 25.0° C[1]

A. N. Campbell and E. M. Kartzmark

ABSTRACT

The above system is a further stage in the study of the five-component system, containing the radicals Li_2, Na_2, K_2, Cl_2, SO_4, and water. The double salts occurring are $Li_2SO_4 \cdot K_2SO_4$ and $3K_2SO_4 \cdot Na_2SO_4$: no ternary salt is formed.

This paper is the fourth instalment of our study of the five-component system containing the radicals Li_2, Na_2, K_2, Cl_2, SO_4, and water, at 25.0° C. So far as we are aware, this is the first complete study which has been made of a five-component system of this type. The work has now been in progress for 4 years: a bibliography is given in references 1 and 2.

According to the Jänecke method of graphic representation the finished study will be represented by a solid model within an equilateral triangular pyramid. All the surfaces of this model have now been studied, the present study being the final one, that of one of the triangular surfaces. It remains only to study the interior of the solid model.

Turning to the present study, the component ternary systems are: (*a*) Li_2SO_4–Na_2SO_4–H_2O; (*b*) Na_2SO_4–K_2SO_4–H_2O; (*c*) Li_2SO_4–K_2SO_4–H_2O. Systems (*a*) and (*c*) have been studied by us and system (*b*) is well known. We have shown (2) that in system (*c*) the double salt $Li_2SO_4 \cdot K_2SO_4$ exists in contact with solution at 25° C, though the solution is not congruently saturating. In system (*a*) no double salt forms (at 25° C) but there is an extensive series of solid solutions of lithium sulphate in sodium sulphate. In system (*b*), the well-known glaserite or Penny's salt ($3K_2SO_4 \cdot Na_2SO_4$) occurs as the end member of a series of solid solutions of potassium sulphate in sodium sulphate.

In the present quaternary system, there is the possibility that ternary salts, containing all three metallic ions, may occur, in addition to the above named double salts, but no such ternary salt has been found.

EXPERIMENTAL

The technique is simple and has been described frequently (1, 2). In previous papers we have referred to the extreme difficulty of determining sulphate radical in the presence of alkalis and we have been forced to such expedients as determining density and viscosity, in order to analyze the systems, procedures which call for extreme experimental accuracy (because of the slight differences in physical property for the different ions), notably in the determination of density. For the present study we turned with relief to the flame photometer as a means of analysis for alkali metals. We used a Beckmann DU instrument with flame photometer attachment. Since this instrument is dependent on constancy of flame intensity, it must be calibrated afresh for each analysis. Standard solutions, containing from 10 to 100 parts per million of lithium sulphate, sodium sulphate, or potassium sulphate, respectively, were made up and preserved in plastic containers. Before each analysis, a curve of instrument reading versus content of given salt was determined experimentally for each salt. The reading for the unknown, in the appropriate region of the spectrum, then gives the salt content in parts per million. Since the unknown always contained the three salts simultaneously present, the possibility existed that

one salt might interfere with another, but we convinced ourselves by the analysis of numerous mixtures of known composition that this was not so here. The accuracy is not high, $\pm 1\%$ at best, but, within these limits, the results are completely dependable. In a study which involved the Schreinemakers' method of the "wet rest", this accuracy would scarcely be good enough but it was sufficient for the present study.

RESULTS

The numerical results are given in Table I and represented graphically in Fig. 1. The isohydrores (lines of equal water content) are of necessity, as in all such studies, to some extent hypothetical, at least in their curvature, but such curves are most instructive in evaporation studies.

DISCUSSION

The dotted lines in the area marked "solid solution" (which would normally be the area of anhydrous sodium sulphate) give a rough indication of the composition of the solid phase (solid solution of sodium sulphate in lithium sulphate). Figure 1 also shows the absence of any ternary salt; all the solid phases are to be found already in the component ternary systems. The main areas of the equilibrium diagram are those of K_2SO_4, $K_2SO_4 \cdot Li_2SO_4$, and $3K_2SO_4 \cdot Na_2SO_4$.

THE REACTION OF SULPHURYL CHLORIDE WITH GLYCOSIDES AND SUGAR ALCOHOLS. PART I[1]

P. D. Bragg, J. K. N. Jones, and J. C. Turner

ABSTRACT

The reaction of sulphuryl chloride with methyl α-D-glucopyranoside, methyl 4,6-*O*-benzylidene-α-D-glucoside, methyl β-D-arabinopyranoside, D-mannitol, 2,5-*O*-methylene-D-mannitol, dulcitol, and sucrose is described.

INTRODUCTION

Helferich and his co-workers in a series of papers (1, 2, 3) described the action of sulphuryl chloride on methyl α- and methyl β-D-glucopyranoside, mannitol, and trehalose. They isolated crystalline products in which the hydroxyl groups had either been replaced by chlorine atoms or bridged by cyclic sulphate groups. The compound derived from methyl α-D-glucopyranoside was shown to contain 2 chlorine atoms and a cyclic sulphate group (1). The cyclic sulphate ring could be opened by treatment with base, and the sulphate group so formed hydrolyzed with hydrochloric or sulphuric acid to yield a dichloro-dideoxy hexose (2).

In the present work, this reaction was applied to glycosides and hexitols, and an attempt was made to determine the structure of the desulphated chloro-sugars.

The dichloro-dideoxy hexose from methyl α-D-glucopyranoside was prepared by Helferich's method (1). On periodate oxidation this compound (I) in 24 hours consumed 2 moles periodate and liberated 2 moles of formic acid.

Although all the periodate was consumed rapidly the second molecule of acid was liberated more slowly suggesting that hydrolysis of the formyl ester (II) was occurring. These results are only consistent with I being 4,6-dichloro-4,6-dideoxy hexose. Periodate oxidation of the methyl glycoside of I (0.87 mole periodate; 26 hours) substantiated this conclusion. Helferich had previously suggested that 1 chlorine atom was at $C_{(6)}$ because of the ease with which it could be removed by alkali (3).

The dichloro-dideoxy hexose was reduced with potassium borohydride. The dichloro-dideoxy hexitol was obtained as an impure syrup which rapidly consumed 1.56 moles periodate liberating 0.73 mole formic acid and formaldehyde (not estimated), which is only consistent with the assignment of chlorine atoms to $C_{(4)}$ and $C_{(6)}$.

The structure of the original compound is therefore probably methyl 4,6-dichloro-4,6-dideoxy-α-D-hexoside 2,3-sulphate. The elimination of the hydroxyl group at $C_{(4)}$ by the chlorine atom might occur with inversion of configuration to give the D-galactose configuration. This problem is now under investigation. The presence of a 2,3-sulphate

group was also suggested by the isolation of an analogous methyl 4,6-*O*-benzylidene-α-D-glucoside 2,3-sulphate by the action of sulphuryl chloride on methyl 4,6-*O*-benzylidene-α-D-glucoside.

Hydrolysis of the cyclic sulphate derivative eliminated the methyl glycoside and benzylidene groups and gave glucose only, showing that removal of the sulphate group occurred without inversion of the hydroxyl groups on $C_{(2)}$ and $C_{(3)}$ unless the initial formation of the cyclic ester had also resulted in inversion.

Methyl β-D-arabinopyranoside was converted by sulphuryl chloride to a methyl monochloro-monodeoxy pentoside cyclic sulphate which could be desulphated to yield a monochloro-monodeoxy pentose. The results of periodate oxidation (2 moles periodate consumed with the liberation of 2 moles acid) indicated that the chlorine atom was located on $C_{(4)}$. Periodate oxidation (1.1 moles; 26 hours) of the methyl α-glycoside confirmed this. The monochloro-monodeoxy pentose gave a *p*-nitrophenylosazone without loss of chlorine showing that the chlorine atom was not on $C_{(1)}$ or $C_{(2)}$ of the pentose. The very probable structure of the original compound would therefore be methyl 4-chloro-4-deoxy-β-pentoside 2,3-sulphate.

Both dulcitol and D-mannitol readily give crystalline compounds with sulphuryl chloride and in both cases 4 chlorine atoms and a cyclic sulphate group are introduced. 2,5-*O*-Methylene-D-mannitol gave a trichloro-trideoxy-mono-*O*-methylene hexitol.

The cyclic sulphate ester of the mannitol derivative is very resistant to acid hydrolysis. Very little acetolysis of this compound occurred at 25° C, but appreciable hydrolysis of the sulphate group followed by acetylation occurred at 100° C. Deacetylation of the product then yielded a substance (contaminated with starting material) with a chromatographic mobility consistent with that of a tetrachloro-tetradeoxy hexitol. The impure product consumed 0.77 mole periodate (46 hours) suggesting that the sulphate group in the original compound bridged adjacent hydroxyl groups (presumably on $C_{(3)}$–$C_{(4)}$).

Sucrose yielded a product which appeared to be a mixture of di- and tri-chlorodeoxy sucrose disulphates. The structure of the glucose moiety is similar to that from methyl α-D-glucopyranoside since the same 4,6-dichloro-4,6-dideoxy hexose can be obtained from both. The remaining cyclic sulphate group and chlorine atom are located on the fructose portion of the molecule. The position of these groups was not determined since the vigorous conditions of hydrolysis necessary to cleave the interglycosidic linkage destroyed the fructose moiety, but it is probable by comparison with the anhydrides of sucrose (4), that the sulphate group spans $C_{(3')}$–$C_{(6')}$ or $C_{(1')}$–$C_{(4')}$ with the chlorine atom on $C_{(1')}$ or $C_{(6')}$ respectively.

EXPERIMENTAL

Melting points are uncorrected and were determined on a Kofler microheating stage. Optical rotations were measured at 24° C. All evaporations were carried out under reduced pressure.

General Method

Redistilled sulphuryl chloride (7 ml) was added to a mixture of pyridine (30 ml) and chloroform (100 ml), which had been dried over potassium hydroxide pellets and anhydrous sodium sulphate respectively. The temperature of the solution was maintained at 5° C while the glycoside or hexitol (4 g; dried over phosphoric oxide) was added with vigorous stirring. After 2 hours the reaction mixture was poured into ice water and the chloroform layer separated, well washed with water, and dried (sodium hydrogen carbonate). Concentration afforded a syrup which was decolorized with charcoal if

For personal use only.

necessary. Crystallization was spontaneous, but purification by extracting the product into ether was sometimes imperative.

Methyl α-D-Glucopyranoside

With sulphuryl chloride, methyl α-D-glucopyranoside gave long colorless needles (1.8 g) which, recrystallized from ether – light petroleum (40–60° C), had m.p. 104–105° C, $[\alpha]_D$ +140° (*c*, 1.99 in methanol). Analysis: Calc. for $C_7H_{10}O_6Cl_2S$: C, 28.7%, H, 3.4%; Cl, 24.2%; S, 10.9%. Found: C, 28.9%; H, 3.4%; Cl, 24.1%; S, 11.1%.

Methyl Dichloro-dideoxy Hexoside and Dichloro-dideoxy Hexose

The above compound (1.8 g) dissolved in methanol saturated with ammonia at 0° C (50 ml) was kept at room temperature for 24 hours. Concentration gave a partially crystalline syrup which was heated at 100° C for 14 hours with *N* sulphuric acid (50 ml). The acid was neutralized with barium carbonate and the solution deionized by passage through Amberlite IR-120 and Duolite A4 resin columns. The eluate was concentrated to a syrup (0.74 g) which slowly crystallized. An aqueous solution of the syrup was continuously extracted with chloroform. The chloroform extract on evaporation yielded crystals, m.p. 158° C, $[\alpha]_D$ +184° (*c*, 2.1 in water). Analysis: Calc. for $C_7H_{12}O_4Cl_2$: C, 36.3%; H, 5.2%; Cl, 30.7%. Found: C, 36.2%; H, 5.3%; Cl, 31.0%. On concentration of the aqueous solution white needle-shaped crystals were obtained. Recrystallized from ethanol–water, the dichloro-dideoxy hexose had m.p. 183–186° C (decomp.), $[\alpha]_D$ +132° (5 minutes) → 98° (equilibrium; 24 hours) (*c*, 0.69 in methanol). Analysis: Calc. for $C_6H_{10}O_4Cl_2$: C, 33.2%; H, 4.6%. Found: C, 33.6%; H, 4.7%.

The dichloro-dideoxy hexose (115 mg) was reduced for 1 hour with potassium borohydride (365 mg) in water (50 ml). Excess borohydride was destroyed with acetic acid, and after deionization with resin, the major component (R_f 0.56) *n*-butanol:ethanol:water = 3:1:1 was separated as a syrup (47 mg) on paper chromatograms, $[\alpha]_D$ 0° (*c*, 1.0 in water).

Methyl β-D-Arabinoside

Methyl β-D-arabinoside and sulphuryl chloride yielded colorless needles (1.6 g) which, recrystallized from ether – light petroleum (80–100° C), had m.p. 108.5° C, $[\alpha]_D$ −89° (*c*, 0.97 in methanol). Analysis: Calc. for $C_6H_9O_6SCl$: S, 13.1%; Cl, 14.5%. Found: S, 13.3%; Cl, 14.1%.

Methyl Monochloro-monodeoxy Pentoside and Monochloro-monodeoxy Pentose

Both were prepared from the compound derived from methyl β-D-arabinoside by treatment with methanolic ammonia followed by sulphuric acid as described above. The methyl pentoside crystallized as white needles which after recrystallization from ether – light petroleum (b.p. 60–80° C) had m.p. 102–104° C, $[\alpha]_D$ +119° (*c*, 2.25 in water). Analysis: Calc. for $C_6H_{11}O_4Cl$: C, 39.5%; H, 6.0%; Cl, 19.5%. Found: C, 39.6%; H, 6.2%; Cl, 19.8%. Monochloro-monodeoxy pentose had m.p. 128–131° C, $[\alpha]_D$ +57° (10 minutes) → 0° (equilibrium, 6 hours) (*c*, 0.98 in methanol). Analysis: Calc. for $C_5H_9O_4Cl$: C, 35.6%; H, 5.3%. Found: C, 35.8%; H, 5.8%.

The product (95 mg) in 50% acetic acid (2 ml) was added to *p*-nitrophenylhydrazine (0.3 g) in glacial acetic acid (2 ml) and heated at 100° C for 1 hour. Crystals of the *p*-nitrophenylosazone were precipitated. After they were washed with water and ether, they had m.p. 224° C. Analysis: Calc. for $C_{17}H_{17}O_6N_6Cl$: N, 13.7%; Cl, 8.7%. Found: N, 11.7%; Cl, 7.1%.

Methyl 4,6-O-Benzylidene-α-D-glucopyranoside

This reacted with sulphuryl chloride to give long colorless needles (2 g) which slowly darkened over a period of days with liberation of benzaldehyde. When recrystallized

from chloroform – light petroleum it had m.p. 107° C (decomp.). A sodium fusion showed chlorine to be absent from the molecule. Analysis: Calc. for $C_{14}H_{16}O_8S$: S, 9.3%. Found: S, 9.0%. Treatment first with methanolic ammonia and then with sulphuric acid gave chromatographically homogeneous glucose which was characterized as its *p*-nitroanilide derivative, m.p. 186° C, $[\alpha]_D$ +192° (*c*, 0.85 in water).

D-*Mannitol*

With sulphuryl chloride, D-mannitol afforded needle-shaped crystals (1.5 g) which when recrystallized from chloroform – light petroleum had m.p. 105° C, $[\alpha]_D$ +88° (*c*, 2.84 in methanol). Analysis: Calc. for $C_6H_8O_4Cl_4S$: C, 22.6%; H, 2.5%; Cl, 44.7%; S, 10.0%. Found: C, 22.8%; H, 2.8%; Cl, 44.3%; S, 10.4%.

The compound (4.2 g) was heated at 95–100° C for $2\frac{1}{2}$ hours in acetic anhydride (30 ml) and sulphuric acid (1.5 ml). The dark brown solution was poured into ice water, which was then extracted with chloroform. The chloroform extract was washed with an aqueous sodium hydrogen carbonate solution, dried (anhydrous magnesium sulphate), and was concentrated to a syrup. Following decolorization with charcoal, the syrup was deacetylated with sodium methoxide at 5° C. Excess sodium methoxide was removed with carbon dioxide, and after dilution with water, the solution was continuously extracted with ether. Concentration of the ether extract afforded a syrup (0.9 g) which gave a single spot (R_f 0.79) with the periodate–anisidine spray (5) on chromatography in butan-1-ol:ethanol:water (3:1:1) solvent.

Mono-anhydro-trichloro-trideoxy Hexitol

The compound (2.7 g) obtained from mannitol was treated with methanolic ammonia and with sulphuric acid, as previously described, to yield colorless needles (0.6 g) m.p. 102° C, $[\alpha]_D$ 0° (*c*, 0.86 in methanol). Analysis: Calc. for $C_6H_9O_2Cl_3$: C, 32.8%; H, 4.1%; Cl, 48.5%. Found: C, 33.0%; H, 4.1%; Cl, 46.2%.

*2,5-O-Methylene-*D*-mannitol*

2,5-*O*-Methylene-D-mannitol and sulphuryl chloride yielded a crystalline product (1.1 g); when recrystallized from ethanol–water it had m.p. 116° C and $[\alpha]_D$ −42° (*c*, 1.73 in methanol). Analysis: Calc. for $C_7H_{11}O_3Cl_3$: C, 33.6%; H, 4.4%; Cl, 42.7%. Found: C, 33.7%; H, 4.3%; Cl, 42.9%. In the infrared a hydroxyl peak was obtained. The methylene group was not removed by treatment with *N*-sulphuric acid at 100° C for 5 hours.

Dulcitol

Dulcitol and sulphuryl chloride gave a crystalline product (1.4 g) m.p. 116° C. Analysis: Calc. for $C_6H_8O_4Cl_4S$: C, 22.6%; H, 2.5%; Cl, 44.7%; S, 10.0%. Found: C, 22.6%; H, 2.7%; Cl, 44.3%; S, 10.4%.

Sucrose

Sucrose (4 g) was dissolved in pyridine (80 ml) at the boiling point and the solution then cooled to 5° C. Chloroform (90 ml) was added and the slight precipitate produced was redissolved by the further addition of pyridine (10 ml). Sulphuryl chloride (7 ml) was added dropwise with stirring to the cooled solution (5° C). After 2 hours the liquid was poured into ice water, the chloroform layer washed with water and dried (magnesium sulphate). Concentration gave a syrup (2.9 g), and from a chloroform solution of this the product was precipitated by ether as a pale yellow solid, m.p. 94–99° C. Analysis: Calc. for $C_{12}H_{16}O_{13}S_2Cl_2$: S, 12.7%; Cl, 14.1%. Calc. for $C_{12}H_{15}O_{12}S_2Cl_3$: S, 12.3%; Cl, 20.4%. Found: S, 12.4%; Cl, 16.8%.

Hydrolysis (*N* sulphuric acid, 24 hours) gave a complex mixture of substances but mainly 4,6-dichloro-4,6-dideoxy hexose identical with that derived from methyl α-D-

glucoside. After separation on a cellulose column using *n*-butanol:water (19:1) it had m.p. and mixed m.p. 186° C (decomp.). Calc. for $C_6H_{10}O_4Cl_2$: C, 33.2%; H, 4.6%; Cl, 32.7%. Found: C, 33.4%; H, 4.7%; Cl, 32.6%.

Compounds reacting with the resorcinol spray (ketoses) (6) were largely absent from the hydrolysis mixture.

TABLE I

Substance	Time of oxidation (hours)	Consumption of periodate (mole/molecule)	Acid production (mole/molecule)
Methyl dichloro-dideoxy hexoside	1.08	0.16	
	20	0.79	0.00

	23	0.67	0.00
	46	0.77	0.00

Periodate Oxidation of Chloro-sugars

About 25 mg of the substance, accurately weighed, was dissolved in water (50 ml) and 0.3 *M* sodium metaperiodate (2 ml) added. Aliquots were removed at intervals and the consumption of periodate and the production of formic acid measured (7, 8). Dichloro-dideoxy hexitol gave formaldehyde (characterized as the dimedone complex, m.p. 188° C) (9) on periodate oxidation.

Mono-anhydro-trichloro-trideoxy hexitol was not attacked by periodate.

REACTIONS OF BUTENES AND METHYL BUTENES ON A ZINC OXIDE CATALYST[1]

M. G. HAMPTON[2] AND R. J. CVETANOVIĆ

ABSTRACT

Reactions of butene-1, isobutene, 3-methyl butene-1, and 2-methyl butene-2 on ZnO catalysts have been investigated at 615°. The formation of the observed products is discussed in terms of a sequence of surface processes incorporating dissociation of the bonds in β position to the double bond, with formation of chemisorbed allyl and substituted allyl radicals.

INTRODUCTION

A study of dehydrogenation of butene-1 on semiconducting oxide catalysts between 500 and 650° has been conducted recently in this laboratory (1). The activity and selectivity to butadiene formation of "valency-controlled" ZnO and NiO catalysts were discussed in terms of their electrical properties. Thus, after it was doped with lithia, zinc oxide became inactive, while the catalysts with small additions of gallia, although showing the same activity as pure zinc oxide, were distinctly more selective. An explanation was suggested by assuming an important role in these reactions of "excess" electrons in the *n*-type semiconductors.

The present work has been carried out in an attempt to obtain further information on the mechanism of dehydrogenation on zinc oxide catalysts from a comparative study of the reactions of several structurally related olefins. Zinc oxide containing 1 atom % Ga^{+++} in the lattice was used because of its somewhat greater selectivity (1). The reactions were carried out at 615°.

EXPERIMENTAL

The apparatus used is illustrated in Fig. 1. It consisted of a reactor, circulating pump, boiler, and storage lines. The reactor consisted of a silica tube connected to the rest of the apparatus by pyrex–silica graded seals. The catalyst pellets were placed in a silica spoon as shown. Two leads through tungsten–glass seals were provided for conductivity measurements. Larger flat pellets containing Pt-foil leads were used for conductivity determinations by means of an a-c. bridge. In most of the work small cylindrical pellets of the catalyst ($\frac{1}{8}$ in. × $\frac{1}{8}$ in. × $\frac{1}{8}$ in.) were used. A 14/30 standard joint facilitated catalyst removal and changing. The temperature of the furnace round the reactor was controlled by a chromel–alumel thermocouple placed in a well in the silica tube.

The olefins were introduced to the evacuated 2-liter flask, then mixed with nitrogen to give a total pressure of about 760 mm Hg. The ratio of the olefin to nitrogen was about 1:12 in all experiments. Nitrogen was also let into the reactor system, so that with the water in the boiler boiling vigorously, the total pressure in the reactor section was also about 760 mm. The stopcocks isolating the 2-liter volume from the reaction system could then be opened, and the gases circulated continuously using a reciprocating plunger pump as described by Watson (2). The pumping rate and the volume of the reaction system were such that the gas phase was circulated once in just over 2 minutes. Average run duration was about 30 to 40 minutes, with occasional runs up to 90 minutes. During a run samples of the gas phase were withdrawn at intervals into 50-ml receiving bulbs, and the condensable content frozen out with liquid nitrogen. The permanent

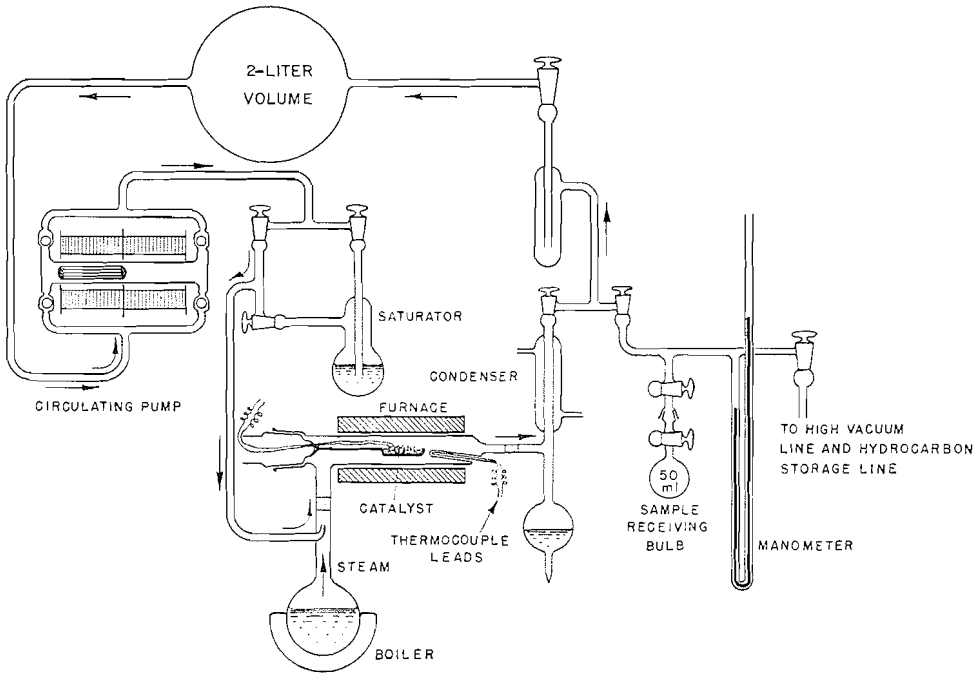

FIG. 1. Diagram of the apparatus.

gases were then pumped away, and the residual samples analyzed by means of a mass spectrometer. Analyses for H_2 and CH_4 in the large excess of non-condensable gas were as a rule not made. To distinguish between certain isomers in the products, gas chromatographic analysis was sometimes used.

Research grade olefins were employed.

RESULTS

Reactions of the following olefins were investigated: butene-1, isobutene, 3-methyl butene-1, and 2-methyl butene-2.

Butene-1

Butene-1 undergoes extensive dehydrogenation, the main products being C_4H_6, C_3H_6, and C_2H_4 in the approximate ratio 2:2:1. The production of butadiene is favored by the presence of moisture, which suppresses side reactions rather than aiding dehydrogenation directly. The results are summarized in Table I. The average dehydrogenation selectivity is about 40% for about 40% decomposition of butene-1.

Isobutene

Isobutene undergoes practically no decomposition and no butadiene is formed. This indicates that no isomerization of the carbon skeleton of the molecule occurs.

3-Methyl Butene-1

3-Methyl butene-1 is very reactive, the main products being C_4H_8 and C_4H_6 in the presence of moisture, that is, the loss of a methyl group is the main reaction. In the presence of oxygen, added to the gas stream, C_5H_8 was the main product, much less C_4H_6 being produced. The presence of oxygen however slowed down the over-all decomposition rate. The results are summarized in Table II.

Dry N_2	62.9	29.6	13.0	21.7	20.0	ZnO + 1% Ga
Steam + N_2	26.0	23.5	5.5	12.3	4.3	Zn metal
Dry N_2	54.1	22.0	11.0	19.6	15.4	Zn metal

*Isomerization is not taken into account in evaluating % reaction.
†Expressed as percentages of the total carbon in the products.

2-Methyl Butene-2

2-Methyl butene-2 produces mainly C_5H_8 and C_4H_8 with only very small amounts of C_4H_6. The results are summarized in Table II. The results show that double-bond isomerization to give 3-methyl butene-1 does not occur, otherwise the products of decomposition of the latter hydrocarbon would also be found. This was confirmed by gas chromatographic analysis.

TABLE II

Dehydrogenation and decomposition of 3-methyl butene-1 and 2-methyl butene-2 on ZnO + 1% Ga

Olefin	Diluting gas	% Reaction* (after 22 min)	Dehydrogenation selectivity, %	Main products†				
				C_5H_8	C_4H_8	C_4H_6	C_3H_6	C_2H_4
	Steam + N_2	30.0	48.0	13.1	9.4	1.1	3.0	3.0
(2-Methyl butene-2)	Steam + N_2 + 44 mm O_2	42.5	41.2	12.6	8.4	—	9.4	—
	Steam + N_2	82.8	9.7	5.0	9.0	21.0	11.5	21.5
(3-Methyl butene-1)	Steam + N_2 + 29 mm O_2	56.0	22.1	12.4	10.0	10.2	8.4	8.4

*Isomerization is not taken into account in evaluating % reaction.
†Expressed as percentages of the total carbon in the products.

As the amount of butadiene produced by the decomposition of 2-methyl butene-2 was very small even after about 20 recycles, it appeared that the butene produced in this reaction was mainly the unreactive isobutene. Gas chromatographic analysis of the C_4H_8 fraction showed that the butene consisted of 75% isobutene, 25% *trans*-butene-2, and no *cis*-butene-2 or butene-1.

DISCUSSION

The processes studied in the present work involve dissociation of C—H and C—C bonds at the surface of the catalyst. In general C—C bonds in hydrocarbons are considerably weaker than C—H bonds and this factor alone would favor cracking over dehydrogenation. Selectivity to dehydrogenation is in general determined by the ability of a particular catalyst to dissociate preferentially the C—H bonds. This in general

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

depends not only on the properties of the catalyst but also on the reaction conditions, such as temperature, contact time, etc. The present experiments were carried out at a single temperature and under conditions which might have favored the cracking processes and somewhat exaggerated their importance. Thus, over a period of time there was some accumulation of metallic zinc on the colder parts of the reaction vessel. For these reasons some of the results were independently checked (3) under similar conditions but with certain additional precautions. The ratio of the dead volume to the catalyst volume in the reaction zone was also reduced. Some differences were observed, particularly a tendency for reduction of cracking relative to dehydrogenation. In the case of 2-methyl butene-2, for example, only isoprene and 2-methyl butene-1 were formed. The main features of the reactions, however, remained very similar. The present results will, therefore, be discussed as obtained under the particular experimental conditions employed. Further study of these processes on the same and some other catalysts at various temperatures is in progress.

The reactions of the individual olefins studied show some characteristic differences. It is known from infrared studies of chemisorbed olefinic hydrocarbons (4) that there are under certain conditions and on some metals at least three and perhaps more than three points of contact (with the necessary corresponding dissociative chemisorption of hydrogen atoms). On hydrogenation–dehydrogenation catalysts the processes of dissociative and associative chemisorption, dehydrogenation and hydrogenation, and of desorption with isomerization or polymerization, are closely related. The predominance of one or the other of these processes depends on the surface concentrations of adsorbed species (in particular that of hydrogen) and on the rates of their formation by adsorption and of their mutual interactions and desorption, both of which are functions of temperature and the nature of the catalyst. The extent of dissociative "stripping" of hydrogen atoms and of the number of contacts with the surface may, therefore, vary widely with the conditions. The kinetic differences observed in the present work should be contrasted with the identical infrared spectra of chemisorbed isomeric *n*-hexenes (4). The adsorbed complexes in the case of 3-methyl butene-1 and 3-methyl butene-2, for example, cannot be identical under conditions of the present work.

In order to explain in a consistent manner the products of dehydrogenation and isomerization observed in the present work a sequence of dissociative processes, following energetically favorable paths, is postulated. This incorporates dissociative chemisorption of the weak C—C and C—H bonds in β position to the double bonds. On the present catalyst at 615° C the weaker β C—C bonds appear to be broken more readily than the stronger β C—H bonds, although this may vary with the type of catalyst used and the temperature. Thus, in the case of butene-1 the breakage of β C—H and β C—C bonds may lead to the formation of butadiene and propylene, respectively. These two compounds are formed in approximately equal amounts in spite of the fact that there are two β C—H bonds and only one β C—C bond indicating that the latter break more readily. In 3-methyl butene-1 there are two β C—C bonds and only one β C—H bond and the reaction involves predominantly cracking to lower hydrocarbons, with butadiene as the main product. The presence of two weak β C—C bonds also explains the high reactivity of this compound. On the other hand, 2-methyl butene-2 possesses no β C—C bonds but only the stronger β C—H bonds, and is consequently much less reactive and direct dehydrogenation is the main reaction. The very low reactivity of isobutene can be partly explained in the same manner, but the main factor appears to be that a conjugated system of double bonds to form C_4H_6 is impossible without rearrangement to a straight chain carbon skeleton. As a result any dissociative chemisorption is eventually

followed by recombination with the initially dissociated H atoms to regenerate isobutene. The dependence of the over-all reactivity under comparable conditions and of the selectivity to dehydrogenation of these olefins on the number of β C—C and β C—H bonds is shown in Table III.

TABLE III

Comparison of the reactivity and selectivity to dehydrogenation with the number of β C—C and β C—H bonds in the olefins

Olefin	% Reaction* (after 22 min)	Dehydrogenation selectivity,* %	Number of β C—C bonds	Number of β C—H bonds
$(CH_3)_2C{=}CH_2$	Small	—	None	6
$(CH_3)_2C{=}C(CH_3)H$	30.0	48.0	None	9
$CH_3{\cdot}CH_2{\cdot}CH{=}CH_2$	41.0	41.4	1	2
$(CH_3)_2CH{\cdot}CH{=}CH_2$	82.8	9.7	2	1

*Isomerization is not taken into account in evaluating % reaction.

The dissociation of the bonds in β position to the double bond may constitute the initial step in the catalytic process (a purely dissociative mechanism), or the dissociation may be preceded by an initial interaction of the catalyst with the double bond (a combined associative–dissociative mechanism). The two possibilities are in many respects very similar and are difficult to distinguish experimentally. Both lead to the formation of chemisorbed allyl or substituted allyl radicals. In the purely dissociative mechanism the double-bond shift can be visualized as occurring through a 1,3 switch in the position of attachment of the allylic radical to the surface, and the dissociative process can then be further propagated through the breakage of bonds β to the shifted double bond, with formation of dienes. Some energetic restrictions have to be imposed to accommodate, for example, the lack of isomerization of 3-methyl butene-2 to 3-methyl butene-1.

In the combined associative–dissociative mechanism the energetic restrictions can be introduced by assuming an "orientation" in the initial interaction of the catalyst with the olefin. It can be assumed that (*a*) the initial attachment to the surface takes place at the "less-substituted" of the two carbon atoms of the olefinic double bond, (*b*) a C—H or a C—C bond in β position to the original double bond is broken and a new double bond is formed, (*c*) if there are C—H (or C—C) bonds in β position to the new double bond, these may be broken in turn and dienes formed, (*d*) alternatively and simultaneously recombination may take place with chemisorbed H atoms to regenerate the olefin but with the double bond shifted one position. This is represented for the olefins of interest in connection with the present work in the following scheme.

Isobutene

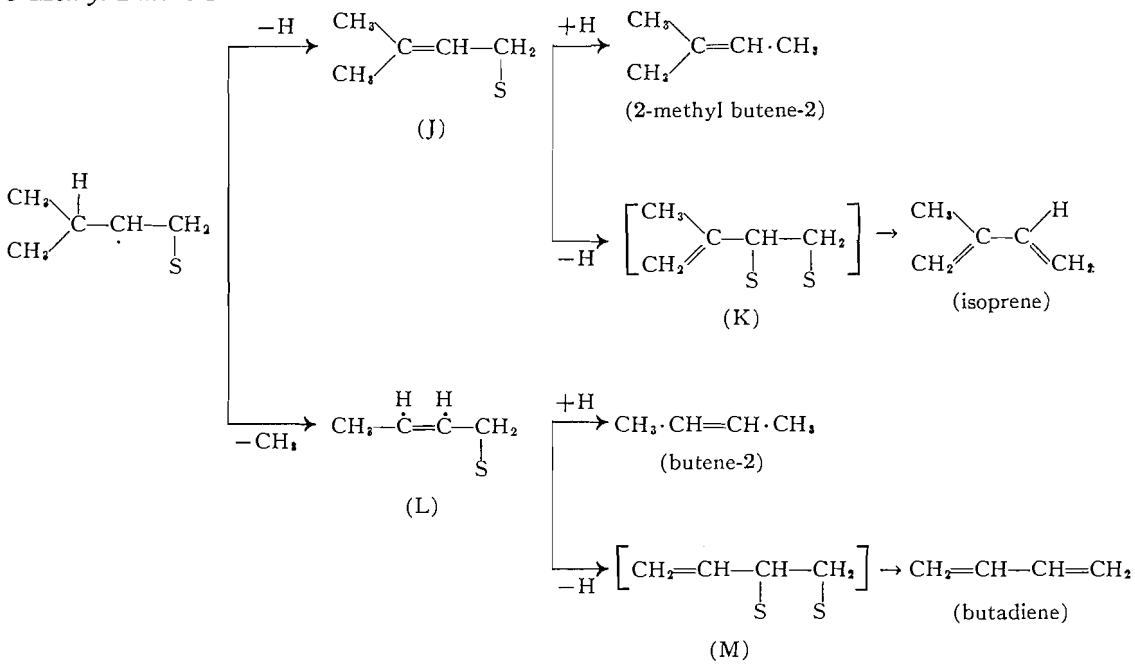
3-Methyl Butene-1



The products predicted in this scheme for various olefins by consistent application of the mechanism summarized in the four points given above agree well with the observed products if, for the moment, the formation of the cracking products ethylene and propylene is disregarded in most cases. Thus, no isomerization of 2-methyl butene-2 to 3-methyl butene-1 is predicted, although the double bond should shift in the opposite direction to form 2-methyl butene-1. This last compound should then produce isoprene and isobutene, which are the main products formed. No butadiene is predicted nor is it formed to any extent. On the other hand, in the case of 3-methyl butene-1, isoprene, butadiene, and butene-2 (but only a trace of butene-1 or isobutene (3)) are all formed in substantial amounts. Furthermore, the primary isomerization product is 2-methyl butene-2, as predicted, rather than 2-methyl butene-1 (3).

In the proposed scheme of reactions no cracking into ethylene and propylene (with one exception) is considered. This type of cracking can be formally explained in a consistent manner by assuming that in the intermediates (B), (G), (J), and (L) the incipient new double bond may break. In the case of the intermediates such as (A), (D), etc. where an analogous split would liberate CH_2, this cracking probably does not occur to any extent. Thus, isobutene is stable, 3-methyl butene-1 forms large amounts of propylene and ethylene, while 2-methyl butene-2 forms very little of these compounds.

The dissociative and associative mechanisms of olefin chemisorption have been the subject of numerous studies and discussions. The difficulty of unambiguous differentiation between the two (and the "hydrogen-switch" mechanism) is well recognized (5) .The number of points of contact indicated for the complexes (A), (B), etc. and their positions in the olefin molecules are necessarily arbitrary. In the case of the complexes (C, H, K, M) preceding dienes the formal application of the associative mechanism leads to 1,2-diadsorbed species with a double bond in 3 position, as shown in the above scheme. The

For personal use only.

purely dissociative mechanism discussed earlier, on the other hand, leads to 1,4-diadsorbed molecules with a double bond in 3 position. Formation of transitory double bonds in chemisorbed hydrocarbons, somewhat similar though not identical with those depicted here, was recently postulated by Burwell *et al.* (6) in order to explain racemization of (+)3-methylhexane occurring concurrently with H—D exchange on some metal surfaces.

The condition of the catalytic surface appears to play an important role in determining the relative extents of cracking, dehydrogenation, and isomerization. Thus in the reaction of butene-1 over-all reaction increased but the amount of butadiene formed remained unaltered in the absence of moisture, as shown in Table I. The presence of moisture seems to be essential in suppressing the cracking. The role of moisture may be to prevent the exposure of the Zn atoms by covering the surface with hydroxyl groups. The promotion of cracking by Zn is perhaps due to the relatively strong bond between this metal and CH_3 (7), which is stronger than the corresponding bond with hydrogen.

The sensitivity of the catalytic surface to the ambient atmosphere reflected itself in a strong increase in conductivity, almost to that of metallic zinc as soon as any hydrocarbon was admitted to the system. This held true even when oxygen was present in the gas phase, in spite of the normally observed decrease in conductivity of *n*-type semiconductors as the partial pressure of oxygen is increased.

Under dry conditions appreciable quantities of benzene (up to 14% after 35 to 40 recycles) were formed from butene-1. While the mechanism of formation of benzene is not understood, it is likely that it results from recombination of acetylenic residues. A mixture of butadiene and ethylene failed to yield any benzene under similar reaction conditions.

ACKNOWLEDGMENTS

The authors are thankful to Dr. A. W. Tickner for mass spectrometer analyses and to the Analytical Section of this Division for several gas chromatographic analyses.

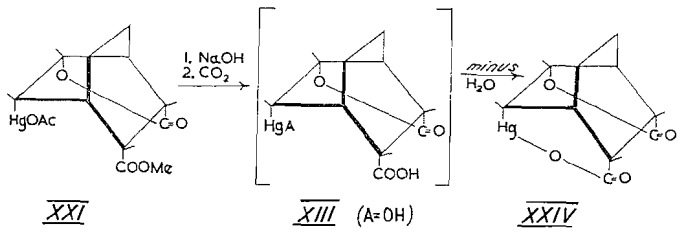
OXYMERCURATION OF Δ^5-[2,2,2]-BICYCLOÖCTENE[1]

D. D. K. Chiu and George F Wright

ABSTRACT

It has now been shown that an earlier assignment of configuration in which 1,4-↑↑-ethylene-Δ^5-cyclohexenedicarboxylic acids and their derivatives were presumed to form with mercuric salts 5-↓-hydroxy-6-↓-anionomercuri-1,4-↑↑-ethylenecyclohexanedicarboxylic acid derivatives is incorrect. Instead 5-↓-hydroxy-6-↑-anionomercuri-1,4-↑↑-ethylenecyclohexanedicarboxylic acid derivatives are formed, similarly with the homologous 5-↓-hydroxy-6-↑-anionomercuri-1,4-methylenecyclohexane-2,3-dicarboxylic acid derivatives. This similarity is exemplified by comparable dipole moments. The exception is 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, which has a configuration opposite to all of the others of these series having boat-type cyclohexane ring conformations. The exception is attributed to steric effects.

The oxymercuration of Δ^5-[2,2,2]-bicycloöctene has been reported and the stereochemistry has been specified (1). It has now been proved that this configurational assignment is incorrect. The error may be summarized in terms of two formulae reproduced here, together with their identifying numbers, from page 719 of the previous report (1).



XXI XIII (A=OH) XXIV

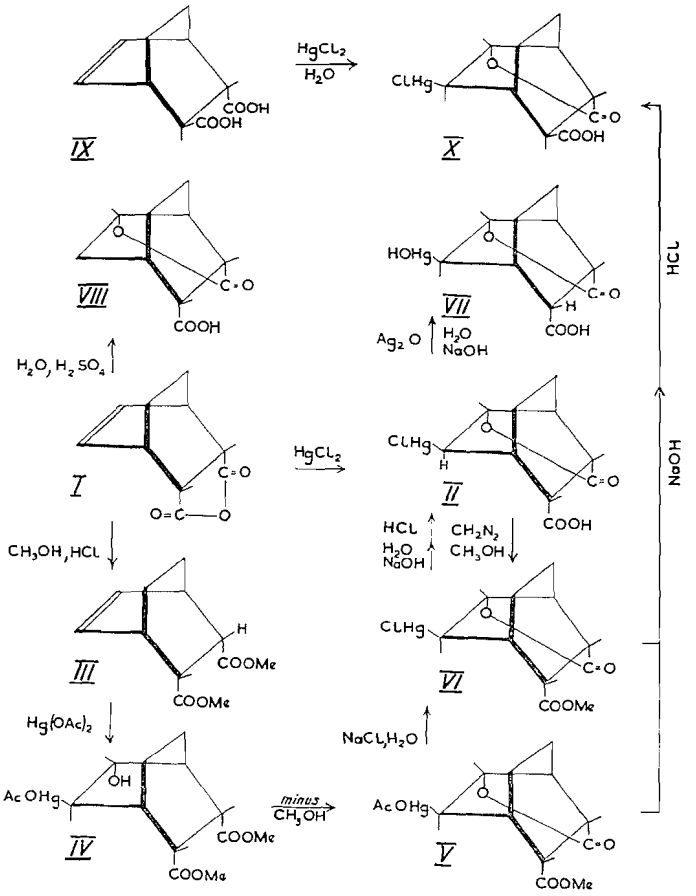
According to the statement of McNeely *et al.* (1), the structure of 2-↓-carbomethoxy-5-↓-hydroxy-6-↓-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (XXI), was proved by its careful saponification to 5-↓-hydroxy-*anhydro*-[6-↓-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (XXIV), the molecular weight of which was demonstrated cryoscopically in diphenylmercury. It will be shown that McNeely *et al.* did not have XXIV at all, but, instead, an hydroxymercurial diastereomeric with XIII (A = OH) which was contaminated with its chloromercurial. The content of this mixture has now been shown by a critical study of the X-ray diffraction pattern (1) of what McNeely *et al.* thought to be XXIV.

During the present investigation it has been found that the same dicarboxylic acid, γ-lactone, may be obtained by oxymercuration of 1,4-ethylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic anhydride (I) as was formerly obtained from dimethyl 1,4-↑↑-ethylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate. The anhydride seems to survive as such in aqueous media. However, a mercuric salt is formed by addition of mercuric chloride to the aqueous solution of the anhydride. Oxymercuration occurs very rapidly in this acidic system, and neutralization is required only to avoid an equilibrium due to the reverse reaction, deoxymercuration. By analogy with the oxymercuration reactions of the 1,4-↑↑-methylene-

[1]*Manuscript received April 8, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

Δ^5-cyclohexene system (2) the reaction with the homologue, I, should be acid-catalyzed and should lead to a ↑↓ (*trans*) configuration of the oxy and mercuri addends. Then the product is 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (II), unless lactonization has occurred with inversion.

A re-examination of the oxymercuration of dimethyl 1,4-ethylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylate (III) shows that inversion during lactonization is very unlikely. The product is clearly dimethyl 5-↓-hydroxy-6-↑-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylate (IV). However, this substance (m.p. 136–137°) is quite unstable. Methanol is eliminated during crystallization and especially at the melting point, whereupon resolidification occurs. The remainder after loss of methanol melts at 188–189°, and is 2-↓-carbomethoxy-5-↓-hydroxy-6-↑-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (V). This substance (reported previously (1) as having acetoxymercuri in the ↓ configuration) is thus formed under conditions where inversion is unlikely.



Treatment of V with aqueous sodium chloride converts it to 2-↓-carbomethoxy-5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (VI). This ester may be saponified by use of the stoichiometric quantity of 10% alkali to the acid identical with II. Therefore, it would seem that the anhydride (I) and the ester (III) were oxymercurated to the same product unless some rearrangement occurred during the saponification.

In order to eliminate this possibility we have converted the acid (II) to the ester (VI) by treatment with diazomethane in diethyl ether – methanol. Although this reagent attacks oxymercurials vigorously, forming chloromethylmercuric chloride (3), the esterification may be accomplished in fair yield at a reaction temperature of −80°. The product is identical with the ester (VI), thus precluding rearrangement during the saponification of VI.

When a chloromercurial such as II is treated with alkali the hydroxymercurial, 5-↓-hydroxy-6-↑-hydroxymercuri-1,4-↑↑-ethylenecyclohexane-2,3-dicarboxylic acid, γ-lactone (VII), is expected. In order to ensure absence of chloromercurial, silver oxide should be included, and acidification should be effected with carbonic acid. In these circumstances the product seems to be VII. Although the elemental analyses show percentage errors of 2% for carbon and 13% for hydrogen they are still much closer to theoretical values than was reported by McNeely *et al.* (1) for their substance, which at any rate contained the chloromercurial II according to its X-ray diffraction pattern.

Indeed the poor analysis is more to be expected of the free hydroxymercurial than of the 5-↓-hydroxy-*anhydro*-[6-↑-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone, which McNeely *et al.* thought the product to be. Hydroxymercuri compounds are difficult to purify, partly because they react with carbon dioxide. Of course, the analysis does not differentiate, at best, between the structure VII and that of the diastereomeric 5-↓-hydroxy-*anhydro*-[6-↓-hydroxymercuri-2-↓-carboxy]-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid predicated on the configurational assignment by McNeely *et al.* However, a potentiometric titration in which only 1 equivalent of alkali is consumed vitiates the possibility of this alternative non-lactonic isomer. In any circumstance there is no evidence for the *anhydro* structure and hence no evidence for the ↓↓ addition reported previously.

Proof for structure II is afforded by its high dipole moment (7.30, Table I) which compares with 7.19 Debye for 5-↓-hydroxy-6-↑-chloromercuri-1,4-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, of proved structure (2). Since the moments of 1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic anhydride (4.8 D) (4), 1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (2.19 D), and 5-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (4.85 D), also are closely comparable with those of the higher homologues (Table I) the structural analogy seems to be reasonable.

A similar comparison can be made between 5-↓-hydroxy-6-↑-chloromercuri-1,4-ethylenecyclohexane-2-↑-3-↓-dicarboxylic acid, γ-lactone (X, 6.91 D), and the methylene homologue (μ = 6.40) (2). The synthesis of X has been effected by prolonged treatment of VI with alkali (1), and also by treatment of 1,4-↑↑-ethylene-Δ^5-cyclohexene-2-↓-3-↑-dicarboxylic acid (IX) (5) with aqueous mercuric chloride. The postulated prototropic configurational shift of 2-carboxyl in II by action of alkali is thus confirmed.

Unfortunately, for a complete demonstration of configurational differences by comparison of dipole moments we have been unable to convert II to the diastereomeric 5-↓-hydroxy-6-↓-anionomercuri-1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone (XIII, A = Cl). When II is treated with hydrazine hydrate a mixture of products is obtained, one of which is the original substance, II. The other seems to be either a hydrolyzate or a polymorph of II since it may be converted to II when it is maintained for a few minutes at a temperature below the melting point. Probably some of XIII is actually formed but we have been unable to isolate it.

In summary the [2,2,2]-bicyclo-2-octenes seem to oxymercurate like the homologous

TABLE I

[2,2,1]-bicyclo-2-heptenes in a manner which is different from that occurring with cyclohexenes, cyclopentenes, α-terpineol, and the stilbenes. Reaction with the bicyclic compounds seems to be acid-catalyzed. An over-all ↑↓ (*trans*) addition occurs in contradistinction to that observed with the other alkenes. The fixed boat conformation of the bicyclic alkenes may be involved in this abnormality.

One difference in oxymercuration between the bicycloheptene and bicycloöctene series is apparent. Although 1,4-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid seems to oxymercurate by an ionic mechanism, it nevertheless yields a 2,3,5,6-↓↓↓↓-diastereomer. By contrast 1,4-↑↑-ethylene-Δ^5-cyclohexene yields the 2,3,5-↓↓↓-6-↑-diastereomer. It would seem that in one instance (XI) the mercuric ion is endo-co-ordinated, while in XII exo-co-ordination maintains. The difference is thus defined as a steric one.

EXPERIMENTAL*

1,4-↑↑-Ethylenecyclohexane-2,3-↓↓-dicarboxylic Anhydride

A solution of 0.20 g (0.00112 mole) of 1,4-↑↑-ethylene-Δ^5-cyclohexene-2,3-↓↓-carboxylic anhydride (6) (I) in 20 ml of absolute ethanol was reduced within 25 minutes by hydrogen in presence of 0.018 g of platinum oxide containing 0.002 g of Darco. The product (0.20 g, 79%, m.p. 176–177°) was crystallized from 1:2 commercial hexane – acetone (30 ml/g), m.p. 186–186.8°. X-Ray diffraction pattern was [10] 5.38; [6] 5.15, 5.02; [5] 3.61; [4] 7.02; [3] 4.60, 3.96, 2.66; [2] 2.96, 3.30, 3.17; [1] 3.04, 3.11, 6.29, 4.15, 3.43, 2.50, 2.19, 2.38, 1.99, 1.93.

Melting points have been corrected against reliable standards (Can. J. Technol. **34, 89 (1956)). The X-ray diffraction patterns are recorded for* Cu K_α (Ni-*filtered*) *radiation in* Å *at relative intensities* $[I/I_1]$.

5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone (II)

To a solution of 34.0 g (0.191 mole) of I in 2840 ml of water at 80° was added 51.8 g (0.191 mole) of mercuric chloride with vigorous agitation. A precipitate appeared immediately and a test for mercuric ion was almost negative. After 10 hours alkali was added to a pH of 4.5. The system tested negatively (20% alkali) for mercuric or mercurous ion. The precipitate was filtered, thrice washed with distilled water, and vacuum-dried, 73 g (85%), m.p. 197–199° (decomp.). Crystallization from acetone (4 ml/g) raised this melting point to 208–208.5° (decomp.); % C, 27.7; % H, 2.67. The X-ray diffraction pattern was obtained as follows: [10] 8.19; [9] 6.15; [8] 4.16; [6] 3.28; [4] 4.84; [3] 3.81, 5.19, 6.77; [2] 3.94, 5.57, 2.92, 4.10; [1] 3.19, 3.14, 3.01, 2.86, 2.74, 2.64. When the substance was treated for 1 hour with concentrated hydrochloric acid the anhydride (I) was regenerated and identified by mixture melting point (147–148°). When II was dissolved in 4 equivalents of alkali and back-titrated with hydrochloric acid it neutralized 2 equivalents.

Dimethyl 5-↓-Hydroxy-6-↑-chloromercuri-1,4-↓↓-ethylenecyclohexane-2,3-↓↓-dicarboxylate (IV)

A suspension of 12 g (0.0535 mole) of dimethyl 1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylate (III) (7, 8) (m.p. 70–70.8°) in a solution of 17 g (0.0535 mole) of mercuric acetate in 120 ml of water was stirred for 8 hours. The filtered precipitate weighed 13.7 g (51%) and melted at 135–137°, with evolution of methanol, demonstrated as the dinitrobenzoate. The melt then resolidified and remelted at 183–185° (decomp.). The diffraction pattern of the filtered precipitate was [10] 6.91; [9] 8.42; [8] 4.09; [7] 5.34, 5.12; [6] 3.53; [5] 3.80; [4] 3.29; [3] 4.84, 2.75. Crystallization of this substance from any medium that we tried, but specifically from methanol (4 ml/g), converted it to 2-↓-carbomethoxy-5-↓-hydroxy-6-↑-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (V), m.p. 188.5–189°, X-ray pattern [10] 10.84; [9] 4.56; [8] 6.44, 6.68; [5] 4.27; [4] 3.57; [3] 2.80, 3.75, 8.54. When this product was treated with aqueous sodium chloride it yielded VI.

2-↓-Carbomethoxy-5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic Acid, γ-Lactone (VI)

Methanol (800 ml) at 0° was freed from acidic substances by treatment with a solution containing 0.0064 mole of diazomethane in diethyl ether which had previously been dried over potassium hydroxide. Into this colorless methanol–ether mixture was dissolved 0.93 g (0.00216 mole) of 5-↓-hydroxy-6-↑-chloromercuri-2-↓-carboxy-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (II), at 0°. This solution at −80° was then mixed with a solution at −80° of ethereal diazomethane (0.0174 mole). The system was allowed to warm to 20° during several hours. Then a gray precipitate was filtered off. The vacuum-evaporated filtrate left 0.65 g, m.p. 182–184° (decomp.). Crystallization from acetone (4 ml/g) gave 0.12 g of unchanged II (mixture melting point). Partial evaporation of the mother liquor gave 0.16 g (17%), m.p. 199–201°. This melting point was raised to 204–205° by crystallization from acetone; a mixture melting point with VI prepared by treatment of V with aqueous sodium chloride was not lowered although admixture with II lowered the melting point 20°.

5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-ethylenecyclohexane-2-↑-3-↓-dicarboxylic Acid, γ-Lactone (X)

To a solution of 0.64 g (0.00327 mole) of 1,4-↑↑-ethylene-Δ^5-cyclohexene-2-↑-3-↓-dicarboxylic acid (IX) (9) in 52 ml of water at 70° was added 0.88 g (0.00327 mole) of mercuric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

chloride. After it was cooled to room temperature the system was neutralized to pH 5.6–6.0 (2 ml 10% aqueous sodium hydroxide). A precipitate appeared which redissolved upon addition of 3.5 ml more of the alkali (pH 7.6, no mercuric oxide). After 20 hours the solution was acidified at 0° by addition of 2.2 ml of 10% hydrochloric acid (pH 3.0). The precipitate, 0.81 g (58%), melted at 194–200° (decomp.). Crystallization from acetone (10 ml/g) raised this melting point to 208.5–209°, mixture melting point with II lowered to 194°. No depression was observed upon admixture with the substance obtained by McNeely *et al.* by 1-day saponification (3 equivalents alkali) of 2-↓-carbomethoxy-5-↓-hydroxy-6-↑-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone, and subsequent acidification with hydrochloric acid. The X-ray diffraction pattern was [10] 4.79; [8] 8.79, 3.24; [7] 1.95; [6] 5.45; [5] 5.98; [4] 6.91; [3] 2.81; [2] 3.00, 2.30; [1] 3.08, 2.70, 2.61. Calc. for $C_{10}H_{11}ClHgO_4$: C, 27.8; H, 2.60. Found: C, 28.0; H, 2.67. Treatment of this product with concentrated hydrochloric acid yielded 1,4-↑↑-ethylene-Δ^5-cyclohexene-2,3-↑↓-dicarboxylic acid, m.p. 210–211°.

5-↓-Hydroxy-6-↑-hydroxymercuri-1,4-ethylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone (VII)

A solution of 3.40 g (0.0073 mole) of 2-↓-carbomethoxy-5-↓-hydroxy-6-↑-acetoxymercuri-1,4-↑↑-ethylenecyclohexane-3-↓-carboxylic acid, γ-lactone (V), in 29 ml of 1% aqueous sodium hydroxide was let stand for 34 hours. The precipitate weighed 1.5 g (53%), m.p. 222–226° (decomp.). This melting point was raised to 239–241° by washing with chloroform, methanol, and diethyl ether. Further purification was effected by solution in 1% aqueous alkali (pH 10) followed by acidification by means of gaseous carbon dioxide. The precipitate, washed with acetone, melted at 244–244.5°. Calc. for $C_{10}H_{12}O_5Hg$: C, 29.1; H, 2.93. Found: C, 28.5; H, 3.17. The X-ray diffraction pattern was found to be [10] 8.72; [9] 6.25; [8] 3.33; [6] 4.27; [5] 2.67; [4] 3.05; [3] 3.65, 4.50, 1.97; [2] 3.92, 3.44, 3.25; [1] 2.03, 7.85, 6.93, 5.55. The same diffraction pattern was obtained for the product obtained when II (0.65 g, 0.0015 mole) in 2.45 ml of 5% aqueous alkali containing 0.46 g (0.002 mole) of silver oxide was filtered and then acidified by means of carbon dioxide gas. A comparison of the diffraction pattern with that reported by McNeely *et al.* shows that their compound must have been a mixture of VII and II.

Treatment of 5-↓-Hydroxy-6-↑-chloromercuri-1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone (II), *with Hydrazine Hydrate*

To an alkaline solution of 5.0 g (0.0116 mole) of II in 46.5 ml (0.058 mole) of 5% aqueous sodium hydroxide was added 0.6 ml (0.012 mole) of hydrazine hydrate. After 1 day the filtered system was acidified (pH 3) by use of hydrochloric acid at 0°. Slow precipitation yielded 3.0 g, m.p. 181–183°, which upon crystallization from methanol (10 ml/g) melted at 208–208.5°, mixture melting point with II not lowered (10%). The filtrate upon evaporation left a residue which was crystallized from methanol (1 ml/g), m.p. 207.5–208° (4%). Although this substance seemed to be different from II in respect of its solubility in methanol and also in respect of its X-ray diffraction pattern: [10] 6.41; [8] 8.84; [5] 5.12, 4.19; [4] 3.17; [3] 3.77, 3.46, 4.31; [2] 3.90, 3.26; [1] 4.56, 4.49, 3.39 (and despite the fact that a mixture melting point with II was not depressed), it was evidently configurationally the same as II. Thus when it was heated to 195° for 5 minutes its X-ray diffraction pattern became identical with II. Moreover, it would not form an anhydromercurial when it was converted to the hydroxymercurial by treatment with silver oxide and alkali. It may be a polymorph or, alternatively, the non-lactonic hydroxy acid.

5-↓-Hydroxy-1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylic Acid, γ-Lactone (VIII)

The substance was prepared by the recorded method (5) by heating 2.0 g (0.0112 mole) of 1,4-↑↑-ethylenecyclohexane-2,3-↓↓-dicarboxylic anhydride (I) in 22 g of 50% (w/w) sulphuric acid for 5 hours at 90°. After neutralization with sodium bicarbonate (pH 3) the precipitate was dissolved by extraction with chloroform. Evaporation of this solvent left 1.15 g (52%), m.p. 168–178°. Two crystallizations from acetone raised this melting point to 198–198.5°. The X-ray diffraction pattern was [10] 5.82; [9] 5.60; [6] 6.72; [5] 4.29; [4] 3.85, 2.90; [3] 4.94, 4.60; [2] 5.15, 2.98, 4.07; [1] 2.76, 3.18, 3.33. Potentiometric titration showed that 1 equivalent of alkali neutralized this substance. Calc. for $C_{10}H_4O_{12}$: C, 61.2; H, 6.16. Found: C, 61.3; H, 6.11.

1,4-↑↑-Ethylene-Δ⁵-cyclohexene-2,3-↓↑-dicarboxylic Acid (IX)

To a solution of 9.56 g (0.0625 mole) of fumaryl chloride in 55 ml of dry diethyl ether at −10° was gradually added a solution of 10 g (0.125 mole) of 1,3-cyclohexadiene in 55 ml of dry ether at −10°. After 1 hour at this temperature the system was maintained at 25° for 12 hours and then was shaken with 20 ml of 10% aqueous sodium hydroxide for 4 hours. Acidification of the aqueous layer yielded 8.40 g (68%), m.p. 199–204°. Crystallization from commercial hexane – acetone (1:5, 5 ml/g) raised the melting point to 210–211°. Calc. for $C_{10}H_{12}O_4$: C, 61.3; H, 6.16. Found: C, 61.0; H, 6.05.

1,4-Ethylenecyclohexane-2,3-↓↑-dicarboxylic Acid

A solution of 0.20 g (0.002 mole) of 1,4-↑↑-ethylene-Δ⁵-cyclohexene-2,3-↓↑-dicarboxylic acid in 20 ml of absolute ethanol plus 0.02 g of platinum oxide with 0.002 g of Darco was reduced within 35 minutes by 26.7 ml of hydrogen. After filtration of the catalyst the solution was evaporated, leaving 0.20 g (99%), m.p. 234–235°. After crystallization from commercial hexane – acetone (1:5, 60 ml/g) it melted at 235.0–235.5°.

PHOTOCHEMICAL SEPARATION OF MERCURY ISOTOPES

V. FURTHER STUDIES ON THE REACTION OF $Hg^{202}6(^3P_1)$ ATOMS, PHOTOEXCITED IN NATURAL MERCURY VAPOR, WITH HYDROGEN CHLORIDE[1]

J. R. McDowell, C. C. McDonald,[2] and H. E. Gunning

ABSTRACT

A further study has been made of the reaction of $Hg^{202}6(^3P_1)$ atoms, in natural mercury vapor (Hg^N), with hydrogen chloride under flow conditions at room temperature. Emphasis has been placed in this study on the effect of reaction parameters and mercury-recovery techniques on the Hg^{202} content of the solid calomel formed in the reaction.

For pure hydrogen chloride the Hg^{202} content of the calomel was found to be $39.9\pm0.3\%$, compared to the natural abundance of 29.8%. With 20–40 mole % of butadiene-1,3 in the hydrogen chloride, calomels containing 83–84% of Hg^{202} were consistently obtained.

The isotopically specific aspects of the reaction in pure hydrogen chloride can be adequately explained by the sequence:

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202}Cl + H \quad [1]$$

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202} + H + Cl \quad [2]$$

$$Cl + Hg^N + M \rightarrow Hg^NCl + M \quad [3]$$

$$H + HCl \rightarrow H_2 + Cl \quad [4]$$

where M in reaction [3] is a third body or the wall. From the Hg^{202}-abundance data and steady-state considerations, it has been shown that the ratio of partitioning of the absorbed radiation to [1] and [2], respectively, $= \Phi_1/\Phi_2 = 0.40\pm0.02$. In short, 29% of the primary reaction proceeds by the isotopically specific step [1].

The Hg^{202} content of the calomel product was found to increase markedly when unsaturated hydrocarbons were added to the hydrogen chloride stream. The addends studied included butadiene-1,3, benzene, isoprene, acetylene, propylene, and ethylene in order of decreasing effectiveness. In the presence of the unsaturated addend (U) two additional reactions were postulated to occur:

$$Cl + U \rightarrow \text{product} \quad [7]$$

$$H + U \rightarrow \text{product}. \quad [8]$$

From steady-state calculations the effectiveness of the addend can be shown to be determined by the rate ratio, k_8/k_4.

For the maximally enriching mixture of hydrogen chloride and butadiene, the effect of variations in lamp temperature and reaction pressure was studied. At lamp temperatures exceeding approximately 35° C, reduced enrichments were obtained owing to emission-line broadening. A progressive reduction in enrichment was also observed with substrate pressures greater than 25 mm, owing presumably to Lorentz-broadening of the hyperfine absorption contours of the Hg^N in the reaction cell.

The Hg^{202} content of the calomel product was determined by resonance radiation absorbiometry. The apparent Hg^{202} abundances of the mercury recovered from the calomel product were found to depend strongly on the method used for isolating the enriched mercury from the calomel. Evidence was obtained for the occurrence of isotopically degradative exchange reactions during the recovery process. A recovery technique was developed which appeared to eliminate this exchange degradation.

INTRODUCTION

In an earlier paper in this series (1), experimental techniques were described for the photoexcitation, in natural mercury vapor (Hg^N), of a specific mercury isotopic species (Hg^i) to the $6(^3P_1)$ state. For mercury-$6(^3P_1)$-photosensitized reactions wherein mercury-containing products are formed, the aforementioned technique of monoisotopic photosensitization may be used to determine the extent to which mercury compounds are formed in the primary process. Primary formation of mercury compounds would be

[1]*Manuscript received April 16, 1959.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.
[2]*Present address: Chemical Department, E. I. du Pont de Nemours Co., Wilmington, Delaware.*

indicated when the mercury product is enriched in the isotope undergoing photoexcitation. For a substrate, XY, the general mechanism may be represented by the sequence:

$$Hg^{i}6(^3P_1) + XY \rightarrow Hg^{i}X + Y \quad [1]$$

$$Hg^{i}6(^3P_1) + XY \rightarrow Hg^{i} + X + Y \quad [2]$$

$$X + Hg^{N} + M \rightarrow Hg^{N}X + M \quad [3]$$

where M represents a third body, including the wall. The two primary processes, [1] and [2], presumably involve the same intermediate. Reaction [3], the isotope-diluting step, may be reduced in importance by the addition of compounds which will react rapidly with the free radicals, X and Y. Under these conditions, products highly enriched in the isotope under photoexcitation can be obtained.

Pertel and Gunning (2, 3) studied the reactions of $Hg^{202}6(^3P_1)$ atoms, in Hg^{N}, with N_2O, O_2, and H_2O under flow conditions. For N_2O and O_2 the HgO product was found to contain the normal abundance (29.8%) of Hg^{202}. However, the HgO product of the water vapor reaction contained 33–35% Hg^{202}. Reaction [1] appears therefore to be significant in the H_2O reaction and unimportant for N_2O and O_2. Evidence in favor of the above-cited general mechanism was obtained by studying the Hg^{202} enrichment when unsaturated addends, such as butadiene-1,3, were added to the water vapor stream. Under these conditions the HgO product was found to contain a maximum of 85% Hg^{202}.

The principles of monoisotopic mercury photosensitization and their application to the study of the mechanisms of reactions involving collisions of the second kind have been reviewed by Gunning (4).

A study has recently been made of the reactions of $Hg^{202}6(^3P_1)$ atoms, in Hg^{N}, with flowing hydrogen chloride (5). Under fast-flow conditions it was found that the pure substrate yielded a calomel product containing 44% Hg^{202}. With butadiene-1,3 and benzene as addends, calomels containing respectively 59% and 55% Hg^{202} were obtained under optimum conditions. In the investigation (5) difficulty was encountered in obtaining good reproducibility in the Hg^{202}-enrichment data. It was suspected that exchange reactions were occurring between Hg^{202} ions and adsorbed Hg^{N} during the recovery for analysis of the isotopic mercury from the calomel product.

The present investigation represents a further study of the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^{N}, with flowing hydrogen chloride. The various experimental factors which influence the Hg^{202}-enrichment values have been sought out in order to obtain maximum precision in the kinetic data. Emphasis has been placed on the reaction in the presence of various unsaturated addends, in order to find conditions of maximum isotopic enrichment.

The details of the investigation follow.

EXPERIMENTAL

For detailed descriptions of the experimental techniques employed in this study, reference should be made to earlier papers in this series (5, 3, 1). The particular experimental assembly used was essentially identical with that described in reference 3. The quartz-electrodeless discharge source used in this study contained mercury, 98.3 atom % in Hg^{202}. The lamp-wall temperature was maintained constant to $\pm 0.05°$ C.

In the earlier study (5) of the hydrogen chloride reaction the calomel reaction product was removed from the cell by filling the cell with hot, concentrated, hydrochloric acid. The acid-filled cell was immersed in boiling water until the product had dissolved. After the acid solution had been neutralized with base to a pH of 5–6, the isotopic mercury was recovered by immersing a coil of pure copper wire in the solution.

For this investigation two, totally different, methods were studied for recovering the isotopic mercury for absorbiometric analysis (6). The two recovery procedures will be referred to as the NH_3 method and the HCl method.

In the NH_3 method, 3 ml of concentrated ammonium hydroxide were poured into the reaction cell, and the cell was shaken so that the liquid completely contacted the calomel product, as evidenced by blackening of the product associated with the formation of $HgNH_2Cl + Hg$. After it was drained, the cell was rinsed thoroughly with distilled water, attached via ground joints to a high-vacuum system, and evacuated for 6 hours. While still under evacuation, the cell was heated strongly with a gas–oxygen flame until the product in the cell was completely white in color, indicating that any free mercury had been driven off. The cell was then removed from the evacuation system, and the product was dissolved in a mixture consisting of 2 ml concentrated nitric acid, 3 ml concentrated hydrochloric acid, and 5 ml of water. The aqua regia was allowed to remain in the cell for 10 minutes. After neutralization to pH 4–5 with sodium hydroxide solution, mercury was recovered from the solution with a copper coil.

In the HCl method, 3 ml of concentrated hydrochloric acid, at 100° C, were poured into the cell and allowed to remain there for a specified time. The solution was then drained from the cell, and neutralized as in the NH_3 method. The isotopic mercury was recovered from the solution by plating on copper as before.

The gases used in this investigation were the highest-purity grades available from the Matheson Company, East Rutherford, N.J. The benzene and isoprene used were A.C.S. grade.

RESULTS

In the runs with pure hydrogen chloride the solid product of reaction was observed to form as a white deposit, mainly in the reaction zone. However, some deposit could be observed in the connecting tubing downstream from the reaction cell. The combined product from several runs was examined by X-ray diffraction. The patterns showed that the material was Hg_2Cl_2, with some weak lines indicating, perhaps, a trace of $HgCl_2$. The product was found to be (*a*) insoluble in cold water, (*b*) slightly soluble in cold, concentrated hydrochloric acid, and (*c*) very soluble in hot hydrochloric acid. In the presence of ammonium hydroxide the product turned black. There is therefore little doubt that the white product is finely divided calomel.

When butadiene was added to the hydrogen chloride stream, the white deposit was observed to form as in the runs with pure substrate. However, during the reaction the white deposit became gradually coated with a thin film of transparent polymer. It was further observed that the quantity of white product formed, in a fixed duration of exposure, decreased with increasing mole fraction of butadiene in the stream. The decreasing yield of product with increasing butadiene concentration can obviously be ascribed to competitive quenching of the photoexcited atoms by the butadiene.

In the first series of runs the Hg^{202} abundance in the calomel product was studied as a function of the butadiene concentration in the stream. A fast flow rate was used, which was maintained essentially constant at 304–383 ml/sec at 25° C and reaction pressure. The total pressure was kept at 9.4 ± 2 mm, while the concentration of butadiene was varied from 0–55 mole %. The lamp-wall temperature was held constant at 23.00 ± 0.05° C. For recovery of mercury from the calomel product, the NH_3 method was used. The results are represented graphically in Fig. 1. It will be noted that as the concentration of butadiene is increased, the Hg^{202} abundance rises rapidly to a maximum

value of 75% at 20 mole % of butadiene. At higher butadiene concentrations, the isotopic abundance slowly decreases toward the natural abundance value.

In order to compare directly the effect of recovery methods on the Hg^{202} abundances, a second series of runs was done on the hydrogen chloride–butadiene system. This series differed from the preceding one only in that the isotopic mercury was recovered from the product by the HCl method. The hot acid was left in the cell for 10 minutes before draining.

The results of this series are shown graphically as the upper curve in Fig. 1. The cell pressure was held within the range, 7.4–12.3 mm. The flow rate was maintained at 360 ± 10 ml/sec. For any given run, the lamp-wall temperature was kept constant to $\pm0.05°$ C. The total range of lamp-wall temperature over the series was 23.0–24.0° C.

A comparison of the two curves in Fig. 1 points up clearly the marked effect of recovery methods on the Hg^{202} abundances in the mercury from the solid reaction product. In the second series an average maximum abundance value of 83% was obtained, and this maximum was invariant in butadiene concentration from 20 to at least 40 mole % of butadiene. Even at 70 mole % butadiene the abundance has only decreased to 72%.

It is also pertinent to note that the two recovery methods did not appreciably influence the Hg^{202} abundance for pure hydrogen chloride. The two methods gave an average value of $39.9\pm0.3\%$.

In the HCl method of mercury recovery, it was found that isotopic degradation occurred if the hot acid was left in contact with the product in the reaction cell for more than 10 minutes. The following example is representative of this degradative effect: In one run the acid was left in contact with the product for 5 minutes, after which time the acid was drained and the cell washed thoroughly with distilled water. The mercury recovered from the acid contained 66.2% Hg^{202}. The undissolved deposit in the cell was then treated with another aliquot of hot acid. The acid was left in the cell for 2 hours. The analysis of the recovered mercury gave 52.8% Hg^{202}. Since the normal abundance of Hg^{202} is 29.8%, the fractional enrichment has decreased from 1.22 to 0.77 in the prolonged acid treatment. This represents a degradation of 37%.

In all subsequent runs reported in this paper, the HCl method was used, with the hot acid left in contact with the product for 10 minutes.

In order to assess the importance of lamp-wall temperatures on the hydrogen chloride–butadiene system, the lamp-wall temperature was varied from 4 to 48.5° C. A maximally enriching mixture of hydrogen chloride and butadiene was used, containing 22 mole % of butadiene. Flow rates were kept within the range 350–370 ml/sec at a cell pressure of 10.9 ± 0.6 mm. It should be noted that difficulty was encountered in maintaining constant lamp intensity at 4° C. At this temperature flickering was observed in the blue emission from the lamp. As the lamp-wall temperature was raised, the brilliance of the lamp steadily increased. The rate of production of product was also observed to increase with increasing lamp-wall temperature.

The data on Hg^{202} abundance vs. lamp-wall temperature are shown in Fig. 2. There is some change in the Hg^{202} abundance when the lamp-wall temperature is lowered from 23° C to 4° C. However, in view of the instability of the lamp at 4° C, it is doubtful whether the small decrease is significant. At temperatures beyond 35° C, the Hg^{202} abundance drops sharply. This effect will be discussed later in this paper.

The variation in Hg^{202} content with increasing cell pressure was studied over the range 10–100 mm. The reaction mixture contained 22 mole % of butadiene as in the lamp-wall temperature studies. The flow rate was held constant at 360 ± 10 ml/sec. The lamp temperature was 23.0° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The data are graphically represented in Fig. 3. It is quite apparent from the graph that pressure-broadening of the absorption contours is an extremely important factor in studies of this type. Maximum enrichments are only obtained for the hydrogen chloride – butadiene mixture at pressures less than about 25 mm.

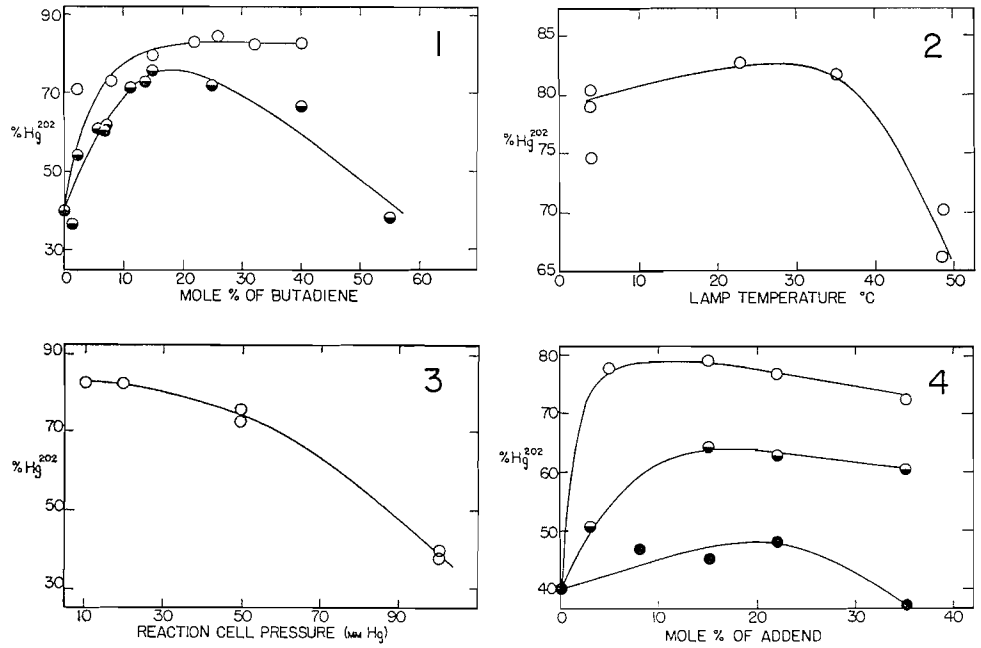

FIG. 1. Hg^{202} abundance vs. mole % of butadiene. ○ HCl method. ◒ NH_3 method.
FIG. 2. Hg^{202} abundance vs. lamp-wall temperature for hydrogen chloride containing 22 mole % of butadiene.

FIG. 4. Hg^{202} abundance vs. mole % of addend. ○ Benzene. ◒ Isoprene. ● Ethylene.

The efficiency of an unsaturated addend in increasing the Hg^{202} abundance will be related directly to its ability to remove radicals associated with the formation of $Hg^{N}Cl$, if the mechanism proposed in this paper is accepted. A number of addends, in addition to butadiene, were therefore studied in order to obtain a measure of relative efficiencies. In Table I, ethylene, propylene, acetylene, isoprene, benzene, and butadiene are compared with respect to their influence on the Hg^{202} abundance. The concentrations of all addends in the hydrogen chloride stream was 35 mole %. The lamp temperature was 20.0° C. The flow rate was held at 350–375 ml/sec at a total reaction pressure of 10 mm. From Table I, it is apparent that at the chosen concentration of 35 mole %, butadiene is the most efficient addend. In order of decreasing effectiveness follow benzene, isoprene, acetylene, propylene, and ethylene. Surprisingly enough, ethylene is quite ineffective as an addend at the chosen concentration.

Since the effectiveness of an addend could depend upon its concentration, three of the above unsaturated compounds, benzene, isoprene, and ethylene were selected for more detailed study. The results are represented graphically in Fig. 4. While the results at varying concentrations do not change the order of effectiveness of the three addends, they do establish the concentrations at which each addend is maximally effective. The maximum abundances obtained for the three addends were 78.7, 64.0, and 48.1 for benzene, isoprene, and ethylene respectively.

TABLE I

The effect of various unsaturated addends on the Hg^{202} content of the solid product of the reaction of $Hg^{202}6(^3P_1)$ atoms in Hg^N with flowing hydrogen chloride*

Addend	Concentration, mole %	Hg^{202} abundance, atom %
Ethylene	35	37·1
Propylene	35	40·6
Acetylene	35	51·5
Isoprene	35	60·6
Benzene	35	72·3
Butadiene	35	82·0

*Lamp temperature = 20.0° C; flow rate = 350–375 ml/sec; cell pressure = 10 mm.

DISCUSSION

For pure hydrogen chloride the general mechanism proposed in the Introduction becomes:

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202}Cl + H \quad [1]$$

$$Hg^{202}6(^3P_1) + HCl \rightarrow Hg^{202} + H + Cl \quad [2]$$

$$Cl + Hg^N + M \rightarrow Hg^NCl + M. \quad [3]$$

In the earlier study (5) it was pointed out that Cl atoms are also likely formed by abstraction reactions of the H atoms, generated in [1] and [2], with the substrate

$$H + HCl \rightarrow H_2 + Cl. \quad [4]$$

It would be expected that [4] would be at least as fast as the corresponding abstraction reaction with methyl radicals:

$$CH_3 + HCl \rightarrow CH_4 + Cl. \quad [5]$$

For this reaction Cvetanović and Steacie [7] found a collision yield of 2×10^{-4} at 28° C, corresponding to a maximum activation energy of 5.1 kcal per mole. Reaction [4] could therefore be of considerable importance in the present investigation. On the other hand, the recombination of H and Cl atoms, discussed in the earlier paper (5),

$$H + Cl + M \rightarrow HCl + M, \quad [6]$$

should be unimportant under our conditions owing to the high concentration of Hg^N, which is being constantly replenished in the fast-flow system. Reaction [3], therefore, should account almost exclusively for Cl atom consumption.

For the four-step mechanism, [1]–[4], the relative rate ratio, from steady-state considerations,

$$R_{Hg^NCl}/R_{Hg^{202}Cl} = (1 + \Phi_2)/\Phi_1 = (100-A)/(A-29.8),$$

where Φ_1 and Φ_2 are the relative fractions of the chemically quenched radiation partitioned to [1] and [2] respectively, and A is the percentage Hg^{202} abundance in the recovered calomel. In the present study the A value for pure substrate was found to be 39.9 ± 0.3, whence $(1+\Phi_2)\,(\Phi_1) = 6.0\pm0.2$, and $\Phi_1/\Phi_2 = 0.40\pm0.02$. In the first paper on this reaction (5), an A value of 44% was obtained, corresponding to $\Phi_1/\Phi_2 = 0.68$. In view of the higher analytical reproducibility obtained in this study, together with the fact that the A values were obtained for two totally different methods of mercury recovery, the Φ_1/Φ_2 value of 0.40 ± 0.02 should be more reliable than the earlier one.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

It is interesting to compare the value of the ratio, Φ_1/Φ_2, for hydrogen chloride to that obtained in the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^N, with water vapor. Pertel and Gunning (2, 3) obtained a value for A of $33.4\pm1.0\%$ for pure substrate. For water vapor the corresponding four-step sequence would be:

$$Hg^{202}6(^3P_1) + HOH \rightarrow Hg^{202}OH + H \quad [1']$$
$$Hg^{202}6(^3P_1) + HOH \rightarrow Hg^{202} + H + OH \quad [2']$$
$$OH + Hg^N + M \rightarrow Hg^NOH + H \quad [3']$$
$$H + HOH \rightarrow H_2 + OH. \quad [4']$$

From the A value $\Phi_1/\Phi_2 = 0.10\pm0.03$. In short, the isotopically specific primary process is some four times more important in hydrogen chloride than in water vapor. It would be expected that the importance of [1] would be related to the stability of the mercury compound formed in the reaction. Since HgCl is considerably more stable than HgOH, compound formation should be favored for hydrogen chloride. The stability consideration would be partially offset, however, by the larger number of vibrational degrees of freedom, available in HgOH, to take up excess energy associated with the quenching process.

It should be emphasized that the Φ_1/Φ_2 values for hydrogen chloride and water vapor are minimum values since any isotopically degradative exchange processes operative either in the reaction, or during recovery of the mercury for analysis, would lower the apparent value of the abundance, and yield a spuriously low value for Φ_1/Φ_2.

As stated earlier in this paper, the major emphasis in the present investigation was placed on the effect of unsaturated addends on the Hg^{202}-abundance values. Here considerable progress was made over the previous investigation (5). Average maximum abundances of 83% were consistently obtained at butadiene concentrations of 20–40 mole %, whereas the highest abundance obtained hitherto was 59% for hydrogen chloride–butadiene mixtures. In this connection the question naturally arises whether degradative reactions have now been completely eliminated in product recovery. In the previous study the calomel was dissolved from the cell in concentrated hydrochloric acid at 100° C. No attempt was made to control the time of contact of the reaction products with the hot acid. From the present study this contact time would appear to be very critical if exchange degradation is to be minimized. Optimum conditions involve a contact time not exceeding 10 minutes, followed by rapid neutralization of the acid extract.

It is instructive to compare the maximum enrichments obtained in the hydrogen chloride and water vapor reactions, for butadiene as the addend. Pertel and Gunning (3) found that the maximally enriched HgO product of the water reaction contained 85% Hg^{202}, at a butadiene concentration of 21 mole %. From Fig. 1, it can be seen that the most highly enriched $Hg^{202}Cl$ contained 84.2% Hg^{202}, and the corresponding butadiene concentration was 26 mole %. Hence the maximum Hg^{202} abundances and the butadiene concentrations are almost identical in the two reactions. Since the HgO product was removed with cold, dilute hydrochloric acid, whereas hot concentrated acid was required to dissolve the HgCl product, and since it has been shown (3) that high acid concentrations favor exchange degradation, it appears probable that exchange reactions are unimportant for the HCl method of calomel recovery. In Fig. 1 the effect of exchange degradation is clearly shown. The consistently lower values obtained by the NH_3 method must be ascribed to this type of isotopic degradation. The fact, apparent from Fig. 1, that exchange degradation becomes more extensive at higher butadiene concentrations, suggests that the controlling factor is the ratio of the quantities of enriched calomel to adsorbed mercury present in the cell. With increasing butadiene concentrations, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

competitive quenching progressively reduces the product yield for a fixed duration of exposure. The quantity of adsorbed mercury on the other hand should be relatively independent of quenching partitioning. The fact that the HCl method, as shown in Fig. 1, leads to maximum Hg^{202} abundances which are invariant in butadiene concentration is further evidence that exchange has been eliminated by using this technique for product recovery.

For the hydrogen chloride reaction the unsaturated addend (U) would serve to remove both Cl and H atoms:

$$Cl + U \rightarrow \text{products} \quad [7]$$
$$H + U \rightarrow \text{products}. \quad [8]$$

If, for the mechanism of the reaction with addend, we consider steps [1]–[4], together with [7] and [8], it can be readily shown by steady-state calculations that the effectiveness of the addend at fixed mole fraction is determined by the ratio of k_8/k_4 only. The corresponding steps for the water reaction would be:

$$OH + U \rightarrow \text{products} \quad [7']$$
$$H + U \rightarrow \text{products}. \quad [8]$$

The fact that almost identical maximum enrichments are obtained in the hydrogen chloride and water vapor reactions, with butadiene as addend, suggests that reaction [8], which is common to both mechanisms, is the dominant factor in determining the effectiveness of the addend. Maximum enrichment would occur when the H atoms are disappearing almost exclusively by reaction [8]. On this basis other reasons must be sought for the failure to obtain maximum abundances identical with the Hg^{202} content of the lamp isotope (98.3% Hg^{202}).

In order to obtain maximum abundances identical with that of the lamp isotope, the emission line must not overlap hyperfine absorption contours adjacent to that of Hg^{202}. If some overlap is occurring at lamp-wall temperatures of 23° C, it would be expected that a decrease in source temperature would reduce the extent of this overlap. Figure 2 shows clearly that reduced lamp-wall temperature does not improve enrichment. On the other hand, increasing lamp temperature does result in a decreased enrichment, showing thereby that the absorption-line width does indeed increase significantly over the range of lamp temperatures studied. No appreciable overlap occurs until lamp-wall temperatures exceeding 35° C are reached. The problem of lamp-wall temperature is, however, complicated by the fact that the enrichment apparently increases with increasing absorbed intensity (5). This effect may obscure any increase in enrichment associated with a decrease in lamp temperature. The slight maximum in enrichment shown in Fig. 2, at approximately 20° C, may arise from the net effect of the intensity and broadening factors. The problem can only be answered unequivocably by a total isotopic analysis of the maximally enriched products in the hydrogen chloride and water reactions. Mass spectrometric studies are now underway in the laboratories of one of us (H.E.G.) as one result of which considerable light should be shed on the importance of overlap in these reactions.

The results shown in Figs. 2 and 3 on the effects of increasing lamp-wall temperature and substrate pressure on the enrichment point up clearly the importance of broadening factors in emission and absorption of the Hg^{202} enrichment. These data offer further confirmation for the proposed mechanism in that these broadening influences would operate only in the primary act of absorption.

The variation of enrichment with substrate pressure for the maximally enriching hydrogen chloride – butadiene system as shown in Fig. 3 serves to define clearly the pressure beyond which Lorentz-broadening becomes significant. At total pressures below 25 mm the Lorentz effect does not appear detectably to broaden the hyperfine absorption contours.

The broadening influences on the emission line apparently cause appreciable overlap when the lamp-wall temperature is increased from 23° C to 48° C. The Doppler effect is quite inadequate to account for this broadening. An increase of 25° C would result in an increase of emission-line half-width by the Doppler effect of only 0.1 mÅ, whereas the hyperfine contours are separated by approximately 10 mÅ (1). However, with increasing lamp temperature, the vapor pressure of mercury will rise rapidly leading to increased self-reversal (1) of the resonance line. Furthermore, there will be a marked increase in the lamp current. Pressure- and current-broadening will therefore be simultaneously operative at higher lamp temperatures.

In Table I,e % effectiveness of six unsaturated addends are compared, at a concentration of 35 mol the. From the foregoing discussion on the mechanism of the reaction in the presence of addends, it would appear that these relative efficiencies are primarily determined by the rate of addition of H atoms to the double bond, as shown in reaction [8]. In Figs. 1 and 4, the curves for the variation in Hg^{202} abundance with concentration for the four addends show that the order of decreasing effectiveness is butadiene, benzene, isoprene, and ethylene. It should be emphasized that the effectiveness of an addend will be very sensitive to small differences in the activation energy of reaction [8], since absolute rate constant ratios are the determining factor.

From the proposed mechanism, it would be expected that the Hg^{202} abundance should increase with increasing addend concentration, and approach asymptotically the Hg^{202} abundance in the lamp. However, even with butadiene, the most effective addend studied, the abundance maximizes at an average value of 83%, some 15% lower than the Hg^{202} abundance in the mercury present in the lamp. From this investigation, it seems unlikely that the discrepancy can be attributed to broadening either in emission or absorption, since the range of influence of these parameters has been examined in the present investigation. There is apparently some other process operative in these reactions, which leads to degradation of the $Hg^{202}Cl$ formed in [1]. The same situation exists in the water reaction. In the laboratories of one of us (H.E.G.) further investigations are in progress on the detailed kinetics of these reactions. It is hoped that these studies will lead to a more complete understanding of the mechanism involved in reactions of this type.

CONCLUSIONS

By minimizing exchange reactions in product recovery, and determining quantitatively the influence of broadening factors in emission and absorption, the kinetics of the reaction of $Hg^{202}6(^3P_1)$ atoms, in Hg^N, with hydrogen chloride has been placed on a more quantitative basis than proved possible in the earlier study (5). It has now been established that the ratio Φ_1/Φ_2 has the value of 0.40 ± 0.02 at room temperature.

Under the conditions defined in this paper, the hydrogen chloride reaction could be used to advantage in the preparation of Hg^{202} from natural mercury. It has now been shown that enrichments equal to those obtainable in the water reaction can be conveniently produced in the hydrogen chloride system.

In both the hydrogen chloride and water vapor reactions, the effectiveness of an unsaturated addend, in increasing the Hg^{202} abundance in the recovered mercury product, is

apparently determined primarily by the rate of addition of H atoms to the double bond in the addend.

In both the hydrogen chloride and water reactions, the maximum abundances obtained are still some 15 atom % lower than that of the lamp isotope. Mass spectrometric studies now in progress on the total isotopic analysis of the enriched mercury in the solid reaction products and related investigations should be of considerable value in determining the reason for the discrepancy.

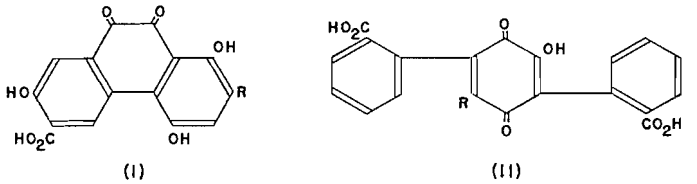
THELEPHORIC ACID[1]

G. READ[2] AND L. C. VINING

ABSTRACT

The electronic and infrared absorption spectra of thelephoric acid and its leucoacetate indicate that the structure at present accepted for the pigment is incorrect. It is suggested from an interpretation of these spectra, together with a re-evaluation of the reported properties of thelephoric acid and its derivatives, that the substance may be a hydroxylated terphenyl containing internal quinhydrone and benzofuran systems (e.g. (V)).

Structure (I), proposed by Kögl, Erxleben, and Jänecke (8), is widely quoted for thelephoric acid, which occurs in several lichens and many of the higher fungi (6, 14). The sparing solubility of a compound of this structure in sodium bicarbonate and sodium carbonate solutions is surprising. Furthermore, (I) does not fall into any of the broad groups of naturally occurring compounds and is difficult to reconcile with accepted theories of biogenesis. Recently Millward and Whiting (10) have shown that synthetic 1,2′-phenanthryl-1,3-butadiene differs in melting point from the hydrocarbon of that structure reported to be formed by zinc dust distillation of acetylthelephoric acid (8). They concede that polymorphism or the unlikely survival of a *cis*-form could account for



(I) (II)

the difference, but their doubt concerning the nature of this product seems especially pertinent in view of Kögl and Erxleben's claim that a dienoic acid side chain is lost from muscarufin (II) in a comparable reaction (7). Only limited amounts of material were available for the classical degradations of the pigment (8), and it seemed desirable to confirm the structure by modern physical methods.

Small samples of thelephoric acid and its "leucopentaacetate" were obtained through the generosity of Professor S. Shibata. The infrared spectrum of the pigment was not well defined suggesting heterogeneity. It showed a single peak (1629 cm^{-1}; (s)) in the carbonyl stretching region. The leucoacetate gave peaks in this region at 1760 cm^{-1} (s) (acetate) and 1630 cm^{-1} (w). In view of the absence of any bands attributable to carboxyl groups, the accepted structure for thelephoric acid is clearly untenable. Moreover, the ultraviolet absorption of the leucoacetate (Fig. 1) is inconsistent with that of an acetoxylated phenanthryldienoic acid.

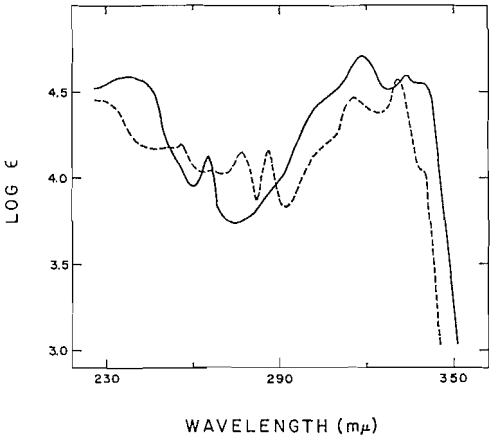

FIG. 1. Absorption spectra of thelephoric acid leucoacetate (———), and 2,11-diacetoxybenzobis-[1,2-*b*,4,3-*b*']-benzofuran (– – –) (III).

A striking property of thelephoric acid is its intense blue-black color in the solid state, whereas a solution in pyridine is wine-red in color and shows an absorption maximum at only 493 mμ. This suggests a quinhydrone, and the color, insolubility, stability to recrystallization, and color reactions of this material are reminiscent of the internal diphenyl quinhydrone systems examined by Erdtman (3). Thomson has also noted (14) that, like thelephoric acid, 5,6-dihydroxy-1,4-naphthoquinone gives a cornflower-blue solution in aqueous pyridine, and the terphenyl quinone, polyporic acid, behaves similarly (11). A quinhydrone structure would account for the single carbonyl band at 1629 cm^{-1} in the infrared spectrum of thelephoric acid. Other possible assignments for this band are a quinomethine, an extended quinone, or a perihydroxylated quinone, but the last can be excluded by the ultraviolet spectrum of the leucoacetate which, if representing a single chromophore, is incompatible with any fused-ring aromatic system. This spectrum is basically similar to that of dibenzofuran, but bathochromic and hyperchromic displacement of the 280-mμ band suggests a more extended system. It, in fact, closely resembles that of 3-aminodibenzofuran (13), but its absorption in the region of 320 mμ is higher (log ε 4.70 vs. 4.22). The absorption from 290 to 360 mμ shows a marked similarity to that of the terphenyl (III) (Fig. 1), but there are differences between 240 and 290 mμ. The infrared spectra of the leucoacetate and (III) are basically similar and show, in common

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

with the pigment, weak aromatic absorption bands between 1550 and 1635 cm^{-1}, and strong bands at ca. 1025 (aromatic ether) and 800 cm^{-1} (two adjacent aromatic hydrogens). The pigment and leucoacetate also show a band at ca. 870 cm^{-1} (isolated aromatic hydrogen). The properties of the materials examined are therefore compatible with highly oxygenated terphenyl derivatives, the occurrence of which in higher fungi and lichens has frequently been reported (6, 14).

In attempting to rationalize the published evidence for structure (I) with the current spectral data, the possibility cannot be ruled out that the two samples of thelephoric acid are different. Unfortunately, the material examined by Kögl *et al.* was not obtainable, but in view of the close agreement in properties reported for the two compounds (2), this possibility seems remote. Moreover, a specimen kindly supplied by Dr. J. Gripenberg had an infrared spectrum virtually identical with that of the Japanese sample.

The initial analytical figures obtained by Asahina and Shibata for the pigment (2) agree with $C_{18}H_{10}O_9$, e.g. (V), in addition to the $C_{20}H_{12}O_9.H_2O$ formula adopted. Carbon and hydrogen analyses obtained by both the Japanese and European workers for the acetate fit a $C_{26}H_{16}O_{12}$ molecule, e.g. (VI; R = Ac), while the analyses obtained by Asahina and Shibata for the leucoacetate agree with the required figures for the leucoacetate of (VI; R = Ac). In reported analyses for thelephoric acid, the hydrogen values are all low for $C_{20}H_{12}O_9$, and the carbon values variable (59.89 to 60.99%). Furthermore, Asahina and Shibata could only approach the required analysis for structure (I) by prolonged drying of the sample at elevated temperatures at which (V) might be expected to dehydrate. Analyses obtained would also be given by a 1:1 mixture of (V) and (VI; R = H). Under the conditions used, acetylation and reductive acetylation of such a mixture might be expected to yield a single acetate, e.g. (VI; R = Ac), and leucoacetate. It is therefore suggested that (V) or a closely related isomer represents the structure for thelephoric acid as initially isolated by the Japanese workers. Such a compound might be formally derived from leucomelone (IV; R = H) (1) by hydroxylation to the terphenyl quinone (IV; R = OH), oxidation to a diquinone, rearrangement, and hydroxylation.

The isolation from compounds such as (VI; R = Ac) of the key hydrocarbon from which 2-phenanthroic acid and subsequently phenanthrene were obtained is conceivable if the initial result of zinc dust distillation is a fission of the quinone ring leading to substituted benzofuran and phenyl fragments. A condensation analogous to that in which phenanthrene is formed by pyrolysis of benzofuran and benzene (9) might then yield a phenanthrene derivative such as 2-vinyl phenanthrene (m.p. 116.5–118° C) (12) which is similar in analysis to the reported 1,2-phenanthrylbuta-1,3-diene (m.p. 126° C).

The authors realize that this hypothesis leaves unexplained many aspects of the chemistry of thelephoric acid but hope that it may serve to stimulate further studies by chemists with access to the substance.

EXPERIMENTAL

Infrared spectra of the compounds in pressed potassium bromide disks were measured with a Perkin–Elmer double beam spectrometer, model 21. Because of the poor solubility and the smallness of the samples, solution spectra could not be obtained.

The ultraviolet and visible absorption spectra were measured on a Warren Spectracord double beam recording spectrophotometer, model 3000. Thelephoric acid was examined in pyridine, the remaining samples in freshly purified dioxane. The leucoacetate of thelephoric acid showed λ_{max} 238, 265, 318, and 334 mμ, log ϵ 4.64, 4.18, 4.77, and 4.64 respectively, based on a molecular formula $C_{30}H_{22}O_{14}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

2,11-Diacetoxybenzobis-[1,2-*b*,4,3-*b*']-benzofuran (III) was prepared according to the method used by Erdtman (4) and had m.p. 236–238° C. (Erdtman reports m.p. 236–237° C.) Found: C, 70.51%; H, 3.92%. Calculated for $C_{22}H_{14}O_6$: C, 70.58%, H, 3.77%. Ultraviolet absorption maxima at 257, 265.5, 277, 286, 315, 331 mμ, log ϵ 4.19; 4.04, 4.16, 4.17, 4.46, 4.55 respectively; inflexion at 233 mμ, log ϵ 4.50. The *p*-terphenyl structure assigned to this compound at the time it was first prepared has since been corrected (5).

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Professor S. Shibata, Tokyo University, Japan, and to Dr. J. Gripenberg, Finland Institute of Technology, Helsingfors, for gifts of samples, and to Miss I. M. Gaffney for measurement of the infrared spectra.

CATALYTIC ACTIVATION OF HYDROGEN IN AQUEOUS SOLUTION BY THE CHLOROPALLADATE(II) ION[1]

J. HALPERN, J. F. HARROD, AND P. E. POTTER[2]

ABSTRACT

The kinetics of the reduction of ferric chloride by molecular hydrogen in aqueous solution, in the presence of chloropalladate(II), were examined. The latter acts as a homogeneous catalyst for the reaction. The rate-law was found to be,

$$-d[H_2]/dt = k[H_2][PdCl_4^{=}]$$

where

$$k = 6.6\times10^{11} \exp[-20{,}000/RT] \text{ liter mole}^{-1} \text{ sec}^{-1}.$$

The mechanism of the reaction is discussed.

INTRODUCTION

Metallic palladium is readily precipitated from aqueous solutions of palladous chloride by reduction with hydrogen. Ipatieff and Tronev (1) found this reaction to be autocatalytic, in line with the well-known heterogeneous catalytic activity of palladium for hydrogenation reactions in general. However, when oxidizing substrates such as ferric chloride were present in the solution, precipitation of the palladium was preceded by an induction period during which the substrate underwent reduction. Since metallic palladium apparently was absent during this stage, this observation suggests that the dissolved palladium salt may be acting as a homogeneous catalyst for the hydrogenation of the substrate. This paper describes a kinetic study of the reaction, the results of which confirm this view.

Previously, the ability to activate hydrogen homogeneously and catalyze its reactions in solution has been demonstrated for ions and complexes of only a few other metals notably copper, silver, mercury, and cobalt (2, 3). Importance has been attached to the study of these systems, not only for their intrinsic interest, but also because of the insight they provide into the mechanism of action of related heterogeneous and enzymic catalysts, which often cannot be elucidated directly because of their greater chemical and kinetic complexity (4).

EXPERIMENTAL

Hydrated palladous oxide, precipitated with NaOH from a solution of reagent grade palladous chloride and washed thoroughly, was dissolved in 3 *M* HCl to give a stock solution of H_2PdCl_4. The concentration of palladium was determined by precipitation with dimethylglyoxime. Hydrogen was obtained from Canadian Liquid Air Co., passed through a "deoxo" catalytic purifier to remove oxygen, and dried over P_2O_5. Other chemicals were of reagent grade.

Several procedures for making the desired kinetic measurements were examined. The most satisfactory of these proved to be the determination of the rate of catalytic reduction

For personal use only.

of ferric chloride by measuring the volume of hydrogen taken up at constant pressure. The results reported in this paper were obtained by this method, the details of which have been previously described (5). An attempt was also made to examine the kinetics of the catalyzed reduction of dichromate by the procedure used earlier to study the activation of hydrogen by silver salts (6), that is, bubbling hydrogen through the solution and following the decrease in dichromate concentration spectrophotometrically. The overlap of the palladium and dichromate absorption bands and the tendency of metallic palladium (a powerful heterogeneous catalyst) to form prior to complete reduction of the dichromate, limited the accuracy of this procedure but, on the whole, the results obtained by the two methods were in satisfactory accord.

RESULTS AND DISCUSSION

The kinetics of the reduction of ferric chloride, in the presence of palladium chloride, were found to be,

$$[1] \qquad -d[H_2]/dt = k[H_2][PdCl_4^{=}].$$

Typical rate plots showing the uptake of H_2 are given in Fig. 1. Since the concentrations of $PdCl_4^{=}$ and of H_2 remain constant while ferric chloride is being reduced the kinetics are of pseudo zero-order. Reduction of palladous chloride itself commenced only when reduction of $FeCl_3$ to $FeCl_2$ was nearly complete and was marked by an increase in the rate of H_2 uptake due to autocatalysis by metallic Pd; prior to this point the reaction is apparently homogeneous.

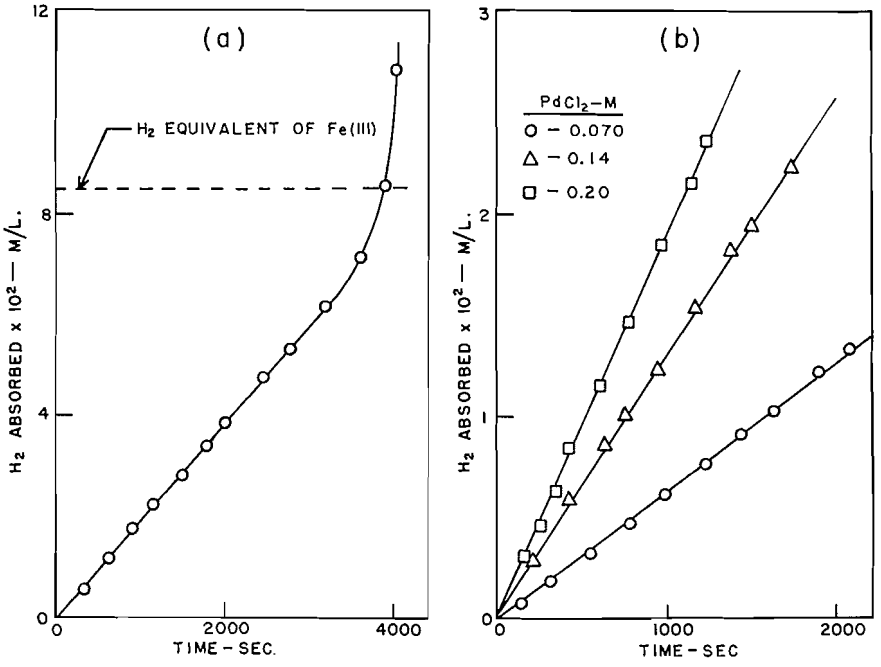

FIG. 1. Typical rate plots at 80°, 450 mm H_2. (*a*) 0.20 *M* $PdCl_2$, 0.17 *M* $FeCl_3$; reduction of $FeCl_3$ carried to completion; (*b*) 0.2 *M* $FeCl_3$, various $PdCl_2$ concentrations.

The kinetic results in Table I are in accord with equation [1]. Values of k, determined from the slopes of the zero-order rate plots using equation [1], are seen to be substantially independent of the initial concentrations of $FeCl_3$, $PdCl_2$, and H_2 over a considerable

range of each. The concentration of H_2 was calculated using the solubility data of Wiebe and Gaddy (7), correcting for the effect of HCl. The latter correction (−18% for 3 *M* HCl) was based on room temperature data (8) but it is unlikely that the error due to this is appreciable.

[a]Based on estimated solubility of H_2 in 3 *M* HCl, 6.1×10^{-4} mole atm^{-1}. Data for other media not corrected for variation in solubility.

Varying the HCl concentration from 3 *M* to 5 *M* had no effect on k. Since the predominant palladium species in this region is the chloropalladate(II) ion, $PdCl_4^=$ (9), it appears probable that this is the catalytic species. Addition of 2 *M* $NaClO_4$ was also without effect on the rate while 2 *M* NaCl decreased, and 2 *M* $HClO_4$ increased, the rate slightly. These effects are small and attributable to changes in the solubility of hydrogen since they follow the same pattern as do the activity coefficients of non-electrolytes in general (10, 11).

At HCl concentrations below 3 *M* erratic results were obtained because of the tendency of metallic palladium to form (resulting in complications due to heterogeneous catalysis) prior to complete reduction of the substrate. Similar complications were encountered in experiments using $Pd(ClO_4)_2$ in perchloric acid solution. While these experiments failed to yield quantitative information, it was possible to conclude qualitatively that the catalytic activities of the uncomplexed Pd^{++} ion and the lower chloride complexes are lower than that of $PdCl_4^=$; this was also the case for the ethylenediamine complex.

Kinetic measurements at temperatures ranging from 66 to 87.5° yielded the Arrhenius plot in Fig. 2, fitted by the equation,

$$k = 6.6\times10^{11}\exp[-20{,}000/RT] \text{ liter mole}^{-1}\text{ sec}^{-1}.$$

The frequency factor corresponds to an entropy of activation of −6.8 e.u.; this value is in the normal range for a simple bimolecular reaction in solution, and suggests that there is little charge redistribution during formation of the activated complex.

The kinetics described above resemble those found previously for the activation of hydrogen by Cu^{++}, Ag^+, Hg^{++}, and their complexes (2, 12). In a number of these systems it has been shown that the rate-determining step involves heterolytic splitting of H_2

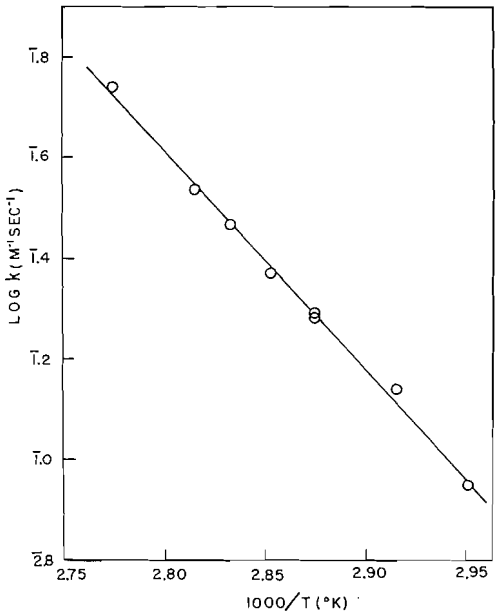

FIG. 2. Arrhenius plot for k.

by the catalytic species* with the formation of a catalyst–hydride complex which is reoxidized in a subsequent rapid reaction with the substrate. It seems likely that the present reaction also proceeds through this type of mechanism, that is,

$$PdCl_4^{=} + H_2 \xrightarrow{k} HPdCl_3^{=} + HCl \qquad [2]$$

$$HPdCl_3^{=} + 2FeCl_3 \xrightarrow{\text{fast}} PdCl_4^{=} + HCl + 2FeCl_2. \qquad [3]$$

Attempts have been made to correlate the catalytic activities of metal ions and complexes with their electron configurations (13, 4). Thus, most of the metal ions which have been found to activate hydrogen in solution have nearly filled or just filled d-shells, and it has been suggested that their catalytic activity is related to their high electron affinities. Attention has also been directed (13, 4) to a link between catalytic activity in homogeneous and heterogeneous systems, suggested by the observation that most of the ions which are catalytically active in solution are "isoelectronic" with metals (Ni, Co, Pd, Pt, etc.) which are good heterogeneous hydrogenation catalysts. The appearance of catalytic activity for a complex of Pd^{++} ($4d^8$; isoelectronic with Ru) is consistent with this pattern. Attention should also be directed to the striking parallel between the postulated hydride intermediate, $HPdCl_3^{=}$, and the electronically analogous complexes of the type $HPtCl(PR_3)_2$, described by Chatt (14).

RELATIONS BETWEEN HEATS OF FORMATION FOR INORGANIC SYSTEMS[1]

A. D. WESTLAND

ABSTRACT

Some empirical relationships dealing with the heats of formation of crystalline compounds are interrelated. A more general relation based upon functions derived from heats of formation and applicable to dissolved species as well as crystals is described. The relation may be used as a criterion for thermal data and for estimation of heats of formation. Deviations of literature values from those predicted by the relation are discussed in the light of structural features.

In recent years a number of empirical relations have been found to exist concerning heats of formation or lattice energies of crystalline ionic compounds (1–5). While presenting one of these (4), Hoppe showed it to be a more general case of the relation discovered by Fomin (3). It is the purpose of this paper to show that both of these relations and that of Karapet'yants (5) are special cases of a more general one.

Hoppe derived his method from certain theoretical considerations which were, however, in error. He supposed that the quantity

$$[1] \qquad \nabla^*(\mathrm{F,O})_{\mathrm{Me}} = -\frac{\Delta H^*(\mathrm{MeF}_{2x})}{\text{equivalents}} - \frac{\Delta H^*(\mathrm{MeO}_x)}{\text{equivalents}}$$

in which ΔH^* is the heat of formation of the compound from gaseous atoms in their ground states, would be invariant for the fluorides and oxides of various metals, Me, providing non-coulombic contributions to the lattice bonding are not involved. The conclusion drawn from this was that ∇^*-functions for various series of compounds of a given set of cations would yield a straight line if plotted one against the other. For example, one might plot ∇^*-functions for the nitrates of group I and II metals against the ∇^*-functions for the chlorides of the same metals. The second term in the expression for ∇^* may be taken as the thermal datum for the oxide in each case. Linearity was indeed observed.

The linearity is more correctly rationalized as follows: If we express ΔH^* by means of the Born–Haber cycle using the fundamental electrostatic expressions of Born, we have

$$[2] \qquad -\Delta H^* = \frac{NAe^2}{r^+ + r^-} + \frac{B}{(r^+ + r^-)^n} + \frac{C}{(r^+ + r^-)^6} - I + E - D$$

in which N is Avogadro's number, e is the charge on the ions in electrostatic units, A is the Madelung factor, B is a constant, C is a function of the ionic polarizabilities and zero-point frequencies, I is the sum of the ionization potentials of the metal, E is the electron affinity of the non-metal, D is the dissociation energy of the non-metal, r^+ is the cation radius, r^- is the anion radius, and n is the so-called Born exponent. Upon substitution of this in equation [1], the I terms disappear by subtraction and in plotting one ∇^*-function against another, the $E-D$ terms make up the constant of linearity. Otherwise the ∇^*-functions consist of a linear combination of terms of the form: $(r^+ + a)^{-p}$ where r^+ is a variable taking the values of the radii of the various cations and a is the constant anion radius. The exponent p may have the values 0, n, or 6. The corresponding terms of ΔH^* have decreasing significance in this order.

[1]*Manuscript received March 9, 1959.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.

Two functions $(r^+ + a_1)^{-p}$ and $(r^+ + a_2)^{-p}$ will be in approximately linear relation one to another, that is the slope at various points of a plot of one function against the other for corresponding values of r^+ will be approximately constant, if

$$[3] \qquad \frac{d(r^+ + a_1)^{-p}}{d(r^+ + a_2)^{-p}} = \left(\frac{r^+ + a_2}{r^+ + a_1}\right)^{p+1}$$

is essentially constant. It follows that the same condition leads to linearity between ∇^*-functions. For $p = 1$ the change in the derivative is never large over the range of values of r^+, a_1, and a_2 encountered in practice. One can easily see upon inserting the ionic radii of alkali halides, oxides, etc., that the maximum change in passing from lithium to caesium amounts to 18%. In terms of the slope of a curve this is not a large change. Thus if a line is being drawn through experimental points governed by this function a departure from linearity is hardly noticed. However, the terms containing higher values of p result in expressions giving plots which are slightly less satisfactory approximations to straight lines.

Since $\nabla^*(F,O)_{Me}$ is not invariant for various metals, Hoppe concluded that there is a certain amount of non-coulombic bonding present. He maintained further that the ∇^*-function is a measure of such non-coulombic bonding. The above development shows that the ∇^*-function indicates not so much departure from purely ionic bonding; rather it simply reflects the change in ionic size.

It is evident that Hoppe's relation is unnecessarily complicated. It is sufficient to plot the quantities ΔH^{**} defined by

$$[4] \qquad -\Delta H^{**} = (-\Delta H_f + S + I)/\text{equivalents}$$

in which ΔH_f is the heat of formation of the compound from the elements in their standard states and S is the sublimation energy of the metal component. This has the advantage that only one thermochemical quantity is required in addition to S and I. The last two quantities are known for most metals to a sufficient degree of accuracy, for good plots are obtained in general. An error of a few per cent in S or I has a negligible effect on the plots in practice.

We are now in a position to compare Hoppe's device with that of Karapet'yants. The latter plotted lattice energies in the same manner that Hoppe plotted ∇^*-functions and obtained straight line plots for compounds of elements in the same valence state. That is, he obtained a straight line for compounds of univalent elements, a different one for bivalent elements, and so on.

By plotting ΔH^{**}-values one combines the two methods to give a more general one. Moreover, since $(r^+ + r^-)^{-p}$ is symmetrical in r^+ and r^-, it follows that series of compounds each containing a common cation instead of a common anion could be employed for setting up a linearity relation. This may be done by defining

$$[5] \qquad -\Delta H^{**} = (-\Delta H_f + D - E)/\text{equivalents.}$$

A better approximation to a straight line plot is possible. If one plots the logarithm of the lattice energies per equivalent, the slope is still more nearly constant in a given case because the exponent p in $(r^+ + a)^{-p}$ is no longer significant, for the expression analogous to [3] is

$$[6] \qquad \frac{d \log (r^+ + a_1)^{-p}}{d \log (r^+ + a_2)^{-p}} = \frac{r^+ + a_2}{r^+ + a_1} .$$

Plots of this sort are shown in Figs. 1 and 2.[2] In the first figure the lines were drawn so as

[2]*These and other heats of formation were taken from the National Bureau of Standards Circular 500.*

to fit the points of the group II metals best. Departure from the line may be expected when there is considerable covalent contribution to the bonding.

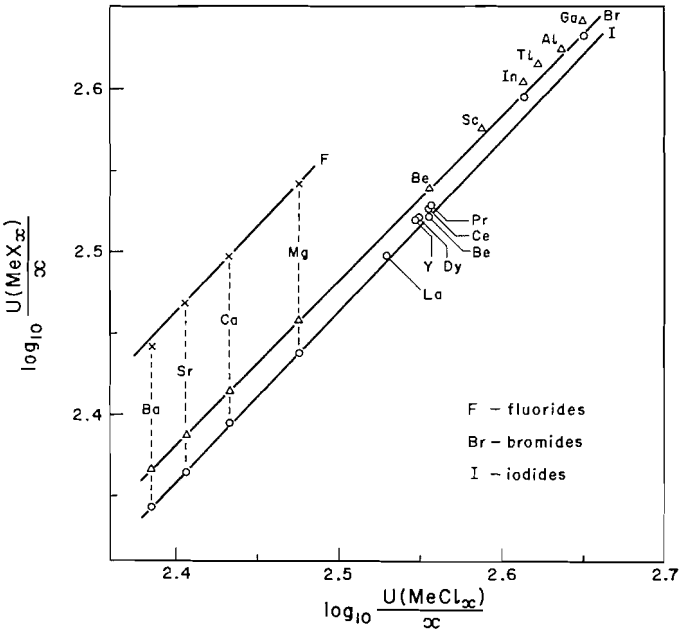

FIG. 1. Logarithmic plots of the lattice energies of fluorides, bromides, and iodides of bi- and ter-valent ions against the lattice energies of the chlorides.

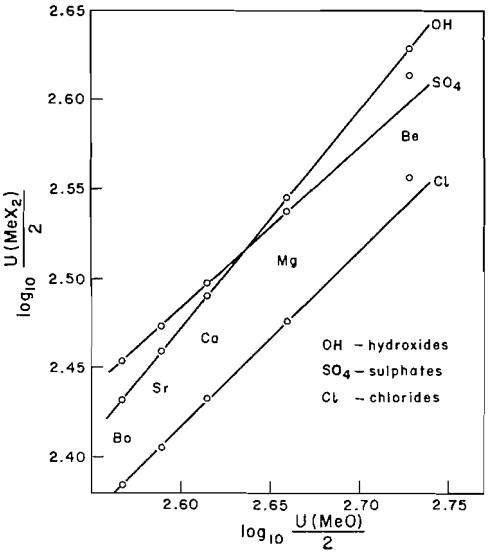

FIG. 2. Logarithmic plots of lattice energies: hydroxides, sulphates, and chlorides of group II*a* elements against the corresponding oxides.

It might be expected that the relation is only as good as the Born equation for lattice energy. It appears to be very much better, however. Thus the form of the Born equation would lead one to expect that the crystal structure, i.e. the value of the Madelung con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

stant, would have to be the same along a series of compounds. Such is not necessarily the case. This is demonstrated in Fig. 2. Thus even though all the group II*a* metal oxides with the exception of BeO have the same crystal structure, this is not true of the sulphates and chlorides for example. Here the magnesium and calcium compounds differ in structure but there is no irregularity in the plots due to this.

It is evident that the difference in the energy due to change in the Madelung factors of the chlorides from magnesium to barium is compensated by some other effect(s). The difference in the Madelung factors of $CaCl_2$ and $MgCl_2$ is not great, so that it would appear that the alteration in ionic radius with change in co-ordination (6) could account for the compensation. The change in co-ordination in this instance is from the asymmetric environment of the chloride ions in $MgCl_2$ to the symmetric environment in $CaCl_2$ and $SrCl_2$. In passing from $SrCl_2$ to $BaCl_2$ there is an increase in co-ordination number; this would be accompanied by an increase in Madelung factor but also an increase of a few per cent in ionic radius. It is remarkable how small is the over-all effect of minor changes in structure. By "minor" is meant such changes as those involving only structures of high co-ordination ($\geqslant 6$). The alkali nitrates provide another example of a series involving several structure changes, but which may yet be related very satisfactorily to the corresponding halides.

If, on the other hand, a structure of 4:4 or 4:2 co-ordination appears in a series otherwise composed of structures of higher co-ordination, a major change in Madelung factor is involved. Such is the case in the series of group II oxides at beryllium. Thus the singularity at this element may be accounted for, provided that the (as yet unknown) chloride structure could be shown to have a Madelung factor close to that of the other group II chlorides. It is significant that there is no discrepancy in a plot of hydroxide and sulphide values against oxide values. In the sulphate–oxide plot there is again a discrepancy at beryllium of exactly the same magnitude as in the chloride–oxide case.

Molecular volume provides an analogous linearity relation. This may, therefore, be used in many cases such as the above-mentioned to decide whether a discrepancy is due to an experimental error or a structural singularity. If the cause is structural, this will in general be reflected in the additivity of atomic increments (7).

APPLICATIONS TO DISSOLVED SPECIES

The coulombic energy of ion–dipole attraction is proportional to $(r^+ + r^-)^{-2}$ in which r is the "thermochemical radius" (8) of the dipole molecule. The polarization energy is proportional to $(r^+ + r^-)^{-4}$. We should therefore expect the linearity relationships to be applicable to heats of solvation (or heats of solution), and this is indeed so.

Figure 3 illustrates the relation between $-\Delta H^{**}$ for solvation of a number of ions and the $-\Delta H^{**}$-values for the corresponding crystalline chlorides. The $-\Delta H^{**}$-values for solvation were obtained by adding $S + I$ to the standard heats of formation of the aqueous ions. It should be noted that the linear relationship demands that either the number of solvent molecules co-ordinated per equivalent of charge on the ion is the same in all cases, or there is a gradual change in effective co-ordination number such that the linearity is preserved. The former condition seems improbable but the latter is quite plausible, representing one more instance of the uniformity of behavior along a series of ions.

A singularity appears in the case of lithium. The point may lie off the curve because of a large covalent contribution to the Li—O bond. This has been suggested previously in explanation of the bond length. It may be seen that the periodic groups are better con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

sidered individually, for a slightly better line could be drawn through the points of the group II*a* metals than that shown and the subgroups of the tervalent metals appear to fall on separate lines.

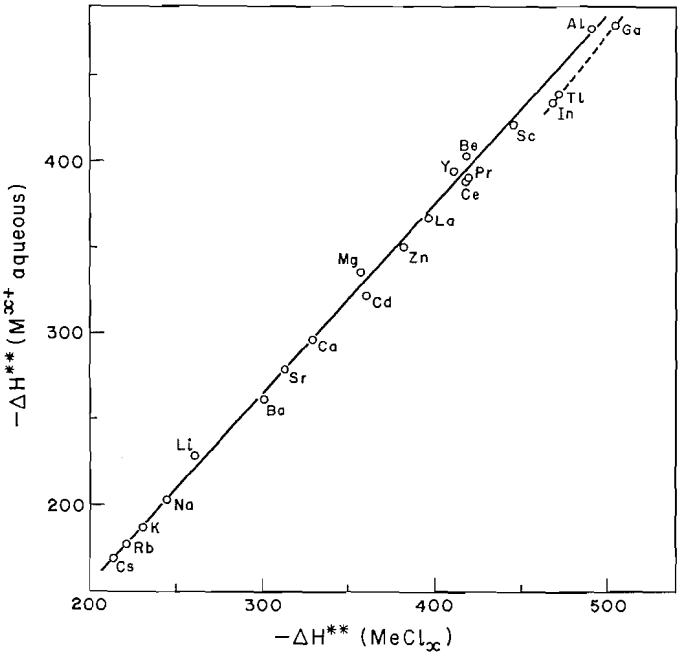

FIG. 3. Plot of $-\Delta H^{**}$-values for uni-, bi-, and ter-valent ions in the aqueous standard state against the corresponding function for anhydrous chlorides.

The heat of formation of a complex compound in aqueous solution may be combined with the solvation energy to obtain the heat of formation of the compound from gaseous ligands and ions (9). The series of group II*a*–EDTA or –citrate complexes serves to demonstrate that the linear relationship extends to these compounds as well. This is hardly a useful fact, however, as the energy of the complex is not much different than the energy of the solvated ion in all cases in which the stability constant is measurable.

THE PHOTOOXIDATION OF AZOMETHANE. II[1,2]

R. L. STRONG[3] AND K. O. KUTSCHKE

ABSTRACT

In a further investigation of the photooxidation of azomethane it was found that the yields of all products depend on the fractional conversion in a manner which suggests that some inhibitor is produced. Products from experiments at lower pressures of azomethane are obtained in yields appropriate to the higher conversions. Only very small changes in yields are observed for relatively large variations in light intensity. The implications of these facts to the mechanism of the photooxidation are discussed.

In an earlier investigation of the photooxidation of azomethane (1) it was postulated that formaldehyde should be a major product of the reaction. It proved impossible to detect this product, however, presumably because of the well-known tendency of the material to polymerize at temperatures below 100° C (2).

Preliminary work, indicating that formaldehyde was indeed an important product, was done as follows. The mixture of reaction products, unreacted azomethane, and oxygen was condensed at −196° C in a small side arm attached to a grease-free reaction system. After the side arm was allowed to warm to room temperature, the vapor phase was removed by pumping for several minutes and the side arm sealed off. The invisible residue in the side arm was dissolved in dilute H_2SO_4 and the chromotropic acid test (3) applied to the resulting solution. Positive identification was achieved, which was not due to hydrolysis of residual azomethane as shown by the absence of a test on the unphotolyzed mixture.

A reaction system was constructed based on this technique for the analysis of formaldehyde.

EXPERIMENTAL

The reaction system consisted of a fused quartz reaction cell (4.8 cm i.d., 10 cm long, ~180 cm^3 volume), a glass-enclosed, magnetically driven stirrer, a U-tube through which the cell contents were circulated, and connecting tubing. Reactants were introduced from storage and manometers through a stainless steel diaphragm valve (Hoke, No. 413) and led to the analytical system through a similar valve. The entire system, including the valves but excluding the U-tube, was housed in a thermostatted air oven. Gradients and fluctuations in the region of the cell were less than 1° C. Other parts of the oven had larger gradients so that temperature differences of as much as 5° C existed between the cell and other units in the oven. The U-tube, which extended through the walls of the oven, could be kept at oven temperature with heating tape or cooled to any temperature desired.

Gases were led from the reaction system through heated tubing to a removable U-tube (Dow Corning Silicone greased joints), and thence to a Hg cutoff leading to LeRoy stills (4) and a grease-free gas burette.

[1]*Manuscript received May 8, 1959.*

[3]*National Research Council Postdoctorate Fellow 1954–55. Present address: Department of Chemistry, Rensselaer Polytechnic Institute, Troy, N.Y.*

After an exposure the products were condensed at −196° C in the U-tube of the reaction system and non-condensables (CO, O_2, N_2, and any CH_4) transferred to the gas burette, measured, and analyzed as before (1). Condensables were transferred to the removable U-tube (with the reaction system U-tube above 100° C to ensure depolymerization of formaldehyde) and the outlet valve closed. Three cycles of warming to room temperature and recondensation at −196° C in the removable U-tube followed to polymerize the formaldehyde. The cutoff to the LeRoy still (held at −196° C) was opened and the removable U-tube warmed quickly to room temperature; after 3 minutes the cutoff was closed. Blank experiments showed that this procedure resulted in complete transfer of azomethane in that no formaldehyde could be detected in unoxidized azomethane subjected to the same analysis. Had any azomethane remained, a positive test would have resulted owing to subsequent hydrolysis of the azo compound.

Carbon dioxide and nitrous oxide were removed from the LeRoy still at −155° C and submitted for mass spectrometric analysis. Usually a small amount of formaldehyde escaped polymerization and contaminated the CO_2–N_2O mixture. Formaldehyde contributes to the peak at m/e 30, which was used as the basis for the N_2O–CO_2 analysis. Since a reproducible sensitivity could not be obtained for formaldehyde in the mass spectrometer, so that a correction could not be made using the formaldehyde peak at m/e 29, it is felt that the N_2O results are slightly high. For similar reasons the subsequent formaldehyde determination may be 10–15% low.

In some experiments azomethane was removed from the LeRoy still at −100° C; the residue of liquid products were identified mass spectrometrically and gas chromatographically. The major constituents were water and methanol with the latter in much greater yield; Φ_{CH_3OH} was of the order of unity.

After separation of all other products, air was admitted to the U-tube, the tube removed, and the polymerized formaldehyde dissolved in 1 *N* H_2SO_4 (three washings, 1 cm^3 each). One cm^3 of this solution was pipetted into a 15×150-mm glass-stoppered tube, 10 drops of chromatropic acid (Eastman Kodak P230, 2.5 g dry powder in 25 cm^3 water) added, and the solution acidified with 7 cm^3 of concentrated H_2SO_4. The tube was stoppered, heated for 30 minutes in boiling water, cooled, and diluted to 50 ml in a volumetric flask. Transmission readings were taken at 570 mμ (using a reagent blank in the Beckman DU) and converted to absolute quantities with the aid of the measured extinction coefficient, 1.7×10^4, obtained with standard formaldehyde solutions.

Azomethane was obtained from Dr. L. C. Leitch of these laboratories. Traces of low-boiling impurities were removed at −119° C, while heavier material was retained at −80° C by low temperature distillation *in vacuo*; large head and tail fractions were rejected. The material retained had a vapor pressure of 6.6 mm at −80° C. Oxygen was generated by heating $KMnO_4$ and dried by passage through traps at −196° C.

The optical system—a S-500 Hanovia Hg arc, lenses, stops, and a Corning 5860 filter—produced a nearly parallel beam which filled the cell. More than 95% of the light absorbed was of wavelength 3660 Å (5). The intensity of the light could be varied by the use of neutral density filters of chromel on quartz, whose transmission was calibrated with a Beckman DU spectrophotometer at the wavelength used.

RESULTS

An attempt was made to do experiments under conditions similar to those described in the second experimental section of the earlier work (1). It became apparent, however, that the stirring was not as effective at low pressures in the present system as it had been in the earlier apparatus. This was shown by the lack of reproducibility of nitrogen yields

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

and the lack of effect when the stirrer was not operated. It was possible to show definitely that formaldehyde was present in large yields, although not as large as had been predicted (1). Moreover, the yield of carbon monoxide was much higher than had been found in Part I. In those experiments in which the liquid product was separated, methanol was found gas chromatographically in approximately the same yield as had been found in the earlier work. It is concluded that formaldehyde is, in fact, a major product under these conditions, but the postulated equality between formaldehyde and methanol was not found. Possibly the necessity of making the experiments at room temperature followed by heating the reaction mixture to ~100° C before analysis contributed to the lack of reproducibility.

A parameter which has received scant attention in photooxidation systems, but which is of major importance in many thermal oxidations, is that of exposure time. Hentz (6) has observed an induction period for the production of carbon monoxide in the photooxidation of acetone. An investigation was made of the effect of the time of exposure on the product ratios in the present system. The general form of the product–time curves is shown by the data of Fig. 1. It is difficult to state unequivocally from these data whether

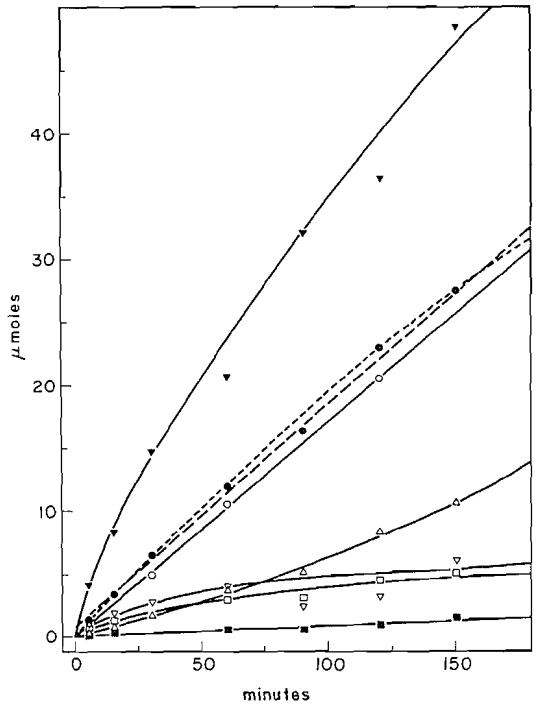

FIG. 1. Variation of products with time at 124° C. Conditions: $p_A \sim 82$ mm, $p_{O_2} \sim 11$ mm, $I_a \sim 1 \times 10^{13}$ quanta/cm³ sec. ○ N_2, $p_{O_2} = 0$; ● N_2, the dotted lines show two possible interpretations; △ CO; ▽ CH_2O; □ N_2O; ■ CO_2; ▼ O_2 consumption.

the nitrogen–time relationship is linear with a small positive intercept or whether it should be extrapolated to the origin as a curve. A careful search was made of possible nitrogen impurities in the reactants and for nitrogen formed in a thermal dark reaction. The total nitrogen expected from such sources was less than about ten per cent of the value of the apparent intercept. This is evidence for curvature in the nitrogen–time plot in the presence of oxygen.

In the absence of oxygen, but with otherwise identical initial conditions, it was observed that the yield of nitrogen was a linear function of time up to rather large fractional decompositions of the order of a few per cent. Thus the ratio of the amount of a product formed in a photooxidation to the amount of nitrogen which would have been formed had oxygen been absent is a measure of the quantum yield of that product since it has been shown that $\Phi_{N_2} = 1$ in the photolysis of azomethane (5). The quantum yields shown in Fig. 2

D_1 and D_2 are approximate measures of the conversion in per cent. The smooth curves were drawn through the open circles and other points plotted later.

were obtained in this manner. The abscissae of Fig. 2 are measures, perhaps arbitrary, of the fractional decomposition of azomethane. D_1 is the ratio of the amount of molecular nitrogen plus that of nitrous oxide found to the amount of azomethane initially introduced in the reaction system (~290 cm³), while D_2 is the similar ratio based on azomethane in the cell alone (~180 cm³). The use of D_1 implies complete and instantaneous efficiency of the stirring mechanism, while D_2 assumes that the stirring is completely ineffective. With the pressures used here it is probable that D_1 is nearer to the true decomposition. Both measures are arbitrary in that it is assumed that each molecule of azomethane which is removed from the system leads either to nitrous oxide or molecular nitrogen. Later work (7) suggests that other nitrogen-containing compounds cannot account for more than 10–15% of the total azomethane disappearance. Thus it would appear that the D_1 abscissae in Fig. 2 are probably accurate to within 10–15%; the relative values are somewhat more precise, of course. Data are shown for N_2, CO, CH_2O, N_2O, and O_2

consumption. The yields of carbon dioxide were always small ($\Phi_{CO_2} \sim 0.1$) and rather badly scattered, owing more to the low value of the yield than to any other factor. For this reason the carbon dioxide data is not included in Fig. 2. No attempt was made to determine methanol in most of the experiments.

DISCUSSION

Two experimental conditions have been investigated in this work, viz., fractional decomposition and light intensity. It is apparent from an examination of Fig. 2 that a variation in light intensity by a factor of about thirty is without large effect, while an increase in the extent of conversion from $\sim 1/2$ to 1% is responsible for a pronounced decrease in the yields of all products except that of carbon monoxide. The first observation is rather surprising, although the second is, perhaps, less so.

In general terms it would seem that as the reaction progresses, some compound is formed which acts as an inhibitor to the main reaction. It is difficult to identify this inhibitor specifically. Because of the low value which has been quoted (8) for the activation energy of the reaction of methyl radicals with formaldehyde, it was thought possible that radicals in the system could react with formaldehyde thus consuming formaldehyde and possibly acting as a source of the carbon monoxide found, as has been suggested before (6, 9). Such a suggestion would, indeed, explain the results, in a qualitative way at least. Assuming that nitrous oxide arises as suggested earlier (1), a competition for radicals will be set up such as reactions [1] and [2]

$$R + CH_2O \rightarrow RH + CHO \qquad [1]$$

$$R + CH_3N_2CH_3 \rightarrow RH + CH_2N_2CH_3 \qquad [2]$$

$$CH_2N_2CH_3 + O_2 \rightarrow CH_2O + N_2O + CH_3. \qquad [3]$$

Step [3] may occur in stages involving $CH_3N_2CH_2O_2$ radicals;* R is some radical in the system. If CHO reacts with oxygen as in [4],

$$CHO + O_2 \rightarrow HO_2 + CO, \qquad [4]$$

it is expected that an induction period should be observed in the production of carbon monoxide, and that the apparent rate of production of formaldehyde should decrease so that the concentration observed approaches a stationary value in time. Moreover, as more radicals are consumed by [1], fewer are available to react in [2] so that the rate of nitrous oxide production and the chain length should decrease with fractional decomposition. If the quantum yield of oxygen consumption is taken as approximately proportional to the probability of chain propagation (reactions [2] and [3]), then both these expectations are realized qualitatively. Further work (7) to be reported later suggests that this concept, while qualitatively correct, cannot withstand quantitative examination in the light of the more extensive data available. Whatever may be the identity of the specific inhibitor produced, it seems obvious that considerable care should be exercised in the interpretation of photooxidation data in which this effect is not studied in detail.

The lack of variation of the quantum yields with intensity also presents considerable difficulties for interpretation. Jolley (10) has observed that the yields of most products from the photooxidation of diethyl ketone vary with intensity according to the equation $\Phi = a + bI_a^{-\frac{1}{2}}$. If the same type of mechanism is applicable here, the numerical value of

*The referee has pointed out that the radical $CH_3N{=}\dot{N}CH_2{-}OO\cdot$ might also exist in the form $CH_3N{-}\dot{N}CH_2OO$, a formulation which enhances the plausibility of [3] as the over-all reaction.

For personal use only.

b must be such that the second term makes a negligible contribution to the yield. The second term involves the formation of a product in a propagation reaction, such as the combination [2] and [3], along with some other reactions which oxidize methyl radicals, presumably to methoxy radicals. The first term, on the other hand, represents the same product formed in an initiation or termination reaction; because of the inverse square root dependence on intensity it would appear that termination was mutual. It is difficult to conceive of a source of nitrous oxide other than [2] and [3]. If this is in fact the sole source of nitrous oxide, then the yields of this product should be the most sensitive to changes in intensity since the first term is missing. The opposite is observed.

A possible explanation is that termination is linear in radicals, e.g., a two-step adduct formation with azomethane, with the first stage rate determining. In this case radical concentration becomes proportional to the first power of light intensity, and the yield of nitrous oxide by the mechanism suggested becomes independent of the light intensity.

A few experiments were done with lower azomethane pressures as indicated in Fig. 1. The yields at lower azomethane pressures are those appropriate to the larger conversions, as determined by extrapolation of the lower conversion data, although a trend to lower yields is just discernible at the lowest pressure for almost all the products. This would be consistent with the decreasing importance of a chain reaction at lower substrate pressures. It has been suggested (11, 12, 13) that the association of a methyl radical and oxygen requires a third body in the usual experimental conditions. The relatively slight effect of azomethane pressure on product yields, if degree of conversion is also considered, is inconsistent with this hypothesis, but the data are insufficient to permit a thorough test.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for his advice and encouragement during this investigation. They are indebted to Mrs. Frances Kutschke and Mrs. June Garlick for the mass spectrometric analyses.

They are indebted to Dr. Calvert for a manuscript of his paper (ref. 13) prior to publication.

THE REACTION OF METHYL RADICALS WITH FORMALDEHYDE[1]

A. R. BLAKE[2] AND K. O. KUTSCHKE

ABSTRACT

The pyrolysis of di-*t*-butyl peroxide has been reinvestigated and used as a source of methyl radicals to study the abstraction reaction between methyl radicals and formaldehyde. At low [HCHO]/[peroxide] ratios the system was simple enough for kinetic analysis, and a value of 6.6 kcal/mole was obtained for the activation energy. At higher [HCHO]/[peroxide] ratios the system became very complicated, possibly due to the increased importance of addition reactions.

INTRODUCTION

The reaction between methyl radicals and formaldehyde has been previously studied by Kodama and Takezaki (1) and by Toby and Kutschke (2), who used the photolysis of azomethane as a source of methyl radicals. They obtained values of 5.6 and 6.2 kcal/mole, respectively, for the activation energy of the process. It seemed desirable to re-investigate the reaction using the pyrolysis of di-*t*-butyl peroxide as a source of methyl radicals. This source possesses the advantage that there is little abstraction reaction between methyl radicals and the molecule which produces the radicals.

EXPERIMENTAL

Methyl radicals were produced by the pyrolysis of di-*t*-butyl peroxide in a Pyrex glass reaction vessel (volume = 550 cm^3) the temperature of which was controlled to within 0.1° C. To start the reaction the reactants were expanded into the cell from a preheater maintained at 80° C, at which temperature no measurable decomposition of the peroxide took place in a period of 30 minutes. The reaction was stopped by expansion into a liquid-nitrogen-cooled trap. The products were analyzed by conventional methods. CH_4 and CO were separated from the remaining products at −210° C, and the CO measured as CO_2 after oxidation in a copper oxide furnace at 260° C. Methane was removed directly from the furnace and measured. Ethane was distilled from Ward stills at −180° C. The purity of each fraction was checked mass spectrometrically in some experiments. The remaining mixture of liquid products and unreacted starting materials was removed for further analysis. Liquid product analyses for acetone, *t*-butanol, and acetaldehyde were carried out gas chromatographically on a 10-ft column consisting of 30% nonyl-phthalate on firebrick, with a small proportion of polyethylene glycol added to the phthalate to cut down tailing of the peaks. No substances were detected other than the residual reactants and those products for which analyses are given.

Di-*t*-butyl peroxide, from the Novadel-Agene Corporation, contained traces of acetone and methanol and approximately 1/2% *t*-butanol. The first two were entirely removed by chromatographic purification; the *t*-butanol content was reduced to $< 0.1\%$ by this treatment. Isobutane was Phillips Research Grade. Formaldehyde was prepared by heating α-polyoxymethylene followed by distillation *in vacuo*. All these materials were thoroughly outgassed before use.

RESULTS AND DISCUSSION

In preliminary experiments the pyrolysis of di-*t*-butyl peroxide was reinvestigated in the temperature range 101–145° C, alone and in the presence of isobutane. The mechanism for the decomposition is well established (3)

$$\text{peroxide} \rightarrow 2(CH_3)_3CO \quad [1]$$

$$(CH_3)_3CO \rightarrow CH_3 + (CH_3)_2CO \quad [2]$$

$$2CH_3 \rightarrow C_2H_6 \quad [3]$$

$$CH_3 + \text{peroxide} \rightarrow CH_4 + \text{radical} \quad [4]$$

$$CH_3 + \text{radical} \rightarrow \text{stable products} \quad [5]$$

$$CH_3 + CH_3 - CH(CH_3) - CH_3 \rightarrow CH_4 + CH_3 - C(CH_3) - CH_3. \quad [6]$$

Peroxide Alone

The results for the decomposition of peroxide alone are given in Table I. Assuming

every molecule of peroxide decomposed gives rise to a molecule of ethane or methane then:

$$k_1 = \frac{1}{t} \ln \frac{a}{a - x}$$

and

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}} = \frac{k_4}{k_3^{\frac{1}{2}}} \cdot \frac{1}{[\text{peroxide}]}$$

where a is the initial peroxide concentration, x the amount of methane and ethane formed, and t the time. A plot of log k_1 against $1/T$ is given in Fig. 1. This leads to a rate constant, $k_1 = 2.5 \times 10^{16} \exp(-38{,}700/RT)$ sec^{-1}, in excellent agreement with those previously determined (3, 4, 5, 6, 7, 8). The amount of methane formed in the reaction was small (usually less than 3% of the ethane) and analysis was difficult. An approximate estimate of $E_4 - \frac{1}{2}E_3$ gave 14.5±2.5 kcal/mole. The correspondence between acetone

formation and total methyl radical recovery was good (Table II).* No *t*-butanol was detected in any experiments

Peroxide in the Presence of Isobutane

These experiments were performed in order to establish that our experimental system produced the same value for E_6 as had been determined by other methods. The results are presented in Table III, and the Arrhenius plot in Fig. 2. The value of $E_6 - \frac{1}{2}E_3 = 7.7$ kcal/mole is in good agreement with the value of 7.6 found by Trotman-Dickenson and

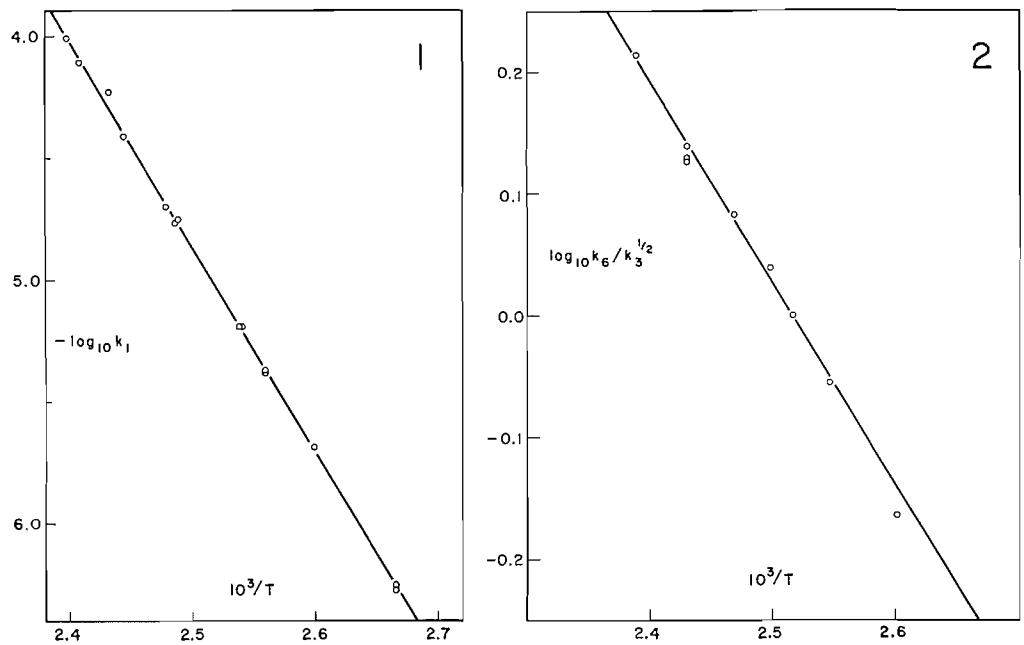

FIG. 1. Arrhenius plot for the pyrolysis of di-*t*-butyl peroxide.
FIG. 2. Arrhenius plot for the reaction of methyl radicals with isobutane.

Steacie (9) from the photolysis of acetone. It is higher than the values of Rebbert and Steacie (10), 7.3 kcal/mole, from the photolysis of $Hg(CH_3)_2$, and Jones and Steacie (11), 6.7 kcal/mole, from the photolysis of azomethane.

Recently Alexandrova, Yu. A., Yui-Li, K., Pravednikov, A. N., and Medvedev, S. S. (Doklady Akad. Nauk, S.S.S.R. **123, 1029 (1958)) have suggested that acetone can be formed in a bimolecular reaction of t-butoxy radicals, the other product being methyl isobutyl ether. The concentration range (> 0.2 mole/l. in isopropyl benzene solution) in which the effect of this reaction was observed, the lack of methyl isobutyl ether among the products in the present work, and the good balance between acetone and hydrocarbon products found here all suggest that the bimolecular reaction is not of importance in our experimental conditions.*

It was found that at low isobutane pressures $k_6/k_3^{\frac{1}{2}}$ decreased with increasing isobutane pressure, but above 20 mm Hg there was no change with increasing pressure. Consequently all rate measurements were made above this pressure.

Peroxide in the Presence of Formaldehyde

At low formaldehyde/peroxide ratios (below 0.2, except at high temperatures), the following simple mechanism is obeyed

$$CH_3 + HCHO \rightarrow CH_4 + CHO \quad [7]$$

$$CHO + CH_3 \rightarrow CH_4 + CO \quad [8]$$

$$CHO + CH_3 \rightarrow CH_3CHO \quad [9]$$

along with reactions [1] to [5]. This leads to the expression

$$[I] \qquad R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}} = (k_7/k_3^{\frac{1}{2}})\,[HCHO]\,(1+k_8/(k_8+k_9)).$$

Acetaldehyde is formed in the reaction at low pressures in very small quantities, the value of R_{CH_3CHO}/R_{CO} being < 0.10. Therefore $k_8/(k_8+k_9)$ can be approximated by unity. This approximation will have little effect on the activation energy as the term will certainly have a small temperature coefficient. Throughout this work we have used the approximate expression

$$[II] \qquad R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}} = 2(k_7/k_3^{\frac{1}{2}})\,[HCHO].$$

We consider that reaction [10] probably does not play an important role in the over-all

$$2CHO \rightarrow HCHO + CO \quad [10]$$

reaction scheme, as the methyl radical concentration, as estimated from the absolute rate of ethane formation, is high throughout. It is difficult to check this point in a satisfactory manner experimentally. Table IV shows the experimental results at low formaldehyde/peroxide ratios, and in Fig. 3 the data are plotted according to equation [II]. The Arrhenius plot is given in Fig. 4. This leads to a rate equation

$$k_7/k_3^{\frac{1}{2}} = 3.8\times10^4 \exp(-6600/RT)\ (\text{mole cm}^{-3})^{-\frac{1}{2}}\ \text{sec}^{-\frac{1}{2}}.$$

The activation energy is in good agreement with the value of 6.2 kcal/mole obtained by Toby and Kutschke (2). It is interesting to compare it with the 6.8 kcal/mole obtained

by Ausloos and Steacie (12) for the corresponding reaction with acetaldehyde. Hoare (13) has also determined $k_7/k_3^{\frac{1}{2}}$ at 120° C. He obtained 10.1 (mole cm^{-3})$^{-\frac{1}{2}}$ sec$^{-\frac{1}{2}}$ compared with our value of 7.9 (mole cm^{-3})$^{-\frac{1}{2}}$ sec$^{-\frac{1}{2}}$ at the same temperature.

At higher HCHO/peroxide ratios the system becomes very complicated. Measurable amounts of hydrogen and acetaldehyde are produced and the plots of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$[peroxide] against [HCHO]/[peroxide] show a very marked deviation from linearity (see, for example, Fig. 5). Some data are shown in the second part of Table IV. This last observation has been made previously in other systems by Brinton and Volman (5) in the reaction between methyl radicals and ethylene imine and by Brinton (14) in the reaction between methyl radicals and ethylene. It seems clear that the deviations are most marked in systems where there is a possibility of methyl radicals undergoing addition reactions. Fuller and Rust (15) have demonstrated recently that alkyl radicals add quite readily to formaldehyde. It is possible that reaction of a second methyl radical

with the methyl radical – formaldehyde complex to produce a molecule of ethane could account for the deviations observed.

The ratio of acetaldehyde/CO in these experiments was approximately 0.25. This is not, however, a reliable measure of the relative rates of reactions [8] and [9], as acetaldehyde might also be produced in the decomposition of methyl radical – formaldehyde addition compounds.

ACKNOWLEDGMENTS

We wish to thank Dr. E. W. R. Steacie for his interest in this work, and Miss Bernice Thornton for mass spectrometric analyses.

THE INFRARED SPECTRA OF SOME DNP-α-AMINO ACIDS[1, 2]

FELIX FRIEDBERG[3] AND MYLOUS S. O'DELL

ABSTRACT

The infrared spectra of some DNP-α-amino acids were examined using the KBr technique in the region 5000 to 625 cm^{-1}. There is sufficient variation in spectra of closely related DNP-amino acids to allow positive identification even though the spectra on the whole are more strikingly similar than they are different. Differences in varying degrees were also noted between L- and DL-forms.

INTRODUCTION

The DNP[4]-derivatives of amino acids recently have assumed importance in amino acid sequence studies on peptides and proteins (1). While the KBr pellet spectra of a large number of the amino acids (2, 3), and also of their 3-phenyl-2-thiohydantoins (4), are reported in the literature, there is little information with regard to the infrared spectra of DNP-derivatives.[5] This study was undertaken to compare the spectra (*a*) of the DNP-derivatives of amino acids with the spectra of the corresponding free amino acids as given in the literature, (*b*) of the DNP-derivatives of comparable L- and DL-amino acids, and (*c*) of the DNP-derivatives of structurally related acids, to see whether such compounds can be identified by their spectra.

EXPERIMENTAL

The spectra were taken on a Model No. 21 Perkin–Elmer spectrophotometer (equipped with sodium chloride optics). Pellets were made by first mixing the DNP-amino acids with KBr in an agate mortar, and then pressing the material in the Perkin–Elmer die, under evacuation. The DNP-amino acids had been prepared in this laboratory by the method of Levy and Chung (5), and each was crystallized several times and found pure by paper chromatography. Melting points for all derivatives were determined and are essentially in agreement with the values given in literature (6).

DISCUSSION

Table I lists and characterizes the spectral absorption bands in the 5000 to 625 cm^{-1} region. As a result of dipolar ion structure many amino acids possess a characteristic absorption frequency at about 1587 cm^{-1} which is related to the COO^- group, as well as a relatively weak absorption at about 2128 cm^{-1} which may be attributed to NH frequencies in the $—NH_3$ ion. The absence of this absorption peak at 2128 cm^{-1} in the case of DNP-derivatives of amino acids, where the amino group is attached to the dinitrophenyl ring, was therefore expected.

Amino acids have been reported to show marked similarity in their infrared spectra in the region of 1587 to 1333 cm^{-1}. Bands at 1587 and 1408 cm^{-1} have been related, respectively, to the antisymmetrical and symmetrical stretching vibrations of the ionized carboxyl group of the dipolar ions. None of the free amino acids studied lacked the 1408 cm^{-1} band. Among those in which the 1587 cm^{-1} band was not observed were L-threonine and L-proline (3). All of the DNP-derivatives examined by us, however, exhibit the bands at 1587 and 1408 cm^{-1}, and hence the implication is possible that these compounds are dipolar ions. For the free amino acids, a band at 1515 cm^{-1} due to an N–H deformation motion of the α-amino group has been reported, L-leucine, L-serine, and hydroxy-L-proline being among the exceptions (3). Again, there are no such exceptions among the DNP-derivatives studied by us; but we believe that the band here represents antisymmetrical aromatic NO_2 stretch rather than NH-deformation. In the case of free amino acids, bands at 1449 and 1370 cm^{-1} are due to antisymmetrical and symmetrical CH_3 and possibly CH_2 deformation motions, respectively. Among the free amino acids in which the 1449 cm^{-1} band was not apparent were L-valine, L-phenylalanine, hydroxy-L-proline, L-aspartic acid, and L-lysine (3). While the DNP-derivatives of L-aspartic acid and L-lysine (both mono- and di-) and in addition of L-cysteine, L-cystine, L-histidine (di-), L-tyrosine (di-), and DL-threonine do not show the band, those of L- and DL-valine, L- and DL-phenylalanine, and hydroxy-L-proline exhibit it weakly or as a shoulder. In the spectrum of free glycine only, the 1370 cm^{-1} band was lacking (3), and in that of its DNP-derivative it is present. Furthermore, the DNP-derivatives of L-cystine (di-), L-lysine (di-) (unlike the monosubstituted forms), and DNP-L-tyrosine (di-) do not show this band. A 1333 cm^{-1} band has been considered to be related to a CH_2 wagging motion and the only exception among the free amino acids was due to L-alanine (3). None of the DNP-amino acids studied lacks this band. It should be emphasized, however, that bands in the region 1330–1370 will be difficult to interpret, as symmetrical aromatic NO_2 stretch is in this region and is usually intense.

While many free amino acids possessed a band at 2564 cm^{-1}, provisionally assigned to the C–H stretching motion (3), but more likely due to overtone or combinations of the strongly anharmonic $N–H_n$ deformations, it is missing in almost all DNP-derivatives. On the other hand, the spectra of DNP-derivatives with the exception of DNP-L-tyrosine (di-) and DNP-L-arginine possess a band at 1724 cm^{-1}, a band which is not exhibited by the free amino acids.

The spectrum of the racemic form of DNP-alanine differs very little from that of its optically active form. The spectrum of the former does not show the band at 1727 cm^{-1} or that at 1261 cm^{-1}. In the case of DNP-isoleucine, the differences are also not very marked. There is an additional band at 733 cm^{-1} in the spectrum of the active form. The spectrum of the active form of leucine shows additional bands at 1206, 1076, 939, and 775 cm^{-1}. The shoulders at 1420 and at 1203 cm^{-1} of DNP-L-phenylalanine turn into medium broad bands for the DL-form. This L-form has an additional band at 1188, while the DL-form also has an additional band at 1294 cm^{-1}. For tyrosine the shoulder at 3390 cm^{-1} of the L-isomer is a definite dip in the spectrum of the racemic mixture. A striking difference is the absence of the intense and sharp band at 1715 cm^{-1}, the medium band at 1479 cm^{-1}, and the weak one at 1161 cm^{-1} in the DL-form of this amino acid. The DL-form has additional bands at 1362, 1239, 1121, 1089, 939, 750, and 711 cm^{-1}. The shoulder at 1529 cm^{-1} for DNP-DL-valine turns into a definite band for the L-form. The major differences, however, between the spectra for the L- and DL-forms of this amino acid lie between 1429 to 1250 cm^{-1} where the L-form has clearly resolved bands at 1427, 1309, and 1261 cm^{-1}.

The question arises as to whether structurally related DNP-amino acids can be readily differentiated. In the case of DNP-L-proline versus DNP-hydroxy-L-proline, for instance, the former has pronounced additional peaks at 1377, 1290, 1221, 1159, 1094, 1040, and 773 cm^{-1}, the latter at 1245, 997, and 927 cm^{-1}. The 3226-cm^{-1} band, however, reported to be present in the free hydroxy-prolines but not in the spectrum of free proline and assumed to reflect the presence of the —OH group in the former (3), is absent in the spectra of the DNP-derivatives of either L-hydroxyproline or L-proline.

The spectra of DNP-L-valine and DNP-L-isoleucine would be expected to resemble each other. DNP-L-isoleucine has additional bands at 3058, 1222, 1121, and 733 cm^{-1}, DNP-L-valine at 1490, 1427, 1176, and 945 cm^{-1}. In the case of the spectrum of the corresponding free amino acids, L-isoleucine, unlike L-valine, shows a sharp and discrete band at 1462 cm^{-1} (3). Such a distinguishing difference is ruled out for the DNP-derivative of these amino acids.

It would be surprising if the infrared spectra of closely related compounds did not reveal some differences by which pure, individual samples of such compounds could be differentiated from each other. A review of the table suggests that among the DNP-L-amino acids studied the spectra on the whole are more strikingly similar than they are different, and that the use of the spectral tool for purposes of identification is much weaker and less reliable than such procedures as chromatography. There are, however, some DNP-amino acids (e.g., leucine and isoleucine) which are difficult to identify by chromatography and hence spectral analysis after purification would still be of value. Even the spectra of structurally very similar DNP-amino acids show sufficient variation to allow positive identification.[6]

FREE RADICALS BY MASS SPECTROMETRY

XVI. Hg-PHOTOSENSITIZED DECOMPOSITIONS OF BIACETYL, ACETYLACETONE, AND ACETONYLACETONE[1]

A. G. HARRISON[2] AND F. P. LOSSING

ABSTRACT

The Hg($^3P_1$)-photosensitized decomposition of biacetyl proceeds by a central bond fission. Of the resulting acetyl radicals, at least 27% survive the primary act long enough to react with other radicals, or with a second excited Hg atom. Under conditions of high illumination, there is evidence that Hg($^3S_1$) atoms produced by stepwise excitation also play a part in the reaction by forming excited biacetyl molecules with a lifetime of the order of 1 millisecond. The photosensitized decompositions of acetylacetone and acetonylacetone were examined qualitatively. The former dissociates mainly into an acetyl and an acetonyl radical, and the latter mainly if not exclusively to form CH_3CO and $C_2H_4COCH_3$ radicals. Further reactions of these radicals, and a possible structure for the $C_2H_4COCH_3$ radical, are also discussed.

INTRODUCTION

The photochemical behavior of biacetyl has been the subject of many investigations, mainly as a result of its well-known fluorescence and the complicating factors which this introduces into the mechanism of the acetone photolysis. However, no study of the reaction of biacetyl with excited mercury atoms appears to have been published. Earlier work supplies ample evidence that both CH_3 and CH_3CO radicals are produced in the direct photolysis. The addition of NO was found (1) to suppress the formation of methane and ethane. Blacet and Bell (2, 3) found that the addition of iodine was also effective in this respect, and they concluded that the primary decomposition step at 2654 Å could most probably be written as:

$$CH_3COCOCH_3 + h\nu_{2654} \rightarrow 2CH_3CO. \qquad [1]$$

As a result of energy carry-over, one or both acetyl radicals could dissociate immediately into CH_3 and CO. This work, in agreement with that of Anderson and Rollefson (1), indicated that the decomposition reaction is wholly free radical in nature, and that no molecular rearrangement to form C_2H_6 occurs. Some evidence (4) that ethane could be formed directly by dissociation of a long-lived excited biacetyl molecule has not been substantiated by later work.

The flash photolysis of biacetyl was examined by Porter (5) and by Porter and Norrish (6). Their observations were in agreement with reaction [1] as a primary step, but they concluded that the more complete dissociation

$$CH_3COCOCH_3 + h\nu \rightarrow 2CH_3 + 2CO \qquad [2]$$

predominated, even at 4200 Å. Since the energy available at 4200 Å is insufficient for reaction [2], there is reason to believe that thermal energy from the flash must have been involved. Their conclusions as to the relative occurrence of reactions [1] and [2] are consequently open to question (7).

The photolysis of biacetyl at 2700, 3650, and 4358 Å and its relationship to fluorescence has been discussed in some detail by Noyes and his co-workers (8, 9). They concluded

[1]*Manuscript received April 29, 1959.*

[2]*National Research Council of Canada Postdoctorate Fellow 1957–59.*

that at 2700 and 3650 Å the primary step [1] given by the earlier work was essentially the correct one, but that the reaction might more correctly be written:

$$CH_3COCOCH_3 + h\nu \rightarrow 2\alpha CH_3CO^* + (2-2\alpha)CH_3CO. \quad [3]$$

The evidence suggested that at 2700 Å one of the acetyl radicals dissociated immediately (i.e. $\alpha = 0.5$) and the primary dissociation was therefore kinetically indistinguishable from a primary dissociation step:

$$CH_3COCOCH_3 + h\nu \rightarrow CH_3 + CH_3COCO \quad [4]$$

followed by an immediate dissociation of the radical:

$$CH_3COCO \rightarrow CH_3CO + CO. \quad [5]$$

At 3650 Å the situation is complicated by the existence of two excited species giving rise to the short-lived and long-lived fluorescences. They found the primary quantum yield at 4358 Å to increase with light intensity. From this observation, and on the basis that the 66 kcal/mole available at 4358 Å is probably insufficient to dissociate biacetyl, they came to the tentative conclusion that the observed dissociation at 4358 Å proceeded by a collision of two excited biacetyl molecules having a lifetime of about 1.8×10^{-3} second. This conclusion, together with the fact that the fluorescence of biacetyl is not excited at wavelengths shorter than 3130 Å (9), is of importance in explaining an unusual feature of the mercury-photosensitized decomposition of biacetyl observed in the present work.

The photochemical behavior of acetylacetone (2,4-pentanedione) and of acetonylacetone (2,5-hexanedione) does not appear to have been investigated before.

EXPERIMENTAL

The mercury-photosensitized reactions were carried out at 55° C in a fast-flow reactor using helium as a carrier. At a point just past the end of the illuminated zone, a small fraction of the reaction stream flowed through an orifice directly into the ionization chamber of a mass spectrometer, enabling observation of free radical products, as well as of stable products, to be made. This apparatus and its operating characteristics have been described (10, 11). A new design of ion source having some modifications to permit a higher pumping speed in the ionization chamber was employed (12).

The effect of light intensity on the biacetyl decomposition was studied by the use of metal screens. Screens with different degrees of transmission were prepared from brass screen having an original transmission of about 39%, by reducing the wire diameter in dilute nitric acid. A rough index of the transmission of the etched screens could be had by measuring the hole-to-wire ratios with a low-power microscope fitted with a micrometer traversing screw. Pieces of suitable width cut from these etched screens were then rolled into cylindrical form so that they could be placed in the annular space between the lamp and the reactor tube. The transmission coefficient for each screen was then measured in place by observing the reduction it caused in the amount of ethylene decomposed in the reactor on illumination by the lamp. The transmission coefficients measured in this way agreed quite closely with those obtained by observation of the hole-to-wire ratios.

MATERIALS

The biacetyl, acetylacetone, and acetonylacetone were Eastman Kodak Co. white label grade, further purified by vacuum distillation. The sample of $Hg(CD_3)_2$ was obtained from Merck and Co. (Montreal).

RESULTS AND DISCUSSION

Biacetyl

A qualitative examination of the products of the mercury-photosensitized reaction of biacetyl, using low-energy electrons for the detection of the parent peaks of free radicals and stable products, showed the presence of CH_3 radicals in considerable abundance. Other parent peaks showing significant increases were those of acetone, ketene, ethane, carbon monoxide, and methane. However, a definite increase for the acetyl radical (mass 43) could not be obtained, even using higher partial pressures of biacetyl. No increase in the mass 85 ($CH_3COCOCH_2$) or mass 71 (CH_3COCO) peaks was found. The failure to detect these radicals using low-energy electrons was not conclusive evidence for their absence, however, since acetyl radicals were also not detected by this means. A further search was made for radicals by means of the addition of mercury dimethyl to the reaction stream. In earlier work (12, 13) it was found that CH_3 radicals produced by the mercury-photosensitized decomposition of $Hg(CH_3)_2$ provided a means for detecting the presence of a free radical R by observation of the formation of the combination product:

$$CH_3 + R \rightarrow CH_3R. \qquad [6]$$

This technique was found to be a valuable aid in detecting radicals for which the sensitivity of detection using low-energy electrons appeared to be rather low. The addition of a small partial pressure of $Hg(CH_3)_2$ to the reaction stream containing biacetyl resulted in a greatly increased yield of acetone, showing that acetyl radicals were present. The combination product of the $CH_3COCOCH_2$ radical with CH_3, on the other hand, was not found, indicating that this radical, which on thermochemical grounds would be stable at 55° C, was not present in significant amounts. To provide a means of detecting the CH_3COCO radical, $Hg(CD_3)_2$ was added to the reaction stream. The combination product $CH_3COCOCD_3$ was not found, although CH_3COCD_3 was produced in abundance. It may be concluded that the CH_3COCO radical, if formed at all, must have dissociated immediately. The addition of CD_3 radicals was found to reduce greatly the yield of CH_3COCH_3, showing that most, if not all, of the acetone was formed by radical combination and not by a molecular rearrangement of biacetyl.

The composition of the reaction products from the biacetyl decomposition was examined quantitatively as a function of the length of the illuminated zone by means of the movable shutter described previously (10, 11). Using 50-volt electrons, mass spectra were obtained at different shutter positions, and analyses were carried out in the usual way. The amounts of biacetyl decomposed, and of the products CO, acetone, ketene, ethane, methane, and methyl produced at the different shutter positions are given in Table I. The amounts of CH_3 were calculated with the assumption that the CH_3^+ contribution

TABLE I

Length of illuminated zone, mm	Biacetyl decomposed, μ	Products from biacetyl, μ						Balance (%) of:	
		CO	$CO(CH_3)_2$	CH_2CO	C_2H_6	CH_3	CH_4	O	C
5	0.096	0.12_1	0.014	0.021	0.020	0.03_5	0.010	81.3	75.5

from the CH_3CO radical was negligible. The actual yields of CH_3 are therefore rather smaller than those given in Table I. The increasing defect in the C and O balances at the shorter lengths of illuminated zone probably results from the inability to include a quantitative measurement for the CH_3CO radical. Although no increase in the mass 43 peak could be detected using low-energy electrons, a small remainder was left in the 50-volt spectra in all cases after correction for contributions from biacetyl and acetone.

The distribution of products is consistent with a primary dissociation into two acetyl radicals:

$$CH_3COCOCH_3 + Hg(^3P_1) \rightarrow CH_3CO + CH_3CO^* + Hg(^1S_0). \quad [7]$$

The present work provides no clear indication as to what fraction of the acetyl radicals formed in this reaction dissociate immediately by the reaction

$$CH_3CO^* \rightarrow CH_3 + CO. \quad [8]$$

However, a significant fraction does survive for an appreciable time, either as a result of receiving insufficient activation in the primary step, or as a result of deactivation:

$$CH_3CO^* + M \rightarrow CH_3CO + M. \quad [9]$$

The following radical combination reactions also occur:

$$CH_3CO + CH_3 \rightarrow CH_3COCH_3 \quad [10]$$

$$2CH_3 \rightarrow C_2H_6. \quad [11]$$

In agreement with the findings of earlier work on acetone (11), the low yield of methane shows that the disproportionation reaction

$$CH_3 + CH_3CO \rightarrow CH_2{=}CO + CH_4 \quad [12]$$

is quite slow compared with reaction [10]. If all the methane were produced by reaction [12] and all the acetone by reaction [10], the ratio k_{12}/k_{10} would be given by the ratio of methane to acetone. At the longest contact time this ratio was 0.095. This probably represents an upper limit to k_{12}/k_{10}. The large excess of ketene over methane supports the conclusion reached in earlier work (11) that acetyl radicals are decomposed by excited mercury atoms as follows:

$$CH_3CO + Hg^* \rightarrow CH_2{=}CO + H + Hg. \quad [13]$$

The fate of the H atom is not known; possibly it reacts with an acetyl radical to give a second molecule of ketene. Since no acetaldehyde is formed, it is evident that ketene is not produced in a primary molecular rearrangement reaction. The rapid decrease in the yield of acetone at shorter contact times supports the evidence given above that acetone was formed by reaction [10] and not by the possible molecular rearrangement:

$$CH_3COCOCH_3 + Hg^* \rightarrow CH_3COCH_3 + CO + Hg. \quad [14]$$

A similar conclusion can be reached for ethane. Assuming, then, that acetone and ketene are formed only by reactions [10] and [13], it may be concluded that at least 0.27 of the acetyl radicals survive the primary dissociation step for a time sufficiently long to permit them to react with methyl radicals or a second excited mercury atom. Whether they survive as a result of deactivation (reaction [9]), or as a result of not being sufficiently excited in reaction [7], cannot be decided from the present results.

A graphical representation of the data on biacetyl, given in Fig. 1, shows an unexpected feature. The amount of biacetyl decomposed did not increase linearly with the length of the illuminated zone as had been found for all other compounds examined, but curved

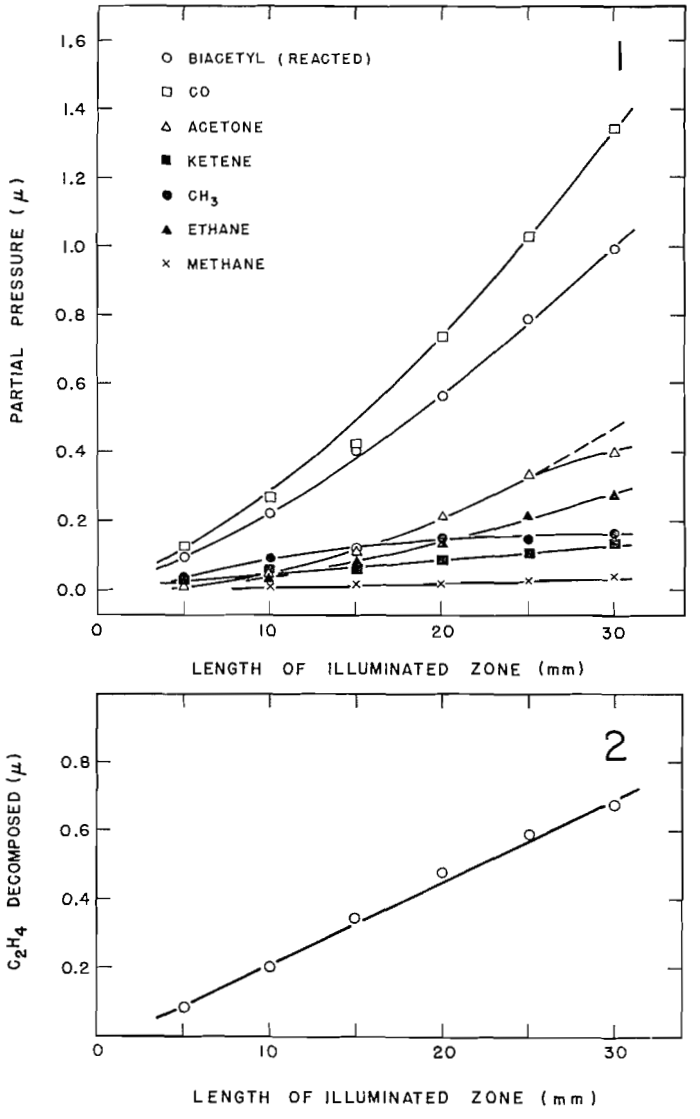

FIG. 1. Decomposition of biacetyl.
FIG. 2. Ethylene decomposed as a function of the length of the illuminated zone.

progressively upward. In order to ensure that this non-linear behavior did not result from inequalities in the amount of 2537-Å radiation entering the reactor at different points along its length (as a result of polymeric deposits, for example), a calibration was carried out using ethylene. As shown in Fig. 2, the relation for ethylene was linear. The curvature evident in Fig. 1 was consequently considered to be a real, and not an instrumental, effect. Such an effect would be produced if an appreciable fraction of the biacetyl decomposed by a process involving an intermediate whose lifetime was not negligible compared to the transit time through the illuminated zone, which was about 1×10^{-3} second. A reasonable assumption would be that this species was the metastable state of biacetyl B**, having a lifetime of 1.8×10^{-3} second. As discussed above, this

species was considered by Noyes and co-workers (8, 9) to account for the dissociation of biacetyl at 4358 Å by a second-order process:

$$2B^{**} \rightarrow B + \text{products.} \qquad [15]$$

If, in the present work, some fraction of the biacetyl were dissociating by this mechanism, the question arises as to how B** could be formed. Since biacetyl shows no fluorescence in the 2380–3130 Å (9) it appears unlikely that B** could be formed by collisions with $^3P_1$ mercury atoms. The radiation from a mercury lamp of the type used in this work does contain an appreciable amount of radiation at longer wavelengths, particularly at 3130, 3650, and 4358 Å. The possibility that B** could be formed by direct absorption of 3650- and 4358-Å radiation was checked by placing a filter, in the form of a split cylinder of Corning 7040 glass, between the lamp and the reactor tube to remove 2537 Å while allowing 3650 Å to pass. With this filter in place, it was found that no measurable decomposition of biacetyl occurred, showing that direct absorption of 3650- or 4358-Å radiation was not responsible for the effect, and that the explanation must be sought in terms of 2537-Å radiation and excited mercury atoms.

The dependence of biacetyl decomposition on the total light intensity was investigated using the metal screens described above, with the result shown in Fig. 3. For purposes of comparison, the dependence for acetone decomposition was also examined. Within the

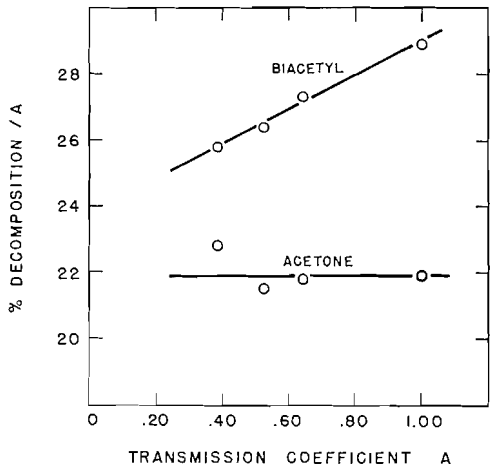

FIG. 3. Dependence of extent of decomposition on the light intensity.

experimental error the amount of acetone decomposed per millisecond was found to be proportional to the amount of light passing through the screen. The amount of biacetyl decomposed, on the other hand, depended on some order of light intensity greater than one. This lends further support to the view that a second-order decomposition process such as reaction [15] must be involved.

A positive identification of this process is not possible from the present work, but it is of interest to speculate as to how the B** state of biacetyl could be activated. Since the incident flux of 2537-Å radiation in the reaction cell is very high (greater than 10^{18} quanta/sec cc (10)) the fraction of the total number of mercury atoms which are at any instant in the $^3P_1$ state is quite appreciable. The probability of absorption of a quantum of 4358 Å by a $^3P_1$ atom to give a mercury atom in the 7^3S_1 state is therefore not negligible. This process of stepwise excitation is well known (14). Since the B**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

state of biacetyl is known to be formed by direct absorption of 4358 Å it is not unreasonable to assume that this state could also be formed by a collision in which a $^3S_1$ mercury atom is quenched to a $^3P_1$ atom. On the assumption that the incident radiation I contains a fraction x of 4358-Å radiation, the remainder being 2537 Å, the following interactions may be considered:

[16] $\quad Hg + h\nu_{2537} \rightarrow Hg^3P_1 \qquad +\frac{d}{dt}[Hg^3P_1] = k_{16}(1-x)I[Hg]$

[17] $\quad Hg^3P_1 + h\nu_{4358} \rightarrow Hg^3S_1 \qquad +\frac{d}{dt}[Hg^3S_1] = k_{17}I[Hg^3P_1]$

[18] $\quad Hg^3P_1 \rightarrow Hg + h\nu_{2537} \qquad -\frac{d}{dt}[Hg^3P_1] = [Hg^3P_1]/\tau_1$

[19] $\quad Hg^3S_1 \rightarrow Hg^3P_1 + h\nu_{4358} \qquad -\frac{d}{dt}[Hg^3S_1] = [Hg^3S_1]/\tau_2$

[20] $\quad Hg^3P_1 + B \rightarrow Hg + B^* \qquad -\frac{d}{dt}[Hg^3P_1] = k_{20}[Hg^3P_1][B]$

[21] $\quad Hg^3S_1 + B \rightarrow Hg^3P_1 + B^{**} \qquad -\frac{d}{dt}[Hg^3S_1] = k_{21}[Hg^3S_1][B]$

Application of the steady-state treatment to these equations gives the relation:

[22] $$\frac{[Hg^3S_1]}{[Hg^3P_1]} = \frac{k_{17}x}{k_{16}(1-x)}\frac{[Hg^3P_1]}{[Hg]}\left(\frac{1/\tau_1 + k_{20}[B]}{1/\tau_2 + k_{21}[B]}\right).$$

The lifetime of Hg^3S_1, $\tau_2 = 5.75\times10^{-8}$ second (15), is not greatly different from that of Hg^3P_1, for which $\tau_1 = 1.0\times10^{-7}$ second (14). Since the absorption coefficients are proportional to the reciprocal of the lifetimes, k_{16} and k_{17} are, to a first approximation, nearly equal. Nothing is known about the quenching efficiency of biacetyl for Hg^3S_1 atoms, but if it is assumed that it is not greatly different from that for Hg^3P_1 atoms, then $k_{20} \approx k_{21}$ and expression [22] reduces to:

[23] $$\frac{[Hg^3S_1]}{[Hg^3P_1]} = \frac{x}{1-x}\frac{[Hg^3P_1]}{[Hg]}f$$

in which the factor f is of the order of unity. On the basis (from Fig. 3) that some 10% of the amount of biacetyl decomposed does so by a second-order process, the right-hand side of equation [23] would have to have a value of about 0.2. Under the existing experimental conditions this may not be beyond the bounds of possibility.

In order to demonstrate conclusively that Hg^3S_1 atoms were the activating agent, it would have been necessary to filter out 4358-Å radiation while allowing 2537 Å to pass. While this might be possible given sufficient space between the lamp and the reactor tube, it could not be accomplished in the 2–3 mm annular space available in the present reaction system.

Acetylacetone and Acetonylacetone

The products of the mercury-photosensitized reactions of acetylacetone and acetonylacetone were very briefly examined, but no quantitative analyses of the products were made. In the decomposition of acetylacetone, the use of low-energy electrons indicated that three free radicals were formed, at mass 15 (methyl), mass 43 (acetyl), and mass 57 (CH_3COCH_2). The stable products were CO, some ethane, ketene, and acetone. Addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

of CH_3 radicals to the reaction stream resulted in an increased yield of acetone and ethane, and the appearance of a peak at mass 72. The latter was attributed to the formation of methyl ethyl ketone by combination of methyl with acetonyl radicals. There was no indication of the formation of $CH_3COCH_2COCH_2CH_3$, suggesting that the $CH_3COCH_2COCH_2$ radical was not present in significant amounts. These qualitative results suggest that acetylacetone decomposes mainly by a split into two radicals:

$$CH_3COCH_2COCH_3 + Hg^* \rightarrow CH_3COCH_2 + CH_3CO. \quad [24]$$

Since the CH_3CO radical could be detected at low-electron energies, it is possible that a considerably larger fraction of the CH_3CO radicals survives the primary step than in the case of biacetyl.

The mode of reaction with acetylacetone with excited mercury atoms is undoubtedly quite complicated in detail. Acetylacetone vapor is 76.5% in the enol form under equilibrium conditions (16) and at first sight it might be thought that the keto and enol forms could be excited at different higher states and dissociate by different modes. However, it appears from the present experiments that CH_3CHO, a reasonable product from the dissociation of an enol-type excited molecule, is not formed to any extent. It is interesting to note that in the mass spectrum (No. 806 in the API Mass Spectral Catalog) there are no ions such as $CH_3{}^+COH$ which might arise from dissociation of an enol-type parent ion. There is no reason to believe, therefore, that the keto–enol tautomerism also exists among the excited and ionic states of acetylacetone.

A qualitative examination of the products formed by the mercury-photosensitized decomposition of acetonylacetone was also carried out in the same way. Using low-energy electrons, products were found having the following parent peaks: mass 15 (CH_3), mass 42 (ketene), and mass 43 (CH_3CO). No increase in the mass 57 peak, corresponding to the acetonyl radical, was found. Other products formed were ethane, acetone, products having parent masses of 70 and 86, and possibly a little ethylene. The addition of CH_3 radicals (from $Hg(CH_3)_2$) to the reaction stream gave a greatly enhanced yield of the products of mass 58 and 86, indicating the presence of radicals of mass 43 and 71. This shows that the predominating mode of dissociation is into two radicals according to the reaction:

$$CH_3COCH_2CH_2COCH_3 + Hg^* \rightarrow CH_3CO + C_2H_4COCH_3 + Hg. \quad [25]$$

Since no methyl ethyl ketone was formed on the addition of CH_3 radicals it may be concluded that the concentration of acetonyl radicals was negligibly small, and that the alternative mode of dissociation

$$CH_3COCH_2CH_2COCH_3 + Hg^* \rightarrow 2CH_3COCH_2 + Hg \quad [26]$$

occurred to a much smaller extent, if at all.

A third mode of dissociation is possible:

$$CH_3COCH_2CH_2COCH_3 + Hg^* \rightarrow CH_3 + COCH_2CH_2COCH_3 + Hg. \quad [27]$$

However, the addition of CD_3 radicals (from $Hg(CD_3)_2$) to the reaction stream did not result in any formation of the combination product $CD_3COCH_2CH_2COCH_3$ at mass 117. Although this experiment strongly suggests that no $COCH_2CH_2COOH_3$ radicals were present, it is possible that some of the radicals at mass 71 arose from reaction [27] followed immediately by a loss of CO from the large radical. On the other hand, the large yield of CH_3CO radicals shows that a large fraction of the radicals of mass 71 was formed by reaction [25]. In view of earlier observations that free radicals may react

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

rapidly with excited Hg atoms (10, 11) the small amount of product of mass 70 may have been formed by the reaction:

$$C_2H_4COCH_3 + Hg^* \rightarrow CH_2 = CHCOCH_3 + H + Hg. \qquad [28]$$

In view of the unexpected stability of the $C_2H_4COCH_3$ radical, further experiments were carried out in an attempt to obtain a more exact identification. A simple bond rupture as in equation [25] would be expected to give a radical having the structure $\dot{C}H_2CH_2COCH_3$. The addition product of this radical with the added CH_3 radicals would therefore be expected to be methyl *n*-propyl ketone. The mass spectrum of this ketone shows major peaks at masses 86, 71, and 57.[3] Although the observed addition product had major peaks at masses 86 and 71, the peak at mass 57 was much too small for this product to be methyl *n*-propyl ketone. The lack of a mass 57 peak would be explained if the addition product were instead methyl isopropyl ketone, which has major peaks at masses 86 and 71, but not at mass 57. This observation suggests that the large radical formed in reaction [25] had the structure $\dot{C}H_3CHCOCH_3$ rather than the structure $\dot{C}H_2CH_2COCH_3$, presumably as a consequence of a hydrogen atom shift in the excited molecule prior to dissociation. If such were the case the stability of the $C_2H_4COCH_3$ radical would be explained, since for the former one can write two resonating structures:

$$CH_3\dot{C}H{-}\underset{\underset{O}{\|}}{C}CH_3 \leftrightarrow CH_3CH{=}\underset{\underset{O\cdot}{|}}{C}CH_3.$$

The $\dot{C}H_2CH_2COCH_3$ radical, on the other hand, would be expected to dissociate easily into C_2H_4 and $COCH_3$. Without a more definite identification of the ketone addition product, this conclusion as to the identity of the $C_2H_4COCH_3$ radical must be regarded as tentative.

[3]*The data in the Mass Spectral Catalog, API Project 44, are in disagreement as to the spectrum of methyl n-propyl ketone. Spectra Nos. 299 and 378 show a large 57 peak, but No. 651 shows instead a mass 57 peak of only 0.35. A spectrum of methyl n-propyl ketone obtained in the present work agreed with spectra Nos. 299 and 378 in this respect. It is possible that a misprint in No. 651 has given 0.35 instead of 10.35 for the mass 57 peak.*

STERIC INHIBITION OF RESONANCE

V. NITROMESITYLENE[1]

JAMES TROTTER[2]

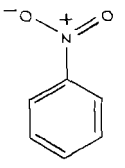
ABSTRACT

A detailed X-ray investigation of the crystal structure of nitromesitylene has shown that the nitro group is twisted 66° out of the plane of the aromatic ring about the C—N bond. The resulting decrease in resonance interaction compared with a completely planar model has been correlated with the characteristic NO_2 vibration frequencies.

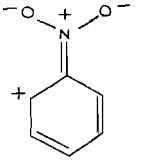
INTRODUCTION

The physical properties of the nitro and acetyl derivatives of mesitylene and durene indicate that resonance interaction between the nitro and acetyl groups and the aromatic rings is markedly reduced in comparison with nitrobenzene and acetophenone, suggesting that the steric effect of the methyl groups prevents the attainment of completely coplanar configurations (1).

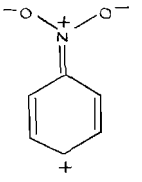
The dipole moments, for example, of conjugated aromatic nitro compounds, such as nitrobenzene (I), are larger than those of the corresponding aliphatic molecules, the moment of nitrobenzene in benzene solution being 3.95 Debye units compared with about 3.3 D for an aliphatic nitro compound. The increased dipole moments are due to contributions from ionic structures (II and III) which are at a maximum when the nitro



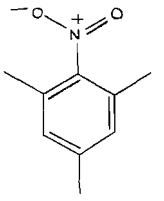
I



II



III



IV

group is coplanar with the aromatic ring. The introduction of methyl groups ortho to the nitro group, as in nitromesitylene (IV), reduces the dipole moment to 3.65 D, suggesting that the nitro group is twisted out of the plane of the benzene nucleus, and the contributions of structures II and III are reduced.

[2]*National Research Council Postdoctorate Fellow.*

Raman spectra evidence leads to similar conclusions. The Raman shift corresponding to the NO_2 symmetrical stretching vibration is at 1367 cm^{-1} in phenylnitromethane, $Ph.CH_2.NO_2$, where the nitro group is not conjugated with the ring, and at 1341 cm^{-1} in nitrobenzene; the frequency in nitromesitylene is 1363 cm^{-1}, much closer to the value in the non-conjugated molecule, again indicating a significant inhibition of the resonance between the nitro group and the aromatic π-electrons. The ultraviolet absorption spectrum of nitromesitylene also suggests a marked reduction in the resonance interaction.

Similar deviations from coplanarity and consequent resonance inhibition are to be expected in 9-nitroanthracene and 9,10-dinitroanthracene where the nitro group environments are similar to those in nitromesitylene. Detailed investigations of the crystal structures of these anthracene derivatives by X-ray diffraction methods have shown that the nitro groups are twisted markedly out of the planes of the aromatic rings, by 64° in crystals of 9,10-dinitroanthracene, and by 85° in crystals of the 9-nitro derivative. The reductions in resonance interaction resulting from these deviations from coplanarity have been correlated with the infrared spectra and with the bond length variations in the molecules, the energy of resonance interaction between a nitro group and the aromatic π-electrons in 9,10-dinitroanthracene in the solid state being about one-fifth of that in a completely planar model, while for 9-nitroanthracene this resonance energy is negligible. Configurations with 64° twist are the most stable for isolated molecules of both substances, but in crystals of 9-nitroanthracene crystal forces apparently result in minimum energy when the twist is 85°. In solution the angles are the same in both molecules, the exact values possibly depending on solvent–solute interactions.

The present communication describes the extension of these investigations to nitromesitylene; the angle between the plane of the nitro group and the aromatic plane has been determined by an accurate X-ray analysis of the crystals, and the resultant resonance inhibition has been correlated with the characteristic vibration frequencies of the nitro group, both in the solid state and in solution.

EXPERIMENTAL

Infrared Spectra

The spectra measured (Fig. 1) were those of pure nitromesitylene in carbon tetrachloride solution and dispersed in a Nujol mull, as observed with a Perkin–Elmer model 21 infrared spectrophotometer with a rock salt prism.

X-Ray Analysis

Crystals of nitromesitylene are orthorhombic with four molecules in a unit cell of dimensions $a = 15.14$, $b = 8.41$, $c = 7.26$ Å, space group $Pna2_1$. The structure was determined from projections along the three principal crystallographic axes. All the carbon atoms and the nitrogen atom lie on one plane, but the oxygen atoms lie one above and one below this plane at distances of 0.95 Å, so that the nitro group is twisted very markedly out of the plane of the aromatic ring about the C—N bond, the angle between the planes of the benzene ring and the nitro group being 66.4°. Figure 2 shows a projection of the structure along the *b*-axis; the benzene ring is perpendicular to the plane of projection so that the individual atoms are not resolved, but the large deviation of the oxygen atoms from coplanarity is well illustrated. Full details of the crystal structure analysis are published elsewhere (2).

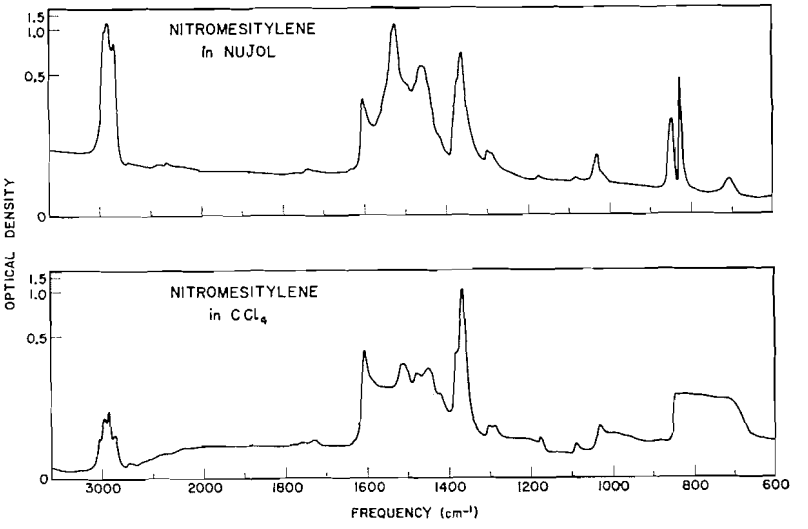

FIG. 1. Infrared spectra.

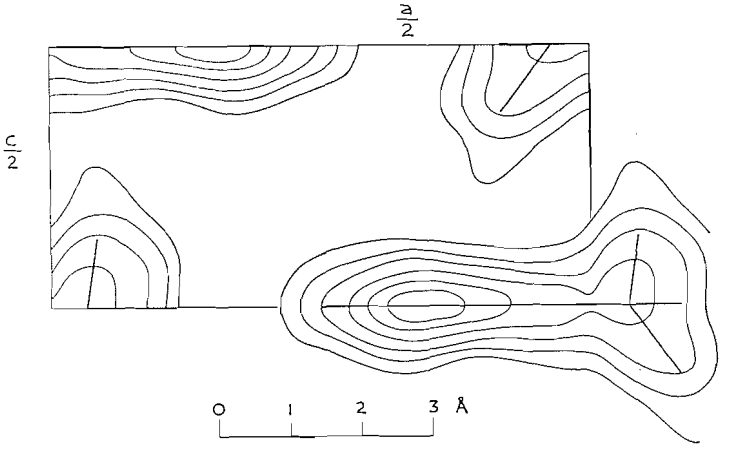

FIG. 2. Projection of the structure of nitromesitylene along the *b*-axis.

DISCUSSION

The spectra of nitromesitylene in the range 3500 cm^{-1} to 600 cm^{-1} in carbon tetrachloride solution and dispersed in a Nujol mull are shown in Fig. 1, and the peak positions and intensities of the absorption bands are listed in Table I, some peaks of course being masked by the carbon tetrachloride or Nujol bands. The strong absorption at 1364 cm^{-1} in solution and 1362 cm^{-1} in the solid state can be assigned to the NO_2 symmetrical stretching vibration. The NO_2 antisymmetrical stretching vibration cannot be assigned quite so unambiguously, as with the nitroanthracenes, but is probably at 1531 cm^{-1}. The absorption maximum at 828 cm^{-1} corresponds to the C—N stretching vibration.

The characteristic NO_2 frequencies in nitromesitylene are compared in Table II with the corresponding frequencies in conjugated (3) and non-conjugated (4) nitro compounds and with those in 9-nitroanthracene and 9,10-dinitroanthracene. The twists of the nitro

1090	w	1085	w	Characteristic aromatic bands
1031	w	1033	w	
		849	m	Aromatic C—H out-of-plane vibration
		828	s	C—N stretching

TABLE II

Characteristic nitro-group frequencies (cm^{-1}) and deviations from coplanarity in nitromesitylene and related molecules

Molecule	NO_2 stretching		C—N stretching	NO_2 twist, θ in degrees
	Symmetrical	Antisymmetrical		
Non-conjugated	1377	1586	800→900	90.0
9-Nitroanthracene	1374	1540	836	84.7
Nitromesitylene	1362	1531	828	66.4
9,10-Dinitroanthracene	1367	1542	831	63.7
Conjugated	1349	1518	849	0

groups out of the aromatic planes are included in the last column of the table. The NO_2 symmetrical stretching vibration in nitromesitylene at 1364 cm^{-1} in solution and at 1362 cm^{-1} in the solid state indicates, as in 9,10-dinitroanthracene, that resonance interaction between the nitro group and the aromatic π-electrons is markedly reduced in comparison with a completely conjugated nitro compound, but is not negligible. This conclusion is in agreement with the effect which would be predicted from the measured twist of the nitro group out of the aromatic plane, the predicted resonance energy being about one-fifth ($\cos^2 66.4° = 0.16$) of that for a planar model.

As with the nitroanthracenes the frequencies in solution cannot be directly correlated with the values in the crystals and with the twists of the nitro groups out of the aromatic planes, since the possible effects of solvent–solute interactions cannot be estimated; it can only be deduced that the angle in solution is between 66° and 90°.

SOLVOLYSIS IN HYDROGEN AND DEUTERIUM OXIDE

III. ALKYL HALIDES[1]

P. M. LAUGHTON[2] AND R. E. ROBERTSON

ABSTRACT

Rate data for the hydrolysis of a series of α- and β-methylated allyl, benzyl, and cycloalkyl halides in light and heavy water are compared. The major factor determining the rate ratio k_{D_2O}/k_{H_2O} appears to be the relative stability of the initial solvation shell. When the relative viscosity of H_2O and D_2O is used as a measure of the relative stability of structure in bulk solvent, the observed kinetic isotope effect and the temperature dependence of the isotope effect can be rationalized in terms of accepted properties of aqueous solutions.

Attention is drawn to the anomalous rate ratio $k_{RBr}/k_{RI} > 1$ which appears to be characteristic of solvolysis of these alkyl halides in pure water in contrast to other media.

In an extension of recent solvolytic studies of strongly solvated substrates, chiefly sulphonates (1), rates were obtained for the solvolysis of a variety of halogen compounds in light and heavy water. This work was done on the premise that the isotope effect derived from the rate ratio k_{D_2O}/k_{H_2O} was insensitive to temperature, a conclusion based on earlier work on the benzenesulphonates and methanesulphonates (2). However, a recent determination of $\Delta C_p^{\ddagger}$ for isopropyl bromide in light and heavy water (3) has cast doubt on the general applicability of this assumption. Since it was not practical to determine the $\Delta C_p^{\ddagger}$ for each of the alkyl halides for which we had a rate ratio at one temperature, we give here the rate ratios at the convenient experimental temperatures, both because we propose to refer to them later and because even subject to the above proviso they provide, for the detailed mechanism of hydrolysis, clues which deserve discussion.

EXPERIMENTAL

The methods of measuring kinetic rates were similar to those used previously (4). Easily volatile solutes were added under vacuum to the reaction flask, containing deaerated water and the potassium salt of the corresponding acid (0.003 *M*) either from a gas burette or from an evacuated side arm. With some solutes of low solubility, especially the benzyl bromides, a saturated solution was formed, and a fritted glass disk in the filling line was required to remove the small undissolved globules of the halide. With these latter solutes, supersaturation difficulties were occasionally encountered, as shown by non-linear rate plots.

Most of the halides were commercial samples (chiefly Eastman Kodak-White Label), distilled before use with a Fenske (low boiling) or Vigreux (high boiling) column, and passed through an alumina column to give refractive indices in agreement with published values. The following compounds were prepared by the methods indicated: cyclopentyl chloride (5), *p*-methylbenzyl bromide (6), neopentyl bromide (7), and *t*-butyl fluoride (8).

DISCUSSION OF RESULTS

The rates of hydrolysis in light and heavy water and rate ratios for a series of saturated alkyl halides are given in Table I. Similar data for a series of unsaturated or cyclic

compounds are given in Table II. The rate ratios for benzal chloride and benzotrichloride were included since Bensley and Kohnstam have recently suggested (16) that these compounds react by an ionizing mechanism.

The model we have used for aqueous solutions in previous papers (4, 17) has approximated to that proposed by Frank and Evans (18). However, the term "iceberg" has a connotation of a greater degree of rigidity than is intended. The problem is to find some graphic word which will take account of the high degree of structure in water and at the same time take cognizance of the dynamic situation demonstrated by self-diffusion (19) and solvation exchange (20, 21). This semantic difficulty is both illustrated and in some degree accommodated by Frank's "fluttering cluster" hypothesis (22). For the sake of simplicity, however, we have chosen to discuss the isotope effect in terms of the static term "structure" in spite of the limitations which this abstraction implies. The opposing effects of non-electrolytes and ions on the associated water in aqueous solutions are conveniently discussed in terms of characteristic changes in structure, and when considered differentially, these changes provide a basis for interpreting the isotope effect observed when D_2O replaces H_2O as a medium for hydrolysis.

Aqueous Solutions of Non-Electrolytes and Ions

When a non-electrolyte is introduced into water, its mere presence removes some degree of librational freedom (23, 18), or in terms of Frank's "fluttering cluster" theory (22) its presence interferes with the shifting centers of organization in such a way as to cause a greater interaction between those molecules immediately contiguous to the non-electrolyte. This has been described as leading to the formation of icebergs about the solute but it is probably a better approximation to specify that a particular water molecule in the primary solvation shell spends more time in each configuration than is characteristic of bulk water (24, 25). The net effect of this loss of freedom will clearly be proportional to the number of water molecules in the surface layer thus leading to such regularities between structures and solvation parameters as are recognized in the Barklay–Butler rule (26).

Evidence that the stability of the solvation shell about non-electrolytes in aqueous solutions decreases with rising temperature is derived from the decrease in the negative enthalpy characterizing the gas–solution equilibria (i.e. $\delta_s C_p$ is positive). In the activation process for hydrolysis the energy required to break down this initial state solvation shell ($\Delta F^{\ddagger}_{str}$) will also be expected to show a similar temperature dependence. This has been invariably found (17) with the obvious difference that since $\Delta H^{\ddagger}$ is positive, $\Delta C^{\ddagger}_p$ is negative for the latter process.

The added energy required to reorganize this initial state solvation shell is given formal recognition in equation [1]

$$[1] \qquad \Delta F^{\ddagger} = \Delta F^{\ddagger}_{I} + \Delta F^{\ddagger}_{str} - \Delta F^{\ddagger}_{R\delta+} - \Delta F^{\ddagger}_{X\delta-}$$

where $\Delta F^{\ddagger}$,* the free energy of activation, is shown to be the difference between (*a*) the energy of bond breaking plus the energy required for the breakdown of the initial state solvation shell and (*b*) the sum of the two terms representing the interaction of the water with the transition state. The intention here is *not* to suggest that complete charge development has necessarily been achieved in the transition state but rather to emphasize interaction with the cationic and anionic functions of the solute.

Ions of intermediate size such as $Cl^{\ominus}$, $Br^{\ominus}$, or $I^{\ominus}$, in contrast to non-electrolytes, appear to have a net structure-breaking effect on water (17), or to use the Bernal–Fowler

*Symbols are the same in this paper as in ref. 17.

description, such ions raise the structural temperature of the water (27). The specific effect will be strongly dependent on the charge density at the surface of the ion, and for singly charged ions this leads to the well-known gradation of solvation properties with size (28, 29). The extension of such considerations to the effect of charge development on adjacent water molecules in the activation process would seem obvious. The majority of salts are known to be more soluble in H_2O than in D_2O (30) presumably because the former already has a less stable structure (see below), and it would seem equally probable that in the hydrolysis of neutral esters, the transition state would be favored by H_2O over D_2O in agreement with the observed isotope effect. It is unlikely, however, that this is the major factor determining the k_{D_2O}/k_{H_2O} ratio.

Kinetic Isotope Effect

In all of those experimental situations where a breakdown of water–water structure is involved, e.g. viscosity (31), mobility of ions (32), self-diffusion (19), dielectric relaxation (33), D_2O invariably gives evidence of a greater degree of structure than H_2O at the same temperature. Since each of the above physical reorganization processes appears to depend on the same elementary step, the similarity found for the isotope effect in each of these processes is to be expected. In terms of the formalism noted above we have adopted this isotope ratio as a measure of the relative structural stability of D_2O versus H_2O toward reorganization. Since the activation process for the hydrolysis of the alkyl halides will involve a reorganization of solvent from a condition characterizing the solvation of non-electrolytes to that characterizing the solvation of the quasi-ionic transition state, it would seem reasonable that the above norm when coupled with recognized differences in the structural stability of water contiguous to non-electrolytes and to ions would provide a convenient basis for discussing the observed isotope effects (k_{D_2O}/k_{H_2O}). To use viscosity as a measure of structural stability in a kinetic equation is by no means novel (34, 35), although this factor is normally considered to have negligible effect on the reaction rate (36).

Formal representation of the kinetic isotope effect follows directly from equation [1]

$$[2] \qquad -RT \ln k_{D_2O}/k_{H_2O} = \delta_M \Delta F^{\ddagger} = \delta_M \Delta F^{\ddagger}_{str} - \delta_M \Delta F^{\ddagger}_{R^{\delta+}} - \delta_M \Delta F^{\ddagger}_{X^{\delta-}}$$

and in the following an attempt will be made to evaluate the relative contribution of the three factors on the right-hand side of equation [2].

If we consider the isotope effect for fluidity (ϕ_{D_2O}/ϕ_{H_2O}) as a normal value for the relative stability of water structure toward reorganization, then it will be apparent that the kinetic isotope effect at any temperature as indicated by the rate ratio (k_{D_2O}/k_{H_2O}) tends toward values either below or above this norm (Fig. 1). This grouping of relative kinetic isotope effects with respect to the assumed "norm" follows, to a remarkable degree, the changes to be expected in the relative stability of the initial state solvation shell.

Just as small ions may be regarded as raising the structural temperature of the water molecules associated with them, so non-electrolytes may be considered to lower the structural temperature of the surrounding water molecules. For solutes such as the alkyl halides, which do not interact strongly with the primary solvation shell, the isotope effect arising from the breakdown of the more stable initial state solvation shell will reflect this added stability, and hence will correspond to a lower temperature, that is, a larger isotope effect than for the corresponding "normal" ϕ_{D_2O}/ϕ_{H_2O} value which reflects the relative stability of the water structures at the experimental temperature. Since on this hypothesis the kinetic isotope effect (k_{D_2O}/k_{H_2O}) will largely arise from water–water

interaction, this ratio will tend to be the same for all esters at a given temperature, a conclusion supported by the results in Tables I and II. That this conclusion is not exactly true is not too surprising, since small effects will be expected to arise as a consequence of characteristic differences in the solvation of the alkyl halides and differentially result in the observed scatter of points (Fig. 1). On the other hand, esters containing the sulphonic group show a much smaller isotope effect and in terms of the present formalism may be regarded as raising the structural temperature of the water solvating the initial state, thus decreasing the relative difference between rates in D_2O and H_2O. The difference between the halides and the sulphonates becomes larger at lower temperatures, the characteristic curve for the halides lying below and roughly paralleling the "normal" viscosity isotope curve while the isotope ratios for the solvolysis of the sulphonates change by but a few per cent through the temperature range 5–80° C.

Apparently *t*-butyldimethylsulphonium ion with a rather weak field also belongs to the class of molecules that interact strongly, like the sulphonates, and hence have a reduced isotope ratio ($k_{D_2O}/k_{H_2O} = 0.94$). On the other hand, methyl nitrate (0.83 at 85° C) and benzenesulphonyl chloride (0.63 at 10° C) and methanesulphonyl chloride (0.63 at 20° C) do not. Indeed the latter compounds, along with benzal chloride (0.66 at 30° C) and benzotrichloride, (0.79 at 5.1° C) show such wide deviations from the norm as to suggest major differences in mechanism.

There appears to be a minor trend toward a decreased isotope effect through the α-methylated series (Table I) and a tendency for some of those molecules which from other considerations would be expected to have a greater degree of charge development in the transition state to give isotopic ratios which lie below the "normal curve". If these molecules were more ionic in the initial state the predicted ratio would lie above

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

the normal curve as shown by the sulphonates. An opposite effect would suggest some minor contribution to the isotope effect from $\delta_M \Delta F^{\ddagger}_{R\,\delta+}$ and $\delta_M \Delta F^{\ddagger}_{X\,\delta-}$ as discussed above. Before any particular significance can be attached to such deviations, however, the temperature dependence of the ratios must be examined for the individual solutes.

The Halide Anomaly

While it is not the purpose of this paper to discuss the effect of changes in structure on the rate of alkyl halides hydrolyzing in water, although this would appear to be the first time that such data have been published for many of the substrates in Tables I and II, it is of interest to note that the relative rates of hydrolysis of alkyl halides are in the unusual order $k_{\text{bromide}} > k_{\text{iodide}} > k_{\text{chloride}}$. This order was first noted by Moelwyn-Hughes 20 years ago (9) for the methyl compounds and is now seen to be characteristic of other alkyl halides hydrolyzing in water. The "normal" order of reactivity $k_{\text{iodide}} > k_{\text{bromide}}$ is found for all bimolecular displacement reactions at a saturated carbon atom of which we are aware (see the recent review by Streitwieser for a summary (37)) save for displacement by OH^- in water (9), and is also the order for the solvolysis of tertiary halides in 80/20 ethanol–water where the mechanism has been assumed to approach a limiting (11), i.e. an ionization or S_N1, type.

Since this reversal of order cannot be attributed to a change in the alkyl group from one which requires a large degree of nucleophilic interaction (primary halides) to the tertiaries where this requirement is reduced if not absent, and since the order for the so-called border line compounds (the isopropyl halides hydrolyzing in 60/40 ethanol–water (37)) is also the normal order $k_{\text{iodide}} > k_{\text{bromide}}$, we are led to conclude that the the reverse order found for halides in pure water derives from some peculiarity in ion–dipole interaction which favors the bromide in the above reactions: note for example the order of the mobilities Br > I > Cl.

ACKNOWLEDGMENT

We wish to acknowledge the careful technical assistance of Mr. S. Sugamori throughout the course of this investigation.

SYNTHESIS OF CYCLIC PHOSPHOROUS ACID ESTERS BY TRANSESTERIFICATION[1]

ALEXIS A. OSWALD

ABSTRACT

Five- and six-membered cyclic phosphorous acid esters were synthesized by transesterification of phosphites with 1,2- and 1,3-glycols: Diethyl hydrogen phosphite was transesterified to give cyclic hydrogen phosphites. Partial transesterification of tris-2-chloroethyl phosphite resulted in cyclic 2-chloroethyl phosphites.

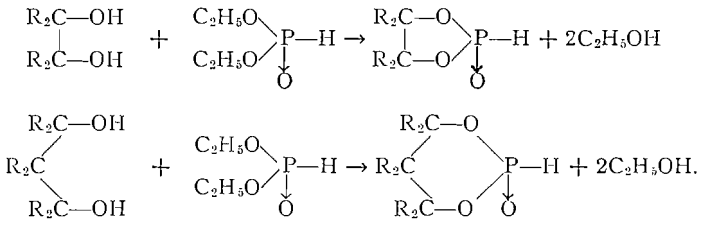
Organic phosphites are potentially important chemicals as antioxidants in the petroleum and plastics industry (1, 2, 3). Their usefulness is limited, however, by their hydrolytic instability. Recently, the extreme resistance of *cis*-1,3-cyclohexylidene phosphate to hydrolysis was reported (4). This report together with earlier knowledge (5) regarding the stability of 2,3-dimethyl-2,3-butylene hydrogen phosphite initiated the present work of synthesizing new cyclic phosphites.

SYNTHESIS OF CYCLIC HYDROGEN PHOSPHITES

One of the earliest methods for synthesizing dialkyl esters of phosphorous acid is the direct esterification (6, 7) by heating phosphorous acid with the appropriate alcohol. The first syntheses of cyclic hydrogen phosphites were probably accomplished by starting from phosphorous acid and various glycols. However, there is little evidence of a single pure product being isolated (8).

Another method for the synthesis of cyclic hydrogen phosphites is the hydrolysis of cyclic chlorophosphites (5, 9, 10, 11) or alkyl phosphites (5). Saunders and his co-workers (12) reported the synthesis of a cyclic secondary diphosphite by reacting phosphorus trichloride with an excess of ethylene glycol.

In the course of this work, the transesterification of diethyl hydrogen phosphite with 1,2- and 1,3-glycols was accomplished. When 3-chloro-1,2-propylene glycol was used for transesterification, the known 3-chloro-1,2-propylene hydrogen phosphite or 2-hydroxy-4-chloromethyl-1,3,2-dioxaphospholane (13) was obtained. Analogously, the formation of other cyclic hydrogen phosphites with five-membered (dioxaphospholane) and six-membered (dioxaphosphorinane) ring structures was presumed according to the following equations:



R = H or alkyl

In the transesterification experiments, 1 mole of 1,2- or 1,3-glycol was used per mole of hydrogen phosphite. The reactions were carried out between 130 and 140° C at

Contribution from the Research Department, Imperial Oil Limited, Sarnia, Ontario, Canada.

120–150 mm. When the liberation of the by-proudct ethanol ceased, the remaining crude product was fractionated at pressures between 2 and 3 mm. The purified compounds are liquids with the exception of the white crystalline 2-hydroxy-5,5-dimethyl-1,3,2-dioxaphosphorinane. Some of the physical and analytical data and the yields of the compounds obtained are shown in Table I.

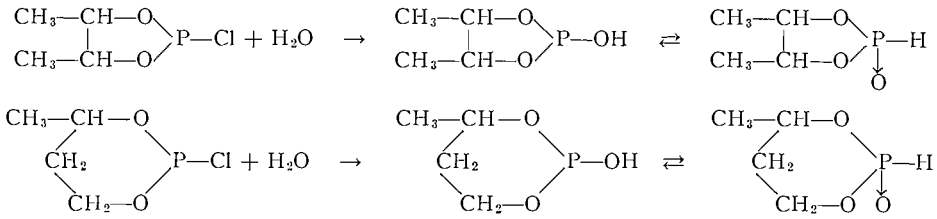
*First synthesized by Arbuzov and Zoroastrova (10).

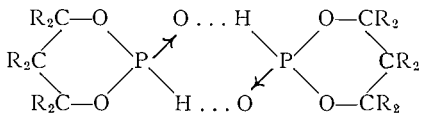
Unequivocal syntheses of the cyclic butylene hydrogen phosphites were also carried out to prove the five- and six-membered ring structures respectively. These syntheses started from the appropriate butanediols and phosphorus trichloride. In this manner, the corresponding cyclic chlorophosphites (11, 12) were prepared. These compounds yielded the cyclic hydrogen phosphites after hydrolysis with the stoichiometric amounts of water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.



It can be assumed from the high yield of the product of hydrolysis that the water attack results in the selective removal of the chlorine without ring opening. The identity of the infrared spectra of the compounds obtained in this manner with the butanediol transesterification products verifies the assumed five- and six-membered ring structures.

All the liquid cyclic hydrogen phosphites prepared are highly viscous materials with high boiling points. These properties probably indicate intermolecular association as shown by B. A. Arbuzov and Vinogradova (13) in the case of dialkyl phosphites. In the case of the hydrogen phosphite tautomer such an association can be depicted as follows:



This assumption is supported by the observation that the cyclic hydrogen phosphites prepared from the chlorophosphites became viscous only after several days' standing after distillation.

Transesterification with ethylene glycol resulted in a compound having an identical boiling point with the cyclic diethylene diphosphite mentioned previously.

SYNTHESIS OF CYCLIC PHOSPHITES

Transesterification of phosphite esters was first performed by Milobendzki and Szulgin (14). They prepared propyl- and butyl-diphenyl phosphite from triphenyl phosphite by the action of the corresponding sodium alcoholates according to the following equation:

$$(Ph—O)_3P + NaOR \rightarrow (Ph—O)_2POR + Ph—ONa.$$

Some patents claim transesterification of triarylphosphites with alcohols (1, 2); for example, the synthesis of alkyl diaryl phosphites by the following reaction:

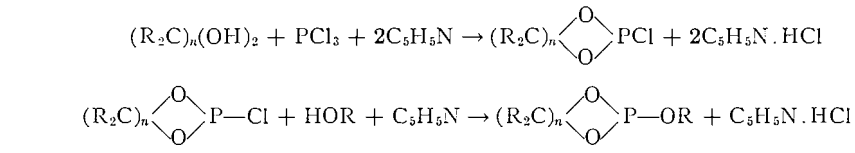
$$(ArO)_3P + HOR \rightarrow (ArO)_2POR + HOAr.$$

A recent German patent (15) claims the transesterification of tris-2-chloroethyl phosphite with several alcohols. However, in this work the transesterification reaction with polyhydric alcohols was mentioned as giving polymeric products.

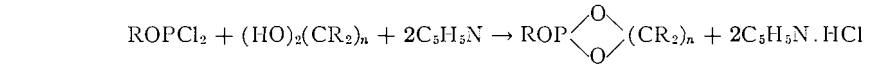
The reinvestigation of the latter transesterification in these laboratories revealed some new facts suggesting the formation of monomeric cyclic phosphite esters by partial transesterification of tris-2-chloroethyl phosphite with 1,2- and 1,3-glycols.

In previous work, cyclic phosphite esters have also been synthesized from the corresponding cyclic chlorophosphites, which in turn were prepared from phosphorus trichloride and diols; in both cases with the help of an acid-binding agent (pyridine) (10, 11, 16, 17).

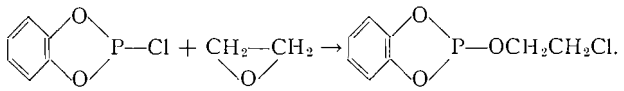
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.



Similar compounds can be synthesized starting with an alkyl dichlorophosphite and a diol.

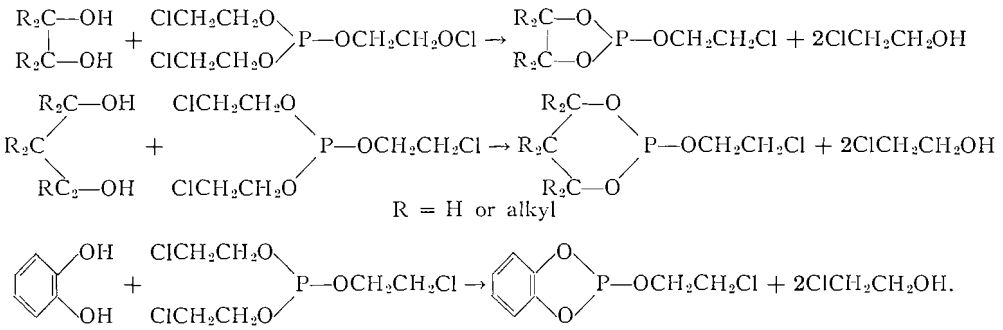


Cyclic catechol phosphites were prepared by an analogous method starting from catechol and phosphorus trichloride (18, 19). Chloroethyl catechol phosphite was synthesized by reacting ethylene oxide with catechol chlorophosphite according to the following reaction equation (20):



The stability of the cyclic phosphite esters is greatest for six-membered rings (10, 11, 16, 17).

Partial transesterification of 1 mole of tris-2-chloroethyl phosphite with 1 mole of 1,2- or 1,3-glycol was attempted. At elevated temperature and reduced pressure about 2 moles ethylene chlorohydrin per mole of phosphite was removed from the reaction mixture as indicated by the amount of the distillate in the receiver and the weight loss of the reaction mixture. After redistillation, the distillate was identified as ethylene chlorohydrin by boiling point, refractive index, and infrared spectrum. The formation of five- and six-membered cyclic chloroethyl phosphites is suggested according to the following general equations:



The lower glycols used in these reactions were not miscible with the tris-2-chloroethyl phosphite, but after standing at room temperature homogeneous mixtures were obtained. For preparative purposes, the reaction was performed by heating the ingredients between 60 and 100° C *in vacuo*, and the ethylene chlorohydrin distilled as it was formed. The remaining crude product was fractionated *in vacuo* yielding the purified, colorless cyclic chloroethyl phosphites usually as liquids, immiscible with water. Some of the physical and analytical data and the yields obtained are shown in Table II.

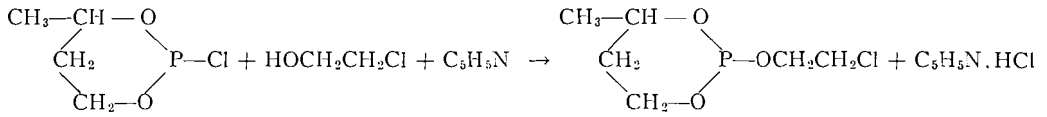
*For data on compound prepared by independent synthesis see Experimental part.

†Highly viscous liquid; tentative formula. For ethylene-2-chloroethyl phosphite Arbuzov (10) gives the following data: b.p. 78.5–79.5° at 65 mm, n_D^{20} 1.4755.

‡The greater part of the raw product is polymeric material, which cannot be distilled.

§Previously prepared by Kabachnik (20), who found b.p. 107–108° at 2.5 mm and n_D^{20} 1.5430. Catechol-2-chloroethane-phosphonic acid has b.p. 167–170° at 4.5 mm and n_D^{20} 1.5502 as reported by Kabachnik and co-workers (21).

Unequivocal syntheses of the cyclic butylene 2-chloroethyl phosphites were also carried out to prove the five-membered 1,3,2-dioxaphospholane and the six-membered 1,3,2-dioxaphosphorinane ring structures respectively. In these syntheses the corresponding cyclic chlorophosphites (10, 11) were reacted with ethylene chlorohydrin to give the cyclic 2-chloroethyl phosphites.



In the course of these reactions, if carried out below room temperature, Arbuzov transformation and ring opening are not likely to occur. Therefore, the identity of the infrared spectra of the compounds with the corresponding transesterification products supports the presence of the cyclic phosphite structures. A further indication of this structure is given by the comparison of the boiling point and refractive index of the catechol transesterification product with catechol 2-chloroethyl phosphite prepared by Kabachnik (20) from catechol chlorophosphite.

EXPERIMENTAL

Preparation of Cyclic Hydrogen Phosphites by Transesterification

Diethyl hydrogen phosphite (27.6 g, 0.2 m (mole)) and 1,2- or 1,3-glycol (0.2 m) were placed in a round bottom flask connected to a Claisen head fitted with a downward condenser and a receiver for vacuum distillation. The resulting solution was heated to 130° C at 120–160 mm pressure under nitrogen. The reaction proceeded as shown by the distillation of ethanol. Ethanol evolution ceased after about 3 hours' heating at the above temperature.

The remaining crude product was fractionated at 2 to 3 mm. The cyclic hydrogen phosphites were obtained as very viscous, colorless liquids. The yields and other data are given in Table I. Some high boiling materials remained in the distillation flask and were probably polymeric.

Preparation of Cyclic Chlorophosphites

To a solution of phosphorus trichloride (68.7 g, 0.5 m) in anhydrous ether (200 ml) a mixture of 2,3- or 1,3-butanediol (45 g, 0.5 m), pyridine (79 g, 1 m), and ether (200 ml) was added with vigorous stirring, while the temperature was kept below −5° C. The precipitated pyridinium chloride was removed by filtration and washed with ether. The combined clear filtrate was fractionated. After the removal of the ether, the cyclic chlorophosphites were distilled in vacuum and were obtained as colorless liquids.

Starting from 2,3-butanediol, 67 g (87%) 2-chloro-1,3,2-dioxaphospholane boiling at 54–56° C at 10 mm was obtained. The refractive index was n_D^{20} 1.4700. (Lucas and co-workers (11) obtained apparently the same product without an acid-binding agent. It had a boiling point of 66° C at 15 mm and a refractive index of n_D^{20} 1.4696.)

When 1,3-butanediol was used, the method gave 2-chloro-4-methyl-1,3,2-dioxaphosphorinane (69.5 g, 98%) boiling at 55–57° C at 10 mm. The refractive index of this product was n_D^{20} 1.4670. (Arbuzov and Zoroastrova (10) reported b.p. 65° C at 12 mm and n_D^{20} 1.4700. Lucas and co-workers (11) gave b.p. 66.6–67.5° C at 15 mm and n_D^{20} 1.4884.)

Synthesis of Cyclic Hydrogen Phosphites by the Hydrolysis of Cyclic Chlorophosphites

To a mixture of water (3.6 g, 0.2 m) and benzene (100 ml), the solution of the chlorophosphite (0.2 m) in benzene (250 ml) was added, while it was shaken. The reaction mixture was then stirred for one-half hour. The resultant clear, homogeneous solution was fractionated in vacuum, when the benzene solvent was removed at first under 160 mm pressure. The raw product was then distilled at 2 mm of mercury.

2-Chloro-4,5-dimethyl-1,3,2-phospholane gave on hydrolysis 2-hydroxy-4,5-dimethyl-1,3,2-phospholane (26 g, 95%). The product was obtained between 81° and 83° C at 2 mm and had a refractive index, n_D^{20} 1.4610. Comparison of infrared spectra showed identity with the 2,3-butanediol transesterification product.

Similarly, by the hydrolysis of 2-chloro-4-methyl-1,3,2-phosphorinane, this procedure resulted in the formation of 2-hydroxy-4-methyl-1,3,2-dioxaphosphorinane obtained as a colorless liquid (25 g, 92%) between 101 and 102° C at 2 mm. The refractive index is n_D^{20} 1.4528. Although this product was a mobile liquid after distillation, it became quite viscous after a few days and was similar to the transesterification product with 1,3-butanediol. The identity of the two products was then proved by comparison of their infrared spectra.

Preparation of Cyclic 2-Chloroethyl Phosphites by Transesterification

Tris-2-chloroethyl phosphite (26.9 g, 0.1 m) and 1,2- or 1,3-glycol (0.1 m) were placed in a round bottom flask connected with a Claisen head, downward condenser, and receiver

for vacuum distillation. The contents became homogeneous within 5 minutes when heated in a water bath. Reaction was performed at 18 mm under nitrogen. The heating was continued for about 1 hour, during which time the evolution of ethylene chlorohydrin was complete.

The colorless crude product was fractionated at 2–3 mm pressure to obtain the pure products as clear, colorless liquids, immiscible in water. See Table II for properties and yields.

Preparation of Cyclic 2-Chloroethyl Phosphites from Cyclic Chlorophosphites

To a solution of the cyclic chlorophosphite (30.9 g, 0.2 m) (2-chloro-4,5-dimethyl-1,3,2-dioxaphospholane and 2-chloro-4-methyl-1,3,2-dioxaphosphorinane respectively) in ether (200 ml), ethylene chlorohydrin (16.1 g, 0.2 m) and subsequently pyridine (15.8 g, 0.2 m) were added dropwise with stirring at 0° C or lower. After the addition, the reaction mixture was allowed to come to room temperature with continued stirring. Pyridinium chloride was removed by filtration and the filtrate was fractionated.

In this manner, beginning with 2-chloro-4,5-dimethyl-1,3,2-dioxaphospholane between 56 and 60° C at 1 mm, 31 g (79%) 2-(β-chloroethoxy)-4,5-dimethyl-1,3,2-dioxaphospholane (2,3-butylene-2-chloroethyl phosphite) was obtained, n_D^{20} 1.4659. The spectrum of this compound was identical with the product of transesterification reported in Table II.

When the same method was used, 2-chloro-4-methyl-1,3,2-phosphorinane gave 33 g (86%) 2-(β-chloroethoxy)-4-methyl-1,3,2-dioxaphosphorinane distilled between 54 and 56° C at 1 mm and having a refractive index of n_D^{20} 1.4697. This compound had an identical spectrum with the corresponding transesterification product reported in Table II.

ACKNOWLEDGMENTS

The author is greatly indebted to Mr. A. J. Stephenson for the infrared spectra, to Mr. E. G. Ulbricht and Miss A. F. Fischel for the phosphorus analyses, and to Mr. J. F. Eagen for the chlorine analyses.

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

V. SUR LA SYNTHÈSE DE 5-ARYLTOLUQUINONES[1]

P. BRASSARD ET P. L'ÉCUYER

RÉSUMÉ

Tout comme la chloroquinone la toluquinone réagit en milieu tampon avec les sels de diazonium aromatiques pour donner des monoaryltoluquinones. Cependant, par contraste avec les réactions de la première, qui donnent naissance à deux isomères monoarylés, les réactions de cette dernière n'ont permis d'isoler qu'un seul isomère monoarylé. Celui-ci est fort probablement la 2-méthyl-5-aryl-1,4-benzoquinone, car il a été vérifié dans un travail ultérieur que tel est bien le cas pour la 2-méthyl-5-phényl-1,4-benzoquinone.

Diverses 1,4-benzoquinones monosubstituées réagissent en milieu tampon avec les sels de diazonium pour donner des 1,4-benzoquinones bisubstituées. Ainsi, selon ces conditions, une monoaryl-1,4-benzoquinone (I = Ar) donne naissance à une 2,5-bisaryl-1,4-benzoquinone (II, X = Ar) (1, 2), tandis que la chloroquinone (I, X = Cl) fournit un mélange de deux monoaryl-1,4-benzoquinones isomères que nous avons d'abord cru être la 2-chloro-3-aryl-1,4-benzoquinone et la 2-chloro-6-aryl-1,4-benzoquinone (II, X = Cl) (3, 4).

X = Cl, CH_3 ou Ar Ar = groupe aryle

Tout comme la chloroquinone, la toluquinone (I, X = CH_3) en milieu tampon aqueux réagit avec les sels de diazonium aromatiques. La réaction est cependant beaucoup plus lente avec cette dernière, à moins que l'activité du sel de diazonium ne compense partiellement la faible réactivité de la toluquinone. Nous avons réalisé la synthèse de diverses monoaryltoluquinones (Tableau I) et nous n'avons toujours isolé qu'une seule substance, bien qu'il soit possible qu'un autre isomère soit présent dans le produit d'au

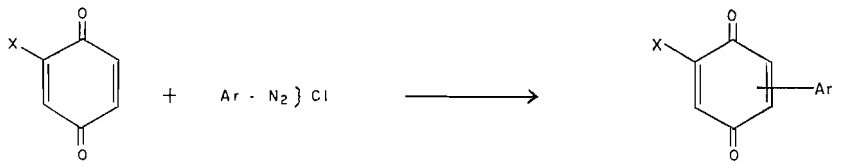
moins quelques réactions. L'isomère isolé est fort probablement la 2-méthyl-5-aryl-1,4-benzoquinone (II, X = CH_3). C'est du moins la conclusion qu'il s'impose de tirer d'un travail ultérieur (5) dans lequel nous avons pu vérifier que, dans le cas de la condensation de la toluquinone avec le chlorure de benzène–diazonium, c'est bien la 2-méthyl-5-phényl-1,4-benzoquinone que l'on obtient.

Les monoaryltoluquinones sont des solides cristallins jaunes. Elles s'obtiennent avec des rendements variant de 20 à 85% selon les difficultés qu'on a à surmonter lors de leur purification.



(I) (II)

PARTIE EXPÉRIMENTALE[2]

On diazote, entre 0 et 5°, l'amine (0.05 mole) dissoute dans un mélange de 12.5 ml d'acide chlorhydrique concentré et de 50 ml d'eau, en ajoutant une solution de nitrite de sodium (3.5 g) dans de l'eau (10 ml). La solution limpide du sel de diazonium est ensuite versée dans un mélange de 6.8 g (0.055 mole) de toluquinone, de 20.4 g (0.3 mole) d'acétate de sodium trihydraté et de 500 ml d'eau, qui est agité mécaniquement. Sauf pour les sels de diazonium les moins actifs, le dégagement d'azote se produit lentement même à la température ambiante. Sinon, on porte le mélange à 35–40° en plongeant le récipient dans un bain-marie. On continue d'agiter pendant quelques heures et on abandonne ensuite le mélange réactionnel à la température ambiante jusqu'à ce que le dégagement gazeux soit terminé (12 à 24 heures). On filtre ou décante la solution aqueuse, lave à l'eau le précipité ou le résidu et sèche ce dernier.

Il est quelquefois assez difficile de purifier l'aryltoluquinone, car elle est parfois contaminée par une quantité variable de résines. Celles-ci sont très solubles dans l'acétone, moins dans le méthanol et presque pas dans l'éther de pétrole. Par ailleurs, les aryltoluquinones sont aussi passablement solubles dans l'acétone, moins dans le méthanol et peu dans l'éther de pétrole. En conséquence, on ne réussit quelquefois à se débarasser complètement des résines par cristallisation dans le méthanol qu'en faisant bouillir à plusieurs reprises la solution avec du noir animal. D'autre part, en cristallisant dans l'acétone (noir animal) non dilué, on obtient vite l'aryltoluquinone à l'état pur. Dans les deux cas toutefois, le rendement s'en trouve considérablement diminué.

Les deux meilleures façons de procéder pour la purification des aryltoluquinones semblent les suivantes: (*a*) Comme la 2-méthyl-5-phényl-1,4-benzoquinone est relativement soluble dans l'éther de pétrole (p.é. 65–110°) bouillant, on l'extrait à plusieurs reprises dans ce solvant, on évapore les extraits à siccité sous pression réduite et on cristallise ensuite dans le mélange acétone–méthanol–eau (1:2:1); (*b*) quant aux autres aryltoluquinones qui sont trop peu solubles dans l'éther de pétrole bouillant, on les cristallise directement dans un mélange de méthanol–acétone ou méthanol–acétone–eau et on les décolore au noir animal.

[2]*Les points de fusion (p.f.) ne sont pas corrigés. Ils ont été déterminés dans un appareil de Vanderkamp.*

EBULLIOMETRY AND THE DETERMINATION OF THE MOLECULAR WEIGHTS OF POLYMERS

PART I. THE SMALL EBULLIOMETER[1]

W. R. BLACKMORE

ABSTRACT

An ebulliometer that has been in routine use for the determination of the number average molecular weight of polymers is described. The results obtained with two different series of polythenes (which were also measured elsewhere) are given. These results show this ebulliometer to be subject to experimental difficulties which limit it to number average molecular weights of perhaps 20,000 depending on the precision required.

INTRODUCTION

Ebulliometry is the measurement of the difference in boiling point between a solution and a pure solvent at the same pressure. The technique may be used to measure the number average molecular weight of a polymer.

In the earliest work in ebulliometry, Beckmann (1) submerged one of his thermometers directly in the boiling liquid, first in the solvent and then in the solution, but the temperature difference thus determined was not accurately reproducible. It was found that there was superheat in the liquid and this was subject to large random fluctuations. Molecular weights of only the simplest compounds could be determined in this way. The situation was markedly improved by Cottrell (2), who first suggested the use of a vapor-lift pump. It was found that when pumped liquid was allowed to trickle down over a surface so that a thin film of liquid was in contact with solvent vapor, then temperature equilibrium was rapidly established. Furthermore this temperature was much more constant than in the main body of the boiling liquid itself (3).

Once the Cottrell pump had been introduced and the noise level reduced so greatly, it was not long before two transducers (4, 5) more sensitive than Beckmann thermometers were used in ebulliometry. These are still used in modern times (6, 7). After World War II new temperature-sensitive resistors, called thermistors (8), were developed to the point of being made available commercially. As applied in ebulliometry a steady-state temperature difference is established between two thermistors, each forming one arm of a Wheatstone bridge circuit. The temperature difference causes a resistance difference between the thermistor arms and this, in turn, produces an unbalance voltage which is amplified and recorded. In our apparatus the measured change in this unbalance voltage corresponding to the addition of weighed polymer pellets permits the polymer number average molecular weight $\bar{M}_n$ to be computed.

APPARATUS

Description of Glassware

The ebulliometer is shown in Fig. 1. This modified form of Ray ebulliometer (7) was designed in the Research Department of the Plastics Division of Imperial Chemical Industries Limited. The drawing was provided through the courtesy of Dr. Burnett.

[1]*Manuscript received April 3, 1959.*
Contribution from the Central Research Laboratory, Canadian Industries Limited, McMasterville, Que. A preliminary account of this work was presented to the Chemical Institute of Canada Meeting, Vancouver, June 1957.

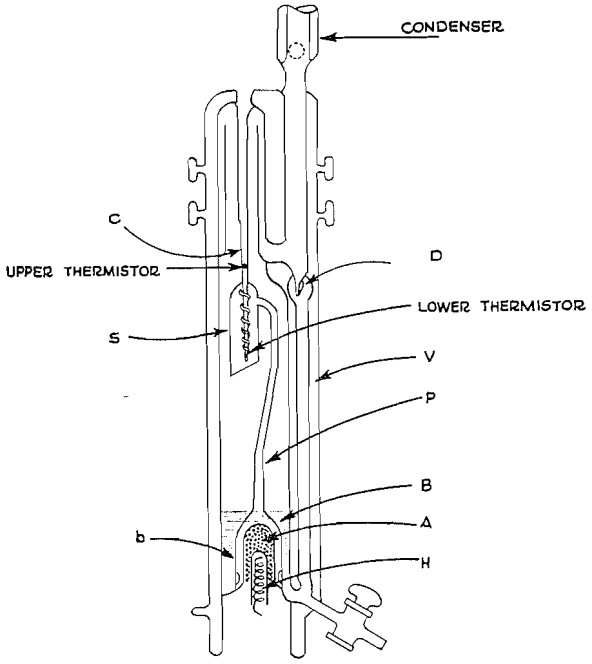

FIG. 1. The small ebulliometer.

The ebulliometer proper is protected from ambient temperature fluctuations by the silvered, vacuum jacket (V). Initially solvent is maintained at its boiling point in the boiler (B) by a bayonet heater (H) which heats by radiation and is not in contact with the boiling liquid. Polymer additions are made through the condenser. The stippled region (A) of the figure indicates crushed glass which has been fused to the inner surface of the boiler to promote boiling. The Cottrell pump (P) consists of a bell (*b*) and the stack up which boiling liquid is lifted by bubbles of vapor. When the liquid is ejected by the pump it is channelled by a spiral down the central core (C) which houses both thermistors. The shield (S) protects the lower tip of the well from any condensate which might roll down from the uppermost regions of the ebulliometer. The positioning of the thermistors is approximately as shown. The drop-counter (D), after Swietoslawski (3), was intended to provide a measure of the boil-up rate. In fact, it is frequently a source of experimental difficulty. Polymer pellets which only dissolve slowly may stick there temporarily and plug the condenser return line. This spreads a film of polymer on the upper reaches of the ebulliometer and spoils the run. The difficulty may be avoided by eliminating the drop-counter entirely. To protect the ebulliometer from atmospheric pressure fluctuations, it is connected by a wide-bore glass tube (2 in. diameter) to a 25-liter surge bottle which vents to the atmosphere through a length of capillary tubing. This does not reduce the pressure fluctuations within the ebulliometer produced by the surging liquid itself but it does remove the effects of draughts. Since improperly matched thermistors in Wheatstone bridge circuits may be very sensitive to atmospheric pressure changes it may be necessary to protect the ebulliometer from relatively long-term pressure drifts during the day. To do this a Cartesian Diver manostat (10) may be employed to control the pressure in the surge bottle.

Another experimental problem is that of thermal e.m.f.'s. Since a direct-current

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

thermistor bridge has been used with this ebulliometer, room temperature changes may produce drifts in the thermal e.m.f.'s which are large enough compared to the signals which are to be measured to seriously affect the results. This problem has been brought under control by mounting the ebulliometer and its associated electrical equipment in a thermostatted air bath. The design is not critical, the only requirement being that the box be large enough. The temperature is controlled at $34\pm0.5°$ C with a thermistor controller (11). The thermistor (32A11 V.E. Co.) (12) is situated close to the fan and main heater so that the response time may be fast. It should be pointed out that thermostatting does not remove the problem of thermal e.m.f.'s but merely renders the effects tractable.

Description of Electrical Components

The Wheatstone bridge is made up of two 52A11 V.E. Co. (12) thermistors which have been calibrated and matched in a manner to be described below. The remaining two arms of the Wheatstone bridge are fixed wire-wound resistors of accurately known resistance (nominally 2500 Ω) in series with a decade resistance box. Initially a Leeds–Northrup Model 9835-B, direct-current microvolt amplifier was used as the bridge output detector but this was replaced several years ago by a Liston–Becker (9), Model 14, breaker-type d-c. amplifier. The latter instrument is more sensitive. The amplifier output is fed through a resistance–capacitance network into a Brown "Electronik" potentiometer recorder (10 mv full scale).

It has been found desirable to use shielded cabling throughout. In those places where space was limited, for instance in the thermistor well, the Teflon coated leads were covered by a braided shield which was slipped as close to the extremities as possible. Thermal-free solder (with a low thermal e.m.f. to copper), supplied by the Liston–Becker Company (9), was used on all bridge connections. Originally all connections in the bridge were soldered. But during the course of time it has been found that it is more useful to have the leads from the bridge resistors enter a shielded junction box fitted with four double-pole single-throw heavy copper switches. With this arrangement it is easily possible to change thermistors, or to substitute wire-wound resistors for the thermistors if the electrical circuitry must be tested. All shields are connected directly to one ground point to avoid ground loops.

Thermistor Calibration

The thermistors which are to be calibrated are maintained at whatever temperature is desired in a large copper block. This copper block is heated by radiation and may be maintained (11) at any temperature, at least up to 300° C, with a precision of 0.001° C. The temperature of the copper block is measured with a platinum resistance thermometer and a Mueller bridge. The thermometer was calibrated at the National Physical Laboratory, Teddington, England. The resistances of the thermistors are measured with a Wheatstone bridge (Type 3352) manufactured by the Tinsley Company (13). A microvolt d-c. amplifier has been used to detect unbalance when thermistors are being calibrated, and this has been either a Liston–Becker (9) or the Leeds and Northrup. The unbalance voltage is fed from the amplifier to a Brown Electronik recorder. It is thus possible to follow slight changes in block temperature as well as measure the thermistor resistance simultaneously. The thermistor current normally used in calibrating a thermistor is about 25 μa so that the thermistor is only heated to a small fraction of a degree above its ambient temperature. Generally four or five thermistors are suspended in oil in the central well of the copper block simultaneously. It is thus possible to measure their

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

resistances consecutively at any one temperature before shifting the block temperature one or two degrees and taking another series of measurements.

BRIEF DESCRIPTION OF THEORY AND CALCULATION OF RESULTS

Fundamentally the apparatus behaves as follows: the two thermistor arms of the Wheatstone bridge are maintained at slightly different temperatures, because one thermistor is at the boiling point of the solvent while the other thermistor is at the boiling point of the solution. This difference in temperature, between the two thermistors, produces a resistance difference between them, and this, in turn, produces an unbalanced voltage signal from the bridge which is amplified and then displayed on the recorder. The actual value of the unbalance voltage which appears with a solution in the ebulliometer is of no particular significance. The only subject of concern is the *change* in this voltage produced when a pellet of solute of known weight is added to the boiling solution (or solvent).

It can be shown (14) that for any Wheatstone bridge in which all arms are of resistance R, except for one which has a resistance $R+\Delta R$, the unbalance voltage e_5 appearing at the detector is given by an expression of the form

$$[1] \qquad e_5 = k \,.\, i_b \,.\, \Delta R$$

where k is a constant,
i_b is the bridge current,
and ΔR the difference in resistance between the arms of the bridge.

The equation relating the resistance of a thermistor and its temperature (8) is

$$[2] \qquad R = R_0 \, e^{B/T}$$

where R is the thermistor resistance at temperature T °K,
R_0 is the thermistor resistance at some arbitrary reference temperature,
B is a constant related to the material of which the thermistor is made,
and T is the absolute temperature at which the resistance is desired.

Hence, assuming that we have two perfectly matched thermistors with the same R_0 and B, then if these are maintained at two slightly different temperatures T and $T+\Delta T$ their resistances will differ by an amount

$$[3] \qquad \Delta R = \frac{-B}{T^2} \,.\, R \,.\, \Delta T \,.$$

Thus substituting [3] into [1] we obtain an expression for the unbalance voltage obtained from a Wheatstone bridge when the two thermistor arms are maintained at temperatures differing by $\Delta T°$. This expression is

$$[4] \qquad e_5 = \frac{-kB}{T^2} \,.\, i_b \,.\, R \,.\, \Delta T \,.$$

The boiling point elevation (15) for an ideal solution (or any solution at infinite dilution) is given by

$$[5] \qquad \Delta T = \frac{R_g T^2}{L_g} \,.\, N_2$$

where R_g is the gas constant,
L_g the molar heat of vaporization,
T the boiling point in degrees Kelvin,
and N_2 the mole fraction of solute.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

When [5] is substituted in [4] and the constants are combined, an expression of the form

$$e_5 = Ki_b \,.\, R \,.\, N_2 \qquad [6]$$

is obtained. This relates the unbalance voltage to the mole fraction of solute in the solution. But as has been mentioned earlier, the *change* in unbalance voltage with *change* in solute concentration is the only measurement actually used in this work. That is

$$\Delta e_5 = Ki_b \,.\, R\Delta N_2. \qquad [7]$$

Now $N_2 = n_2/(n_1+n_2)$ where n_1 is the number of moles of solvent; and for dilute solutions $n_1+n_2 \simeq n_1$. Therefore $N_2 \simeq n_2/n_1$ and since $n_2 = w_2/M_2$ where w_2 is the weight of solute of molecular weight M_2, equation [7] becomes

$$M_2 = K \,.\, i_b \,.\, R \,.\, \frac{M_1}{w_1}\frac{\Delta w_2}{\Delta e_5} \qquad [8]$$

and the molecular weight M_2 of the desired component is given in terms of quantities which are either measurable or known. When the second component is a polymer then M_2 is identical with $\bar{M}_n$, the number average molecular weight (16). Equation [5] for the boiling point elevation was used for simplicity and is not strictly applicable to polymer solutions. An equation of the type used by Smith (17) would be more precise.

During the course of a run the values of interest are the changes in e_5 brought about by the addition of a series of polymer pellets. The cumulative shift ($\Sigma\Delta s$) of the recorder pen, which is proportional to the boiling point elevation, is plotted versus the cumulative weight Σw (proportional to the concentration) of polymer added. It is found experimentally that for low molecular weight materials the cumulative shift so obtained is frequently a linear function of the total weight of material added, i.e.

$$\Sigma\Delta s = a \,.\, \Sigma w; \qquad [9]$$

but as the molecular weight of the material increases it is sometimes necessary to go to a quadratic equation

$$\Sigma\Delta s = a_0\Sigma w + a_1\Sigma w^2. \qquad [10]$$

This, however, is quite a common finding with polymer solutions (e.g. with osmotic pressures) and it is only in the limit of infinite dilution that one might expect a simple linear relation to hold. In the case where the linear relationship holds, the value of interest is the slope of the plot of $\Sigma\Delta s$ versus Σw. In the quadratic case ($\Sigma\Delta s/\Sigma w$) is plotted versus Σw and the value of the intercept at $\Sigma w = 0$ is used. The values of ($\Sigma\Delta s/\Sigma w$) for the polymer so obtained must then be related to the molecular weight of the polymer. The simplest method of doing this is to use a standard material, the molecular weight of which is known. Then using the relation

$$\bar{M}_n\left(\frac{\Sigma\Delta s}{\Sigma w}\right)_{\text{polymer}} = M_s\left(\frac{\Sigma\Delta s}{\Sigma w}\right)_{\text{standard}} \qquad [11]$$

it is possible to calculate the molecular weight of the unknown. This comparative procedure is recommended by Swietoslawski ((3), pp. 171–173). The technique, as we have used it frequently, consists of adding benzil pellets (the standard material) consecutively to establish the benzil sensitivity, i.e. the ($\Sigma\Delta s/\Sigma w$) for benzil for that day; then polymer pellets are added to this benzil solution and the $\Sigma\Delta s/\Sigma w$ for the polymer determined. The molecular weight of the polymer is then calculated using equation [11].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

It may be objected at this point that the possibility of interaction between polymer and standard when both are added to the same solvent would vitiate this procedure entirely. This problem is discussed in greater detail later (21). Our results to date indicate that the procedure is safe, at least for benzil and polythene.

It may be mentioned as an aside, at this point, that the sensitivity attainable with thermistors and high gain amplifiers is so great that choosing a solvent because of its high ebullioscopic constant is no longer meaningful. Most ebullioscopic constants are within a factor of 10 of each other and any change in this value from solvent to solvent is easily compensated for by increasing the amplifier gain. A similar argument may be applied to the question of using a two-thermistor bridge or a four-thermistor bridge. The latter has twice the sensitivity of the former but the difficulty of matching four thermistors is more than twice that of matching two. Hence a two-thermistor bridge is used and gives more than adequate sensitivity.

EXPERIMENTAL RESULTS

The small ebulliometer has been in routine use for 4 years. During this time a large number of different samples has been determined with molecular weights ranging from the low hundreds to about 30,000. Rather than reproduce all the results, two series only will be discussed. These show, as well as any, the nature of the difficulties encountered. Furthermore each series was independently determined in another laboratory so that a check is provided. Those polymers other than polythene which have been measured gave similar problems.

The first series tested consisted of four polythene fractions (17) which had been prepared at Imperial Chemical Industries Limited, Alkali Division, where they were designated 47A/3/1, 2, 4, and 9. The results obtained at Imperial Chemical Industries Limited and Canadian Industries Limited are listed in Table I.

TABLE I

Comparison of I.C.I. and C-I-L results with some polythene fractions

	I.C.I. ebulliometer		C-I-L ebulliometer		
Sample No.	CCl_4	Toluene	CCl_4	Toluene	No. of runs
47A/3/1	4500	4000	4300	4320±130	2
47A/3/2		7090		6910, 6950, 6870	3
47A/3/4		11700		10000, 10500	2
47A/3/5	17280	13000			
47A/3/9	29400	20300	28200	16000, 17800	2

Sample No. 47A/3/5 has been included in this table even though it was not measured at Canadian Industries Limited because a tentative explanation for the different results obtained with the two solvents will be given in the discussion.

The next series of comparative determinations was performed by Dr. F. Sirianni of the Division of Applied Chemistry, National Research Council, Ottawa. The apparatus employed (18) permits a measurement of the depression of the vapor pressure over a solution compared with that over the solvent. His measurements were made with toluene solutions at 75° C. The results are listed in Table II.

One other sample has been determined both elsewhere and at Central Research Laboratory. This was a polystyrene which had been characterized both by osmometry and the method of radioactive end groups (22). The results were given as 24,000 and 20,000 respectively. Our result was 17,000.

TABLE II

Comparison of N.R.C. and C-I-L results with whole polythene samples

Alkathene melt index	N.R.C. results	C-I-L	
		CCl_4	Toluene
200000	2550	2400	2500
20000	4800	4680	4660
7000	6850	7100	7300, 6900
700	7750		7200, 6700
2	14150		10400
0.2	24350		18400

DISCUSSION OF RESULTS

It will be seen from Table I that the results obtained with the same samples in both ebulliometers agree quite well. The uncertainty with any one sample in toluene in the Canadian Industries Limited ebulliometer was least for low values of M_n and increased to about 10% at the highest M_n. The individual results are plotted in Fig. 2.

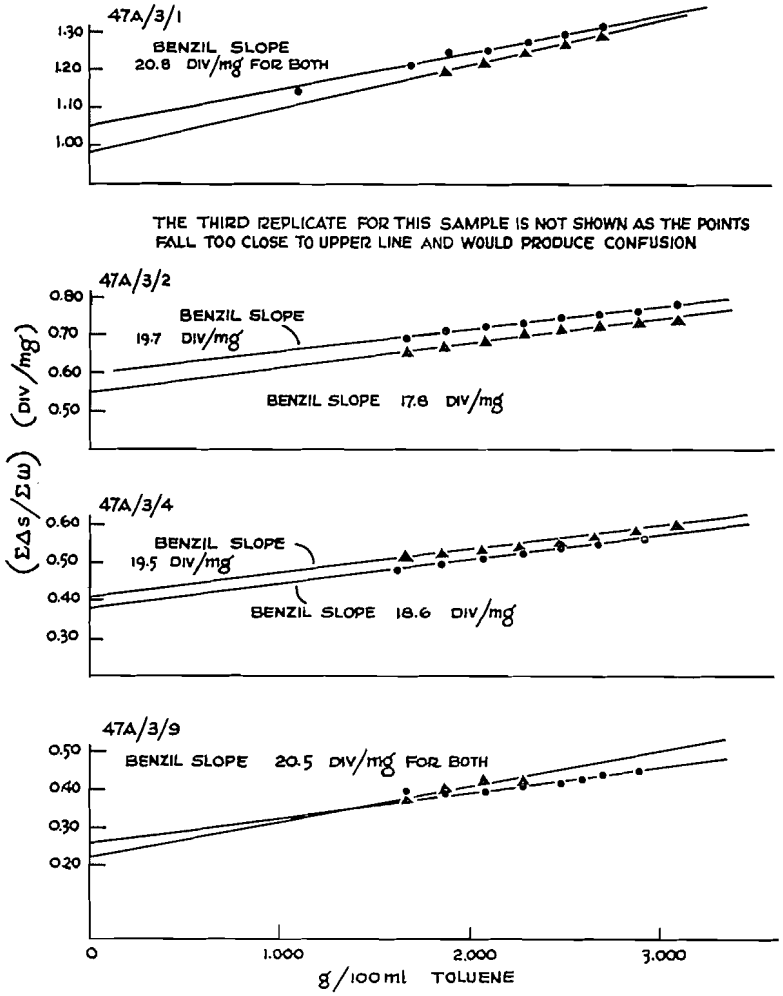

FIG. 2. Replicate runs on polythene fractions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Two major points concerning the results in Table II and Fig. 2 should be discussed. The first is the remarkably large discrepancy between the value of M_n for sample 47A/3/9 in toluene compared with CCl_4, both at Imperial Chemical Industries and Canadian Industries Limited. A tentative explanation is that the high molecular weight species present in each added pellet do not dissolve in CCl_4 because of its low boiling point. Richards (19) and Myers (20) have both shown that the solubility of a polythene may be very sensitive to temperature. The percentage deviation between the results in CCl_4 and toluene increases as the value of M_n increases, which is in keeping with this explanation. Experimentally, since polythene floats on CCl_4, undissolved portions of the added pellets would be difficult to see because of the foam and the narrow viewing slit in the small ebulliometer. This explanation is, however, only tentative because Smith (17) also obtained high results in *n*-octane (boiling point 125° C) where the effect should not occur.

The second major point concerns the foam level during these runs. The "constant foam level" zone (see Foam, Part II (21)) was reached by using about 250 mg polythene in 15 ml solvent as the first addition. Subsequent additions were about 30 mg each. This means that the error introduced by the "foam shift" is hidden in the first value of $\Delta s/w$. Since this initial value of $\Delta s/w$ affects all subsequent values when the cumulative sums in $\Sigma\Delta s/\Sigma w$ are formed the error must be transmitted to the whole line. The magnitude of this error is unknown but the fact that it exists probably explains the increasing difference in results obtained between the next series measured at the National Research Council and Canadian Industries Limited.

The results of the second comparative series are shown in Table II. The agreement is good for the low molecular weight materials but there is an increasing disparity as the value of M_n increases. It is believed that the fault lies in the ebulliometer. This series provided a more stringent test of the ebulliometer for two reasons: (1) whole polymer produced more foam at lower polymer concentrations than did a fraction of comparable molecular weight and (2) the initial polymer concentration was low in each run of this series. This meant usually that the foam level changed during the run with consequences which are discussed later (21).

ACKNOWLEDGMENTS

The author wishes to thank Dr. D. C. West for his assistance in the early stages of this study, Mr. E. Lister for the skill and willingness with which this and other ebulliometers were constructed, Messrs. D. Hudson and R. Richard, by whom most of the measurements were made. The author is also indebted to Mr. H. Smith, Imperial Chemical Industries, Alkali Division, for having provided the series of polythene fractions; to Dr. A. F. Sirianni, National Research Council, Ottawa, for having performed the comparative measurements on the whole polythene samples; to Dr. H. T. Hookway for providing the polystyrene sample which had been characterized osmotically at the National Chemical Laboratory, Teddington, England, and which had been prepared and characterized radioactively by D. P. W. Allen of the British Rubber Producers Research Association.

EBULLIOMETRY AND THE DETERMINATION OF THE MOLECULAR WEIGHTS OF POLYMERS

PART II. BACKGROUND NOISE IN THE SMALL EBULLIOMETER[1]

W. R. Blackmore

ABSTRACT

It is shown that the usual form of ebulliometer is subject to at least three sources of noise. Those discussed here are (1) pressure fluctuations over the boiling liquid surface, (2) the Cottrell pump, and (3) the foam which appears on many polymer solutions when maintained at the boiling point. Background noise in this, and other ebulliometers commonly employed, may be large compared to the size of the signals expected for dilute high polymer solutions. Consequently further progress in ebulliometry is dependent on the development of a new ebulliometer with a much lower background noise.

INTRODUCTION

In any measurement the most important quantity is the signal-to-noise ratio. In ebulliometry, with high polymer solutions, the signal is frequently only a small boiling point elevation of perhaps 1000 microdegrees (μ° C). But the ebulliometer itself, because of the nature of its operation, introduces random temperature fluctuations, called noise. This noise is often an appreciable fraction of the signal to be measured. Thus even with pure solvent boiling and being pumped, the noise may be ± 150 μ° peak to peak, while as the concentration of polymer increases the noise also increases and may rise by a factor of five or six over the pure solvent noise. It is obvious that reducing the noise in an ebulliometer is greatly to be desired. The object of this work was to discover the sources of noise in the small ebulliometer (1).

EXPERIMENTAL SECTION

(1) *To Show the Principal Source of Background Noise*

The thermistor bridge normally used in the small ebulliometer only measures differential temperatures. To discover at which thermistor the noise is greater, the thermistor bridge was opened and the behavior of the thermistors was followed individually. To do this the Tinsley Wheatstone bridge (1), the Leeds and Northrup microvolt d-c. amplifier, and the Brown recorder were used. To facilitate the measurements the conditions were chosen so that the background noise would be much greater than normal. The ebulliometer was connected to a 25-liter surge bottle which was closed off from the atmosphere. The three traces obtained are shown in Fig. 1. It is obvious that most of the temperature fluctuation is produced at the lower thermistor which is exposed to the pumped liquid. The fluctuations recorded for the lower thermistor represent peak-to-peak fluctuations of ± 2.7 m° C. By comparison the upper thermistor trace shows only a slow drift produced by a slight increase in pressure in the surge bottle. The third trace is also most instructive. This was obtained when the tube connecting the ebulliometer to the surge bottle was closed off near the ebulliometer. This meant that pressure waves travelling up inside the ebulliometer from the surging boiling surface were now unable to dissipate themselves in the surge bottle and were reflected back down into the ebulliometer. The disastrous effect on

[1]*Manuscript received April 3, 1959.*
Contribution from the Central Research Laboratory, Canadian Industries Limited, McMasterville, Que.

the temperature stability at the upper thermistor is obvious. This noise represents peak-to-peak temperature fluctuations of ± 4.8 m° C. It must be emphasized that these conditions have been chosen for purely illustrative purposes; in normal operation the noise level is considerably lower.

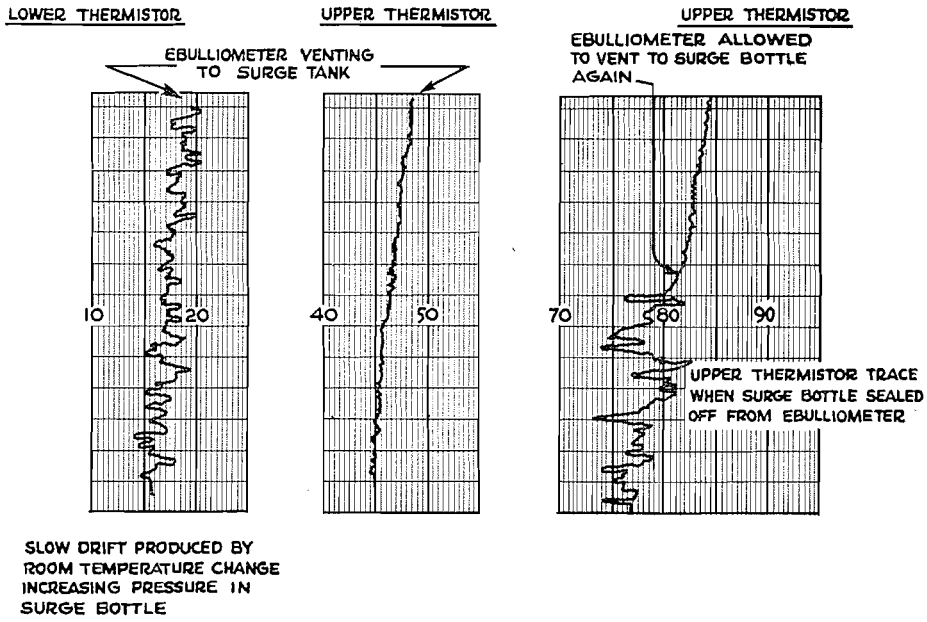

FIG. 1. Temperature fluctuations at individual thermistor wells.

The similarity of the trace obtained from the lower thermistor compared with that from the upper thermistor when the ebulliometer was closed off from the surge bottle raises one of the fundamental questions about background noise in ebulliometry. The question is this. The lower thermistor is subject in this ebulliometer to pressure fluctuations coming from (*a*) the boiling surface in the pot and (*b*) vapor puffs as the liquid is ejected by the the pump. Are these responsible for the noise at the lower thermistor? Under normal operating conditions the trace noise is of the order of $\pm(100 \rightarrow 150)$ μ° C for toluene. Differences of only $\pm(2 \rightarrow 3)$ μ Hg in the pressures of the vapors around each thermistor region would produce temperature fluctuations of the order mentioned.

(*2*) *To Show the Effects of the Boil-up Rate and Radiation from the Pump Heater on the Thermistors*

The first method used to investigate the effect of heater current variations was to follow the unbalance voltage from the differential bridge as a function of heater current, with a constant volume of solvent in the ebulliometer and the amplifier gain set high enough so that the background noise was clearly visible on the recorder. A curve typical of the results obtained is shown in Fig. 2. This curve was calculated from the differential thermistor bridge output by attributing the temperature changes to the lower thermistor and assuming the upper thermistor temperature was constant. The vertical bar at each point on the graph indicates the peak-to-peak noise level. The volume chosen was 15 ml of pure toluene for which the minimum heater current required in order for the pump just to operate is 3.0 amperes. The unbalance voltage from the thermistor bridge at this heater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

current was chosen as the arbitrary zero. For any heater current above or below 3.0 amperes the trace indicated that the lower thermistor came to an equilibrium temperature which was higher than its temperature at the minimum heater current required for pumping. The noise increased with increased current too.

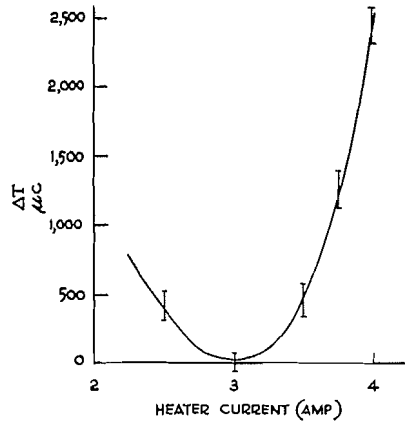

FIG. 2. Temperature difference between thermistors vs. pump heater current.

To understand this it was necessary to open the thermistor bridge and measure the resistances of the thermistors individually with the Tinsley Wheatstone bridge. The results obtained are indicated graphically in Fig. 3. The temperature change experienced by each thermistor was calculated relative to its temperature at the lowest heater current shown; pressure corrections were applied where necessary. No attempt to establish

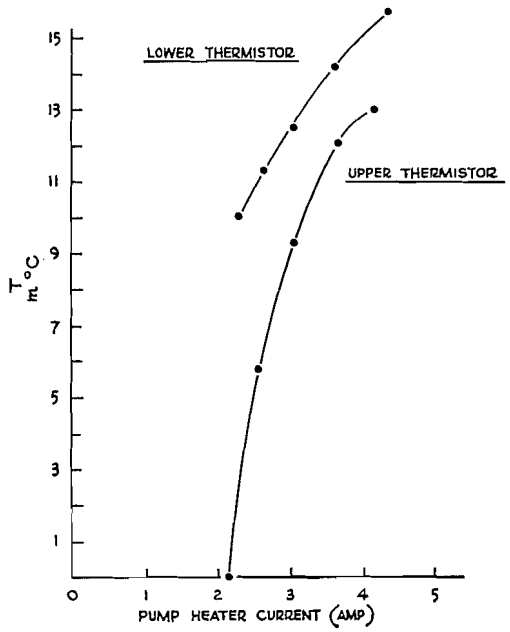

FIG. 3. Individual thermistor equilibrium temperature vs. pump heater current.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

the absolute true minimum temperature difference between the thermistors was made since equipment of greater precision would have been required. For any one heater current each thermistor assumed an equilibrium temperature which was quite stable. Since the same form of curve was obtained with 10 ml in the boiler the relationship was not a function of the pumping rate. The results were attributed to (1) the changed boil-up rate, which established a new pressure head within the ebulliometer, and (2) radiation from the heater, which affected each thermistor, after multiple reflections by the silvered wall of the vacuum jacket.

(3) The Cottrell Pump

It seems reasonable to suppose that the energy required for any Cottrell pump to just operate must be proportional to the height through which the liquid is to be lifted and the mass of liquid to be pumped. Thus the energy required may be written as equal to

$$k.h.V.d.g.,$$

where k is a constant relating to pump efficiency, h is the height from boiling surface to pump exit, V and d are the volume and density of the fluid in the pump stack, and g is the acceleration due to gravity. This expression was tested by comparing CCl_4 and toluene at heater currents such that the pump just worked. From the equation we have $h_2d_2 = h_1d_1$, and since the density of CCl_4 (2) at its boiling point (76.7° C) is 1.483 g/ml while that of toluene at its boiling point (110.6° C) is 0.779 g/ml we would expect that the pump would only operate if the height for CCl_4 were half of that for toluene. An experimental check showed qualitative agreement with this analysis. The height was altered by working with different volumes of solvent. This relation also shows why a Cottrell pump works so much more easily (with less energy input from the heater) when foam, with its low density, is being pumped.

(4) To Show the Effect of Hydrostatic Head on Superheat

The unbalance voltage from the thermistor bridge was measured as a function of different volumes of solvent in the boiler. The heater current was held constant and the ebulliometer surge bottle was closed off from the atmosphere so that the pressure would not change. The experiment was started with 30 ml of toluene in the ebulliometer. After enough of a trace had been taken to allow a measure of the noise and to prove that this value of unbalance voltage was constant at that volume, 5 ml of toluene were allowed to drain out the stopcock without disturbing the heater current or the pressure. The recorder pen shifted to its new position and the whole procedure was repeated until the final volume was 10 ml. Once again the temperature difference between thermistors was least when the pump was just working. And the pump noise was also least at this point. When the volume was so low that the pump no longer worked the upper thermistor temperature was lower compared with that of the lower thermistor than it had been. To make sure that this interpretation was correct once again the thermistor bridge was opened up and the resistances of the individual thermistors followed separately. The curve obtained with the differential bridge is shown in Fig. 4 while the other two are given in Fig. 5. The curve shown in Fig. 4 was calculated from the thermistor bridge output by attributing the temperature changes to the lower thermistor and assuming the upper thermistor temperature was constant. In Fig. 5 the temperature change experienced by each thermistor was calculated relative to its temperature at a volume of 20 ml. A vapor ring was visible in the condenser at all volumes.

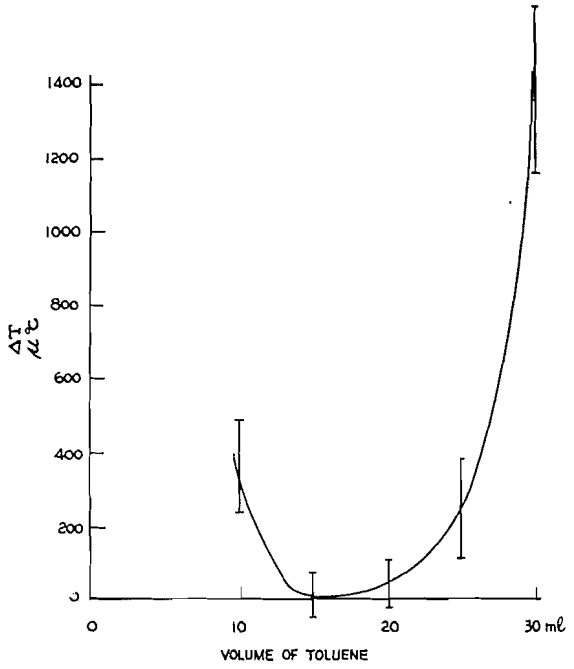

FIG. 4. Temperature difference between thermistors vs. volume of pure toluene in boiler at constant heater current (2.8 amperes).

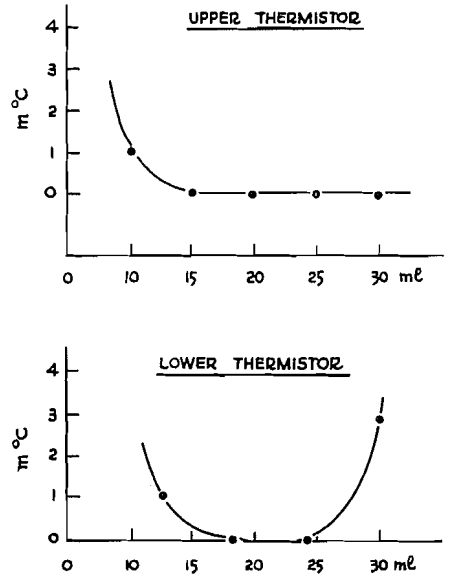

FIG. 5. Individual thermistor equilibrium temperature vs. volume of toluene in the boiler at constant heater current (2.8 amperes).

When these results are interpreted we are almost forced to conclude that the superheat in the liquid leaving the pump does not flash off immediately but rather requires more time to come to equilibrium than is available in the short run down the spiral around the

thermistor well. Since the hydrostatic head acting on the liquid in the pump bell is greatest at 30 ml, and the superheat and the pump rate are also greatest at this point the relatively vast quantity of liquid pouring over the lower thermistor may not have time to come to true equilibrium.

(*5*) *To Demonstrate the Effects of Foam in an Ebulliometer*

Many polymer solutions produce foam in the ebulliometer when maintained in a state of vigorous boiling. We have found, as did Smith (3), that both increasing molecular weight and wider molecular weight distribution in a polymer increase the amount of foam formed in the ebulliometer. Usually all the foam does not appear at once. Thus for a given polymer, in a low concentration region, there may be no foam, then in a slightly higher concentration zone there is increasing foam until finally another concentration zone of constant foam appears. Graphically this may be illustrated as in Fig. 6. When different

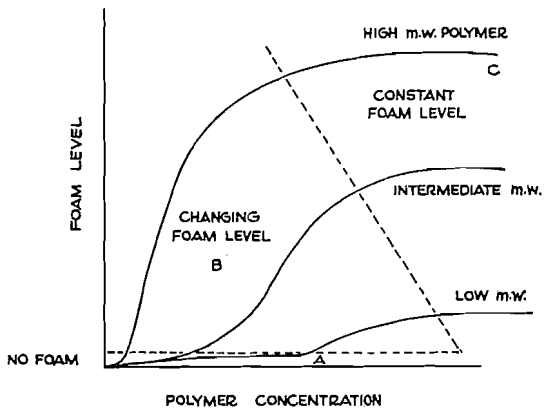

FIG. 6. Schematic representation of the foam level vs. polymer concentration for polymers of increasing molecular weight.

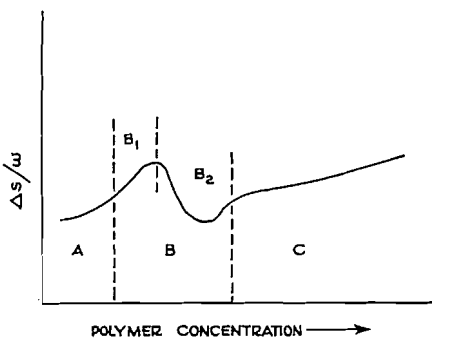

FIG. 7. Schematic representation of effect of foam level on sensitivities of successive polymer additions.

solvents are compared it is found that the behavior is similar but the "changing foam level" zone may have shifted along the concentration axis. For instance a polythene in CCl_4 produces more foam at lower concentrations than the same polythene in toluene.

Experiments to show the "foam shift" are reported below, but meanwhile a schematic representation will be given, which shows the effect most simply. Suppose successive polythene pellets, each of the same weight, are added to an ebulliometer operating with pure solvent in the boiler. Depending on the molecular weight of the material, we might obtain a curve such as that shown in Fig. 7. In region A no foam is present. In region B_1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

foam begins to be established and the measurement indicates a total elevation which is the sum of the true boiling point elevation plus an elevation associated with the change in foam level. In region B_2, although the foam increases slightly, one measures lower values for $\Delta s/w$. Finally in region C the foam level is constant and $\Delta s/w$ increases with Σw as one expects for a polymer. Quite obviously the presence of changing amounts of foam accompanies serious changes in the polymer sensitivity.

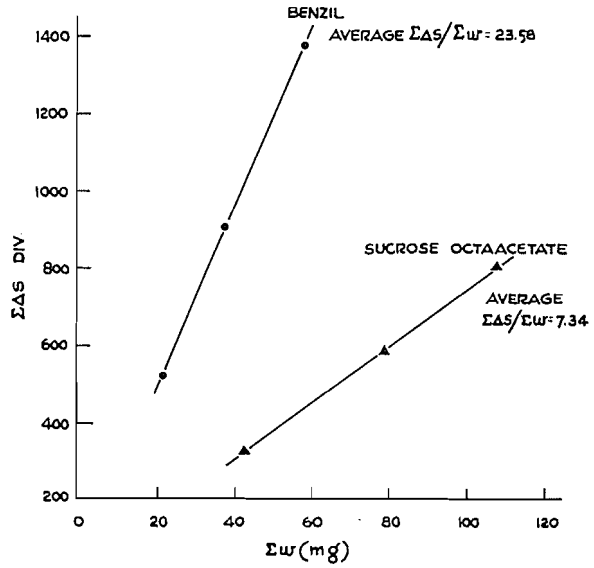

FIG. 8. Typical plots of $\Sigma\Delta s$ vs. Σw for alternate additions of low molecular weight materials.

Some experiments with foam will now be described. The first demonstrates that once the foam level is constant the sensitivity is constant. This fact was established as follows: the small ebulliometer operating with toluene was given a few benzil additions and the sensitivity measured. Then 60 mg of a polythene known to produce a great deal of foam were added, and the benzil sensitivity was measured again. The results are given in Table I.

TABLE I

Effect of foam on benzil sensitivity

Foam level	Trace noise, div peak-to-peak	Benzil		
		Δs, div	w, mg	$(\Delta s/w)$, div/mg
None	±2	54	4.3	12.6
None	±2	39	3.1	12.6
	Polythene foamer added			
Large amount of foam	±3	69	4.7	14.7
	±3	70	4.8	14.6
	±3	139	9.5	14.6
	±4	109	7.5	14.5
	More foamer added			
Extremely heavy foam	±9	161	8.9	18.1
	±9	143	8.8	16.3
This solution boiled all night and another benzil addition was made in the morning				
	±9	126	7.4	17.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

It is now necessary to establish whether (*a*) the changing foam level, (*b*) the different polymer concentration, or (*c*) the different benzil concentration produces the different benzil sensitivity. First it will be established (Table II) that the benzil sensitivity is independent of the benzil concentration.

TABLE II

Benzil sensitivity as a function of benzil concentration in toluene

Next, the results in Table III show that the benzil sensitivity increases slowly with polymer concentration but not with the amount of foam present, while the individual polymer sensitivities change with the foam level established by the particular polymer addition. In the final stages of the polymer additions when the amount of foam present is not altered by an addition then the $\Sigma\Delta s/\Sigma w$ increases with Σw along a respectable straight line.

(6) Solvent Purity and Benzil–Polymer Interaction

In this work the comparative method requiring the addition of a standard substance to the solution of the unknown has been employed for the reasons advanced by Swietoslawski ((4), pp. 171–173). The solvent used has been toluene ("from Sulfonic Acid") produced by Distillation Products Inc. It was assumed that neither the polythenes nor the benzil would associate with any impurity. Given this, the only difficulty which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

might have arisen was a volatile impurity. To measure the effect of a volatile impurity increasing concentrations of water were added to boiling toluene in the small ebulliometer with the results given in Table IV.

TABLE IV

% water, g/100 cc	Ratio of wet toluene noise to noise for pure dry toluene
0	1
1.4	5
4.8	7
12.0	20

The toluene normally used was tested with Karl Fischer reagent and found to be dry (.0016 g/100 cc). No regularly repeating fluctuations were ever observed in a trace which would have indicated a volatile impurity. The reasons for using benzil (diphenyldiketone) as a reference substance are that it is (1) easily purified, (2) stable to heat and light, (3) non-hygroscopic, and (4) easily soluble in common organic solvents.

The next problem is whether the introduction of benzil may produce some interaction with the polythene solutions. To test this several experiments were performed. First a series of benzil additions was made to pure boiling toluene. This gave a completely linear plot of cumulative shift $\Sigma\Delta s$ versus total weight added Σw. The relationship has been proved linear up to concentrations as high as 10% (g/cc). The next experiment was to measure the benzil sensitivity ($\Delta s/w$) for alternate additions both before and after the introduction of a quantity of low molecular weight material, e.g. sucrose octaacetate. No change in sensitivity (Fig. 8) could be detected. If the formula weight for benzil is assumed known the molecular weight calculated for sucrose octaacetate from the data in Fig. 8 is 676.7, which is in error by 0.28%. This proved the feasibility of the method for solutions in which neither sensitivity was a function of the concentration. The next step was to do a run on a pure polythene solution. This was a low molecular weight material ($M_n = 3000$) and a plot of ($\Sigma\Delta s/\Sigma w$) versus Σw for this polymer was a straight line. No attempt was made to calculate a molecular weight from this series of polythene additions; the run was being used simply to determine whether the polymer sensitivity ($\Delta s/w$) increased with Σw. It did, in fact, quite slowly. Then a new run was made; this time the benzil sensitivity was measured after each polythene addition. It was found that the benzil sensitivity increased with increasing polymer concentration with the same slope as had the polymer plot of ($\Sigma\Delta s/\Sigma w$) versus Σw. Consequently it was concluded that the benzil did not affect the polymer, and conversely.

DISCUSSION OF RESULTS

The problems which may arise from (*a*) pressure fluctuations in the ebulliometer, (*b*) changes in the boil-up rate, (*c*) radiation from the heater acting on the thermistors, and (*d*) uneven delivery from the pump each may be corrected by fairly obvious changes in design. This has, in fact, been done with an ebulliometer to be described later in this series.

The real problems are to understand (1) why polymer solutions produce noise which increases as a function of the concentration and (2) how to explain the "foam shift". From the foregoing results it appears that a constant amount of foam in the ebulliometer is not troublesome. The principal difficulty arises when the amount of foam is changed by the addition of polymer for then the shift measured is not necessarily the true boiling point elevation but also has associated with it what is called a "foam shift".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The first attempt to explain the foam shift was an argument to the effect that the dissipation constant of foam at the lower thermistor was less than that of liquid. Consequently, since thermistors must always float slightly above the ambient temperature, if less heat were taken away from the lower well by foam than by liquid, then the boiling point elevation measured on the addition of a material which changed the foam level would be greater than the true value. Unfortunately, measurements of the dissipation constant proved that this was not the case. The dissipation constant was unchanged whether foam or liquid engulfed the well.

The next approach was to consider the hypothesis advanced by Smith (3) to explain the curves he obtained. It was supposed there that adsorption in the foam at low bulk concentrations gave a polymer "excess" in the foam which consequently produced a greater boiling point elevation than that expected. At higher polymer concentrations this foam adsorption represented a much smaller percentage of the material present and, as well, approached a saturated value so that the measured elevations corresponded much more closely to the true values. This satisfactorily explained the shape of the curves obtained with toluene. But the same shape curve was not obtained with CCl_4 although foam (3) appeared even earlier in this solvent. Hence surely the effect should have been found there too.

CONCLUSIONS

The results quoted have shown three sources of noise in an ebulliometer of a design similar to most now employed throughout the world. These are:

(1) instantaneous pressure differences in the vapors surrounding each detector element,

(2) remnants of superheat in the liquid ejected by the Cottrell pump, and

(3) the foam produced by most polymer solutions when maintained at the boil.

Each of these may be corrected by fairly obvious changes in design. This has been done with the new ebulliometer to be described later in this series.

ACKNOWLEDGMENTS

The author wishes to thank Drs. A. T. Williamson and S. S. Grimley for the many clarifying discussions of the problems mentioned in this paper.

ELECTROMIGRATION OF IONS ABSORBED BY FILTER PAPER[1]

R. A. BAILEY[2] AND L. YAFFE

ABSTRACT

The variation with absorbance of the zone mobilities and obstructive factors for a number of inorganic ions has been investigated in acetic acid and in ammonium hydroxide at several concentrations. The results agree with the form of the semiempirical equation of Crawford and Edward. For a given ion the apparent obstructive factor defined as

$$\rho_{app} = \frac{\text{zone mobility}}{\text{free solution mobility}}$$

remains fairly constant as the concentration of the background electrolyte is changed, except in the very dilute region. However, the apparent obstructive factor varies with the ion and the background electrolyte indicating that specific effects, which are not considered in the equation, are important.

INTRODUCTION

The separation of ions by electromigration in paper has received much attention in recent years, but it is for the most part an empirical technique. Theories have been proposed to account for the behavior of ions under the conditions which prevail in this process and, although they are based on a somewhat naive model, they seem to be at least qualitatively valid. In order to see to just what extent these theories are applicable, there is a great need for accurate and reproducible measurements of zone mobilities under conditions where all of the many variables are fixed. This is especially so in the case of inorganic ions. In this paper we shall show that, while the zone mobilities (defined as the velocity under unit voltage gradient of the zone of ions on the paper) of inorganic ions in paper do follow the existing theories in a general manner, specific effects are present which cannot be accounted for satisfactorily.

Electromigration of ions in paper was first treated fundamentally by Kunkel and Tiselius (1). Their treatment was later modified by Edward (2). In the model used, the zone mobility U_z of an ion migrating in paper is given by the expression

[1] $$U_z = \rho U_F$$

where U_F is the mobility of the ion in free solution, and ρ is a correction factor called the obstructive factor (2) which is the reciprocal of the square of the conventional tortuosity factor (3). This correction factor stems from the fact that the path followed by the ion in paper would be more tortuous than in free solution since the ion must now detour around the inert fibers of the paper.

If L is the length of the paper and L^1 the length of the crooked channel in it, which the ion must follow, it is readily shown that

[2] $$\rho = \left(\frac{L}{L^1}\right)^2 = \frac{K^1}{K}$$

where K^1 is the conductance of the solution when it is in the paper, and K its conductance in the free state. It is possible, then, to estimate the value of the obstructive factor from conductance measurements.

Crawford and Edward (4) have considered the variation of the obstructive factor ρ with the volume of liquid present per unit weight of paper (the absorbance) and, in certain cases, their results make it possible to calculate this obstructive factor. Their treatment was based on a semiempirical equation devised by Biefer and Mason (5) giving the conductance of pads of randomly oriented, non-conducting, non-swelling fibers, which in turn was obtained from the theoretical equation

$$K^1 = \frac{kf(\theta)A\epsilon}{L}. \qquad [3]$$

Here, k is the specific conductivity of the solution, A is the cross-sectional area of the pad and solution, L is its length, and ϵ is its void fraction:

$$\epsilon = \frac{V_L}{V_L + V_s}$$

where V_L is the volume of the liquid, and V_s the volume of the solid fibers. $f(\theta)$ is an orientation factor which was originally equated to the void fraction on experimental grounds. Subsequent work (5) has shown that better agreement with experiment is obtained if $f(\theta) = \alpha\epsilon$ where α is a constant which is close to unity. Measurements with cellulose acetate, Dacron, nylon, and glass fibers give a mean value of 0.955 (5). Then

$$K^1 = \frac{kA\alpha\epsilon^2}{L}. \qquad [4]$$

Since $A = (V_L + V_s)/L$, then substituting for A and ϵ gives

$$\alpha\epsilon = \frac{K^1L^2}{kV_L},$$

but

$$\rho = \frac{K^1}{K} = \frac{K^1L^2}{kV_L}. \qquad [5]$$

Thus

$$\alpha\epsilon = \rho.$$

The absorbance a is

$$a = \frac{V_L}{\text{weight of solid}}.$$

Applying this we get

$$\rho = \alpha\left(\frac{a}{a + v_s}\right) \qquad [6]$$

where v_s is the specific volume of the fibers.

Cellulose fibers are known to swell in aqueous solution. If X is the fractional increase in fiber volume that is effective in hindering ion migration, then

$$\epsilon = \frac{V_L - XV_s}{V_L + V_s}.$$

Then, from equations [4] and [5]

$$\rho = \alpha\left(\frac{a - 2v_sX}{a + v}\right). \qquad [7]$$

Crawford and Edward, using conductance measurements, found that values of X between 0.1 and 0.2 fitted most of their experimental obstructive factors for inorganic salt solutions; α was taken as unity.

From equation (6) it is possible to calculate the obstructive factor for non-swelling fibers such as glass, if the theory is correct. The only uncertain factor in the equation is α. This can be assumed to be unity with only a small error, or it can be taken as 0.96 from the work of Biefer and Mason. The expression $f(\theta) = \alpha\epsilon$, on which equations [6] and [7] depend, is admittedly empirical, but it does seem to be well founded experimentally.

The above model makes no allowance for specific interactions between the ions and the fiber. It is true that the value of ρ obtained from conductance measurements may include effects of adsorption and may therefore show a dependence on the electrolyte used, but the measurements so far made in this connection have been with solutions of much higher concentrations than is usual for the ions moving in a separation, so that the paper is 'overloaded'. It is possible that adsorption effects at low concentrations are more marked. Furthermore, the background electrolyte itself may well affect the way in which the ion interacts with the paper. This would not be shown from conductance measurements.

By the use of radioactive tracers, we have been able to check any low concentration effects and test the validity of these empirical equations.

EXPERIMENTAL

The paper was placed between two brass plates, 60×25 cm in size, and insulated by polythene film of about 0.01-in. thickness. Water from a constant temperature bath ($25.0 \pm 0.5°$ C) was circulated through copper tubing which was soldered to the backs of these plates. In a few experiments at lower temperature, the control was not as good. Measurements with a thermocouple in contact with the paper showed that at an applied potential of 30 v/cm, a current of 1 milliampere could be carried for each centimeter width of the paper with an increase of less than 0.5° C in the actual temperature of the strip. This is approximately the rise calculated by assuming an equilibrium between the amount of heat generated in the paper and that conducted across the polythene insulation.

Wood and Strain (6) have shown that electroosmotic flow of the background electrolyte is largely eliminated if the electrodes are placed in direct contact with the paper. We used this arrangement and, when necessary, prevented interference from the electrolytic products by moistening the zones at the ends of the paper with a suitable buffer solution which trapped the ions so formed without itself giving an interfering ion. These buffer zones also served to keep the voltage drop across the electrodes nearly constant without manual control. This procedure was chosen in preference to correcting for electroosmotic flow by the motion of zones of uncharged substances. Such corrections are always subject to uncertainty about the relative effects of adsorption on the motion of the ion and the indicator substance. Also, if the flow of electrolyte is not uniform, as when the liquid flows from both ends of the strip toward the center (the 'wick effect') (7), the effect of this flow on the migrating ion is difficult indeed to determine from the motion of the indicator zones. When uncharged materials, particularly H_2O_2, were used as indicators in our technique, these materials showed no measurable motion.

Voltages were measured by means of a vacuum tube voltmeter connected to platinum probes that were at some distance from the ends of the paper strip so that voltage

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

drops across the platinum foil electrodes and the buffer zones were not considered. Separate measurements showed that the voltage gradient in that part of the strip where the migration took place was uniform, and remained so for the duration of an experiment.

In order to obtain known reproducible absorbances of the paper, the desired volume of electrolyte was spread as uniformly as possible over the strip from a pipette. The buffer zones were moistened to the same absorbance. The electrolyte was allowed to spread for $\frac{1}{2}$ hour or more and the solution to be investigated was applied at the starting line as a spot or a streak. This method of moistening the strip was quite satisfactory except at very low absorbances.

There are certain advantages in using radioactive materials in this work. The zones of material are very easily detected by their radiations so that no chemical tests are necessary, and exceedingly small amounts of material can be used so that the ionic strength of the moving zone is not appreciably different from that of the background solution. Although the influence of concentration of the moving ion on its zone mobility has not yet been adequately studied, it is known that there is an effect. Our work indicates that, at least in non-complexing media, the zone mobility decreases slowly with increasing concentration, while at the same time the zone becomes broader. The latter was reported also by Maki (8). The solutions used here were sufficiently dilute to render the effects of concentration entirely negligible; indeed, the Na^{22} was effectively 'carrier-free', i.e. ca. 10^{-8} molar.

Na^{22}, Cs^{137}, Tl^{204} (as Tl^{+}), Cl^{36} (as chloride), Co^{60}, and Zn^{65} were the radioactive tracers used. Inactive Cu^{++}, Cd^{++}, and Fe^{+++} were used in the form of 0.001 *M* solutions of the nitrate; some of the experiments with Zn^{++} and Co^{++} were done with similar inactive solutions. The volume applied was in most cases 10 microliters. The volume of Tl^{+} was usually 5 μl, however, and in other cases some experiments were made with 20 or 50 μl of solution.

The active ions were detected by cutting the strip into sections 1 cm (occasionally 0.5 cm) broad, and measuring each with a Geiger counter. The inactive ions were detected with a solution of dithizone in CCl_4 or by exposure to H_2S.

The papers used were Whatman No. 52 chromatography paper, 5.1 cm wide, and Reeve Angel 934AH glass fiber filter paper, 2.9 cm wide. The length of the paper available for migration varied in different experiments from 20 to 50 cm, and actual distances of migration ranged from about 15 to 50 cm.

RESULTS AND DISCUSSIONS

In order to calculate the zone mobility, U_z, it is first necessary to determine U_F, the mobility of the ion in question in the solution used as background electrolyte. This must be estimated from the ionic conductance at infinite dilution by taking into account the effects of ionic strength and viscosity. We must consider the effects of foreign ions and uncharged molecules on the ion studied, and this makes an accurate calculation of U_F very difficult. For instance, the value of the dielectric constant, which enters into all conductance equations, is probably appreciably different in 6 *M* acetic acid from what it is in pure water, but we are unable to make a satisfactory allowance for such changes. Fortunately all solutions used have quite a low ionic strength, and the correction given by the limiting form of the Onsager equation, taking the constants to be those for pure water, probably serves as well as that which could be obtained from more complicated equations which are largely untested under conditions such as we are considering. In addition, the change in mobility due to ionic strength alone is small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

compared with the effect of viscosity. Therefore, we have corrected for ionic strength by the Onsager equation and divided this result by the relative viscosity to get U_F. The result, although perhaps crude, is not likely to involve an error greater than that in the experimentally determined zone mobilities.

Each of the zone mobilities included in these results represents the mean of three or more experiments, usually carried out with different voltage gradients and migration times. Figure 1 shows the variation of the zone mobilities of Fe^{+++}, Co^{++}, Ni^{++}, Cu^{++}, Zn^{++}, and Cd^{++} with absorbance in 2.36 M acetic acid at 5° C. The curves are linear in most cases. The precision of these measurements is not sufficient to show the slight curvature that would be present if equation [7] were valid.

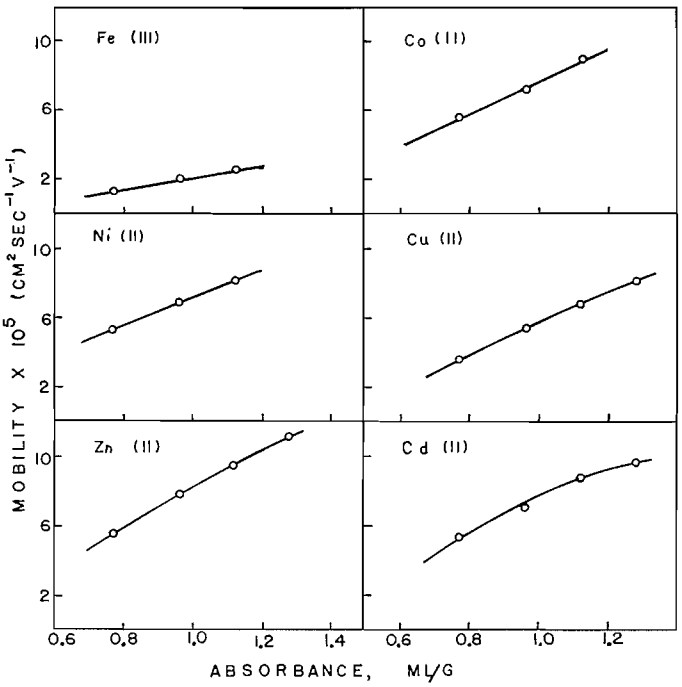

FIG. 1. Zone mobility vs. absorbance for several positive ions in 2.36 M acetic acid. Whatman No. 52 paper; 5±1° C.

Results for Cs^+ at 25° C in a variety of background electrolyte solutions are given in Fig. 2. They show the same nearly linear form as do the previous examples. In Fig. 3 the apparent obstructive factor is compared with the obstructive factor calculated from equation [7] using the values of X that give the best over-all fit for the experimental data. The calculated and experimental curves agree very well in most instances.

It is of interest to consider ρ_{app}, i.e. zone mobility/free solution mobility, as a function of concentration of background electrolyte at fixed absorbance. This is given for a number of ions in acetic acid and ammonium hydroxide in Tables I and II. The zone mobility is plotted as a function of concentration for Cs^+ in acetic acid, in Fig. 4, and is typical of all examples investigated. At acetic acid concentrations above about 0.05 M, the curve of zone mobility concentration decreases. This is the sort of behavior that would be expected from ionic strength and viscosity considerations. In this region, ρ_{app} has a nearly constant value for most ions, although there seems to be a tendency

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

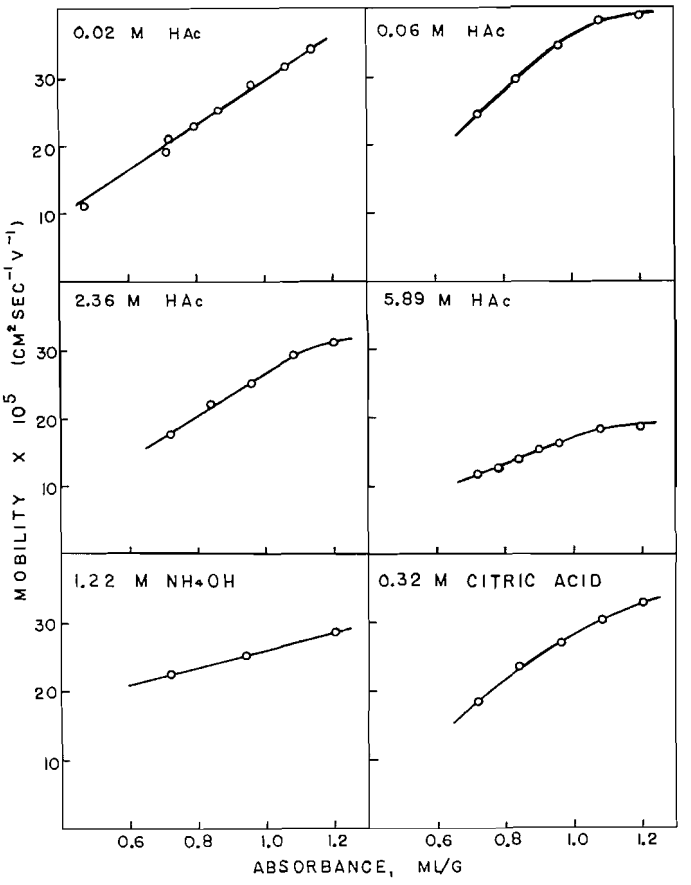

FIG. 2. Zone mobility vs. absorbance for Cs^+ in several background electrolytes. Whatman No. 52 paper; 25.0±0.5° C.

for it to fall off to some extent at higher concentrations. In the more dilute region, the zone mobility decreases quite markedly, and consequently ρ_{app} decreases also. Although this would require a corresponding increase in X if equation [7] were to be obeyed, there is no suggestion that the swelling of the cellulose fibers undergoes any particular change at this point. In fact the reduction of mobility with decreasing concentration seems to set in at a value more characteristic of the valence type of the moving ion than of the nature of the background electrolyte. The maximum zone mobility seems to occur close to 0.06 M for the univalent ions in both acetic acid and ammonium hydroxide, but at 0.5 M for the bivalent ions in acetic acid. Extensive measurements in this dilute region have been made only with Cs^+, however, and for other ions mainly the behavior at the higher concentrations is considered.

The cause of the decrease in zone mobility at low background electrolyte concentrations may be due to adsorption effects, since considerable trailing of the zones occurs, and the spots have the 'comet' shapes typical of adsorption (9). The fact that, in the more highly ionized citric acid, the decrease does not occur until a considerably lower concentration is reached indicates that the ionic strength may be important in this connection, and there are also other factors that cannot be excluded.

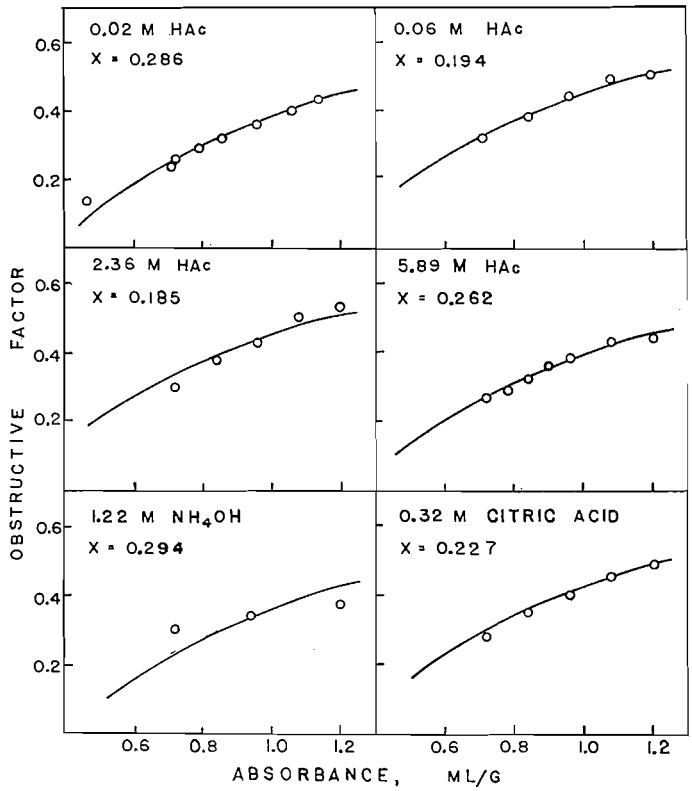

FIG. 3. Comparison of calculated and experimental (or apparent) obstructive factors as a function of absorbance for Cs^+ in several background electrolytes. The curves are calculated from equation [7] using the values of X indicated. The circles represent experimental points. Whatman No. 52 paper; 25.0±0.5° C.

Equation [7] assumes that there is no specific interaction between the migrating ion and the paper, and that consequently the obstructive factor is the same for all ions. That this is not the case is shown by the data in Tables I and II. ρ_{app} differs quite appreciably from ion to ion, and for the same ion in different background electrolytes. Evidently, since Na^+ has the largest ρ_{app}, it is the least obstructed, or hindered, of the ions studied, followed by Cs^+ and then by Tl^+. Zn^{++} and Cd^{++} are hindered somewhat more, while Cu^{++} shows the lowest ρ_{app} and is slowed to the greatest extent. It is obvious that the picture of an ion moving down a crooked channel is too simple to explain this process completely. By postulating absorption, one can explain the variation of ρ_{app} on the basis of different strengths of binding between the cellulose and the various ions. It is known that ions may travel through a portion of the swollen fiber (i.e. that the fractional increase, X, that is effective in hindering ion migration is less than the total fractional increase in volume on swelling (10, 11)). The bivalent ions seem to be more hindered than the univalent, but there are not enough examples to make any generalization between ρ_{app} and size or charge. Greater interaction with the negative acetate ions may be in part responsible for this increased hindrance.

A negative ion such as Cl^- might have different absorptive properties with respect to cellulose, but for the most part there seems to be little difference in its behavior, as shown in Table III. The mobility drops sharply in very dilute solutions, as for positive ions.

TABLE III

Zone mobility of Cl^- in varying concentrations of acetic acid and ammonium hydroxide

Background electrolyte	Concentration of background electrolyte, moles/liter	U_z, $cm^2\ v^{-1}\ sec^{-1} \times 10^5$	ρ_{app}
Acetic acid	0.02	15.2	0.20
	0.06	30.3	0.39
	0.59	26.3	0.37
	1.18	24.1	0.36
	2.36	20.1	0.35
	5.89	16.0	0.38
NH_4OH	0.6	24.8	0.33
	2.4	24.0	0.34
	6.1	22.2	0.34

NOTE: Absorbance 0.96 ml/g, Whatman No. 52 paper, 25.0±0.5° C.

Fibers such as glass do not swell in aqueous solutions, so it should be possible to apply equation [6] to electromigration in glass fiber filter paper. In Figs. 5 and 6 are shown the mobilities of Na^+ and Cl^- respectively, in such a medium with acetic acid as background electrolyte. Glass paper appears to absorb positive ions to a much greater extent than does cellulose paper. At any rate both Cs^+ and Tl^+ showed very extensive trailing, and Na^+ trailed considerably in acetic acid of less than 1 M concentration. The calculated value of ρ, assuming v_s to be 0.43 and α to be 0.96, is 0.84 for the absorbance used. In the high-concentration regions (above 1 M) U_z, calculated using this value of ρ, agrees fairly well with the experimental value, considering the errors involved in both the experimental and the calculated values.

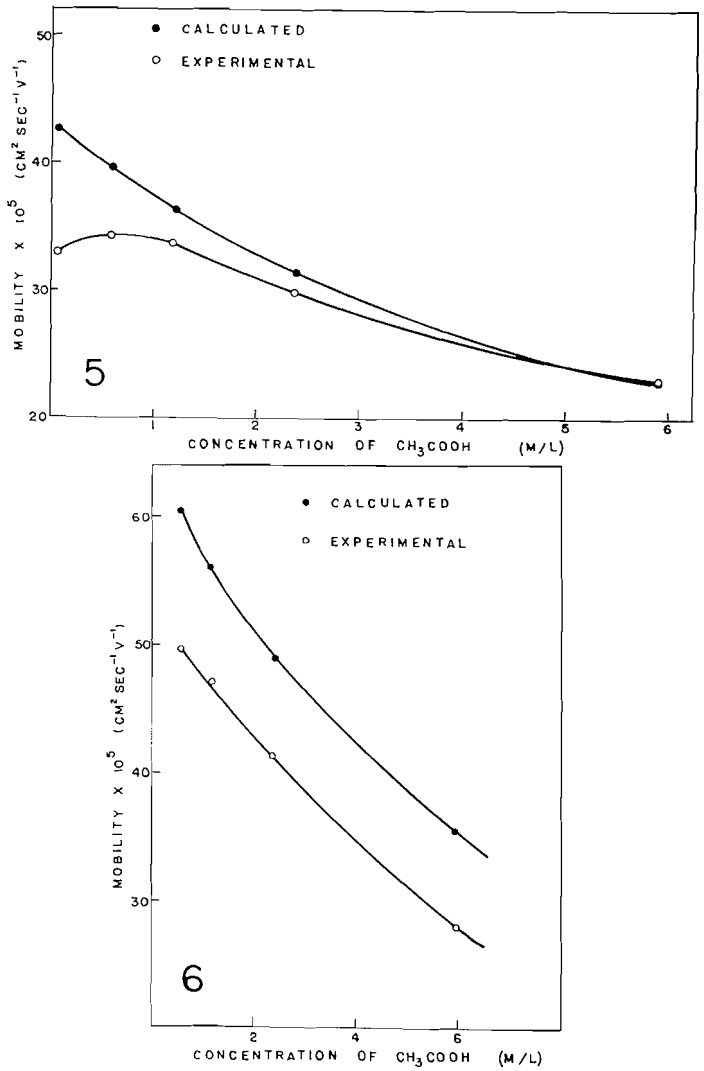

FIG. 5. Comparison of experimental zone mobilities of Na^+ in acetic acid with those calculated from equation [6]. Reeve Angel 934AH glass fiber filter paper; absorbance 3.36 ml/g; 25.0±0.5° C.

FIG. 6. Comparison of experimental zone mobilities of Cl^- in acetic acid with those calculated from equation [6]. Reeve Angel 934AH glass fiber filter paper; absorbance 3.36 ml/g; 25.0±0.5° C.

However, the data for Cl^- under the same conditions show very poor agreement between calculated and experimental results; the hindrance of Cl^- in glass is considerable compared with that for Na^+.

The results shown here indicate that specific interactions of appreciable magnitude can affect the zone mobilities of ions in both cellulose and glass papers. The equation of Crawford and Edward, relating obstructive factor to absorbance for cellulose papers, gives an approximate fit to the experimental results if the value of the swelling factor is properly chosen. In general, this factor varies for each ion and for each background electrolyte, usually falling between 0.13 and 0.45. It is apparent that these changes in X reflect factors other than swelling of the fibers. These may include adsorption of the ions and migration through the swollen volume of the fiber.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Using glass fiber paper, it is possible to calculate an idealized obstructive factor free from any uncertain swelling factor, and for Na^+ in fairly concentrated acetic acid the calculated zone mobilities agree quite well with the experimental. For Cl^-, on the other hand, they do not. Most of the ions studied so far in glass paper showed a large amount of trailing indicative of adsorption. It is clear that further work in this or in a similar non-swelling material with ions which show no adsorption is required.

THE STRUCTURE OF AN ARABOGALACTAN FROM MONTEREY PINE (PINUS RADIATA)[1]

D. J. BRASCH[2] AND J. K. N. JONES

ABSTRACT

The two major components of the water-soluble polysaccharides from Monterey pine (*Pinus radiata*) are an arabogalactan and a glucomannan. The arabogalactan contained L-arabinose and D-galactose in the ratio 1 to 8. The polysaccharide is highly branched in structure and contains end groups of L-arabofuranose and of D-galactopyranose. Removal of the L-arabinose residues leaves a highly ramified galactan.

INTRODUCTION

When wood meal which has been extracted with organic solvents is exhaustively washed with cold water a mixture of polysaccharides is readily obtained. The quantities and constituents of this mixture vary widely with the species of wood used, but usually the polysaccharides isolated are one or more of four general types: wood starches, pectic materials, arabogalactans, or glucomannans.

Starch is known to occur to the extent of 0.5% to 5% in woods and can be detected by the usual blue coloration with iodine. Care must be taken in the interpretation of this test since certain wood hemicelluloses are also stained blue with iodine (1). When starch is present it usually occurs in the sapwood, and often the starch granules can be detected microscopically. Wood starches on hydrolysis give mainly D-glucose, although a starch-like polysaccharide which apparently contained uronic acid groups has been isolated from oakwood.

The second group of polysaccharides which may occur in the cold water extracts of wood are the pectic materials. The main polysaccharide of the pectic group is a polymer of α-1 $\rightarrow$ 4-linked D-galacturonic acid units which are either fully or partly esterified and which may have attached to them residues of L-arabinose or D-galactose. Araban and galactan are frequently found associated with pectic acid.

The term arabogalactan has been given to the third group of polysaccharides occurring in the cold water extracts, especially of coniferous woods, since these polysaccharides on hydrolysis give mainly L-arabinose and D-galactose. Western larch (*Larix occidentalis*) contains up to 15% of an arabogalactan (2), European larch (*Larix decidua*) yields the so-called ϵ-galactan (3), while many other gymnosperms (4, 5, 6, 7, 8, 9, 10) contain lesser amounts of polysaccharides which are structurally similar to the arabogalactan of western larch. It is not yet clear whether or not the arabogalactans are homogeneous polysaccharides, (but see (2)).

The last of the types of polysaccharides which occurs in the aqueous extract of coniferous woods belongs to the glucomannan group. Several coniferous woods are known to yield polysaccharides of this type (11, 12, 13), but their chemistry has not yet been investigated in such detail as that of the associated arabogalactans.

When wood meal from Monterey pine (*Pinus radiata*) is extracted with water a complex mixture of polysaccharides is obtained. These can be separated, as described by Adams (10) and by Jones and Painter (11) into a polysaccharide fraction which is

[2]*Present address: Dominion Laboratory, Department of Scientific and Industrial Research, Wellington, New Zealand.*

precipitated by Fehling's solution; the glucomannan fraction; and one which is not precipitated by this reagent, the arabogalactan. This paper discusses the chemistry of the arabogalactan.

The polysaccharide was obtained as a white, water-soluble powder which on hydrolysis gave L-arabinose and D-galactose in a ratio of 1 to 8.2. All attempts to separate this polysaccharide into fractions with different properties were unsuccessful even when the polysaccharide, its acetate, or methyl ether was used.

Oxidation of the polysaccharide with sodium metaperiodate resulted in the consumption of approximately 1 mole of metaperiodate and the formation of 0.35 mole of formic acid per 162 g of polysaccharide. These figures indicate that for every sugar unit which is oxidized with the production of formic acid one other sugar residue is oxidized without the formation of formic acid, and one sugar residue is unattacked. This suggested that the polysaccharide is highly branched or that it consists of a linear polymer which contains a variety of differently linked sugars.

When the polysaccharide was hydrolyzed under mild conditions oligosaccharides were produced and two were tentatively identified as 6-*O*-β-D-galactopyranosyl- and 3-*O*-β-D-galactopyranosyl-D-galactose.

The methylated polysaccharide on hydrolysis gave a complex mixture of sugars. The following major constituents were identified: 2,3,5-tri-*O*-methyl-L-arabinose (I), 2,3,4,6-tetra-*O*-methyl-D-galactose (II), 2,4,6-tri-*O*-methyl-D-galactose (III), 2,3,4-tri-*O*-methyl-D-galactose (IV), and 2,4,-di-*O*-methyl-D-galactose (V).

The molar ratio of sugars I + II:III + IV:V was approximately 1:1:1. This proves that the polysaccharide is of the branched-chain type. When the arabogalactan was heated in dilute oxalic acid solution (14) all the L-arabinose was eliminated together with a small quantity of D-galactose and traces of other sugars. The ease of elimination of the L-arabinose indicated that it was all present in the polysaccharide in the furanoside form and probably as end group since no L-arabinose-containing oligosaccharides were isolated.

The arabinose-free polysaccharide termed "galactan" had a low positive rotation which indicated that the sugars were united by β-galactosidic linkages. The galactan was oxidized by sodium metaperiodate, approximately 1.1 moles of periodate were consumed and 0.5 mole of formic acid produced per 162 g of polysaccharide. The increase in yield of formic acid indicated that removal of the L-arabinose residues (probably from the —OH at C_3 of D-galactose) has resulted in the exposure of D-galactose residues which possess hydroxyl groups on each of three adjacent carbon atoms. These hexose residues thus become end groups or 1,6-linked D-galactose residues.

The methylated "galactan" on hydrolysis gave sugars II, III, IV, and V. The ratio of these sugars was II:III + IV:V of 1.0:1.1:1.0. The amount of 2,4,6-tri-*O*-methyl-D-galactose (III) was 10 times less than that of 2,3,4-tri-*O*-methyl-D-galactose (IV). It is evident that the formic acid produced on oxidation of the galactan by metaperiodate was derived almost equally from the end groups D-galactopyranose residues and from 1,6-linked D-galactopyranose residues.

These results do not allow the advance of a unique structure for the arabogalactan. However, it can be said that the polysaccharide is of the branched-chain type and that it resembles in structure the several other arabogalactans which have been isolated by other workers (4, 5, 6, 7, 8, 9, 10).

The structure of the glucomannan which is associated with arabogalactan will form the subject of a later communication.

EXPERIMENTAL

All melting points are uncorrected. Optical rotations were determined at 25° C and in water unless otherwise stated. All solutions were concentrated under reduced pressure and at a temperature not exceeding 40° C.

Sheet paper chromatography was carried out on Whatman No. 1 chromatographic paper by the descending method (15). The following solvent systems were used: A_1, ethyl acetate:acetic acid:formic acid:water (18:3:1:4); A_2, ethyl acetate:acetic acid:water (9:2:2); B, butan-1-ol:pyridine:water (10:3:3), and C, butan-1-ol:ethanol:water (10:3:3, all v/v). After development the sugars and derivatives were located on the chromatograms by spraying them with a 1% solution of *p*-anisidine hydrochloride in butan-1-ol (16) or with a 1% solution of silver nitrate in acetone followed by spraying with 2% ethanolic sodium hydroxide (17). The rates of movements of sugars are quoted relative to a standard sugar, e.g. R_{gal} (relative to galactose), while the movement of methyl sugars is quoted relative to tetramethyl-D-glucose (i.e. the R_g value). Infrared absorption spectra were recorded using a Perkin–Elmer Model 21 instrument in conjunction with potassium bromide pellets or 7% chloroform solution (w/v) in sodium chloride cells.

Description and Preparation of Wood Sample

The sample of Monterey pine wood used in this work was from a 25-year-old tree grown in North Island, New Zealand. The wood was received in log form, each log being about four feet long. The wood showed 2.8 to 4.2 annual growth rings per inch. It was converted into wood meal using a circular wood-working saw and air-dried to a moisture content of 9.8%. The wood (3 kg) was then extracted under reflux with ethanol (95%):benzene (2:1, v/v) for 16 hours. The residue was then extracted with ethanol (95%) under reflux for 8 hours, and dried in air.

Isolation of the Water-soluble Polysaccharide

The air-dried wood meal (500 g) was extracted with stirring, with water (10 liters) at 20° C for 16 hours. During this process toluene was added to the top of the slurry to obviate bacterial action. The wood was filtered through linen, and the process repeated using fresh water. The combined washings from 3 kg of wood were concentrated to 1 liter and centrifuged. The clear solution was then poured into ethanol (12 liters) which contained a little barium chloride and the precipitate collected. The precipitate was redissolved in water (200 ml) and reprecipitated by the addition of ethanol (800 ml). Repetition of this process (twice) gave a white product (4.3 g). Anal. ash, 2.9%; Klason lignin, 3.4%.

A sample of the product (50 mg) was hydrolyzed with 2 *N* sulphuric acid for 6 hours at 98° C. Paper chromatographic examination of the hydrolyzate (solvents A_1, A_2, and C) revealed the presence of arabinose, galactose, glucose, and mannose together with traces of xylose, rhamnose, and uronic acid.

Separation of Polysaccharides by Electrophoresis on Glass Paper

The crude polysaccharide was examined by electrophoresis on glass fiber paper (18) using both borate buffer (0.025 *N*) and sodium hydroxide (2 *N*). In one experiment at 400 v and 40 ma for 2 hours, using buffer at pH 10.7, the crude polysaccharide was separated into two distinct components. It was possible to repeat the separation, though reproducibility was not always satisfactory. In all experiments the endosmosis was considerable. Two components were also indicated by electrophoresis at 120 v, 60 ma, using sodium hydroxide (2 *N*) to dissolve the polysaccharide.

For personal use only.

Fractionation of the Crude Polysaccharide by Copper Complex Formation

The polysaccharide (25 g) was dissolved in water (3 liters) and the solution centrifuged. Fehling's solution (100 ml) was added to the clear solution and, after 4 hours, the precipitated copper salts were collected. The top clear solution was dialyzed and, when the solution was free from copper salts, it was concentrated to 1 liter and Fehling's solution again added. The precipitated copper complex was collected and the top clear solution dialyzed until it was free from salts. The solution was concentrated and poured into alcohol and the precipitated polysaccharide (11.2 g), an *arabogalactan*, was collected. The combined precipitated copper complexes were washed with water and decomposed by maceration for 1 minute with ice-cold ethanol which contained concentrated hydrochloric acid (1% v/v). The residue was washed with ethanol and then redissolved in water. It was purified via its copper complex twice more and finally isolated as a white powder (10.7 g), a *glucomannan*.

Characterization of the Sugars from the Arabogalactan

The polysaccharide (0.30 g) was hydrolyzed for 6 hours with N hydrochloric acid at 100° C. The sugar mixture was isolated and separated chromatographically. L-Arabinose, $[\alpha]_D$ +96° (c, 2.0), was characterized as its diphenylhydrazone, m.p. 201° C, not depressed in admixture with an authentic specimen, and D-galactose, $[\alpha]_D$ +78° (c, 0.5), was characterized as its N-methyl-N-phenyl hydrazone, m.p. and mixed m.p. 190° C. The ratio of sugars, determined chromatographically (19), was found to be 1:8.2 (mean value). (Attempts to separate an araban from the arabogalactan by extracting the solid with 70% ethanol (v/v) were unsuccessful.)

Acetylation of Arabogalactan

The arabogalactan (0.20 g) was dissolved in formamide (10 ml), pyridine (10 ml) was then added followed by acetic anhydride (20 ml), which was added in 10 portions of 2 ml over a 2-hour period. After 16 hours the solution was poured on to ice and the precipitate collected. The dried product was reacetylated as described above and yielded arabogalactan acetate, $[\alpha]_D$ −5° (c, 1.2 in chloroform), which was readily soluble in dioxane, chloroform, and acetone. All attempts to fractionate this material were unsuccessful.

Periodate Oxidation of the Arabogalactan

A sample of arabogalactan was deionized by passing its solution in water through columns of Amberlite Resin IR-120 (H form) and Duolite A-4 Resin (OH form), and the polysaccharide was isolated.

Duplicate samples (approximately 50 mg each) were dissolved in water. Sodium metaperiodate solution (3 ml, 0.3 M) was added and the solution was made up to 100 ml. Oxidations were carried out at 23° C with the exclusion of light. At intervals aliquots (5 ml) were withdrawn and the amounts of metaperiodate consumed and formic acid liberated were determined. Found: moles of metaperiodate consumed and formic acid produced per mole of anhydro hexose: 0.52, 0.20 (3 hours); 0.91, 0.36 (8 hours); 1.04, 0.39 (20 hours); 1.10, 0.43 (44 hours); 1.19, 0.51 (68 hours).

Methylation of the Arabogalactan Acetate

Acetylated arabogalactan (6.9 g) was dissolved in acetone (500 ml) and methylated by the dropwise addition of sodium hydroxide (30% v/v; 150 ml) and dimethyl sulphate (50 ml) in the usual way. The resulting partially methylated polysaccharide (5.5 g) was remethylated as described above. After eight such treatments examination of the product in the infrared indicated that the amount of free hydroxyl groups had become small and constant. The product was therefore methylated by the procedure of Kuhn *et al.*

(20) and a practically completely methylated product was isolated. The pale yellow solid (3.9 g) had $[\alpha]_D$ −57° (*c*, 4.5 in chloroform) and $[\alpha]_D$ −37° (*c*, 3.9 in acetone). The infrared spectrum showed a very low concentration of hydroxyl (band at 3500–3600 cm^{-1}). Attempts to fractionate the methylated product by solution in chloroform – light petroleum (b.p. 60–80° C) were unsuccessful. Practically all the material dissolved when a ratio of chloroform – light petroleum of 3:1 (v/v) was reached.

Hydrolysis of the Methylated Arabogalactan

The methylated galactoaraban (2.5 g) was dissolved in formic acid (50% v/v) and heated at 97° C until no further change in optical rotation occurred (6 hours). The water was distilled off and the residual formic acid was removed by three codistillations with water. The hydrolysis was completed by dissolving the syrup in sulphuric acid (2 *N*) and heating the solution at 90° C for 4 hours. The cooled solution was neutralized ($BaCO_3$), centrifuged, and the clear solution concentrated with the addition of 1 drop of acetic acid. The syrup (2.1 g) had $[\alpha]_D$ +55° (*c*, 3.1 in methanol) and contained at least five components (paper chromatography).

Separation of the Methylated Sugars

A portion (1.7 g) of the mixture of methylated sugars was separated by partition chromatography on a column of powdered cellulose (21) using butan-1-ol and light petroleum (b.p. 100–120° C) (3:7) as eluent. The solvent mixture was later changed to a 1:1 ratio, followed by pure butan-1-ol and then by water. The following seven fractions were collected and their components identified.

Fraction 1. The first fraction (141 mg) was chromatographically identical with 2,3,5-tri-*O*-methyl-L-arabinose in solvents A and B. A portion (0.12 g) of the syrup was oxidized with bromine water and converted to 2,3,5-tri-*O*-methyl-L-arabonic acid which was characterized as its derived amide. The product had m.p. 134–135° C, not depressed on admixture with an authentic specimen, and $[\alpha]_D$ +20° (*c*, 2.0).

Fraction 2. This fraction (155 mg) was a mixture of 2,3,5-tri-*O*-methyl-L-arabinose and 2,3,4,6-tetra-*O*-methyl-D-galactose (which could be separated paper chromatographically) (solvents A_1, B, and C). The ratio of sugars was judged to be approximately 2:1 from chromatographic evidence. It was not further examined.

Fraction 3. Fraction 3 (133 mg) behaved in solvents A and B like 2,3,4,6-tetra-*O*-methyl-D-galactose. It had $[\alpha]_D$ +102° (*c*, 1.5) but did not crystallize. When a portion of the syrup (0.1 g) was heated with ethanolic aniline for 3 hours 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine crystallized, it had m.p. and mixed m.p. 196° C and $[\alpha]_D$ −80° (*c*, 2.0 in acetone). No other sugar could be identified in this fraction.

Fraction 4. This fraction (30 mg) crystallized. The crystals possessed properties which were indistinguishable from those of 2,4,6-tri-*O*-methyl-D-galactose, m.p. 99–100° C, $[\alpha]_D$ +85° (*c*, 1.1). On heating its solution in ethanol with aniline, needlelike crystals of 2,4,6-tri-*O*-methyl-*N*-phenyl-D-galactosylamine separated, m.p. and mixed m.p. 178° C.

Fraction 5. This fraction (208 mg) consisted of two components which moved at the same rate as 2,3,4- and 2,4,6-tri-*O*-methyl-D-galactose. The syrup was heated with ethanolic aniline for 8 hours and the solvent then removed. The residue on recrystallization from ethanol yielded a mixture of needle- and plate-like crystals, the latter predominating. The two products were separated by hand picking. The needlelike crystals were identical with 2,4,6-tri-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. 175° C. The plates were not distinguishable from 2,3,4-tri-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. 162–164° C not depressed on admixture with an authentic specimen. No other derivative was isolated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Fraction 6. Fraction 6 (315 mg) contained one component only. This sugar was indistinguishable from 2,3,4-tri-*O*-methyl-D-galactose on paper chromatograms (solvents A and B). With ethanolic aniline it yielded 2,3,4-tri-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. and mixed m.p. 166–168° C, $[\alpha]_D$ −60° → +40° (equil.) (*c*, 1.3 in methanol).

Fraction 7. The last fraction (521 mg) crystallized. Recrystallization from acetone – light petroleum yielded 2,4-di-*O*-methyl-D-galactose, monohydrate, m.p. 98–100°, $[\alpha]_D$ 119° → 85° (24 hours) (*c*, 2.0). When the sugar was heated with ethanolic aniline it gave the derived *N*-phenyl-galactosylamine, m.p. 218°–220° C, $[\alpha]_D$ −180° (*c*, 1.0 in pyridine).

The molar ratios of the sugars were determined by the method of Hirst and Jones (19). Found: total end group in molar ratios (0.97), tri-*O*-methyl fraction (1.0), di-*O*-methyl fraction (1.0).

Partial Hydrolysis of the Arabogalactan

The arabogalactan (0.10 g) was hydrolyzed for 1 hour at 95° C with sulphuric acid (0.1 *N*). Chromatographic analysis of the neutralized solution revealed the presence of substantial amounts of galactose and arabinose plus minor amounts of three oligosaccharides with (*a*) R_{gal} 0.34 (solvent A_1) and 0.42 (solvent A_2), (*b*) R_{gal} 0.20 (solvent A_1) and 0.26 (solvent A_2), and (*c*) R_{gal} 0.13 (solvent A_1) and 0.14 (solvent A_2). The oligosaccharide (*a*) and (*b*) moved at rates very similar to those of galactobiose (1,6-β-linked) and galactobiose (1,3-β-linked). In a second experiment arabogalactan (4.98 g) was dissolved in oxalic acid solution (0.026 *N*, 200 ml) and heated at 95° C for 5 hours. The cooled solution was neutralized ($CaCO_3$), centrifuged, the clear solution concentrated, and the concentrate poured into ethanol. The precipitated degraded polysaccharide was collected, washed with ethanol, dissolved in water, and reprecipitated in ethanol, yield 3.49 g. The supernatant solutions were concentrated and the syrupy concentrate (1.19 g) was examined chromatographically (solvents A_1, A_2, and C). The major component of the syrup was arabinose; associated with it were significant quantities of galactose and trace quantities of xylose and rhamnose. The ratio of arabinose to galactose was 2 to 1.

The degraded polysaccharide, henceforth termed *galactan*, on hydrolysis yielded D-galactose only (paper chromatography).

The galactan had $[\alpha]_D$ +13° (*c*, 3.5) and contained 0.9% ash and 0.3% Klason lignin. Attempted fractionation of the galactan by (*a*) ethanol precipitation from neutral or acidic aqueous solution, (*b*) by copper complex formation, and (*c*) by glass paper electrophoresis was unsuccessful.

Periodate Oxidation of the Galactan

The galactan (ash-free) was oxidized with sodium metaperiodate solution as described for the oxidation of the arabogalactan. Found: moles of metaperiodate consumed and moles of formic acid produced per anhydrohexose residue: 1.17, 0.60 (8 hours); 1.35, 0.80 (25 hours); 1.61, 1.12 (48 hours); 1.95, 1.45 (72 hours). Extensive over-oxidation had occurred.

Methylation of the Galactan

Prior to methylation the galactan was reduced with sodium borohydride. The galactan (2.97 g) was dissolved in water (50 ml), and a solution of sodium borohydride (25 mg) in water (10 ml) was added. After 4 hours acetic acid (1 ml) was added and the reduced polysaccharide was methylated by adding dropwise to its solution sodium hydroxide (300 ml, 30%) and dimethyl sulphate (100 ml) during 5 hours. After 16 hours the partially methylated product (2.71 g) was isolated and the methylation procedure was repeated. The product was then methylated (twice) by the Kuhn procedure (20) in dimethyl-

For personal use only.

formamide. The resultant methylated polysaccharide (2.1 g) was a crisp pale yellow solid. Anal. Found: OMe, 45.3%. The product had $[\alpha]_D$ −49° (*c*, 5.3 in chloroform) and −29° (*c*, 4.9 in methanol). Infrared examination of the solid indicated that it contained very little free hydroxyl.

An attempt was made to fractionate the methylated polysaccharide by dissolution in a series of mixtures of boiling *n*-hexane and chloroform in the usual way. Almost all of the material (1.58 g) was soluble in the solvent when the ratio of *n*-hexane to chloroform was 4:1 (v/v).

Fission of the Methylated Galactan

The methylated galactan (1.4 g) was dissolved in formic acid (90% v/v) and the solution was heated at 95° C for 6 hours. The solution was evaporated to dryness and formic acid removed by three codistillations with water. The hydrolysis was then continued by heating the syrup in *N* sulphuric acid for 5 hours at 95° C. The mixture was cooled, neutralized ($BaCO_3$), and centrifuged. The top clear solution was acidified (acetic acid) and evaporated to a syrup, (1.2 g), $[\alpha]_D$ +65° (*c*, 2.0 in methanol).

Isolation of the Methylated Sugars

Paper chromatographic examination of a portion (1 g) of the syrup indicated the presence of at least four methylated sugars. These were separated on a column of cellulose using the procedure described above.

Fraction 1. The first component (0.34 g) eluted from the column behaved chromatographically like 2,3,4,6-tetra-*O*-methyl-D-galactose (solvents A_1 and B) and had $[\alpha]_D$ +112° (*c*, 1.4). A sample when heated with ethanolic aniline yielded 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. 195–197° C, not depressed on admixture with an authentic specimen.

Fraction 2. The second fraction (0.03 g) was identified chromatographically as 2,4,6-tri-*O*-methyl-D-galactose (solvents A_1 and B) and was characterized as the *N*-phenyl-D-galactosylamine derivative, m.p. and mixed m.p. 179° C.

Fraction 3. This fraction (0.08 g) was a mixture of two methyl sugars. The slower moving and major component moved at the same rate as 2,3,4-tri-*O*-methyl-D-galactose. It gave a characteristic brown color with the *p*-anisidine hydrochloride spray, while the faster moving component gave a pink color and was indistinguishable from the 2,4,6-tri-*O*-methyl isomer. The mixed sugars were converted into the mixed crystalline *N*-phenyl-D-galactosylamines which were separated by hand.

Fraction 4. Fraction 4 (0.15 g) was homogeneous and identical with 2,3,4-*O*-trimethyl-D-galactose. Treatment with ethanolic aniline yielded the corresponding D-galactosylamine derivative, m.p. and mixed m.p. 167–169° C, $[\alpha]_D$ −65° → 45° (5 hours) *c*, 1.1) in methanol.

Fraction 5. This fraction (0.27 g) crystallized and was identified as 2,4-di-*O*-methyl-D-galactose monohydrate, m.p. and mixed m.p. 100° C, $[\alpha]_D$ 116° (5 minutes, *c*, 1.7). When it was heated with ethanolic aniline 2,4-di-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. and mixed m.p. 216° C was obtained.

Fraction 6. The last fraction (0.005 g) was eluted from the column with water. It represented 0.5% of the original hydrolyzate and was probably a monomethyl galactose.

Estimation of Molar Ratios of the Methylated Sugars

The molar ratios of the methylated sugars in the hydrolyzate were determined by the method of Hirst, Hough, and Jones (19). Anal. Found: ratio of 2,3,4,6-tetra-, to tri-,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

to 2,4-di-*O*-methyl-D-galactose: 1.0:1.1:1.0. The ratio of 2,4,6-tri-*O*-methyl- to 2,3,4-tri-*O*-methyl-D-galactose was 1 to 10 as determined from the weight of fractions isolated from the cellulose column.

THE PHOTOOXIDATION OF AZOMETHANE. III[1]

F. WENGER[2] AND K. O. KUTSCHKE

ABSTRACT

It is confirmed that the yields of all products in the photooxidation of azomethane at relatively high oxygen pressure depend on conversion in a manner which would be explained if a reactive hydrogen donor were produced in the early stages of the reaction. Evidence is presented which indicates that formaldehyde cannot be active as an inhibitor in the system at 162° C. It is suggested that methyl radicals react with oxygen in two ways. The third order formation of methyl peroxy radicals leads to methoxy radicals and, eventually, to methanol, while the bimolecular reaction between methyl radicals and oxygen leads to a vibrationally excited state of formaldehyde. The latter is thought to undergo oxidization to performic acid, which acts as the inhibitor in the system. Yields of formaldehyde, of nitrogen in excess of that formed in the primary process, and of nitrous oxide are linearly related regardless of the conversion up to about 4%. Methanol is a major product of the oxidation and, if account is taken of its yield, a carbon balance of the order of 90% is obtained.

INTRODUCTION

In view of the convenience of azomethane as a photochemical source of methyl radicals, this compound has been used in the past for studies of the reaction of methyl radicals with oxygen (1, 2, 3). While it was possible to obtain an approximate value for the rate constant of this association reaction (1), assuming it to be bimolecular (see (3) and (4) for a discussion of this point), many of the features of the over-all photooxidation remained unsettled. This was particularly true with respect to the dependence of the rates of formation of most of the products on the extent of conversion.

Earlier work was hampered by the lack of reliable techniques for formaldehyde detection (1) and measurement (2). The present report describes the techniques for measurement of formaldehyde and methanol yields. Experimental conditions have been limited to the region of high oxygen pressure where methane and ethane are absent (1), an observation which was confirmed in the present study. The absence of methane renders highly improbable the participation of "hot" methyl radicals such as have been postulated from other methyl radical sources (5). Data have been obtained at 121° and 161° C. The lower limit was chosen to ensure that formaldehyde would not polymerize in the system, while the upper limit was dictated by the appreciable rate of a thermal reaction at temperatures slightly above it.

EXPERIMENTAL

Apparatus

The apparatus was basically the same as used in an earlier investigation (2). Improvements in the thermostatted air bath housing the cell lowered local temperature differences from point to point within the oven to 1° C. The volume of the reaction system—U-tube, reaction cell, and circulating pump—was 255 cm^3; that of the cell itself, 180 cm^3. Some changes were made in the analytical system to permit the use of the modified procedures for liquid product analysis described below. Actinic light, mainly of 3660 Å, was obtained from a Hanovia S-500 mercury arc and a Corning 5860 filter (6).

Materials

Azomethane was obtained from Merck of Canada (Montreal). After several bulb-to-bulb distillations a middle fraction was stored at room temperature in a blackened bulb

behind a mercury cutoff. Oxygen was prepared by heating potassium permanganate and purified by passage through a trap at −196° C. Formaldehyde-O^{18} was obtained as paraformaldehyde from Dr. L. C. Leitch of these laboratories; it had been prepared by exchange of the polymer with enriched water under reflux. Heating of the polymer liberated the monomer, which was freed of residual water by distillation from −78° to −196° C. Mass spectrometric analysis indicated an O^{18} content of 2.4%, although the water used in the exchange was more highly enriched. It is thought that only the surface layers of the polymer had been exchanged by the treatment used.

The trisodium salt of chromotropic acid (4,5-dihydroxy-2,7-naphthalene disulphonic acid, trisodium salt) used in formaldehyde and methanol analyses was prepared by titration of an aqueous solution of Eastman Kodak chromotropic acid, disodium salt. On adding ethanol a white, crystalline material separated, which was filtered and dried. This crude material soon turned violet when left to stand. The substances causing the colored oxidation products—impurities and probably the quarternary salt of the acid—were less soluble in ethanol–water mixtures and were removed by fractional precipitation. Material prepared in this manner was stored for months in the dark with no change in its analytical behavior.

Photooxidation Procedure

Azomethane was outgassed in the storage bulb prior to each run; the required pressure, as measured on a manometer at room temperature, was built up in the hot cell; and the contents of the reaction system were condensed at −196° C in the U-tube. Oxygen was admitted to the reaction system to the required pressure and measured on a McLeod gauge external to the oven. The volume of the cold U-tube was small relative to that of the whole reaction system so that negligible error was introduced by measuring oxygen pressure with the U-tube at −196° C. After the valve leading to the storage and measuring manifold was closed, the U-tube was heated to the cell temperature and the gases mixed by means of the circulating stirrer.

Considerable care was taken in the experiment with added formaldehyde to ensure that the results would not be uncertain due to polymerization of that material. An accurately known amount of formaldehyde was introduced as follows. Two bulbs of known volume ratio and equipped with breakoff points were connected via stopcocks to a manifold containing formaldehyde vapor at approximately the required pressure. After time was allowed for pressure equilibration, the stopcocks were closed, the formaldehyde condensed at −196° C, the bulbs detached from the stopcocks at a sealoff point, and the contents of one bulb analyzed by the chromotropic acid procedure (see below). From the known volume ratio, the quantity in the second bulb could be calculated. This second bulb was sealed to the reaction system in the oven, and azomethane was introduced as usual and stored temporarily outside the oven in a trap on the analytical system. The breakoff was broken, the monomeric formaldehyde condensed in the U-tube at −196° C, and the formaldehyde introduction bulb sealed from the system. Azomethane was returned to the cold U-tube, oxygen introduced as usual, and the gases mixed.

Analysis of Products

(*a*) *Gaseous Products*

After photolysis the contents of the reaction system were condensed in a trap at −196° C and the non-condensable gases (N_2, CO, and O_2) were transferred to a gas burette, measured, and analyzed over copper – copper oxide at 250° C with a contact time of 2 hours as described earlier (1, 2). The contents of the trap were allowed to warm to room

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

temperature in a volume of connecting tubing defined by the valve leading to the reaction system and a stopcock near the trap, and were recondensed and warmed three times thus polymerizing the bulk of the formaldehyde (2). Unpolymerized material was transferred to a LeRoy still (7) held at −196° C. Nitrous oxide, carbon dioxide, unpolymerized formaldehyde, and some of the azomethane were transferred at −130° C from this still to a second at −196° C. By heating the second still to −160° C, nitrous oxide and carbon dioxide were transferred to the gas burette, measured, and submitted for mass spectrometric examination. By following this procedure in detail less than 1% formaldehyde impurity was found in the carbon dioxide – nitrous oxide fraction.

(*b*) *Formaldehyde*

A method based on the chromotropic acid procedure (8) was used. Formaldehyde and any azomethane from the second LeRoy still, along with the formaldehyde from the U-tube (depolymerized by heating), were condensed with liquid nitrogen on top of 4 ml of a frozen aqueous solution containing 150 mg of the trisodium salt of chromotropic acid contained in a small pear-shaped reaction flask. The flask was removed from the vacuum system at a ground joint, warmed to room temperature, and mixed well. Azomethane was removed by bubbling a stream of water-saturated nitrogen through the solution. Blank experiments showed that this procedure removed completely the excess azomethane and retained formaldehyde quantitatively. The solution was acidified with 12 ml concentrated H_2SO_4, heated in boiling water for 30 minutes, and cooled. After dilution the extinction at 570 mμ was measured on a Beckmann DU spectrophotometer and the amount of formaldehyde determined from a calibration curve. For samples expected to contain more than 200 γ formaldehyde proportionally larger quantities of reagents were used.

(*c*) *Methanol*

Products remaining in the first LeRoy still (mainly methanol, water, and the bulk of the unreacted azomethane) were distilled to a reaction flask containing 4 ml distilled water. Azomethane was removed on a stream of nitrogen as before; 400 mg chromotropic acid, disodium salt, and 0.5 ml concentrated H_2SO_4 were added and a 3-ml fraction, containing all the methanol (as shown by calibration experiments), was transferred by distillation to a second reaction flask. Methanol was oxidized by potassium permanganate and the resulting formaldehyde determined with chromotropic acid as described above (9). A set of similarly treated methanol standards was used to construct the calibration curve of extinction vs. amount of methanol.

Since the yield in the oxidation step of this procedure is small (~10%) small amounts of formaldehyde, present in this liquid product fraction or produced by hydrolysis of azomethane or other products of the photooxidation, if carried over in the distillation step will yield high values for the amount of methanol. In using the method of Bricker and Vail (10) to separate synthetic methanol – formaldehyde mixtures, formaldehyde was always found in the methanol fraction. This could be prevented by heating the solution to 100° C for a half an hour prior to distillation or by maintaining a low pH during the distillation as was outlined above. This latter method was adopted because the liquid products from the first LeRoy still appeared to contain small amounts of unidentified compounds, presumably products of the addition of radicals to azomethane. These compounds were not removed by the stream of nitrogen. Moreover, they did not react with the chromotropic acid salt (as would free formaldehyde if present) so that they appeared in the methanol distillate where they were hydrolyzed to formaldehyde during subsequent acid treatment causing high methanol yields. The addition of sulphuric acid prior to distillation yielded a distillate free of formaldehyde and hydrolyzable substances.

In some parallel experiments the methanol determination was verified by gas chromotography or, after removal of the bulk of the azomethane by distillation, by infrared analysis.

RESULTS

Analyses are given for the amounts of nitrogen, carbon monoxide, carbon dioxide, methanol, and formaldehyde formed and for oxygen disappearance. Water was detected mass spectrometrically and the rough estimate of its yield on this basis was in essential agreement with that calculated from a consideration of the hydrogen and oxygen material balances. Formic acid and acetaldehyde were detected mass spectrometrically in very small yields in the liquid product fraction. An otherwise unidentifiable peak at mass number 104 was tentatively assigned to the compound $CH_3OOCH_2N_2CH_3$. It is possible that this compound is an important intermediate in nitrogen production at low oxygen pressure.

In the early series of experiments (Table I and Fig. 1) methanol analyses were not attempted and formaldehyde yields are probably low due to adsorption or polymerization on room temperature connecting tubing; this was corrected in the later experiments by heating the tubing to about 140° C.

Table I shows the data for a set of experiments at 120° C using two different light intensities. An examination of these data shows that light intensity changes of a factor of about five have little effect on product ratios for any given degree of conversion as indicated by the amount of nitrogen and nitrous oxide found. The data for the lower intensity are plotted in Fig. 1 showing the general trend of the amounts of the various products formed with illumination time. Both the very small intensity dependence and the trend shown in Fig. 1 confirm results reported previously (2).

The data shown in Table II were taken after the improvements in the analytical system noted above had been achieved. If it is assumed that each molecule of azomethane which is decomposed leads to either a molecule of nitrogen or of nitrous oxide, then the

ratio $(n_{N_2}+n_{N_2O})/n_A$ is an approximate measure of the fractional conversion of the azomethane. Here $n_{N_2}+n_{N_2O}$ represents the total number of moles of nitrogen and nitrous oxide found and n_A represents the initial number of moles of azomethane in the reaction system (255 cm^3). This corresponds to the conversion D_1 of the earlier work (2); to obtain conversions based on the cell volume (D_2 of (2)) multiply by 1.42. By plotting the data against fractional conversion rather than time of illumination at least some compensation is achieved for the effects of small variations in light intensity from one experiment to another.

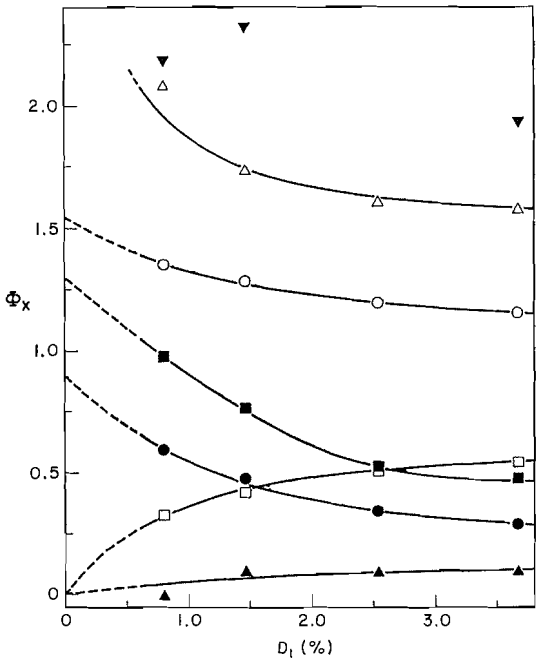

FIG. 2. Dependence of quantum yields on conversions, 162° C. ○ N_2; ● N_2O; □ CO; ■ CH_2O; △ CH_3OH; ▲ CO_2; ▼ O_2.

Figure 2 contains the data taken at 162° C (Table II) plotted as apparent quantum yields Φ_X, calculated as the ratio of the amount of product X actually found to the amount of nitrogen which would have been formed had oxygen been absent in the experiment. Extrapolations to zero conversion are arbitrary except in the case of carbon monoxide where the shape of the amount vs. time curve (similar to that of Fig. 1) strongly suggests that the quantum yield vanishes at zero conversion. The large increase in Φ_{CO} is accompanied by a decrease in Φ_{N_2O} and Φ_{CH_2O}. The actual decrease in Φ_{CH_3OH} might not be as large as indicated because the curve drawn is strongly dependent on the yield at the lowest conversion where small errors in the analytical method would be exaggerated. However, it seems quite certain that Φ_{CH_3OH} does decrease as conversion is increased.

Data for the lower temperature experiments are illustrated in Fig. 3. Instead of Φ_X the quantity ρ_X, defined as $n_X/(n_{N_2}+n_{N_2O})$, is plotted against conversion. ρ_X is a measure of the yield of the product X per molecule of azomethane decomposed. The use of ρ eliminates any assumption regarding the comparison of experiments in the presence and absence of oxygen and the possibility that such a comparison is not valid over a large range of intensity. In general the trends of ρ_X with conversion are similar to those of Φ_X except when X is N_2. ρ_{N_2} decreases at low conversion because of the increase in the relative amount of nitrous oxide, although Φ_{N_2} in fact increases in this region in a manner analogous to that shown in Fig. 2. Values of Φ_X at 120° C, read from a graph similar to that of Fig. 2 at conversions such that the yields had attained their approximately steady values, are, $\Phi_{N_2} \sim 1.0$; $\Phi_{N_2O} \sim 0.1$; $\Phi_{CO} \sim 0.4$; $\Phi_{CO_2} \sim 0.06$; $\Phi_{CH_3OH} \sim 1.0$; $\Phi_{CH_2O} \sim 0.2$. In drawing curves to obtain these values, no account was taken of the very low intensity experiments in Table II; owing to the lack of data at high conversion and low intensity it is not possible to make an estimate of limiting quantum yields for these conditions. However, it would seem definite that all Φ_X increase at low intensity. This fact, together with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

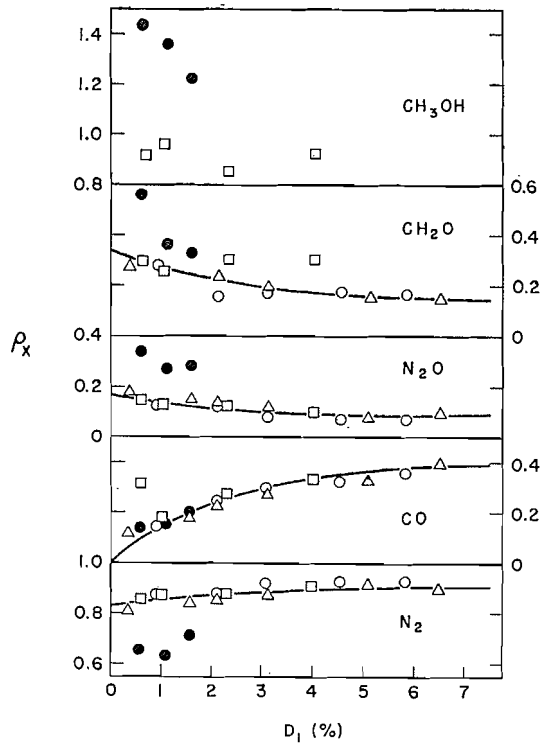

FIG. 3. Change of product ratios (ρ_x) with conversion, ~ 120° C. ○ Table I, $I_a = 6.3\times10^{13}$; □ Table II, $I_a = 4.5\times10^{13}$; △ Table I, $I_a = 1.3\times10^{13}$; ● Table II, $I_a = 2.7\times10^{11}$.

Φ_{CH_3OH} 2.5 at about 1% conversion strongly suggests that a short chain is operating which is inhibited at higher conversions and higher light intensity. Inhibition of a chain by increase in oxygen pressure is suggested by other work, but the present data are taken at an oxygen pressure such that any inhibition from this source should be fully developed.

Earlier work on this problem (1, 2) as well as other photooxidation studies has been hampered by very low product balances. Using the assumption mentioned earlier, to the effect that nitrogen and nitrous oxide found are proportional to azomethane decomposition, it is seen that carbon recovery in per cent is given by $m_C = (100/2)\Sigma\rho_X$ where the summation extends over all products containing carbon. Similarly, the hydrogen recovery is $m_H = (100/6)\,(4\rho_{CH_3OH}+2\rho_{CH_2O})$. Oxygen recovery is given by $m_O = 100(n_{CO}+2n_{CO_2}+n_{N_2O}+n_{CH_2O}+n_{CH_3OH})/2n_{O_2}$ where the n_X is the numbers of moles of products X recovered and n_{O_2} is the oxygen consumption. Values calculated on this basis are reported in Table II; the data of Table I have not been treated in this way since methanol was not determined. Rather surprisingly, methanol yields are sufficiently large to raise the carbon balance to reasonably high values. It would thus appear that no major products of the reaction have been neglected. One possibility cannot be ruled out entirely. If some high molecular weight nitrogenous compound were produced possessing a carbon to nitrogen atomic ratio less than unity, the balances cited would be too large. It is difficult to visualize the formation of such compounds in this system, however. The converse hypothesis, that high molecular weight products are formed, but that they possess a carbon–nitrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

ratio greater than unity, is probably true and could account for $m_C < 1$. Such compounds could be formed by radical addition to the nitrogen–nitrogen double bond, a reaction of considerable importance in the absence of oxygen (1, 6).

DISCUSSION

Nitrogen, Formaldehyde, and Nitrous Oxide

Following our earlier work (1) it is considered that the primary process in the photolysis is unaffected by the presence of oxygen.

$$CH_3N_2CH_3 + h\nu \rightarrow 2CH_3 + N_2 \quad [1]$$

The strongest evidence supporting this hypothesis is data taken at low azomethane pressure, high oxygen pressure, and low temperature. It was shown (1) that for these conditions $-\Phi_{azo} = \Phi_{N_2} \sim 1$, which could hardly be true if deactivation of excited molecules were occurring. The low temperature is expected to favor deactivation if it occurred.

For other conditions values of $\Phi_{N_2} > 1$ have been observed here and in earlier work (1, 2). A similar observation has been made in the azoethane photooxidation (11). The data may be correlated empirically as is done in Fig. 4. In this plot, at 162° C, the amount of formaldehyde produced is linearly related to the amount of nitrous oxide, as is the amount of secondary nitrogen. The latter is defined as the nitrogen produced in excess of that which would have been formed had oxygen been absent in the experiment. Although curvature may be present in these plots, a linear relation represents the data adequately within experimental error. Such a correlation strongly suggests a common source for secondary nitrogen, nitrous oxide, and formaldehyde. Nitrous oxide has been considered (1) to arise via the mechanism

$$R + CH_3N_2CH_3 \rightarrow RH + CH_2N_2CH_3 \quad [2]$$

$$CH_3N_2CH_2 + O_2 \rightarrow CH_3 + N_2O + CH_2O. \quad [3]$$

Reaction [3] is written as an over-all reaction and might occur in stages involving the $CH_3N_2CH_2O_2$ radical. R is some radical in the system capable of abstracting hydrogen from azomethane. A parallel reaction yielding the secondary nitrogen might be

$$CH_3N_2CH_2 + O_2 \rightarrow CH_3O + N_2 + CH_2O. \quad [4]$$

If these are the only important reactions producing secondary nitrogen, nitrous oxide, and formaldehyde, the difference between formaldehyde and secondary nitrogen should equal the amount of nitrous oxide found. The broken line in Fig. 4, which is drawn with a slope of unity, is a reasonable representation of the data. At the lower temperature the correlation does not hold. Data at 124° C from an earlier investigation (2) show a similar trend but are rather badly scattered. Thus it is not possible to obtain the activation energy difference between [3] and [4]. From Fig. 4 a value $k_3/k_4 = 1.8$ is obtained at 162° C.

Earlier data show that [3] and [4] are slow compared to the third order (3, 12) reaction [5]

$$CH_3 + O_2 + M \rightarrow CH_3O_2 + M. \quad [5]$$

This may be seen by comparing (at 161° C) the oxygen pressure at which Φ_{N_2O} attains its approximately limiting value (~ 1 mm) with that required for Φ_{CH_4} to decrease to negligible values (~ 0.1 mm) (Figs. 3 and 4 of (1)). Thus there exists a region of oxygen pressure between these limits where CH_3O_2 and $CH_2N_2CH_3$ are present in the system. If these may react as in [6] and the resulting peroxide decomposes, in part, by [7] and [8],

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Φ_{N_2} should increase at oxygen pressures below about 1 mm and decrease again at a very low oxygen pressure where [5] becomes a less predominant fate for methyl radicals.

$$CH_3O_2 + CH_2N_2CH_3 \rightarrow CH_3O_2CH_2N_2CH_3 \quad [6]$$

$$CH_3O_2CH_2N_2CH_3 \rightarrow CH_3O + OCH_2N_2CH_3 \quad [7]$$

$$OCH_2N_2CH_3 \rightarrow CH_2O + N_2 + CH_3 \quad [8]$$

A careful examination of the dependence of Φ_{N_2} on oxygen pressure (Fig. 1 of (1)) shows that such a trend exists. The tentative mass spectrometric identification of $CH_3O_2CH_2N_2CH_3$ among the products in the current work supports this hypothesis as well. An analogous effect has been observed in the photooxidation of azoethane (11), and a similar scheme might be used to explain part of the variation in Φ_{CO} with oxygen pressure in acetone photooxidation (13).

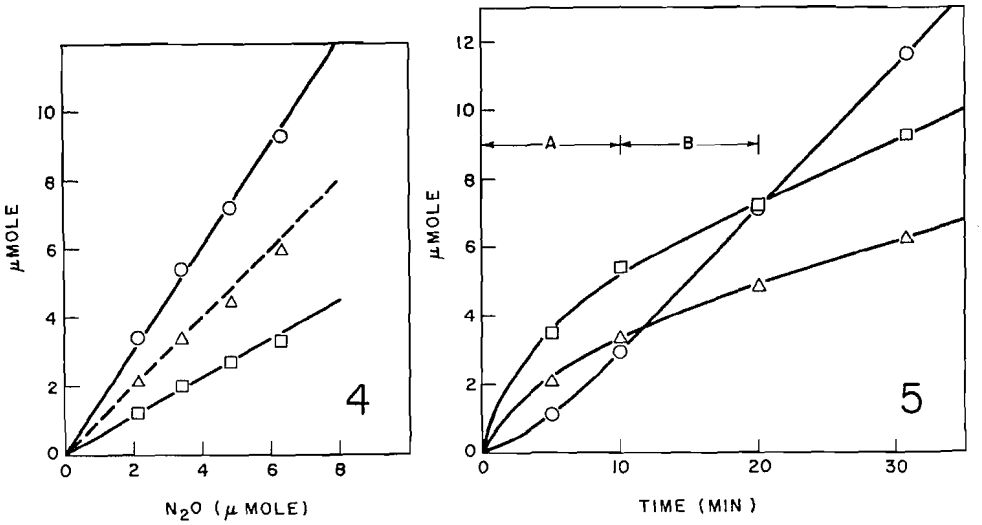

FIG. 4. Correlation of formaldehyde, secondary nitrogen, and nitrous oxide, 162° C. ○ CH_2O; □ $(N_2)_{secondary}$; △ CH_2O–$(N_2)_{secondary}$. The broken line has a slope of unity.
FIG. 5. Possible formaldehyde inhibition, 162° C. ○ CO; □ CH_2O; △ N_2O.

If the reactions analogous to [2], [3], [4], [6], [7], and [8] occur in the acetone photooxidation, the material balance method (4) of determining the third body requirement for [5] is open to some question since more than two methyl radicals are released to the system per quantum absorbed. The determination of k_5 using azomethane photooxidation (1) included the chain steps [2] and [3] but did not consider [6], [7], and [8]. Occurrence of [4] further complicates the situation in either case.

Formation of Methanol

It seems unlikely that the large yields of methanol found here can be explained without the presence of relatively high concentrations of methoxy radicals. If such is indeed the case then methanol could arise in reaction [2], with R the CH_3O radical, and possibly in [9] as well.

$$2CH_3O \rightarrow CH_3OH + CH_2O \quad [9]$$

Empirically it is found that the material balance [I] holds reasonably well over a large range of conversion and temperature.

$$CH_3OH = 2CO + CO_2 + CH_2O \quad [I]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

This is shown in the last column of Table II as the ratio $m_I = (2CO + CO_2 + CH_2O)/CH_3OH$. At the very low intensity the relationship is no longer obeyed.

It would appear that, in addition to [2] and [9], which produce equivalent quantities of methanol and formaldehyde if [3] and [4] are the sole fates of $CH_2N_2CH_3$ radicals, there is another source of methanol. This further source involves the production of 2 molecules of methanol and 1 of carbon monoxide or 1 each of carbon dioxide and methanol. A single source need not lead to both oxides of carbon; possibly two such sources are involved. Moreover, the inclusion of carbon dioxide in [I] is somewhat dubious. Because of the relatively small yields of this product, an equally reasonable value of m_I could be obtained if carbon dioxide were not considered. Since methanol production by this means appears to be associated with carbon monoxide formation and the yield of this product depends most strongly on conversion, a discussion of the additional methanol formation is deferred to a later section.

Occurrence of [2] and [9] as sources of methanol requires the presence of methoxy radicals. Reaction [4] is not, of course, a sufficiently copious source of that radical. The product of [5] is almost certainly a methyl peroxy radical, and some scheme must be devised to transform the peroxy methyl radical to a methoxy. Using an earlier suggestion of Bell *et al.* (14) reaction [10] has been postulated for this conversion (1).

$$2CH_3O_2 \rightarrow 2CH_3O + O_2 \qquad [10]$$

Unless other fates are possible for CH_3O_2 radicals, [10] is inevitable regardless of intensity. Such another fate might be abstraction from some hydrogen donor in the system to form methyl hydroperoxide. All attempts to identify this compound have been fruitless (1). While it might be objected that mercury vapor present in the system might catalyze the decomposition of the peroxide, the results of Marcotte and Durbetaki (15) in the acetone photooxidation are inconsistent with this objection. Thus it is concluded that if [10] occurs it will be unaffected by light intensity. Recently McDowell and Sharples (16) have shown that reactions, thought to be analogous to [10], of acetyl and propionyl peroxy radicals proceed with almost unit collision yield. The products in those cases were written as diacetyl or dipropionyl peroxides and molecular oxygen, but the products were not isolated. In view of the higher temperatures used here it might be anticipated that the products would be those of O—O bond fission in the resulting peroxide. Hence [10] is considered an efficient reaction.

Other mechanisms have been suggested for this conversion. The identification of small, stationary concentrations of ozone in some photooxidation systems has led to the suggestion (3, 17) that [11] might be efficient in the transformation.

$$RO_2 + O_2 \rightarrow RO + O_3 \qquad [11]$$

Ozone is thought to be consumed by rapid reaction with alkyl radicals so that its concentration never reaches readily detectable levels.

While the precise mechanism operating in this system remains unknown, it seems necessary to postulate that the methyl radicals produced in [1], [3], and [8] are, for the most part, rapidly and efficiently converted to methoxy radicals probably via the methyl peroxy radical.

Dependence of Products on Conversion

The decrease with conversion of the apparent yields of nitrogen, nitrous oxide, formaldehyde, and methanol, as illustrated in Figs. 1 to 3, accompanied by an increase in the carbon monoxide yield, strongly suggests that an inhibitor is produced in the early stages of the reaction. Radicals, presumably mostly methoxy, react with this inhibitor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

rather than with azomethane, resulting in a decreased chain length for the over-all reaction and production of carbon monoxide from the inhibitor. The time scale of the events—many minutes—precludes the possibility that the phenomenon involves a radical acting as an inhibitor.

Because of the relatively small energy requirements for abstraction of the aldehydic hydrogen, aldehydes have been thought to act in the manner required by the present observations. A scheme involving formaldehyde has been suggested in the azomethane photooxidation (2). This involved the mechanism outlined below in which the radical R is probably methoxy.

$$R + CH_2O \rightarrow RH + CHO \qquad [a]$$

$$R + CHO \rightarrow RH + CO \qquad [b]$$

$$O_2 + CHO \rightarrow CO + HO_2 \qquad [c]$$

$$R + CH_3N_2CH_3 \rightarrow RH + CH_2N_2CH_3 \qquad [d]$$

$$CH_2N_2CH_3 + O_2 \rightarrow CH_2O + N_2O + CH_3 \qquad [e]$$

If, as seems reasonable, [*c*] and [*e*] are considered to follow rapidly after [*a*] and [*d*] respectively, so that the latter reactions are rate determining, it is seen that the instantaneous rate ratio is obtained as [II]

$$[II] \qquad r_{CO}/r_{N_2O} = k_a[F]/k_d[A].$$

Figure 5 is used to test this suggestion. During the period from 10 to 30 minutes r_{N_2O} is essentially constant while the instantaneous concentration of formaldehyde, [F] of equation [II], has increased from about 2.1×10^{-5} mole/l. at 10 minutes to about 3.6×10^{-5} mole/l. at 30 minutes. Thus r_{CO} should have increased by a factor of about 1.7 if [II] is to hold. Obviously r_{CO} is essentially constant in this interval.

Further confirmation of the incorrectness of the hypothesis is obtained from the experiment with added formaldehyde-O^{18}, done at 162° C. Formaldehyde was added in an amount (5.13 μmole) calculated to be equivalent to that found at the end of a 10-minute exposure. If formaldehyde were essentially inert in the system, the amounts of various products expected are those corresponding to the time interval A of Fig. 5. Conversely, if formaldehyde acts as the inhibitor, the amounts expected are those pertaining to time interval B. Products observed and those expected under the two conditions are shown in Table III. It is seen that the observed values are in excellent agreement with those expected if formaldehyde were inert in the system.

A further observation from this experiment involves the isotopic composition of carbon monoxide. This product, along with unreacted oxygen, was compressed into the copper – copper oxide furnace and the resulting carbon dioxide submitted for mass spectrometric examination. Blacet and Taylor (17) have concluded that oxygen required for the conversion of carbon monoxide to the dioxide arises solely from the excess gas phase oxygen, and that no exchange occurred. Hence it was anticipated that exchange of any CO^{18} present was unlikely. However, conditions were not identical in the two cases (especially in regard to contact time and the state of oxidation of the catalyst) so that the results might not be significant. It was observed that the carbon dioxide so formed had precisely the naturally occurring composition (obs. $CO^{16}O^{16}$ 99.59%, $CO^{16}O^{18}$ 0.41%, $CO^{18}O^{18}$ absent; natural composition $CO^{16}O^{16}$ 99.60%, $CO^{16}O^{18}$ 0.399%, $CO^{18}O^{18}$ 0.0004%). Had abstraction occurred from the added formaldehyde somewhat less than 2.4% of the carbon dioxide should have been enriched. By itself the isotopic result is of little value because of low O^{18} concentrations and lack of proved techniques. Agreement between the conclusions reached here and those outlined above, however, suggests that the results are more than fortuitous. It is hoped to continue work along these lines in the future.

On the basis of the evidence outlined, it is difficult to treat formaldehyde differently from any other product in the system. The parallelism between the yields of formaldehyde, secondary nitrogen, and nitrous oxide (Fig. 4) had already suggested this. It is, however, possible to obtain a qualitative explanation of this parallelism even if further oxidation of formaldehyde occurs (2). As shown here this explanation leads to quantitative inconsistencies and must be abandoned.

Various other intermediates have been suggested in thermal oxidation reactions but no direct evidence is available from the present work which would permit a decision in this matter. Another qualitatively correct hypothesis is worthy of examination, however. It has been suggested by Hoare and Walsh (4) and by Christie (12) that the oxidation of a methyl radical proceeds via the third order reaction [5] and a bimolecular reaction [12].

$$CH_3 + O_2 \rightarrow CH_2O + OH \qquad [12]$$

The products of [12] were not discussed in detail but Christie's evidence is strongly in favor of its occurrence; she suggests those shown as probable products. It might be pointed out further that if the products of [12] retain the energy of the exothermic reaction, it is conceivable that a goodly percentage of this energy is held by the formaldehyde. The products of [3], [4], [8], and [9], the latter being especially exothermic, are not thought to be in high vibrational levels. The activated complex for [9], for example, presumably involves a relatively simple H-abstraction type of configuration in which vibrations are not excited (18). High vibrational levels must be involved in the complex of [12], however, and it is thought that these are carried over in the formaldehyde product.

It is suggested that this excited formaldehyde is oxidizable by some mechanism which cannot be specified in detail, but which must not be available to normal formaldehyde. Such a process can be designated by the over-all reaction [13].

$$CH_2O^* + O_2 \rightarrow HCO_3H \qquad [13]$$

It is possible to devise a scheme, on the basis of performic acid as the elusive intermediate, which does in fact satisfy most of the data.

$$CH_3O + HCO_3H \rightarrow CH_3OH + CO_3H \qquad [14]$$

$$CO_3H \rightarrow CO_2 + OH \qquad [15]$$

$$CH_3O + CO_3H \rightarrow CH_3OH + O_2 + CO \qquad [16]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The mechanism is thought to operate in a manner generally similar to the formaldehyde mechanism discussed before. At very low conversions, $\backsim 1/2\%$ in this work, the concentration of performic acid is too low to affect the course of the reaction and a short chain reaction occurs (at 162° C $\Phi_{N_2} + \Phi_{N_2O}$ extrapolates to 2.5 at zero conversion). As conversion increases performic acid is consumed in [14], [15], and [16], leading to new products—the oxides of carbon—so that its concentration is held at a low, stationary level which was not detected analytically. This particular scheme has the advantage that the production of carbon dioxide with an induction period is also accounted for explicitly. Because of the small yields the actual presence of an induction period cannot be demonstrated conclusively (Figs. 2 and 3), but its occurrence would not be inconsistent with data. An alternative suggestion, that excited formaldehyde itself acts as the intermediate, can be eliminated on the basis of the time scale of the phenomenon.

Over-all Mechanism

Hydroxyl radicals, formed in [12] and [15], are thought to react as do methoxy. Thus [17], [18], [19], and [20] are postulated for their disappearance.

$$OH + CH_3N_2CH_3 \rightarrow H_2O + CH_2N_2CH_3 \qquad [17]$$

$$OH + HCO_3H \rightarrow H_2O + CO_3H \qquad [18]$$

$$OH + CO_3H \rightarrow H_2O + CO + O_2 \qquad [19]$$

$$OH + CH_3O \rightarrow H_2O + H_2CO \qquad [20]$$

An over-all mechanism composed of reactions [1] to [20] will explain the time dependence and is consistent with stability of formaldehyde in the system. The weakest point is, of course, the formation of performic acid for the presence of which no direct evidence has been obtained. It is seen that water is the only product not determined aside from presumably small quantities of performic acid. In the range of oxygen pressure used here, reactions [6], and thus [7] and [8], are unimportant. Conversion of methyl peroxy to methoxy is assumed to proceed via [10] only; reaction [11] is not considered here. Formaldehyde is formed in [3], [4], [9], and [20]. The difference

$$(H_2CO)_{total} - ((N_2)_s + N_2O) = (H_2CO)_{9,20} \qquad [III]$$

is shown in Fig. 4 to be negligible so that [9] and [20] cannot be significant at this temperature.

Unfortunately only the series of experiments at 162° C are sufficiently complete to be used as a test of the mechanism. In view of this, only material balances can be used to evaluate the scheme proposed. Moreover, because of the effect of conversion on the rates, comparisons can be made only after the rates have attained limiting values. These have been estimated graphically yielding limiting values at 162° C as follows; N_2 0.77, CO 0.42, CO_2 0.069, N_2O 0.14, CH_2O 0.25, CH_3OH 1.07, O_2 consumption 1.27 (all values are in μmole/minute). Since nitrogen is produced in the primary step at a rate of 0.70 μmole/minute, the limiting rate for secondary nitrogen is 0.07 μmole/minute.

If the amount of performic acid remaining at the end of an experiment can be neglected, the sum of the rate of formation of carbon monoxide and of carbon dioxide is a direct measure of the rate of [12]. Moreover, since [9] and [20] are not important, the difference between the limiting rates of formation of methanol and that of secondary nitrogen is a measure of the rate of [5]. Hence,

$$[IV] \qquad k_{12}/k_5[M] = (R_{CO}+R_{CO_2})/(R_{CH_3OH}-(R_{N_2})_s).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Using the limiting rates given above, $k_{12}/k_5[M] = 0.49$. A number of expressions may be derived relating $k_{12}/k_5[M]$ to the limiting rates of various products; all such expressions lead to similar values for the rate ratio. This value may be compared to that of 0.12 obtained from Christie's data (12) where M was methyl iodide. Differences in the temperature of the two experiments and possibly different efficiencies of methyl iodide and azomethane as third bodies might account for the factor of four difference. The uncertainties in both determinations are large.

It can be shown that oxygen consumption is given by either [V*a*] or [V*b*].

$$[Va] \qquad -R_{O_2} = \frac{4k_{12}+k_5[M]}{k_{12}+k_5[M]}\left((R_{N_2})_{prim}+\tfrac{1}{2}R_{N_2O}\right)+(R_{N_2})_s+R_{N_2O}-R_{CO}$$

$$[Vb] \qquad = \frac{2k_{12}+k_5[M]}{k_{12}+k_5[M]}\left((R_{N_2})_{prim}+\tfrac{1}{2}R_{N_2O}\right)+(R_{N_2})_s+R_{N_2O}+R_{CO_2}$$

[V*a*] yields 1.22 and [V*b*] 1.30 to be compared to an observed rate of 1.27 μmole/minute when limiting rate values are used. Thus the mechanism suggested yields the observed rate with reasonable success once approximately steady rates are reached.

Since water was not determined quantitatively it is not possible to test the predications of the mechanism for this product. It might be pointed out, however, that if each hydroxyl radical formed in [12] and [15] abstracts hydrogen to form water (as suggested by [17], [18], [19], with [20] thought not important) then the rate of water production when steady rates are attained is given by

$$[VI] \qquad R_{H_2O} = R_{CO}+2R_{CO_2}.$$

If [VI] is evaluated using the limiting rates, $R_{H_2O} = 0.56$ μmole/minute corresponding to a limiting value of the quantum yield of 0.8. The mechanism also predicts that

$$[VII] \qquad R_{CH_3OH}+R_{H_2O} = (R_{N_2})_s+R_{N_2O}+2R_{CO}+R_{CO_2}.$$

Comparison of [I] and [III], which are correct empirically as demonstrated earlier, with [VII] suggests that the yield of water should be negligible, which cannot be reconciled to the prediction of [VI]. Until more extensive data are available it seems fruitless to speculate further in regard to the formation of water.

A decrease of intensity yields an increase in the relative yields of products formed in propagation reactions (Fig. 3). However, the fact that the rates depend on conversion as well makes an investigation of the effect of intensity difficult to interpret until more data are available at various conversions and intensities.

It is concluded that the mechanism suggested is not complete, especially in regard to water formation, but that the trends of the product yields are reasonably well accounted for by that mechanism.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for his continued interest in this work and to acknowledge the assistance of Mrs. Frances Kutschke and Miss Bernice Thornton with the mass spectrometric analysis.

They also wish to thank Dr. J. G. Calvert for manuscript copies of his papers (see ref. 3) prior to publication.

THE SYNTHESIS OF 5-DEOXY-5-*S*-ETHYL-D-THREO-PENTULOSE[1]

J. K. N. JONES AND D. L. MITCHELL

ABSTRACT

The microbiological oxidation of 1-deoxy-1-*S*-ethyl-D-arabitol by *Acetobacter suboxydans* has yielded syrupy 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose from which a crystalline phenylosazone identical with the one prepared from 5-deoxy-5-*S*-ethyl-D-*xylo*-pentose was obtained. A syrupy 3,4-*O*-isopropylidene-5-deoxy-5-*S*-ethyl-D-*threo*-pentulose and its crystalline 2,5-dichlorophenylhydrazone were prepared.

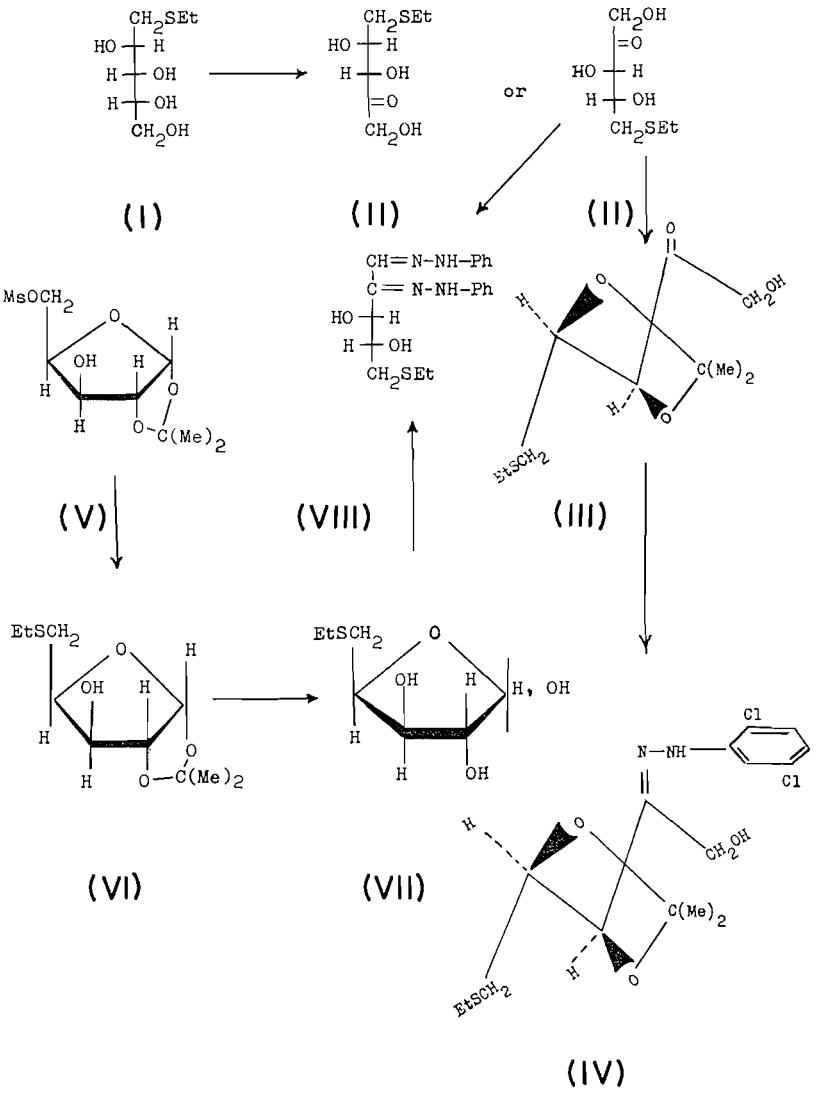
INTRODUCTION

The microbiological oxidation of terminal substituted polyhydric alcohols by *Acetobacter suboxydans* has been the subject of investigation in several laboratories (1, 2, 3). Recently, we reported that 1-deoxy-1-*S*-ethyl-D-glucitol was oxidized to 6-deoxy-6-*S*-ethyl-L-sorbose (3), and in this communication we report the microbiological oxidation of a structurally similar polyol, 1-deoxy-1-*S*-ethyl-D-arabitol (I), to 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose (II). The ω-deoxy analogue, 5-deoxy-D-*threo*-pentulose, $[\alpha]_D$ −5° in water, has been prepared by an aldolase-catalyzed condensation between acetaldehyde and dihydroxyacetone monophosphate (4); it was also most likely obtained when 1-deoxy-D-arabitol was oxidized by *A. suboxydans* (1).

When the culture medium contained sorbitol (0.4%), 1-deoxy-1-*S*-ethyl-D-arabitol was completely oxidized after 10 days to a strongly reducing compound. Copper reducing values previously published also support this conclusion (3). However, when sorbitol was not included in the medium, oxidation proceeded at a slower rate and was incomplete after 8 days. The oxidation product (II), $[\alpha]_D$ −41° in ethanol, which was obtained as a chromatographically pure syrup, revealed a strong absorption band in the carbonyl stretching frequency at 1710 cm^{-1}, while the corresponding 5-deoxy-5-*S*-ethyl-(D-*xylo*- and L-*arabino*-pentoses) possessed only a trace of carbonyl absorption and must therefore exist almost entirely as furanoses. Periodate oxidation of (II) at pH 3.7 followed by an estimation of the liberated formaldehyde (0.6 mole) indicated that the reducing compound had a primary alcohol group and that the site of enzymic oxidation was not at carbon 1. It appeared that periodate oxidation took place mainly between carbons 1 and 2. However, cleavage between carbons 2 and 3, or carbons 3 and 4, is possible although it could lead to an intermediate (i.e. glycollic acid) which is very stable to further attack by periodate ion (5). If enzymic oxidation occurred at a site other than the first carbon atom, the formation of a furanol ring system would be prohibited and the molecule would most likely exist in a zigzag conformation. The hydroxyl groups at carbons 3 and 4 would then be favorably situated for scission by periodate ion and also for ketal formation. Reaction of the ketose (II) with acidified acetone led to the formation of a strongly reducing *O*-isopropylidene derivative which possessed strong absorption at the carbonyl and carbon–hydrogen stretching frequencies. Considerable reduction of the absorption peak in the hydroxyl region of this compound was observed when its spectrum was compared with that of the ketose (II). Periodate oxidation of the *O*-isopropylidene derivative at pH 7 liberated formaldehyde (0.6 mole), which indicated

[1]*Manuscript received May 19, 1959.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

that carbons 1 and 2 were not involved in ketal formation. Reaction of the *O*-isopropylidene derivative (III) with 2,5-dichlorophenylhydrazine produced a small amount of the crystalline 2,5-dichlorophenylhydrazone (IV) which gave absorptions in the infrared corresponding to hydroxyl, —C=N—, and ketal groups (6). This evidence indicates that the biochemical oxidation product is the acyclic 2-pentulose, 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose (II) and that the derived ketal is 3,4-*O*-isopropylidene-5-deoxy-5-*S*-ethyl-D-*threo*-pentulose (III). These conclusions are also consistent with the well-known enzyme specificity for oxidations at pH 6.



Independent proof of the structure (II) was obtained through the synthesis of 5-deoxy-5-*S*-ethyl-(D-*xylo*- (VII) and L-*arabino*-pentose) via the 1,2-*O*-isopropylidene-5-*O*-toluene-*p*- (or methane-) sulphonyl ester (e.g. (V) → (VI)). The thioethyl aldoses (VII) displayed physical properties different from the thioethyl ketose (II). However, 5-deoxy-5-*S*-ethyl-

D-*xylo*-pentose gave a phenylosazone (VIII) identical with that which was prepared from (II) but which differed from the phenylosazone of 5-deoxy-5-*S*-ethyl-L-*arabino*-pentose. Therefore, the hydroxyls at carbons 3 and 4 of (II) possess the D-*threo*-configuration.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (ca. 15 mm) and at 40° C or less. Melting points were uncorrected and optical rotations were determined in water unless otherwise stated. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*b*) ethyl acetate – acetic acid – water (9:2:2); (*c*) butan-1-ol–ethanol–water (9:3:3); and (*d*) butan-1-ol–pyridine–water (10:3:3). Non-reducing compounds were detected on paper chromatograms with an alkaline silver nitrate spray reagent (7) and reducing compounds were detected with *p*-anisidine hydrochloride reagent (8). The rate of movement of the compound on paper chromatograms is quoted relative to that of rhamnose (R_{Rh} value). Infrared absorptions were measured as solutions in chloroform or as a powder suspended in a potassium bromide pellet on a Perkin–Elmer Model 21 spectrophotometer and wave numbers are given to within ± 10 cm^{-1}.

*5-Deoxy-5-S-ethyl-*D*-threo-pentulose*

A broth consisting of 1-deoxy-1-*S*-ethyl-D-arabitol (3) (0.42 g), sorbitol (0.2 g), yeast extract* (0.1 g), and potassium dihydrogen phosphate (0.01 g) in tap water (50 ml) was autoclaved (15 p.s.i., 30 minutes), cooled, inoculated with *Acetobacter suboxydans* (A.T.C.C. No. 621), and stored at 28° C for 10 days. Paper chromatographic examination of the medium then indicated the formation of a single major reducing constituent, besides sorbose, which gave an orange-red (apricot) color with the *p*-anisidine hydrochloride reagent. Chromatographic comparison with 5-deoxy-5-*S*-ethyl-L-*arabino*-pentose and 5-deoxy-5-*S*-ethyl-D-*xylo*-pentose, which both gave bright pink colors with the same reagent, indicated that it was a different compound because its rate of movement was slower in solvent systems (*c*) and (*d*). The rates of movement were practically identical in solvent systems (*a*) and (*b*). With the orcinol – trichloroacetic acid spray reagent no color reaction was produced but with the silver nitrate reagent a very rapid formation of silver resulted.

The broth was poured with stirring into ethanol (150 ml) and the cell debris was separated by filtration. After concentration of the filtrate, the oxidation product was separated on Whatman 3 MM filter paper and was obtained as a chromatographically pure syrup (0.20 g, 67%). The syrup was soluble in water, ethanol, acetone, and chloroform. A specimen which was dried *in vacuo* for 4 days was dissolved in chloroform (3% w:v) and its absorption measured in the infrared. A strong, sharp peak in the carbonyl stretching frequency at 1710 cm^{-1} was observed; $[\alpha]_D$ $-41° \pm 2°$ (*c*, 0.9, ethanol). After 3 weeks' storage at room temperature, the syrup was re-examined by paper chromatography, and revealed streaking in the vicinity of the constituent, presumably due to the development of isomers via keto $\rightleftarrows$ enol tautomerism. Some time later a second reducing constituent appeared with a rate of movement approximately that of rhamnose (solvent *a*).

In another experiment, *Acetobacter suboxydans* was grown on the same medium described above except that sorbitol was not included. After 8 days' oxidation, the

substrate and oxidized product appeared to be present on paper chromatograms in a ratio of 1:1.

TABLE I

Paper chromatographic values

Solvent system	(*c*)	(*d*)
R_{Rh} value of:		
5-Deoxy-5-*S*-ethyl-L-*arabino*-pentose	2.11*	1.98*
5-Deoxy-5-*S*-ethyl-D-*threo*-pentulose	2.02	1.86
5-Deoxy-5-*S*-ethyl-D-*xylo*-pentose	2.14	2.00

*Mean of two measurements.

*5-Deoxy-5-S-ethyl-*D*-threo-pentulose Phenylosazone*

A portion of the syrupy 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose (ca. 50 mg) was dissolved in a mixture of phenylhydrazine (0.1 ml), acetic acid (0.2 ml), and water (2 ml) and the solution was heated to 80° C for 2 hours. The derived phenylosazone was collected after the solution had been cooled and diluted with water. It was recrystallized from a small volume of ethanol and the product was washed with cold (−60° C) ethanol. Several recrystallizations gave a product of constant melting point 158–159° C (decomp.) which possessed an infrared absorption spectrum identical with that of the phenylosazone derived from 5-deoxy-5-*S*-ethyl-D-*xylo*-pentose. Mixed melting point 155–156° C, $[\alpha]_D^{20} -29° \pm 4°$ (*c*, 1.2, pyridine). Anal. Calc. for $C_{19}H_{24}N_4O_2S$: C, 60.0; H, 6.7. Found: C, 59.5; H, 6.4.

*3,4-O-Isopropylidene-5-deoxy-5-S-ethyl-*D*-threo-pentulose*

Syrupy 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose (ca. 75 mg) was dissolved in acetone (50 ml) containing concentrated sulphuric acid (1 drop) and the solution was shaken for 18 hours. After neutralization with barium carbonate, filtration, and concentration of the filtrate, the resulting syrup was examined by paper chromatography and infrared spectroscopy. A compound which moved much faster than the original material and which had R_{Rh} 2.7 (solvent (*a*)) was detected on the chromatogram as an orange-colored spot (*p*-anisidine hydrochloride); it also gave an immediate reaction with the silver nitrate – sodium hydroxide reagent. Traces of acetone were removed by repeated codistillation with chloroform, and a chloroform solution of the *O*-isopropylidene derivative was examined in the infrared. It possessed a medium weak absorption band at 3350 cm^{-1} and a medium strong absorption band at 1709 cm^{-1}. When the syrup was examined chromatographically in high concentration, a trace of 5-deoxy-5-*S*-ethyl-D-*threo*-pentulose was detected, $[\alpha]_D$ 21.5° (*c*, 0.6, ethanol).

*3,4-O-Isopropylidene-5-deoxy-5-S-ethyl-*D*-threo-pentulose 2,5-Dichlorophenylhydrazone*

A solution of the syrupy *O*-isopropylidene derivative (30 mg) and 2,5-dichlorophenylhydrazine (30 mg) in methanol (10 ml) were heated under reflux for 3 hours. After removal of the solvent, the light brown syrup was redissolved in *n*-hexane (5 ml), the solution was chilled in a solid carbon dioxide – ethanol mixture, and crystallization was induced by rubbing the walls of the flask with a spatula. The white powder (10 mg), m.p. 89–91° C, absorbed strongly in the infrared at 1595 cm^{-1} and the carbonyl absorption at 1710 cm^{-1} was present as a very weak peak barely detectable over the background fluctuation. Absorptions were also recorded at 1458 (m), 1378 (vs), 1250 (s), 1234 (vs), 1200 (s), 1160 (vs), 1087 (vs), 1033 (vs), and 794 (s) cm^{-1}. Anal. Calc. for $C_{16}H_{22}Cl_2N_2O_3S$: C, 48.8; H, 5.6. Found: C, 48.5; H, 5.4.

*1,2-O-Isopropylidene-5-deoxy-5-S-ethyl-*D*-xylo-pentose*

1,2-*O*-Isopropylidene-5-*O*-methanesulphonyl-D-xylose (1.08 g, m.p. 136–137° C (9)) and freshly prepared sodium thioethylate (0.70 g) in acetone (25 ml) were heated to 100° C in a pressure bottle for 2 hours. The solution was cooled and concentrated, and the acetone removed by several codistillations with water. The aqueous solution was extracted thrice with ether and the ethereal extracts were shaken once with ice cold, dilute sulphuric acid, twice with water, and were finally dried (Na_2SO_4). The ethereal extract was concentrated and the residual pale yellow syrup was dissolved in a small volume of *n*-hexane and the solution was cooled in a solid carbon dioxide – ethanol mixture. Crystallization was induced by rubbing the walls of the vessel with a spatula. The product (0.4 g, 42%) was collected and washed thoroughly with cold (−60° C) *n*-hexane. The product had m.p. 64–65° C, and $[\alpha]_D$ −58° (*c*, 0.9, ethanol).

The reported constants were: m.p. 66.5–67.5° C, $[\alpha]_D$ −57.5° (ethanol) (10).

A test portion of the product was hydrolyzed with acetic acid for 3 hours under reflux. Removal of the solvents and acetic acid left a syrup which was soluble in chloroform. Examination of this solution in the infrared revealed only a trace of absorption in the vicinity of 1710 cm^{-1}.

*5-Deoxy-5-S-ethyl-*D*-threo-pentose Phenylosazone*

A solution of 1,2-*O*-isopropylidene-5-deoxy-5-*S*-ethyl-D-*xylo*-pentose (100 mg) in 50% aqueous alcohol (10 ml) and glacial acetic acid (5 drops) was hydrolyzed by heating for 3 hours under reflux. Water was added and the ethanol and acetone were removed by several codistillations with water. Phenylhydrazine (0.2 ml) and acetic acid (0.2 ml) were added and the phenylosazone was prepared according to the method previously described. The bright yellow product after recrystallization from a small volume of ethanol followed by washing with cold (−60° C) ethanol melted at 155–156° C, $[\alpha]_D^{20}$ −28°±4° (*c*, 1.1, pyridine). Anal. Calc. for $C_{19}H_{24}N_4O_2S$: C, 60.0; H, 6.7; S, 8.4. Found: C, 59.9; H, 6.3; S, 8.3.

*1,2-O-Isopropylidene-5-deoxy-5-S-ethyl-*L*-arabino-pentose*

1,2-*O*-Isopropylidene-5-*O*-toluene-*p*-sulphonyl-L-arabinose (1.09 g, m.p. 129–130° C (11)) and freshly prepared sodium thioethylate (0.5 g) in acetone (25 ml) were heated at 100° C in a pressure flask for 2 hours. Water was added and the acetone was removed by several codistillations with water. The aqueous solution was then extracted twice with chloroform and the chloroform extracts were washed successively with cold, dilute sulphuric acid and then with water. The dried (Na_2SO_4) solution was concentrated to a crystalline mass which was readily recrystallized from a small volume of *n*-hexane to yield needles (0.61 g, 82%) melting at 88° C, $[\alpha]_D$ 1.3° (*c*, 0.8, ethanol). Anal. Calc. for $C_{10}H_{18}O_4S$: C, 51.3; H, 7.7; S, 13.7. Found: C, 51.2; H, 7.8; S, 13.8.

*5-Deoxy-5-S-ethyl-*L*-arabino-pentose*

1,2-*O*-Isopropylidene-5-deoxy-5-*S*-ethyl-L-*arabino*-pentose (0.46 g) was hydrolyzed for 3 hours with Amberlite IR-120 (H) resin (20 cc, wet volume) suspended in 50% aqueous ethanol (25 ml). The solution was filtered through a charcoal pad, concentrated, and the resulting syrup was redissolved in ethyl acetate. The solution was clarified by percolation under gravity through a fine porosity sintered glass funnel. Concentration yielded a colorless syrup (0.38 g) which revealed a single reducing constituent by paper chromatography and possessed no carbonyl absorption in the infrared; $[\alpha]_D$ −32°±2° (*c*, 0.9, ethanol).

Further hydrolysis with 0.05 *N* hydrochloric acid for 1.5 hours at 80° C, followed by deionization on Duolite A-4 (OH) resin, yielded a colorless syrup with $[\alpha]_D$ −29.5° (*c*, 3.3, ethanol). Since the optical rotation of the product was not significantly changed by the second acid hydrolysis, hydrolysis by the resin was considered complete.

*5-Deoxy-5-S-ethyl-*L*-erythro-pentose Phenylosazone*

The crystalline phenylosazone was prepared from syrupy 5-deoxy-5-*S*-ethyl-L-*arabino*-pentose (66 mg) in the usual way to yield a product that melted at 157° C after recrystallization from aqueous ethanol. The infrared absorption spectrum differs in minor features from 5-deoxy-5-*S*-ethyl-D-*threo*-pentose phenylosazone; the major difference was the absence of a peak at 817 cm^{-1} in the 5-deoxy-5-*S*-ethyl-L-*erythro*-derivative. The mixed melting point with both specimens of 5-deoxy-5-*S*-ethyl-D-*threo*-pentose phenylosazone was 120–135° C; $[\alpha]_D^{20}$ +19°±4° (*c*, 0.9, pyridine). Anal. Calc. for $C_{19}H_{29}N_4O_2S$: C, 60.0; H, 6.7; S, 8.4. Found: C, 59.5; H, 6.8; S, 8.7.

Determination of the Formaldehyde Liberated

Samples (0.5–1.5 mg; accurately weighed) were dissolved in buffer solution or 40% aqueous pyridine containing 0.3 *M* sodium metaperiodate solution (0.5 ml) and were made up to 10 ml. At intervals, aliquot samples (1 ml) were withdrawn and the formaldehyde was estimated by the chromotropic acid method (12). A trial experiment indicated that pyridine did not interfere in the estimation.

TABLE II

Liberation of formaldehyde during periodate oxidation

Compound	pH	Time (hours) 0.08	0.25	0.50	1.0	20
5-Deoxy-5-*S*-ethyl-D-*threo*-pentulose	3.7[a]	0.60[c]		0.63	0.60	
	40% pyridine		0.64			0.59
3,4-*O*-Isopropylidene-5-deoxy-5-*S*-ethyl-D-*threo*-pentulose	7.6[b]	0.33				0.61
	40% pyridine		0.38			0.43

[a, b] 0.5 *M* acetate buffer.

[c] Moles of formaldehyde liberated per mole of substrate.

ACKNOWLEDGMENTS

The authors wish to thank Dr. N. K. Richtmyer of the National Institute of Arthritis and Metabolic Diseases, National Institute of Health, Bethesda, Maryland, for cultures, and Dr. D. H. Ball for generous specimens of 1,2-*O*-isopropylidene-5-*O*-methane-sulphonyl-D-xylose and 1,2-*O*-isopropylidene-5-*O*-toluene-*p*-sulphonyl-L-arabinose. One of us (D.L.M.) thanks the Ontario Research Foundation for a scholarship.

SODIUM DITHIONITE, DECOMPOSITION IN AQUEOUS SOLUTION AND IN THE SOLID STATE[1]

M. W. Lister and R. C. Garvie

ABSTRACT

The decomposition of sodium dithionite has been investigated in alkaline aqueous solution. Under these conditions it decomposes by a first order reaction with a rate constant of 4.5×10^{-4} min^{-1} at 88.5° C and an activation energy of 26.5 kcal/g-molecule. The ionic strength, and the concentration of the sodium hydroxide also present, affect the rate to some extent. A possible mechanism is suggested. The decomposition of solid sodium dithionite was also examined, and was found to give the best fit to the equations deduced assuming random nucleation, followed by linear growth of nuclei, with possible ingestion and interference of reacting zones. The activation energy of nucleus growth is 32 to 33 kcal/g-molecule, and that for nucleation probably between 40 and 45 kcal/g-molecule.

The decomposition of aqueous solutions of sodium dithionite was examined by K. and E. Jellinek (1). They established that the products were sodium thiosulphate and bisulphite, so that the equation for the reaction is:

$$2Na_2S_2O_4 + H_2O \rightarrow Na_2S_2O_3 + 2NaHSO_3.$$

The quantities of the various products agreed with this equation. They measured the rate of decomposition in solutions containing varying, but usually large, amounts of sodium bisulphite. From the ionization constants of sulphurous acid (2), the pH of these solutions must have been about 4.5. They found a second order reaction, fairly rapid even at room temperature: the rate constant was 0.044 $(g\text{-molecule/l.})^{-1}$ min^{-1} at 32° C. The rate constants at various temperatures give only a moderately straight line in a plot of log (rate constant) against 1/temperature (they did not themselves put their results in this form); the activation energy appears to be close to 8 kcal/g-molecule.

This is a remarkably low activation energy, when it is remembered that the mechanism proposed is one involving the collision of two doubly charged ions, followed by the breaking of at least one chemical bond. The details of the reaction are not entirely clear, but whatever mechanism is suggested must include at least one bond rupture. The most obvious solution of this difficulty would be to suppose that at the pH used, the dithionite is partly present as $HS_2O_4^-$, or even as $H_2S_2O_4$ molecules, and that these react. Accordingly, experiments were made on the decomposition of sodium dithionite in alkaline solution; and, as will be seen below, these show that the rates in alkaline solution are quite different from those reported by K. and E. Jellinek. The reaction was examined over a range of ionic strength and temperature.

The decomposition of solid sodium dithionite has been examined by Deines and Elstner (3), who found the products to be sodium thiosulphate and sulphite and sulphur dioxide. This is sufficiently similar to the reaction in solution that it seemed worth while to obtain some quantitative information on the decomposition of the solid, particularly in order to compare the activation energies of the reaction under the different circumstances.

EXPERIMENTAL

The chief difficulty in these experiments is that sodium dithionite solutions can be

[1]*Manuscript received April 17, 1959.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

oxidized by atmospheric oxygen, so air must be rigorously excluded, both during the run, and during manipulation of samples. The apparatus used was similar to that of K. and E. Jellinek, modified only in details. The solutions were made up in a flask under a positive pressure of purified nitrogen. During the run this flask was immersed in a water thermostat, and the contents were stirred with a mercury sealed stirrer. At intervals samples were sucked up into a nitrogen-filled burette, and then a measured volume of solution was immediately run into excess oxidizing agent. The details of the analysis are given below.

In the experiments with solid sodium dithionite, the apparatus consisted of a long pyrex tube, with a sintered glass disk fixed across the middle of it. The tube was wound with suitable resistance wire and insulation, and a thermocouple was placed just above the glass disk. During the actual run the thermocouple was embedded in the sodium dithionite. The temperature at the thermocouple was maintained constant by connecting it to a potentiometer, and sending the off-balance current through a light-and-mirror galvanometer, the light being reflected on to a photocell. The photocell activated a relay which introduced a small extra resistance into the heating circuit when the temperature rose. The temperature was thus controlled to 0.1° C. Nitrogen was passed through the tube and disk, and, for a run, sodium dithionite was placed on the disk. As soon as it had come to temperature, a sample was removed by a small glass scoop, weighed, and analyzed; further samples were taken at suitable intervals.

In the solution runs, the solutions were always kept alkaline with sodium hydroxide. This is slowly used up, as the total reaction is:

$$2Na_2S_2O_4 + 2NaOH \rightarrow Na_2S_2O_3 + 2Na_2SO_3 + H_2O,$$

but the runs were never carried beyond the point where the sodium hydroxide was exhausted. The ionic strength was adjusted by addition of sodium fluoride. This salt was chosen because it did not interfere with the analyses, and is of a simple ionic type. As the equation shows, the ionic strength rises during the reaction. In the results given below, the initial ionic strength is recorded. Most of the runs were kept fairly short, so that the change in ionic strength was not above 0.05, as it was expected that the rate would vary considerably with ionic strength. As it turned out, there is some such variation, but it was not very large. For the most part, evidence of the order of the reaction was obtained by starting runs at different dithionite concentrations, but in the run shown in Fig. 1, the analyses were continued long enough to give fairly definite evidence of this from this run alone.

The analysis for dithionite in alkaline solution presents some difficulties that are not encountered in neutral or weakly acid solution. K. and E. Jellinek used the reduction of ammoniacal copper (II) sulphate for their analyses. In alkaline solution this reagent gives a heavy black precipitate (probably a sulphide) with dithionite, and the method is impracticable. Hahn (4, 5) used titration with ferric chloride, in the presence of a mixed indicator of potassium thiocyanate and ferricyanide, but this was found to give irregular results in alkaline solution. However, it worked well for the analyses of solid sodium dithionite, and was used in runs with the solid. The method finally used in the solution runs was that due to Smith (6). A known volume of dithionite was run into excess ammoniacal silver nitrate; silver is then precipitated. This was filtered off, washed, dissolved in nitric acid, and titrated with chloride by the Volhard method. The chief difficulty was that sometimes the precipitate was so finely divided that filtration was virtually impossible, and samples were occasionally lost because of this.

The reagents used were all of analytical reagent quality, with the exception of the sodium dithionite. The purest available solid was about 90% sodium dithionite, the main impurities being the decomposition products, sodium thiosulphate and sulphite. Recrystallization did not much improve this as some decomposition always occurred. Solutions were made from this, and were then analyzed in order to be able to calculate the ionic strength. This was then adjusted to the desired value by adding sodium fluoride.

RESULTS

The runs were generally not long enough to distinguish unambiguously the order of the reaction solely from one run. Accordingly in Table I the results are given in the form of the best values of the first order rate constants (k_1), and the second order rate constants (k_2), obtained in the usual way from a plot of time against log (concentration) or (concentration)$^{-1}$. This table also gives runs at various ionic strengths, at various temperatures, and at various initial sodium hydroxide concentrations.

TABLE I

Decomposition of sodium dithionite in aqueous solution

Run	Temp., °C	Initial ionic strength	Initial ($Na_2S_2O_4$), molar	Initial (NaOH), molar	k_1, min^{-1}	k_2, (g-molecule/l.)$^{-1}$ min^{-1}

The first thing that is apparent from this table is that the reaction is first order in dithionite. Runs 1 to 4, or 5 to 7, where all other variables are kept constant show this clearly. Figure 1 shows a plot of log (concentration) and (concentration)$^{-1}$ against time for run 16. This gives a better straight line for a first order reaction. This, as well as the great differences in over-all rate, proves that the reaction in alkaline solution is not the

same as that examined by K. and E. Jellinek. The obvious explanation of this is that under the conditions of their experiments the solution contained $HS_2O_4^-$ or $H_2S_2O_4$, and that these decompose faster than $S_2O_4^{--}$. Similar behavior is, of course, found with other acids and their salts, e.g. thiosulphates and hypochlorites. There seem to be no reliable values of the ionization constants of dithionous acid, so it is impossible to calculate the concentrations of $HS_2O_4^-$ or $H_2S_2O_4$ in K. and E. Jellinek's experiments. With an activation energy as low as 8 kcal, as calculated from their results, it seems quite probable that molecules of dithionous acid are reacting.

The effect of varying concentrations of sodium hydroxide can be seen from runs 8, 1, 9, and 5. The rate increases somewhat at higher sodium hydroxide concentrations, but the change is very small at lower concentrations. Presumably hydroxide ions catalyze the reaction to some extent, but the effect is not proportional to their concentration.

Ionic strength was varied in runs 10 to 12, taken together with earlier runs at an ionic strength of 0.7. The results show a moderate change in rate with ionic strength, higher ionic strengths giving increased rates. Somewhat similar behavior is, of course, found in other ionic reactions.

Variation in temperature in runs 13 to 15 gave rate constants which show a reasonably linear plot of log k against $1/T$ of the usual sort. The activation energy is 26 kcal/g-molecule (or perhaps, $26\frac{1}{2}$ kcal/g-molecule). If $k = A\,e^{-E/RT}$, then, expressing k_1 in (seconds)$^{-1}$, log $A = 10.9$, or ln $A = 25.1$. This is a somewhat low figure, but not exceptionally so. This is for concentrations of hydroxide ion low enough for them apparently not to affect the rate to any great extent.

The mechanism of the reaction cannot be deduced with any certainty from these results. The most plausible suggestion, perhaps, is that the initial, and slowest, stage is a reaction with water:

$$S_2O_4^{--} + H_2O \rightarrow HSO_2^- + HSO_3^-$$

followed by a more rapid further reaction of HSO_2^- with dithionite ions:

$$HSO_2^- + S_2O_4^{--} \rightarrow HSO_3^- + S_2O_3^{--}.$$

This suggestion is very tentative. However, if it is correct, the reaction is really bimolecular, and $d[S_2O_4^{--}]/dt = -k_2[S_2O_4^{--}].[H_2O]$. Allowing for the concentration of water, and if $k_2 = A_2\,e^{-E/RT}$, then log $A_2 = 9.2$ (time in seconds), a fairly typical figure (7).

DECOMPOSITION OF THE SOLID

It seemed of interest to compare rates in the solid with those in solution, although if the above suggestion about the mechanism is correct, the reaction must necessarily go by a different route in the solid. Finely ground solid (between 100 and 200 mesh) was used, and the fraction decomposed at different times is given in Table II.

These results give typical S-shaped curves when the fraction decomposed (represented by α in the equations below) is plotted against time. Various equations have been proposed to explain similar curves for other reactions of solids (e.g. (8)), the different equations being based on different mechanisms. In applying them, there is a difficulty because the sample took a finite time to come to the temperature of the run, and consequently there is some doubt about the true zero of time for the reaction. To avoid this difficulty the method generally adopted was to plot the observed time to reach a given value of α against the calculated time to reach the same value. This was done for the range of α from 0.1 to 0.95, and a suitable equation should give a straight line for the resulting graph. Even so the decision between various equations is not too easy, since all give, if

α	0.076	0.204	0.507	0.741	0.902	0.978	0.989	

α is plotted against time, roughly linear middle sections, similar to what is found experimentally; and consequently graphs of calculated against experimental times were always linear over a considerable range in the middle. Hence a decision for or against a possible mechanism largely depended on the ends of the curves.

The equations quoted by Garner (8) may be divided into those which take account of overlap and interference between growing reaction zones, and those which do not. The latter are only applicable in the early stages of the reaction, and so cannot be applied here. On the former, the following deductions seem possible.

1. Branching Nuclei, Interfering During Growth

Garner and Hailes (9) suggested that nuclei might initially form very rapidly up to a certain maximum number, and thereafter increase by branching. At the same time nuclei might disappear as centers of reaction by becoming totally surrounded by reacted material. The chance of this happening was taken to be proportional to α. If N is the number of nuclei at time, t, these assumptions mean that

$$dN/dt = k_3N - k_4\alpha N$$

where k_3 and k_4 are constants. If each nucleus grows linearly with time, $d\alpha/dt = k_1N$, the nuclei being supposed to grow out in one dimension and not as spheres. Hence the curve of α against t will have an inflexion at $\alpha = \alpha_1 = k_3/k_4$. If $N = 0$ at $\alpha = 0$, these equations lead to

$$\ln [\alpha/(2\alpha_1 - \alpha)] = k_3t + C$$

where C is an integration constant.

In the present curves α_1 is about 0.5 (as was found in other cases by Garner and Hailes), and a plot of $\ln [\alpha/(1-\alpha)]$ against t was fairly linear. The values of k_3 were calculated to be:

T	155	160	165	170	° C
k_3	1.9	3.3	5.4	8.2×10^{-2}	min^{-1}.

These values make the activation energy for the growth process 36 kcal/g-molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

There is some deviation from this equation if α is small, but in any case the approximations made in deriving it are not valid at low values of α. This is because the assumption that $N = 0$ at $\alpha = 0$ is not really correct. If we assume that $N = N_1$, a small number, when $\alpha = 0$, the equation becomes:

$$\ln \{(\alpha - N_1k_1/k_3)/(2\alpha_1 - N_1k_1/k_3 - \alpha)\} = k_3(1 - N_1k_1/k_3\alpha_1)t + C.$$

As α evidently approaches unity at large values of t, presumably

$$2\alpha_1 - N_1k_1/k_3 = 1.$$

Fairly good lines are obtained if $N_1k_1/k_3 = 0.04$ for all runs; the resulting values of k_3 are:

T	155	160	165	170	°C
k_3	2.35	3.65	5.6	9.05×10^{-2}	min^{-1}.

These give an activation energy of 34.1 kcal/g-molecule.

2. Random Surface Nucleation Followed by Rapid Surface Growth

Here it is proposed that random nucleation occurs, but once it has occurred on a grain of the material either the entire surface, or certain faces of it, is rapidly covered with a reaction zone, which then moves slowly towards the center. If N_0 is the total number of grains, and N of these are nucleated, then $dN/dt = k_1(N_0 - N)$. If the reaction zone moves at a constant speed, α is given by:

$$\alpha = (1/k_1t_0)\ (e^{-k_1t} + k_1t - 1)$$

where t_0 is the time any one grain takes to decompose. This is valid up to $t = t_0$, as it does not allow for some grains having totally decomposed. If $t > t_0$, α is given by:

$$\alpha = 1 - (1/k_1t_0)\ (e^{k_1t_0} - 1)\ e^{-k_1t}.$$

When these equations were compared with the experimental curves, it was not possible to get a good fit. In particular they make α rise much too rapidly at first as compared with experiment, though this improves somewhat if k_1t_0 is very large. However, it seems unlikely that this is the correct mechanism. Other assumptions about the proportion of the surface nucleated led to modified equations, but none were found to give a good agreement with experiment.

3. Random Surface Nucleation, but no Rapid Surface Growth

On this picture nucleation starts at a point on the surface of the grain, and the reacted zone spreads inwards like a growing sphere. If each grain is itself spherical, the fraction of any grain reacting in time, t, is

$$\alpha_1 = 4(t/t_0)^3 - 3(t/t_0)^4$$

where t_0 is the time for any grain to react completely. If nucleation is random the equations for α are:

[i] $t < t_0$; $\alpha = (24A^3 + 72A^4)\ (e^{-U/A} - 1) - 3U^4 + 4U^3 + 12AU^3 - 12AU^2 - 36A^2U^2 + 24A^2U + 72A^3U$

[ii] $t > t_0$; $\alpha = 1 - e^{-U/A}[24A^3 + 72A^4 - (12A^2 - 48A^3 + 72A^4)\ e^{1/A}]$

where $U = t/t_0$ and $A = 1/k_1t_0$, and k_1 is the rate constant for the nucleation process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

These equations make the rise in α too steep at first unless k_1t_0 is fairly large (about 7 or more), under which conditions the rate of nucleation is rapid compared with the time for a particle to react. However, even if k_1t_0 is large a plot of U against experimental times for the same α does not give a good straight line. Hence this is probably not the correct mechanism.

4. Random Nucleation with Ingestion of Nuclei

Here it is proposed that nuclei are formed at random throughout the material, and the radii of the nuclei grow at a constant rate. Allowance is made for the impingement of the nuclei on each other. This leads to the equation:

$$-\ln (1-\alpha) = B(e^{-U}-1+u-u^2/2+u^3/6)$$

where $u = k_1t$, and k_1 is the rate constant for nucleation. B is a constant equal to $8\pi N_0k_2^3/V_0k_1^3$, where N_0 is the total number of nuclei, k_2 is the rate of nucleus growth, and V_0 is the total volume of material (10).

The form of the curves is little altered by changes in B, so that it is not possible to deduce the best value of B with any precision. Plots of u against the experimental time for the same values of α give good lines if B is fairly large (about 10), though the data for 170° C fit a somewhat smaller value of B (about 2 to 5). If B is 10 at all temperatures, values of k_1 are:

T	155	160	165	170	° C
k_1	2.55	4.3	7.15	10.2×10^{-3}	min^{-1}.

This gives a linear plot of log k_1 against $1/T$ corresponding to an activation energy of 35.7 kcal/g-molecule.

However, B should vary with temperature, and as the activation energy of nucleation is presumably larger than that of growth, B should fall with increasing temperature. Different values of B at 170° C, with $B = 10$ at 155° C, give the following activation energies:

B (170° C)	10	5	2	1
E_1	35.7	39.0	45.4	50.4 kcal/g-molecule
E_2	35.7	33.2	31.9	31.1 kcal/g-molecule.

Here E_1 is the activation energy of nucleation, and E_2 that of growth. If $B = 5$ at 170° C, then $k_1 = 12.0\times10^{-3}$ min^{-1}; if $B = 2$, $k_1 = 15.5\times10^{-3}$ min^{-1}, both at 170° C.

As a general conclusion, this last equation undoubtedly gives the best agreement with the experimental points, and is somewhat superior to the equation for the branching mechanism; so probably the correct mechanism is one of random nucleation and linear growth. Although some other mechanisms have been definitely excluded above, one cannot be certain that some hitherto unsuggested mechanism might not also fit the experimental points. Because of the small change in the curves representing random nucleation and linear growth as B varies, it is not possible to separate all the rate constants, but that for the nucleation rate must be approximately as indicated above. The activation energy for growth is 32 to 33 kcal/g-molecule, while the most that can be said about the activation energy for nucleation is that it is probably 40 to 45 kcal/g-molecule. As is to be expected, these are considerably larger than the solution activation energy of $26\frac{1}{2}$ kcal/g-molecule.

GAS ADSORPTION CHROMATOGRAPHY[1]

JAMES F. HANLAN AND MARK P. FREEMAN[2]

ABSTRACT

It is found that the "retention volume" in gas adsorption chromatography may be identified in a very simple way with the concept of "apparent volume" in the equation of state for high temperature physical adsorption first derived by Halsey *et al.* It is shown that a considerable body of experimental chromatographic data reduces down to the two parameters of the theory in a reasonable way. The single parameter describing temperature dependence is seen to be related simply to the number of carbons in the skeleton for a series of hydrocarbons, while the parameter describing column capacity shows regular, though unanticipated, behavior. This theoretical connection provides a complete link between static measurements and gas adsorption chromatography.

Gas adsorption chromatography or gas solid chromatography is the name applied to the chromatographic process using an adsorbent as the fixed phase and a gas as the mobile phase. It is useful chiefly in the chromatographic separation of mixtures of permanent gases and vapors of low-boiling liquids for which purpose it seems more suitable than the more frequently encountered gas–liquid partition chromatography.

As it is commonly used, gas adsorption chromatography apparatus is very similar to that employed in gas–liquid partition chromatography with the substitution of an adsorbent for the fixed bed. It is characterized by requiring a much more sensitive temperature control for reproducible results. Elution chromatography and frontal analyses may be performed in either case, but the adsorption chromatogram is characterized by asymmetric break-through curves which have thus far defied a simple quantitative interpretation. This latter fact has complicated a theoretical interpretation by the "theoretical plate" analysis so useful in the partition chromatogram (1).

At the same time, the aforementioned sensitivity to temperature change in adsorption chromatography makes it possible to separate virtually any mixture on the same column by judiciously selecting the temperature (barring chemisorption), whereas in partition chromatography it is often necessary to change the liquid employed in the fixed phase.

This work represents an attempt to present a comprehensive theoretical framework for the interpretation of gas adsorption chromatographic results in terms of the rigorously derived equation of state for the interaction of gases and surfaces developed by Halsey *et al.* (2, 3, 4, 5, 6) also (7, 8). Such an interpretation would necessarily link gas chromatographic results to the static measurements employed in these investigations, as well as provide the desired predictive information about temperature dependence for the chromatogram.

The experimental data (9) used in the verification of the theory derived here were obtained by Dr. H. Habgood of the Research Council of Alberta, Edmonton, Alberta, Canada, and one of us (James F. Hanlan) at that laboratory.

The experimental observation made by these investigators indicating the suitability of the gas–surface interaction state equation was that when the logarithm of the retention volume (10) (which is defined as the volume of gas leaving the column while a given

[1]*Manuscript received in original form December 18, 1958, and, as revised, April 7, 1959.*
Contribution from the Department of Chemistry, University of California, Berkeley, California.
[2]*Present address: Research Division, American Cyanamid Company, Stamford, California.*

constituent is passing through the column) of gas A minus that for H_2 is plotted vs. $1/T$, a fairly good straight line relationship holds (Fig. 1). This is reminiscent of the concept of "excess volume" in the theory of Halsey *et al.* which exhibits similar behavior.

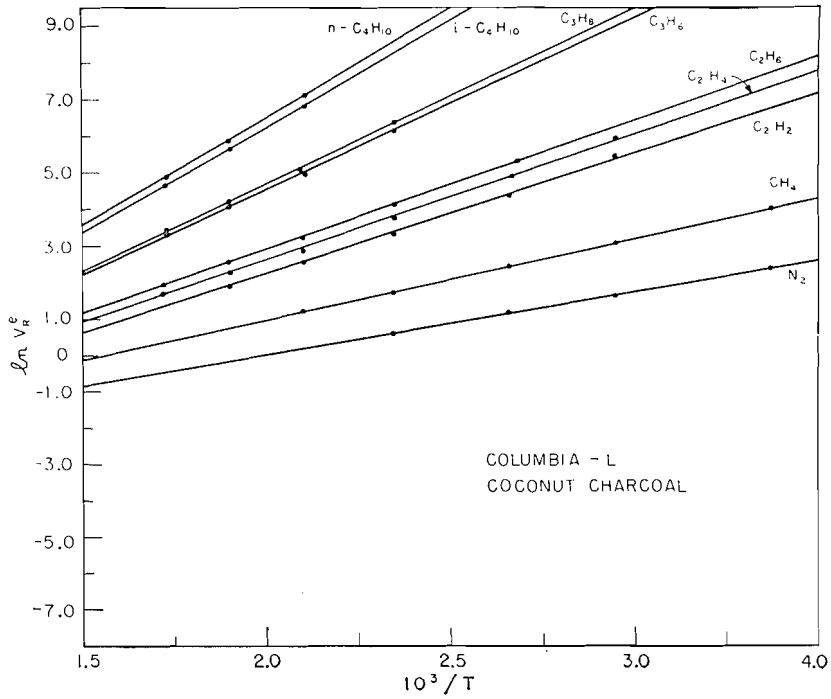

FIG. 1. The natural logarithm of the experimental excess retention volume on Columbia L charcoal plotted vs. reciprocal temperature for several gases. Five points of the original data have been discarded where marked deviations from the trend were observed. These deviations were not systematic and were probably attributable to experimental error.

THEORY

A basic underlying assumption will be implicitly made in the following derivation. Namely, it will be assumed that some sort of equilibrium exists within the gas phase passing through the column so that the gas systems (molecules or atoms) are always at their equilibrium distribution with respect to the gas surface potential well. This assumption is supported by the observation (10) that retention volume is independent of flow rate over a wide range of flow rates.

The retention volume is given as the product of retention time and flow rate through the column:

$$[1] \qquad V_R = F \cdot t_A = (\eta kT/P) \cdot t_A$$

where F is the flow rate in cm³/sec (at column temperature T and pressure P) and η is the flow rate in systems per second; t_A is the time lag between introducing the mixture and detection of constituent A at the other end. Now, the apparent volume of a vessel containing an adsorbent is just given by:

$$[2] \qquad V_a = NkT/P$$

where V_a is just the imaginary volume that would be required to hold N systems of ideal gas at temperature T and pressure P. If these two concepts are linked, a very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

simple picture emerges for the adsorption chromatogram in terms of the time required for constituent A to get through the column. Namely, if all gas systems pass through the column at the same flow rate, the time to get through is going to vary directly as the apparent volume traversed. That is, one could think of equivalent empty columns of the same diameters, but of lengths proportional to the apparent volumes. This would suggest an immediate formal identification of apparent volume and retention volume so that for a pure constituent the equation of state would be immediately applicable. Unfortunately, gas chromatography always involves a mixture of gases and although the gas–surface equation of state gives an apparent volume in this case, it is not immediately obvious what this means in terms of retention volume. This becomes particularly true when considering gas imperfections and lateral interactions on the surface.

The equation of state (5) for the interaction of a binary mixture of gases and a surface is given by:

$$\frac{1}{V_a} = \frac{X_A}{V_A^0} + \frac{X_B}{V_B^0} - N\left(\frac{C_0}{V_a^{0\,3}}\right) \qquad [3]$$

where the mole fraction of G is X_G(G = A, B) and

$$V_G^0 = V_{geo} + B_{GS} \qquad [4]$$

and is the apparent volume for pure constituent G at zero pressure.

Further,

$$\frac{C_0}{V_0^3} = \frac{X_A^2 C_{AAS}}{(V_A^0)^3} + \frac{X_B^2 C_{BBS}}{(V_B^0)^3} + \frac{X_A X_B C_{ABS}}{V_A^0 V_B^0}\left(\frac{1}{V_A^0} + \frac{1}{V_B^0}\right) \qquad [5]$$

V_{geo} is the true or geometric volume enclosed by the vessel in which the gas is interacting with the surface and excluded by a geometric surface running through the gas–solid interface beyond which gas systems are assumed not to penetrate.

$$B_{GS} = \int_{V_{geo}} [\exp\{-\phi_{ls}^G/kT\} - 1]\, d\tau_i^G \qquad [6]$$

where $d\tau_i^G$ is the differential volume element for the ith gas system of species G and ϕ_{ls}^G is the potential energy function for the interaction of a specific system of this type with the surface. This integral has been tabulated for two potential energy models both of which have been quite successful in interpreting experimental results:

(1) the hard sphere–inverse cube model (2):

$$\phi_{ls}^G = -\epsilon_G^* \frac{D^3}{x^3} \qquad [7]$$

where ϵ_G^* is the depth of the potential energy well at the hard sphere repulsion distance, $x = D$, and

(2) the 9-3 model (7):

$$\phi_{ls}^G = \left(\frac{3\sqrt{3}\epsilon^*}{2}\right)\left[\left(\frac{s_0}{s}\right)^9 - \left(\frac{s_0}{s}\right)^3\right] \qquad [8]$$

where ϵ^* is as before and s_0 is the gas–surface separation where the attractive and repulsive energies just cancel. This second potential energy model will be used throughout the paper as it is somewhat easier to use. A reduced form of this integral (B_{GS}/As_0) (where A is the area) for this potential model is in reference (7) with three additional values tabulated in Table I.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

TABLE I
Addition to the Appendix in reference 7

ϵ^*/kT	B_{AS}/As_0
13.087	8.291×10^4
14.627	3.625×10^5
16.166	1.579×10^6

$C_{GG'S}$ can be broken up into a gas imperfection factor and a term involving the simultaneous interaction of two gas systems of type G and G′ and the surface (8):

$$C_{GG'S} = -2(V_G^0 + V_{G'}^0 - V_{geo})B_{GG'} + C' \quad [9]$$

where $B_{GG'}$ is the (mixed) second virial coefficient and

$$C' = \int \{\exp[-\phi_{1s}^{G}/kT]-1\} \int \{\exp[-\phi_{2s}^{G'}/kT]-1\}\{\exp[-\phi_{12}^{GG'}/kT]-1\}\, d\tau_1^G, d\tau_2^{G'}. \quad [10]$$

The most successful model for this integration to date is tabulated in the appendix of reference (8) for a single constituent. This involves the 9-3 potential model for gas–surface attraction and a hard sphere repulsion at distance $^n r_0$ between the interacting gas systems. This integral is given as a function of the reduced gas–surface potential energy and the distance ratio $\delta = s_0/^n r_0$.

Equations [3], [4], and [5] undergo considerable simplification if it is assumed that the carrier gas, B, has no net attraction to the surface or to other gas systems (apparently true for He at room temperature and above). If ideal behavior is likewise assumed for the bulk carrier phase, then

$$B_{BS} = B_{BB} = B_{AB} = C_{BBS} = C_{ABS} = 0 \quad [11]$$

and equation [5] becomes

$$\frac{C_0}{V_0^3} = \frac{X_A^2 C_{AAS}}{V_A^{0\,3}}. \quad [12]$$

Equation [4] for the carrier reduces to:

$$V_B^0 = V_{geo}. \quad [13]$$

Substituting [12] and [13] in [3] yields:

$$\frac{1}{V_a} = \frac{X_A}{V_A^0} + \frac{X_B}{V_{geo}} - \frac{NX_A^2 C_{AAS}}{V_A^{0\,3}}. \quad [14]$$

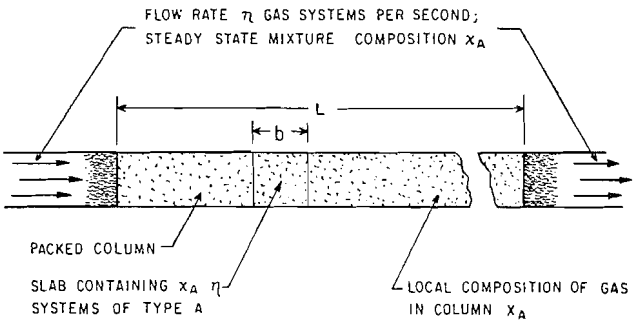

FIG. 2. Schematic representation of the adsorption chromatographic column.

To effect the necessary derivation, it is convenient to assume a steady state mixture (composition χ_A) to be flowing in and out of the column (Fig. 2) at a flow rate of η systems per second. The necessary enrichment of A in the column results in a local composition of X_A which is generally different from χ_A. Clearly $\chi_A\eta$ is the number of systems of type A leaving the column each second. The same number of systems of type A must cross every boundary in the column each second so that b, the length of a slab of column containing $\chi_A\eta$ systems of type A, divided into L, the length of the column, will give the time required for a labeled front in gas A to travel the length of the column. (This does not allow for column end effects, but this will be taken care of below.)

[15] $$t_A = L/b$$

If the extensive quantities in the slab are denoted by double primes and use is made of the definition of mole fraction, then [14] may be rewritten:

[16] $$\frac{N''}{V_{a''}} = \frac{N_{A''}}{V^0_{A''}} + \frac{N_{B''}}{V_{geo''}} - \frac{N_{A''}{}^2 C_{AAS''}}{V^{0\,3}_{A''}}.$$

But by definition $N_{A''} = \chi_A\eta$. Using the assumed ideality of the carrier gas

$$N_{B''} = P_B V_{geo''/kT} = (1-\chi_A) P V_{geo''/kT}$$

and relation [2] [16] may be written:

[17] $$\frac{P}{kT} = \frac{\eta}{V^0_{A''}} - \chi_A\eta^2 \frac{C_{AAS''}}{V^{0\,3}_{A''}}.$$

If the extensive quantities per unit length are denoted by single primes, [17] becomes:

[18] $$\frac{P}{kT} = \frac{\eta}{bV^0_{A'}}\left[1 - \chi_A\eta \frac{C_{AAS'}}{bV^{0\,2}_{A'}}\right]$$

or solving for b (assuming the term on the right in the brackets, eq. [18], to be small):

[19] $$b \approx \frac{\eta kT}{PV^0_{A'}}\left[1 + \frac{\chi_A P C_{AAS'}}{kTV^0_{A'}}\right]^{-1}.$$

Using relations [15] and [1] one finally obtains for V_R

[20] $$V_{R_A} = V^0_A + \chi_A P \frac{C_{AAS}}{kT}.$$

The retention volume for the carrier gas by the same analysis is just

[21] $$V_{R_{carrier}} = V_{geo}.$$

To be consistent with the data as they were received and to subtract out the effect of unpacked parts of the column and end effects so far as possible, one must subtract equation [21] from equation [20] to get an excess retention volume:

[22] $$V^e_R = B_{AS}\left(1 + \frac{\chi_A P}{kT}\frac{C_{AAS}}{B_{AS}}\right).$$

One sees that under the conditions of the derivation if χ_A is zero then the excess retention volume is just equal to B_{AS} which is identical with

[22a] $$V_{ex}|_{p=0} = V^0_A - V_{geo} = B_{AS}$$

for the static measurements. C_{AAS} has generally been observed to be negative while

B_{AS} is always positive or negligible so that the usual case will have a higher concentration of gas A going through the column faster (lower retention volume), which means that a narrow rectangular initial distribution will tend to skew forward. This is what is observed and in fact the gas adsorption chromatogram is usually characterized by sharp anterior and sloping posterior edge. At very low partial pressures where chromatograms are usually run, this will produce a negligible error if retention time is measured to the peak which is the easiest part of the chromatogram to identify. At the same time, if frontal analysis is performed at different mole fractions, one may determine C_{AAS} experimentally. This would seem like a good way to obtain this experimentally elusive parameter, which is still of considerable theoretical interest (8).

It was found necessary in the course of the derivation to assume $1 \gg \chi_A P C_{AAS}/kTV_A^0$ or its equivalent. For a specific system all these quantities may be evaluated independently by static measurements. Take as an example argon on carbon black (Black Pearls No. 71) (7) at 273° K,

$$\begin{aligned}
&\text{sample wt.} = 10.63 \text{ g},\\
&C_{AAS} = -240\times10^{-20}(\text{cm})^6,\\
&V_A^0 = 150 \text{ cm}^3,\\
&kT = 3.72\times10^{-20} \text{ cc atm},\\
&V_{geo} = 28.5 \text{ cm}^3,\\
&B_{AS} = 121.5 \text{ cm}^3,
\end{aligned}$$

or

$$\frac{\chi\Delta P C_{AAS}}{kTV_A^0} = -.43\,\chi_A|_{p=1 \text{ atm}}.$$

If the mole fraction of A in the gas phase is kept below, say, 0.1 then the assumption that this product is much less than unity is clearly all right for this particular assembly. It would seem that if it were not small, no peak would be distinguished, which probably sets the lower temperature limit to gas adsorption chromatography.

Enthalpy of Adsorption

Using a model for physical adsorption based on the Gibbs boundary condition, one may consider the interaction to be a phase change from the gas phase to an imaginary two dimensional phase of zero volume. It has been shown (7) that the surface excess partial molar enthalpy at zero coverage is given by the derivative:

$$[23] \qquad \frac{\partial \ln T/V_{ex}^0}{\partial\, 1/RT} = \Delta H = \frac{\partial \ln T/V_R^e}{\partial\, 1/RT}$$

where V_{ex}^0 and V_R^e are those volumes at zero pressure and mole fraction respectively. Finally, using the definition of retention volume and keeping a constant flow rate (systems/second)

$$[24] \qquad \frac{\partial \ln (t_A - t_B)}{\partial\, 1/T} = \frac{-\Delta H}{R}$$

where B is as before a noninteracting constituent. This enthalpy may be related unambiguously to the parameter ϵ^* (7) which provides a way of getting this parameter without curve fitting. The enthalpy derived thus is of questionable predictive value because of a considerable temperature coefficient, especially at high temperatures, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

it is equal to the initial calorimetric heat of adsorption (L'Hospital's rule) and as such is of interest. Equation [23] is of course easier to apply than equation [24], which has been derived by a different approach (11). These authors did not correct for the interstitial dead space, but they did correct for the time spent in the unpacked region of flow at the ends of the column.

Effect of a Column Pressure Differential

Because of the short loosely packed columns and low rate used in gas adsorption chromatography, one would not expect the relatively large difference between P_i (inlet pressure) and P_o (outlet pressure) encountered in gas–liquid partition chromatography. However, in the framework of this theory any differential that exists can be handled readily.

Recognizing that [1] holds in any differential slab of the column, we obtain

$$\frac{\partial t_A}{\partial \zeta} = \frac{P(\zeta)}{\eta k T} \frac{\partial V_R}{\partial \zeta} \qquad [25]$$

where ζ is the distance from the exit of the column. Making use of d'Arcy's formula for the laminar seepage of a perfect gas through a long capillary* and our boundary conditions,

$$P_{(\zeta)}^2 = P_o^2 + \frac{P_i^2 - P_o^2}{L} \zeta. \qquad [26]$$

From differentiation of [20]

$$\frac{\partial V_R}{\partial \zeta} = V_{A'}^0 + \frac{\chi_A C_{AAS'}}{kT} P_{(\zeta)} \qquad [27]$$

where the primed quantities are again the values per unit length. One may now write an expression for the retention time (using [25], [26], and [27]):

[28]

$$t_A = \int_{\zeta=0}^{\zeta=L} \frac{\partial t_A}{\partial \zeta} d\zeta = \frac{V_{A'}^0}{\eta k T} \int_{\zeta=0}^{\zeta=L} \left(P_o^2 + \frac{P_i^2 - P_o^2}{L} \zeta \right)^{\frac{1}{2}} d\zeta + \frac{\chi_A C_{AAS'}}{\eta (kT)^2} \int_{\zeta=0}^{\zeta=L} \left(P_0^2 + \frac{P_i^2 - P_o^2}{L} \zeta \right) d\zeta.$$

Integrating the right-hand side of equation [28] yields:

$$t_A = \frac{2 V_{A'}^0}{3 \eta k T} \left\{ \frac{P_i^3 - P_o^3}{P_i^2 - P_o^2} \right\} + \frac{\chi_A C_{AAS}}{\eta (kT)^2} \{ (P_i + P_o)^2 - 2 P_i P_o \} \qquad [29]$$

where V_A^0 and C_{AAS} are those quantities for the entire volume. If one makes the approximation that the geometric mean pressure is equal to the arithmetic mean pressure P_m, (a completely justified approximation if $P_i \leqslant 1.30\ P_o$)

$$P_m^2 = \left[\frac{(P_i + P_o)}{2} \right]^2 = P_i P_o. \qquad [30]$$

Equation [29] may be written

$$t_A = \frac{V_A^0}{\eta k T} P_m + \frac{\chi_A C_{AAS}}{\eta (kT)^2} P_m^2. \qquad [31]$$

*Suggested by referee I.

For personal use only.

Leaving P in equation [1] undefined for the moment, one may substitute from [31] for t_A and solve for the measured V_R:

$$[32] \qquad V_R = V_A^0 \frac{P_m}{P} + \frac{\chi_A C_{AAS}}{kT} \frac{P_m^2}{P}.$$

In practice, the flow rate is determined in a measuring device at some other temperature and pressure and is corrected to column conditions assuming ideal gas behavior. If the P used in the correction is the mean column pressure, then clearly

$$[33] \qquad V_R = V_{geo} + B_{AS} + \chi_A \frac{C_{AAS}}{kT} P_m.$$

Comparing [20] and [22*a*] with [33] it is apparent that if the mean pressure is used a column pressure drop introduces no difficulty in the interpretation of the data in terms of the integrals B_{AS} and C_{AAS}.

It may be pointed out that the correction factor for pressure drop along the column (12) proposed by James and Martin:

$$\frac{2}{3} \frac{(P_i/P_o)^3 - 1}{(P_i/P_o)^2 - 1}$$

reduces to

$$P_m/P_o$$

(where P_i, P_o, and P_m have the same significance as above) if the approximation [30] is assumed valid.

Effect of Another Elutant

Helium is moderately hard to obtain and so the question arises whether this theory can be used with a cheaper elutant such as hydrogen or nitrogen. An analysis of the behavior of B_{AS} and the relations leading to the derivation of equation [22] leads to the following conclusions:

(*a*) If the elutant is hydrogen, He may be used as the marker with no other modification.

(*b*) If the elutant is N_2 or a heavier gas, He or H_2 may still be used as the marker. The mixture must be run at a somewhat lower mole fraction for each constituent in order to preserve peaks.

(*c*) Even if the parameter C_{AAS} is quite large the pressure behavior will be dominated (5) (and hence obscured) by $C_{N_2N_2S}$.

Clearly this theory should be no more difficult to use for N_2 than for He but the sensitivity will necessarily be decreased due to the requirement of lower mole fraction for the major components and of course the fact that nitrogen is quite likely to be less different from the gas analyzed for than is He or H_2.

It is interesting that there is nothing in this theory to contradict the notion that a helium marker can move through the column considerably faster than the eluting nitrogen. This is probably easiest to understand in terms of the motion of equivalent empty columns.

Interpretation of Data

The data received by the authors were in the form V_R^e as a function of T. However, the V_R^e had been corrected to 273° K and were converted back to column temperature for application of the theory. The adsorbents used were three coconut charcoals designated Columbia L, BC-4, and BC-90. The last two charcoals were identical except for degree of activation. A hydrogen marker was used to measure the retention time of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

helium, which introduced some error because of the higher interaction energy of hydrogen and the surface, but an attempt to estimate the effect of this error on the part of the authors showed the error to be negligible within experimental error. The time interval was measured between the peak of the hydrogen marker and the peak of the constituent. As the authors had no way of determining this peak height all data were assumed to be at zero-mole fraction of A. The usual practice does not exceed this by much. The V_R^e's received had been divided by the weight of the adsorbent, but this is by no means necessary for use of the theory.

To fit the data and evaluate the parameters As_0 and ϵ^*/k, it is convenient to use a plot (7) of

$$\ln \frac{B_{AS}}{As_0} \quad \text{vs.} \quad \epsilon^*/kT.$$

One then estimates an ϵ^*/k and plots

$$\ln V_R^e \quad \text{vs.} \quad \left(\frac{\epsilon^*}{k}\right)_{\text{trial}}.$$

Next a

$$\ln As_0$$

is chosen for the data such that the sum of the deviations is zero when

$$\ln \frac{V_R^e}{As_0} \quad \text{vs.} \quad \left(\frac{\epsilon^*}{k}\right)_{\text{trial}}$$

is plotted. The trial value of ϵ^*/k is then systematically varied until the sum of the squares of the deviations of the data from the theoretical plot is a minimum. This procedure may be programed for an electronic computer and the result obtained accurately and rapidly as was done for this work. The final values of ϵ^*/kT and $\ln (B_{AS}/As_0)$ are shown in Table II along with the standard deviation from the curve. A deviation of .03 represents, for example, an average error in V_R^e of 3%. The data are shown thus fitted in Fig. 3. The fit is entirely satisfactory. The values of the parameters required are given in Table III. Since one has two parameters characterizing the chromatogram it would be desirable to make them independent of the amount of column packing used. By its nature ϵ^*/k is already this way, but, of course, the product As_0 is simply extensive in the area (and presumably in the weight) of the packing material. One way to reduce this product to a reproducible parameter would be to divide by the weight of packing material as was done here. Another way would be to subtract the logarithm of As_0 for some calibrating gas such as nitrogen from $\ln As_0$ for each gas and thereby remove the extensive element.

How reproducible any of these parameters would be when determined by different investigators with different columns is of course not known, nor has an attempt been made as yet to directly compare parameters derived from chromatographs with those from static measurements.

Analysis of Trends in the Parameters

Once ϵ^* is known, the complete temperature dependence of V_R^e is known so that it is of interest to see what sorts of predictions one might make about this quantity. The data presented here correlate well with several molecular and bulk properties, but the best correlation for the hydrocarbon series is to the number of carbon atoms in the skeleton (Fig. 4). This is clearly a good linear correlation suggesting the possibility that

in a more heterogeneous series one could sum over different types of heavy atoms or functional groups in the molecule to obtain an accurate estimate of ϵ^*/k. This possibility should be thoroughly checked because of the obvious analytical applications of such a correlation.

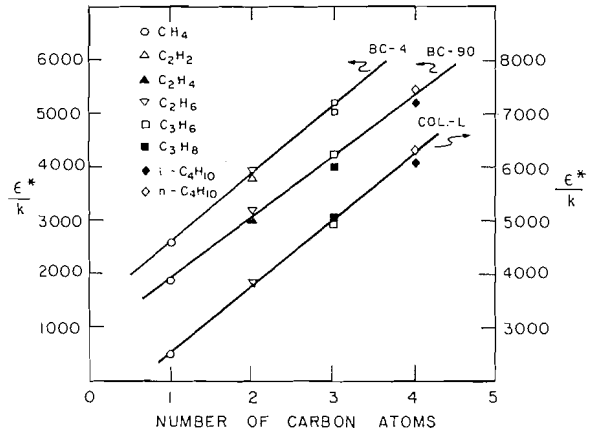

FIG. 4. Observed trends in the value of the parameter ϵ^*/k for all hydrocarbon assemblies analyzed as a function of the number of carbon atoms in the interacting gas.

The parameter As_0 when suitably normalized is as characteristic of a given gas–surface interaction as is ϵ^*/k, and so the two parameters together should serve as positive means to identify a particular molecular species for a precalibrated solid whether or not the column itself has been precalibrated. The detailed behavior of As_0 as an area-depen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

For personal use only.

dent parameter is somewhat less satisfactory than has been observed for rare-gas atoms on carbon blacks. Even in this case there was the rather remarkable phenomenon that As_0 decreased as atomic size (and interaction energy) increased. For a constant area, this could mean a somewhat closer distance of balanced attractive and repulsive potentials. Likewise, it could mean a considerable area of small crevices or capillaries more accessible to the smaller atom than the larger. Finally, it could indicate the presence of hot-spots (7) (portions of the surface with much higher energy of interaction). This effect is much magnified in these chromatographic data (possibly because of the non-spherical systems?). For example, the parameter As_0 for Columbia L charcoal increases by 400% in going from normal butane to methane, whereas by way of comparison, changing from argon to helium on carbon black with static measurements increased As_0 by only 30%. Finally, note that when the charcoal is activated as in going from BC-4 to BC-90 (presumably by the water gas or some similar reaction) the energy of interaction for all hydrocarbons drops by about 20–30% at the same time the specific values of the parameters As_0 increase by a factor of 3.25. This is in contrast to the behavior of nitrogen which decreases in energy by 2.6% and increases in the value of the product As_0 by 52% in the same activation process.

In Table IV can be seen the increase of the area with activation. This calculation, of course, requires the approximation that s_0 be nearly the same for a given gas on the two

TABLE IV

A	$\ln \frac{As_0\vert_{\text{BC-90}}}{As_0\vert_{\text{BC-4}}}$	$\frac{A\vert_{\text{BC-90}}}{A\vert_{\text{BC-4}}}$

C_3H_6	1.12	3.06
C_3H_8	1.20	3.32
Mean value	1.178	3.25

different surfaces. The values for the different gases are remarkably uniform with a mean value of 3.25 for the ratio of the area of charcoal BC-90 to that of BC-4. This compares well with the monolayer areas of 630 and 200 m^2/g respectively (9). If s_0 is estimated as one half the interlayer thickness of graphite, 1.7 Å, (13) plus one half the van der Waal's radius of the adsorbate, the area is calculated from the parameter As_0 to be of the order of the monolayer area. The decrease of ϵ^* with activation points to surface heterogeneity, for example, crevices which upon widening with activation would permit fewer adsorbent nearest neighbors per adsorbed molecule. This might be expected to appear under these conditions, i.e., low pressure and high temperature, where such effects would not be "washed out" by large numbers of strong lateral interactions. The similarity of the ratios of the monolayer areas and of our A's may be taken to mean that all portions of a heterogeneous surface increase equally. On the other hand, this may be interpreted as indicating that the surface is, in fact, homogeneous. More work is definitely indicated in this area.

Note that acetylene stands out as being rather exceptional. This gas was used on the BC-4 charcoal where it gave a reasonable value of ϵ^*/k but an apparently anomalous

value of the parameter As_0. At the time the experiments were performed the investigators felt that this gas was somehow interacting chemically with the column and therefore did not use it, throughout their experiments.

DISCUSSION

It has been shown that the concept of excess retention volume in gas adsorption chromatography not only provides a simple physical analog in terms of equivalent empty column lengths but also relates in a simple way to the concept of excess apparent volume. This quantity was introduced by Halsey *et al.* when treating the theory of the van der Waals interaction of gas and surface in the same temperature region where gas adsorption chromatography is carried out.

A considerable number of data were fitted to the curve and were found to fit within experimental error yielding reasonable values of the two parameters. The parameter describing the temperature dependence was seen to be highly predictable from a knowledge of the number of carbons in a hydrocarbon and the parameter describing column capacity showed some interesting though as yet uninterpreted behavior. Even without this interpretation the theoretical framework should be very useful to the practicing chromatographer.

To the theoretical investigator, it is clear that gas adsorption chromatography though possibly less accurate than static measurements makes up for it in much greater speed and ease of manipulation. The use of frontal analyses to get C_{AAS} looks especially promising.

ACKNOWLEDGMENTS

The authors wish to express their appreciation for the co-operation of Dr. Habgood and the Research Council of Alberta. In addition, they would like to thank Professor T. Vermeulen of this university for many helpful discussions.

The calculations reported here were done under the free time allocation for unsupported research on an IBM 701 computer. This computer is supported jointly by the Regents of the University of California, International Business Machines Corporation, and the National Science Foundation.

ALKALOIDS OF LYCOPODIUM ANNOTINUM

PART II. ISOLATION OF FOUR NEW ALKALOIDS[1, 2]

F. A. L. ANET AND N. H. KHAN

ABSTRACT

Countercurrent distribution of the alkaloids of *Lycopodium annotinum* gave four new bases: annofoline, lycofoline, and α- and β-lofoline. Annofoline, $C_{16}H_{25}O_2N$, contained a keto and a hydroxyl group. Lycofoline, $C_{16}H_{25}O_2N$, possessed at least one hydroxyl group and possibly a double bond. α- and β-Lofoline each had the formula $C_{18}H_{29}O_3N$ and contained a hydroxyl and an O-acetyl group.

Anet and Eves (1) described the separation of the crude alkaloid mixture from *Lycopodium annotinum* by countercurrent distribution into a "chloroform-soluble" and a "buffer- (pH 6.0) soluble" fraction. From the former fraction they isolated a new alkaloid, lycodine. In the present paper we report work on the latter fraction, as a result of which four new alkaloids have been isolated and characterized.

The buffer-soluble fraction mentioned above (1) was subjected to 57-transfer countercurrent distribution with the system chloroform–buffer of pH 7.0, with the buffer solution as the moving phase. Weight analysis of the distribution gave the pattern shown in Fig. 1A. Although the alkaloid concentration used was such that overloading resulted, causing changes in the pH of the buffer, the separation obtained was not far from that expected on the basis of a constant distribution coefficient for each alkaloid. The alkaloids in tubes 10 to 42 are at present under investigation, but it may be noted here that acrifoline (2, 3) could be isolated from tubes 26 to 34.

The peak represented by tubes 46 to 57 (Fig. 1A) was too wide to represent a single alkaloid, a conclusion supported by the results of paper chromatography and infrared analysis. Due to the high partition coefficients, however, the various components making up the peak were badly resolved. All the same, tubes 46 to 52 readily yielded a crystalline alkaloid (α-lofoline described below), but only in small yield. In order to improve the separation, the alkaloid contents of tubes 46 to 57 were mixed and subjected to another countercurrent distribution, but this time with the system chloroform–buffer of pH 8.0. The distribution (Fig. 1B) obtained showed three peaks, two of which overlapped.

The tubes 21 to 32 (Fig. 1B) yielded a crystalline alkaloid, and paper chromatography indicated that this was the main component present. The compound obtained had m.p. 211–212°, and its properties were unchanged after chromatography on alumina or after repeated recrystallizations. Analysis gave the formula $C_{18}H_{29}O_3N$ and further showed the presence of one O-acetyl group and at least two C-methyl groups. The infrared spectrum (Fig. 2A) confirmed the presence of an O-acetyl group (bands at 1720 cm^{-1} and at 1225 cm^{-1}, 1240 cm^{-1}) and also indicated the presence of a hydroxyl group (band at 3200 cm^{-1}), thus accounting for all the oxygen atoms. The general properties and formula of this compound do not correspond with any known alkaloid and we therefore propose the name α-lofoline for it. α-Lofoline gave a methiodide, m.p. 266–267°.

Paper chromatography indicated the presence of two alkaloids in tubes 36 to 51 (Fig. 1B) which were not completely resolved in the distribution. It was found best to

[1]*Manuscript received May 19, 1959.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.
[2]*Part I of this series is considered to be the paper entitled "Lycodine, a new alkaloid of Lycopodium annotinum" by F. A. L. Anet and C. R. Eves (see reference 1).*

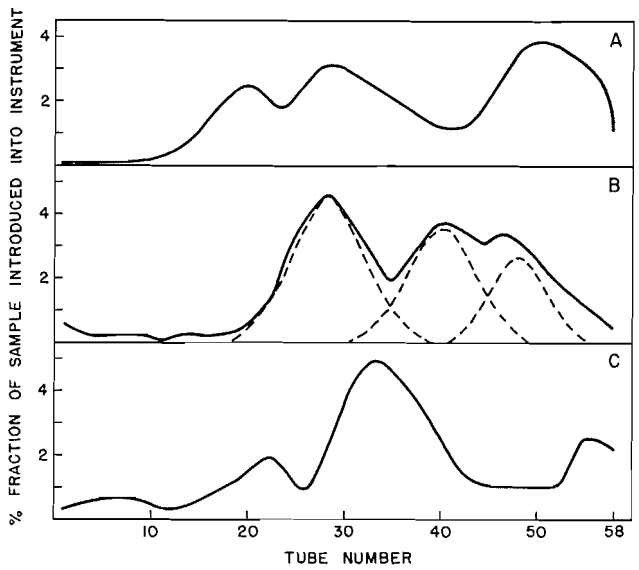

FIG. 1. Countercurrent distribution of various alkaloid fractions mentioned in the text: A, with the system chloroform–buffer of pH 7; B, chloroform–buffer of pH 8.0; C, chloroform–buffer of pH 8.2. In each case the buffer solution is the moving phase. The dotted lines represent theoretical distributions.

mix the contents of all these tubes and to separate the two components by chromatography on alumina. The first alkaloid eluted had, after recrystallization and sublimation, m.p. 156–157°. Analysis gave the formula $C_{16}H_{25}O_2N$ and showed the presence of at least one C-methyl group. The infrared spectrum (Fig. 2B) indicated a hydroxyl group (band at 3400 cm^{-1})and a carbonyl group (band at 1700 cm^{-1}, probably a ketone in a six-membered ring). The properties of this alkaloid showed it to be new, and we propose the name annofoline for it. Annofoline gave a perchlorate, m.p. 234–236°, and a methiodide, m.p. 308–309°.

The second alkaloid eluted from the alumina chromatogram had, after recrystallization, m.p. 144–145°. Analysis indicated the formula $C_{16}H_{25}O_2N$ and the presence of a C-methyl group. The infrared spectrum (Fig. 2C) showed the presence of one or more hydroxyl groups (band at 3300 cm^{-1}), but no carbonyl group. A very faint band at 1670 cm^{-1} may indicate unsaturation. This compound also appeared to be new and we have named it lycofoline. It gave a hydrobromide, m.p. 274–275°, and a methiodide, m.p. 263–264°. In the last few tubes of the distribution (Fig. 1B) there was present a small amount of a compound showing a band at 1740 cm^{-1} (in CCl_4) in the infrared, but no attempt was made to isolate the compound responsible for this absorption.

It was noticed that the distribution shown in Fig. 1A had a pronounced minimum at tube 42. It was already known (1) that alkaloids with a partition coefficient (buffer of pH 5.0 versus chloroform) near unity were not present to any appreciable extent in the crude alkaloid mixture. These facts enabled us to modify our original preliminary separation, which divided the alkaloid into two groups, into one where three groups were obtained. This was done (Fig. 3) without greatly increasing the number of transfers, and without any of the major components of the crude alkaloid mixture occurring in more than one group. The solvent system used was chloroform–buffer of pH 7.0. The buffer-soluble fractions B_1' to B_3' gave after a 60-transfer countercurrent distribution in

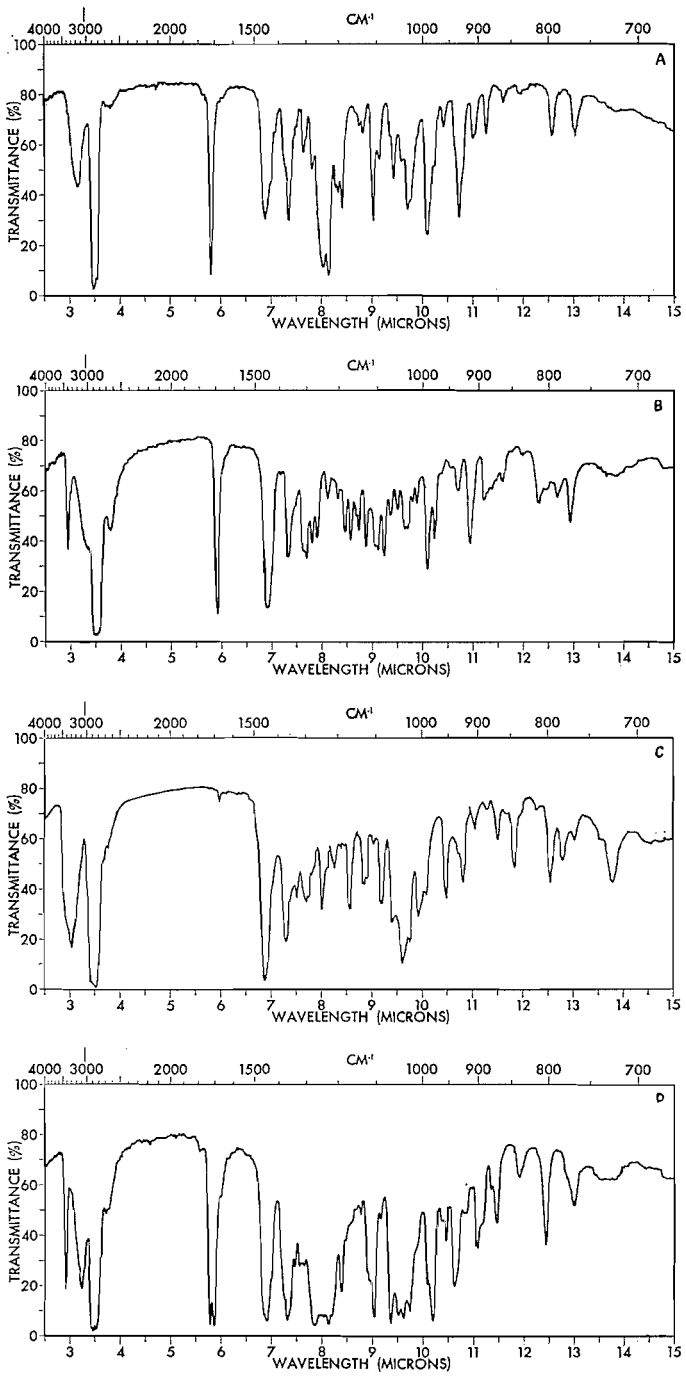

FIG. 2. Infrared absorption spectra in Nujol mull measured on a Perkin–Elmer "Infracord": A, α-lofoline; B, annofoline; C, lycofoline; D, β-lofoline.

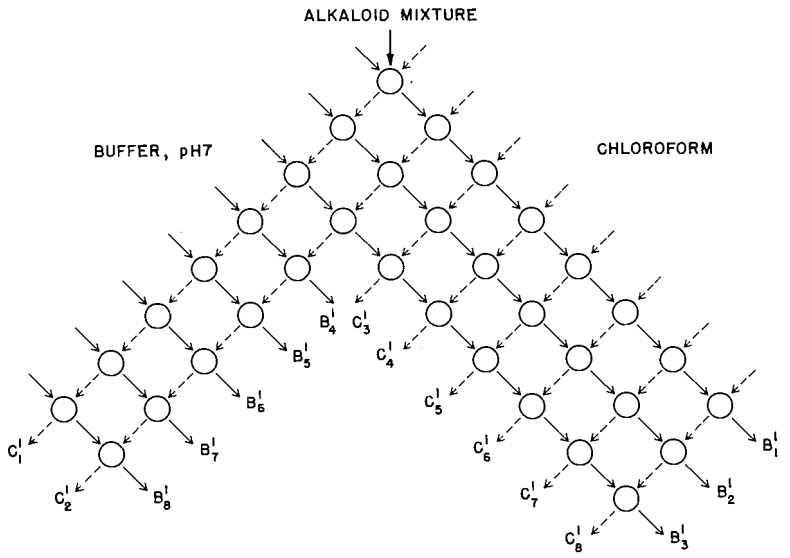

FIG. 3. Modified Bush and Densen extraction pattern. The circles represent phase separation, and the full lines show the advancement of the buffer solutions, and the dotted lines that of the chloroform solutions.

the system chloroform–buffer of pH 8.2 the pattern shown in Fig. 1C. Thus about the same separation was obtained as before but with one 60-transfer countercurrent distribution less.[3]

The distribution pattern of Fig. 1C was somewhat different from that of Fig. 1B. In the first place the peak corresponding to α-lofoline was much less intense in Fig. 1C than in Fig. 1B, and there was a new peak (tubes 52 to 58) in Fig. 1C not present in Fig. 1B. Furthermore, the peak occurring at tubes 16 to 26 contained not only α-lofoline, but also another new alkaloid resembling it closely, and which we have named β-lofoline. The two alkaloids were separated by careful chromatography on alumina. β-Lofoline had m.p. 166–167°, and analysis gave the formula $C_{18}H_{29}O_3N$ and showed the presence of one O-acetyl group and two C-methyl groups. The infrared spectrum (Fig. 2D) indicated a hydroxyl group (free hydroxyl, 3400 cm^{-1}, and bonded hydroxyl, 3100 cm^{-1}) and an O-acetyl group (bands at 1700 cm^{-1}, 1730 cm^{-1} and at 1225 cm^{-1}, 1270 cm^{-}).[1] The splitting of the carbonyl band of the acetyl group is probably related to the fact that there are two hydroxyl frequencies. In carbon tetrachloride solution both α- and β-lofoline showed only one (free) hydroxyl band and one carbonyl band (1720 cm^{-1}); therefore the effect with β-lofoline is not intramolecular. Thus in the crystals of β-lofoline the carbonyl groups of some molecules are not hydrogen-bonded whilst the carbonyl groups of other molecules are intermolecularly hydrogen-bonded. The new peak at tubes 52 to 58 (Fig. 1C) may represent hydrolysis products of α-lofoline and β-lofoline. Preliminary experiments have shown that the hydrolysis products of α- and β-lofoline have the same R_f values and partition coefficients as the alkaloids present in the new peak. This would also explain why the amount of lofolines in the second lot of alkaloid (see Fig. 1C) was less than in the first lot (Fig. 1B).

[3]*The middle fractions (B_4' to B_8' and C_3' to C_8') have been found by Mr. G. Dong in these laboratories to contain the same alkaloids as those present in tubes 10 to 42 of the countercurrent distribution given in Fig. 1A. Also, the chloroform-soluble fractions (C_1' and C_2') have been found by Mr. M. V. Rao to contain all the anno-tinine, lycodine, and lycopodine present in the original mixture.*

The pK_a's, rotations, and other properties of the alkaloids are summarized in Table I. Degradative work on these alkaloids will be reported in a future paper.

TABLE I

New alkaloids isolated from *L. annotinum*

Alkaloid	Formula	M.p.	pK_a in 50% aqueous methanol	$[\alpha]_D$ in ethanol	R_f*	Methiodide, m.p.
α-Lofoline	$C_{18}H_{29}O_3N$	211–212°	9.7	− 52°	0.58	266–267°
β-Lofoline	$C_{18}H_{29}O_3N$	166–167°	9.55	− 6°	0.51	296–297°
Annofoline	$C_{16}H_{25}O_2N$	156–157°	9.15	−131°	0.31	308–309°
Lycofoline	$C_{16}H_{25}O_2N$	144–145°	9.1	− 75°	0.53	263–264°

*Chromatography on Whatman No. 1 paper buffered to pH 7.0 and developed with *n*-butanol saturated with water (see also Experimental).

In a recent paper (4) Achmatowicz and Rodewald described the isolation of some new alkaloids, in the form of their methiodides, from *L. annotinum* of European origin. However, none of these alkaloids seems to correspond with the alkaloids which we have isolated.

EXPERIMENTAL

The infrared spectra, apart from those given in Fig. 2, were measured in carbon tetrachloride solution (1%) in a 1-mm cell on a Perkin–Elmer single-beam double-pass instrument. The paper chromatograms were obtained on Whatman No. 1 paper buffered with the pH mentioned in the text, and developed with butanol saturated with water. The absolute R_f values of the alkaloids varied appreciably, but the relative values were constant. The alkaloidal spots were revealed by spraying with a modified Dragendorff reagent (5). Equivalent weights (E.W.) and pK_a were determined by microtitrations with 0.1 *N* hydrochloric acid in 50% aqueous methanol.

Preliminary Separation of the Crude Alkaloid

The first lot of alkaloid to be investigated was the same as that described (1) previously. The crude alkaloid left after the removal of most of the annotinine by crystallization was partitioned repeatedly between chloroform and a buffer of pH 6 using the extraction scheme of Bush and Densen (6) so as to obtain six chloroform phases and six buffer phases. The alkaloid in the first four buffer phases (B1 to B4 of reference (1)) were combined for the present study and will be referred to as fraction B.

A second lot of alkaloid mother liquors from a different extraction of plant material was also investigated, but was treated differently from the above in view of the results obtained with fraction B.

Countercurrent Distribution with the System Chloroform–Buffer of pH 7.0

Fraction B (8.6 g) was dissolved in chloroform (120 ml) and the solution was placed in the first three tubes of a 60-tube Craig countercurrent distribution apparatus (7) and partitioned between chloroform and citrate–phosphate buffer of pH 7.0. Fifty-seven transfers were made, after which every third tube was analyzed. Aliquots (usually 2 ml) of each phase of a tube were removed, mixed, and made alkaline and the bases extracted with chloroform. The alkaloid left after removal of the solvent was weighed to give the distribution shown in Fig. 1A. The samples obtained from the weight analysis were submitted to paper chromatography (paper buffered at pH 6.0) and their infrared

For personal use only.

spectra measured. Whilst α-lofoline could be crystallized from the alkaloid in tubes 46 to 52, the yield was small and it was preferable to separate the alkaloids present in tubes 46 to 57 by another countercurrent distribution.

Countercurrent Distribution with the System Chloroform–Buffer of pH 8.0

The alkaloid was recovered from tubes 46 to 57 in the usual way and submitted to 58 transfers in the above system, the alkaloid being placed in the first two tubes of the apparatus. The tubes were analyzed as described before and the distribution pattern of Fig. 1B was obtained.

Isolation of α-Lofoline

The alkaloid in tubes 21 to 32 of the above distribution was isolated and crystallized from methanol to give thick colorless prisms, m.p. 211–212°. To obtain a good yield it was found desirable to chromatograph the mother liquors on alumina, using successively benzene, benzene–chloroform, and chloroform as the eluants. α-Lofoline was very soluble in methanol and chloroform but sparingly soluble in ether or petroleum ether. The alkaloid was best recrystallized from benzene, and was sublimed (120–130° at 0.05 mm) for analysis. Calc. for $C_{18}H_{29}O_3N$: C, 70.32; H, 9.51; N, 4.56; 2C—CH_3, 9.8; O—$COCH_3$, 14.0%; M.W., 307.4. Found: C, 70.56, 70.56; H, 9.54, 9.54; N, 4.63; C—CH_3, 10.60; O—$COCH_3$, 14.21%; M.W. (Rast), 291, 312; E.W., 310, 310; pK_a, 9.7, 9.7; $[\alpha]_D$ −52° (*c*, 2.0 in ethanol).

α-Lofoline Methiodide

α-Lofoline (20 mg) was dissolved in a mixture of methanol (1 ml) and methyl iodide (0.5 ml) and the mixture was refluxed for 10 minutes. The solvent was removed by evaporation and the methiodide was crystallized from methanol–acetone. Yield, 16 mg, m.p. 266–267°. Calc. for $C_{18}H_{29}O_3N.CH_3I$: C, 50.78; H, 7.18; I, 28.24%. Found: C, 51.08; H, 7.04; I, 28.04%.

Isolation of Annofoline

The alkaloid in tubes 36 to 41 of the above distribution (with the buffer of pH 8) was isolated and crystallized from methanol–ether, but the m.p. was 115–130°. Three recrystallizations raised the m.p. to 148–150° and this changed to 156–157° after sublimation (120–130° at 0.05 mm). It was found that a much better yield of pure annofoline could be obtained by chromatography on alumina of the contents of tubes 36 to 51. Elution with benzene–chloroform gave annofoline, whilst elution with chloroform gave lycofoline (see below). Annofoline had similar solubilities to α-lofoline, and when its solution in carbon tetrachloride (but not chloroform) was allowed to evaporate in the presence of air, an intense orange-yellow residue was left. This test was not given by α- or β-lofoline but lycofoline gave a crimson-red color. For analysis a sublimed sample was used. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57; N, 5.32; C—CH_3, 5.96%; M.W., 263.4. Found: C, 72.85, 73.05; H, 9.51, 9.59; N, 4.91; C—CH_3, 6.91%; M.W. (Rast), 270, 283; E.W., 259, 267; pK_a, 9.1, 9.2; $[\alpha]_D$ −131° (*c*, 2.0 in ethanol).

Annofoline Methiodide

The methiodide of annofoline crystallized on addition of methyl iodide (0.8 ml) to a solution of the alkaloid (60 mg) in acetone (2 ml). The mixture was refluxed for 5 minutes, cooled, and the methiodide collected. It was recrystallized from water, m.p. 308–309°. Yield, 40 mg. Calc. for $C_{16}H_{25}O_2N.CH_3I$: C, 50.37; H, 6.94; I, 31.31%. Found: C, 50.30; H, 6.70; I, 31.50%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Annofoline Perchlorate

A methanolic solution of perchloric acid was added to a solution of the alkaloid in methanol until a slight excess was present. Ether was added to the solution and the perchlorate crystallized on scratching. After recrystallization from methanol–ether it melted at 234–236°. Calc. for $C_{16}H_{25}O_2N.HClO_4.H_2O$: C, 50.30; H, 7.65%. Found: C, 50.08; H, 7.35%.

Isolation of Lycofoline

The alkaloid in tubes 42 to 51 of the above distribution (with the buffer of pH 8.0) was isolated and converted into the hydrobromide by the addition of concentrated hydrobromic acid to the methanolic solution of the alkaloid. Addition of ether gave a crystalline salt, which after three crystallizations from methanol–ether was converted to the base. The base was sublimed (110–130° at 0.05 mm) and then crystallized from ether. Lycofoline was obtained as prisms, m.p. 144–145°. For analysis it was sublimed *in vacuo*, m.p. unchanged. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57; N, 5.32; C—CH_3, 5.69%; M.W., 263.4. Found: C, 72.77, 72.66; H, 9.51, 9.59; N, 5.11; C—CH_3, 4.96%; M.W. (Rast), 239; E.W., 264, 267; pK_a, 9.05, 9.1; $[\alpha]_D$ −75° (*c*, 2.0 in ethanol). A better yield of lycofoline was obtained by chromatography of the mixture of annofoline and lycofoline as described in the procedure for the isolation of annofoline.

Lycofoline Hydrobromide

For analysis the hydrobromide was recrystallized from methanol–ether and dried at 117° *in vacuo*, m.p. 274–275°. Calc. for $C_{16}H_{25}O_2N.HBr$: C, 56.05; H, 7.61%. Found: C, 55.64, 55.68; H, 7.55, 7.42%.

Lycofoline Methiodide

Lycofoline (34 mg) was dissolved in methanol (1.5 ml) and the solution was refluxed for 10 minutes with methyl iodide (0.5 ml). The solvent was removed and the methiodide was crystallized from methanol. Yield, 15 mg, m.p. 263–264°. Calc. for $C_{16}H_{25}O_2N.CH_3I$: C, 50.37; H, 6.94; I, 31.31%. Found: C, 50.65; H, 6.99; I, 31.58%.

Improved Separation of Crude Alkaloid

A second batch of crude alkaloid (after removal of the annotinine) (60 g) was partitioned between chloroform and a citrate–phosphate buffer of pH 7.0 using the modified Bush and Densen extraction pattern of Fig. 3. The extractions were carried out with 1 liter of each phase. The fractions B_1' to B_3' were combined and the alkaloid extracted in the usual way. The mixture (20 g) so obtained was divided into three equal lots, and each was subjected to a 60-tube countercurrent distribution with the solvent system chloroform and boric acid – sodium hydroxide buffer of pH 8.2. The distribution pattern given in Fig. 1C was obtained.

Isolation of β-Lofoline

Annofoline and lycofoline were isolated from tubes 28 to 43 and were separated as described above by chromatography on alumina. Tubes 16 to 26, however, did not give α-lofoline in pure state easily. Indeed, paper chromatography (paper buffered at pH 7.0) showed two spots of very similar R_f values (0.58, 0.51). The mixture was therefore chromatographed on alumina. Elution with benzene, benzene–chloroform, and chloroform gave first β-lofoline, followed by α-lofoline. The β-lofoline was crystallized from methanol–ether, m.p. 160–166°, raised to 166–167° after two recrystallizations from ether. For analysis a sample was sublimed (120–130° at 0.05 mm). Calc. for $C_{18}H_{29}O_3N$: C, 70.32; H, 9.51; N, 4.56; 2C—CH_3, 9.8; O—$COCH_3$, 14.00%; M.W., 307.4. Found: C, 70.18,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

70.14; H, 9.45, 9.69; N, 4.84; C—CH_3, 8.83; O—$COCH_3$, 15.6%; M.W. (Rast), 322; E.W., 311; pK_a, 9.55; $[\alpha]_D$ −6° (*c*, 2.0 in ethanol).

β-Lofoline Methiodide

To a solution of the alkaloid (20 mg) in methanol (2 ml), methyl iodide (0.5 ml) was added, and the mixture was refluxed for 10 minutes. The solvent was removed and the methiodide was crystallized from methanol. Yield, 10 mg, m.p. 296–297° (decomp.). Calc. for $C_{18}H_{29}O_3N.CH_3I$: C, 50.78; H, 7.18%. Found: C, 50.90; H, 6.80%.

ACKNOWLEDGMENTS

The authors thank Dr. Léo Marion for providing the mother liquors from the crystallization of annotinine. One of us (N. H. K.) wishes to thank the Colombo Plan authorities for the award of a scholarship and the Pakistan Council of Scientific and Industrial Research for financial support.

SYNTHESIS OF 2,4-THIAZOLIDINEDIONE-2-AZINES AND 2,4-THIAZOLIDINEDIONE-2-DIMETHYLHYDRAZONES FROM THIOCYANOESTERS AND HYDRAZINES[1]

PAUL E. GAGNON, JEAN-L. BOIVIN,[2] AND GORDON M. BROWN[3]

ABSTRACT

Thiocyanoesters were prepared from 2-bromoesters and potassium thiocyanate, and a series of substituted thiazolidinedione-2-azines was obtained from these thiocyanoesters using hydrazine hydrate. The structure of the thiazolidinedione-2-azines was determined by hydrolysis using hydrochloric acid in ethanol. The reaction of thiocyanoesters with dimethylhydrazine, generally speaking, was analogous to their reaction with hydrazine, but there were many differences. Only 1 mole of alcohol was eliminated rather than 2, and there was no apparent reaction for the ethyl 2-thiocyanononanoate and the methyl phenylthiocyanoacetate. Furthermore, the reaction of methyl 2-thiocyanoisobutyrate with dimethylhydrazine did not give a 2,4-thiazolidinedione-2-dimethylhydrazone but rather an addition product, *N*-dimethylamino-*S*-(1-methyl-1-carbomethoxy) ethylisothiourea. To illustrate the reactivity of the thiocyano group, benzyl thiocyanate was treated with hydrazine and the product was found to be dibenzyldisulphide, and ammonia was evolved. Similarly, trimethylene dithiocyanate gave the dimer of trimethylene disulphide. Finally, benzyl thiocyanate formed an addition product with dimethylhydrazine which was *N*-dimethylamino-*S*-benzylthiourea.

INTRODUCTION

Ethyl thiocyanoacetate, which was prepared for the first time by Heintz (1) from ethyl chloroacetate and potassium thiocyanate, contains an active methylene group and, consequently, is structurally similar to ethyl cyanoacetate which is easily alkylated in the presence of a catalyst. Thus for a time it was considered that a series of thiocyanoesters might be prepared from ethyl thiocyanoacetate itself. However, Claesson (2) discovered that if ethyl thiocyanoacetate was treated with ethyl bromide, the products were ethyl thiocyanate and ethyl bromoacetate.

$$C_2H_5Br + NCSCH_2COOC_2H_5 \rightarrow C_2H_5SCN + BrCH_2COOC_2H_5$$

Therefore, the thiocyanoesters had to be synthesized from the corresponding 2-bromoesters which, in turn, were obtained by esterification of the bromoacids.

$$RCH_2COOH \rightarrow RCHBrCOOH \rightarrow RCHBrCOOR' \rightarrow RCH(SCN)COOR'$$

In 1910, Frerichs and Förster (3) reported that when an aqueous solution of hydrazine hydrate was shaken with ethyl thiocyanoacetate, an exothermic reaction ensued producing a precipitate which was insoluble in all common solvents. The analysis suggested the formula $C_6H_6N_4O_2S_2$. This compound decomposed without melting and was assigned the structure of 3,3-bis-pseudothiohydantoin.

$$2NCSCH_2COOC_2H_5 + H_2NNH_2 \rightarrow \begin{array}{l} CH_2\text{——}CO \quad CO\text{——}CH_2 \\ \quad | \quad\quad | \quad\quad | \quad\quad | \\ S\text{—}C\text{—}N\text{——}N\text{—}C\text{—}S \\ \quad\quad \| \quad\quad\quad \| \\ \quad\quad NH \quad\quad NH \end{array} + 2C_2H_5OH$$

The authors also claimed that the above compound was obtained from hydrazodithiodicarbonamide and chloroacetic acid in aqueous solution.

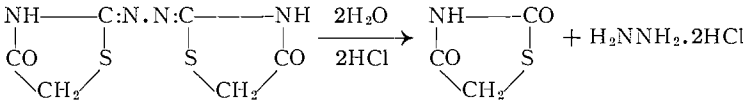
Some years later, Stephen and Wilson (4) investigated the reaction between hydrazodithiodicarbonamide and ethyl chloroacetate. They established the structure of the product by treating it with boiling concentrated hydrochloric acid in which it gradually dissolved. After evaporation, the solid obtained was extracted with hot chloroform, giving 2,4-thiazolidinedione identified by a mixed melting point with an authentic sample. The residue, after the extraction, was proved to be hydrazine hydrochloride. From the two hydrolysis products, then, it is obvious that the original compound obtained from hydrazodithiodicarbonamide and ethyl chloroacetate was 2,4-thiazolidinedione-2-azine.



Stephen and Wilson claimed that the compound prepared by Frerichs and Förster gave the same products when boiled with concentrated hydrochloric acid. The compound of which they spoke was prepared from hydrazodithiodicarbonamide and chloroacetic acid; no mention was made of the reaction between ethyl thiocyanoacetate and hydrazine hydrate.

In 1913, Frerichs and Höller (5) studied the reactions of hydrazodithiodicarbonamide with haloacids, specifically 2-bromopropionic and 2-bromobutyric acids. The compounds obtained were regarded as substituted 3,3-bis-pseudothiohydantoins. The melting points reported by Frerichs and Höller were not sharp, which leads one to believe that difficulties in purification were encountered.

Stephen and Wilson (6) also undertook the preparation of the same compounds by the method of Frerichs and obtained from hydrazodithiodicarbonamide and 2-bromopropionic acid a solid melting at 289° C which, on hydrolysis with concentrated hydrochloric acid, gave rise to the known 5-methyl-2,4-thiazolidinedione. Similarly, the compound obtained from hydrazodithiodicarbonamide and 2-bromobutyric acid melting at 233° C gave on acid hydrolysis the known 5-ethyl-2,4-thiazolidinedione. The structure of these two compounds must be, therefore, 5-methyl- and 5-ethyl-2,4-thiazolidinedione-2-azine, respectively.

RESULTS AND DISCUSSION

Thiocyanoesters

The thiocyanoesters were prepared from the corresponding bromoesters using a 50% excess of potassium thiocyanate as recommended by Allen (7). Generally speaking, 80% alcohol was used for the lower members, and as the chain length increased to seven and eight carbons 90% alcohol was employed since the latter were not completely miscible with 80% alcohol.

The methyl phenylthiocyanoacetate was not synthesized using the sequence of reactions followed for alkyl thiocyanoacetates. Direct bromination of phenyl acetic acid puts the bromine in the ring, not in the side chain, even when no catalyst is used (8). To prepare the desired ester, then, mandelic acid was employed as the starting material. Esterification by the method of Clinton and Laskowski (9) gave the corresponding methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

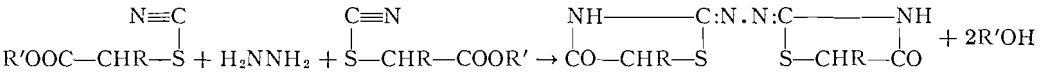
ester in good yield. The methyl phenylchloroacetate was then prepared by treatment of the mandelate with thionyl chloride in accordance with the procedure given by McKenzie and Barrow (10), and the phenylthiocyanoacetate was obtained directly from the above compound by the usual method.

It was noted that the inductive effect played a very important part in the time required to form the thiocyanoesters. In the case of ethyl chloroacetate, both the chlorine atom and the carbethoxy group are electron attracting, leaving the alpha carbon atom with a residual positive charge which attracted the attacking thiocyanate ion. The substitution, therefore, took place quite rapidly. The alpha carbon atom, in the case of alkyl-substituted thiocyanoesters, is more negatively charged than in the non-substituted ester, due to the fact that alkyl groups are electron repelling, and so the attacking thiocyanate ion approaches less rapidly as is seen by the reflux time necessary for the completion of the reaction.

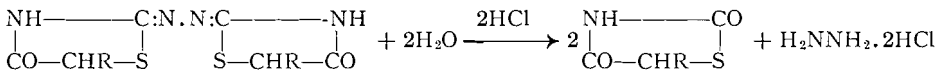
The methyl 2-thiocyanoisobutyrate and the methyl 2-thiocyanoisovalerate required a much longer period of heating, due to the electron repulsion of the two methyl groups toward the same carbon atom. The approach of the negatively charged thiocyanate ion is greatly hindered by the strongly negative charges on the second carbon atom. True to the electronic theory that the inductive effect dies out after one methylene group, the preparation of methyl 2-thiocyanoisohexanoate was performed easily. In spite of the repulsion of the methyl groups, the site of the perturbation was too far removed from the second carbon atom to hinder the replacement of the bromine atom, and no extra time was required in the preparation of the above-mentioned ester. The phenylthiocyanoacetate required but a small reflux period due to the fact that the phenyl group is electron attracting, leaving the alpha carbon atom with a net positive charge and facilitating greatly the approach of the attacking thiocyanate ion.

2,4-Thiazolidinedione-2-azines

A method of improving the yields was devised for the azines by finding a suitable solvent. Methanol was finally selected as the medium in spite of the fact that it itself is a by-product of the reaction and thus tends to set up an equilibrium. If the addition of the reagent was not performed with care, the reaction mixture boiled; however, by introducing a dropwise solution of hydrazine hydrate in methanol, the temperature did not become too great and solid products were obtained.



The structure was established by boiling these compounds with concentrated hydrochloric acid in ethanol (11). Substituted 2,4-thiazolidines were obtained and their melting points compared favorably with those reported in the literature. The second product of hydrolysis was identified as hydrazine hydrochloride, thus establishing without a doubt the structure of the compounds being hydrolyzed as 2,4-thiazolidinedione-2-azines.



The above results prove conclusively that thiocyanoacetates and hydrazine hydrate give the same azines as hydrazodithiodicarbonamide and 2-haloacetic acids.

2,4-Thiazolidinedione-2-dimethylhydrazones

If dimethylhydrazine and thiocyanoesters, which were mutually soluble, were mixed without a solvent, the reaction, which was endothermic at the time of the addition, after a few minutes became uncontrollably exothermic with charring of the reaction mixture. It was found that for the preparation of lower molecular weight members of this series, formamide was an excellent solvent as the product was insoluble and precipitated out when the mixture was left to stand overnight.

$$RCH(SCN)COOR' + (CH_3)_2NNH_2 \rightarrow \begin{matrix} NH\text{———}C{:}N.N(CH_3)_2 \\ | \qquad\qquad | \\ CO\text{—}CHR\text{—}S \end{matrix} + R'OH$$

The reaction mixture generally darkened to amber, but the reactions themselves were not exothermic, except in the case of ethyl thiocyanoacetate, which was moderately so.

Unfortunately, the complete series of thiocyanoesters was not soluble in formamide and another solvent had to be found for those of higher molecular weight. If the reaction between dimethylhydrazine and methyl 2-thiocyanohexanoate was performed using nitrobenzene as the solvent, a solid product was obtained which separated out when the mixture was left to stand overnight. No exothermic reaction was observed and the mixture darkened only slightly to yellow. The yield obtained by this method was almost the same as that obtained by using formamide. Another solvent employed was *o*-nitroanisole which gave results similar to those obtained by nitrobenzene. To determine the structure of these compounds, they were hydrolyzed with hydrochloric acid in ethanol and two products were obtained, the known 2,4-thiazolidinediones and dimethylhydrazine hydrochloride.

$$\begin{matrix} NH\text{———}C{:}N.N(CH_3)_2 \\ | \qquad\qquad | \\ CO\text{—}CHR\text{—}S \end{matrix} + H_2O + HCl \rightarrow \begin{matrix} NH\text{———}CO \\ | \qquad\quad | \\ CO\text{—}CHR\text{—}S \end{matrix} + (CH_3)_2NNH_2.HCl$$

There was no apparent reaction when ethyl 2-thiocyanononanoate and methyl phenylthiocyanoacetate were treated with 1,1-dimethylhydrazine. The lack of reaction on the part of the thiocyanononanoate is not easily explained. The fact that it is an ethyl ester rather than a methyl ester might have some effect on the cyclization but could scarcely inhibit the addition of the hydrazine to the thiocyano group. Since no product was obtained, even when the solution was cooled strongly, it must be concluded that the addition did not occur which could possibly be explained by steric hindrance. Perhaps the coiled heptyl chain blocks the thiocyanate group from the attacking hydrazine. The absence of reaction of the phenylthiocyanoacetate can be theoretically explained. The triple bond in methyl phenylthiocyanoacetate is less polar than in the alkyl-substituted thiocyanoacetates, as the phenyl group is electron attracting.

In the reaction between methyl 2-thiocyanoisobutyrate and 1,1-dimethylhydrazine using the same conditions as before, it was found that the product had a much lower melting point than expected. This posed a problem until it was found that the substance was water soluble and all the 2,4-thiazolidinedione-2-dimethylhydrazones were insoluble in water. It was suspected then that the reaction between dimethylhydrazine and methyl 2-thiocyanoisobutyrate consisted of a simple addition which was confirmed by analysis. No coloration was obtained upon treatment with ferric chloride. The fact that no cyclization occurred must be due to the effect of the two methyl groups on the second carbon atom.

Disulphides

When benzyl thiocyanate was treated with hydrazine hydrate in ethanol at reflux temperature, the product was found to be dibenzyldisulphide.

$$2C_6H_5CH_2SCN + 4H_2NNH_2.H_2O \rightarrow C_6H_5CH_2SSCH_2C_6H_5 + 8NH_3 + N_2 + 2CO_2$$

(HN=CH—N=N—CH=NH) ↓

The same product was formed when the reaction was carried out at room temperature although, due to occlusion of the solvent which had deepened in color to dark red, the product was not as pure. However, the yields obtained at room temperature are greater than at the reflux temperature of ethanol.

The reaction at room temperature was very interesting since certain effects were discovered which had escaped notice at the higher temperature. A strong smell of ammonia was produced, and a small amount of precipitate was obtained which contained no sulphur. This compound was suspected to contain a guanidine function and accordingly benzaldehyde and cinnamaldehyde derivatives were prepared. However, the melting points of the condensation products did not correspond with the melting points of the mono-, di-, or tri-amino/guanidine derivatives reported in the literature (12, 13). It was not possible, then, to establish the identity of this by-product.

Also trimethylene dithiocyanate was treated with hydrazine hydrate in ethanol at room temperature. A solid separated out almost immediately, which on being subjected to qualitative test showed the absence of nitrogen. Its melting point was similar to that of a compound described by Hagelberg (14), who prepared it by the treatment of trimethylene dithiocyanate with potassium hydroxide.

$$NCS(CH_2)_3SCH + 2KOH \rightarrow (CH_2)_3S_2 + KCN + KOCN + H_2O$$

However, he was not certain whether it was the simple trimethylene disulphide that was formed or its dimer. Therefore, a molecular weight determination was made using the method of Rast (15), and calculations proved that indeed the dimer hexamethylene tetrasulphide had been formed.

Isothioureas

Benzyl thiocyanate was also treated with 1,1-dimethylhydrazine. The reaction was performed at room temperature in ether, and the product started to separate almost immediately as a viscous liquid which crystallized upon standing. The suspected *N*-dimethylamino-*S*-benzylisothiourea was soluble in water as expected and the analysis was correct for $C_{10}H_{15}N_3S$.

$$C_6H_5CH_2SCN + (CH_3)_2NNH_2 \rightarrow C_6H_5CH_2SC(=NH)NHN(CH_3)_2$$

However, upon treatment of an aqueous solution of the compound with ferric chloride, a blood-red coloration was obtained, characteristic of thiocyanate ion. In addition, aqueous mercurous nitrate gave a grey precipitate of mercury, also indicative of a thiocyanate.

When the substance was dissolved in ethylene chloride and treated with concentrated sulphuric acid, a solid separated out which, according to analysis results, was the sulphate salt of 1,1-dimethyl-2-benzylhydrazine, $C_6H_5CH_2NHN(CH_3)_2.H_2SO_4$. At the same time, these results definitely eliminated the possibility of the product being a sulphate salt of the isothiourea mentioned above.

It is obvious that a rearrangement has occurred, perhaps due to the acidic medium induced by the sulphuric acid, or else by the basicity of the original mixture of benzyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

thiocyanate and dimethylhydrazine, in which case the product $C_{10}H_{15}N_3S$ must be the thiocyanic acid salt of 1,1-dimethyl-2-benzylhydrazine. If, however, the rearrangement is brought about by hydrogen ions, then treatment of the isothiourea with ferric chloride and mercurous nitrate, both of which are acidic in aqueous solution, could still conceivably give a positive test for thiocyanate ion.

The addition product obtained from dimethylhydrazine and methyl 2-thiocyanoisobutyrate gave no red coloration when treated with ferric chloride; therefore it must be an isothiourea derivative, and one would suspect the formation of a similar type of compound from the analogous reaction under discussion.

EXPERIMENTAL

2-Bromoacids

The 2-bromoacids were obtained by treatment of aliphatic fatty acids with dry bromine in the presence of phosphorus trichloride, according to the procedures of Clarke and Taylor (16) and of Marvel (17), although the conditions varied slightly from those suggested by the above authors in that, in general, the reactions were performed at lower temperatures for longer periods of time.

Methyl 2-Bromoesters

The esters were synthesized from the bromoacids by the method of Clinton and Laskowski (9). The following preparation is representative.

Methyl 2-bromoheptanoate.—2-Bromoheptanoic acid (150 g, 0.72 mole), methanol (70 g, 2.2 moles), ethylene chloride (250 ml), and concentrated sulphuric acid (3 ml) were heated under reflux for 11 hours and diluted with water. The organic layer was washed with carbonate solution and water and dried over sodium sulphate. After removal of the solvent, the ester was distilled, b.p. 87–88° C/6 mm, n_D^{25} 1.4531. Yield, 117 g (73%). Calc. for $C_8H_{15}BrO_2$: C, 43.06; H, 6.79; Br, 35.82%. Found: C, 43.18; H, 6.70; Br, 35.72%.

Methyl 2-bromoöctanoate.—This ester was obtained in the same manner, b.p. 105° C/7 mm, n_D^{25} 1.4544. Calc. for $C_9H_{17}BrO_2$: C, 45.57; H, 7.24; Br, 33.70%. Found: C, 45.86; H, 7.07; Br, 33.78%.

2-Thiocyanoesters

The bromoesters (or in the case of ethyl thiocyanoacetate and methyl phenylthiocyanoacetate, the chloroesters) were transformed into the corresponding thiocyano-compounds by the action of potassium thiocyanate in aqueous alcohol. The particulars are given in Table I.

2,4-Thiazolidinedione-2-azines

When thiocyanoesters were treated dropwise at room temperature with a solution of hydrazine hydrate in alcohol, a precipitate was produced after the whole had been left to stand overnight. The properties of the azines are recorded in Table II.

Hydrolysis of the azines.—5-Ethyl-2,4-thiazolidinedione-2-azine (1 g) was heated under reflux for 18 hours with concentrated hydrochloric acid (40 ml) and ethanol (80 ml). After the solution was evaporated to dryness, the solid was extracted several times with boiling benzene. When the benzene solution was concentrated to small volume and cooled, crystals were obtained, which upon recrystallization from benzene ligroine (2:1) melted at 64–66° C (6). The residue was dissolved in a small quantity of water and buffered with a slight excess of sodium acetate. Upon the addition of a solution of benzaldehyde in ethanol, a yellow precipitate of benzalazine was obtained, m.p. 91–93° C (18).

2,4-Thiazolidinedione-2-dimethylhydrazones

When thiocyanoesters were treated with 1,1-dimethylhydrazine in a suitable solvent at room temperature, solids separated out after the whole had been left to stand overnight. No special precautions were required in the additions. The dimethylhydrazones prepared in this manner are listed in Table III.

Hydrolysis of the dimethylhydrazones.—5-Ethyl-2,4-thiazolidinedione-2-dimethylhydrazone (2 g) was treated with ethanol (80 ml) and concentrated hydrochloric acid (40 ml) at reflux temperature for 12 hours and the resulting solution was evaporated to dryness. After the benzene solution was extracted thoroughly with boiling benzene and concentrated to small bulk, the residue was left to stand in the refrigerator where crystals of 5-ethyl-2,4-thiazolidinedione were obtained, m.p. 63–64° C. The fraction insoluble in benzene was dissolved in water, a little sodium acetate was added, and this solution was treated with *m*-nitrobenzaldehyde in ethanol. After the solution was heated for a few minutes on a hot plate, a cloudiness developed, and solidification occurred when it was left to stand in the cold. The *m*-nitrobenzaldehyde dimethylhydrazone so formed caused no depression in the melting point of an authentic sample of this material, prepared as follows: *m*-Nitrobenzaldehyde dissolved in a small quantity of warm ethanol was treated with an excess of 1,1-dimethylhydrazine and two drops of glacial acetic acid. The solution was heated on a hot plate until little solvent remained, whereupon it was allowed to cool and the residue crystallized, m.p. 57–58° C. The compound was recrystallized from methanol, leaving the melting point unchanged. Calc. for $C_9H_{11}N_3O_2$: N, 21.75%. Found: N, 21.58%.

N-Dimethylamino-S-(1-methyl-1-carbomethoxy) Ethylisothiourea

Methyl 2-thiocyanoisobutyrate (15.0 g, 0.094 mole), dimethylhydrazine (6.0 g, 0.100 mole), and nitrobenzene (15 ml) were mixed at room temperature and allowed to stand for 4 days. After it was filtered out and washed with ligroine, the solid product was recrystallized from *t*-amyl alcohol, m.p. 136–138° C. Yield, 5.8 g (28%). Further recrystallization using the same solvent gave a sample melting at 140° C. Calc. for $C_8H_{17}N_3O_2S$: C, 43.80; H, 7.83; N, 19.16%. Found: C, 44.19; H, 7.88; N, 19.02%.

Dibenzyl Disulphide

Benzyl thiocyanate was prepared from benzyl chloride in the usual manner, m.p. 42–44° C (19). The thiocyanate (10 g, 0.067 mole) in ethanol (50 ml) was treated with hydrazine (3.4 g, 0.068 mole) at room temperature, and the resulting solution was allowed to stand for 3 days. The color of the reaction mixture deepened to dark red and a small amount of precipitate of the same color was obtained. After the solution was diluted with ether (100 ml), the product was filtered and when the filtrate was concentrated, a solid separated out, m.p. 70.5–72° C, which contained no nitrogen. Recrystallization from ethanol gave 4.2 g (51%) of the dibenzyl disulphide, m.p. 72–73° C (20).

Trimethylene Disulphide

Hydrazine hydrate (6.3 g, 0.126 mole) was added to a solution of trimethylene dithiocyanate (10 g, 0.063 mole) in ethanol (50 ml) at room temperature. The reaction was slightly exothermic, accompanied by darkening of the mixture to deep yellow. After the mixture was left to stand for 20 hours, the precipitate was filtered and washed with alcohol and ether, m.p. 73–75° C. Yield, 6.4 g (95%). Recrystallization from chloroform gave a product containing no nitrogen, m.p. 75–76° C (14). Molecular weight determinations showed that this material was in reality the dimer of trimethylene disulphide. Calc. for $C_6H_{12}S_4$: 212. Found (Rast method): 198.

N-dimethylamino-S-benzylisothiourea

Dimethylhydrazine (4.3 g, 0.072 mole) was introduced, with shaking, into a solution of benzyl thiocyanate (10 g, 0.067 mole) in ether (25 ml) at room temperature. After 5 minutes had elapsed, an oil started to separate out, and at the end of 65 hours solidification occurred. The white solid was filtered and washed with ether, m.p. 72–74° C. Yield, 12.1 g (86%). Six recrystallizations from *t*-amyl alcohol afforded a pure product, m.p. 76–77° C. Calc. for $C_{10}H_{15}N_3S$: C, 57.37; H, 7.24; N, 20.08%. Found: C, 57.56; H, 7.23; N, 20.17%.

A small quantity of the above compound was dissolved in ethylene chloride and treated with a few drops of concentrated sulphuric acid. The solution was allowed to stand overnight in a refrigerator and a solid product was obtained, m.p. 114–115° C. Recrystallization from butanol gave rise to the pure sulphate salt of 1,1-dimethyl-2-benzylhydrazine, m.p. 116° C. Calc. for $C_9H_{14}N_2.H_2SO_4$: C, 43.53; H, 6.51; N, 11.29%. Found: C, 43.80; H, 6.63; N, 11.31%.

THE CHEMICAL COMPOSITION OF THE HEARTWOOD EXTRACTIVES OF TAMARACK (LARIX LARICINA (DU ROI) K. KOCH)[1]

G. V. NAIR[2] AND E. VON RUDLOFF

ABSTRACT

The acetone-soluble constituents of the heartwood of tamarack have been investigated. The flavanonols taxifolin and aromadendrin were isolated in 0.30 and 0.05% yield and a trace amount of quercetin was obtained. Tropolones could not be detected, nor was there any evidence for resin acids. The major portion of the extract consisted of esters of ferulic, phthalic, and long-chain fatty acids. Eicosanyl ferulate was isolated as such, whereas the other constituents were identified after saponification. Gas liquid chromatography of the fatty acid mixture indicated the presence of palmitic, palmitoleic, oleic, linoleic, and linolenic acids as well as small amounts of C_{14}, stearic, and C_{20} acids. From the non-saponifiable portion β-sitosterol, eicosanol, and nonan-2-ol were isolated. The acetone extract also contained free D-galactose and L-arabinose.

INTRODUCTION

Whereas the heartwood constituents of pine trees (1, 2) and those of the commercially important west coast conifers (1, 2, 3) have been studied extensively, larch heartwood constituents have not been investigated to any great extent. Gripenberg (4) has isolated from *Larix decidua* (*L. europea*) taxifolin ((+)-2,3-dihydroquercetin) and aromadendrin ((+)-2,3-dihydrokaempferol) and has shown that the distylin isolated from *L. leptolepis* (5, 6) is a mixture of these two flavanonols (nomenclature (2)). Brewerton (7) made a thorough investigation of the heartwood constituents of *L. decidua* and *L. leptolepis* grown in New Zealand and found, besides taxifolin and aromadendrin, trace amounts of a flavanone (m.p. 252° C), a phytosterol, and unidentified lignin- and tannin-like material, but no resin acids.

Tamarack is a small- to medium-sized larch tree found across Canada from the Atlantic coast to northern British Columbia and in Alaska. The wood of this species is often quite oily and is resistant to decay. Although it is used for railway ties, telegraph poles, and posts, it has found little commercial use. The present study of the acetone-soluble heartwood constituent was made on mature trees obtained from the Prince Albert and the Winnipeg areas. The freshly milled heartwood contained about 2.5% (on a dry weight basis) of acetone-soluble, non-volatile extractives.

Preliminary investigation on the total extract and a saponified portion thereof, by spot tests and paper chromatography, indicated the presence of a steroid, flavanoid constituents, and free sugars. Tropolones of the thujaplicin type were not detected on a paper chromatogram (8), nor were resin acids encountered. The concentrated acetone extract deposited a mixture of sugars, consisting of D-galactose (0.15% over-all yield, based on the dry weight of heartwood extracted) and L-arabinose (0.04%). The extraction of these acetone-insoluble sugars is explained by the presence of 15% moisture in the wood. The proportion of galactose to arabinose is the same as that found by Campbell *et al.* (9) in the ε-galactan of larch wood (*Larix decidua*), and it is conceivable that the free sugars were derived from polysaccharides by hydrolysis in the plant.

Conventional fractionation of the extract into petrol- or ether-soluble neutral compounds and acidic and phenolic constituents by treatment with aqueous alkali was unsatisfactory because of emulsion formation and incomplete separations. Therefore, the extract was divided into acetone-, benzene-, and petrol-soluble portions and then further fractionated as indicated (see Fig. 1). The acetone-soluble, benzene-insoluble portion (0.34%) consisted of flavonoid material. Paper chromatography of this material gave two spots corresponding to aromadendrin (R_f 0.8) and taxifolin (R_f 0.6) with the solvent system of Gripenberg (4), containing 1% acetic acid to prevent tailing. The

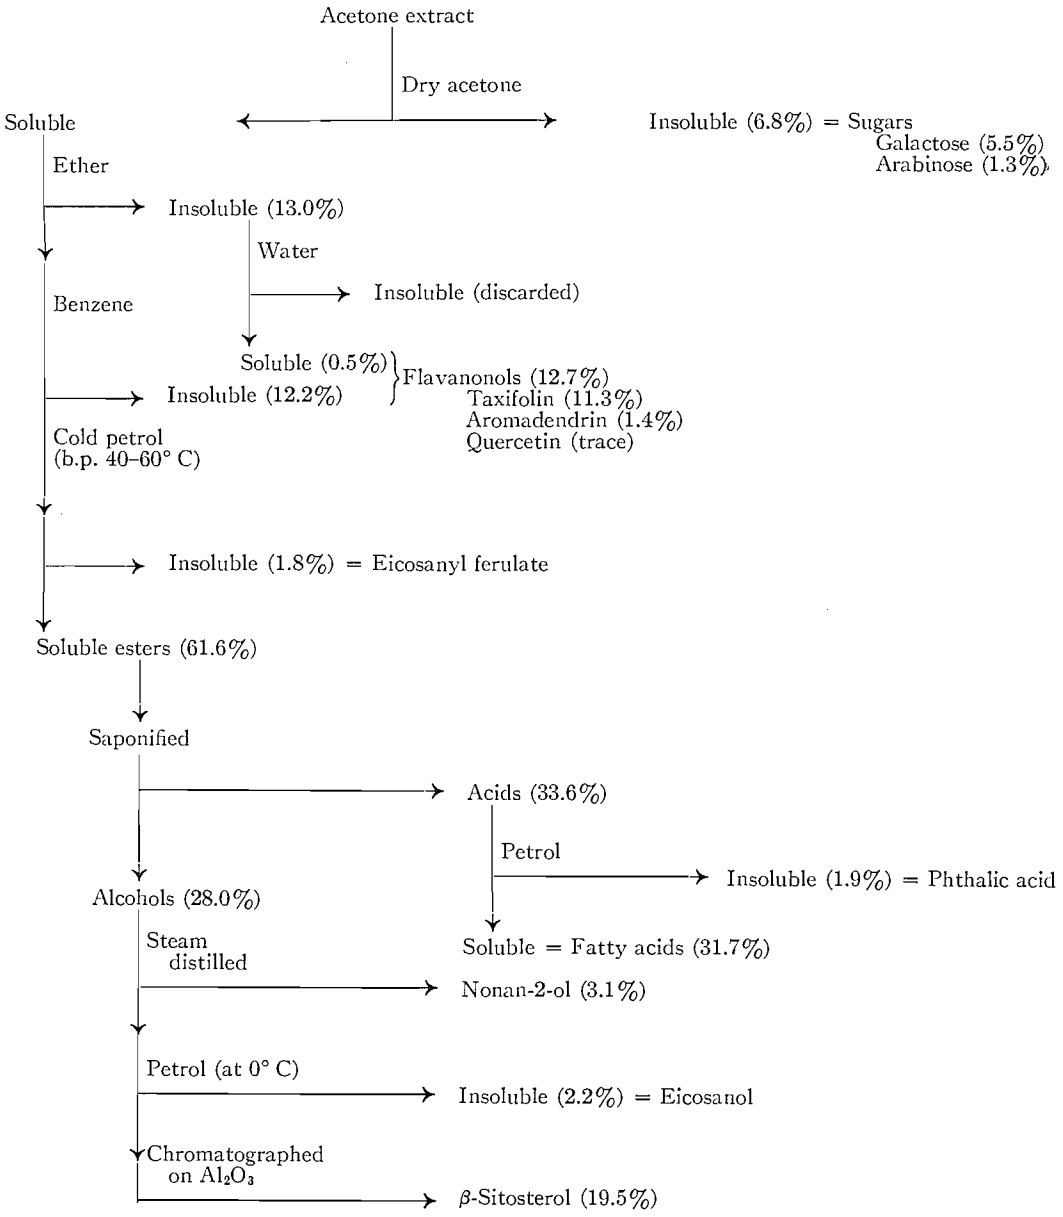

FIG. 1. Fractionation scheme and yields of compounds (based on the weight of acetone extract).

mixture was resolved almost completely on a cellulose powder column, giving an over-all yield of 0.04% of aromadendrin and 0.30% of taxifolin. When the column was washed with 50% aqueous ethanol a trace amount of quercetin was obtained.

The benzene-soluble, cold petrol-insoluble portion contained an ester, m.p. 61–62° C (0.05%), which was soluble in very dilute alkali, but which precipitated in more concentrated solutions. The infrared spectrum suggested an aromatic ester with a free hydroxyl group and a double bond in conjugation with the aromatic ring. It resembled closely the spectrum of methyl ferulate, except that the C–H absorption was much more intense. Alkaline hydrolysis produced eicosanol and ferulic acid in equimolar proportions, showing the ester to be eicosanyl ferulate.

The petrol-soluble portion formed the major part of the extract and it was comprised mainly of long-chain esters (infrared spectrum). Fractional distillation *in vacuo* did not yield pure components, and gas liquid chromatography was not feasible because of the low volatility of these esters. A portion of the material was saponified and the acidic and neutral fractions were investigated separately. From the non-saponifiable mixture nonan-2-ol, eicosanol, and β-sitosterol were isolated. From the acidic portion phthalic acid was obtained by crystallization. Phthalic acid or its esters are not often found in nature. Haagen-Smit *et al.* (10) report phthalic acid to occur in Zinfandel grapes and recently Kohlbrenner and Schuerch (11) have found *l*-2-octyl-β-sitosteryl phthalate in the extractives of Sitka spruce wood. The major portion of the acidic fraction was composed of long-chain fatty acids, with the unsaturated members predominating. Gas liquid chromatography resolved the methylated mixture and major peaks corresponding to palmitic, palmitoleic, oleic, linoleic, and linolenic acids and minor peaks corresponding to C_{14}, stearic, and C_{20} acids were recorded.

The resistance of heartwood to decay is ascribed to the presence of compounds having phenolic properties, e.g. the pinosylvins in pine heartwood (1, 12) and thujaplicins in thuja species (13). The present findings would indicate, therefore, that tamarack owes its resistance to decay to the presence of the flavanonols and ferulic acid esters.

EXPERIMENTAL

Melting points were measured with a Leitz hot stage microscope. Gas liquid chromatograms were obtained with a Beckman GC-2 chromatograph using washed silicone (14) or polyester (15) on C-22 firebrick columns (18 to 24 in. long, $\frac{1}{4}$ in. diameter). Infrared spectra were recorded by the KBr disk method or the film technique on a Perkin–Elmer Model 21 double beam recording spectrophotometer. All known compounds were identified by mixed melting point and infrared spectra comparison with authentic samples.

Extraction of the Wood

Logs of mature tamarack trees were obtained from the Prince Albert district, Saskatchewan, and from the Winnipeg area, Manitoba. The heartwood was cut out and milled in a hammer mill and then reduced to coarse sawdust in a Wiley mill. The air-dried wood (12.7 kg, 15% moisture content) was extracted with acetone in a Soxhlet extractor for 36 hours. The acetone extract was reduced to dryness by evaporation *in vacuo* in a rotary evaporator, at about 50° C, giving a dark brown, viscous material (302 g).

Preliminary Tests

The magnesium – hydrochloric acid test on an alcoholic solution of the extract was positive for flavanonols. Precipitation tests with digitonin or cyclohexylamine on the extract did not indicate the presence of free sterols or resin acids. When the test was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

repeated on a saponified portion, positive results were obtained with digitonin. Paper chromatography, using *n*-butanol – acetic acid – water (4:1:1.8 v/v) (16) and *p*-anisidine spray (17) showed that the mixture contained sugars with R_f values corresponding to galactose and arabinose. With impregnated paper, petrol (b.p. 50–60° C), and diazotized benzidine spray (8) the chromatograms showed no spots corresponding to tropolones. When Gripenberg's method (4) was applied, spots corresponding to aromadendrin and taxifolin (see below) were obtained.

Isolation and Identification of Sugars

The concentrated acetone extract when left to stand yielded crystalline material (14.1 g). The total extract was then taken up in dry acetone (0.5 l.) when more solid material was deposited (6.4 g). The solid material was removed by filtration and crystallized from methanol to yield a crude product, m.p. 142–155° C, $[\alpha]_D^{24.6}$ +79.12 (*c*, 0.77, H_2O). Paper chromatography showed the presence of galactose and arabinose only, and the mixture was resolved by treatment with α-methyl-α-phenyl hydrazine (9). D-Galactose-*N*-methyl-*N*-phenyl hydrazone (1.636 g, corresponding to 80.55% galactose), m.p. 185–186° C, $[\alpha]_D^{22.8}$ −18.98 (*c*, 0.66, pyridine), and arabinose, m.p. 158–160° C, $[\alpha]_D^{23.8}$ +121.59 (*c*, 0.52, H_2O), were isolated.

Isolation and Identification of Flavanonols

The acetone-soluble material, after filtration and reduction to a small volume, was taken up in excess ether (1.25 l.). The ether-insoluble material was separated, dried (39 g), and extracted repeatedly with boiling water, the insoluble residue being discarded. The ether-soluble portion was evaporated to dryness and re-extracted with benzene. The benzene-insoluble portion (36.5 g) was combined with the water-soluble portion (1.5 g) and analyzed by paper chromatography (4). When 1% acetic acid was added to the solvent mixture (chloroform–ethanol–water, 8:2:1 v/v, lower phase) tailing of the flavanonols was prevented. With the bis-diazotized benzidine spray reagent (18) brown spots corresponding to aromadendrin (R_f 0.8) and taxifolin (R_f 0.6) were obtained. An aliquot of the mixture of flavanonols (3.75 g) was resolved on a cellulose powder column (50×4.5 cm), using the same solvent system (4.5 l.) as eluent. Fractions of 20 ml were collected and tested individually by paper chromatography. Tubes 1 to 70 contained aromadendrin (0.314 g), m.p. 236–237° C (from $CHCl_3$), $[\alpha]_D^{24.6}$ +44.72 (*c*, 0.5, water–acetone, 1:1). When the compound was recrystallized from water the m.p. was 128–130° C. This dimorphism has apparently not been noted before. Tubes 71 to 89 contained a mixture (0.077 g) of aromadendrin and taxifolin in about equal amounts. Taxifolin (3.307 g) was obtained from tubes 90 to 195, m.p. 238–240° C (from $CHCl_3$ and ethanol), $[\alpha]_D^{24}$ +47.71 (*c*, 0.75, water–acetone). When the column was washed with 50% aqueous ethanol (1:1) a yellow solid (0.006 g) was obtained on evaporation of the solvent. Crystallization from aqueous ethanol gave quercetin, m.p. 310–312° C, $[\alpha]_D^{24}$ +142.2 (*c*, 0.53, water–acetone).

Isolation and Identification of Eicosanyl Ferulate

The benzene-soluble material (191 g) was repeatedly triturated with cold petrol (b.p. 40–60° C). The petrol-insoluble material (5.5 g) on recrystallization from cyclohexane gave a compound, m.p. 61–62° C. Found: C, 75.76%; H, 10.70%; molecular weight (Rast), 533. Calc. for $C_{30}H_{50}O_4$: C, 75.95%; H, 10.54%; molecular weight, 474.52.

The ester (0.5 g) in chloroform (5 ml) was treated with excess bromine in chloroform. Evaporation of the solvent left a solid tribromide, m.p. 98° C (from petrol, b.p. 40–60° C). Found: C, 51.96%; H, 7.21%. Calc. for $C_{30}H_{49}O_3Br_3$: C, 51.65%; H, 7.03%. The ester

(2.1 g) was hydrolyzed by refluxing in a 20% aqueous potassium hydroxide solution (150 ml) containing ethanol (50 ml) for 15 hours. The ethanol was removed by distillation, and the cold aqueous residue was extracted with ether. The ether extract was washed, dried, and evaporated to dryness (1.3 g). The residue was recrystallized (from acetone) to yield *n*-eicosanol, m.p. 71–72° C. Found: C, 80.70%; H, 14.10%. Calculated for $C_{20}H_{42}O$: C, 80.53%; H, 14.06%. The aqueous soap solution was acidified to pH 2–3 with 10% aqueous sulphuric acid and extracted three times with ether. The ether extract was washed with a saturated aqueous solution of sodium chloride, dried, and the solvent was distilled off. The residual solid (0.85 g) was recrystallized from ethyl acetate – cyclohexane to give pure ferulic acid, m.p. 175–176° C. Found: C, 62.05%; H, 5.19%. Calc. for $C_{10}H_{10}O_4$: C, 61.86%; H, 5.19%.

Petrol Extract

The petrol-soluble portion formed the major part of the heartwood extract (185 g). Fractional vacuum distillation did not resolve the mixture into single components. Because of the low volatility of the mixture, gas liquid chromatography was not successful. However, an infrared spectrum of the mixture indicated the presence of a large amount of long-chain esters. An aliquot (40 g) of the material was saponified under reflux with 20% aqueous potassium hydroxide solution (200 ml) and ethanol (100 ml) for 15–20 hours. The reaction mixture was separated into non-saponifiables (18.7 g) and acids (22.25 g) in the usual manner.

The non-saponifiable material was exhaustively steam distilled, the distillate (2 l.) saturated with sodium chloride and thrice extracted with ether (200 ml each). The ethereal solution was washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate, and then distilled, yielding a sweet-smelling liquid (2.3 g), b.p. 75–77° C at 12 mm. Found for a redistilled sample: C, 74.78%; H, 14.00%; n_D^{27} 1.4310. Calc. for $C_9H_{20}O$: C, 74.46%; H, 14.48%. The derived α-naphthyl urethane was crystallized from carbon tetrachloride, m.p. 55–56° C. This corresponds to the melting point of the α-naphthyl urethane of nonan-2-ol (m.p. 55.5° C) (19).

The non-volatile residue was dissolved in petrol (b.p. 40–60° C) and kept at 0–2° C for several days, when eicosanol (1.3 g), m.p. 71–72° C, crystallized. A portion of the residual material (2.4 g) was chromatographed on neutral alumina (Brockmann). Elution with petrol (b.p. 40–60° C) and ether (1:1 v/v) gave 0.3 g of unsaponified esters. With ether-ethanol (1:1 v/v) a solid (1.8 g) was eluted which had m.p. 141° C after crystallization from ethanol. It gave a positive Lievermann–Burchard reaction, and formed an acetate, m.p. 123–124° C, and a benzoate, m.p. 143–144° C, which correspond with those of β-sitosterol (20). Found: C, 83.78%; H, 12.30%. Calc. for $C_{29}H_{50}O$: C, 83.99%; H, 12.15%.

The acid mixture contained petrol-insoluble material (1.25 g) which crystallized from acetone to give phthalic acid, m.p. 201–203° C; anilide, m.p. 165–166° C. The petrol-soluble acids were converted to their methyl esters with diazomethane and analyzed by gas liquid chromatography. When the polyester column was used, peaks corresponding to two C_{14} acids (0.5% and 0.6% respectively), palmitic (7.0%), palmitoleic (7.1%), stearic (1.9%), oleic (20.0%), linoleic (31.8%), linolenic (25.2%), and two C_{20} acids (1.5% and 3.0% respectively) were obtained.

ACKNOWLEDGMENTS

We wish to express our thanks to the Forestry Branch of the Department of Natural Resources for obtaining the wood, to Mr. M. Granat for technical assistance, to Miss

NOTES

4-NITROPYRENE*

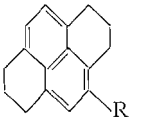
P. M. G. Bavin†

Nitration of pyrene has afforded only the 1-isomer (1, 8). Since the introduction of the nitro group into polycyclic hydrocarbons through the diazonium compounds does not proceed in high yield (3), other indirect routes to the unknown nitropyrenes seemed to offer advantages.

One such alternative, the dehydrogenation of the nitrohexahydropyrene (I*a*) with chloranil, has been used to prepare 4-nitropyrene (II*a*) for the first time.

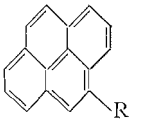
The nitrohexahydropyrene (I*a*) and the corresponding amine (I*b*) and its N-acetyl derivative (I*c*) have been described previously (7). These have been prepared again and the fluoro compound (I*d*) has been described for the first time. Other substitution products of *sym*-hexahydropyrene have been described (5, 6, 8).

It is curious that Neresheimer's work (7) was not included in Vollmann's paper (8) although carried out in the same laboratory and at the same period.



I

I*a*, R = NO_2 I*c*, R = $NH.CO.CH_3$
I*b*, R = NH_2 I*d*, R = F



II

II*a* R = NO_2
II*b* R = NH_2

EXPERIMENTAL

Melting points are uncorrected.

4-Nitro-1,2,3,6,7,8-hexahydropyrene (I*a*)

In a typical experiment, *sym*-hexahydropyrene (3 g) was nitrated with nitric acid (0.8 ml, d. 1.42) in acetic anhydride (250 ml). The solution rapidly turned red. After 48 hours at room temperature, acetic anhydride was destroyed with water and the products isolated with chloroform. Purification of the crude nitro compound by chromatography from pentane–benzene (5:1) on acid-washed alumina followed by crystallization from methanol–acetone afforded pure (I*a*) (1.9–2.4 g) as bright yellow needles, m.p. 92–93° (lit. m.p. 92–95° (7)). Calculated for $C_{16}H_{15}NO_2$: C, 75.87; H, 5.97%. Found: C, 75.97; H, 5.74%.

The impure nitro compound rapidly turned brown when exposed to light.

4-Amino-1,2,3,6,7,8-hexahydropyrene (I*b*)

4-Amino-1,2,3,6,7,8-hexahydropyrene was prepared by reducing the nitro compound (I*a*) with hydrazine and palladized charcoal (2). It crystallized from heptane as almost

*Ring index numbering.
†I.C.I. Fellow.

colorless slender needles, m.p. 132–133° (lit. m.p. 134–135° (7)). Calculated for $C_{16}N_{17}N$: C, 86.05; H, 7.67; N, 6.27%. Found: C, 86.15; H, 7.76; N, 6.28%.

N-*Acetyl-4-amino-1,2,3,6,7,8-hexahydropyrene* (I*c*)

N-Acetyl-4-amino-1,2,3,6,7,8-hexahydropyrene crystallized from toluene as colorless slender needles, m.p. 290–292° (lit. m.p. 280–282° (7)). Calculated for $C_{18}H_{19}NO$: C, 81.47; H, 7.22; N, 5.28%. Found: C, 81.28; H, 7.28; N, 5.26%.

4-Fluoro-1,2,3,6,7,8-hexahydropyrene (I*d*)

4-Fluoro-1,2,3,6,7,8-hexahydropyrene, prepared in the usual way (4), crystallized from methanol as slender white needles, m.p. 111–112°. Calculated for $C_{16}H_{15}F$: C, 84.93; H, 6.68%. Found: C, 84.73; H, 6.91%.

4-Nitropyrene (II*a*)

The pure hexahydro compound (I*a*), (1 g), was boiled under reflux for 24 hours with a solution of chloranil (5 g) in xylene (30 ml). After it was cooled the mixture was diluted with hexane (30 ml), decanted from the dark hydroquinone, and passed through a column of alumina. Elution was continued with hexane–benzene (5:1). The eluted material was further purified by rechromatographing from hexane, only the orange-brown band eluting as a yellow solution being retained. (These colors correspond exactly to those shown by 1-nitropyrene (1).)

Crystallization from methanol containing a little acetone afforded slender orange needles, m.p. 196–197.5°. Calculated for $C_{16}H_9NO_2$: C, 77.72; H, 3.67%. Found: C, 77.40; H, 3.51%.

4-Aminopyrene (II*b*)

4-Aminopyrene was prepared from (II*a*) by reduction with hydrazine and palladized charcoal (2). It crystallized from heptane as bright yellow platelets, m.p. 191–193° with decomposition (lit. m.p. 182° (7)).

KINETICS OF THE THERMAL REACTION OF HYDROGEN PEROXIDE WITH HYDROGEN*

W. FORST

The thermal reaction of hydrogen peroxide with hydrogen has been studied by McLane (1), who worked around 500° C in a flow system without reaching any definite conclusions. In the present brief study it was found that under suitable conditions the reaction of hydrogen peroxide with hydrogen proceeded with a pressure increase in a closed system. This means that in addition to the over-all process

$$H_2 + H_2O_2 \rightarrow 2H_2O,$$

the reaction

$$H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2$$

must also be occurring because it is the only conceivable process capable of increasing the number of molecules. Presence of oxygen in the system was confirmed by following the reaction to completion. The pressure in the system rose to a maximum, and then slowly declined (Fig. 1), indicating a slow hydrogen–oxygen reaction. Sometimes there occurred an explosion shortly before the pressure maximum was reached (i.e. shortly before all the

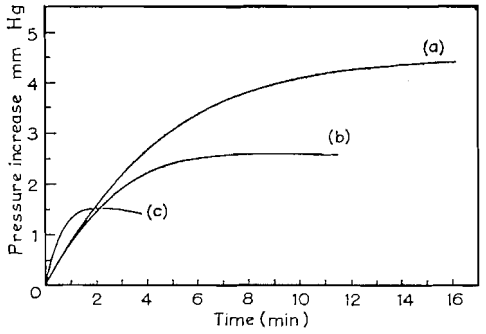

FIG. 1. Rate curves in the presence and absence of hydrogen. (*a*) Peroxide only. (*b*) Peroxide + 19.2 mm H_2 initially. (*c*) Peroxide + 96.2 mm H_2 initially. Initial pressure of peroxide 9.6 mm Hg in all three cases.

hydrogen peroxide had disappeared). This behavior finds a ready explanation in the inhibiting action of hydrogen peroxide in hydrogen–oxygen explosions at the second limit (2). Comparison of rate curves in the presence and absence of hydrogen (Fig. 1) shows that qualitatively the effect of hydrogen is twofold: (1) the rate is faster; (2) the pressure increase is smaller.

Apparatus and technique were described previously (3). All experiments were done at 431.5° C, where the slow hydrogen–oxygen reaction is not important. However, to avoid all complications arising from this reaction, only initial rates were measured and considered significant; these results are summarized in Figs. 2 and 3. Each point is the average of two successive runs on the same H_2–H_2O_2 mixture.

The interpretation of the results is complicated by two factors: (1) the time-dependence of the pressure rise in the H_2O_2–H_2 reaction system represents the rate of formation of oxygen, which, unlike in the case of the pressure rise in the H_2O_2 system, bears no simple

relationship to the rate of disappearance of peroxide; (2) under the experimental conditions (H_2O_2 pressure below 20 mm Hg, hydrogen pressure below 100 mm Hg) the decomposition of hydrogen peroxide is unimolecular and second order (3, 4). If the proposed (3) scheme for this decomposition is accepted, then the initial rate of oxygen formation R_0, in the presence of one inert foreign gas X, is given by (cf. eq. VII′, ref. 3)

$$[1] \qquad R_0 = (d[O_2]/dt)_{t\to 0} = a_1[H_2O_2]_0^2 + a_4[H_2O_2]_0[X]_0,$$

where the subscript zero refers to initial conditions, and

a_1 = second order rate constant for activation with peroxide,
a_4 = second order rate constant for activation with inert gas X.

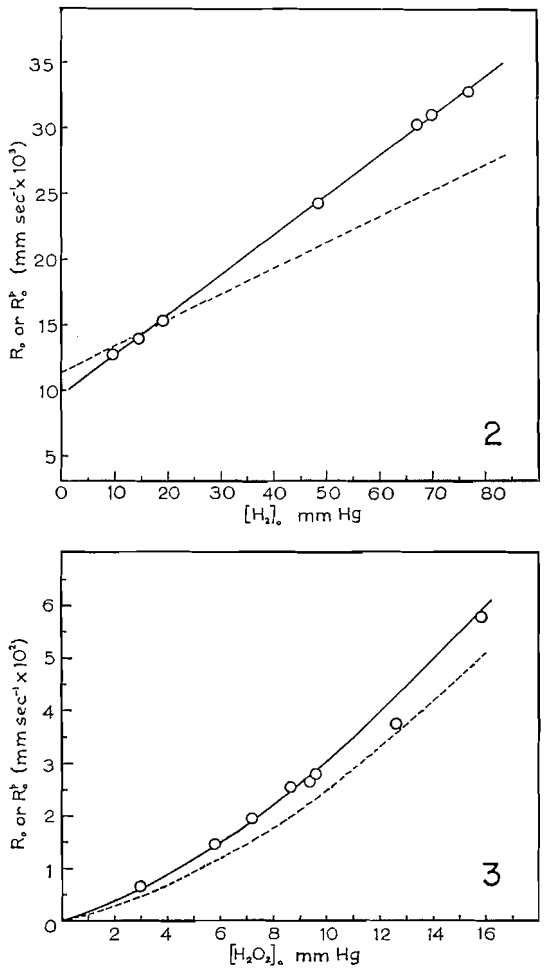

FIG. 2. Solid line: Experimental initial rate R_0 plotted vs. initial hydrogen pressure. Broken line: R_0^p (theoretical physical component of initial rate) plotted vs. initial hydrogen pressure. Initial hydrogen peroxide concentration constant at 9.6 mm Hg in both cases.

FIG. 3. Solid line: Experimental initial rate R_0 plotted vs. initial peroxide pressure. Broken line: R_0^p (theoretical physical component of initial rate) plotted vs. initial peroxide pressure. Initial hydrogen pressure constant at 57.9 mm Hg in both cases.

Equation [1] makes it at once apparent that the initial rate of oxygen formation R_0 will depend on initial hydrogen concentration even if hydrogen did not chemically react, that is, the mere presence of hydrogen as a collision medium will increase R_0. This may be referred to as the physical effect of hydrogen, the magnitude of which depends on $a_4^{H_2}$, the second order rate constant for activation with hydrogen. The experimentally determined initial rate R_0 must contain the contribution of both the physical and chemical effects of hydrogen, because it is difficult to account for the results in Fig. 1 by physical activation alone. By working out the necessary algebra it is easy to show that R_0 will be equal to the sum of the two contributions:

$$\begin{aligned} R_0 &= R_0^{p}+R_0^{c} \\ &= a_1[H_2O_2]_0^2+a_4^{H_2}[H_2O_2]_0[H_2]_0+R_0^{c}, \end{aligned}$$

where R_0^{p} is a term representing the physical effect and R_0^{c} a term representing the chemical effect of hydrogen on initial rate. This equation shows that for constant $[H_2O_2]_0$, R_0^{p} is linear in initial hydrogen concentration. From Fig. 2 it is apparent that for $[H_2O_2]_0$ = constant the experimentally determined R_0 is also linear in $[H_2]_0$, and therefore R_0^{c} must be likewise linear in initial hydrogen concentration at constant $[H_2O_2]_0$; hence the reaction is seen to be first order with respect to hydrogen.

The broken line in Fig. 2 represents a plot of R_0^{p} vs. $[H_2]_0$ for $[H_2O_2]_0$ = constant = 9.6 mm Hg taking $a_4^{H_2} = 2.1\times10^{-5}$ mm sec^{-1}, a value obtained by assuming that the collision/collision efficiency of hydrogen relative to H_2O_2 reactant is the same as that of He relative to the same reactant. This is a first approximation based on results of Volpe and Johnston (5), who found experimentally that these efficiencies were equal in the case of nitryl chloride reactant. The value of a_1 was taken from ref. 3. The discrepancy in the intercepts of the two lines is partly due to error in peroxide concentration (which enters the intercept squared), and partly to a slight shift in surface condition.

Figure 3 represents experimental results obtained at fixed initial hydrogen concentration. The broken line is a theoretical plot of R_0^{p} vs. $[H_2O_2]_0$ assuming $a_4^{H_2} = 2.1\times10^{-5}$ mm sec^{-1}, as before. If R_0^{c} is now written

$$R_0^{c} = k[H_2O_2]_0^{x}[H_2]_0,$$

where k = rate constant for the reaction of peroxide with hydrogen, and x = the unknown power of the peroxide concentration in the rate expression, then the plot of $R_0-R_0^{p}$ vs. $[H_2O_2]_0$ will be a curve if $x > 1$, and a straight line if $x = 1$. This is plotted in Fig. 4, again for $a_4^{H_2} = 2.1\times10^{-5}$ mm sec^{-1}, and is seen to result in a straight line. The linearity of

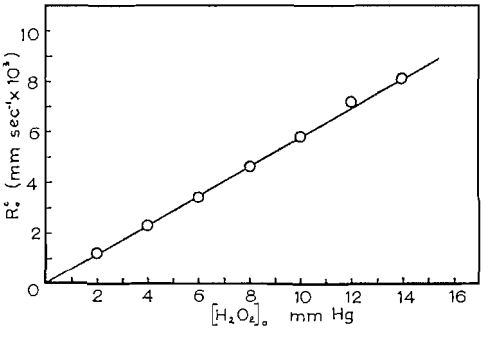

FIG. 4. The difference $R_0 - R_0^{p}$ (from Fig. 3) plotted vs. initial peroxide concentration, with initial hydrogen pressure constant at 57.9 mm Hg.

this plot does not depend on the assumed value for $a_4^{H_2}$, although the slope does. The reaction is thus seen to be first order in peroxide as well, and so the reaction may be described by the equation

$$R_0 = a_1[H_2O_2]_0^2 + (a_4^{H_2} + k)\,[H_2O_2]_0[H_2]_0. \qquad [2]$$

On the basis of this result some speculation may be made concerning the probable mechanism. If reactions involving oxygen are neglected on the ground that they would not affect the initial rate, hydrogen is likely to enter only into reactions

$$OH + H_2 \rightarrow H_2O + H \qquad [a]$$

$$H + H_2O_2 \rightarrow H_2O + OH, \qquad [b]$$

for which there seems to be good evidence from other sources ([*a*], ref. 6; [*b*], refs. 2, 7, 8). It turns out, however, that these two reactions, when combined with reactions postulated (3) in the decompostion of hydrogen peroxide, will not result in an increase of oxygen formation as required by eq. [2]. A closer look at the mechanism shows that there are two types of reactions that will increase the rate of formation of oxygen (but will not necessarily lead to the desired order in peroxide or hydrogen).

(1) Reactions in which one radical disappears and another radical appears, with the simultaneous formation of oxygen, for example,

$$HO_2 + H_2O_2 \rightarrow OH + O_2 + H_2O$$

or

$$HO_2 \rightarrow H + O_2.$$

These reactions do not involve the intervention of hydrogen and therefore presumably should occur also in the decomposition of pure peroxide. However, they lead there to unsatisfactory results (9, 10).

(2) Chain-branching reactions not involving oxygen. This restricts the choice of likely reactions considerably; in fact, the only reaction seems to be

$$H_2 + HO_2 \rightarrow 2OH + H \qquad [c]$$

suggested by Kassel and Storch (11) and used by them to derive a mechanism for the second explosion limit in the hydrogen–oxygen reaction. If reactions [*a*], [*b*], and [*c*] are added to the reactions postulated in the decomposition of pure peroxide (3), a rate expression for the rate of formation of oxygen may be derived which has the form [2]. However, reaction [*c*] has a very high endothermicity, some 67 kcal if $D(H–O_2)$ is taken as 47 kcal (12), so that a more direct evidence for reaction [*c*] would be required before this mechanism can be accepted.

TRANSIENTS IN THE FORMATION OF ANODIC OXIDE FILMS

L. YOUNG

With certain metals, in particular, tantalum (1) and niobium (2) when the ionic (film-building) current density through the anodic oxide film is suddenly increased, the field strength in the oxide "overshoots" before settling to the new steady state value corresponding to the new current density. Dewald (1) has shown that the behavior is inconsistent with the model (which he advanced to explain the Tafel slope anomalies) in which the space charge due to the mobile metal ions is uncompensated by other sources of space charge. A more realistic model would have a concentration (say, ϕ cm^{-3}) of mobile metal in the electrically neutral oxide. The net space charge may then be either negative or positive. The steady state equations for this model, with ϕ independent of field strength, have been published (3).

The purpose of the present communication is to show that Dewald's result for his case (which corresponds to $\phi = 0$) may be generalized to $\phi \neq 0$.

We have

$$\partial E/\partial t = (pI_0 - i)/KK_0 \quad \text{(differentiated Gauss' equation)}$$
$$\partial E/\partial x = q(n-\phi)/KK_0 \quad \text{(Poisson's equation)}$$
$$i = q\mu_0 \exp \beta E \quad \text{(conventional equation for the ionic current at high fields)}$$

where E = field strength in the oxide at distance x from the metal, t = time after current is changed, I_0 = current density for $t < 0$, pI_0 = current for $t > 0$, i = current in oxide at distance x from the metal, n = concentration of mobile metal ions,

$$\mu_0 = \nu \exp(-W/kT)$$

where ν = vibration frequency and

$$W = \text{activation energy at zero } E, \text{ and } \beta = qa/kT$$

where a = half ionic jump distance within the oxide. By eliminating n and i, and putting (following Dewald)

$$R = \mu_0 KK_0 \exp(\beta E)/\beta pI_0 t$$
$$T = \beta pI_0 t/KK_0$$
$$z = x/D$$

where D = total oxide thickness; with, in addition,

$$\alpha = \phi\beta Dq/KK_0$$

and

$$\epsilon = (n_0 - \phi)/\phi$$

The purpose of the present communication is to show that Dewald's result for his case (which corresponds to $\phi = 0$) may be generalized to $\phi \neq 0$.

We have

$$\partial E/\partial t = (pI_0 - i)/KK_0 \quad \text{(differentiated Gauss' equation)}$$
$$\partial E/\partial x = q(n-\phi)/KK_0 \quad \text{(Poisson's equation)}$$
$$i = q\mu_0 \exp \beta E \quad \text{(conventional equation for the ionic current at high fields)}$$

where E = field strength in the oxide at distance x from the metal, t = time after current is changed, I_0 = current density for $t < 0$, pI_0 = current for $t > 0$, i = current in oxide at distance x from the metal, n = concentration of mobile metal ions,

$$\mu_0 = \nu \exp(-W/kT)$$

where ν = vibration frequency and

$$W = \text{activation energy at zero } E, \text{ and } \beta = qa/kT$$

where a = half ionic jump distance within the oxide. By eliminating n and i, and putting (following Dewald)

$$R = \mu_0 KK_0 \exp(\beta E)/\beta pI_0 t$$
$$T = \beta pI_0 t/KK_0$$
$$z = x/D$$

where D = total oxide thickness; with, in addition,

$$\alpha = \phi\beta Dq/KK_0$$

and

$$\epsilon = (n_0 - \phi)/\phi$$

where n_0 is the concentration of metal ions just inside the oxide for $t < 0$, we obtain

$$\partial R/\partial z + (1/R)\partial R/\partial T + \alpha R = 1.$$

The general solution is

$$f\{z + (1/\alpha)\log(1-\alpha R),\ T - \log(R/(1-\alpha R))\} = 0.$$

The boundary conditions are

$$R(z, 0) = R(0,0)\{1+\epsilon(1-\exp(-\alpha z))\}$$
$$R(0,T) = R(0,0)p^r/(1+(p-1)e^{-T/r})^r$$

where r = ratio of ionic jump distance at the interface to that within the oxide.

Solutions satisfying these conditions are

$$R = \{(1-\alpha R(0,0)p)e^{-\alpha z}-1\}/\{\alpha(1-p)e^{-T}-\alpha\}$$
$$(p-1)(e^{\alpha z}e^{-T}R)^{1/r} = p(R(0,0))^{1/r} - ((1-e^{\alpha z})/\alpha + R e^{\alpha z})^{1/r}.$$

These solutions join at

$$z = z_s$$

where

$$(e^{\alpha z_s}-1)/\alpha = R(0,0)(e^T-1).$$

For a given z, $\partial R/\partial T$ is always positive for $p > 1$ and always negative for $p < 1$, so that there is no overshoot.

SELF-DIFFUSION IN POLYCRYSTALLINE NICKEL[1]

J. R. MACEWAN,[2] J. U. MACEWAN, AND L. YAFFE

ABSTRACT

The self-diffusion of nickel has been studied in polycrystalline samples by a sectioning technique. There is evidence of grain boundary diffusion below temperatures of 1150° C. The results obtained between 1150° and 1400° C are representative of volume diffusion and are represented by the expression

$$D = 3.36\, e^{-69,800/RT}.$$

A comparison is made with the results of other self-diffusion studies using Zener's hypothesis.

INTRODUCTION

The most precise measurements made on the rate of volume self-diffusion in metals have been carried out with single crystal specimens. Measurements made with polycrystalline specimens have been in good agreement with those made with single crystal specimens only when the diffusion study was confined to temperatures close to the melting point of the metal. None of the reported investigations (1, 2, 3) made of the self-diffusion of nickel in polycrystalline samples have satisfied this criterion. Therefore, it was thought worth while to report some work on the rate of nickel self-diffusion in the temperature range 1050° to 1400° C.

EXPERIMENTAL

Diffusion coefficients were obtained by the standard sectioning method (4) and by a modification of Gruzin's integral residue method (5). In some cases both techniques were employed to analyze the same specimen, which permitted a direct comparison of the results obtained with each.

The nickel tracer employed contained two long-lived isotopes, Ni^{63} decaying with the emission of a 67-kev β-particle and Ni^{59} decaying by K-electron capture with the emission of a Co K_α X-ray (6). A Co^{58}, gamma-emitting impurity present in the tracer solution was completely removed by an ion exchange procedure (7). In the 2π internal source proportional counter employed, the ratio of detected disintegrations of Ni^{63} to Ni^{59} was in excess of 5×10^3 for almost all sources counted. Thus, with one exception which will be discussed later, it was assumed that the tracer consisted of a single active species, Ni^{63}.

The diffusion specimens consisted of polycrystalline nickel cylinders about 0.60 in. in diameter with the active tracer electroplated on one face. The total analyzed impurity

[1]*Manuscript received May 22, 1959.*

[2]*Present address: Fuel Development Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.*

content in the cylinders was less than 0.08%, with the principal impurities being Fe, 0.04; Co, 0.015; and Cu, 0.01%. Each cylinder was annealed at 1400° C for 24 hours to produce a coarse stable grain size prior to the electrodeposition of the tracer from an ammonia – ammonium sulphate solution. Grain diameters in individual specimens varied from 3 to 10 mm. Thickness of the tracer layer was about one micron. Uniformity of the active plating was checked by measuring the counting rate at nine positions on the active surface through an aluminum diaphragm with a 3/32-in. hole. These counting rates were converted to thicknesses with a self-absorption curve for Ni^{63} (8), and specimens with thickness variations greater than $\pm 3\%$ were rejected.

For the diffusion anneal, duplicate specimens were positioned in recrystallized alumina crucibles with the active faces touching to minimize loss of the tracer by evaporation. This assembly was placed in a preheated tube furnace with a constant temperature zone 5 in. in length where the samples were surrounded by a pure hydrogen atmosphere to prevent oxidation. By charging and discharging the samples to and from a hot furnace, errors in the length of the diffusion anneal were less than 0.2%, even for the shortest times. Temperatures were controlled to within $\pm 0.5°$ C by backing off most of the potential from the Pt/(Pt – 13% Rh) control thermocouple with a standard potential source and feeding the amplified difference to a Speedomax proportional temperature controller. The temperature of the specimens was measured during each run with a certified Pt/(Pt–Rh) thermocouple, corrections being made for thermocouple sheath losses. The diffusion anneal temperatures should be accurate to $\pm 2.0°$ C.

After the diffusion anneal, one of the duplicate specimens was sectioned in the standard manner. The specimen was mounted in a lathe-collet so that the face ran true to ± 0.002 mm, and at least 1.2 mm was removed from the diameter to eliminate edge effects. Then successive facing cuts from 0.025 to 0.040 mm, in thickness were made to provide samples for activity measurements. The turnings were weighed to determine the slice thickness for comparison with direct micrometer measurements made on the specimen. As the nickel cuttings did not represent a suitable source for counting of the low energy Ni^{63} β-particles, the cuttings were dissolved in concentrated hydrochloric acid and the nickel electroplated on to copper planchets to form a 0.70-in. diameter deposit. The method employed has been described elsewhere (8). In all cases, sufficient nickel was deposited to form an infinitely thick source (4.5 mg/cm^2 or greater), so that the observed counting rate was directly proportional to the specific activity of the source. The reproducibility in preparing sources in this manner was better than $\pm 1\%$. Whenever possible, sufficient counts were recorded to give counting statistics of $\pm 1\%$.

The second specimen was treated in an identical fashion except for the following change in procedure. Before taking each facing cut, the activity of the active face was measured by mounting the specimen in the 2π internal source counter using a special baseplate. A diaphragm with a central hole smaller than the specimen diameter prevented β-particles emitted from the specimen sides being detected. The activity measured in this manner represents the specific activity of the Ni^{63} in a layer less than one micron below the surface. Previous work (8) on the self-absorption of Ni^{63} showed that over half the detected activity in an infinitely thick sample of uniform specific activity is emitted from a depth within 0.5 μ of the sample surface. Thus in a diffusion couple where the activity is decreasing in a Gaussian manner with increasing depth below the surface, the counting rate measured on the surface can be assumed to be proportional to the specific activity of the metal forming the surface layer.

RESULTS AND DISCUSSION

For volume diffusion, the concentration $C(x, t)$ of the tracer isotope in a layer at distance X below the surface after an annealing time t is given by the equation,

$$C(x, t) = C_0/\sqrt{\pi Dt}\, e^{-X^2/4Dt},$$

where C_0 is the total quantity of tracer deposited on the specimen face and D is the diffusion coefficient. The diffusion coefficient is calculated from the slope of the straight line plot of log $\bar{C}$ versus $\bar{X}^2$. Typical plots obtained at temperatures of 1197° and 1152° C are shown in Fig. 1. The plot at 1197° C is typical of those obtained at all temperatures equal to or above 1200° C. It can be seen that log $\bar{C}$ varies as $\bar{X}^2$ for all values of $\bar{X}$ indicating that the diffusion occurring at these temperatures is typical of volume diffusion. However, in the concentration penetration curve obtained at 1152° C, log $\bar{C}$ varies as $\bar{X}^2$ for shallow penetrations, while at deeper penetrations log $\bar{C}$ varies as $\bar{X}$. This mixed type of penetration curve is obtained when neither grain boundary nor volume diffusion predominate in a diffusion couple. Wajda (9) has shown that with this type of specimen the volume diffusion coefficients obtained from the initial linear portion of the log $\bar{C}$ versus $\bar{X}^2$ are generally higher than those obtained from single crystal specimens at the same temperature.

Excellent agreement, within 1%, was obtained between duplicate diffusion couples treated by the standard sectioning method. However, when the same specimen was treated by both surface-activity-sectioning and sectioning techniques, the D values for the former method were always slightly lower. For the five samples treated by both methods, this difference varied from 1.5 to 9.0%, with an average deviation of 5.6%. This is reflected in Fig. 1 where the penetration curve determined by the surface-sectioning method has a steeper slope than that obtained in the conventional manner for the same specimen. About one per cent of this diffusion is a result of neglecting the enhanced counting rate at the surface for low values of $\bar{X}$ due to detection of the more penetrating Ni^{59} radiation from much deeper portions of the diffusion specimen. This effect would tend to make the diffusion coefficients obtained with the surface-activity-sectioning method too low. The diffusion coefficients obtained by the normal method are about 1.0% too high as a result of using slices of finite thickness. No convincing explanation can be offered for the residual discrepancy of 3.6%.

The activation energy, Q, and frequency factor, D_0, for volume diffusion are related by the Arrhenius equation:

$$D = D_0\, e^{-Q/RT}.$$

To obtain values for Q and D_0, the measured values of D were plotted against $1/T$ as in Fig. 2. The open circles represent the average values found by the normal sectioning method for the duplicate specimens annealed at one time, while the solid points represent the surface-activity-sectioning value for one of these specimens. A correction was made to the diffusion constants for lattice expansion, but no allowance was made for an isotopic mass effect. Johnson's (10) original work, which suggested that Graham's law applied to metallic diffusion as well as to gaseous diffusion, has not been substantiated by more recent work (11).

It can be seen that the values found for the temperature range 1150° to 1400° C lie on a straight line. The coefficients measured below 1150° C lie above the extrapolated line of best fit for the high temperature results indicating that sufficient grain boundary

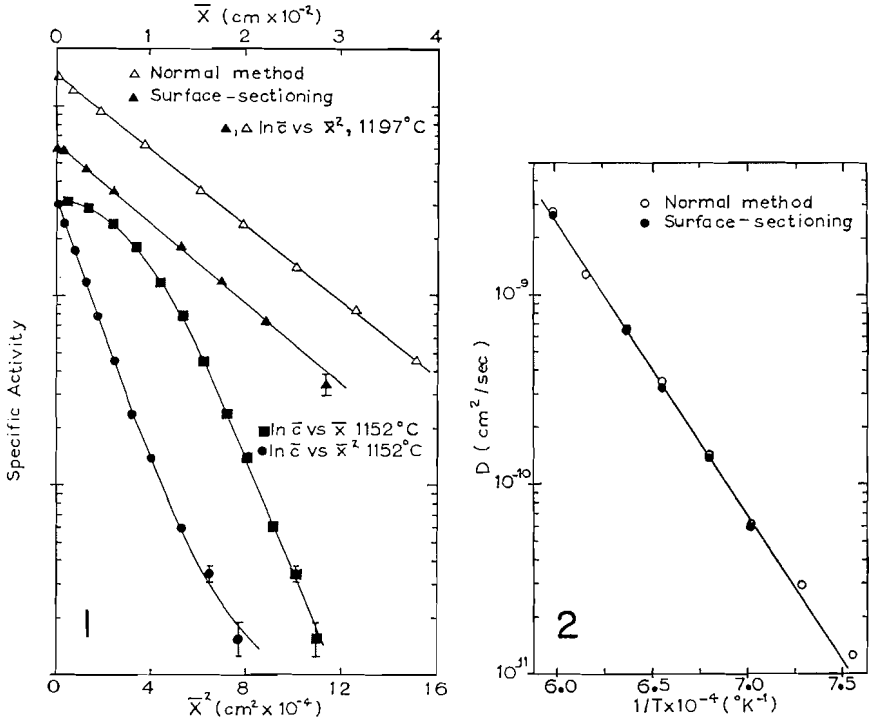

FIG. 1. Concentration penetration curves obtained at 1152° C and at 1197° C. The curves at 1152° C assume the form generally associated with grain boundary diffusion.
FIG. 2. Activation energy plot.

diffusion has occurred in those specimens to invalidate the results. To obtain a comparison between the results obtained by both methods employed, both sets of data were fitted individually by least mean squares. For the standard sectioning method

$$D = 3.66\, e^{-(70{,}000\pm1700)/RT}$$

and for the surface-activity-sectioning method

$$D = 3.04\, e^{-(69{,}000\pm600)/RT}.$$

The results obtained by the two methods of analysis are in good agreement although the surface-activity-sectioning data have a slightly smaller standard deviation. Thus this work gives an average value of 3.36 cm²/sec for the frequency factor, D_0, and 69.8 kcal/mole for the activation energy, Q.

For comparison, the values found in other investigations are tabulated below:

TABLE I
Self-diffusion data for nickel

Burgess and Smoluchowski's work, apparently incomplete, can be regarded only as a preliminary study. Their results were obtained by a surface activity technique, not specified in detail, below a temperature of 1250° C. No value was reported for the frequency factor.

The activation energy obtained by Reynolds *et al.* in a study of nickel self-diffusion throughout the Au–Ni system cannot be given too much weight because of the narrow temperature range investigated. However, their measured diffusion coefficients differ by only 4% from those obtained in this work.

Hoffman, Pikus, and Ward's reported diffusion coefficients in the temperature range 1150–1250° C are also in good agreement with the results obtained in this work. The differences in activation energy are reflected in a small but consistent difference in D values at temperatures outside the range where the two investigations overlap. Hoffman *et al.* employed a decrease in surface activity technique for their measurements below 1150° C. However, inspection of their data shows that all their diffusion coefficients obtained above a temperature of 1147° C, both by surface activity and sectioning techniques are consistent with an activation energy higher than that reported. Therefore, if their low temperature measurements yielded results which were high, their reported activation energy would be low.

There are two factors which could cause high values for the D values obtained by the decrease in surface activity method employed in the investigation by Hoffman *et al.*: grain boundary diffusion or an incorrect choice of k, the absorption coefficient of the β-radiation from Ni^{63}. Direct measurements of k by the present authors (8) and by Schweitzer *et al.* (12) for self-absorption of Ni^{63} in a 2π geometry have shown that at least two absorption coefficients are needed to explain the observed results assuming exponential absorption of radiation. One of these coefficients is much larger than, and the other comparable to, that obtained in an external absorption measurement. The narrow angle counter geometry employed by Hoffman will tend to minimize this effect but certainly not eliminate it. The combined effect of these two absorption coefficients is to make self-absorption more rapid in the source than anticipated and will lead to high values for D in samples where little diffusion has taken place, i.e. at low temperatures.

Zener (13) in a theoretical analysis of the activation process for diffusion in face-centered cubic metals proposed the following correlation between the entropy of activation for diffusion, ΔS, the temperature coefficient of Young's modulus, μ^1/μ_0, and the activation energy

$$(\Delta S/R) = \ln (D_0/a^2\nu) = \lambda(\mu^1/\mu_0)(Q/R)$$

where a is the lattice parameter, R the gas constant, and ν the Debye frequency. The particular choice of the constant, $\lambda = 0.55$, was such as to make the correlation exact for the accurately determined values of D_0 and Q for the self-diffusion of silver (14).

A plot of $\Delta S/R$ versus $(\mu^1/\mu_0)(Q/R)$ is given in Fig. 3 for the commonly accepted self-diffusion data for Ag, Au, Cu, Ni, Pb, and Pt. The straight line shown has a slope of 0.55, corresponding to Zener's suggested value for the constant λ. The dotted lines connecting various points for the same metal are not intended to have any particular significance, but rather to simplify inspection of the graph.

Inspection of the graph shows that there is a rough correlation between values of $\Delta S/R$ and $(\mu^1/\mu_0)(Q/R)$. A point of some interest is that the value from Makin, Rowe, and LeClaire's (15) recent careful study of gold self-diffusion falls just above the curve.

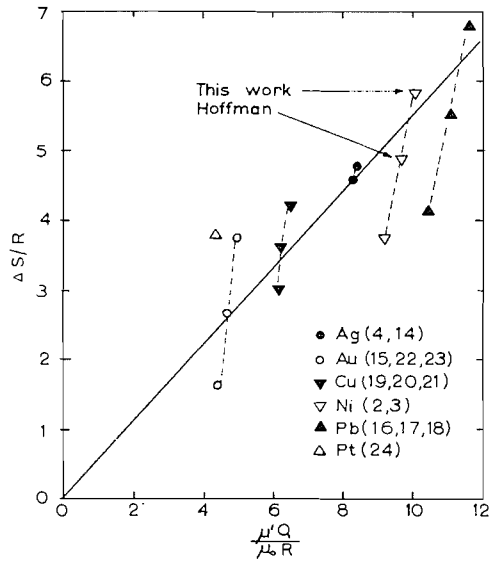

FIG. 3. Correlation between $\Delta S/R$ and $(\mu^1/\mu_0)(Q/R)$ for self-diffusion in various face-centered cubic lattice metals.

Thus, if we accept Zener's correlation with $\lambda = 0.55$ as exact, it is apparent that the activation energy for self-diffusion in nickel falls somewhere between that found in this work and that found by Hoffman *et al.* While there is no real justification for this observation, it is interesting to note that with $\lambda = 0.57$, the correlation line would pass through or close to points representing self-diffusion studies in Au, Ag, Cu, Pb, and the value found for nickel in this research.

ACKNOWLEDGMENT

The authors wish to express their gratitude to the Defence Research Board for grants received.

DIFFUSION OF Ni^{63} IN IRON, COBALT, NICKEL, AND TWO IRON–NICKEL ALLOYS[1]

J. R. MacEwan,[2] J. U. MacEwan, and L. Yaffe

ABSTRACT

The self-diffusion of nickel and the diffusion of Ni^{63} into iron, cobalt, and two iron–nickel alloys was studied using the technique of decrease in surface activity, The nickel self-diffusion results are compared to previously reported values. Nickel is found to diffuse more slowly than iron in the iron-rich portion of the iron–nickel system. The rate of nickel diffusion increases with increasing nickel content. A comparison is made between the present results for diffusion of Ni^{63} into iron, cobalt, and nickel with reported values for diffusion of Co^{60} and Fe^{59} in the same metals. In each solvent, the magnitudes of the activation energies, Q, are such that $Q_{Ni} > Q_{Co} > Q_{Fe}$.

INTRODUCTION

The transition elements iron, cobalt, and nickel are interesting both theoretically and experimentally because they exhibit marked similarities in properties. All assume a face-centered cubic lattice structure at high temperatures and possess nearly similar atomic radii. Therefore, it was thought worth while to investigate the rate of diffusion of Ni^{63} in pure iron, cobalt, and nickel. The studies were in a temperature range where only face-centered cubic lattice phases exist, and all diffusion data refer to the three metals in this condition. These results should permit some conclusions to be drawn concerning diffusion in these metals as other investigators have already reported data for diffusion of cobalt and iron tracers in iron, cobalt, and nickel.

The rate of self-diffusion of nickel in the iron-rich portion of the iron–nickel system was investigated to complement work reported by other investigators on the rate of self-diffusion of iron in the same region. The results should permit a comparison to be made between rates of diffusion of iron and nickel atoms in this technologically interesting portion of the iron–nickel system.

EXPERIMENTAL

The self-absorption characteristics of Ni^{63} β-radiation are such that, in a thick sheet containing the tracer isotope, over half the activity detected over a face comes from radiation emitted within 0.5 μ of that surface (1). Since the specific activity of the tracer decreases in a Gaussian manner below the diffusion interface, it has been shown (2) that in a specimen where diffusion has taken place the counting rate determined over the surface is directly proportional to the specific activity of the tracer on the surface. This characteristic of Ni^{63} β-radiation suggested the use of the following technique for measuring diffusion coefficients.

The solution to Fick's law corresponding to the diffusion of an infinitely thin layer of tracer into a semi-infinite medium, the diffusion coefficient D assumed constant, is

$$C(x, t) = (C_0/\sqrt{\pi D t})\, e^{-x^2/4Dt} \qquad [1]$$

where C_0 is the quantity of tracer deposited on the surface, $C(x, t)$ is the concentration in a layer at distance x below the surface, and t is the diffusion time. For the limiting

[2]*Present address: Fuel Development Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.*

case where $x = 0$ the above equation becomes

$$C(0,t) = C_0/\sqrt{\pi Dt}. \quad [2]$$

If C_0 is evaluated, the diffusion coefficient can then be determined by measuring the change of surface activity with time. This method overcomes the necessity of knowing accurately the self-absorption coefficients for Ni^{63} β-radiation.

The purified tracer isotope employed contained two long-lived isotopes, Ni^{63} decaying by the emission of a 67-kev β-particle and Ni^{59} decaying by K-electron capture with the emission of a Co K_α X-ray (3). Even in a specimen diffused for a long time, the contribution of the more penetrating Ni^{59} radiation to the counting rate measured at the active surface was less than 0.5%. Therefore, it was assumed that the tracer contains only one active species, Ni^{63}. All samples were measured in a 2π internal source counter (1).

The rate of diffusion of Ni^{63} was studied in five metals, 99.92% purity nickel, 99.91% purity iron, 99.5% purity cobalt, and two iron–nickel alloys prepared from electrolytic iron and nickel containing 5.79 and 14.88% Ni. All these metals were melted and cast *in vacuo*. The three pure metals were obtained from National Research Corporation, Cambridge, Mass., and we are indebted to Mr. H. V. Kinsey, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Ontario, for preparing the two alloys. Disks, 0.650 in. in diameter and 0.15 in. thick, were machined from these metals for diffusion specimens. After each specimen was annealed at 1400° C for 24 hours, it was carefully faced on a lathe followed by grinding on a series of polishing papers, finishing on 4/0 grade. Aliquots containing equal amounts of Ni^{63} tracer then were electrodeposited on the face of each specimen from an ammonia – ammonium sulphate electroplating solution. The active deposit was about one micron in thickness. Satisfactory deposits were obtained only when the specimens were given an anodic pretreatment in a 25% sulphuric acid solution to remove the oxide layer. Specimens where the tracer was non-uniformly plated or where the total quantity deposited differed by more than $\pm 1.5\%$ from the intended amount were discarded.

Ten specimens, a pair for each metal investigated, were placed in a recrystallized alumina crucible and diffusion-annealed simultaneously. Loss of tracer by evaporation was minimized by placing the faces of duplicate specimens in contact. Welding of the specimens was prevented by washing the active faces with a dilute suspension of fine alumina powder in alcohol. The furnace was maintained at the annealing temperature and specimens were introduced and removed at this temperature. Corrections were made when necessary to keep the error in the effective diffusion time within 0.4% by a method suggested by Ham, Parke, and Herzig (4). The furnace had a constant temperature zone 5 in. in length and was controlled to $\pm 0.5°$ C. The specimen temperatures were measured to $\pm 1.5°$ C with a certified Pt/(Pt – 10% Rh) thermocouple. An atmosphere of purified hydrogen was employed to prevent oxidation of the specimens.

At least four successive annealing treatments at the desired annealing temperature were employed to obtain each diffusion coefficient. These times were chosen to give equal intervals on a $1/\sqrt{t}$ axis. The surface activities were measured using a diaphragm with an opening 0.55 in. in diameter over the active surface to minimize edge effects arising from surface diffusion.

In addition to the slope of the plot of $C(0,t)$ versus $1/\sqrt{t}$, it is necessary to know C_0, in order to calculate the diffusion coefficient. The following procedure was selected as giving the most accurate value for C_0. Two nickel specimens, annealed at 1209° C, were sectioned on a lathe. Before each section was removed, the counting rate of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

exposed face was measured to determine $C(x,t)$ for various values of x. The area under the curve of $C(x,t)$ versus x was integrated to determine a value for C_0. Agreement between the duplicate specimens was within 1%. The diffusion coefficient calculated from equation [2] for the mean value of C_0 was in excellent agreement with that calculated from the sectioning data in the normal manner using equation [1]. This agreement indicates that good results should be obtainable with this surface activity technique. As an identical quantity of tracer was deposited on each specimen, it was sufficient to measure C_0 in this manner for one pair of specimens.

RESULTS AND DISCUSSION

The experimental curves for all specimens at a diffusion temperature of 1209° C are shown in Fig. 1, and are typical of those obtained at all temperatures. For surface activities below 4500 c.p.m., the curves are linear conforming to equation [2] and extrapolate to pass through the origin. However, for the diffusion of nickel into iron, cobalt, and the two iron–nickel alloys the plots are curved in the initial region, the curvature corresponding to a decrease in the diffusion coefficients with time. This curvature represents either a concentration dependence of the diffusion coefficient or a failure to satisfy the boundary conditions of equation [2] by using a tracer layer of finite thickness. This latter supposition was not substantiated, as a check experiment showed that a plot of $C(0,t)$ versus $1/\sqrt{t}$ is linear for nickel self-diffusion even for diffusion times short enough to promote much less diffusion than that obtained in those specimens where curvature was observed. Therefore, while the tracer layer was thin enough to satisfy the boundary

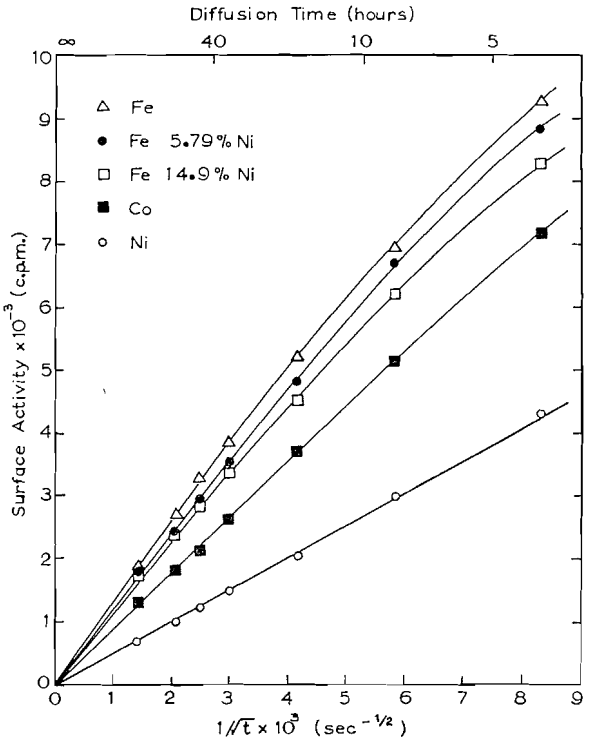

FIG. 1. Variation of surface activity with diffusion time for Ni^{63} diffusing into various metals and alloys at 1209° C.

For personal use only.

conditions of equation [2], it appears to have been thick enough to cause a concentration effect.

A similar time dependence of the diffusion coefficient was observed by Martin, Johnson, and Asaro (5), who studied the rate of diffusion of Au^{198} into copper at low solute concentrations. At 1000° C the diffusion coefficient varied with annealing time, decreasing steadily for the first 30 hours and then assuming a constant value for longer times. No noticeable improvement was obtained when the thickness of the Au^{198} layer was decreased by a factor of 50. Therefore, this time dependence of the diffusion coefficient for short annealing times may not be entirely associated with a dependence of the diffusion coefficient on concentration, but it may be partially associated with an enhanced rate of diffusion caused by lattice strains introduced by the large concentration gradient existing at the start of an experiment.

The diffusion coefficients were calculated in each case from the linear portions of the plots. In this region, the concentration of tracer atoms has decreased sufficiently that each diffusing tracer atom is completely surrounded by host atoms so that there is a negligible concentration effect. Diffusion coefficients were obtained for each system at the following temperatures: 1152°, 1209°, 1271°, 1327°, and 1400° C.

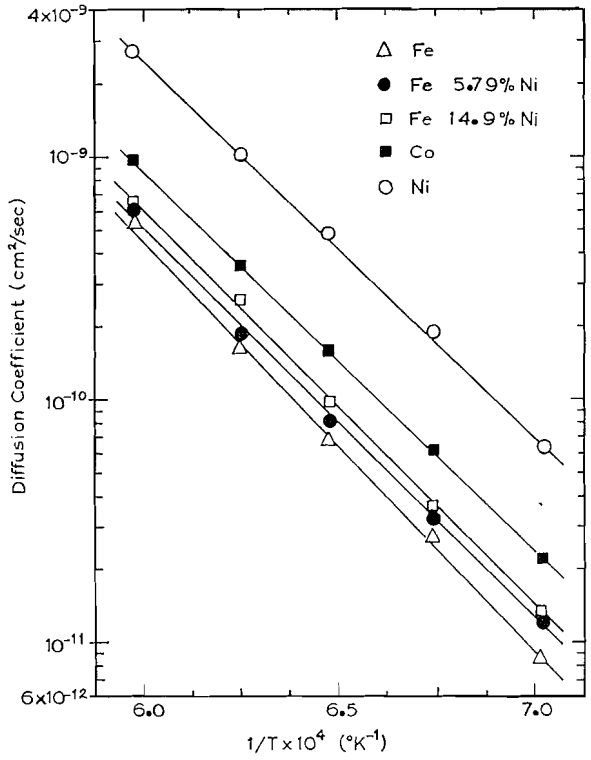

FIG. 2. Activation energy plots for Ni^{63} diffusion.

The activation energy, Q, and frequency factor, D_0, for volume diffusion are related by the Arrhenius equation:

$$D = D_0 e^{-Q/RT}.$$

To obtain values for Q and D_0, the experimental D values were plotted against $1/T$ as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

in Fig. 2. A correction was made to each coefficient to compensate for lattice expansion. The data for each system were fitted by the method of least squares, on the assumption that the temperatures were correct, and gave the values for the activation energy and frequency factor shown in Table I.

TABLE I

Values of Q and D_0 for Ni^{63} diffusion

Solvent	D_0 (cm^2/sec)	Q (kcal/mole)
Ni	5.12	71.0±1.8
Co	1.25	72.1±1.4
Fe	6.92	77.6±2.0
Fe 5.8% Ni	2.11	73.5±2.0
Fe 14.88% Ni	5.00	75.6±1.2

A comparison of the present results for self-diffusion of nickel with those of a previous investigation (2) shows that the two studies are in close agreement as is shown in Table II where the values are tabulated. Both investigations gave higher values for the activation energy than that reported by Hoffman, Pikus, and Ward (6).

TABLE II

Summary of D_0 and Q values for nickel self-diffusion

Reference	D_0 (cm^2/sec)	Q (kcal/mole)	Method
(6)	1.27	66.8	Sectioning and surface activity
(2)	3.36	69.8	Sectioning
This work	5.12	71.0	Surface activity

The slightly higher activation energy found in this investigation compared with that previously reported by the same authors may be a result of slight errors introduced by evaporation of tracer from the active face, as a surface activity method is more sensitive to these losses than a sectioning method. However, any losses must have been negligible as no traces of activity were found on the supporting crucible even after the anneals at 1400° C. The good agreement between this and the previous investigation where a sectioning method was employed can be taken as evidence for the accuracy of the surface activity method employed in this investigation. No comparison of these results for nickel self-diffusion to those for other face-centered metals will be attempted here, as this topic was fully discussed when the previous results were reported (2).

Theoretical attempts to correlate the diffusion rate of various solutes in the same solvent at low solute concentration have been based on two different concepts. Lazarus (7) has deduced expressions for D_0 and Q for solute diffusion in a monovalent solvent taking into account the screened coulombic potential surrounding the impurity atom. These expressions suggest that elements to the left of the solvent atom in the periodic table should diffuse more slowly with higher values of D_0 and Q, while those to the right should diffuse more rapidly with lower values of D_0 and Q. This theory has had partial success in correlating the results for various solute atoms in silver and copper. Swalin (8) has attempted to correlate the results for the diffusion of various solutes in nickel solely on a size effect. He argues that the increased strain induced when solute

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

atoms larger than the solvent atoms pass through the saddle point should result in slower rates of diffusion and higher values for D_0 and Q, and the converse for smaller impurities.

The three transition elements iron, cobalt, and nickel are interesting from the theoretical viewpoint because of the similarity in their properties. All assume a face-centered cubic structure at high temperatures and have atomic radii which are nearly equal. Therefore, any differences in diffusion rates should be associated with the valency these atoms assume when dissolved in one another. Thus a comparison of the activation energies for self-diffusion and tracer-impurity diffusion is of interest. The appropriate values of Q and D_0, are tabulated in Table III for diffusion in the solvents iron, cobalt, nickel, and copper.

TABLE III

D_0 and Q values for self-diffusion and tracer-impurity diffusion in some transition elements

Ni		2.70	56.5	(14)
Cu		0.32	46.8	(14)

Before discussing the significance of the data in Table III it should be pointed out that the data for the diffusion of iron into nickel and for cobalt into iron seem questionable. The value of D_0 found for diffusion of Fe^{59} into nickel is 8.4×10^{-3} cm^2/sec. This is suspect on the basis of Zener's (16) theory because it corresponds to a negative entropy of activation. The activation energy for the diffusion of Co^{60} into iron seems very high. It will be interesting to see if these values are confirmed in future investigations.

As observed by Mackliet (14) in the case of diffusion in the solvent copper, the tracer impurities iron, cobalt, and nickel all have larger activation energies than was obtained for copper self-diffusion. This is in general agreement with the Lazarus screening theory which predicts that elements which have a negative value of excess valency, Z, should have higher activation energies than for solvent self-diffusion. However, he found that $Q_{Ni} > Q_{Co} > Q_{Fe}$, which is contrary to the predictions expected if we assign to these elements their excess valence on a basis of their position in the periodic table. It is of interest to note that this trend also holds when the solvents are respectively iron, cobalt, and nickel with the single exception for diffusion of cobalt into iron. An explanation of this trend in activation energies for these transition elements will have to await clarification of the concept of valence in these metals.

Darken (17) has deduced expressions relating the interdiffusion coefficients, D_c, in a binary alloy at a given composition to the self-diffusion coefficients D_a^* and D_b^* of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

individual species in the same alloy. In the case of the iron–nickel system, which is thermodynamically ideal in the gamma region (18), these expressions reduce to

$$[3] \qquad D_c = N_{Fe}D_{Ni}^* + N_{Ni}D_{Fe}^*$$

where N_{Fe} and N_{Ni} are the atomic fractions of iron and nickel in the alloy. The variation of the interdiffusion coefficient, D_c, with composition in the iron–nickel system was investigated by Wells and Mehl (19) at 1300° C. Their data for D_c are plotted along with our data obtained for D_{Ni}^* in Fig. 3. A complete study of the variation of D_{Fe}^* with composition in the iron–nickel system was made by Neiman and Shinyaev (20) in the temperature range 1055 to 1148° C. Unfortunately their data are suspect at the nickel-rich end, because their D_0 values for diffusion in this range are low enough to correspond to negative entropies of activation. Therefore, in Fig. 3, we have only shown Gruzin's data for D_{Fe}^* in pure iron (9), and for D_{Fe}^* in two iron–nickel alloys containing 20% and 25% nickel (21).

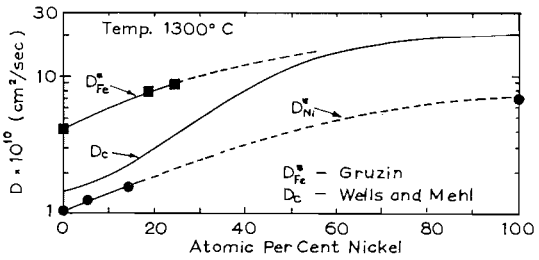

FIG. 3. Variation of the diffusion coefficients with composition in the iron–nickel system.

Considering that the data represent the results of four separate investigations, the correlation is remarkably good. While there is no evidence to justify the extrapolations shown, it is apparent that nickel atoms diffuse at about one-quarter the rate of iron atoms in the iron-rich portion of this system and probably throughout the entire system. This is in agreement with the observations of Seith and Kottman (22), who observed porosity in the iron-rich portion of an iron–nickel couple during a Kirkendall-effect experiment (23). While the data are not in sufficient agreement to test the validity of Darken's equations it is interesting to note that $D_c \rightarrow D_{Ni}^*$ as $N_{Fe} \rightarrow 1$ in agreement with equation [3].

Examination of the data in Table II indicates that there may be a trend towards lower activation energies for nickel self-diffusion in this system with increasing nickel content. There is a definite trend towards faster rates of nickel self-diffusion with increasing nickel content, which also suggests that the activation energy should decrease.

THE REACTION BETWEEN DIPHENYLAMINE AND NITRATES IN ULTRAVIOLET LIGHT[1,2]

B. B. Coldwell and S. R. McLean[3]

ABSTRACT

Under the activating influence of short-wave ultraviolet light, diphenylamine and nitrate ions in solution or on filter paper react to yield a yellow-colored product. Between pH 4 and 10 this consists mainly of 2-nitrodiphenylamine and 4-nitrodiphenylamine. Over this range of pH, the absorption maxima at 405 mμ did not shift; however, the intensity of absorption appeared to reach a minimum at or near neutrality and then increase rapidly as the solution was made more alkaline. The reaction rate was not affected by lowering the concentration of diphenylamine from 0.38% to 0.038%. A similar change in nitrate concentration decreased the rate 5.4 times. No evidence of nitroso compounds was found. Possible mechanisms are suggested.

INTRODUCTION

In a previous paper (1), it was noted that diphenylamine and nitrate ions reacted to form a yellow-colored product when irradiated with short-wave ultraviolet light. The reaction appeared specific and was made the basis of a spot test for inorganic nitrates. Subsequently, Hayward (2) found the reaction applicable to nitrate esters and used it for detecting these on paper chromatograms. We have confirmed Hayward's observation and, also, have found the reaction useful in identifying various kinds of explosives (3). The present work is concerned mainly with the identification of the products of the photochemical reaction.

EXPERIMENTAL AND RESULTS

(*A*) *Identification of Products Formed on Paper*

Sixty sheets of Whatman No. 1 filter paper (18×22 in.) were immersed for a few seconds in aqueous 1% sodium nitrate solution, air-dried, then immersed again in an ethanolic solution of diphenylamine (1% in 95% ethanol), air-dried, and exposed to short-wave ultraviolet radiation for 10 minutes on each side. The source and filters used have been described (1). The yellow-colored material was extracted from the paper with 95% ethanol in a modified Soxhlet assembly. The alcoholic extract was evaporated to dryness under vacuum on a constant temperature bath at 80° C. A total of 14.4 g, mostly unreacted diphenylamine, was recovered.

The material was dissolved in warm, redistilled petroleum ether (boiling range 30–50° C), and chromatographed on alumina columns (1×30 cm) which were prewashed with ethyl ether followed by petroleum ether. The columns were developed with petroleum ether. Two yellow bands separated, one (1P) weakly and the other (2P) very strongly absorbed by the alumina. Fraction 1P together with most of the unreacted diphenylamine was eluted from the columns with petroleum ether; the eluates were combined and evaporated to dryness under vacuum on a constant temperature bath at 35° C. Approximately 12.4 g were recovered. Repeated passes through the column eventually gave a fraction (44.8 mg) whose absorption maxima (see Table I) in the visual

and ultraviolet regions were in good agreement with those reported for 2-nitrodiphenylamine (4). The near- and far-infrared spectra of this fraction also were identical with those of 2-nitrodiphenylamine (see Figs. 1 and 2). From the absorptivity of 2-nitrodiphenylamine and the absorbance at 420–425 mμ, it was calculated that fraction 1P contained approximately 80% of 2-nitrodiphenylamine. The spectra, melting point[4] (35–50° C),

[4]*All melting points are uncorrected.*

and adsorbent characteristics of a 4 to 1 mixture of 2-nitrodiphenylamine and diphenylamine were identical with those of fraction 1P. It was concluded, therefore, that the yellow component of fraction 1P was 2-nitrodiphenylamine.

Fraction 2P was eluted from the adsorbent with acetone and evaporated to dryness under vacuum at 35° C. Approximately 0.24 g was recovered. This was rechromatographed on alumina using benzene – petroleum ether (1:1) as the developing solvent.

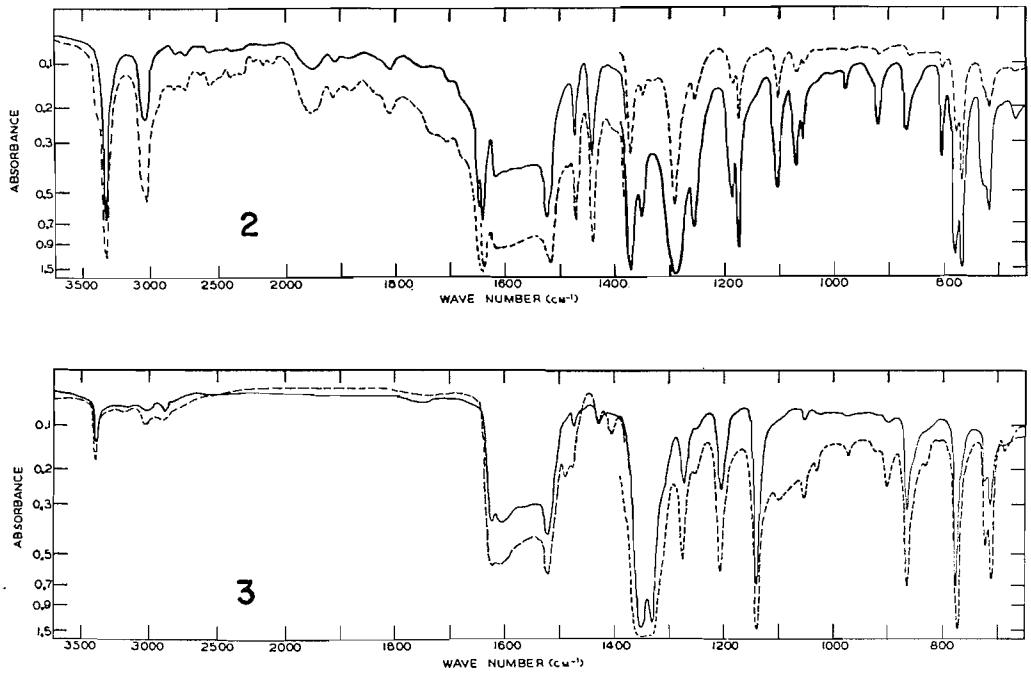

FIG. 2. Infrared spectra of 2-nitrodiphenylamine (———) and fraction 1P (– – –). Instrument: Perkin–Elmer Model 21, double beam, with sodium chloride optics. Solvent: carbon tetrachloride from 3600 to 1385 cm^{-1}, carbon disulphide from 1385 to 650 cm^{-1}.

FIG. 3. Infrared spectra of 4-nitrodiphenylamine (———) and fraction 2P (– – –). Conditions: as given in Fig. 2.

The colored eluate when concentrated gave 187.5 mg of yellow crystals. After recrystallizing twice from carbon tetrachloride the material melted at 133.5–134° C. A mixed melting point determination with a known[5] sample of 4-nitrodiphenylamine (m.p. 136–137° C) gave no depression. Absorption maxima in the ultraviolet and visible spectral regions were in agreement with those reported for 4-nitrodiphenylamine (see Table I). The infrared spectra of 2P and 4-nitrodiphenylamine were also identical (see Fig. 3). It was concluded that fraction 2P was 4-nitrodiphenylamine.

(B) Identification of Products Formed in Solution

A saturated solution of calcium nitrate tetrahydrate in 95% ethanol was made 1% with respect to diphenylamine. Ten 100-ml aliquots of this solution in a 1-l. beaker were exposed to short-wave ultraviolet radiation for 1 hour. The solutions were combined, taken to dryness, and chromatographed on alumina using petroleum ether to develop the chromatogram, as described above. Four bands gradually developed. The first band

For personal use only.

(1S), yellow in color, was eluted with petroleum ether. To elute the remaining bands off the column, ethyl ether was added to the petroleum ether, the proportions being increased gradually from 4:1 to 1:1. The second (2S) and third (3S) bands were orange and yellow, respectively. The fourth band (4S) was colored blue and remained at the top of the column. It was removed from the adsorbent with 95% ethanol.

Fraction 1S was concentrated and rechromatographed several times until finally crystals were obtained having an absorption maximum in the visible region characteristic of 2-nitrodiphenylamine (see Table I). Because of the difficulty in separating diphenylamine from 2-nitrodiphenylamine, additional purification of this fraction was not attempted.

Fraction 2S was concentrated and rechromatographed with 1:1 petroleum ether – ethyl ether. The absorption maxima exhibited in the ultraviolet and visible regions are given in Table I. There was insufficient material available to characterize this fraction further.

Fraction 3S was concentrated to a small volume and the orange-yellow crystals which separated were recrystallized twice from carbon tetrachloride (m.p. 132–132.5° C) and identified as 4-nitrodiphenylamine by a mixed melting point determination. The absorption maxima in the ultraviolet and visual regions (see Table I) and the infrared spectra of this material corresponded to those of 4-nitrodiphenylamine.

The wavelengths of maximum and minimum absorption of fraction 4S were almost identical in acidic and alkaline solutions (see Table I). The blue-colored material was insoluble in water. It appeared to be different from the blue quinoidal compound formed on the oxidation of diphenylamine with strong oxidizing agents (5). The latter on dilution with alcohol changed from a deep blue to a brownish yellow with the formation of a greenish brown precipitate. Similar changes were not observed with fraction 4S.

(C) Effect of pH on Reaction in Solution

Mixtures of diphenylamine and sodium nitrate, each 0.38% in aqueous ethanol (13 parts ethanol to 8 parts distilled water by volume), were adjusted to a known pH with hydrochloric acid or potassium hydroxide and exposed to short-wave ultraviolet radiation for 30 minutes without stirring. The pH, color, and visual spectra were then recorded. Some of the data are summarized in Table II and in Fig. 4.

TABLE II

Effect of pH on the ultraviolet-light-induced reaction between diphenylamine and nitrate. (Diphenylamine, 0.38%; sodium nitrate, 0.38%; solvent, ethanol 13 parts and water 8 parts; exposure, 30 minutes)

pH				
Initial	After exposure	Position of maxima,* mμ	Absorbance	Color of solution
3.0	3.0	398–401	0.240	Dark blue
		525–550	0.500	
4.0	5.5	402–408	0.595	Red-brown
		525–550	0.220	
5.0	7.2	405	0.490	Dark yellow
6.0	7.3	405	0.480	Yellow
8.0	8.0	405	0.565	Yellow
10.0	9.0	405	0.780	Yellow

*Determined with Spectracord using 1-cm Corex cells.

At pH 3, the main end product of the reaction appears to be the blue-colored substance found in fraction 4S. This is quite evident from curve 1, Fig. 4. As the pH rises,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

the blue substance disappears and the absorption at 405 mμ becomes more pronounced. There is evidence that the absorption at 405 mμ reaches a maximum at pH 4, decreases to a minimum at or near neutrality, and then rises sharply as the solution is made more alkaline. This trend is evident from the data in Table II and was observed in another series of experiments where the concentration of diphenylamine and nitrate was 0.038% for each. The production of 2-nitrodiphenylamine and 4-nitrodiphenylamine would appear to be responsible for the absorption at 405 mμ. A 1 to 1 mixture of these two compounds in 13 to 8 ethanol–water exhibited an absorption maximum at 403–404 mμ, which shifted to 406 mμ when the mixture contained twice as much 2-nitrodiphenylamine as 4-nitrodiphenylamine.

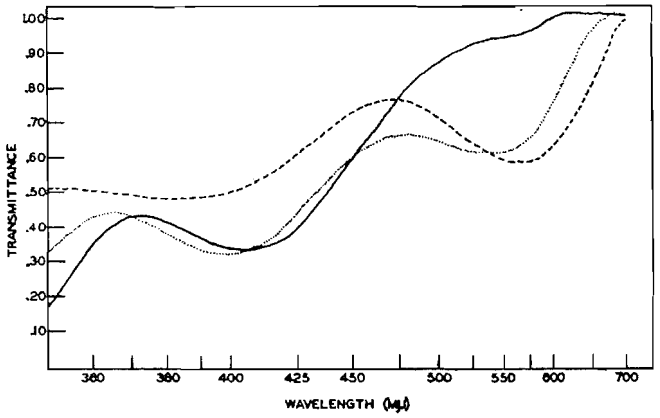

FIG. 4. Effect of pH on the visible spectra of diphenylamine–nitrate solutions irradiated with ultraviolet light. Solvent: 13 parts ethanol to 8 parts distilled water by volume. Concentration: diphenylamine and sodium nitrate each 0.38% (w/v). Exposure time: 30 minutes. Instrument: Spectracord with 1-cm Corex cells. Curve 1: – – –, pH 2.5. Curve 2: . . ., pH 3.0. Curve 3: ———, pH 5.0.

The magnitude of the absorbance at 405 mμ was not affected by lowering the diphenylamine concentration from 0.38% to 0.038% but was decreased 5.4 times by the same change in the nitrate concentration. At these concentrations a linear relationship was observed between absorbance and time of exposure, over a period of 2.5 hours.

(D) Nitrite and Diphenylamine

A solution of sodium nitrite (0.038%) and diphenylamine (0.038%) in aqueous ethanol (13 parts ethanol to 8 parts water by volume) was colorless between pH 11.0 and 6.2 and exhibited no absorption between 360 and 700 mμ. When irradiated for 1 hour the mixture turned a light yellow color and showed weak absorption in the region of 435 to 460 mμ (also given by irradiated diphenylamine solution) and strong absorption below 360 mμ (not shown by irradiated diphenylamine solution).

Increasing the acidity, without exposure to ultraviolet light, caused the solution to turn yellow. At pH 5.1 relatively sharp absorption maxima were observed at 388, 372, and 358 mμ. As the pH was lowered still further, the absorption below 360 mμ became stronger and overshadowed the absorptions at higher wavelengths which appeared as a shoulder between 370 and 390 mμ. Neutralization of the acidic solution did not change its visible spectrum. The spectrum at pH 2 was similar to that at pH 10 and resembled that of N-nitrosodiphenylamine. Similar results were obtained with more concentrated solutions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

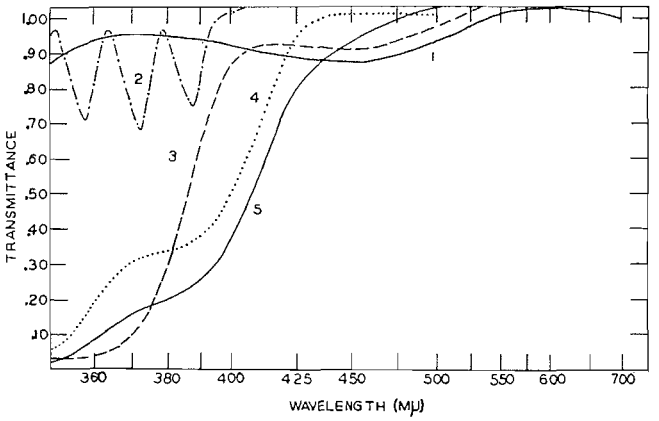

FIG. 5. The effect of ultraviolet radiation and pH on the visible spectra of diphenylamine, diphenylamine–nitrite solutions, and N-nitrosodiphenylamine. Solvent: ethanol 13 parts and distilled water 8 parts by volume. Instrument: Spectracord with 1-cm Corex cells. Curve 1: 0.038% diphenylamine exposed 1 hour to short-wave ultraviolet light. Curve 2: a solution of diphenylamine and sodium nitrite, each 0.038%, pH 5.1. Curve 3: same as curve 2, pH 7.5, irradiated 1 hour. Curve 4: same as curve 2, pH 2 and pH 10. Curve 5: N-nitrosodiphenylamine (0.1%).

The spectra of acidic (pH 5.5) diphenylamine–nitrite solutions could not be duplicated by exposing the corresponding original mixtures (pH 7.5) to short-wave ultraviolet light for varying periods of time. The spectrum of irradiated N-nitrosodiphenylamine (0.1% in 13 to 8 ethanol–water solution) was unchanged from the original. These results are illustrated in Fig. 5.

DISCUSSION

It is evident that between pH 4 and 10 the yellow end products formed during short-wave ultraviolet radiation of diphenylamine–nitrate mixtures, either in solution or on paper, consist largely of 2-nitrodiphenylamine and 4-nitrodiphenylamine. While the actual mechanism whereby these derivatives are formed remains uncertain, two pathways appear possible, (*a*) direct N-nitrosation of diphenylamine followed by rearrangement to the C-nitroso compound and subsequent oxidation (6), and (*b*) direct nitration of the phenyl rings (7).

Nitrate ion is reduced to nitrite ion by ultraviolet light, particularly at wavelengths below 2650 Å and around 3000 Å (8, 9). The reduction proceeds more rapidly in alkaline than in neutral or acidic solutions (10). It is claimed also that solid nitrate salts form nitrite near the surface when irradiated at 2500 Å (11, 12). Under our experimental conditions, the concentration of nitrite, determined with a modified Griess reagent (13), in aqueous alcoholic sodium nitrate solutions increased linearly with time of exposure to short-wave ultraviolet radiation. A 10-fold increase in nitrate concentration increased the rate of nitrite production by a factor of 3.

Further, the concentration of nitrite increased with rising pH, the amount present at pH 10 being more than twice that present at pH 3. These results agree with those of Villars (7) and Warburg (8). Thus, with increasing alkalinity there is an increase in the amount of yellow product and nitrite. Both of these increase linearly with time of exposure and both are affected in a similar manner by a change in concentration of nitrate. Warburg (8) pictures the reduction of nitrate by light as a unimolecular reaction in which the nitrate ion becomes activated by absorption of a quantum of light energy (90 to 100 kcal) and subsequently dissociates into nitrite and oxygen:

$$NO_3^- + h\nu \rightarrow (NO_3^-)^1 \rightarrow NO_2^- + O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

These facts suggest that the nitro derivatives might have resulted from very rapid oxidation of the C-nitroso derivatives of diphenylamine. In the presence of oxygen, oxidation of the labile nitroso compounds would be expected to take place rapidly, particularly in alkaline solution. This may explain why no evidence of nitroso derivatives was found on chromatographing the yellow reaction products or on spectral examination of irradiated diphenylamine–nitrate solutions. Certainly, the differences in the reactions taking place in irradiated diphenylamine–nitrate solutions, irradiated diphenylamine–nitrite solutions, and acidified solutions of the latter, as evidenced from a study of their spectra, suggest atomic oxygen plays a key role.[6]

On the other hand, the absence of nitroso compounds in the reaction products enhances the possibility of derivative formation through direct nitration of the ring. The activated nitrate radical might react with diphenylamine in this manner.

ACKNOWLEDGMENT

The authors are indebted to Mr. R. Ironside, Division of Applied Chemistry, National Research Council, Ottawa, for recording the infrared spectra.

A STUDY ON THE STRUCTURE OF THE CYCLOPENTADIENYL ANION WITH C^{14} AS TRACER[1]

R. TKACHUK[2] AND C. C. LEE

ABSTRACT

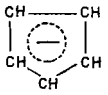
Starting with formaldehyde-C^{14}, 1,2-dibromocyclopentane-4-C^{14} (XI) was synthesized in eight steps. Conversion of XI to cyclopentadiene was accomplished in three different ways, namely: the dehydrobromination of XI with quinoline at 195–198° C, the preparation of 1,2-bis-(trimethylammonium)-cyclopentane-4-C^{14} hydroxide from XI followed by thermal decomposition, and the conversion of XI to 3,5-dibromocyclopentene followed by reaction of the latter with magnesium in dry ether. Degradations of the samples of cyclopentadiene obtained by these three synthetic routes showed a completely randomized distribution of the C^{14} activity, with 20% of the total activity on each of the five carbon positions. These results led to the conclusion that these preparations of cyclopentadiene very likely involved ionization to the cyclopentadienyl anion. The randomized distribution of C^{14} in the resulting products thus furnishes a strong indication that all five carbon positions in the cyclopentadienyl anion are equivalent.

INTRODUCTION

The acidity of cyclopentadiene was first recognized in 1900 by Thiele (1), and its potassium salt was prepared in 1901 (2). This salt is stable, though very reactive. The reason for the stability of salts containing the cyclopentadienyl anion has been given as early as 1928, by Goss and Ingold (3), and is that this ion has six (π) electrons, distributed over the entire five-membered ring, thus constituting a stable aromatic system similar to benzene. The resonance energy of this ion has been calculated to be about 42 kcal per mole (4).

Salts of cyclopentadiene with organic cations are also known. Pyridinium cyclopentadienylide has been described by Lloyd and Sneezum (5) and by Kosower and Ramsey (6). Triphenylphosphonium cyclopentadienylide has also been reported (7).

From theoretical considerations and physical chemical measurements, a number of workers (4, 8–12) have predicted that the negative charge on the cyclopentadienyl anion will not be localized on a particular carbon atom but will be distributed over the



(I)

ion as a whole, as depicted by I. In the present study, attempts were made to obtain, by the tracer technique, some direct experimental evidence in support of these theoretical predictions.

If it were possible to synthesize cyclopentadiene-5-C^{14} (II), conversion of this compound to its potassium salt followed by regeneration should yield a cyclopentadiene in which the C^{14} distribution could provide definitive evidence for the structure of the cyclopentadienyl anion. Should the anion have the symmetrical electronic structure I, on

[1]*Manuscript received June 8, 1959.*

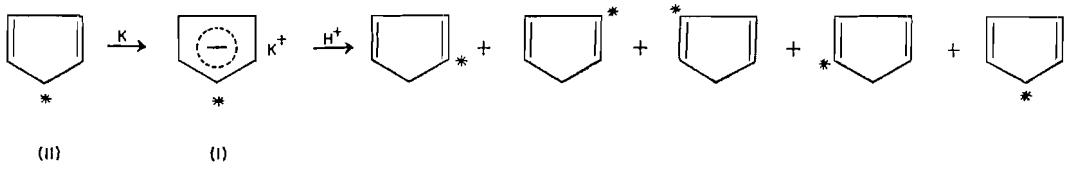
[2]*Canadian Industries Limited Fellow, 1956–1958.*

regeneration of cyclopentadiene from the anion, the proton would have an equal probability of attaching itself to any one of the five equivalent carbons, resulting in the formation of a mixture of equal amounts of cyclopentadiene with the C^{14} label on the 1-, 2-, 3-, 4-, or 5-position.

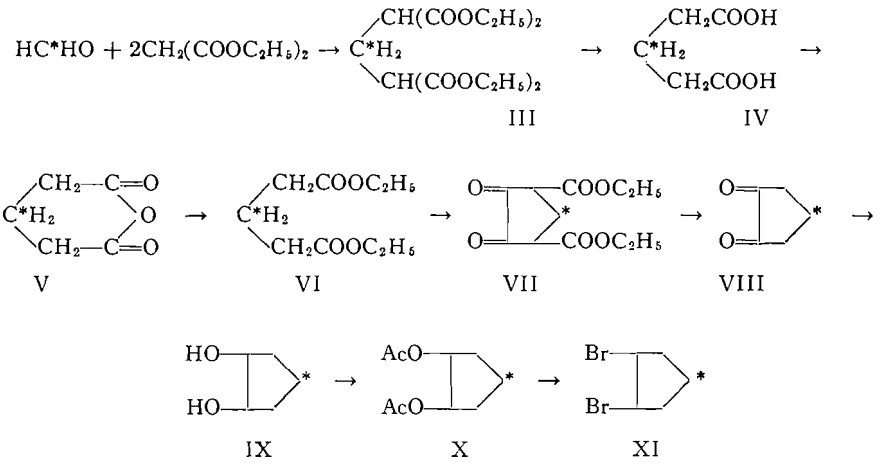


(II) (I)

Effectively, on degradation, one-fifth of the original C^{14} activity in II would be located on each carbon position of the sample of regenerated cyclopentadiene.

RESULTS AND DISCUSSION

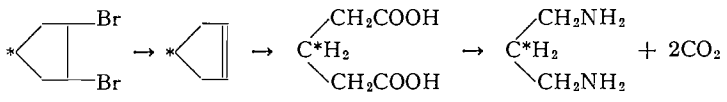
As a suitable precursor for the attempted syntheses of cyclopentadiene-5-C^{14} (II), *trans*-1,2-dibromocyclopentane-4-C^{14} (XI) was chosen because it can give rise to cyclopentadiene by a number of different routes. The synthesis of XI was accomplished according to the following sequence of transformations.



Tetraethyl propane-1,1,3,3-tetracarboxylate-2-C^{14} (III) was prepared by the condensation of formaldehyde-C^{14} and diethyl malonate. It was hydrolyzed to give glutaric acid-3-C^{14} (IV), which was, in turn, converted to glutaric anhydride-3-C^{14} (V) by treatment with acetic anhydride. Esterification of V gave diethyl glutarate-3-C^{14} (VI), which, on a Dieckmann condensation with diethyl oxalate, yielded 3,5-dicarboethoxy-1,2-cyclopentanedione-4-C^{14} (VII). Hydrolysis of VII afforded 1,2-cyclopentanedione-4-C^{14} (VIII). Reduction of VIII with sodium borohydride in water gave *trans*-1,2-cyclopentanediol-4-C^{14} (IX), which in turn was acetylated with acetic anhydride in pyridine to give *trans*-1,2-diacetoxycyclopentane-4-C^{14} (X). Treatment of X with hydrogen bromide in anhydrous acetic acid yielded *trans*-1,2-dibromocyclopentane-4-C^{14} (XI). The over-all yield of XI from formaldehyde-C^{14} was 11.4%.

To ascertain that *trans*-1,2-dibromocyclopentane-4-C^{14} (XI) was labeled as designated, it was degraded by the following scheme.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.



XI XII XIII XIV XV

The debromination of XI with zinc dust in ethanol yielded cyclopentene-4-C^{14} (XII). Ozonolysis of XII gave glutaric acid (XIII), which was degraded by the Schmidt reaction to give trimethylene-1,3-diamine (XIV) and carbon dioxide (XV). Radioactivity assays were carried out on the glutaric acid (XIII), on the diamine (XIV) as its dihydrogen bromide, and on the carbon dioxide (XV) precipitated as barium carbonate. The results, given in Table I, indicated that XIV contained all and XV contained none of the activity originally present in XI, showing that the label was not in positions 1 and 2. Thus, the designation that XI was labeled only in position 4 was likely correct.

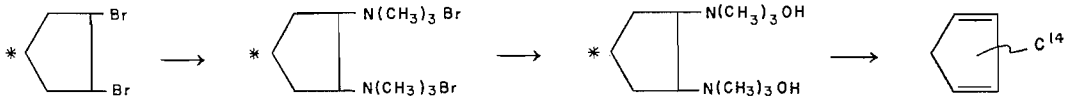
TABLE I

C^{14} activities in products from degradation of 1,2-dibromocyclopentane-4-C^{14}

Compound analyzed	C^{14} activity[a] (mμc/mmole)
Glutaric acid (XIII)	415
Trimethylene-1,3-diamine dihydrogen bromide from XIV	421
Barium carbonate from XV	0.18

[a]C^{14} activity in millimicrocuries per millimole of sample was assayed as CO_2 gas with a vibrating reed electrometer supplied by Nuclear-Chicago Corporation.

The synthesis of cyclopentadiene from XI was accomplished by three different routes. The first synthesis was effected by the heating of XI with quinoline at 195–198° C to give cyclopentadiene-*x*-C^{14} (XVI*a*). The procedure was similar to one reported in 1904 for the preparation of 1,3-cyclohexadiene from 1,2-dibromocyclohexane (13). The second synthesis involved the thermal decomposition of 1,2-bis-(trimethylammonium)-cyclopentane-4-C^{14} hydroxide (XVIII) according to the following sequence of conversions.

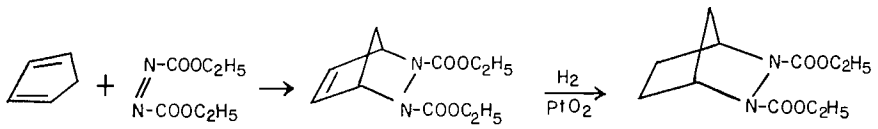


(XI) (XVII) (XVIII) (XVIb)

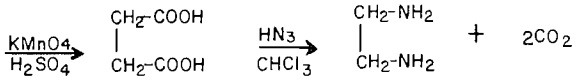
Treatment of XI with trimethylamine in acetone gave 1,2-bis-(trimethylammonium)-cyclopentane-4-C^{14} bromide (XVII). In turn, XVII was converted to XVIII with silver oxide in water. The decomposition of XVIII at 150° C afforded another sample of cyclopentadiene-*x*-C^{14} (XVI*b*). The third synthesis was carried out according to procedures reported fairly recently in the literature. It involved first the conversion of XI to cyclopentene-4-C^{14} (XII). Treatment of XII with N-bromosuccinimide and benzoyl peroxide in carbon tetrachloride gave 3,5-dibromocyclopentene (XIX)(14). Reaction of XIX with magnesium in dry ether (15) yielded a third sample of cyclopentadiene-*x*-C^{14} (XVI*c*).

The samples of cyclopentadiene-*x*-C^{14} obtained from the various syntheses were degraded by the following series of reactions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.



(XX) (XXI)



(XXII) (XXIII) (XXIV)

A Diels–Alder type of reaction between cyclopentadiene-x-C^{14} and diethyl azodicarboxylate gave the adduct, the diethyl ester of 2,3-dihydrazabicyclo (2.2.1)-5-heptene-2,3-dicarboxylic acid-x-C^{14} (XX). Hydrogenation of XX gave the diethyl ester of 2,3-dihydrazabicyclo (2.2.1) heptane-2,3-dicarboxylic acid-x-C^{14} (XXI). To yield succinic acid (XXII), XXI was oxidized with potassium permanganate. A Schmidt reaction with XXII resulted in the formation of ethylene-1,2-diamine (XXIII) and carbon dioxide (XXIV); XXIII was isolated as the dihydrogen bromide and XXIV as barium carbonate. C^{14} assays were carried out on XXI, XXII, the dihydrogen bromide from XXIII, and the barium carbonate from XXIV; XXI contained the total activity originally present in the cyclopentadiene-x-C^{14}. The difference in activities between XXI succinic acid (XXII) represented the activity in the 5-position (the methylene position) of cyclopentadiene. The activity in the 1- and 4-positions of cyclopentadiene was represented by the C^{14} in the carbon dioxide (XXIV) as well as by the difference between the activities of succinic acid (XXII) and ethylene-1,2-diamine (XXIII). Finally, the activity in the 2- and 3-positions of cyclopentadiene was given by the C^{14} in XXIII. The results of the C^{14} measurements are summarized in Table II.

TABLE II

C^{14} activities in products of degradation of cyclopentadiene-x-C^{14}

Source of cyclopentadiene	Compound analyzed	C^{14} activity (mμc/mmole)	% activity (XXI = 100)	% activity calc. for randomized distribution
Synthesis No. 1[a]	Hydrogenated Diels–Alder adduct (XXI)	26.73	100	100
	Succinic acid (XXII)	21.76	81.3	80

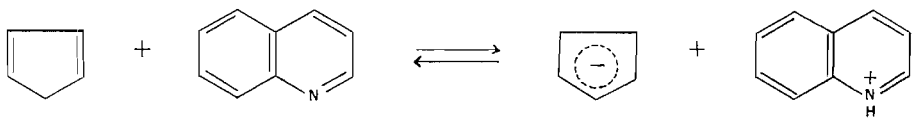
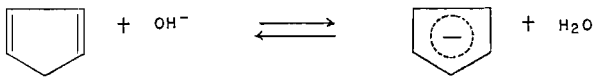
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The data in Table II clearly show that the samples of cyclopentadiene-*x*-C^{14} (XVI*a*, XVI*b*, XVI*c*) obtained from *trans*-1,2-dibromocyclopentadiene-4-C^{14} (XI) by the three synthetic routes were not the hoped for cyclopentadiene-5-C^{14}. Instead, they were samples of cyclopentadiene with the C^{14} activity completely randomized over all the five carbon positions. Such a distribution of C^{14} activity may be explained on the assumption that the cyclopentadienyl anion with symmetrical structure I is involved in these preparations. In the dehydrobromination of XI with quinoline (synthesis No. 1), the cyclopentadiene formed may immediately undergo reversible ionization-regeneration with quinoline acting as proton acceptor.



Considering the thermal decomposition of 1,2-bis-(trimethylammonium)-cyclopentane-4-C^{14} hydroxide (XVIII) (synthesis No. 2), first of all, the designation of the C^{14} location in XVIII is most probably correct since the conversion of XI to XVIII involved an S_N2 type of direct displacement and a double decomposition reaction both of which are not likely to cause isotope position rearrangements. Moreover, XVIII was prepared in a manner analogous to the synthesis of *n*-propyl-3-C^{14}-trimethylammonium hydroxide, which has been found to undergo successful thermal decomposition to propene-1-C^{14} (16). The randomized C^{14} distribution in the cyclopentadiene from synthesis No. 2 may, therefore, be again explained on the basis that the cyclopentadiene formed immediately undergoes reversible ionization-regeneration.



The interpretation of the results from synthesis No. 3 is more difficult. In the conversion of cyclopentene-4-C^{14} (XII) to 3,5-dibromocyclopentene (XIX) by treatment with N-bromosuccinimide and benzoyl peroxide, the possibility of allylic shifts cannot be excluded. Thus, the location of the C^{14} labels in XIX cannot be definitely designated. Furthermore, the mechanism for the transformation of XIX to cyclopentadiene in the presence of magnesium and dry ether is not well understood. Therefore, it is uncertain at what stage of the synthesis randomization of the C^{14} activity occurs. If one were to assume that there is no isotope position rearrangement in the conversions of XII to XIX and XIX to cyclopentadiene, then the randomized C^{14} distribution in the cyclopentadiene obtained from synthesis No. 3 might be explained in the same manner as in syntheses 1 and 2, namely, the cyclopentadiene formed immediately undergoes a reversible ionization-regeneration. Under the conditions employed in this synthesis, a Grignard reagent type of species may be present and serve as a base in promoting the ionization of the cyclopentadiene to its anion.

From the above considerations, it is clear that although the original intention of securing evidence on the structure of the cyclopentadienyl anion via cyclopentadiene-5-C^{14} was not successfully realized, the C^{14} distribution found in the samples of cyclopentadiene synthesized in these experiments does have a bearing on the problem under study. The completely randomized distribution of the C^{14} labels in the synthetic cyclopentadiene, at least in the samples from syntheses No. 1 and 2, likely resulted from an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

involvement of the cyclopentadienyl anion during the synthetic processes. Thus, this randomization of the C^{14} activity in the cyclopentadiene furnishes a strong, though indirect, indication that all five carbon positions in the cyclopentadienyl anion are equivalent, as depicted in structure I.

EXPERIMENTAL

The condensation of formaldehyde-C^{14} with diethyl malonate to give tetraethyl propane-1,1,3,3-tetracarboxylate-2-C^{14} (III), the hydrolysis of III to glutaric acid-3-C^{14} (IV), and the conversion of IV to glutaric anhydride-3-C^{14} (V) were carried out according to procedures given in Cason and Rapaport (17). Starting with 16 g (0.53 mole) of formaldehyde-C^{14} (0.5 mc) as 35% formalin and 160 g (1.0 mole) of diethyl malonate, the yield of III, b.p. 163–166° C at 1.4 mm (lit. (17), b.p. 168–171° C at 4 mm), was 138.5 g (83%). Hydrolysis of the 138.5 g of III in 138 ml of concentrated hydrochloric acid gave a crude glutaric acid (IV), which was heated at 100° C for 1 hour with 85 ml of acetic anhydride to give glutaric anhydride-3-C^{14} (V). After vacuum distillation and crystallization from benzene and dry ether, the yield of product, m.p. 55–56° C (lit. (17), m.p. 55–56° C), was 24.8 g (52% based on the tetraethyl ester III).

Diethyl Glutarate-3-C^{14} (VI)

The conversion of glutaric anhydride-3-C^{14} to the diethyl ester was effected by treatment with absolute ethanol in the presence of toluene and concentrated sulphuric acid. The method used was similar to that given by Micovic for the preparation of diethyl adipate (18). From 24.8 g of V, 40 g (99% of theoretical) of diethyl glutarate-3-C^{14}, b.p. 84–85° C at 1.4 mm (lit. (19*a*), b.p. 103–104° C at 7 mm), was obtained.

3,5-Dicarboethoxy-1,2-cyclopentanedione-4-C^{14} (VII)

The Dieckmann condensation between diethyl glutarate-3-C^{14} (40.0 g, 0.21 mole) and diethyl oxalate (31.5 g, 0.22 mole) was carried out according to a procedure given by Hauser and Hudson (20). The product (VII), crystallized twice from ethanol and water, melted at 116–117° C (lit. (20), m.p. 115° C). The yield was 41.4 g (81%).

1,2-Cyclopentanedione-4-C^{14} (VIII)

Under an atmosphere of carbon dioxide, a mixture of 41.3 g (0.17 mole) of 3,5-dicarboethoxy-1,2-cyclopentanedione-4-C^{14} and 160 g of 20% sulphuric acid was refluxed gently in a wax bath for 2.5 hours. The reaction mixture was cooled, saturated with ammonium sulphate, and then continuously extracted with ether for 10 hours. A carbon dioxide atmosphere was also maintained throughout the extraction period. After removal of the ether from the extract, the residue was distilled under reduced pressure to give 12.7 g (76%) of product, b.p. 67–69° C at 1.4 mm; m.p. 54–55° C (lit. (21), m.p. 56° C).

Air rapidly decomposes this diketone, especially at room temperature. However, when kept under nitrogen or carbon dioxide at approximately −5° C, it is stable for at least two years.

trans-1,2-Cyclopentanediol-4-C^{14} (IX)

To 4.0 g (0.041 mole) of 1,2-cyclopentanedione-4-C^{14} in 50 ml water, 2.31 g (0.61 mole) of sodium borohydride was slowly added with cooling and shaking. The reaction which took place was quite vigorous, and the mixture turned yellowish during the reduction. After standing at room temperature for 3 hours, the solution was heated to boiling to destroy any excess sodium borohydride. The resulting solution, after cooling, was extracted continuously with ether for 72 hours. On removal of the ether from the extract and vacuum distillation of the residue, 2.3 g (65%) of product was obtained with a b.p.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

of 80–82° C at 1.2 mm (lit. (22), b.p. 93° C at 2 mm). The di-*p*-nitrobenzoate derivative melted alone and on admixture with the same derivative from authentic *trans*-1,2-cyclopentanediol at 141–142° C (lit. (22), di-*p*-nitrobenzoate derivative, m.p. 143° C). It is reasonable that only the *trans*-isomer was isolated since the *cis*-isomer is known to form a stable complex with boric acid (23).

trans-1,2-Diacetoxycyclopentane-4-C^{14} (X)

The *trans*-1,2-cyclopentanediol-4-C^{14} was acetylated by treating 2.3 g (0.023 mole) of the diol with a mixture of 20 ml of acetic anhydride and 40 ml of pyridine at 100° C for 4 hours. After cooling, the reaction mixture was neutralized with 10% hydrochloric acid and then extracted three times with 35-ml portions of ether. The extract was dried over potassium carbonate, the ether removed, and the residue vacuum-distilled to give 2.7 g (65%) of product, b.p. 61–65° C at 1.4 mm (lit. (24), b.p. 85.5–86.5° C at 3.5 mm). Analysis: Calc. for $C_9H_{14}O_4$: C, 58.05%; H, 7.58%; acetyl, 46.3%. Found: C, 57.88%; H, 7.54%; acetyl, 46.4%.

In another preparation of the diacetate (X), 0.81 g of the diol (IX), 4.0 g of acetic anhydride, and 12 ml of pyridine were refluxed for 1.5 hours, the reaction mixture being protected from atmospheric moisture by means of a drying tube containing Drierite. The excess acetic anhydride and pyridine were removed under reduced pressure with a water aspirator pump and the residue vacuum-distilled, yielding 1.4 g (95%) of product boiling at 60° C at 1.2 mm.

trans-1,2-Dibromocyclopentane-4-C^{14} (XI)

This preparation was carried out in a manner similar to that used in the synthesis of 2,3-dibromobutane from 2,3-diacetoxybutane (25).

Into a 12-mm (O.D.) Pyrex glass tube with wall thickness of 1 mm was placed 1.38 g of *trans*-1,2-diacetoxycylopentane-4-C^{14} and 7.0 ml of saturated hydrogen bromide in acetic acid, the latter prepared by saturating pure acetic acid with dry hydrogen bromide gas at 35° C. The glass tube was sealed and then heated for 2 hours in boiling water. During this period, the reaction mixture darkened appreciably. After the mixture had cooled, the tube was opened and the solution poured onto crushed ice, neutralized with sodium bicarbonate solution, and extracted three times with 40-ml portions of low boiling petroleum ether. The extract was dried with anhydrous sodium carbonate, the solvent removed, and the residue vacuum-distilled, yielding 1.33 g (78%) of product, b.p. 44–46° C at 1.4 mm (lit. (26), b.p. 76.5–77.5° C at 18.5 mm). Analysis: Calc. for $C_5H_8Br_2$: Br, 70.2%. Found: Br, 70.8%.

Degradation of trans-1,2-Dibromocyclopentane-4-C^{14} (XI)

Cyclopentene-4-C^{14} (XII)

Cyclopentene-4-C^{14} (XII) was prepared from XI by a method similar to that used in the preparation of 2-pentene from 2,3-dibromopentane (27). To 2.0 g of granular, 20-mesh zinc metal in 3 ml of ethanol at 50° C, 1.3 g (0.0057 mole) of *trans*-1,2-dibromocyclopentane-4-C^{14} was added dropwise over a period of 10 minutes. A vigorous reaction took place, the cyclopentene being distilled over as it was formed into a receiver cooled in a dry ice – acetone bath. To insure complete recovery of the cyclopentene, the reaction mixture was heated just to the boiling point of ethanol. The weight of the product was 0.35 g (84%).

Ozonolysis of Cyclopentene-4-C^{14}

Ozonolysis of cyclopentene-4-C^{14} (XII) was effected in the same manner as reported

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

for the ozonolysis of cyclohexene (28). Starting with a solution of XII from 1.3 g of XI in 20 ml of absolute methanol, ozonization followed by decomposition of the ozonide in formic acid and hydrogen peroxide gave 0.62 g (87% based on the dibromide XI) of glutaric acid-3-C^{14} (XIII), m.p. 97° C (lit. (19*a*), m.p. 97–98° C).

The Schmidt Reaction on Glutaric Acid-3-C^{14}

This was carried out according to procedures already described in the literature (29, 30). From 198 mg (1.5 mmoles) of XIII, the yield of barium carbonate from the carbon dioxide absorbed in carbonate-free sodium hydroxide solution was 300 mg (52%), while the yield of trimethylene-1,3-diamine-2-C^{14} dihydrogen bromide was 49.5 mg (14%). Analysis: Calc. for $C_3H_{12}N_2Br_2$: C, 15.27%; H, 5.13%; N, 11.87%; Br, 67.7%. Found: C, 15.32%; H, 5.05%; N, 12.02%; Br, 68.0%.

Cyclopentadiene-x-C^{14} (XVI*a*) *from Dehydrobromination of trans-1,2-Dibromocyclopentane-4-*C^{14} (XI) *with Quinoline* (*Synthesis No. 1*)

In a 25-ml pear-shaped flask with a side arm as gas inlet was placed 2.82 g (0.0124 mole) of XI and 7.98 g (0.0168 mole) of freshly distilled quinoline. The flask was also fitted with a reflux condenser whose jacket temperature was kept at 45–47° C. The whole system was swept with dry nitrogen leading to a receiver cooled in a dry ice – acetone bath. The reaction mixture was heated in a wax bath to 195–198° C, whereupon a reaction set in as evidenced by much charring and bubbling. After the main evolution of volatile material had ceased, the mixture was kept at 198° C for an additional 10 minutes to insure complete reaction. The product in the receiving vessel was distilled into a calibrated centrifuge tube by heating the original receiver to 50–53° C. This distillation separated the cyclopentadiene from higher boiling materials such as quinoline that may have been present. The volume of product was 0.5 ml, corresponding to an approximate yield of 50% if all this product were pure cyclopentadiene.

A solution of the above product in ether was treated with maleic anhydride giving rise to the cyclopentadiene – maleic anhydride adduct which melted at 162–163° C (lit. (15), m.p. 163–164° C).

Another derivative of the above cyclopentadiene was the liquid adduct formed with diethyl azodicarboxylate which, on reaction with bromine, yielded the diethyl ester of 2,3-dihydraza-5,6-dibromobicyclo (2.2.1) heptane-2,3-dicarboxylic acid, m.p. 66–67° C (lit. (31), m.p. 67° C).

There was some indication that some cyclopentene may also have been formed in this reaction. After treatment of the redistilled product with excess diethyl azodicarboxylate, a small amount of liquid boiling at 39–41° C (lit. (19*b*), b.p. for cyclopentene, 44–46° C) was recovered. This liquid was unsaturated and showed an infrared spectrum similar to that of authentic cyclopentene.

Cyclopentadiene-x-C^{14} (XVI*b*) *from Thermal Decomposition of 1,2-Bis-(trimethylammonium)-cyclopentane-4-*C^{14} *Hydroxide* (*Synthesis No. 2*)

1,2-Bis-(trimethylammonium)-cyclopentane-4-C^{14} *Bromide* (XVII)

A mixture of 0.639 g (0.0028 mole) of *trans*-1,2-dibromocyclopentane-4-C^{14} (XI) and 2.0 ml of acetone[3] containing 2.65 g (0.045 mole) of trimethylamine was placed in a Pyrex glass tube, 12 mm O.D., with 1 mm wall thickness. The tube was sealed and heated at 80° C for 66 hours. During this period a mass of white crystals was deposited in the

[3]*A search for a suitable solvent for this reaction showed that acetone gave the best results as compared with nitromethane, nitrobenzene, acetonitrile, benzyl alcohol, and acetophenone* (*cf. discussion of the effects of solvent on the Menschutken reaction given by Streitwieser* (*32*)).

reaction mixture. After the mixture had cooled, the sealed tube was opened and the solvent and excess trimethylamine evaporated off. The product was recrystallized from a mixture of ethanol and ethyl acetate. The yield of the quaternary ammonium salt (XVII) was 1.11 g (76%). Analysis: Calc. for $C_{11}H_{26}N_2Br_2$: C, 38.15%; H, 7.57%; N, 8.10%; Br, 46.2%. Found: C, 38.24%; H, 7.39%; N, 8.07%; Br, 46.2%.

1,2-Bis-(trimethylammonium)-cyclopentane-4-C^{14} *Hydroxide* (XVIII)

To a solution of 1.11 g of 1,2-bis-(trimethylammonium)-cyclopentane-4-C^{14} bromide (XVII) in 20 ml of water, moist, freshly prepared silver oxide was slowly added until the color of silver oxide persisted after the solution had been standing for 1 hour at room temperature. The silver bromide which precipitated was filtered off and washed with 15 ml of water. The filtrate and washings were combined, and the water removed at 45–50° C with the aid of a water aspirator pump. The quaternary ammonium hydroxide, which remained behind as a yellowish oil, was used directly for the next reaction.

Cyclopentadiene-x-C^{14} (XVI*b*)

The above quaternary ammonium hydroxide (XVIII) was transferred to a 15-ml pear-shaped flask equipped with a nitrogen bubbler and a reflux condenser with its jacket temperature maintained at 50° C. The reflux condenser was connected to a receiver immersed in a dry ice – acetone bath. With a slow stream of dry nitrogen flushing through the system, the reaction flask was heated in a wax bath to 150° C whereupon a smooth reaction took place. The reaction temperature was kept at 150° C for 10 minutes and then raised to 160° C for an additional 15 minutes. The product trapped in the receiver was dissolved in 15 ml of low boiling petroleum ether containing 0.4 g of ordinary cyclopentadiene as carrier. This solution of diluted cyclopentadiene-*x*-C^{14} was washed four times with 15-ml portions of cold water, dried with Drierite, and then it was used directly for degradation to determine the C^{14} distribution. In preliminary preparations, the yield of cyclopentadiene, identified by the formation of the maleic anhydride adduct, m.p. 162–163° C, was found to be of the order of 20%.

Cyclopentadiene-x-C^{14} (XVI*c*) *from Reaction of 3,5-Dibromocyclopentene with Magnesium in Dry Ether* (*Synthesis No. 3*)

Cyclopentene-4-C^{14} (XII)

Cyclopentene-4-C^{14} (XII) was prepared from *trans*-1,2-dibromocyclopentane-4-C^{14} (XI) as described under the method of degradation of XI.

3,5-Dibromocyclopentene-x-C^{14} (XIX)

One gram (0.015 mole) of cyclopentene-4-C^{14} was brominated by refluxing for 4 hours with a mixture of 5.4 g (0.030 mole) of N-bromosuccinimide and 50 mg of benzoyl peroxide in 70 ml of carbon tetrachloride. The product, recovered as described by Cope and co-workers (14), weighed 2.12 g (64%), b.p. 50–60° C at 1.2 mm (lit. (14), b.p. 52–73° C at 3 mm).

Cyclopentadiene-x-C^{14} (XVI*c*) (*15*)

In a 15-ml pear-shaped flask fitted with reflux condenser, dropping funnel, and inlet to provide a nitrogen atmosphere was placed 0.432 g (0.018 mole) of magnesium turnings and 5.0 ml of absolute ether. The magnesium was activated by the addition of a few drops of ethyl bromide. Then with frequent shaking, 2.00 g (0.0088 mole) of 3,5-dibromocyclopentene-*x*-C^{14} (XIX) in 5.0 ml of absolute ether was added dropwise over a period of 15 minutes. The reaction was very vigorous. After the addition of XIX was completed, the mixture was allowed to stand at room temperature for 30 minutes with frequent shaking. The product, along with ether, was distilled, the distillate being

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

collected in a dry-ice-cooled receiver. This distillate was used directly for the degradation of the cyclopentadiene-*x*-C^{14}. In preliminary preparations, the cyclopentadiene was identified by the formation of the adduct with maleic anhydride, m.p. 162–163° C.

Degradation of Cyclopentadiene-x-C^{14}

Diethyl Ester of 2,3-Dihydrazabicyclo (2.2.1)-5-heptene-2,3-dicarboxylic Acid (XX)

An ether solution containing 0.50 g (0.0076 mole) of cyclopentadiene-*x*-C^{14} and 1.32 g (0.0076 mole) of diethyl azodicarboxylate, the latter prepared from reaction of hydrazine with ethyl chloroformate followed by oxidation with chlorine (33), was heated in a sealed tube at 45° C for 12 hours. After removal of the solvent, the residue was distilled under vacuum, yielding 1.73 g (95%) of a very viscous product, b.p. 110–113° C at 0.12 mm (lit. (31), b.p. 121° C at 0.5 mm). On addition of bromine, the dibromo derivative obtained melted at 66–67° C (lit. (31), m.p. 67° C).

Diethyl Ester of 2,3-Dihydrazabicyclo (2.2.1) heptane-2,3-dicarboxylic Acid (XXI)

In the glass liner of the hydrogenator bomb were placed 2.00 g (0.0083 mole) of the above Diels–Alder adduct (XX) in 20 ml of absolute ethanol and 0.05 g of platinum oxide. Hydrogenation was effected by shaking the system for 4 hours under a hydrogen pressure of about 450 p.s.i. The required drop in pressure for the small quantity of reactant used was negligible so it was not recorded. The product was isolated by filtering off the catalyst, removing the ethanol by means of a water aspirator pump, and vacuum-distilling the residue. The fraction collected weighed 1.77 g (88%), b.p. 112–114° C at 0.2 mm (lit. (31), b.p. 121° C at 5 mm).

Succinic Acid (XXII) *from* XXI

A mixture of 1.00 g (0.0041 mole) of hydrogenated ester XXI, 6.5 g (0.041 mole) of potassium permanganate, and 100 ml of water was heated on a steam bath with occasional shaking for 25 minutes. After the mixture had cooled, the excess permanganate and manganese dioxide were reduced by slow addition of sodium bisulphite. The resulting colorless solution was continuously extracted with ether for 48 hours. The extract was dried with Drierite, the ether removed by distillation, and the residue maintained at 60–70° C under water pump vacuum until a yellowish, crystalline residue remained. This residue, after being washed with chloroform, weighed 0.253 g (52%). It was purified by three successive recrystallizations, suitable solvent for the recrystallization being diethyl ketone, anhydrous tetrahydrofuran, or water acidified with hydrochloric acid. The m.p. of the purified product was 184–185° C (lit. (19*c*), m.p. 184.5–185° C).

Schmidt Reaction with Succinic Acid

Succinic acid (50 mg, 0.42 mmole) was converted to succinic anhydride by treatment with 30 λ (0.34 mmole) of phosphorus oxychloride, and then the anhydride was subjected to reaction in 0.43 ml of 100% sulphuric acid containing 85 mg (1.3 mmoles) of sodium azide. The detailed procedure has been reported by Phares and Long (34). The carbon dioxide liberated was trapped in carbonate-free sodium hydroxide solution and then precipitated as barium carbonate. The yield of barium carbonate was in the order of 80%. The reaction mixture was made basic with sodium hydroxide solution and distilled to give an aqueous solution of ethylene-1,2-diamine as described by Phares and Long (34). Isolation of the ethylene-1,2-diamine as a solid derivative was effected by acidifying the distillate with hydrobromic acid, evaporating almost to dryness, adding ethanol, and collecting the crystalline product formed. The yield of ethylene-1,2-diamine dihydrogen bromide was 52 mg (55%). Analysis: Calc. for $C_2H_{10}N_2Br_2$: N, 12.63%; Br, 72.0%. Found: N, 12.59%; Br, 72.4%.

A PRELIMINARY STUDY OF THE VAPOR PERMEABILITY OF CELLOPHANE[1]

W. L. ARCHER[2] AND S. G. MASON

ABSTRACT

The water vapor permeability of cellophane was measured over adsorption–desorption cycles and was found to parallel the sorption isotherm. When a constant vapor pressure was applied on the low pressure side of the membrane, the mass flow rate was independent of the vapor pressure used and showed hysteresis on desorption. The permeabilities of methanol, ethanol, and benzene were found to increase with increasing vapor pressure.

INTRODUCTION

In this note we describe some rather careful measurements of the diffusion of water and other substances through cellophane when a controlled difference in vapor pressure was maintained across the membrane. The measurements were made originally to determine their usefulness in studying swelling phenomena in cellulose. Because the measurements were time-consuming and the permeation phenomena complicated, the technique was abandoned in favor of liquid permeability methods (1, 2).

Since the transmission of gases and vapors through polymeric films is receiving considerable attention (3, 4), our results may prove to be of some interest. Doty, Aiken, and Mark (5) have shown that the water vapor permeability of cellophane varies non-linearly with the vapor pressure gradient. They proposed a mechanism of vapor transfer comprising an activated diffusion by the sorption and desorption of water molecules at active spots on the internal surface of the cellulose.

Several investigators have pointed out the similarity in shape between the water sorption isotherm and permeability of cellophane (6, 7). This observation has been confirmed and extended in the present study.

EXPERIMENTAL PART

Apparatus

Measurements were made in an evacuated system consisting essentially of a vapor source, a cellophane barrier, and a cold trap to condense the permeating vapor. The sorption of the vapor by a separate piece of cellophane was measured simultaneously on the high pressure side of the membrane.

The same cellophane membrane was used in all the permeability measurements and was held in a stainless steel cell (Fig. 1). The cell consisted of two half-cells bolted together at central flanges by eight symmetrically placed steel bolts. The membrane was clamped between the inner lapped ring surfaces of the flanges. A groove B cut in the flanges provided a mercury well to seal the edges of the membrane. The free area of membrane was 19.68 cm^2.

The cell was connected to the vacuum system by two tapered ends machined to fit female standard ground glass joints. Effective bonding of the steel and glass was obtained with high vacuum cement. The cell was immersed in a constant temperature water bath. A vacuum of 10^{-4} mm Hg was readily obtained.

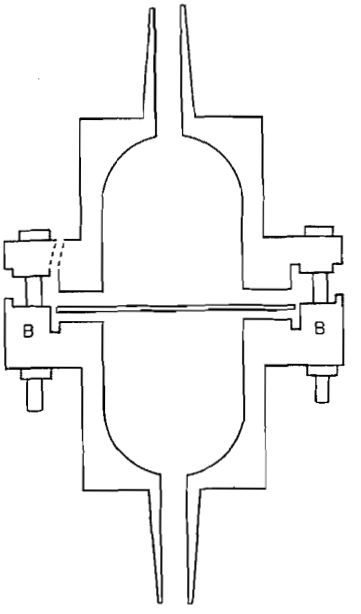

FIG. 1. Vapor permeability cell.

Vapor was supplied from bulbs at C (Fig. 2), thermostatted separately from the permeability cell to provide the required relative vapor pressures next to the membrane. Saturated solutions of potassium acetate and potassium thiocyanate, and distilled water, provided a complete range of relative humidities. A mixture of methanol and glycerol provided low methanol vapor pressures. Due to the low loss rate of vapor by permeation, mechanical agitation of the reservoir was not required. Dissolved air was removed by several cycles of freezing and thawing under vacuum. The temperature of the vapor tube bath was controlled to $\pm 0.02°$ C.

The vapor pressure gradient across the membrane was measured by mercury manometers at D and E (Fig. 2).

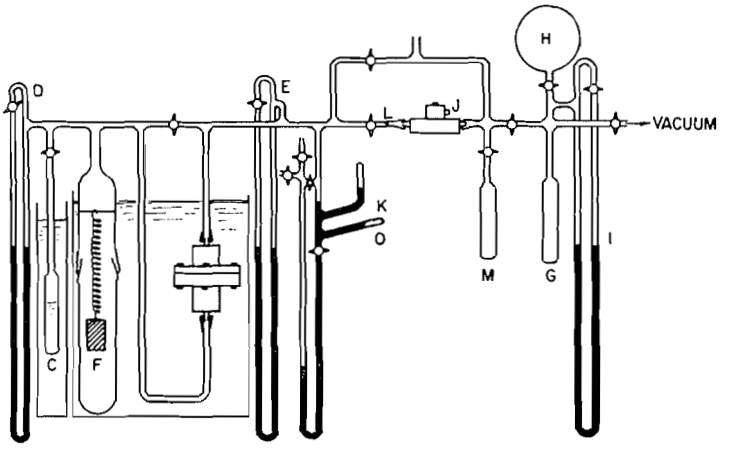

FIG. 2. Vapor permeability apparatus.

Sorption measurements were carried out with a cellophane sample suspended by a quartz spiral spring (sensitivity = 1.08 mg/mm) in a sorption cell at F. Vapor sorption was determined by measuring the extension of the quartz spring with a cathetometer, and was expressed as a percentage of the dry weight.

The vapor passing through the membrane was condensed in a cold trap G using liquid nitrogen, and measured by subsequent expansion into a known volume of the system. A calibrated volume H was used both to determine the volume of this portion of the system and to provide extra space for the expansion of large amounts of condensate. The resulting pressures were measured with a mercury manometer I.

Constant vapor pressures were maintained as required on the "dry" or low pressure side of the membrane by a solenoid-operated needle valve J. Valve action was controlled by a mercury contact switch K operating through a relay. For increased sensitivity, a fine orifice L was inserted in advance of the needle valve. Dry side vapor pressures were maintained constant to ± 0.1 mm Hg.

Materials

Both the permeability membrane and the sorption sample were cut from a single sheet of Canadian Industries Limited PT 600 (non-waterproofed) cellophane. The glycerol plasticizer was removed by extraction in water at 60° C for 2 hours.

Procedure

For several days prior to each sorption–desorption cycle, the system was continuously evacuated to remove sorbed vapors and gases from the glass tubing and the cellophane. During the time required to reach a constant transmission rate, the vapors passing through the membrane were collected in a cold trap M (Fig. 2). For a permeability measurement, this cold trap was closed off and the transmitted vapor collected in cold trap G.

All permeability and sorption measurements were carried out at $30 \pm .01$° C.

The permeabilities were expressed in terms of the mass flow rate q in g sec^{-1}, and a vapor permeability P_v defined by

$$[1] \qquad q = P_v A(\Delta p)$$

where A is the area of membrane (= 19.68 cm^2), and (Δp) is the vapor pressure difference across the membrane in dynes/cm^2. In view of the uncertainty of the thickness of the partially swollen membrane and of other complications, no attempts were made to calculate absolute permeability coefficients.

RESULTS AND DISCUSSION

Permeability to Water Vapor

1. Steady State

To ensure that a constant vapor transmission rate was attained, a series of flow rate measurements was made at each relative humidity until a constant flow rate was reached. A typical curve illustrating the change in flow rate accompanying an increase in relative humidity on the "wet" side is shown in Fig. 3. The time to reach a constant flow rate was found to decrease with increasing relative humidity, and to be shorter during sorption than during desorption. These trends were evident from the times to half-value, i.e. the time for the initial 50% change in flow rate to occur. The corresponding times to half-value for sorption were approximately one-half those of P_v at low R.H.; above 40% R.H. the times were substantially the same.

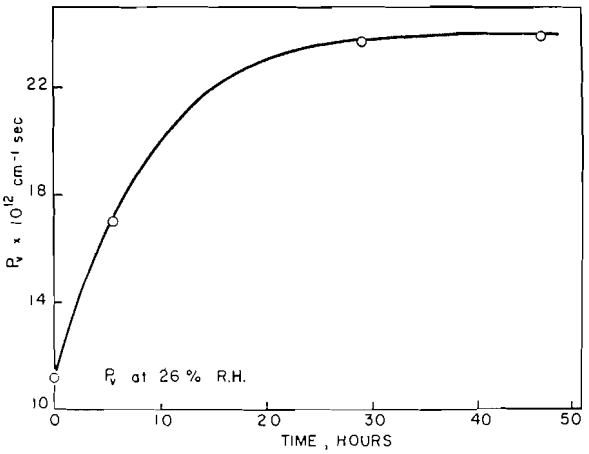

FIG. 3. Approach of permeability to equilibrium value on increasing relative humidity from 26 to 40%. Dry side at 0% R.H. The time to half-value in this experiment was 6.0 hours.

2. Permeability at Zero Back Pressure

Permeabilities for a complete sorption–desorption cycle are given in Table I. These measurements were made with zero vapor pressure on the low pressure side of the membrane.

TABLE I

Water vapor permeability (zero back pressure)

Relative humidity (wet side), %	Δp, mm Hg	$q \times 10^8$, g sec^{-1}	$P_v \times 10^{12}$, cm^{-1} sec	Moisture content, %
Adsorption				
11	3.5	6.12	0.67	4.5
26	8.2	24.2	1.12	6.5
40	12.8	79	2.38	8.3
55	17.5	234	5.03	10.8
80	25.5	1000	14.8	17.9
Desorption				
94	30.0	2000	25.1	30.6
80	25.5	1016	15.0	19.1
60	19.1	294	5.80	12.8
40	12.8	116	3.43	10.0
26	8.2	56.4	2.61	8.1
11	3.5	13.6	1.47	5.8

The permeabilities in Table I are approximately four times those reported by Doty *et al.* (5) for a comparable grade of cellophane. This is not a serious discrepancy in view of the wide variations in permeability reported by these authors for commercial films of different manufacture.

The permeability and sorption data are plotted in Fig. 4 and as others have found (6, 7) roughly parallel one another. During desorption, the curve of Fig. 4 is seen to exhibit a permeability hysteresis at relative humidities below 60%. This behavior was confirmed several times. Both the adsorption and desorption portions of the P_v curve in Fig. 4 extrapolate smoothly to the origin indicating that dry cellophane is impervious to water.

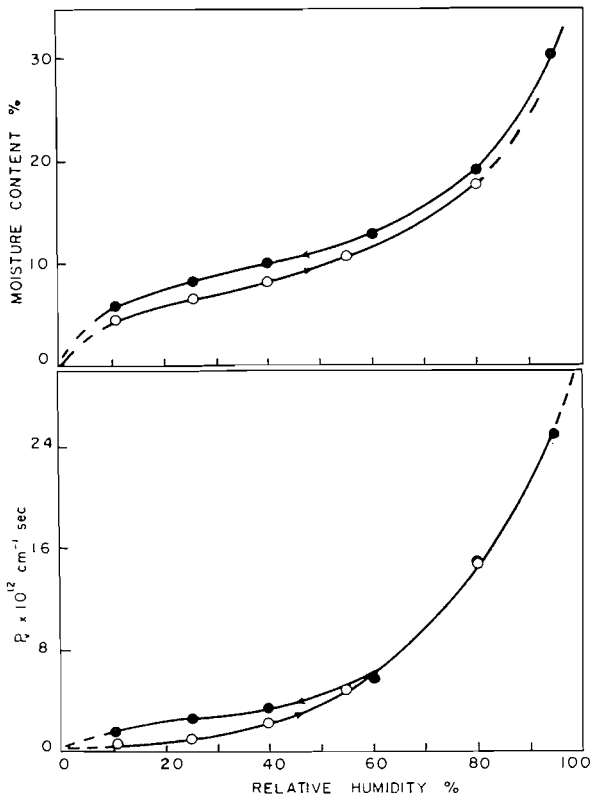

FIG. 4. Water vapor sorption (upper part) and permeability at zero back pressure (lower part) for adsorption (open circles) and desorption (solid circles).

3. Reduced Moisture Gradients

The effect of reducing the moisture gradient across the membrane was studied by introducing constant water vapor pressures on the low pressure side of the membrane. The results obtained with pressures corresponding to 20% R.H. are given in Table II

TABLE II

Water vapor permeability
(20% relative humidity on low pressure side)

Relative humidity (wet side), %	Δp, mm Hg	$q \times 10^8$, g sec^{-1}	$P_v \times 10^{12}$, cm^{-1} sec
Adsorption			
26	1.8	12.9	2.7
55	11.2	360	12.1
65	14.1	730	21.2
75	17.0	1320	29.2
Desorption			
70	15.5	1080	26.2
65	14.1	920	24.8
55	11.2	500	16.8
33	4.2	105	9.5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

for a complete cycle. These data together with values at 0, 10, and 15% R.H. are shown in Fig. 5. In order to show the trends more clearly, values of q have been plotted.

Figure 5 shows that the reduction in moisture gradient across the membrane has caused an increase in the vapor transmission rate at all relative humidities. The q curves during adsorption for the three back pressures used coincide, indicating that the increase in q is independent of the pressure used.

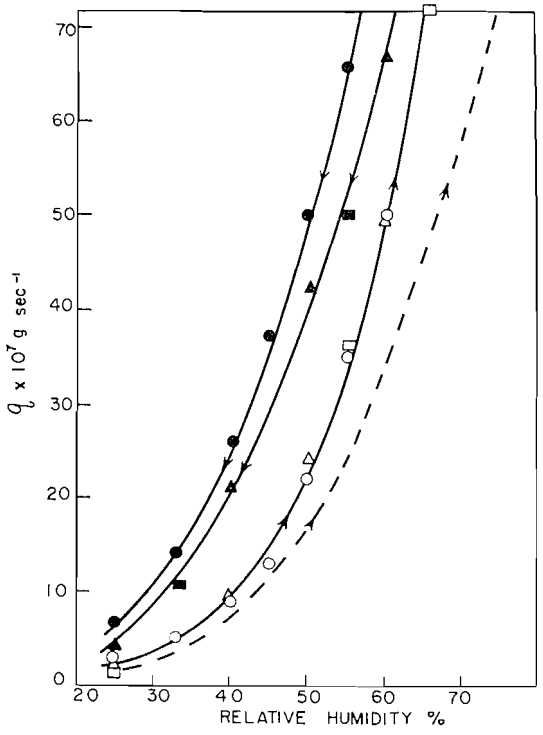

FIG. 5. Water vapor flow rates during adsorption (open points) and desorption (solid points) at 10% (circles), 15% (triangles), and 20% (squares) relative humidity on the low pressure side. The broken line is for adsorption at zero R.H. on the low pressure side.

A second effect of a reduced moisture gradient is seen in the extension of the permeability hysteresis to relative humidities above 60%. There also appears to be a trend toward a reduction in the magnitude of the hysteresis as the low pressure side relative humidity is increased.

TABLE III

Organic vapor permeabilities (zero back pressure)

Permeant	Δp, mm Hg	$q \times 10^8$, g sec^{-1}	$P_v \times 10^{14}$, cm^{-1} sec	% sorption
Methanol	45.5	1.47	1.21	1.4
	81.9	10.5	4.85	1.8
	133	94	26.7	6.9
Ethanol	40.0	0.93	1.08	—
	60.1	2.50	1.57	—
	79.0	7.09	3.39	—
Benzene	67.6	2.32	1.3	0.03
	97.7	7.26	2.8	0.08

Permeability to Organic Vapors

Various organic vapors are adsorbed less than water and it was thought that P_v might be independent of Δp when the sorption became negligible. The permeabilities of methanol, ethanol, and benzene at zero back pressure are given in Table III. These data show that the permeability to organic vapors is considerably less than to water vapor. The flow rate of methanol vapor, for example, at 45.5 mm Hg pressure is less than 1/600 that of water vapor at 25.5 mm Hg pressure (Table I).

Sorption measurements on methanol and benzene are included in Table III and show that P_v increases with the sorptions.

It is seen from Table III that P_v did not remain constant but in all cases increased with increase in Δp.

PARTIAL SPECIFIC VOLUME MEASUREMENTS BY DIFFERENTIAL SEDIMENTATION[1]

W. G. MARTIN, C. A. WINKLER,[2] AND W. H. COOK

ABSTRACT

The partial specific volumes of several macromolecules were determined from their sedimentation rates in aqueous and heavy water solutions with results comparable to those obtained by conventional methods. Corrections for the changes in weight due to isotopic exchange were obtained from measurements on small quantities of material with a quartz spiral balance. Measurements of the partial specific volumes of bovine plasma albumin, polyvinyl alcohol, glycine, and triglycylglycine in both aqueous and heavy water media, made with a magnetic float apparatus, indicate that isotopic exchange has no significant effect on the macromolecular volume. The sedimentation method is therefore a micro method that does not require a knowledge of the concentration of macromolecules and which is applicable to mixtures that are resolvable during sedimentation.

INTRODUCTION

In a recent paper (1) it was shown that measurement of the differential rate of sedimentation of macromolecules dissolved in water or deuterium oxide solvents could yield a sufficiently accurate estimate of their partial specific volume ($\bar{v}$) to be useful in estimating molecular size by sedimentation methods. Although the inherent accuracy is less than that of the conventional methods (pycnometry and magnetic float), the procedure has several advantages: it can be used when only small amounts of material (ca. 10 mg) are available; other methods require purified material whereas the sedimentation method should be applicable to mixtures, provided the boundaries can be resolved; finally, this method is applicable to materials (lipoproteins) where density and other properties are altered by contact with immiscible organic liquids used to establish density gradient columns. These advantages are so great in the preparative stages of any new biological macromolecule, or with any scarce material, that further study and development of the method were well justified.

As mentioned in the earlier paper (1), other investigators (2) have used salts and nonelectrolytes to alter the density of the media of sedimentation. Since these substances interacted with the sedimenting solutes and brought about spurious results, Sharp *et al.* (3) sedimented viruses in heavy water media. Recently polystyrene latex spheres were sedimented in aqueous and heavy water mixtures (4, 5), but here hydration and isotopic exchange of labile hydrogen were not involved. Katz and Schachman (6) have obtained an adequate value of $\bar{v}$ from sedimentation of deoxyribonucleic acid at constant concentration in media in which the density was altered by the addition of heavy water. However, with most biological macromolecules it is necessary to consider the extent of exchange of labile hydrogen atoms in heavy water media. True, as in our earlier paper, isotopic exchange may be estimated for well-known materials, but not so for new unknown macromolecules. Therefore a procedure for determining the degree of substitution on micro quantities of material by direct weighing was developed and critically compared with the substitution indicated by density methods. In addition to measurements on

proteins, some relatively extensive measurements were made on glycine and triglycylglycine where substitution is proportionately higher. Finally, the aqueous – heavy water sedimentation procedure was tested on mixtures of proteins of known and unknown $\bar{v}$ to confirm the applicability and accuracy of the procedure as applied to such systems.

MATERIALS

Crystalline bovine plasma albumin lot No. A1201 (Pentex Inc.), crystalline bovine β-lactoglobulin lot No. 0053B (Armour and Co.), and triglycylglycine lot No. 7484 (Nutritional Biochemicals Corp.) were used without further purification and will be referred to as BPA, βLG, and TGG, respectively. Polyvinyl alcohol (Shawinigan Chemicals Ltd.), termed PVA, was dissolved in distilled water, centrifuged, filtered, and then lyophilized. The PVA had a remnant of 12 acetate groups per 100 mers owing to incomplete alcoholysis. Glycine (Eastman) was dissolved in warm water and filtered from a slurry of charcoal and celite, then precipitated with methanol, washed with methanol–ether, and dried at 45° C *in vacuo*.

Livetin (7), the water-soluble protein of hen egg yolk, was separated into its α–β-components and γ-components by the procedures of Martin *et al.* (8, 9). Lipovitellin of yolk was prepared by the method of Joubert and Cook (10). It was possible to store the α–β-livetin in a lyophilized condition but the lipovitellin and γ-livetin had to be stored at 5° C in solution.

A stock of distilled water was prepared by adding potassium permanganate to alkaline tap water and distilling with a minimum of reflux. The distillate, redistilled with a minimum of reflux, was assumed to have a density of 0.997074 g/ml at 25.000° C.

Deuterium oxide (99% D_2O) and a quartz spiral were purchased from Merck & Co., Inc., and Microchemical Supply Co., respectively.

METHODS

The sedimentation procedures were as described previously (1) with some modifications. Solutes in appropriate solvents were dialyzed at 5° C against solvent. Suitable dilutions were then made using diffusate as diluent. Viscosity and density measurements on diffusates were made with Ostwald–Fenske type viscometers and with a Mohr–Westphal balance, respectively, at 20° C, since sedimentation experiments were controlled at this temperature. Solute concentrations were determined from measurements with a differential refractometer (11) from previously determined values of the specific index increments. Transfer of solutions was effected by use of dry syringes to minimize exchange of heavy water with atmospheric moisture.

In order to interpret the changes in $\bar{v}$ of macromolecules brought about by isotopic exchange, the direct weight increase upon exposure to heavy water was measured on a McBain–Bakr quartz spiral balance (Fig. 1). The balance apparatus consisted of vacuum pump A, oil diffusion pump B, gas inlet control system C and D, trap E, ionization gauge F, pyrex glass balance case containing quartz spiral and sample basket, and movable permanent magnets L. Capillary tube G permitted insertion of syringe needles. Heater M containing thermometer N was removable. Auxiliary apparatus could be connected at H.

Aluminum foil baskets were dipped into silicone grease dispersed in benzene, and then dried at 110° C. Baskets with capacity of 1 or 2 ml weighed about 40 to 60 mg. The spiral was calibrated *in vacuo* by measuring the extension caused by the addition of calibrated platinum weights. Extensions were measured with a Wild cathetometer

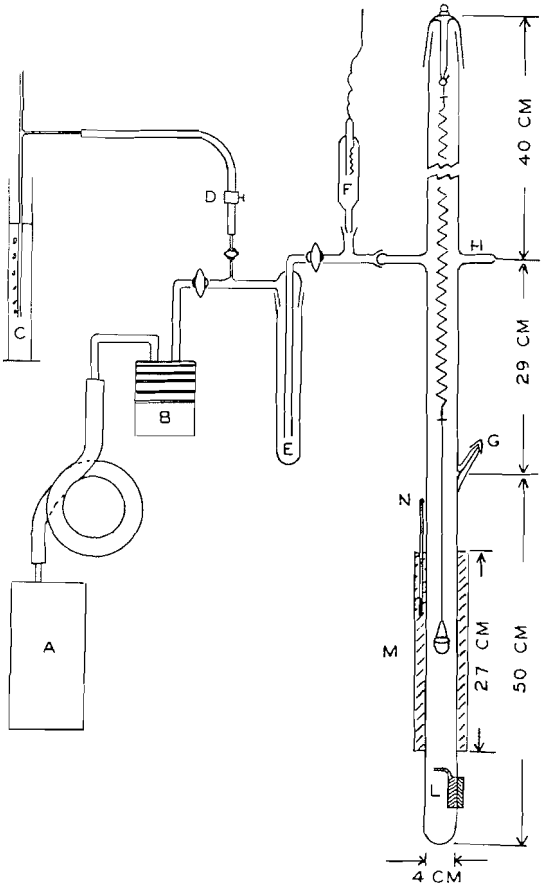

FIG. 1. Quartz spiral balance apparatus.

at 25° C to 0.01 mm with a precision of reading of ±0.02 mm. The sensitivity of the spiral was 1.00±0.02 mg/mm extension with loads ranging from 24 to 198 mg.

Measurements were made of spiral extension *in vacuo* with the empty basket suspended and the trap E immersed in liquid nitrogen. Then nitrogen gas was slowly admitted to the system through the trap until atmospheric pressure was reached. About 150 mg of sample was added to the basket and the system evacuated until constant weight was reached. Nitrogen gas was admitted to the system through the trap and about 1 ml of water was directed into the basket through capillary G while the basket was supported by the magnets. After an equilibrium period of 15 to 20 hours the basket was lowered in the balance case and the sample was frozen *in situ*. Lyophilization was brought about and evacuation continued until constant weight again occurred. Similarly, two to three applications of deuterium oxide were applied to the sample and sometimes followed by two more applications of water. Equilibrium weights were also obtained at selected temperatures (< 105° C) by adjustment of the movable furnace M about the basket. Once a sequence of exchanges had commenced, the trap E was kept immersed in liquid nitrogen. When deuterium oxide was added to samples, a small flow of nitrogen gas passed through the system by way of the trap.

To provide a standard of comparison with $\bar{v}$ obtained by the sedimentation method, $\bar{v}$ was also determined from measurements of density made with a magnetic float apparatus (12, 13). Usually weighed quantities of diffusate were placed in the float chamber and then weighed amounts of concentrated stock solutions were added, with density measurements being made upon each addition. However, owing to the impossibility of dialysis of glycine or TGG solutions, solvents were obtained by cryosublimation from their frozen solutions, and solvents and residual concentrated solutions used in the manner of the diffusates and solutions mentioned above.

Solute concentrations for the float measurements were based on dry weight. Deuterated samples were brought to constant weight, then two additions of water were made with intervening drying to get the dry weight of the protonated sample. At the temperature of 105° C *in vacuo*, employed for the other materials, glycine samples failed to reach constant weight, and therefore the effect of temperature on glycine was examined with the spiral balance. Based on these measurements, glycine was brought to constant weight at 70° C *in vacuo*.

RESULTS

Difficulty in achieving constant dry weight of glycine samples at 105° C *in vacuo* is understandable in view of the results shown in Fig. 2 for the spiral extension when the basket containing glycine was heated to various temperatures. Rapid loss of weight, accompanied by sublimation of the sample, occurred *in vacuo* at temperatures above 74° C. The other materials presented no serious drying difficulties. Even with the lipid-containing lipovitellin, only a slight loss in weight occurred between 25 and 91° C *in vacuo*.

The extent of exchange of deuterium for hydrogen atoms in the materials is shown in Table I, 97.4% deuterium oxide being the exchange medium. In a few instances experiments with the spiral balance had to be repeated owing to dusting or loss of small pieces of the material during drying. Concentrated solutions gave less trouble in this respect.

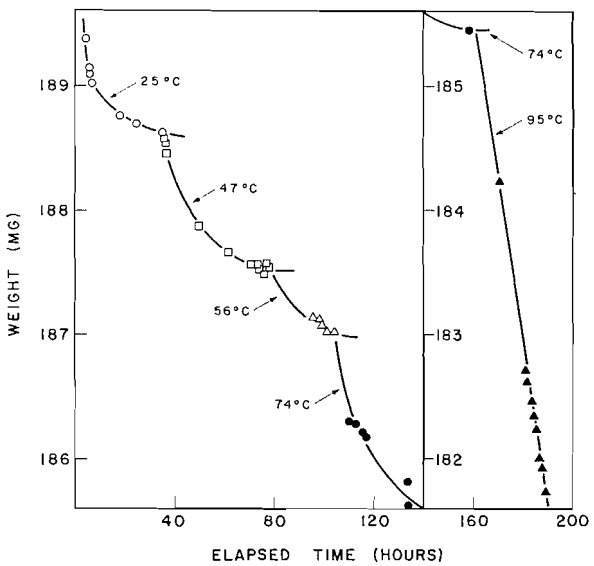

FIG. 2. Weight (extension) of glycine as a function of temperature and heating time *in vacuo*.

γ-Livetin	1.36	—

*Based upon 97.4% of D_2O and equilibrium at 25° C.

The isotopic exchange of deuterium with the labile hydrogen atoms of BPA was investigated at intermediate concentrations of heavy water and the results shown in Fig. 3 illustrate the essential linearity of the relation between volume per cent of heavy water and the percentage weight increase of the material.

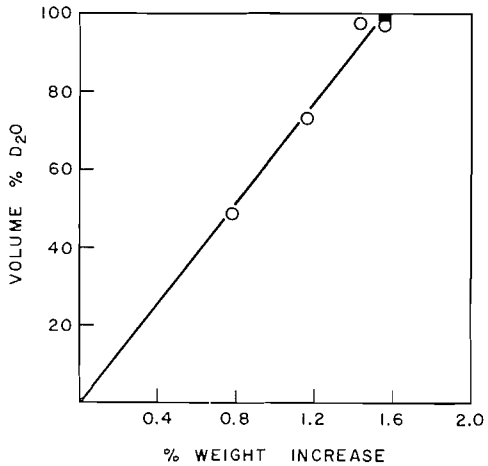

FIG. 3. Relation between D_2O concentration and weight increment of bovine plasma albumin. ○ Experimental. ■ Calculated.

From the exchange measurements or, lacking these, published data, the value of k (1) was calculated from

$$[1] \qquad k = 1+[(\Delta w)(d_1-d_0)/\Delta d]$$

where Δw is the weight increase per gram of sample, (d_1-d_0) is the increment in density of the solvent due to deuterium oxide, and Δd is the increment in density of 100% deuterium oxide over the density of water.

$$[2] \qquad f\eta s = Mk(1-\bar{v}k^{-1}d)$$

was given in the previous paper (1), where f, η, s, M, d are the frictional coefficient, solvent viscosity, sedimentation coefficient, molecular weight of the macromolecule, and solvent density, respectively. As shown in Fig. 4 the relation between $\eta s/k$ and d/k for BPA and PVA (concentration 0.4 g/100 ml) in media of varying concentrations of heavy water

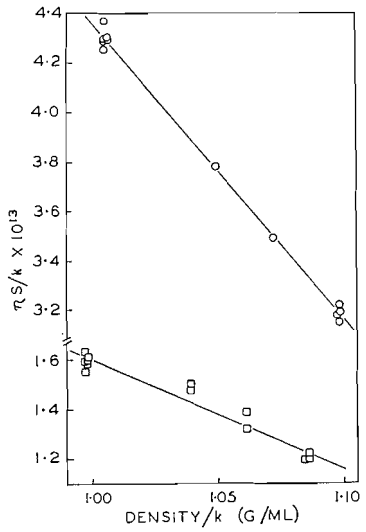

FIG. 4. Relation between $\eta s/k$ (solvent) and d/k (solvent) for bovine plasma albumin and polyvinyl alcohol. ○ BPA. □ PVA.

is essentially linear, as expected from inspection of equation [2]. Moreover, from the intercepts at the values of $\eta s/k$ equal to zero, where $\bar{v}$ equals the reciprocals of the intercepts d/k, $\bar{v}$ was 0.735±0.003, and 0.735±0.013, for BPA and PVA, respectively.

Since the above results and those of others (2, 3, 6) demonstrate the linearity of equation [2] when heavy water is used to alter the density of the solvent, the equation

$$[3] \qquad \bar{v} = (\eta_2/\eta_1 - ks_1/s_2)(d_1\eta_2/\eta_1 - d_2s_1/s_2)^{-1},$$

derived in the earlier paper (1), was used to calculate $\bar{v}$ from sedimentation experiments on macromolecules including single solutes and mixtures. Sedimentation coefficients were extrapolated to zero solute concentration by use of relative values of diluted initial stock solutions and are recorded in Table II, as are also the related solvent viscosities

and densities. The values of k were based upon measured values (Table I) except for βLG, where k was estimated from the amino acid composition (14). Values of $\bar{v}$ obtained by the sedimentation method are shown in Table III. The errors were calculated according to equation

$$[4] \qquad \Delta\bar{v} = \eta_1\eta_2(kd_1-d_2)(s_1+s_2)(d_1s_2\eta_2-d_2s_1\eta_1)^{-2}[(\Delta^2s_1 + \Delta^2s_2)/2]^{\frac{1}{2}}$$

where Δ is to be read "the standard error of" (1).

From measurements of density with the magnetic float apparatus of solutions BPA, PVA, glycine, and TGG in water and heavy water, $\bar{v}$ values were computed for the protonated and deuterated macromolecules, as shown in Tables III and IV. Based upon the measured $\bar{v}$, the fractional changes in $\bar{v}$ upon exchange of labile hydrogen atoms with deuterium atoms were calculated and compared with the values to be expected from the degree of substitution given in Table I.

Values without references are from this work.

In Table III the calculated values of $\bar{v}$ for BPA and βLG were reported by McMeekin and Marshall (15), while that of PVA was obtained by use of the atomic volume increments derived by Traube (16). Of the published values of $\bar{v}$, that of BPA (13), lipovitellin (10), and γ-livetin (9) were obtained by use of a magnetic float, while that of βLG (17) was obtained presumably by use of pycnometers.

DISCUSSION

The weight increases (Table I) that occur upon exchange of labile hydrogen atoms with deuterium atoms are accompanied by changes in $\bar{v}$ as shown by the data in Table IV. The experimentally determined decreases in $\bar{v}$ of PVA, TGG, and glycine were in reasonable agreement with the values calculated on the assumption that the volume occupied by deuterium atoms in a material is similar to that of the displaced hydrogen atoms. The decrease in $\bar{v}$ of BPA was less than the theoretical value, although complete exchange would be expected on the basis of the spiral balance measurements. However, Robertson (18) has reported that an expansion is likely to occur in the direction of the hydrogen bonds upon deuteration, an effect of greater importance in BPA than in PVA, TGG, or glycine. The extent of such an effect on proteins would be unpredictable owing to the several types of hydrogen bonding. Errors in $\bar{v}$ due to measurements with the

float apparatus have already been discussed (12, 13) and, even with the added difficulties of dealing with heavy water, are not enough to account for the small $\Delta\bar{v}$ for BPA.

Specific volumes of organic substances with known composition and functional groups can be calculated from atomic volume increments derived by Traube (16) and recently employed by others to evaluate $\bar{v}$ of proteins (19, 15). Calculated and experimental values of $\bar{v}$ for BPA and other proteins agree well if the decrease in volume due to charged groups (electrostriction) is ignored. Electrostriction should occur in proteins as it does in amino acids and peptides. Cohn and Edsall (19) report electrostriction values of 13.5, 16.1, and 16.1 for glycine, glycylglycine, and diglycylglycine, while in this work values of 12.6 and 19.1 ml/mole were obtained for glycine and triglycylglycine, respectively. Thus the effect of electrostriction in proteins must be nullified by a compensating factor. There may be a steric effect due to the folding and packing of the peptide chains whereby a small volume (excluded volume) is rendered inaccessible to solvent (20, 13), although the exchange reactions in heavy water showed a ready accessibility in BPA.

The available and observed $\bar{v}$ values for the macromolecules used in this study are summarized in Table III. Obviously, calculated values can be reported only for materials of known composition and functional groups. Clearly, the sedimentation method with BPA permits evaluation of $\bar{v}$ in complete agreement with calculated and magnetic float values, despite the small $\Delta\bar{v}$ value discussed above. Applied to a mixture of BPA and βLG, the value of $\bar{v}$ for BPA was about 1.5% lower and that for βLG in agreement with the calculated and reported values. The agreement of $\bar{v}$ of lipovitellin by the sedimentation and float methods indicates the applicability of the sedimentation method to lipoproteins. The minor sedimenting component, termed protein X, which always accompanies lipovitellin at pH 9.0, had a $\bar{v}$ value of 0.79±0.03 by the sedimentation method, which serves to distinguish it from γ-livetin, which had a $\bar{v}$ of 0.70±0.02 by sedimentation and 0.726±0.001 by the float method, although these two substances have similar sedimentation and electrophoretic characteristics in aqueous media. It is likely that protein X is a lipoprotein. Although the α–β-livetins could not be resolved sufficiently for accurate measurement of their individual $\bar{v}$ values, the value obtained for the mixture is reasonable for protein material.

It is worth mentioning, perhaps, that values of $\bar{v}$ are obtainable by sedimentation measurements without recourse to knowledge of solute concentration. In fact, the evaluations of $\bar{v}$ from the experiments on mixed macromolecules were made on the basis of relative concentrations only. Also, since the concentrations of the macromolecules in the mixtures were low and extrapolations were made to zero concentration, the Johnston–Ogston effect (21) would be small. In any case, the effect would be similar in aqueous and heavy water solutions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Thus it would be possible to obtain $\bar{v}$ of macromolecules even in impure preparations in which resolvable boundaries are evident upon sedimentation in aqueous and heavy water media. A 1-ml sample containing about 10 mg of solute may be dialyzed versus solvent, dilutions made, and sedimentation coefficients determined. Density and viscosity may easily be measured upon the diffusate. The extent of isotopic exchange may be estimated or measured by direct weight increase on a quartz spiral balance of suitable sensitivity. By differentiation of equation [3] it may be estimated that neglect of this factor will introduce an error of about four to six per cent in $\bar{v}$. However, by taking an estimated figure of about 1.015 for k of protein, the error involved would be within the error of the sedimentation method of evaluating the partial specific volumes.

THE MECHANISM OF THE PHOTOOXIDATION OF ACETALDEHYDE AT ROOM TEMPERATURE[1]

JACK G. CALVERT AND PHILIP L. HANST[2]

ABSTRACT

The initial rates of product formation in the photooxidation of acetaldehyde at room temperature have been determined through the use of infrared spectrometry. The rates of formation of the products peroxyacetic acid, carbon monoxide, carbon dioxide, methanol, formic acid, and acetic acid were determined in experiments with various pressures of acetaldehyde, oxygen, and added gases. The amounts of methylhydroperoxide and acetylperoxide formed in all of the experiments were below the detection limit of the analytical methods. The results require that some modification and corrections be made to the mechanism suggested by McDowell and Sharples.

INTRODUCTION

Recently McDowell and Sharples (1) published a series of kinetic studies of the photooxidation of acetaldehyde and propionaldehyde. The reactions were followed by the titration of the peroxyacid formed. Reported here is a study of the photooxidation of acetaldehyde in which a more detailed product analysis has been made through infrared absorption spectroscopy. The results show that the simple mechanism which McDowell and Sharples have inferred from their rate studies is very incomplete, and in some respects, it is incorrect. Some suggested modifications and corrections to their mechanism are presented.

EXPERIMENTAL

Apparatus and Materials

Our experiments were basically similar to those of McDowell and Sharples (1). We used comparable amounts of acetaldehyde in oxygen, and we photolyzed at room temperature with light in the range 3000–3300 Å. In order to accelerate the rates and facilitate the identification of the products of the chain-initiating and chain-terminating reactions, we used intensities about 1000 times those employed by McDowell and Sharples.

The acetaldehyde (Eastman-Kodak, white-label, fractionated at reduced pressure), oxygen (Linde tank gas), and other added gases were mixed in a 10-cm Pyrex-body infrared absorption cell which was mounted in the sample beam of a Perkin–Elmer Model 21 double beam infrared spectrometer. The side of the cell was exposed to the radiation from a Pyrex-jacketed, water-cooled, high pressure mercury arc (AH-6) which was fastened about 10 inches from the cell. The absorption characteristics of the water jacket and the cell body limited the effective radiation to the range 3000–3300 Å. The maximum intensity of the light absorbed by the aldehyde was near 3100 Å.

The other reactant gases and standards for analysis were obtained as follows: tetramethylethylene was the research grade Phillips product; peroxyacetic acid and acetylperoxide were obtained from Becco and purified by distillation at reduced pressure; ozone was prepared as needed by a simple ozonizer apparatus; the oxides of carbon were reagent gases of the Air Reduction Co.; methanol was the Mallinckrodt Analytical

Reagent; acetic acid was the DuPont Reagent product; nitrogen was the Linde dry tank gas.

Procedures and Results

The total pressure of the reaction mixture was adjusted to about 740 mm by the addition of nitrogen gas. Infrared absorption spectra of the products of the runs and standard gases were measured under similar conditions of pressure, resolution, and absorption.

The scale expansion feature of the Perkin–Elmer Model 21 infrared spectrometer made possible the determination of initial rates of formation of the products. Since it appears that similar application of this valuable technique has not been made in previous published kinetic studies, we wish to describe the method briefly. The scale expansion enables one to magnify small absorptions by selection of a 5-, 10-, or 20-fold signal amplification. With this amplification "initial" rates are easily measurable on amounts of material which normally would escape detection by infrared analysis. In the study here reported an accurate rate could be determined after only a few tenths of one per cent conversion of the reactants. The concentrations of the products were determined at the characteristic absorption regions: peroxyacetic acid, 8.1 and 3.05 μ; acetic acid, 7.7 μ; carbon dioxide, 4.31 μ; carbon monoxide, 4.63 μ; methanol, 9.68 μ; formic acid, 9.05 μ; methylhydroperoxide, 12.2 μ; acetylperoxide, 8.6 and 11.75 μ; methane, 7.7 μ; ethane, 12.4 μ; acetaldehyde, 3.7, 5.69 μ. There were no unexplained regions of absorption. Illustrative of the rate data obtained by this method is that given in Fig. 1

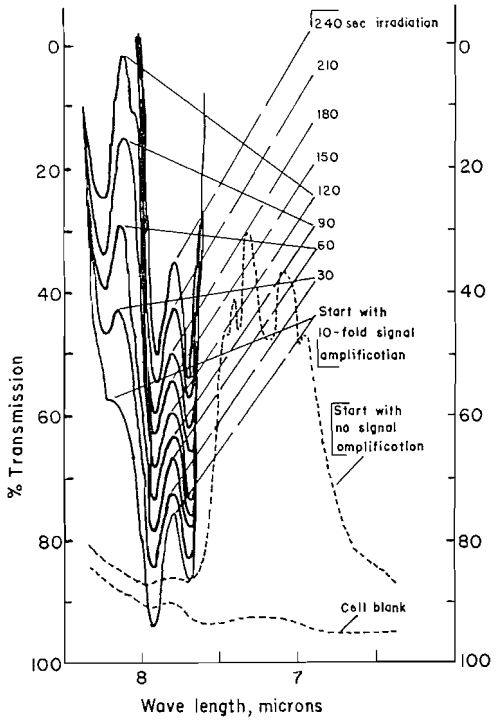

FIG. 1. A typical portion of the infrared absorption spectrum of an irradiated acetaldehyde–oxygen mixture, recorded during run 2 of Table I: the upper dotted curve shows the initial absorption of the mixture without amplification; the multiple peaks at 7.8 (due to CH_3CO_2H) and 8.1 μ (due to CH_3CO_3H) were recorded with a 10-fold signal amplification after successive 30-second exposures.

[a]After 10 minutes' exposure there was no detectable amount of CH_3O_2H (on 20-fold amplification) at its absorption band at 12.2 μ or $(CH_3CO_2)_2$ at its 8.6- and 11.8-μ bands; $R_{CH_3O_2H} < 0.003$ mm/minute; $R_{(CH_3CO_2)_2} < 0.0005$ mm/minute.

[b]Other measurable product rates in this O_2-free run were: $R_{C_2H_6} = 0.01_4$; $R_{CH_4} = 0.083$.

[c]These rates have been corrected for a large thermal reaction, so the accuracy of them is not large.

[d]Possible traces of CH_3COCH_3 formed as detected at the characteristic band near 8.2 μ.

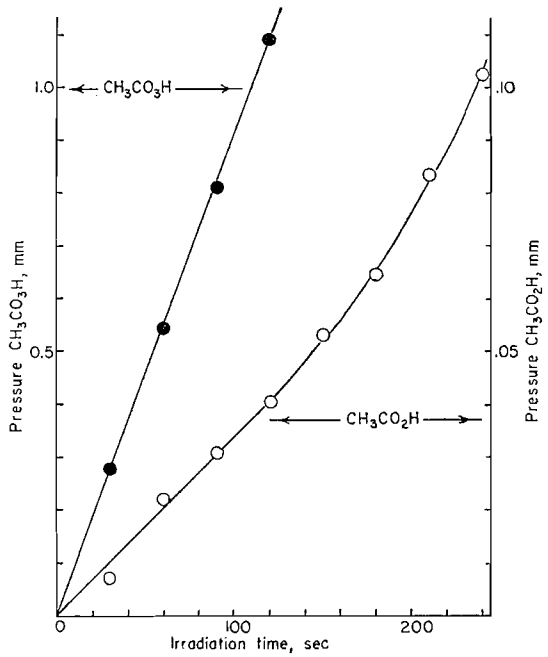

FIG. 2. Pressures of the peracetic acid and acetic acid products as a function of irradiation time (calculated from the data of Fig. 1, and recorded during run 2 of Table I).

(obtained for run 2 of Table I). Shown are the 7.8- (acetic acid) and 8.1-μ (peroxyacetic acid) regions scanned with 10-fold signal amplification after successive exposures each of 30 seconds' duration. These data yielded the product pressure – time plot of Fig. 2. All of the initial product rate data summarized in Table I were obtained from similar absorption measurements.

One of the products of the reaction, formic acid, is not shown in Table I since it was impossible to determine it accurately with small conversions; the major absorption bands

overlapped those of the reactant, acetaldehyde. A test for the mass balance of the products was made in similar experiments in which a more extensive conversion was allowed (exposure time 30 minutes). These results are shown in Table II. It is seen that an adequate accounting can be made for all of the acetaldehyde which has reacted.

There was no measurable dark reaction between oxygen and acetaldehyde under any of the conditions used. When ozone was added to the oxygen–aldehyde mixture a rapid dark reaction occurred for which correction was made to estimate the "photochemical" rates (run 13, Table I).

DISCUSSION

Limitations of the McDowell and Sharples Mechanism

Our data show that the McDowell and Sharples mechanism (1) of acetaldehyde photooxidation should be revised in several important respects. First, the conventional chain-initiating steps which they suggest involving peroxy radicals seem unimportant for this system:

$$CH_3CHO + h\nu \rightarrow CH_3 + CHO \qquad [I]$$

$$R + O_2 \rightarrow RO_2 \ (R = CH_3 \text{ or } CHO) \qquad [1]$$

$$RO_2 + CH_3CHO \rightarrow RO_2H + CH_3CO. \qquad [2]$$

Methylhydroperoxide, one of the expected products of reaction [2], was below the detection limit of the infrared equipment using the most sensitive 20-fold signal amplification. We estimate that the rate of formation of this product, if formed at all, must be less than 0.003 mm/minute. If this result is coupled with the facts that the chain lengths are relatively short in our experiments,* and methylhydroperoxide is comparatively stable under the conditions used (2), then reaction [2] of the McDowell and Sharples mechanism must be unimportant in the photooxidation of acetaldehyde.

Secondly, the expected product of the termination step of the McDowell and Sharples mechanism, acetylperoxide, was not formed in detectable quantities in our experiments; its rate of formation in run 4 of Table I must have been less than 0.0005 mm/minute, if it was formed at all. Obviously, one should question the McDowell and Sharples assignment of the kinetic rate constant of the termination reaction derived from rotating sector experiments to the reaction [3]:

$$2CH_3CO_3 \rightarrow (CH_3CO)_2O_2 + O_2. \qquad [3]$$

Thirdly, cognizance should be taken of the variety of products other than peroxyacetic acid which are formed in the photooxidation of acetaldehyde, as they are not insignificant, and a proper consideration of them should help in the correct mechanism choice.

Revised Mechanism of Acetaldehyde Photooxidation

In view of our findings in the study of the azomethane photooxidation (2) and data here presented, we favor a mechanism of acetaldehyde photooxidation involving ozone as an intermediate product. Ozone has not been detected by direct spectroscopic observations in the irradiated acetaldehyde–oxygen system. However, it is a reasonable extrapolation

*$\Phi_{CO} \cong 0.2$ *in the oxygen-free acetaldehyde photolysis at 25° and 3130 Å (3). Using the rate data of Table I, run 8 (in the absence of oxygen) and run 7, one estimates the maximum chain length for peroxyacetic acid formation in these experiments to be about 20; this assumes that the primary efficiency of free radical formation in acetaldehyde photolyses at 3130 Å is 0.2 (4, 5). The estimate of chain length represents a maximum since the primary efficiency may be considerably higher (0.8) in experiments at low oxygen pressures. See the discussion in the section on the primary efficiency.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

to this system from the systems in which it has been observed. If we accept the hypothesis of ozone participation in the mechanism, we expect the steady state concentration of ozone to be very low (10^{-3} to 10^{-5} mm) because of its rapid reaction [4] with free radicals.

$$O_3 + R \rightarrow RO + O_2 \qquad [4]$$

Reaction [4] would not have the three-body restriction which has been observed for the reaction of methyl radicals with O_2 (6, 7, 8), and it would be considerably faster. We consider the mechanism here proposed to be a reasonable postulate which is consistent with the facts at hand and is worthy of further testing.

Chain-initiating Steps

It is probable that the formation of CH_3O_2 (and CHO_3) radicals in the photooxidation of acetaldehyde occurs as the first step in the reaction of CH_3 (and CHO) with O_2. The fact that the expected products, CH_3O_2H and HCO_3H, are not found in the photooxidation of acetaldehyde, but rather CH_3OH and HCO_2H are observed, suggests the rapid removal of these radicals by some other path than H-abstraction. We feel that the removal of CH_3O_2 (and HCO_3) may occur either by the mechanism of Bell and coworkers (9),

$$2CH_3O_2 \rightarrow 2CH_3O + O_2, \qquad [5]$$

or by the alternative reactions which we have favored in the azomethane photooxidation (2);

$$CH_3O_2 + O_2 \rightarrow CH_3O + O_3 \qquad [6]$$

$$HCO_3 + O_2 \rightarrow HCO_2 + O_3. \qquad [7]$$

In either case chain initiation in the photooxidation of acetaldehyde is presumed to involve the CH_3O and HCO_2 radicals; this interpretation is consistent with the observed products. If reaction [5] were the source of CH_3O we would expect some H-abstraction from aldehyde and a detectable yield of CH_3O_2H (the rate of [5] is proportional to $[CH_3O_2]^2$); to expect this reaction to occur to the exclusion of [2], whose rate is proportional to $[CH_3O_2][CH_3CHO]$, seems unrealistic. Thus we favor the alternative mechanism of CH_3O and HCO_2 formation in reactions [6] and [7].

Chain-termination Reactions

Some obvious alternatives to the unobserved acetylperoxide formation for chain termination are reactions [8], [9], and [10]:

$$2CH_3O \rightarrow CH_3OH + CH_2O \qquad [8]$$

$$CH_3O + CH_3CO_3 \rightarrow CH_2O + CH_3CO_3H \qquad [9]$$

$$CH_3O + CH_3CO_2 \rightarrow CH_2O + CH_3CO_2H. \qquad [10]$$

Under our conditions CH_2O would be rapidly converted to CHO_2H, with small amounts of CO, CO_2, and possibly other products (2).

The Efficiency of Radical Formation in Acetaldehyde Photooxidation

Note in Fig. 3 the increase in the rate of formation of the peroxyacetic acid, methanol, and carbon dioxide products as the oxygen pressure is lowered. We interpret this to indicate an increased quantum efficiency of radical formation at the lower oxygen pressures. That is, a certain fraction of the excited acetaldehyde molecules are deactivated by oxygen, and the fraction so deactivated before the possible decomposition into radicals decreases with decrease in oxygen pressure. With this interpretation we estimate from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

the relative rates of CH_3CO_3H formation at the high and the low oxygen pressures that about 76% of the electronically excited ($\lambda \cong 3100$ Å) molecules of acetaldehyde which normally decompose in the absence of oxygen can be deactivated at the high concentrations of oxygen. This value checks well with the observed deactivation of 3130 Å light-activated acetaldehyde by added iodine. In this case it has been estimated that 75% of the electronically excited aldehyde molecules which decompose in the absence of iodine are deactivated when iodine is added (10).

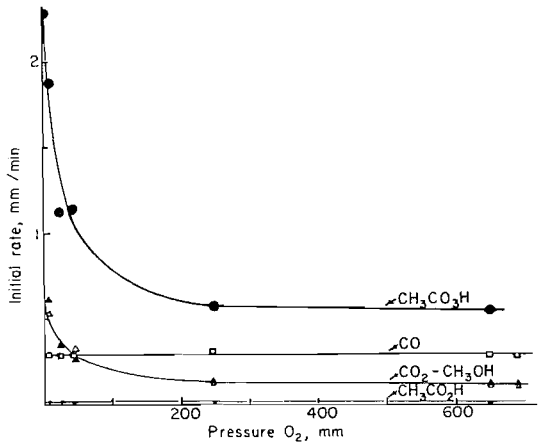

FIG. 3. Initial rates of formation of products of the photooxidation of acetaldehyde as a function of oxygen pressure: $P_{CH_3CHO} = 42.5$ mm; $P_{N_2} + P_{O_2} + P_{CH_3CHO} \cong 740$ mm; wave lengths of absorbed light, 3000–3300 Å; temperature, 20°.

Mechanism of Formation of CO_2 *and* CH_3OH

From the data of Table I the ratio R_{CH_3OH}/R_{CO_2} is seen to be near unity. In Fig. 3 it is seen that the rate of increase of CO_2 and CH_3OH at low oxygen pressures parallels that for CH_3CO_3H. In view of these results we first postulated that the CO_2 and CH_3OH arose from the thermal or photochemical decomposition of a portion of the primary product peroxyacetic acid. However, the initial rates of formation of CO_2 and CH_3OH are not measurably increased when peroxyacetic acid is added at the start of the run (see runs 11 and 12 of Table I), so that these products clearly are not derived from peroxyacetic acid. The only difference in the runs with added peroxyacid is the acceleration of the rate of CH_3CO_2H formation. This effect will be described later.

If we accept the conversion of CH_3 to CH_3O in the acetaldehyde–oxygen system, then there are several alternatives which may be considered in the explanation of the CO_2 and CH_3OH rate data.

$$CH_3CO_3 + M \rightarrow CH_3O + CO_2 + M \quad [11]$$

$$CH_3CO_3 + O_2 \rightarrow CH_3CO_2 + O_3 \quad [12]$$

$$CH_3CO + O_3 \rightarrow CH_3CO_2 + O_2 \quad [13]$$

$$CH_3CO_2 \rightarrow CH_3 + CO_2. \quad [14]$$

The relative constancy of the ratio, $(R_{CO_2} + R_{CH_3OH})/2R_{CH_3CO_3H}$, of Table I, is consistent with the occurrence of reaction [11], provided that the CH_3CO_3 radical decomposition is in the second order region and that [11] is usually followed by CH_3OH formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

by H-abstraction. It is likely that peroxyacetic acid is formed in the chain-propagating reaction [15], which is commonly proposed.

$$CH_3CO_3 + CH_3CHO \rightarrow CH_3CO_3H + CH_3CO. \qquad [15]$$

If we assume that [11] and [15] are homogeneous reactions and that these reactions are the major sources of the CO_2, CH_3OH, and CH_3CO_3H, then we can explain the small variation of the ratio, $(R_{CO_2} + R_{CH_3OH})/2R_{CH_3CO_3H}$, in terms of the differences in the efficiencies of CH_3CHO, O_2, and N_2 as M in reaction [11]. However, the increase in this ratio at low aldehyde pressures suggests that CH_3CHO is a poorer M than N_2 and O_2, a result which is unexpected.

We favor the alternative reactions for CO_2 and CH_3OH formation, [12], [13], and [14]; these suggest the formation and participation of ozone. In terms of this mechanism choice, the observed simultaneous increase in CH_3OH, CO_2, and CH_3CO_3H can be rationalized as follows: as the oxygen pressure is lowered, the rate of radical formation from the photodecomposition of acetaldehyde is increased; assuming reactions [6] and [7], we expect the ozone concentration to increase, and thus [13] and [14] would become more important. As the ratio of $[O_2]/[CH_3CHO]$ is increased, one expects that the fraction of the CH_3CO_3 radicals which form peroxyacetic acid in [15] would decrease compared to that reacting by [12]. This is the trend observed in the last column of Table I.

Some support for the participation of ozone in the photooxidation of acetaldehyde was obtained in runs 13, 14, and 15 of Table I. In run 13 a small quantity of ozone was added at the start of the run. Ozone initiates the thermal oxidation of acetaldehyde, and dark reaction was observed. However, after correction for the large dark rates, the "photochemical" rates of CO_2 and CH_3OH formation were much in excess of their normal values; compare runs 2 and 13 of Table I. The conclusions from this experiment are not unambiguous, but the results provide indirect support of the reactions [13] and [14]. In experiments 14 and 15 quantities of tetramethylethylene were added to the acetaldehyde–oxygen mixture. The indication of a trace of infrared light absorption near 8.2 μ suggests the formation of CH_3COCH_3 in these experiments. We have interpreted this as evidence for the presence of ozone in these experiments; ozone reacts rapidly with tetramethylethylene to form acetone (2). The amount of acetone formed in these experiments was much less than that found in the azomethane–oxygen–tetramethylethylene experiments reported previously (2), but the thermal reactivity of ozone with acetaldehyde might account for the difference.

Until the spectroscopic tests for ozone in the irradiated acetaldehyde–oxygen mixtures are made, one can consider ozone participation only as an interesting possibility, but we feel that there is strong indirect evidence that favors its consideration.

The Formation of Carbon Monoxide and Acetic Acid

The mechanism of formation of carbon monoxide and acetic acid is by no means clear from this work. It has been demonstrated that peroxyacetic acid is converted to acetic acid in the irradiated aldehyde–oxygen mixtures (see runs 11 and 12 of Table I). The acceleration of rate of formation of acetic acid with time is apparent in Fig. 2, even after only 2 minutes of irradiation. However, initial rates of formation of acetic acid do not parallel those of the peroxyacetic acid, so that the origin of the acetic acid formed initially by the conversion of peroxyacetic acid is ruled out. Perhaps the acetic acid is formed from CH_3CO_2 radicals which do not react entirely by [14] but to a minor extent abstract hydrogen from acetaldehyde or disproportionate with CH_3O reaction [11]. The alternative of acetic acid formation directly from electronically excited acetaldehyde molecules can not be excluded.

There are several possible sources of CO, for example, CH_2O photodecomposition, or reactions of the radicals, HCO, HCO_3, and CH_3CO. It appears to be formed in non-chain processes at a rate proportional to the absorbed light intensity.

In conclusion it should be stated that the photooxidation of acetaldehyde is a complex process, quite different from the simple oxidation mechanism which seems to be accepted currently. Much additional experimentation will be necessary to establish many of the interesting details of this reaction.

THE STUDY OF ELECTRICALLY DISCHARGED O_2 BY MEANS OF AN ISOTHERMAL CALORIMETRIC DETECTOR[1]

L. ELIAS, E. A. OGRYZLO,[2] AND H. I. SCHIFF

ABSTRACT

Molecular oxygen was subjected to an electrodeless discharge in the pressure range 0.1–3 mm Hg. The oxygen atom concentration was measured as a function of time in a flow system by means of a movable atom detector which consisted of a platinum wire coated with a suitable catalyst for atom recombination. The atom concentration was calculated from the heat liberated when the detector was operated under isothermal conditions. The surface recombination was found to be first order in the atom concentration. A value of 7.7×10^{-5} was obtained for the recombination coefficient (γ) on Pyrex. No temperature dependence for γ was observed. The gas phase recombination of oxygen atoms was found to be consistent with the mechanism

$$O + O_2 + M \rightarrow O_3 + M$$
$$O + O_3 \rightarrow 2O_2$$

The rate constant for the third-order reaction was found to have a value of 1.0×10^{14} cc^2 mole^{-2} sec^{-1}, and a small negative temperature dependence.

Evidence was also obtained for the presence of considerable amounts of excited molecular oxygen in electrically activated O_2.

INTRODUCTION

Considerable interest has been shown recently in the reactions of atomic oxygen, particularly those which occur in the upper atmosphere. To study the rates of recombination or reaction of oxygen atoms, it is necessary to know how their concentration changes with time. Such rapid reactions are often best studied in flow systems with movable atom detectors. Of the various methods available for measuring atom concentrations, isothermal calorimetry appears to be the most readily adaptable for use as a movable probe. This method was used successfully by Tollefson and Le Roy (1) to study the kinetics of hydrogen atom reactions. They measured the heat liberated by the recombination of H-atoms on a platinum or tungsten wire mounted on an adjustable column of mercury. The same technique has been used in the present study with minor modifications.

The present work was undertaken to study the kinetics of the recombination of oxygen atoms obtained by subjecting molecular oxygen to an electrical discharge. In the course of the investigation, evidence was obtained which strongly suggests the presence of considerable amounts of excited molecular oxygen.

EXPERIMENTAL

Principle of the Method

Normal oxygen is passed over a spiral of platinum wire coated with a material of high catalytic activity for recombining atoms. A known electric current "i_0" is passed through the wire, and its resistance R is measured. The gas is then activated by electrical discharge. The atoms which reach the wire are recombined on its surface. To compensate for the heat liberated by the atom recombination, the current through the wire is reduced to some new value "i", such that its resistance, and consequently its temperature, is restored

[1]*Manuscript received June 18, 1959.*

to the initial value. The difference in electrical energy required to keep the wire isothermal can readily be calculated from the relation:

$$[1] \qquad \Delta W = R(i_0^2 - i^2).$$

Since the temperature of the wire is the same in the presence and in the absence of atoms, loss of heat by radiation or conduction through the leads should be unaltered. Thus, if the wire removes all the atoms from the gas stream, the flow rate of atoms F_0 can be deduced from the equation

$$[2] \qquad F_0 = \Delta W/\Delta H$$

where ΔH is the heat of atom recombination, 58.5 kcal/mole of O-atoms. The validity of this relation will be considered below.

Materials

Reproducible results could be obtained only when the nitrogen content in the oxygen was low. The presence of this impurity could be detected readily from the afterglow produced by the reaction of O-atoms with the NO formed in the discharge. U.S.P. grade tank oxygen supplied by Linde Air Products, rated at less than 0.1% nitrogen, was used. Oxygen was also produced by thermal decomposition of $KMnO_4$ and from liquified tank oxygen from which the first 80% of the distillate had been discarded. The oxygen from all three sources gave identical results for the recombination rates.

Nitric oxide, obtained from the Matheson Company, was purified by repeated trap-to-trap distillations; NO_2 was made by reaction of NO with O_2. All other gases were commercial products of reagent grade purity.

Apparatus

A conventional flow system was used for all experiments. A linear velocity of 20 to 40 cm/sec and a pressure of 0.5 to 5 mm Hg was found to be suitable for atom recombination studies. The flow rates of all gases were adjusted by means of fine-control needle valves and measured by calibrated U-tube flowmeters. All mercury surfaces were covered with "octoil".

The oxygen was activated by a "Raytheon" microwave generator operating at 2450 Mc/sec with a maximum power output of 125 w. The discharge could be excited in a 13 mm O.D. quartz tube over a pressure range from 0.1 to 20 mm Hg. The use of a Pyrex rather than a quartz tube resulted in some foreign material being liberated from the glass which produced erratic results.

The discharge tube was connected at A by a 20-cm length of Pyrex tubing to the reaction tube shown in Fig. 1; the inner diameter was 17.5 mm and its length was 35 cm. It was surrounded by a jacket B through which thermostatted liquid could be circulated and which was, in turn, surrounded by a vacuum jacket C. Inert gases, NO and NO_2 were introduced at G into the gas stream through a multiple jet located a few centimeters below the top of the jackets. The pressure was measured by McLeod gauges connected at M_1 and M_2. The reaction tube was cleaned frequently with dilute solutions of HF.

The detector D_1 was mounted on a rack which could be moved by rotation of a pinion attached to a standard taper joint equipped with an "O"-ring. The platinum ring R was attached to the top of the rack to ensure that the detector maintained a central position in the reaction tube.

The movable detector D_1, and the stationary detector D_2, were made of 60-cm lengths of No. 30 gauge platinum wire coiled into spirals. Since platinum was found to be in-

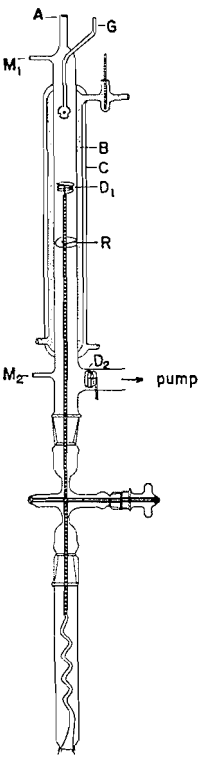

FIG. 1. Reaction tube: A, O_2 and O entry; G, multiple jet for reactant entry; M_1 and M_2, McLeod gauges; B, thermostatting jacket; C, vacuum jacket; D_1, movable detector; D_2, fixed detector.

efficient in recombining O-atoms, a layer of silver was deposited on the wire by electrolysis. A more adherent coating was obtained by heating the electroplated wire until the surface became shiny. When subjected to an atmosphere containing O-atoms, the metal is rapidly converted to the oxide, which forms an excellent catalyst for O-atom recombination.[3]

The oxides of cobalt, nickel, manganese, and copper were also found to be good catalysts. For the length of platinum wire used, zinc and cadmium coatings were only about half as efficient in destroying the atoms.

The detector formed one arm of a Wheatstone bridge. The current through the detector was determined from the potential drop across a standard resistor forming the adjacent arm of the bridge. To keep the bridge in balance when the oxygen was activated, the current through the detector was altered by means of a variable resistor in series with the bridge.

RESULTS AND DISCUSSION

(1) *Test of Detector*

Equation [2] is valid only if the detector removes all the atoms from the gas stream. To test this, measurements were made simultaneously with detectors D_1 and D_2. When the movable detector D_1 was above the pumping lead, D_2 showed no heat effect. When D_1 was lowered below the pumping lead, D_2 showed the same change in wattage previously shown by D_1 when it was just above the pumping lead.

A further test for the catalytic activity of the detector is obtained when a small amount

[3]*A stable detector could not be made from silver metal, since the thickness of the oxide layer would change with time.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

of NO is added to the gas stream. The green glow resulting from the reaction

$$O + NO \rightarrow NO_2 + h\nu$$

provides a very sensitive test for the presence of O-atoms.[4]

The glow was found to be completely extinguished by the detector. The sharp discontinuity of the glow at the detector also indicated that the rate of removal of atoms from the gas stream was controlled by the linear flow rate of the gas, and not by diffusion resulting from the atom concentration gradient established at the detector.

If the heat measured corresponds to the heat of recombination of all the atoms, it should be independent of the detector temperature. For the silver detector used, this was found to be true up to a detector temperature of 100° C. At higher temperatures the measured atom concentration decreased, and the NO–O glow was seen to extend beyond the detector. The temperature at which this occurs depends on the size of the detector. This indicated that, as the temperature increases, the silver oxide surface becomes less efficient, so that a larger surface area is required to effect complete recombination.

This observation is interesting for another reason. The method can be criticized on the grounds that the temperature distribution along the detector will be different when it is heated electrically only, and when the upper rings of the spiral are also heated by atom recombination, even though the electrical resistance may be the same in both cases. However, the atom concentration measured when the atoms are recombined on the first few rings (at the lower temperatures) was the same as when a number of rings were required (at higher temperatures). This effect must therefore be negligible.

(*2*) *Effect of Thermal Conductivity*

If the detector is to operate under truly isothermal conditions, it is necessary for the rate of heat loss to be identical in the presence and in the absence of atoms. This condition will be satisfied for radiation and conduction along the leads. However, the heat lost by conductivity in the gas could be altered if the gas temperature or composition changes upon activation of the gas.

The temperature of the discharged gas was measured by substituting a 1-mm glass-covered thermistor for the detector. Argon and helium, passed through the discharge at the same pressure, showed no increase in temperature at distances greater than 10 cm beyond the discharge. A maximum temperature rise of 2° C was observed in the center of an activated O_2 stream at the same distance. To determine the effect of such a temperature change on the detector readings, normal oxygen, initially at 25° C, was passed through the reaction tube which was thermostatted at 5° C. The difference in electrical energy required to keep the temperature of the wire constant at the top and in the middle of the reaction tube was found to be less than 0.004 w. This can be compared with a maximum value of 0.03 w calculated from the heat capacity of the oxygen. The heat given to the detector by atom recombination is in the order of 1.0 w. Thus, the effect of a 2° rise in gas temperature will be well within experimental error.

The change in thermal conductivity due to change in composition of the oxygen when it is subjected to electrical discharge will also have a negligible effect on the detector readings. The steady-state ozone concentration is very low, while excited molecular oxygen will not be expected to have a thermal conductivity appreciably different from normal oxygen. The slight change in thermal conductivity due to the presence of O-atoms above the detector would be expected to produce a change in detector reading which is less than the experimental error.

[4]*The glow also provides a good test for the design of the inlet jet, since the mixing pattern can be readily observed. Furthermore, it can be used to determine the upper limit of reactant flow rate in an O-atom reaction which can be used before encountering back diffusion of reactant.*

(3) Comparison with other Techniques for Determining Atom Concentrations

Experiments with discharges through mixtures of oxygen and argon or helium at a fixed total pressure showed that the ratio of atomic to molecular oxygen increased as the partial pressure of oxygen in the mixture decreased. An attempt was therefore made to prepare a known atom concentration by complete dissociation. However, the maximum atom concentration measured by the detector never exceeded 85% of that corresponding to complete dissociation. It is possible that complete dissociation could not be achieved in this way.

A comparison was made between the atom concentrations measured by the detector and by a Wrede gauge (2). The gauge was constructed from a fritted disk having a maximum pore diameter of 5 μ; the pressure difference across the disk was measured with a sensitive pressure transducer (Statham Instrument Co.). A small silver coil was placed near the disk, on the transducer side, to ensure complete atom recombination. Comparisons were made over the pressure range 0.7 to 3.3 mm. In this region the atom concentration measured by the detector was proportional to that measured by the Wrede gauge but higher by about 10%.

An attempt was made to measure the atom concentration by chemical titration. This method had previously been found to be very successful in testing the accuracy of a platinum detector in measuring deuterium atom concentrations (3). Since the reaction between D-atoms and ethylene is very rapid, introduction of an excess of C_2H_4 consumed all the D-atoms within a few millimeters of the inlet jet. The amount of deuterium atoms in the products was determined mass spectrometrically and used to calculate the atom concentration. The concentrations determined in this manner were found to agree with those determined by the detector within 0.5%.

Kaufman (4) has recently used an NO_2 titration for estimating O-atom concentrations. The reaction

$$NO_2 + O \rightarrow NO + O_2 \qquad [1]$$

is much faster than the light-emitting reaction

$$NO + O \rightarrow NO_2 + h\nu. \qquad [2]$$

Consequently, if the flow rate of NO_2 is gradually increased, a glow will be observed until the NO_2 concentration equals the O-atom concentration. At this point all the O-atoms will be consumed by reaction [1] and the glow will recede to the jet. This method was found by us to yield the same atom concentration within experimental error as the method of Spealman and Rodebush (5). These workers titrated the O-atoms with a large excess of NO_2, trapped the products at liquid air temperature, and measured the amount of NO formed. The O-atom concentration measured by NO_2 titration was found to be proportional to that measured by the silver oxide detector but lower by approximately 25%.

(4) Evidence for the Existence of Excited Molecules

The discrepancy between the atom concentrations determined by the detector and by the NO_2 titration may be due to the presence of some other species which does not react with NO_2 but which liberates heat on the detector. A cobalt oxide detector was found to show an even greater discrepancy with the titration value, which suggests that it is an even more efficient surface for deactivating the second species. To test this suggestion, a number of additional experiments were performed.

When the movable detector D_1 (Fig. 1) was coated with cobalt oxide while the fixed

detector D_2 was coated with silver oxide, no heat was liberated on D_2. However, when D_1 was silver oxide while D_2 was cobalt oxide, an appreciable amount of heat was measured by D_2.

When a sufficient amount of C_2H_4 was introduced through the inlet jet to consume all the atoms, the cobalt oxide detector still measured an appreciable quantity of heat. When an excess of NO_2 was used to destroy all the atoms, a silver oxide detector at D_1 measured only a very small amount of heat, while a cobalt detector below this at D_2 measured an amount of heat which was even greater than it measured before the NO_2 was introduced. This could be due to the additional excited O_2* formed in the reaction

$$NO_2 + O \rightarrow NO + O_2^*.$$

When a mercury mirror was deposited just beyond the discharge tube, no atoms passed this point, as evidenced from the lack of glow when NO was introduced through the inlet jet. Nevertheless, heat was liberated on the cobalt detector, which corresponded to over 25% of the heat measured by the detector in the absence of the mercury mirror. The magnitude of this heat effect decreased only very slowly down the reaction tube, thus indicating a long lifetime for the excited species.[5]

Addition of NO, NO_2, CO_2, and C_2H_4 after the mercury mirror had no effect on the heat measured by the cobalt detector. The new species therefore does not appear to be ozone, which is known to react rapidly with NO and C_2H_4.

Norrish and co-workers (6) have presented evidence that vibrationally excited O_2 molecules are deactivated in approximately one collision in 5000 by CO_2, and in one collision in 500 by NO_2. However, addition of these gases in large amounts did not decrease the heat measured by the detector. The species therefore does not appear to be vibrationally excited molecules.

The most likely excited species appears to be electronically excited O_2. If these molecules are in the $^1\Delta g$ state as suggested by Foner and Hudson (7), and by Herron and Schiff (8), the observed heat effect would correspond to about 10% of the gas being present in this form, in agreement with estimates made by these authors.

As a result of these studies, it was learnt that a freshly prepared silver oxide coated detector of the dimensions given would recombine all the atoms but deactivate only a negligible amount of the excited molecules. After five or six experiments the detector measured an increasing proportion of excited molecules and was then replated. Freshly prepared detectors were used to measure the recombination of oxygen atoms.

(5) *Recombination of* O-*Atoms*

The oxygen atom concentration was measured along a 20-cm length of the reaction tube over a pressure range from 0.5 to 5 mm Hg. Figure 2 shows typical second-order, and Fig. 3 typical first-order, plots for the atom concentration – time dependence. It is apparent that the atom recombination follows first-order kinetics. The following mechanism is consistent with these observations:

$$O + \text{wall} \rightarrow \tfrac{1}{2}O_2 + \text{wall} \quad [3]$$

$$O + O_2 + M \rightarrow O_3 + M \quad [4]$$

$$O + O_3 \rightarrow 2O_2 \quad [5]$$

where M is any third body.

[5]*The same effect could be obtained if the atoms were destroyed by addition of* NO_2 *rather than by the mercury deposit.*

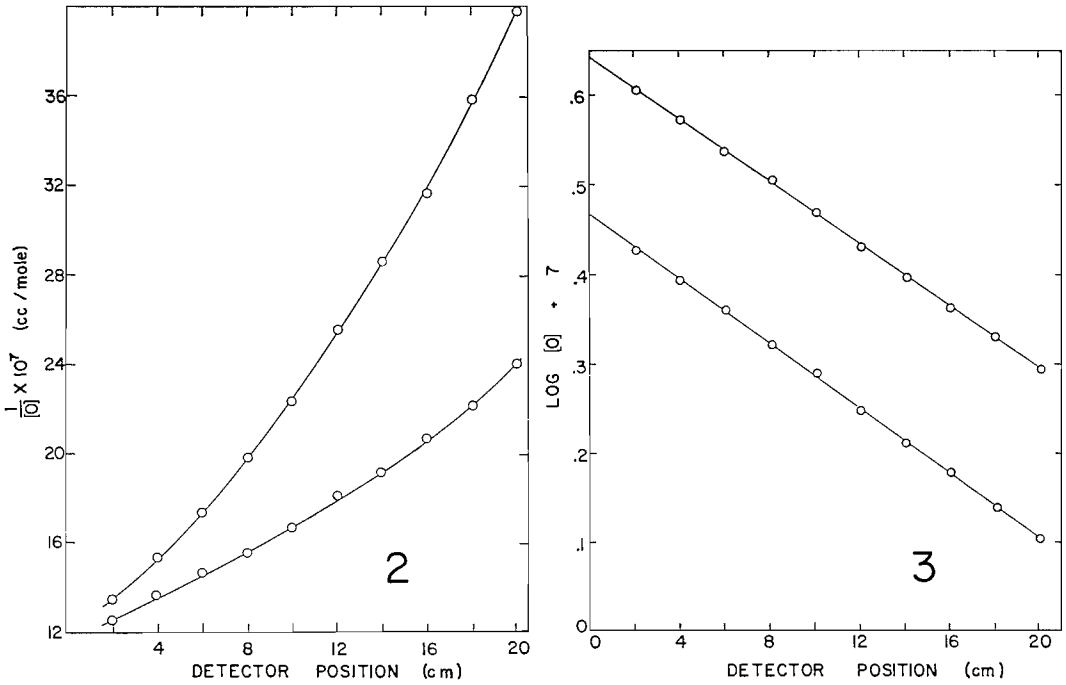

FIG. 2. Typical second-order plots of oxygen atom disappearance.
FIG. 3. Typical first-order plots of oxygen atom disappearance.

A steady-state condition can be assumed for the ozone concentration. Benson and Axworthy (9) give values of 1.3×10^9 cc mole^{-1} sec^{-1} for k_5, and 7.9×10^{13} cc^2 mole^{-2} sec^{-1} for k_4 at 293° K. If O-atoms form 10% of the gas leaving the discharge, calculations show that 70% of the steady-state ozone concentration is attained before the gas enters the reaction vessel at 0.5 mm Hg pressure, and virtually 100% at higher pressures. With this assumption the rate equation for the atom disappearance can be integrated to give:

$$\frac{1}{t}\ln\frac{[O_0]}{[O]} = k_3 + 2k_4[O_2][M]$$

where $[O_0]$ is the atom concentration at the top of the reaction tube, where t is taken as zero.

Figure 4 shows a plot of the left-hand side of this equation against $[O_2][M]$ for M = O_2. The intercept of this curve, k_3, can be used to calculate the surface recombination coefficient γ from the relation:

$$\gamma = 2k_3r/c$$

where r is the radius of the reaction tube and c is the average velocity of the atoms.

The average value of γ obtained from several sets of measurements was 0.77×10^{-4}. This can be compared with the value of 1.2×10^{-4} obtained by Linnett and Marsden (10) and 0.2×10^{-4} by Kaufman (11). Kistiakowsky and Volpi (12) deduced a minimum value of 2×10^{-4} from indirect measurements of N-atom reactions. Herron and Schiff (8) reported a value of 1.1×10^{-4} based on the assumption that all recombinations occur on the wall, and their figure therefore represents an upper limit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The slopes of the curves in Fig. 4 yielded an average value for k_4 of 1.0×10^{14} cc^2 mole^{-2} sec^{-1}. This figure is in good agreement with the value of 2×10^{14} cc^2 mole^{-2} sec^{-1} reported by Kaufman (4) and the value of 0.79×10^{14} cc^2 mole^{-2} sec^{-1} obtained by Benson and Axworthy (9) from the thermal decomposition of ozone.

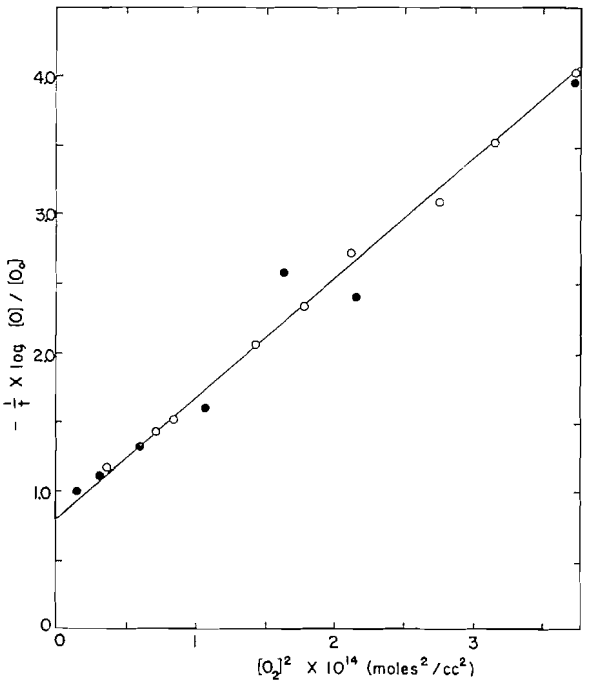

FIG. 4. The dependence of the oxygen atom disappearance on the pressure.

No differences in the rate of recombination were observed when helium or argon molecules were used as third bodies. Addition of CO_2 increased the rate of recombination but in a somewhat erratic way. If CO_2 acts simply as a third body, i.e.

$$O + O_2 + CO_2 \rightarrow O_3 + CO_2, \qquad [6]$$

the integrated rate equation could be written in the form

$$\frac{1}{t}\ln\frac{[O_0]}{[O]} - 2k_4[O_2]^2 = k_3 + 2k_6[O_2][CO_2].$$

A plot of the left-hand side of this equation against $[O_2][CO_2]$ should yield a straight line with slope $2k_6$. However, the data deviated from linear behavior to a larger extent than the estimated experimental error. No unequivocal explanation can be offered for this deviation at the present time. The best straight line through the data gave a value of $k_6 = 2.6\times10^{14}$ cc^2 mole^{-2} sec^{-1}. Thus the relative efficiency of M in reaction [4] was found to be 1.0, 1.0, 1.0, and 2.6 for O_2, He, A, and CO_2 respectively. Kaufman (4) found relative values of 1.0, 1.0, 1.0, and 10 for O_2, A, N_2, and CO_2. Benson and Axworthy (9) found relative values of 1.0, 0.78, 0.93, and 2.4 for O_2, He, N_2, and CO_2.

In order to estimate the effect of temperature on the rate of atom recombination, measurements were made with the reaction tube thermostatted at $-60°$ C. The results are plotted as closed circles in Fig. 4. They suggest that the temperature coefficients for both the gas phase and wall recombinations are zero.

However, at this temperature it is doubtful whether the assumption of a steady-state ozone concentration is justified. Benson and Axworthy (9) have reported an activation energy of 6 kcal mole^{-1} for reaction [5], which yields a rate constant for this reaction at $-60°$ C of 2×10^7 cc mole^{-1} sec^{-1}. Assuming that the room temperature steady-state O_3 concentration is achieved before the gas enters the reaction zone, then, at this temperature and at the pressures used in these experiments, the rate of removal of O-atoms by reaction [5] is 400 times slower than by reaction [4], and can therefore be neglected. The integrated rate equation for atom recombination then becomes:

$$\frac{1}{t}\ln\frac{[O_0]}{[O]} = k_3+k_4[O_2][M].$$

On this basis the results obtained indicate no temperature coefficient for k_3 but a small negative Arrhenius activation energy of about 0.7 ± 0.2 kcal mole^{-1} for k_4, which can be compared with a value of 0.6 kcal mole^{-1} reported by Benson and Axworthy (9).

Oxygen atoms recombine much more slowly in the gas phase than do other atoms such as iodine (13, 14, 15), bromine (13, 16), nitrogen (17, 18), or hydrogen (19). Moreover, these atoms recombine by the reaction

$$X + X + M \rightarrow X_2 + M \qquad [7]$$

which is second order in the atom concentration, while the recombination of oxygen atoms was found to be first order in the atom concentration.

The rate of oxygen atom recombination by reactions [4] and [5] relative to recombination by reaction [7] when $M = O_2$ would be

$$\frac{2k_4}{k_7}\frac{[O_2]}{[O]}.$$

Since k_4 was found to be 1.0×10^{14} cc^2 mole^{-2} sec^{-1} and $[O_2]/[O] \simeq 20$ for most of the experiments, the relative rates are $4\times10^{15}/k_7$. If 10% of the recombination had occurred by reaction [7], curvature would have been found in the first-order plots. This leads to the conclusion that $k_7 \leqslant 4\times10^{14}$ cc^2 mole^{-1} sec^{-1}.

Third-order recombination reactions such as [7] can be expressed in terms of elementary reactions by at least three mechanisms:

$$[A]\quad X + X \rightleftharpoons X_2^* \qquad [a]$$
$$X_2^* + M \rightarrow X_2 + M \qquad [b]$$
$$[B]\quad X + M \rightleftharpoons XM^* \qquad [c]$$
$$XM^* + X \rightarrow X_2 + M \qquad [d]$$
$$[C]\quad X + M \rightleftharpoons XM^* \qquad [c]$$
$$XM^* + M' \rightleftharpoons XM + M' \qquad [e]$$
$$XM + X \rightarrow X_2 + M \qquad [f]$$

If reactions [a], [c], and [e] represent equilibria, the rates of atom recombination will be: by mechanism [A]

$$-d[X]/dt = K_a k_b[X]^2[M],$$

by mechanism [B]

$$-d[X]/dt = K_c k_d[X]^2[M],$$

by mechanism [C]

$$-d[X]/dt = K_c K_e k_f[X]^2[M].$$

Mechanism [*A*] predicts the correct order of magnitude for the third-order rate constant for many atom recombinations on the basis of simple collision theory. However, it encounters difficulties in explaining the variation of the rate constant with the nature of the third body, and the negative temperature coefficients observed for these reactions. Keck (20) has recently suggested means of circumventing these difficulties.

Mechanism [*B*] was originally proposed by Rabinowich (21) and is capable of explaining the effects of different third bodies, and the negative temperature coefficients.

Mechanism [*C*] has been strongly supported by Bunker and Davidson (15) to explain their observations of the recombination of iodine atoms. It possesses several inherent advantages over mechanism [*B*]. The negative temperature coefficient is immediately accounted for by the difference in bond strength of XM and the activation energy of reaction [*f*]. The relative efficiencies of third bodies can be explained in terms of the XM bond strength.

The results of the present study can be considered in the light of mechanism [*C*]. In the presence of large amounts of oxygen, $M = O_2$ and $MX = O_3$. Since the bond strength in O_3 is 24 kcal/mole, $k_e \gg k_{-e}$, and a steady-state rather than an equilibrium ozone concentration is established. The mechanism then reduces to that proposed earlier for the disappearance of O-atoms. Under these conditions the over-all third-order reaction becomes first order in [O], in agreement with experiment—a fact which cannot be explained by mechanism [*A*] or [*B*] alone.

Bunker and Davidson (15) have attributed the large differences in the third-body efficiencies for iodine recombination to the differences in the XM bond strengths. In the case of O-atom recombination, added inert gas can only influence reaction [*e*] and only small differences in third-body efficiencies should be observed. Although this is found to be true, Benson and Axworthy (9) report the same order of efficiencies for third bodies in the O-atom system as do Bunker and Davidson (15) in the I-atom system. Further studies of relative third-body efficiencies seem indicated.

THE REACTION OF OXYGEN ATOMS WITH NO[1, 2]

E. A. Ogryzlo[3] and H. I. Schiff

ABSTRACT

In the reaction between NO and O-atoms, the concentration of NO remains essentially unaltered. The reaction can therefore be considered as a NO-catalyzed recombination of O-atoms. Its rate can be conveniently studied by following the disappearance of O-atoms by an isothermal calorimetric technique. The reaction was found to be third order, first order in the concentrations of O, NO, and M, where M is some third body. The third-order rate constant was found to be 1.85×10^{16} cc^2 mole^{-2} sec^{-1} when M = O_2, A, or He and 2.0×10^{16} cc^2 mole^{-2} sec^{-1} when M = CO_2. The rate constant was found to have a slight negative temperature coefficient which corresponded to a negative Arrhenius activation energy of about 0.2 kcal/mole. A detailed mechanism for the reaction has been proposed.

INTRODUCTION

The preceding paper (1) described an isothermal calorimetric technique for following the rate of disappearance of oxygen atoms. The present section describes the application of this technique to the study of the reaction of O-atoms with nitric oxide. This reaction proceeds by the sequence:

$$O + NO + M \rightarrow NO_2 + M \quad [1]$$

$$O + NO_2 \rightarrow NO + O_2 \quad [2]$$

where M represents some third body. Since reaction [2] is much more rapid than reaction [1] at the pressures used in this study (2, 3), the NO concentration is essentially constant, and the entire reaction may be considered as a NO-catalyzed recombination of O-atoms. It can therefore be studied conveniently by the isothermal calorimetric method.

The purpose of the study was to determine the rate constant for the reaction, and to attempt to learn something of the detailed mechanism.

EXPERIMENTAL

The apparatus, the method of purification of the materials, and the method used to measure the atom concentration have been described in the previous paper (1). The reaction was studied over a total pressure range from 1.21 to 3.05 mm Hg. Helium, argon, and CO_2 were used in addition to O_2 as third bodies; the partial pressures of these gases were varied by a factor of 5. Argon and helium were added with the oxygen through the discharge, while the CO_2 was added through a separate jet in the reaction vessel.

The O-atom concentration was first measured along the reaction tube, in the absence of NO, with a silver oxide detector. NO was then added through the multiple jet inlet and, after steady conditions had been established, the atom concentration was again determined as a function of position in the reaction tube. Finally, the discharge was extinguished and the detector readings again taken to give the "i_0" readings for the conditions obtaining while NO was flowing through the tube.

In the preceding paper (1), evidence was presented to indicate that a freshly prepared silver oxide surface detected O-atoms only and did not detect any excited molecules.

Since such a detector is imperative for the present work, it was frequently tested by introducing a large excess of NO, sufficient to destroy all the atoms. Under these conditions a satisfactory detector registered no heat effect below the reaction zone (as delineated by the glow). Since studies made with a cobalt oxide detector indicated that NO does not deactivate excited molecules, it can be concluded that the silver oxide detector measures atoms only. Further support for this conclusion will be presented in the following discussion.

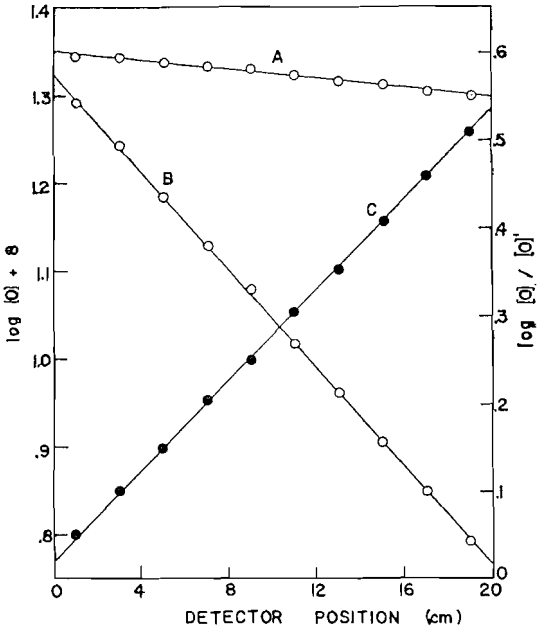

FIG. 1. Oxygen atom decay curves: A, in the absence of NO; B, in the presence of NO; C, the difference between A and B.

RESULTS AND DISCUSSION

Figure 1 shows the O-atom decay curves obtained for a typical experiment. Curve A shows the decrease in O-atom concentration obtained in the absence of NO; curve B shows the more rapid decay of O-atoms in the presence of NO. This decay also appears to be first order in the atom concentration.

It has been shown that, in the absence of NO, the first-order decay of O-atoms is consistent with the mechanism

$$O + W \rightarrow \tfrac{1}{2}O_2 + W \qquad [3]$$

$$O + O_2 + M \rightarrow O_3 + M \qquad [4]$$

$$O + O_3 \rightarrow 2O_2 \qquad [5]$$

where W represents the wall of the reaction vessel.

The integrated rate equation is

$$[i] \qquad \frac{1}{t}\log\frac{[O_0]}{[O]} = k_3[W] + 2k_4[O_2][M]$$

where $[O] = [O_0]$ at $t = 0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

When NO is introduced, the following additional reactions may be considered:

$$O + NO + M \rightarrow NO_2 + M \quad [1]$$

$$O + NO_2 \rightarrow NO + O_2 \quad [2]$$

$$O_3 + NO \rightarrow NO_2 + O_2. \quad [6]$$

The reaction of O_3 with NO_2 need not be considered, since it is a relatively slow reaction (4) and the steady-state concentrations of both these species are low.[4]

If steady-state conditions are assumed for both O_3 and NO (or NO_2), the integrated rate equation for O-atom disappearance becomes:

$$[ii] \qquad \frac{1}{t}\log\frac{[O_0]'}{[O]'} = k_3[W]+2k_4[O_2][M]+2k_1[NO][M].$$

Since the flow rate of NO was always kept below 10% of the total flow rate, the values of t and $[O_2]$ in equations $[i]$ and $[ii]$ can be assumed to be identical for the same detector position. The equations can then be subtracted to yield

$$[iii] \qquad \log\frac{[O]}{[O]'} = \log\frac{[O_0]}{[O_0]'}+2tk_1[NO][M].$$

Thus, if the difference of the logarithms of the atom concentrations at a given detector position is plotted against the detector position, a straight line should be obtained with slope equal to $2k_1[NO][M]$. This plot is shown as curve C in Fig. 1. Similar straight line plots were obtained in all cases where the detector measured atoms only. If, however, the detector also measured excited molecules, the plots showed considerable curvature, as

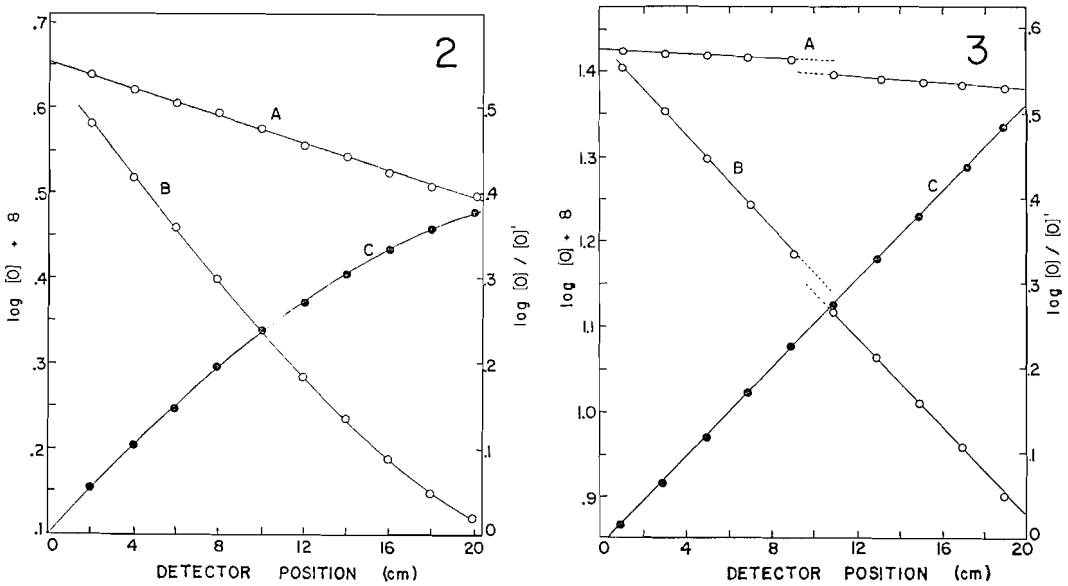

FIG. 2. Oxygen atom decay curves measured with a detector which also measured excited molecules: A, in the absence of NO; B, in the presence of NO; C, the difference between A and B.

FIG. 3. Oxygen atom decay curves showing the effect of a piece of silver placed half way down the reaction tube: A, in the absence of NO; B, in the presence of NO; C, the difference between A and B.

[4]*Similarly, the reactions*

$$NO_2 + O + M \rightarrow NO_3 + M$$

$$NO_3 + O \rightarrow NO + O_2$$

if they occur, can be shown, by using estimates of the rate constants (5), to have a negligible effect on the rate of O-atom disappearance.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

shown in Fig. 2. A detector which gave such a curve always registered a heat effect when sufficient NO was added to consume all the atoms.

There remained the possibility that some reaction might be occurring on the detector. To test this, a piece of silver oxide was placed half way down the reaction tube. The discontinuities in curves A and B of Fig. 3 show that this silver oxide destroys some of the atoms. Nevertheless, the difference curve C shows no discontinuity at this position, which clearly indicates that the NO–O-atom reaction is occurring predominantly in the gas phase.

B-8	2.75	213	51.3	3.50	67.9	9.80	2.40

The results are shown in Table I. The capital letters prefixing the experiment numbers refer to separate series in which the same detector and reaction vessel were employed. Column 7 gives the slope of equation [*iii*].

Inspection of the data indicates that the over-all reaction is third order, first order in the concentrations of atomic oxygen, nitric oxide, and third body. Wall reactions cannot be significant since they would show zero or reciprocal pressure dependence. Helium, argon, and molecular oxygen appear to be equally efficient as third bodies within experimental error. The average value of the rate constant at 20° C is $1.85 \pm 0.10 \times 10^{16}$ cc^2 mole^{-2} sec^{-1} and $2.04 \pm 0.20 \times 10^{16}$ cc^2 mole^{-2} sec^{-1} at 6° C. Although the mean deviations in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

these values would cause them to overlap, there does seem to be an indication of a small negative temperature coefficient. These values can be compared with the value of 1.8×10^{16} cc^2 mole^{-2} sec^{-1} obtained by Ford and Endow (5) at 25° C from a study of the photolysis of NO_2, and the value of 2.5×10^{16} cc^2 mole^{-2} sec^{-1} obtained by Kaufman (6) and the value of 2.7×10^{16} cc^2 mole^{-2} sec^{-1} obtained by Harteck *et al.* (7) from a study of the rate of decrease in the light intensity accompanying this reaction.

Carbon dioxide appears to be more efficient as a third body by about 10%. This is a somewhat smaller effect than found by Kaufman (6), who reported a rate constant for the reaction with CO_2 as third body of $4-5\times10^{16}$ cc^2 mole^{-2} sec^{-1}. An estimate of the temperature coefficient for the reaction can be obtained for the reactions in which CO_2 was introduced. Pairs of experiments in series B were performed in rapid succession with all conditions kept constant with the exception of the reaction tube temperature. The ratios of the rate constants for the pairs B-2 and B-1, B-4 and B-3, B-6 and B-5, B-8 and B-7, are 1.1, 1.3, 1.1, and 1.1 respectively. The average of these ratios corresponds to a negative Arrhenius activation energy of 0.24 kcal/mole.

Mechanism of the Reaction

A third-order association reaction can be analyzed in terms of successive bimolecular collisions. A collision between the two associating partners can be considered to produce a short-lived intermediate which will dissociate again unless it experiences a collision with a third body M, which removes sufficient energy to leave the product in a potential well. Thus, reaction [1] can be considered to be the result of the successive reactions

$$O + NO \rightarrow NO_2^* \quad [7]$$

$$NO_2^* \rightarrow NO + O \quad [8]$$

$$NO_2^* + M \rightarrow NO_2 + M. \quad [9]$$

Reaction [8] must be much faster than reaction [9] if third-order kinetics is to be obtained. The over-all rate will depend mainly on the lifetime of NO_2^*, i.e. on the rate of reaction [8]. Due to its greater number of degrees of freedom, the NO_2^* complex may have a considerably longer lifetime than the complexes formed by collision of two atoms.

An additional fate for the excited NO_2^* must also be considered. The reaction is accompanied by the emission of radiation, in what appears to be a continuum, but might have a closely banded structure. This radiation could be produced in the reaction:

$$NO_2^* \rightarrow NO_2 + h\nu. \quad [10]$$

Kaufman (6) has found that the rate of light emission is much slower than the rate of oxygen atom disappearance in the pressure range used here. This would correspond to the condition that $k_9[M] \gg k_{10}$. This condition, along with the assumption of steady-state concentrations for NO_2^* and NO, can be used to derive an expression for the rate of oxygen atom disappearance in the form:

$$-\frac{d[O]}{dt} = 2\frac{k_7}{k_8}k_9[O][NO][M]$$

in agreement with the empirical rate equation.

Furthermore, it can be readily shown that the rate of light emission is

$$I = \frac{d[h\nu]}{dt} = \frac{k_7}{k_8}k_{10}[NO][O]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

in agreement with the second-order dependence found by Kaufman. However, recent studies of the recombination of iodine atoms (8, 9, 10) suggests that an alternate mechanism might be proposed in which M participates in the initial step:

$$O + M \rightarrow OM^* \quad [11]$$

$$OM^* \rightarrow O + M \quad [12]$$

$$OM^* + NO \rightarrow NO_2^{\ddagger} + M \quad [13]$$

$$NO_2^{\ddagger} \rightarrow NO_2 + h\nu \quad [14]$$

$$NO_2^{\ddagger} + M \rightarrow NO_2 + M. \quad [15]$$

This mechanism is also capable of explaining a third-order rate for atom disappearance and a second-order rate for light emission.

The relative importance of the two mechanisms will depend on the relative lifetimes of NO_2^* and OM*. It might be expected that the second mechanism would be much more sensitive to the nature of the third body. For example, one would expect quite different lifetimes for O_3^* and OA*. The observation that O_2 and A seem to be equally efficient as third bodies might therefore be considered to favor the first mechanism. Furthermore, if O_3^* is the excited molecule formed in the first step when O_2 is the third body, one would expect the rate of oxygen atom disappearance to be similar in the presence and in the absence of NO, i.e. the rate of reaction [13] should not change appreciably if O is substituted for NO. However, the presence of NO increased the rate of atom disappearance by at least an order of magnitude.[5]

It might also be argued that the reaction [14] in the second mechanism seems less likely to give rise to a continuum than does reaction [10] since $NO_2^{\ddagger}$ will be more stabilized than NO_2^*. However, Neuberger and Duncan (11) found a "pseudo" continuum emitted when NO_2 was irradiated with light of energies insufficient to cause dissociation, although there may be some doubt as to whether the excited state of NO_2 reached in this way has any connection with the one reached by the NO–O reaction. The data available at present do not permit an unequivocal choice between these two mechanisms. It is hoped that some work currently in progress in these laboratories on the light-emitting step will help in a decision.

THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF BENZALDEHYDE, ACROLEIN, AND CROTONALDEHYDE[1]

A. G. HARRISON[2] AND F. P. LOSSING

ABSTRACT

The Hg^3P_1-photosensitized decomposition of benzaldehyde at low pressure and high radiation intensity forms predominantly a polymeric material. In the fraction of the reaction which forms the identifiable final products benzene and carbon monoxide, both a direct molecular rearrangement and a free radical split to phenyl and formyl radicals occur. The decomposition reactions of acrolein and crotonaldehyde involve the three primary processes:

$$\begin{aligned} RCHO + Hg^* &\rightarrow RH + CO + Hg \\ &\rightarrow R + CHO + Hg \\ &\rightarrow RCO + H + Hg. \end{aligned}$$

INTRODUCTION

In the photolytic and mercury-photosensitized decompositions of aldehydes three possible primary processes can occur:

$$RCHO \rightarrow R + CHO \quad [1]$$

$$RCHO \rightarrow RH + CO \quad [2]$$

$$RCHO \rightarrow RCO + H. \quad [3]$$

Where R is an alkyl group other than methyl, further primary processes involving rearrangements and bond splitting in this group are possible, and the course of the reaction may become quite complicated.

The direct photolysis and the mercury-photosensitized decomposition of acetaldehyde have both been studied in some detail. In the direct photolysis at 2537 to 3130 Å the main primary process is reaction [1], although part of the reaction appears to proceed by reaction [2] (1). In the reaction of acetaldehyde with $Hg(^3P_1)$ atoms (2) the primary decomposition is almost exclusively to form methyl and formyl radicals, although the experimental results could not rule out the possibility that 5% of the reaction proceeded by reaction [2]. There was no evidence for the occurrence of reaction [3].

Very little work has been done on the relative importance of these primary processes when R is an unsaturated group capable of conjugating with the aldehydic function. In this case it might be expected that the proportions of the three possible steps would change. Blacet and Roof (3) studied the photolysis of crotonaldehyde in the 2400–2600 Å region and found no decomposition; however, Volman, Leighton, Blacet, and Brinton (4) found that during the photolysis of crotonaldehyde at 2537 Å tellurium mirrors were removed, indicating the presence of radicals. They postulated the following reaction:

$$CH_3{-}CH{=}CH{-}CHO + h\nu \rightarrow CH_3{-}CH{=}CH + CHO. \quad [4]$$

Blacet, Fielding, and Roof (5) studied the direct photolysis of acrolein and postulated that the primary process was to some extent the following:

$$CH_2{=}CH{-}CHO + h\nu \rightarrow CH_2{=}CH + CHO. \quad [5]$$

[2]*National Research Council of Canada Postdoctorate Fellow 1957–59.*

By mirror-removal experiments Volman and co-workers (4) showed that radicals were produced at 2537 and 2810 Å.

No work has been reported on the direct photolysis of benzaldehyde or on the mercury-photosensitized decomposition of any of the three conjugated aldehydes: crotonaldehyde, acrolein, and benzaldehyde. In view of the few results available it was thought that some information on the relative importance of the three primary processes in the mercury-photosensitized decomposition of these aldehydes would be of interest.

EXPERIMENTAL

The reactions were studied by passing the reactant at a few microns pressure, together with mercury vapor, in a stream of helium through a photochemical reactor attached to a mass spectrometer. The apparatus and procedure have been described previously (2, 6, 7).

In recent work (7, 8) the addition of methyl radicals, produced by the photosensitized decomposition of dimethyl mercury, to the reaction products has been found to be a convenient method of detecting free radicals, particularly those which are difficult to detect directly with low energy electrons. This method of detection of a radical R depends on the occurrence of the combination reaction

$$R + CH_3 \rightarrow RCH_3. \qquad [6]$$

It is worth while to consider briefly the conditions upon which the success of this method of radical detection and identification depends. The method will work only if conditions are such that radical recombination reactions predominate over radical attack on stable molecules. Although radical–radical reactions are several orders of magnitude faster than radical–substrate reactions, the concentration of radicals in conventional photochemical work is usually so small that radical–substrate reactions nevertheless predominate. However, as has been pointed out previously (7), conditions in the present reactor are considerably different. In the present system some 10–20% of the parent compound is decomposed in the order of 10^{-3} second with the result that the concentrations of radicals can be relatively high. In the case of acetone (2) the concentration of methyl radicals was approximately 1/10 that of the parent compound for most of the contact time. Under such conditions radical–radical reactions would be expected to predominate.

Of course, as the fraction of the reaction proceeding by a free radical mechanism decreases the occurrence of radical–radical reactions will also decrease. However, when using methyl radicals as a radical detector this effect can be counterbalanced by increasing the amount of methyl radicals added to the system.

The sensitivity of this method for the detection of a radical R is dependent on many variables: among others, the rate of recombination, the ratio of recombination to disproportionation, and the sensitivity of the mass spectrometer to the product RCH_3. It is therefore impossible to put the limits of radical detection by this method on an absolute scale.

Materials

The benzaldehyde, acrolein, and crotonaldehyde were all Eastman-Kodak "White-Label" materials purified by bulb-to-bulb distillation and degassed before use. The benzaldehyde-d_6 was prepared by Dr. L. C. Leitch and was 94.7% pure. The impurity was chiefly benzaldehyde-d_5.

RESULTS AND DISCUSSION

Benzaldehyde

The only identifiable products found in the mercury-photosensitized decomposition of benzaldehyde were benzene and carbon monoxide. The major part of the reaction ($\sim 80\%$) appeared to proceed to the formation of a yellowish polymer which deposited on the walls of the reactor and rapidly caused a reduction in the amount of light transmitted. As the results in Table I show, the amounts of benzene and carbon monoxide produced were equal, suggesting that the deposit was a polymer of benzaldehyde and not of one of the reaction products.

TABLE I
Benzaldehyde decomposition

Benzaldehyde decomposed		Products		Yield (%)	
(μ)	(%)	C_6H_6	CO	C_6H_6	CO
0.92	11.7	0.166	0.172	18.1	18.8

No radicals could be detected at low electron energies. A search was therefore made for radicals by the addition of methyl radicals as previously discussed. Upon the addition of methyl radicals a peak at mass 92 of approximately 7 mm was produced. A peak was also produced at mass 91, the intensities at mass 92 and 91 being in the correct ratio for toluene. These results demonstrate the presence of the phenyl radical in the system, suggesting as a primary step the reaction:

$$C_6H_5CHO + Hg^* \rightarrow C_6H_5 + CHO + Hg. \quad [7]$$

However, one cannot rule out the possibility that the primary reaction proceeds by the formation of the benzoyl radical, which then rapidly decomposes to form a phenyl radical and carbon monoxide.

$$C_6H_5CHO + Hg^* \rightarrow C_6H_5CO + H + Hg \quad [8]$$

$$C_6H_5CO \rightarrow C_6H_5 + CO \quad [9]$$

No formation of acetophenone, the addition product of C_6H_5CO and CH_3, was observed, indicating that the C_6H_5CO concentration was very small. An estimate of the bond dissociation energy $D(C_6H_5—CO)$ can be made from the heat of formation of CO and recent estimates of the heat of formation of the phenyl radical ($\Delta H_f = 70$ kcal/mole) (9) and the benzoyl radical ($\Delta H_f = 15.6$ kcal/mole) (10). These values lead to $D(C_6H_5—CO) = 28$ kcal/mole. Since the benzoyl radical should therefore be stable at 55° C, the failure to detect it either directly or by CH_3 addition must be taken as evidence that reaction [8] does not occur to a significant extent.

Reaction [7] undoubtedly occurs to some extent, the observed products benzene and carbon monoxide being formed by the subsequent reaction:

$$C_6H_5 + CHO \rightarrow C_6H_6 + CO. \quad [10]$$

To determine the importance of reactions [7] and [10] relative to a possible direct molecular rearrangement to benzene and carbon monoxide:

$$C_6H_5CHO + Hg^* \rightarrow C_6H_6 + CO + Hg \quad [11]$$

experiments were carried out with C_6H_5CHO–C_6D_5CDO mixtures. In the absence of the free radical processes [7] and [10] all the benzene produced in such mixtures should be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

either C_6H_6 or C_6D_6. The amount of isotopically mixed benzenes relative to the C_6H_6 and C_6D_6 benzenes should therefore provide an index of the amount of benzene formed by reaction [11].

TABLE II

Decomposition of C_6D_5CDO–C_6H_5CHO mixtures

Aldehyde decomposed (μ)		Product benzenes (μ)				% free radical reaction
C_6D_5CDO	C_6H_5CHO	C_6D_6	C_6D_5H	C_6H_5D	C_6H_6	
1.46	—	0.257	0.026_6	—	—	—
0.599	1.36	0.078_7	0.031_4	0.016_3	0.190	34.0
0.646	0.569	0.090_7	0.017_9	0.013_6	0.075_4	32.0

In Table II are recorded the results obtained in the decomposition of benzaldehyde-d_6 and of two mixtures of benzaldehyde-d_6 and ordinary benzaldehyde. Because of the formation of polymer it was necessary to keep the period of illumination as short as possible, therefore the yield of carbon monoxide was not measured in these experiments. The small amount of C_6D_5H formed in the decomposition of benzaldehyde-d_6 alone arises from the small percentage of benzaldehyde-d_5 present in the original material. The results given for the two mixtures were corrected by this factor.

Assuming that for the isotopic aldehydes the same fraction of the total reaction proceeds by formation of free radicals, and similarily that the rate of reaction [10] is the same for all isotopic species, it is possible to calculate from the results of the two experiments the fraction proceeding by steps [7] and [10]. If these assumptions are valid the amount of the mixed benzenes, C_6D_5H and C_6H_5D, formed in each experiment should be equal. The observed agreement was not too satisfactory, presumably because the amounts formed were quite small compared to the experimental error. For purposes of calculation the amounts of C_6H_5D and C_6D_5H were averaged. The final column of Table II shows that of that fraction of the total reaction which produced benzene, 33% did so by a free radical mechanism. There was no evidence for the formation of mixed aldehydes suggesting that the recombination reaction

$$C_6H_5 + CHO \rightarrow C_6H_5CHO \qquad [12]$$

must be much slower than the disproportionation reaction [10].

Acrolein

Using low energy electrons no free radicals could be detected in the photosensitized decomposition of acrolein. From a comparison of the 50-v spectra with and without illumination the principal products were found to be ethylene, acetylene, carbon monoxide, and a small amount of hydrogen. At higher partial pressures of aldehyde a substance of mass 54 was formed. This was identified as 1,3-butadiene, presumably formed by the dimerization of vinyl radicals.

On the addition of methyl radicals to the system a compound of parent mass 42 was formed. This compound was identified as propylene and confirms the presence of the vinyl radical. This suggests the primary step:

$$CH_2{=}CH{-}CHO + Hg^* \rightarrow CH_2{=}CH + CHO + Hg. \qquad [13]$$

In addition, a small amount of product of mass 70 was also formed. This compound was probably vinyl methyl ketone, suggesting the occurrence to some extent of the additional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

primary step:

$$CH_2{=}CH{-}CHO + Hg^* \rightarrow CH_2{=}CH{-}CO + H + Hg. \quad [14]$$

The product yields obtained by varying the length of the illuminated zone are given in Table III and shown graphically in Fig. 1. The carbon and oxygen balances were low,

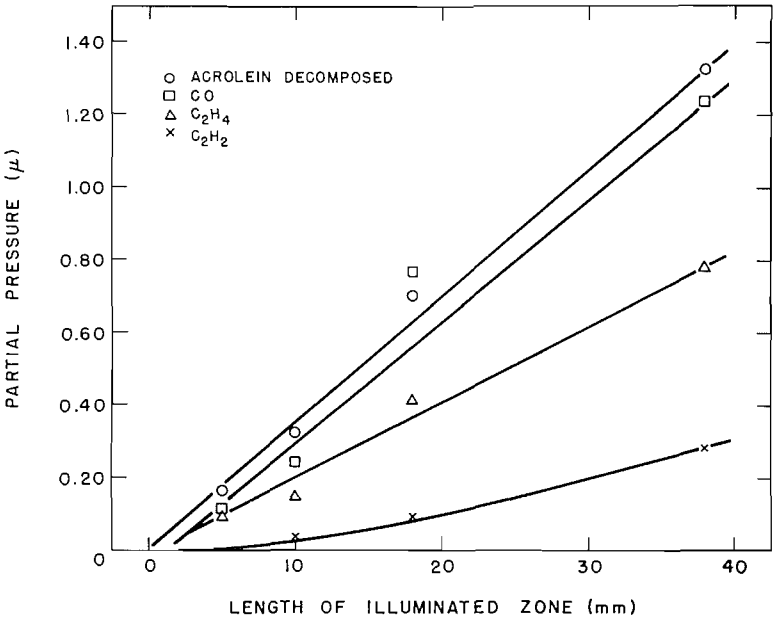

FIG. 1. Mercury-photosensitized decomposition of acrolein.

TABLE III

Acrolein decomposition (partial pressure acrolein 4.85 μ)

Length of illuminated zone (mm)	Acrolein decomposed		Products (μ)			Product balance	
	(μ)	(%)	CO	C_2H_4	C_2H_2	% C	% O
38	1.33	27.4	1.23	0.783	0.282	84.5	92.9
18	0.700	14.4	0.768	0.417	0.095	68.9	(109.7)

5	0.165	3.38	0.114	0.095	0.00	61.4	69.1

probably as a result of the presence of radicals which were not included in the material balances. The curved nature of the plot of the acetylene yield versus the length of illuminated zone suggests that acetylene was not produced in a primary step. The only primary step producing acetylene which would be energetically possible is the reaction:

$$CH_2{=}CH{-}CHO + Hg^* \rightarrow C_2H_2 + CH_2O + Hg. \quad [15]$$

The absence of formaldehyde as a product indicates that this reaction does not occur. Several secondary reactions can be postulated to explain the formation of acetylene

$$C_2H_3 + Hg^* \rightarrow C_2H_2 + H + Hg \quad [16]$$

$$C_2H_3 \rightarrow C_2H_2 + H \quad [17]$$

$$2C_2H_3 \rightarrow C_2H_2 + C_2H_4 \quad [18]$$

$$C_2H_4 + Hg^* \rightarrow C_2H_2 + H_2 + Hg. \quad [19]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

From heats of formation, assuming $D(C_2H_3—H) \leqslant 110$ kcal/mole, $D(H—C_2H_2)$ can be calculated to be $\geqslant 36$ kcal/mole; therefore the decomposition reaction [17] should be very slow at the temperature of the reactor (55° C). It is possible that the acetylene could be produced by reaction [18]. However, most of the ethylene must arise by some other mechanism since in all cases more ethylene was produced than acetylene. The relatively large yield of ethylene, the apparent low concentration of vinyl radicals, and the absence of products containing the CHO group all suggest that a large proportion of the reaction proceeds by a molecular rearrangement mechanism:

$$CH_2{=}CH—CHO + Hg^* \rightarrow CH_2{=}CH_2 + CO + Hg. \quad [20]$$

The presence of the vinyl and acrylyl radical, as shown by the methyl addition products propylene and vinyl methyl ketone, strongly suggest the occurrence of two other primary processes:

$$CH_2{=}CH—CHO + Hg^* \rightarrow CH_2{=}CH + CHO + Hg \quad [13]$$

$$CH_2{=}CH—CHO + Hg^* \rightarrow CH_2{=}CH—CO + H + Hg. \quad [14]$$

From the present experiments it is not possible to determine the relative importance of the three primary processes.

Crotonaldehyde

Difficulties were encountered in identifying the products formed in the mercury-photosensitized decomposition of crotonaldehyde. For this reason an identification of all primary reactions and an estimate of their relative importance could not be made. The main products detected were carbon monoxide, propylene, a product of mass 40, a small amount of acetylene, and a very small amount of a product of mass 56. Use of low energy electrons led to detection of a radical mass 41. The addition of methyl radicals caused a small but definite increase at mass 84 indicating the presence of the crotonyl radical in small amounts and thus suggesting the occurrence of the primary reaction:

$$CH_3—CH{=}CH—CHO + Hg^* \rightarrow CH_3—CH{=}CH—CO + H + Hg. \quad [21]$$

The large amount of propylene produced suggested that the main primary step was the molecular rearrangement:

$$CH_3—CH{=}CH—CHO + Hg^* \rightarrow CH_3—CH{=}CH_2 + CO + Hg. \quad [22]$$

It was not possible to determine whether the radical of mass 41 was formed by the primary reaction:

$$CH_3—CH{=}CH—CHO + Hg^* \rightarrow CH_3—CH{=}CH + CHO + Hg \quad [23]$$

or by the reaction of Hg* with propylene produced in reaction [22] as follows:

$$CH_2{=}CH—CH_3 + Hg^* \rightarrow CH_2{=}CH—CH_2 + H + Hg. \quad [24]$$

Since a considerable amount of propylene was present, and since propylene has a large cross section for reaction with excited Hg atoms (6), the latter alternative appears more probable.

CONCLUSIONS

The mercury-photosensitized decomposition of benzaldehyde under the present conditions leads primarily to the formation of a polymeric material. However, that portion of the reaction which results in identifiable products has been shown to involve two primary processes, a molecular rearrangement to form benzene and carbon monoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

and a free radical split to form phenyl and presumably formyl radicals, with 33% of the reaction occurring by the free radical mechanism. No evidence was found for the formation of benzoyl radicals and hydrogen atoms. This mode of decomposition is quite different from that of acetaldehyde, in which no molecular rearrangement was found to occur, and free radicals only were formed.

The reactions of both acrolein and crotonaldehyde appear to involve three primary processes

$$RCHO + Hg\ ^3P_1 \rightarrow RH + CO + Hg \quad [25]$$

$$\rightarrow R + HCO + Hg \quad [26]$$

$$\rightarrow RCO + H + Hg. \quad [27]$$

For both these compounds the results suggest that the main reaction is the molecular rearrangement [25], with reaction [26] occurring to a lesser extent and reaction [27] only to a very slight extent. The results for acrolein and crotonaldehyde do not permit quantitative determinations of the relative importance of the three steps.

THE POLYOXYPHENOLS OF WESTERN RED CEDAR (THUJA PLICATA DONN.)

I. ISOLATION AND PRELIMINARY CHARACTERIZATION OF PLICATIC ACID[1]

J. A. F. Gardner, G. M. Barton, and Harold MacLean

ABSTRACT

An amorphous, optically active, heat and light sensitive, polyoxyphenolic acid ($pK_a = 3$) has been isolated from the mixture of polyoxyphenols present in the aqueous extractive of western red cedar. Analyses of crystalline derivatives are consistent with a molecular formula of $C_{20}H_{22}O_{10}$. Color tests, spectra, methylation, and alkaline nitrobenzene oxidation results indicate it to be a propylphenol dimer, a lignan acid, in which one aromatic ring is 3-methoxy-4-hydroxyphenyl and the other is 3,4-dihydroxy-5-methoxyphenyl. Acetylation results and lactone formation require the presence of three alcoholic hydroxyls, one of which is in the γ position to the carboxyl.

In a previous paper (1), the presence in the acetone extractive of western red cedar of several water-soluble polyoxyphenols was reported. This phenolic mixture constituted 4 to 5% of wood samples having acetone solubilities of 10 to 14%. These substances were also extracted with water and accounted for the main portion (85–95%) of the hot-water extractive of butt outer heartwood which was found to have hot-water solubilities ranging from 10 to 23% (2). This indicated high content of natural phenolic substances together with the availability of large volumes of western red cedar wood as mill and forest residue in British Columbia prompted a detailed investigation of the chemistry of the phenolic constituents.

Paper chromatography of the aqueous extractive, a brown resin, showed the presence of at least seven different phenols and arabinose. By steaming the mixture during aqueous extraction of the wood, the steam-volatile tropolones, thujic acid and methyl thujate, were virtually eliminated. The arabinose and other non-phenols in the extractive were removed by treatment with lead acetate solution and regeneration of the phenols from the precipitated lead salts. Attempts to fractionate the regenerated phenols with a variety of solvents were made, and the separation efficiency was checked by means of paper chromatography of the fractions. In this manner it was established that a major component ($R_f = 0.9$, carbon dioxide – water) was very soluble in water and, compared with the others, practically insoluble in ethyl acetate. Thus, thorough extraction of the phenolic mixture with ethyl acetate gave a residue which was paper chromatographically pure in respect to carbohydrates and other phenols. This product was an amorphous brown powder which gave positive tests for pyrocatechol, methoxyl, and carboxyl groups. In view of its acidity and source, this substance was termed plicatic acid.

Additional quantities of plicatic acid were isolated simply by extracting it from the mixture of phenols in methyl ethyl ketone with sodium bicarbonate solution. The yield was 40% of the aqueous extractive, but since the product was brown in color and failed to crystallize or give crystalline methyl ethers with diazomethane, milder methods of isolation not involving the use of acids and alkalis were investigated.

Column chromatography with a variety of packings including cellulose, magnesol–

celite, alumina, and ion-exchange resins was examined. The low solubility of the aqueous extractive in most solvents limited the loading of most columns to very small quantities. Also, although weakly basic ion-exchange resins separated plicatic acid from the other phenols, acid was required to elute the plicatic. The most successful column separation of the phenols was obtained with a weakly acid (carboxylic) cation-exchange resin which is also useful in the separation of flavonoids (3). Elution with water of a column loaded with the aqueous extractive yielded plicatic acid and the phenols, R_f .7 and .5 (carbon dioxide – water), in that order with some overlapping. Subsequent graded elution with water–ethanol gave the phenols of R_f .52 and .03 and finally a mixture of the remainder, R_f .03, .06, and .1. Paper chromatography showed that the first plicatic acid eluted from the column was contaminated with arabinose. Subsequent fractions showing no contamination were combined and lyophilized to provide amorphous plicatic acid in small quantities (1 g or less).

Consideration of the high solubility of plicatic acid in water and very poor solubility in ethyl acetate together with the poor solubility of the other phenols in water and their good solubility in ethyl acetate led to isolations on a larger scale by a six-stage countercurrent distribution of the aqueous extractive between these two solvents. This procedure provided almost equal quantities of chromatographically pure plicatic acid and plicatic acid contaminated with 5–6% of arabinose and traces of other sugars in a combined yield of 40% on the aqueous extractive.

As obtained by the column or countercurrent distribution technique, the plicatic acid was a very light tan-colored, amorphous, optically active powder, very soluble in water, soluble in absolute acetone and ethanol, and very slightly soluble in ethyl acetate and ether.

The color reaction with aqueous ferric chloride was pinkish purple shifting to blue-green at neutrality and thence to deep red in sodium carbonate solution. This indication of the presence of adjacent phenolic hydroxyls was confirmed by positive tests with ferrous sulphate, ammonium molybdate, titanium chloride, and bromine solutions. A test for three vicinal phenolic hydroxyls with ferrous sulphate – potassium tartrate solution was negative, but the chlorine – sodium sulphite test for pyrogallol derivatives was positive. Alkaline nitrobenzene oxidation gave a 4% yield of vanillin. A test for methylenedioxy groups was negative.

Solutions of plicatic acid were unstable to sunlight, rapidly turning dark red-brown in color. Heating the solid or an aqueous solution caused a gradual conversion to another phenol of R_f 0.7 (carbon dioxide – water) having an infrared absorption characteristic of a γ-lactone. This substance, according to paper chromatography, was identical with one of the other phenols occurring with plicatic acid in the cedar extractive. Acidification of an alkaline solution regenerated plicatic acid.

Elementary analyses and molecular weight determinations indicated an empirical formula for plicatic acid of $C_{20}H_{24}O_{10}$. For two methoxyl groups and one carboxyl group per molecule, this requires a methoxyl content of 14.6% and a neutral equivalent of 424. The best values found were 13.7% and 432 respectively. The heating (65–100° C) necessary for moisture removal prior to analyses also caused some decomposition making analytical results on plicatic acid itself subject to question.

Methylation of plicatic acid with dimethyl sulphate and alkali in aqueous acetone solution followed by diazomethane in dioxane gave a crystalline product which could also be obtained in poorer yield directly from plicatic with diazomethane. Analytical values for carbon, hydrogen, and methoxyl content and molecular weight fitted an empirical

formula of $C_{24}H_{30}O_{10}$. This corresponds to the methyl ester of the trimethyl ether of a plicatic acid containing two fewer hydrogens per molecule than the formula above. Since dehydrogenation during diazomethane methylation is unlikely and the analytical values for plicatic are based on amorphous heat-labile material, the $C_{20}H_{22}O_{10}$ formula for plicatic acid is favored.

The methyl ester of the trimethyl ether effervesced when heated above its melting point, evolving methanol and yielding a crystalline product which analyzed as the trimethyl ether lactone, $C_{23}H_{26}O_9$. The lactone character was confirmed by the appearance of a strong band in the infrared absorption spectrum at 1784 cm^{-1}, the region assignable to the carbonyl group of five-membered lactones (4) and disappearance of the band at 1716 cm^{-1} assignable to the carbonyl group in the ester (5). The infrared absorption spectrum of the lactone also indicated additional hydroxyl group content.

Acetylation of plicatic acid in acetic anhydride and pyridine gave an amorphous product analyzing for methoxyl content as a hexaacetate.

The neutralization curve for plicatic acid disclosed it to be a strong acid, $pK_a = 3$, comparable to orthohydroxybenzoic acids. However, in acids of this type having strong intramolecular hydrogen bonding the absorption band in the infrared spectrum assignable to the carbonyl occurs below 1680 cm^{-1} (5), whereas for plicatic acid the band assignable to the carbonyl is at 1713 cm^{-1}, a frequency normal for monobasic aliphatic acids.

The high acidity of plicatic acid indicated it would displace acetic acid from its salts. Treatment of an alcoholic solution with alcoholic potassium acetate precipitated a crystalline monopotassium salt, $C_{20}H_{21}O_{10}K$, in high yield. Therefore the possibility of isolating and purifying plicatic acid directly from the aqueous extractive by precipitation as the potassium salt is now being examined.

The analytical and molecular weight results on plicatic acid and its crystalline derivatives indicate it to be a propylphenol dimer of the lignan type and, pending completion of degradative studies, some deductions may be made as to the nature of the aromatic nuclei. The formation of some vanillin by oxidation indicates one aromatic ring to be 3-methoxy-4-hydroxyphenyl. The presence of two additional phenolic hydroxyls adjacent to one another is shown by the methylation data and the color tests. This together with the positive test for pyrogallol derivatives indicates a vicinal arrangement of these two phenolic hydroxyls with the other methoxyl on the other aromatic ring. In addition to the three phenolic hydroxyls and one carboxylic hydroxyl which, with two methoxyls, account for seven of the 10 oxygens required by the empirical formula, $C_{20}H_{22}O_{10}$, there are three alcoholic hydroxyls as shown by formation of a hexaacetate. One of these is used in γ-lactone formation by the methyl ester of the trimethyl ether, and the other two account for the hydroxyl band remaining in the infrared absorption spectrum of the lactone. Thus the formula for plicatic acid can be provisionally written: $C_6H_3(OH)(OCH_3).C_5H_4(OH)_3(COOH).C_6H_2(OH)_2(OCH_3)$, and it is reasonable to conclude that it is a highly hydroxylated lignan acid. Structural investigations are continuing.

While no lignan acids have been isolated from plant material heretofore, many of the lactones have (6), and it is significant that the infrared absorption spectrum of the lactone of methylated plicatic acid is similar to those published for the podophyllotoxin series (4).

The presence in plicatic acid of unetherified neighboring phenolic hydroxyls as in another lignan, nordihydroguaiaretic acid, a well-known commercial antioxidant, justifies its testing as an antioxidant. Similarly, biological testing of it and its lactone derivatives is in order in view of the fact that many lactones have marked physiological activity and some are valuable medicinals (7).

EXPERIMENTAL

Evaporations were conducted under reduced pressure at 40° C. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Carbon and hydrogen analyses were by Clark Microanalytical Laboratory, Urbana, Illinois. Infrared absorption spectra were determined on a Baird Atomic KM-1 spectrophotometer. Solvent mixtures for paper chromatography were carbon dioxide – water and butanol – acetic acid – water (40–10–50) for phenols and the latter and butanol–pyridine–water (10–3–3) for sugars.

Preparation of the Aqueous Extractive of Western Red Cedar

Straw-colored shingle mill spalts were ground in a Wiley mill to pass a 20-mesh screen. The wood meal (1.49 kg moisture-free basis, TAPPI hot-water solubility, 14.5%) was leached with four batches of hot water in an earthenware crock. The temperature was maintained at 100° C and agitation achieved by passing steam into the mixture. Results were as follows:

Extraction time (hours)	Volume of extract (liters)	Solids content (g)
2	14.3	84.4
1	7.7	27.1
1	7.0	13.4
1/2	9.3	11.8
Totals	38.3	136.7

After the solution was cooled, the combined extract was decanted from settled solids (10 g) and evaporated at reduced pressure to a viscous brown syrup, (168 g, 25% moisture). Yield based on the wood, 8.5% or 59% of the TAPPI hot-water solubility. Paper chromatograms (carbon dioxide – water) showed spots for phenols at R_f 0, .03, .07, .12, .16, .50, .70, .90. Color tests for thujaplicins were negative. Paper chromatograms showed arabinose and traces of other sugars.

Isolation of Plicatic Acid from Aqueous Extractive

(*a*) *By Sodium Bicarbonate Extraction of Lead-precipitated Phenols*

Aqueous extractive (331 g, moisture-free basis) in water solution was treated with lead acetate solution (900 g in 2 l.) and the precipitated white lead salts (427 g) removed by filtration. A portion (273 g) of the lead salt was agitated with 2-butanone (2 l.) containing excess sulphuric acid (6 *N*). After filtration, the 2-butanone solution was extracted with 5% sodium bicarbonate solution (500 ml, 3×250 ml). The bicarbonate solution after back extraction with 2-butanone was saturated with sodium chloride, acidified with dilute sulphuric acid (12 *N*), and extracted with 2-butanone (2×500 ml, 2×100 ml). The 2-butanone solution was dried over sodium sulphate and evaporated to yield brown amorphous plicatic acid (119 g), which in paper chromatography showed no contamination with sugars or other phenols.

(*b*) *By Column Chromatography*

Aqueous extractive (2.6 g, moisture-free basis) in warm water (400 ml) was added to a column bed (5 cm × 30 cm) of Amberlite IRC-50 (H) (Rohm and Haas, Philadelphia, Penn.) at a rate of 1.5 ml/minute. The column was eluted at the same rate, first with water and then with graded ethanol–water using a fraction collector loaded with 15-ml tubes. The contents of each fifth tube were checked by paper chromatography. The water

eluted arabinose and phenols of R_f .9, .7, and .5 in that order with partial overlapping. The ethanol–water eluted phenols of R_f .52, .03, and a mixture of R_f .03, .06, and .1 in that order. Fractions which were pure by paper chromatography were combined and lyophilized. Total yields were estimated from the pure yields and paper chromatographic data on fractions showing overlapping as follows:

Tube No.	Eluant	R_f of phenols	Yield of pure material (mg)	Total yield estimated (mg)
0–40	H_2O	—	—	—
40–80	H_2O	.90	650	1250
65–140	H_2O	.70	—	200
80–200	H_2O	.50	215	525
200–320	5–20% EtOH	.52	110	225
310–330	20–25% EtOH	.03	30	100
330–340	25–30% EtOH	.03		
		.06	200	200
		.10		
	Totals		1105	2500

The plicatic acid (R_f 0.9) obtained was a light tan, amorphous powder.

(*c*) *By Countercurrent Distribution with Ethyl Acetate – Water*

Aqueous extractive solids (12 g) were added to a 1-liter separatory funnel containing water-saturated ethyl acetate (400 ml) and ethyl-acetate-saturated water (400 ml) and the mixture shaken 5 minutes before separation. The water layer was transferred to a second funnel and similarly treated with fresh ethyl acetate while the ethyl acetate layer was treated with fresh water in the first funnel. This procedure was repeated through six stages involving six funnels until the original water was in funnel six in contact with the last added ethyl acetate and the original ethyl acetate was in funnel one in contact with the last added water. The water layer in funnel six on lyophilization yielded plicatic acid (2.5 g) contaminated with 7–9% arabinose (as determined by quantitative paper chromatography). The combined water layers from funnels four and five with the ethyl acetate layers from five and six yielded paper chromatographically pure plicatic acid (2.3 g), R_f in carbon dioxide – water, 0.9; in butanol – acetic acid – water, 0.4, a light tan-colored powder; $[\alpha]_D^{21}$ −9.99 (water). Ultraviolet absorption in water: min. 256 mμ (log ϵ = 3.23); max. 281 mμ (log ϵ = 3.58); shoulder, 307 mμ (log ϵ = 2.42). Infrared absorption, ν_{max}^{KBr} in cm^{-1}: 3340, 1713, 1611, 1518, 1200, 1088. Calc. for $C_{20}H_{24}O_{10}$: C, 56.6; H, 5.71; OCH_3, 14.6; mol. wt. and neutral equivalent, 424.2; for $C_{20}H_{22}O_{10}$: C, 56.9; H, 5.26; OCH_3, 14.67; mol. wt. and neutral equivalent, 422.2. Found: C, 56.24; H, 5.84; OCH_3, 13.7; mol. wt. (Rast), 433; neutral equivalent, 432. Approximate pK_a from pH at half-neutralization, 3.0.

Color tests with aqueous solutions of plicatic acid were as follows: aqueous ferric chloride, pinkish purple shifting to blue and then red on addition of sodium carbonate; ammonium molybdate and acetic acid (8), reddish brown; with Folin–Denis reagent (9) blue; ferrous sulphate – sodium potassium tartrate at pH 5.6 (10), negative; titanium chloride, yellow; chlorine – sodium sulphite (11), red; Gaebel test for methylenedioxy groups (12), negative.

A quantitative alkaline–nitrobenzene oxidation test, using the technique of Stone and Blundell (13) showed 4% vanillin formation.

Repeated attempts to obtain a crystalline acetate or benzoate of plicatic acid were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

unsuccessful. The amorphous product of treatment with acetic anhydride and pyridine in benzene solution was precipitated in fractions by stepwise addition of ligroin. The last most soluble fraction had a methoxyl content of 9.1; calculated for a hexaacetate, $C_{32}H_{34}O_{16}$, 9.17.

Plicatic Acid Trimethyl Ether Methyl Ester

Plicatic acid (5 g) in a mixture of water (5 ml) and acetone (9 ml) was treated with dimethyl sulphate (4 ml) and 5 *N* sodium hydroxide dropwise at reflux for 2 hours while maintaining the pH at 8–9. The methylated plicatic precipitated as the white sodium salt during the latter stages of the reaction. The reaction mixture was acidified to pH 3, the acetone removed, and the mixture extracted with chloroform. The residue from evaporation of the chloroform solution was methylated in dioxane with excess diazomethane to yield a product which crystallized from benzene in 42% yield. Melting point after recrystallization from benzene 204–205° C $[\alpha]_D^{22}$ −29.9 ($CHCl_3$).

A methylation of plicatic acid in methanol directly with diazomethane gave the same product contaminated with large amounts of black ether-soluble tar which complicated the purification and reduced the yield of pure product to 23%.

The product, recrystallized from benzene, contained benzene of crystallization. Recrystallization from ethanol gave colorless crystals m.p. 203–204° C. Calc. for $C_{24}H_{30}O_{10}$: C, 60.24; H, 6.32; OCH_3, 38.9; mol. wt., 478.6. Found: C, 59.91; H, 6.02; OCH_3, 38.7; mol. wt. (Rast), 478. Infrared spectrum, ν_{max}^{KBr} in cm^{-1}: 3460, 1716, 1588, 1522, 1511, 1451, 1422, 1256, 1235, 1215, 1128, 1002, 861.

Plicatic Acid Trimethyl Ether Lactone

The trimethyl ether methyl ester on the melting point stage was observed to evolve a gas after melting and then recrystallize. The material evolved was condensed and found to be methanol and the solid, m.p. 252–255° C had an infrared absorption characteristic of a γ-lactone. Accordingly the ester (0.1 g) was heated under nitrogen at 220° C until evolution of gas had ceased and the material had resolidified. Recrystallization from ethanol gave colorless crystals, m.p. 257° C. Calc. for $C_{23}H_{26}O_9$: C, 61.93; H, 5.88; OCH_3, 34.72. Found: C, 61.82; H, 5.99; OCH_3, 34.66. Infrared spectrum, ν_{max}^{KBr} in cm^{-1}: 3450, 1784, 1593, 1518, 1465, 1425, 1322, 1255, 1220, 1126, 992, 862.

Potassium Plicatate

Plicatic acid (2 g) in anhydrous ethanol (50 ml) was treated with anhydrous potassium acetate (0.6 g) in ethanol (10 ml). The white salt which precipitated immediately was separated on the centrifuge and washed well with ethanol (70 ml) before drying under pressure at 65° C. Yield 1.5 g (68.5% of theory). The product was quite soluble in methanol and could be reprecipitated by addition of ethanol. Calc. for $C_{20}H_{21}O_{10}K$: C, 52.16; H, 4.60; OCH_3, 13.45; K as sulphated ash, 18.82. Found: C, 52.17; H, 5.11; OCH_3, 13.39; K as sulphated ash, 18.7. The infrared absorption spectrum was characteristic of the salt of an organic acid (5), ν_{max}^{KBr} in cm^{-1}: 3340, 1610 and 1600 (broad doublet), 1515, 1350–1320 (broad), 1205, 1090, 872.

INFRARED SPECTRA AND STRUCTURE OF POLYALDEHYDES

III. POLYACETALDEHYDE AND POLYPROPIONALDEHYDE[1]

A. NOVAK[2] AND E. WHALLEY

ABSTRACT

Acetaldehyde and propionaldehyde have been polymerized at room temperature and pressures of about 10 kb. The infrared spectra of the polymers have been investigated and it is shown that the polymers have the formula $HO(CHR.O)_nH$. The spectra are too complicated to be understood if there is only one monomer unit in the repeating unit of the chain; there are at least two units.

1. INTRODUCTION

Polyacetaldehyde was first made approximately simultaneously by Letort (1) and by Travers (2) by cooling acetaldehyde in liquid nitrogen. The molecular weight of a sample was about a half-million (3). A note (4) describes briefly its infrared spectrum, which indicates that its structure is $(CHCH_3.O)_n$, confirming Staudinger's suggestion (5). Attempts to polymerize propionaldehyde by this method failed (6). The higher aliphatic aldehydes, butyraldehyde and higher homologues, polymerize under pressures of about 10 kb (7, 8) to give compounds that are presumed to have the structure $(CHR.O)_n$, but an attempt to polymerize acetaldehyde by subjecting it to a pressure of 9 kb and 40° C failed (9). Low-molecular-weight polymers of acetaldehyde have been made (10) by treating mixtures of acetaldehyde and acetaldehyde diethylacetal with a small amount of concentrated sulphuric acid at −40 to +20° C, and the structure $C_2H_5O(CHCH_3.O)_nC_2H_5$ was suggested. Propionaldehyde has apparently not been polymerized previously except by the aldol condensation.

In this paper we describe the preparation of polymers of acetaldehyde and propionaldehyde by subjecting the monomers to pressures of about 9 kb at room temperature. The infrared spectra and X-ray diffraction patterns of these polymers, of low-temperature polyacetaldehyde, and of the polymer from acetaldehyde and acetal have been obtained in order to help elucidate the structures.

2. EXPERIMENTAL METHODS AND RESULTS

Eastman-Kodak White-Label acetaldehyde, acetal, and propionaldehyde were used. They were dried with Drierite and distilled before use in a fractionating column in an atmosphere of dry air. Acetaldehyde-d_1 (CH_3CDO) and propionaldehyde-d_1 (C_2H_5CDO) were prepared from nitroethane and nitropropane respectively by the method described by Leitch (11).

High-pressure Polymerization

The monomers were subjected to pressures of about 9 kb for 1–2 days at room temperature. The reaction vessel was a 1-cm³ stainless-steel test tube closed by a piston that was fitted with an *o*-ring. The vessel was filled with aldehyde, stoppered, and put into the high-pressure end of an intensifier which was then pressurized. When the monomers were almost free of water the polymerization was almost complete in 1–2 days and the

[1]*Manuscript received March 25, 1959.*

Issued as N.R.C. No. 5309.
[2]*N.R.C. Postdoctorate Fellow, 1956–58.*

polymers were tacky solids. The proportion polymerized and the viscosity of the product decreased rapidly when small amounts of water were added to the monomer. For example, the azeotropic mixture of propionaldehyde and water, which contains about 1.9% of water in the form of the hydrate (12), polymerized under pressure only to the extent of about 30%, as estimated from the intensity of the C=O stretching band in a solution of the mixture in carbon tetrachloride, and after evaporation of the monomer the polymer remained as a liquid probably of low molecular weight as estimated from the intensity of the OH end group stretching band (see below). If we can anticipate our conclusions about structure, this is probably due to the equilibrium

$$\frac{1}{n}H_2O + RCHO \rightleftharpoons \frac{1}{n}HO(CHR.O)_nH$$

being dependent upon the amount of water present. At 1 atm pressure and room temperature the polymers depolymerized spontaneously to the parent aldehyde. The depolymerization of the solid polymer was rather slow and took several weeks at room temperature if it was exposed to the atmosphere so that the monomer could evaporate. If the monomer was not allowed to evaporate, or if the polymer was liquid, or if it was dissolved in carbon tetrachloride, depolymerization was complete, as determined by the infrared spectrum, in a few days. Presumably depolymerization occurs faster in a less viscous medium.

Low-pressure Polymerization of Acetaldehyde

The low-temperature polymer was made by condensing the vapor at liquid-nitrogen temperatures as described by Bevington and Norrish (13). A polymer of low molecular weight was prepared by treating a mixture of acetaldehyde and acetal in molar ratio 6:1 at −40° C with a drop of concentrated sulphuric acid (10). After 2 hours the acid was neutralized with sodium bicarbonate and the mixture dried with Drierite and filtered. The dimer and trimer were distilled off under reduced pressure; an oily liquid remained.

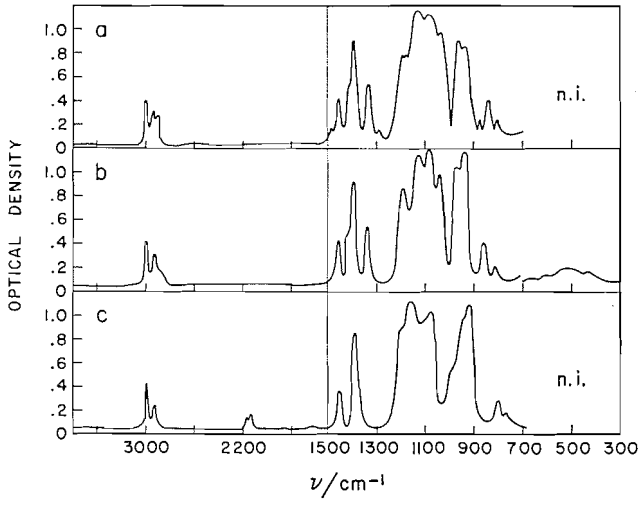

FIG. 1. Infrared spectrum of polyacetaldehyde: (*a*) low-molecular-weight polymer from acetaldehyde and acetal, (*b*) high-pressure polyacetaldehyde, (*c*) high-pressure polyacetaldehyde-d_1.

The polymers were examined spectroscopically as thin films pressed between sodium chloride or cesium bromide windows and as solutions in carbon tetrachloride. The spectra were recorded between 4000 and 700 cm^{-1} using a Perkin–Elmer Model-21 infrared spectrophotometer equipped with a rock salt prism, and between 700 and 300 cm^{-1} with a Beckmann IR-4 spectrophotometer equipped with a cesium bromide prism. The infrared spectra of polyacetaldehyde and polypropionaldehyde are shown in Figs. 1 and 2, and the wave numbers and relative intensities of the bands are given in Tables I and II.

X-ray diffraction photographs of films were taken with a Debye–Scherrer powder-camera, diameter 114.7 mm, using nickel-filtered copper radiation. Polyacetaldehyde gave two diffuse rings corresponding to interplanar spacings of 3.9 and 7.2 Å; polypropionaldehyde gave three diffuse rings corresponding to interplanar spacings of 2.1, 4.1, and 9.0 Å.

3. DISCUSSION

(*i*) *Polyacetaldehyde*

The infrared spectra of low-temperature and high-pressure polyacetaldehyde were identical, except for the intensity of the minor bands in some samples in the region of 3300 cm^{-1} which we ascribe to end groups (see below). Chemical evidence (14) and previous spectroscopic evidence (4) show that the low-temperature polymer has the structure $(CHCH_3.O)_n$. Detailed examination of the spectra, which is described below, fully agrees with this. Hence, the low-temperature and high-pressure polymers are identical, except perhaps for molecular weight. There is a weak band at 3440 cm^{-1} which varies in intensity from sample to sample. It is probably due to OH end groups; the formula is thus $HO(CHCH_3.O)_nH$.

The X-ray diffraction patterns of thin films of both low-temperature and high-pressure polymer show only two diffuse rings which correspond to spacings of about 3.9 and 7.2 Å, in agreement with the spacings reported for the low-temperature polymer (14). Filaments were drawn from the polymers, but X-ray diffraction photographs of them showed no orientation. It has been suggested (14) that the broad rings are due to intrachain spacings. However, the corresponding spacings of other polyaldehydes are greater than those of polyacetaldehyde by an amount that increases as the bulk of the side chain increases (15). It seems more likely, therefore, that these broad bands are due to interchain and not to intrachain distances.

The infrared spectrum of the polymer obtained from acetaldehyde and acetal is similar

to that of polyacetaldehyde and confirms the proposed structure (10) $C_2H_5O(CHCH_3.O)_n$-C_2H_5. The bands in the skeletal stretching region (1200–900 cm^{-1}) are slightly displaced from, and their relative intensities are somewhat different from, those of high-molecular-weight polyacetaldehyde. In addition, a few weak bands or shoulders appear near 2880, 1470, 1295, 1170, and 870 cm^{-1}; they are probably due to the ethyl end groups.

The infrared spectra of high-pressure polyacetaldehyde and polyacetaldehyde-d_1 are shown in Fig. 1. The bands in the skeletal stretching and skeletal bending regions are broad, in contrast to those of polychloral (15), probably because there are many rotational isomers present. However, if, as seems likely, the polymer chain is kinked at a small proportion of the C—O bonds and the interaction between the chains is small, the spectrum will resemble that of the isolated regular (i.e. repeating) chain. In particular, the number of strong bands observed should be close to the number expected for an isolated regular chain, and the bands will be broader than for the regular chain because rotational isomers are present. Similar assumptions about other polymers have been made by others (16, 17), and we tentatively assume that they are true for polyacetaldehyde and poly-propionaldehyde. The observation that the infrared spectrum of polyacetaldehyde in solution is similar, except that the bands are broader, to the spectrum of the pure polymer verifies that interaction between chains does not produce major changes in the number of strong bands. Davison (18) has shown that the presence of rotational isomers causes broadening of the bands in polyesters and related compounds. The assumption that the number of strong bands in a moderately kinked chain is close to the number expected for a regular chain allows us to obtain some tentative information about the structure of the polymer chain. Unfortunately, there appears to be no simple way of counting the number of kinks and so of verifying our assumption directly. We were not able to obtain oriented specimens of polyacetaldehyde or polypropionaldehyde and so could not obtain the dichroisms, probably because the melting point is below room temperature.

If there is one monomer unit in the repeat of polyacetaldehyde there are $3\times7-4 = 17$ fundamental frequencies that may be optically active, because only those vibrations that are in phase in all repeat units can be active in a perfect chain. These frequencies may be approximately divided as follows. Between 3000 and 2700 cm^{-1} two asymmetrical (which are probably not resolvable) and one symmetrical CH_3 stretching frequency and one CH stretching frequency are expected. Between 1500 and 1300 cm^{-1} two asymmetrical (which may not be resolvable) and one symmetrical CH_3 bending frequency are expected. Only one CH bending frequency is expected in this region, the other being probably below 1200 cm^{-1}, because deuterated chloral hydrate (19) has only one band in this region, and a band near 1100 cm^{-1} that is present in acetals and absent in ketals has been ascribed (20) to the CH bending mode. Between 1300 and 700 cm^{-1} two CH_3 rocking (which may not be resolved), one CH bending, and three skeletal (CO and CC) stretching bands are expected.

In the spectrum of polyacetaldehyde there are three bands in the 3-μ region, 2980, 2920, and 2860 cm^{-1}. The 2860-cm^{-1} shoulder disappears on deuteration and is replaced by two bands at 2160 and 2140 cm^{-1}. The 2860-cm^{-1} shoulder is thus a CH stretching band and the 2980- and 2920-cm^{-1} bands are the CH_3 asymmetrical and symmetrical stretching bands respectively. The two bands at 2160 and 2140 cm^{-1} may both be CD stretching fundamentals of the regular chain or one may be a band characteristic of the non-crystalline polymer, as occurs in the CH stretching region in polychloral (15), or one may be an overtone whose intensity is increased by Fermi resonance.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

In the range 1500–1300 cm^{-1} there are three medium or strong bands, 1445, 1380, and 1335 cm^{-1}, and a shoulder, 1400 cm^{-1}. The 1400- and 1335-cm^{-1} bands disappear on deuteration and are thus CH bending bands; two CH bending bands are also present in polychloral (15) at 1360 and 1325 cm^{-1}. The bands at 1445 and 1380 cm^{-1} do not shift on deuteration and are straightforwardly assigned to the asymmetrical and symmetrical CH_3 bending modes, respectively.

The bands below 1200 cm^{-1} are not so easily identified. There are very intense and broad bands at 1187, 1130, 1085, 1040, 970, and 935 cm^{-1}. No band similar to the 1187-cm^{-1} band is observed in the spectra of the polyaldehydes which do not contain methyl groups, such as polymers of formaldehyde (21), chloral (15), and mono- and di-chloroacetaldehyde (22), and it might be due to the CH_3 rocking vibrations which are expected in this region (23). This mode involves appreciable skeletal stretching motion (23) and so may absorb strongly. The remaining bands in the 1200–900 cm^{-1} region are likely to be due to C—O and C—C stretching vibrations; they are similar to bands in the spectra of acetals and of other polyaldehydes. The changes in this region on deuteration are difficult to interpret because the bands overlap and are broad. Two CD bending bands, corresponding to the CH bending bands 1400 and 1335 cm^{-1}, should be here.

There is a medium band at 845 cm^{-1} and a weak band at 810 cm^{-1} which are replaced on deuteration by bands at 787 and 760 cm^{-1}. They might be associated with the low-frequency C—H bending mode. The shifts, however, are small and if they are CH bending bands they must be strongly coupled with skeletal motions; presumably other bands in the region 1200–1000 cm^{-1} shift but the shifts are masked by the overlapping of bands.

In the remaining part of the spectrum there occurs only one very broad weak band at 490 cm^{-1} with shoulders at 510 and 450 cm^{-1}. Similar bands occur in the spectra of acetals (20) and other polyaldehydes (15, 21, 22, 25) and are probably due to skeletal bending motions.

It is not easy to interpret the spectrum on the grounds of one monomer unit in the repeat unit. Thus, there are two higher-frequency C—H bending bands where only one is expected; there are eight bands in the region 1250–700 cm^{-1} where there are only six expected if the two CH_3 rocking modes are resolved and only five if, as seems very likely, they are not. If the assumption that we have made, that the kinking of the chain does not greatly effect the number of strong bands, is true then there are at least two monomer units in the repeat unit of the polymer chain.

(ii) Polypropionaldehyde

Polypropionaldehyde is very similar to polyacetaldehyde in chemical properties and in infrared spectrum. It is therefore a substituted polyoxymethylene and has the monomer unit $(CHC_2H_5.O)$, as expected from the ease of polymerization and depolymerization. A broad weak band at 3460 cm^{-1} occurs in some samples; it is probably an OH stretching band due to the end groups. The polymer is therefore $HO(CHC_2H_5.O)_nH$. The X-ray powder diagram has two diffuse rings that correspond to spacings of about 9.0 and 4.1 Å. This and the broadness of the skeletal stretching and bending bands show (see below) that the polymer is amorphous. The broad rings on the X-ray diagram probably relate to interchain rather than to intrachain distances, as argued above for polyacetaldehyde. The infrared spectra can be analyzed, as was that of polyacetaldehyde, to show that there is probably more than one monomer unit in the repeat. The assumptions made are the same as those made for polyacetaldehyde, i.e. that rotational

isomerism and interaction between chains broadens the infrared bands but does not produce much change in the number of strong bands. By analogy with polyacetaldehyde and polychloral it is likely that only the CH bending and skeletal stretching and possibly the CH stretching modes will give information about the structure. If there is one monomer in the repeat unit then one CH stretching, one CH bending, and four skeletal stretching bands are expected.

There are three strong bands in the 3-μ region, at 2960, 2925, and 2870 cm^{-1}. They do not shift on deuteration, and so are due mainly to methyl and methylene groups. Though no shifts are observed on deuteration, two bands, 2150 and 2125 cm^{-1}, appear in the spectrum of polypropionaldehyde-d_1. At least one band is CD bending and, as with polyacetaldehyde, both may be fundamentals of the crystalline polymer, one may be a band characteristic of the disordered regions of the polymer, or one may be an overtone in resonance with the fundamental.

In the region 1500–1200 cm^{-1} there are medium or strong bands at 1468, 1443, 1380, 1345, 1305, and 1265 cm^{-1}. The 1360- and 1305-cm^{-1} bands disappear on deuteration and, as we argued for similar bands in polyacetaldehyde, are probably higher-frequency CH bending bands. The 1443- and 1380-cm^{-1} bands are close to those of polyacetaldehyde and are therefore probably respectively asymmetrical and symmetrical CH_3 bending bands. The remaining three bands, 1468, 1345, and 1265 cm^{-1}, are not present in polyacetaldehyde and shift but slightly on deuteration. They are therefore probably CH_2 bending modes and, on grounds of frequency by comparison with small molecules, are probably the bending, wagging, and twisting modes respectively.

The 1200–900 cm^{-1} region is less straightforward. There are about nine strong or very strong bands. A shoulder at 1175 cm^{-1} might, by analogy with polyacetaldehyde and smaller molecules, be due to the CH_3 rocking modes. The remaining are probably skeletal stretching bands. There are therefore about eight skeletal stretching bands. If there is one monomer unit in the repeating unit only four are expected. This together with the two CH bending bands at 1400–1300 cm^{-1} shows that, if kinking does not cause many new strong bands, then there is probably more than one monomer unit in the repeating unit of the chain. In the spectrum of polypropionaldehyde-d_1 the bands in this region are shifted and their intensities changed. The interpretation of this is uncertain because CD bending bands are expected here.

In the remaining part of the spectrum there are medium or weak bands at 895, 795, 780, and 480 cm^{-1}. The 895-cm^{-1} band is replaced on deuteration by a band at 855 cm^{-1}. It is likely that CH bending is an important contributor to this mode. The bands at 795 and 780 cm^{-1} shift little on deuteration and are not observed in polyacetaldehyde. They may be CH_2 rocking modes, which are expected about here. The very broad weak band at 480 cm^{-1} accompanied by a shoulder at about 590 cm^{-1} is due to skeletal bending vibrations.

We have seen that the spectra of polyacetaldehyde and polypropionaldehyde are considerably more complicated than they would be if there was only one monomer unit in the repeat unit. In particular, there are twice as many high-frequency CH bending and somewhat less than twice as many skeletal stretching bands as are expected for one monomer unit. No further information is obtainable from the infrared spectrum at present. It is interesting to note, however, that polyformaldehyde has a helical configuration (24) which is probably formed from gauche conformations of the C—O bonds (25). The stable conformation of the smallest molecules derived from polyformaldehyde dimethoxymethane, is the double gauche form (26, 27). It seems not unlikely that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

higher homologues of dimethoxymethane, i.e. 1,1-dimethoxyethane and 1,1-dimethoxypropane, have a stable conformation similar to that of dimethoxymethane. If this is so then a chain of such units, such as are polyacetaldehyde and polypropionaldehyde, would be expected to have at equilibrium at low temperatures a spiral structure similar to that of polyformaldehyde. The infrared spectra are certainly consistent with a spiral structure, but do not prove it. As outlined previously (21), for all cyclic structures but the trivial plane zigzag, each mode of vibration of the monomer splits into two infrared-active modes, of species A and E_1 (E in some of the simpler spirals). Consequently, if the spiral were perfect, then two high-frequency CH bending and six (polyacetaldehyde) and eight (polypropionaldehyde) skeletal stretching modes would be expected to be active. These are approximately the number of strong bands found in the spectra, and so, if rotational isomerism does not cause many new strong bands, the spectra are consistent with the structures' being spirals.

ACKNOWLEDGMENTS

The authors are very grateful to Dr. L. D. Calvert for taking the X-ray diffraction photographs and to Mr. A. Lavergne for help with the high-pressure equipment.

THE INFRARED SPECTRA AND STRUCTURE OF POLYALDEHYDES

IV. THE HIGHER POLYALDEHYDES[1]

A. NOVAK[2] AND E. WHALLEY

ABSTRACT

The polymers of *n*- and iso-butyraldehyde and *n*-valeraldehyde, which were made by subjecting the aldehydes to pressures of about 8 kb, have been examined by infrared spectroscopy. They are homologues of polyformaldehyde, having the formula $HO(CHR.O)_nH$.

I. INTRODUCTION

The polymerization under pressure of aliphatic aldehydes was first observed by Bridgman and Conant (1) and by Conant and Tongberg (2). The polymers were quite different from those obtained by the aldol condensation, and they readily reverted to the monomers at normal temperature and pressure. Conant and Peterson (3) suggested that they were homologues of polyformaldehyde on the grounds that polymerization and depolymerization was relatively easy and was not catalyzed by bases.

We have investigated the infrared spectra of polymers of *n*- and iso-butyraldehyde, *n*-valeraldehyde, and *n*-heptaldehyde and confirm the structure suggested by Conant and Peterson. This paper reports this work.

2. EXPERIMENTAL METHODS AND RESULTS

The aldehydes were Eastman Kodak White-Label products; they were dried with Drierite several times and were fractionated in an atmosphere of dry air before use. Their infrared spectra were recorded for comparison purposes and to check the substantial absence of water and hydrates. The polymers were prepared by subjecting the monomers to pressures of about 9 kb at room temperature for about one day; this was done by placing them in 1-cm^3 stainless-steel test tubes which were sealed with a plug carrying an *o*-ring and put into the high-pressure end of a pressure intensifier of standard design. Polymerization was usually almost complete; monomer and lower polymers were removed if necessary by extraction with ethanol. Poly-*n*-butyraldehyde was a waxy solid, poly-*n*-valeraldehyde was a viscous liquid, and poly-*n*-heptaldehyde was a solid; all were soluble in ether and carbon tetrachloride and insoluble in ethanol. Poly-isobutyraldehyde was a hard transparent solid that was insoluble in the commoner solvents.

At room temperature all the polymers reverted to monomer. The depolymerization of poly-*n*-butyraldehyde in carbon tetrachloride solution was followed by infrared spectroscopy; depolymerization was complete in about 30 hours at room temperature. Poly-*n*-butyraldehyde was stored for several months in ethanol at about $-10°$ C without apparent depolymerization. No attempt was made to store the other polymers.

The polymers were investigated spectroscopically as films or as suspensions in nujol and hexachlorobutadiene. The spectra were recorded between 4000 and 700 cm^{-1} using a Perkin–Elmer infrared spectrophotometer, Model 21, with a sodium chloride prism, and between 700 and 300 cm^{-1} using a Beckmann IR-4 spectrophotometer with a cesium bromide prism. The spectra are shown in Fig. 1, and the wave numbers and relative intensities of the bands are listed in Table I.

X-ray diffraction photographs were taken on a Debye–Scherrer powder-camera using Ni-filtered Cu radiation. The lattice spacings are listed in Table II.

3. DISCUSSION

The infrared spectra (Fig. 1 and Table I) confirm Conant and Peterson's suggestion (3) that the polymers are substituted polyoxymethylenes. Thus, there are strong bands in the region 1200–900 cm^{-1}; i.e. in the region of C—O stretching bands, and there are no very strong broad bands near 3400 cm^{-1}, showing that OH groups in quantity are absent. Broad weak bands at about 3440 cm^{-1} occur in the spectra of some samples and are probably due to OH end groups; those samples in which the band is missing are probably of higher molecular weight. The chemical formula of the polyaldehydes is thus $HO(CHR.O)_nH$ and they are analogues of polyformaldehyde (4–6), polychloral (7), polyacetaldehyde (8), and polypropionaldehyde (8). The polymerization can be represented thus,

$$RCHO + \frac{1}{n}H_2O \rightleftharpoons \frac{1}{n}HO(CHR.O)_nH,$$

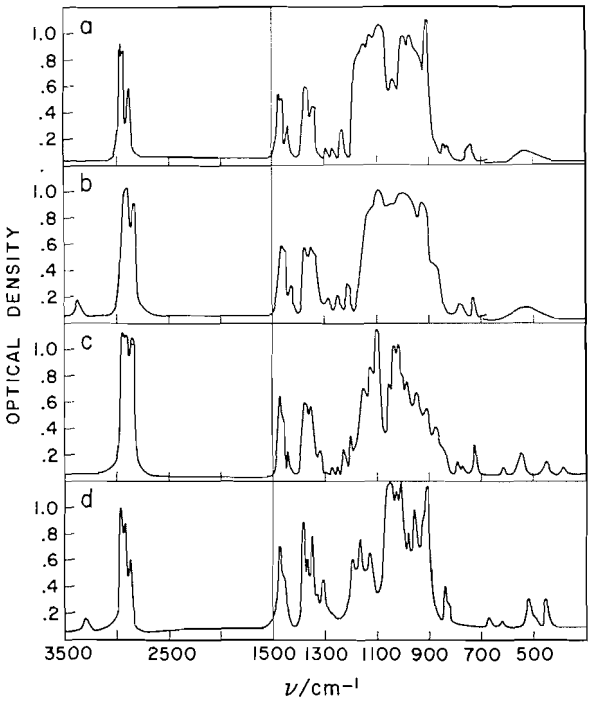

FIG. 1. Infrared spectra of polyaldehydes: (*a*) poly-*n*-butyraldehyde film; (*b*) poly-*n*-valeraldehyde film; (*c*) poly-*n*-heptaldehyde mull in nujol and hexachlorobutadiene; (*d*) poly-isobutyraldehyde mull in nujol and hexachlorobutadiene.

and the position of equilibrium is evidently displaced from almost completely on the left to nearly completely on the right by pressures of about 9 kb.

It is not possible to identify the infrared bands in detail. Undoubtedly C—H stretching modes are in the region 3000–2700 cm^{-1}, C—H bending modes in the region 1500–1200 cm^{-1}, skeletal stretching modes in the region 1200–700 cm^{-1}, with probably some of the lower-frequency C—H bending modes, and skeletal bending modes in the region 700–300 cm^{-1}. The spectra are too complicated to analyze in more detail at the present time.

It should be noted that the bands in the skeletal bending and stretching regions are broad in poly-*n*-butyraldehyde and poly-*n*-valeraldehyde and that the X-ray diagram of poly-*n*-butyraldehyde shows only a few diffuse halos. The X-ray diffraction diagram of poly-*n*-valeraldehyde could not be taken because it decomposed rapidly; since it is a viscous liquid it is likely to be amorphous. On the other hand, the infrared spectra of poly-isobutyraldehyde and poly-*n*-heptaldehyde in the skeletal bending and stretching regions are sharp and the X-ray diagrams for these polymers have relatively sharp rings. We conclude from this evidence that the polymers of *n*-butyraldehyde and *n*-valeraldehyde are amorphous and that the broadness of the infrared bands is caused by the presence of rotational isomers. It is unlikely that the broadness is due to intermolecular effects because the spectrum of poly-*n*-butyraldehyde in carbon tetrachloride solution is similar to that of the film. The polymers of isobutyraldehyde and *n*-heptaldehyde are relatively crystalline, and the sharpness of the infrared bands confirms that they contain relatively few rotational isomers.

The lattice spacings corresponding to the rings of the most intense lines of the X-ray diffraction photographs (Table II) increase with increasing length of the side groups. As we have pointed out before (8), it is likely because of this increase that these spacings are related to interchain rather than to intrachain distances.

INFRARED SPECTRA AND STRUCTURE OF POLYALDEHYDES

V. POLYMONOCHLOROACETALDEHYDE AND POLYDICHLOROACETALDEHYDE[1]

A. NOVAK[2] AND E. WHALLEY

ABSTRACT

The polymers of monochloroacetaldehyde and dichloroacetaldehyde have been examined by infrared spectroscopy. They are homologues of polyformaldehyde, having the formula $HO(CHR.O)_nH$. X-ray-diffraction powder photographs show that they are fairly crystalline.

1. INTRODUCTION

It has been known for some time that mono- and di-chloroacetaldehyde form trimers and polymers (1–3). Trimers are produced when the aldehydes are treated with concentrated sulphuric acid; they are crystalline substances with well-defined melting points (1–3) and are probably analogous to paraldehyde. Monochloroacetaldehyde polymerizes fast when allowed to stand in sealed tubes to give a substance described as amorphous (1) which has the same empirical formula as the aldehyde. Dichloroacetaldehyde, when purified, rapidly forms a similar substance that has the same empirical formula as the aldehyde. Both polymers are insoluble in water and alcohol, and that derived from monochloroacetaldehyde is insoluble also in ether and chloroform. They have no sharp melting points and they decompose to the parent aldehyde when heated to above 120° C. No work on the nature of these substances has been reported.

As part of our program of investigation of the structures of polyaldehydes (4–7) we have investigated the infrared spectra and X-ray powder diagrams of these polymers in order to elucidate their structure. This paper reports the results of this work.

2. EXPERIMENTAL AND RESULTS

Monochloroacetaldehyde (40% water solution) and dichloroacetaldehyde were commercial samples. Monochloroacetaldehyde solution was treated with concentrated sulphuric acid and distilled. The distillate formed a crystalline substance of melting point about 40–50° C which is probably the hydrate (1); this was treated again with concentrated sulphuric acid, and the vapor of the aldehyde which was obtained was dried by being passed through a tube containing calcium chloride heated at 100° C. The vapors when condensed polymerized rapidly to a solid which had similar properties to the polymer previously described (1). The commercial dichloroacetaldehyde was a rather viscous substance whose infrared spectrum indicates that it is a mixture mainly of a polymer whose structure is described below, aldehyde, and water. A small amount of concentrated sulphuric acid was added to this mixture and it was then distilled, and the vapor was dried in a similar manner to that used for monochloroacetaldehyde. The distillate polymerized into a block of translucent soft solid. The polymer was dissolved in acetone and precipitated with methanol. The precipitate was filtered and dried under reduced pressure.

The samples were examined as mulls in nujol and hexachlorobutadiene; the polymer of dichloroacetaldehyde was examined also in chloroform solution and as a film that was obtained by evaporating a solution of the polymer in acetone. The spectra were recorded

3. DISCUSSION

The infrared spectra have very strong bands in the region 1200–900 cm^{-1} that must involve C—O stretching motions. There are no carbonyl stretching bands and only very weak bands in the region of the OH stretching band. This evidence together with the ease of polymerization and depolymerization shows that the structure of the polymers is $(CHR.O)_n$ where R is either the monochloromethyl or dichloromethyl group. There are weak bands in the spectra of some samples in the region of 3400 cm^{-1} which are probably due to OH stretching vibrations. It is likely that the OH groups are at the ends of the chains, and so the formulas are $HO(CHR.O)_nH$. The polymers are thus substituted polyoxymethylene glycols, entirely analogous to the other polymers discussed in this series of papers.

The X-ray diffraction photographs have relatively sharp rings, indicating that the polymers are fairly crystalline, as we found also for polychloral. The bands in the skeletal stretching region of the spectra are broader than those of polychloral and narrower than those of polyacetaldehyde and polypropionaldehyde. It seems likely that the broadness is due, at least partly, to the presence of rotational isomers in the non-crystalline parts of the spectrum. This is supported by the skeletal stretching bands in the spectrum of polydichloroacetaldehyde in chloroform solution, which probably contains more rotational isomers than the solid, being much broader than those of the solid.

We have seen previously (4–7) that the spectra of the simpler polyaldehydes have more bands than they would have if there were only one monomer unit in the repeating unit, and it is pertinent to inquire if this is so also for polymonochloroacetaldehyde and polydichloroacetaldehyde. We make the same assumption that we have made previously, viz. that the amorphous regions of the polymers cause the infrared bands to broaden but do not cause many new bands.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Polydichloroacetaldehyde

If there is one monomer unit in the repeating unit then there are $3\times7-4 = 17$ potentially active fundamentals, which can be approximately divided into 6 CH and 11 skeletal vibrations, though there may, of course, be strong interaction between the lower-frequency CH and the skeletal vibrations. There are two kinds of CH group $CC(O—)_2H$ and $CCCl_2H$. The two CH bending frequencies of the $CC(O—)_2H$ group are expected, according to arguments presented in reference 5, to be one above 1300 cm^{-1} and one below 1200 cm^{-1}. The two CH bending frequencies of the $CCCl_2H$ group are expected to be between 1300 and 1200 cm^{-1} by analogy with smaller molecules containing a similar group (8). Thus, the bands expected are summarized as follows: 3000–2700 cm^{-1}, two C—H stretching bands; 1500–1200 cm^{-1}, three C—H bending bands; 1200–600 cm^{-1}, one C—H bending and five skeletal stretching bands.

In the observed spectrum there are three medium bands near 3005, 2950, and 2870 cm^{-1}; they are probably all fundamentals, being strong for ternary combinations, but one may be characteristic of the amorphous polymer, as we found with polychloral.

In the region 1500–1200 cm^{-1}, there are weak bands at 1460 and 1430 cm^{-1} and medium or strong bands at 1370, 1339, 1287, 1265, and 1217 cm^{-1}. The weak 1460- and 1430-cm^{-1} bands are probably combination bands; CCl vibrations frequently give bands about here. The others are likely to be all CH fundamentals.

In the region 1200–600 cm^{-1} there are 10 bands, at 1132, 1087, 1040, 955, 815, 800, 775, 725, 710, and 675 cm^{-1}. Most are very strong and they are probably all fundamentals, mostly skeletal stretching bands. The 1132-, 1087-, 1040-, and 955-cm^{-1} bands are, by analogy with other polyaldehydes, probably due mainly to C—O stretching modes.

There are many more bands than expected for a one-monomer-unit repeat. Thus, there are five C—H bending bands, where only three are expected; there are nine bands in the skeletal stretching region, where only six are expected. We conclude, therefore, that there are at least two monomer units in the repeat.

Polymonochloroacetaldehyde

If there is one monomer unit in the repeating unit the number of bands expected in the different regions are as follows: 3000–2700 cm^{-1}, one CH and two CH_2 stretching bands; 1500–1200 cm^{-1}, one CH bending and CH_2 bending, wagging, and twisting bands; 1200–600 cm^{-1}, one CH bending, one CH_2 rocking, and four skeletal (C—O, C—C, and C—Cl) stretching bands.

In the region 3000–2700 cm^{-1} there are four bands, 3000, 2935, 2890, and 2820 cm^{-1}; as with polychloral, they may not all be fundamentals of the crystalline polymer.

In the region 1500–1200 cm^{-1} there are bands at 1445, 1434, 1375, 1350, 1298, 1265, 1230, 1216, and 1192 cm^{-1}. Allowing for the possibility that some of these are overtone or combination bands, or bands due to non-crystalline regions, there are many more than the four expected for a one-monomer repeat.

In the region 1200–600 cm^{-1} there are bands at 1135, 1105, 1065, 1025, 975, 942, 915, 862, 852, 790, 762, 730, 716, 660, and 610 cm^{-1}. Again, allowing for the possibility of overtones and combination bands, and the possibility that a few may be due to amorphous regions (cf. the 630-cm^{-1} band in polychloral) there are many more than the six bands expected for a one-monomer repeat.

We conclude, therefore, that there is more than one monomer unit in the repeating unit.

ACKNOWLEDGMENT

We are very grateful to Dr. L. D. Calvert for taking the X-ray diffraction photographs.

INTERACTION BETWEEN KETONE AND TERTIARY AMINE GROUPS[1]

OWEN H. WHEELER[2] AND ERIC M. LEVY[3]

ABSTRACT

Vapor pressure studies of trimethylamine and ketones in heptane solution have shown that unstable complexes are formed with cyclohexanone at 0° and with cyclohexanone and cyclopentanone at −40°. No complex formation was observed with methylethyl ketone, diethyl ketone, or cyclopentanone at 0°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Robinson and co-workers (1, 2) originally suggested that there was some type of interaction between a keto group and a tertiary amine group in certain alkaloids having these groups in a large-membered ring, to explain the masked reactivity of the keto group (1) and the large displacement of its infrared stretching frequency from its normal value (2). Later Leonard and co-workers (3, 4, 5) prepared a series of cyclic aza-acyloins and found evidence for transannular interaction in 8- (3, 5), 9- (4), and 10- (5) membered rings between the ketone and tertiary amine group. This was demonstrated by infrared and ultraviolet absorption (6) studies.

Anet, Bailey, and Robinson (2) found no evidence for interaction between acetone and triethylamine or between cyclopentanone and N-methyl piperidine by infrared measurements in chloroform solution. However, the amine would preferentially interact with the chloroform (7) and hinder association between the amine and ketone, and the evidence of these workers cannot be considered conclusive. Thus, though interaction between keto and amine groups within the same ring has been amply proved, no sound evidence has been published concerning possible interaction between ketone and amine groups in separate molecules.

Infrared and ultraviolet measurements are probably not the best method of observing weak interactions resulting in unstable complex formation, since such measurements must be carried out in dilute solution and cannot readily be made at low temperatures. Moreover these measurements will only detect interactions which result in a change in the electron density of the keto group. Vapor pressure studies, however, are usually made with solutions of moderate concentration, and the lower limit of temperature is only governed by the measurable vapor pressure of one (or more) component, and the method is not limited to specific types of interaction. In this study the vapor pressure of trimethylamine above a *n*-heptane solution and above solutions of the ketones, methylethyl ketone, diethyl ketone, cyclohexanone, and cyclopentanone in *n*-heptane has been measured. Trimethylamine was chosen as a conveniently volatile, non-sterically hindered amine and methylethyl ketone and diethyl ketone as examples of reactive and unreactive acyclic ketones, and cyclohexanone and cyclopentanone as examples of a very reactive and a moderately reactive cyclic ketone. The results are expressed in terms of Henry's law (8) (P solute $= K.N$ solute) and negative deviations are assumed to be due to complex formation (8) caused by interaction between the ketones and the amine.

Trimethylamine

Eastman-Kodak white-label grade was dried over calcium hydride as described below.

Ketones

Eastman-Kodak white-label samples were dried over anhydrous calcium sulphate and fractionally distilled before use (see Table I).

Apparatus

The apparatus was similar to that used by Brown and Brady (9) and consisted of a flat-bottomed reaction flask of known volume (65.00 ml) joined by narrow-bore glass tubing to a differential mercury barometer, connected by a narrow-bore stopcock to a storage vessel of known capacity (534.0 ml), itself joined to another differential mercury barometer. The whole was attached to a conventional high-vacuum line which incorporated bulbs for the purification and storage of trimethylamine.

Method

A sample of 10 ml of purified *n*-heptane was introduced into the reaction flask together with two small Teflon-covered magnetic stirring bars, and was frozen and pumped out several times to remove dissolved air. Trimethylamine, which had been dried with calcium hydride, and freed from non-condensable gases, was distilled into the storage vessel. Small quantities were introduced into the reaction vessel and the amount admitted obtained from the known volume of the storage vessel and the pressure decrease on its manometer. The reaction vessel was immersed in a constant temperature bath (at 0° of ice; at −39.50° a slush bath of diethyl ketone (10), and at −63.55° of chloroform (11), and stirred by a strong permanent bar magnet mounted externally on a slow-speed motor. The reaction vessel was stirred continuously for about 10 to 15 minutes when the pressure ceased to drop and the residual pressure was noted. This process was repeated a number of times with pressures up to 160 mm of mercury, taking about 15 readings. All pressure readings were taken at constant volume by adjusting the amount of mercury in the barometers to a fixed mark on one limb.

The experiments were repeated with 10-ml samples of 1.0 *M* solutions of the ketones in *n*-heptane.

The amount of trimethylamine in solution is the difference between the amount added from the storage vessel and the amount remaining in the gas phase above the reaction vessel (this was usually $< 3\%$ the total amount; see Table II for typical data).

*1 M in n-heptane (10 ml).
†Pressure difference on "storage" manometer.

The amount of trimethylamine was converted to its mole fraction and these values are plotted against the pressure of trimethylamine above the solution (corrected for the small vapor pressure of the solvent) in Figs. 1 and 2. The Henry's law constants (K in $P = K.N$) were determined from the slope of the straight lines and are given in Table III.

DISCUSSION

The slopes of the graphs at both 0° C (Fig. 1) and −40° C (Fig. 2) for solutions containing the ketones are little different from the slopes of the graphs for pure n-heptane, showing that no very stable complex is formed. The vapor pressures at −63.55° were too small to obtain reliable data.

The graphs of methylethyl ketone, diethyl ketone, and cyclopentanone at 0° (Fig. 1 and Table III) all lie above that of n-heptane itself. Such positive deviations from Henry's law can be attributed to a decrease in the association (8) of the solute ketone molecules in the presence of trimethylamine. Cyclohexanone, however, shows a small but definite negative deviation and this must be due to association (8) between the ketone and trimethylamine. Assuming that a 1:1 complex is formed the dissociation constant

of the complex will be given (9) by $K_D = N$ (ketone) $\times P(Me_3N)/N$ (complex). At any given pressure of trimethylamine above the solution the difference between the mole fraction of trimethylamine in the cyclohexanone solution and in pure n-heptane must be the amount which has reacted with the cyclohexanone. The mean of three values of the dissociation constant so calculated is 1550 mm, which corresponds to a very unstable complex with a dissociation pressure of some 2 atmospheres. This result neglects any possible positive deviation from Henry's law, resulting from decreased association of the ketone itself, which will be masked by the negative deviation produced by association of the ketone and amine. If the graph of cyclohexanone is compared with that of diethyl ketone, for which complex formation is very unlikely, then the value of K_D is 1010 mm, which still corresponds to a very unstable complex.

The results at −40° (Fig. 2 and Table III) show small negative deviations from Henry's law in the cases of methylethyl and diethyl ketone and larger negative deviations for cyclohexanone and cyclopentanone. These larger deviations must be due to complex formation and give values of K_D for cyclohexanone of 95 mm and only 165 mm for cyclopentanone.

The data for cyclohexanone may be treated in another manner. In general the reaction may be expressed by

where n is the number of moles of trimethylamine reacting with 1 mole of cyclohexanone. If a is the original concentration of ketone and b and c are the equilibrium concentrations of trimethylamine and the complex, respectively, then

$$K_D = (a-c).b^n/c.$$

The concentration of the complex c is measured by the amount of trimethylamine which has reacted (say d) and $c = d/n$. Since the concentration of complex is very small compared to the initial concentration of the ketone, then

$$a-c = a-d/n = a.$$

The equation thus reduces to

$$K_D = nab^n/d$$

or

$$\log d = n \log b + \log na - \log K_D.$$

In any experimental run b and d are the only variables and thus a graph of log d against log b will be linear with slope of n and an intercept of (log na − log K_D). The results of cyclohexanone at 0° give a straight line through nine points which has a slope of 1.02 (see Fig. 3), corresponding to the formation of a 1:1 complex, and a value of K_D of 14.3 moles $l.^{-1}$. A similar graph for the data at −40° gives $n = 1.04$ and $K_D = 13.1$ moles $l.^{-1}$. These values should be compared to the very high reactivity of cyclohexanone in equilibrium reactions involving addition to the ketone group, such as cyanohydrin formation with $K_D = 0.00059$ in 95% ethanol (12) and $K_D = 0.060$ mole $l.^{-1}$ in 80% dioxane (13) (both at 25° C). The small difference (if real) between the dissociation constants of complex formation at 0° and −40° C corresponds to a heat of formation (ΔH) of only +0.27 kcal mole.

While the non-reactivity of methylethyl and diethyl ketones towards trimethylamine is not surprising, since these ketones are known to be unreactive (14), the low reactivity of cyclohexanone is surprising, and must be contrasted with the ready interaction of ketone and amine groups in the same ring. The interaction in ring compounds, however, occurs more readily in 8- (3, 5), 9- (4, 15), and 10- (5, 16, 17) membered rings, in which the bridged product will have fused 5- or 6-membered rings, and may have a favorable free energy or entropy difference (18) with respect to the monocyclic compound.

A SHORTER SYNTHESIS OF GLUTATHIONE[1]

CASIMIR BERSE, ROGER BOUCHER, AND LUCIEN PICHÉ

ABSTRACT

A preparation of glutathione is proposed, in which the cystinyl residue is at one stage only partially reduced, to uncover the basic groups necessary for ensuing condensation, but without cleavage of the disulphide linkage. This affords an economy of intermediate steps but it does not provide a substantial increase in over-all yield of the hormone.

Synthesis of glutathione was accomplished with difficulty and in low over-all yields (1–5). The latest preparations (6, 7) report yields of 4 to 6% and the peptide is still prepared from yeast (8, 9). New synthetical methods are of potential value for its production and also to the study of analogues of glutathione.

Can. J. Chem. Vol. 37 (1959)

In a previous publication (10), we have shown the possibility of reducing peptidic derivatives of di-(N-*p*-nitrocarbobenzoxy)-L-cystine either partially to L-cystinyl peptides or completely to L-cysteinyl derivatives by appropriately controlled hydrogenation on palladium catalyst. This has afforded a favorable short route to glutathione through the following steps: di-(N-*p*-nitrocarbobenzoxy)-L-cystine I was condensed with glycine ethyl ester in the presence of N,N′-dicyclohexylcarbodiimide (11); the intermediate ester II was partially reduced to uncover the amino groups of the L-cystine residue without cleaving its disulphide linkage. The resulting diethyl L-cystinyldiglycinate III was condensed with 2 equivalents of *p*-nitrocarbobenzoxy-L-glutamic acid to provide an ester IV in which the glutathione structure has been assembled. Saponification (*a*) and partial reduction (*b*) of IV lead to oxidized glutathione V. Complete hydrogenation on palladium catalyst leads to glutathione VI.

This procedure, involving fewer steps to oxidized glutathione, affords an over-all yield of 10% on cystine; the reduced form of the hormone is provided in 6.6% yield.

EXPERIMENTAL

Melting points, unless otherwise indicated, have been determined in semicapillary tubes and are uncorrected. In some cases where the materials decomposed, instantaneous melting points have been determined on the Maquenne block.

Diethyl di-(N-*p-nitrocarbobenzoxy*)-L-*cystinyldiglycinate* II

To a solution of glycine ethyl ester hydrochloride (5.6 g, 0.04 mole) in 50 ml of dimethylformamide and 10 ml of acetonitrile, 9.5 ml of tri-*n*-butylamine and di-(N-*p*-nitrocarbobenzoxy)-L-cystine (12 g, 0.02 mole) were added. After cooling of the solution to −5°, dicyclohexylcarbodiimide (9 g) was added and the mixture was kept at this temperature for 30 minutes. The reaction mixture was allowed to come to room temperature and set aside for 1 day. It was acidified with 5 ml of glacial acetic acid (to decompose excess reagent). The insoluble urea was removed; 200 ml of chloroform and 350 ml of water were added. The chloroformic solution was washed with *N* HCl, 5% aqueous sodium bicarbonate, and dried over anhydrous sodium sulphate. The solvent was evaporated *in vacuo* and the residue was recrystallized from nitromethane. Yield: 12.3 g (80%). Identity was ascertained through comparison by melting point, mixed melting point, and optical rotation with the product described in a previous publication (10).

*Diethyl-*L-*cystinyldiglycinate Dihydrochloride* III

Diethyl di-(N-*p*-nitrocarbobenzoxy)-L-cystinyldiglycinate (6 g, 0.08 mole) was dissolved in a mixture of dimethylformamide (25 ml) and ethanol 80% (50 ml). The compound was hydrogenated for 10 hours at room temperature and at atmospheric pressure over 10% palladium on carbon (2 g). The catalyst was removed by filtration and the solvent was evaporated *in vacuo* at 50°. The resulting syrup was triturated with *N* HCl (30 ml) and the filtrate evaporated *in vacuo*. The residue after treatment with water and Norit gave a white amorphous hygroscopic powder. Yield: 2.5 g (70%). Anal. Calc. for $C_{14}H_{26}N_4O_6S_2.2HCl$: C, 34.78; H, 5.84; N, 11.59%. Found: C, 34.79; H, 5.82; N, 11.70%.

*p-Nitrocarbobenzoxy-*L-*glutamic Acid*

L-Glutamic acid (12.3 g) was dissolved in 42 ml of 4 *N* NaOH; 20 ml of purified dioxane were added. The solution was stirred vigorously and cooled to 0°; *p*-nitrocarbobenzoxyl chloride (19 g) dissolved in 50 ml of dioxane was added in 5 portions (30 minutes). During

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

reaction, the pH was maintained at 11 with 2 *N* NaOH. Stirring was continued for 0.5 hour after the addition of all reactants. The mixture was allowed to come to room temperature and 300 ml of water were added. The resulting alkaline solution was washed twice with ethyl acetate and acidified to Congo red with 1 *N* HCl. The precipitate was collected and recrystallized from a mixture of ethanol and water. Yield: 21 g (77%); m.p. 157–158°; $[\alpha]_D^{25}$ −8.0 (*c*, 0.9 in ethanol, 95%). Anal. Calc. for $C_{13}H_{14}O_8N_2$: C, 47.85; H, 4.32; N, 8.58%. Found: C, 47.68; H, 4.32; N, 8.55%.

Diethyl di-(N-*p-nitrocarbobenzoxy-γ-*L-*glutamyl*)-L-*cystinyldiglycinate* IV

To a solution of diethyl L-cystinyldiglycinate dihydrochloride (2.2 g, 4.5 mmole) in 30 ml of dimethylformamide and 5 ml of acetonitrile, 2 ml of tri-*n*-butylamine and *p*-nitrocarbobenzoxy-L-glutamic acid (2.7 g, 8 mmole) were added. After the solution had been cooled to −5°, dicyclohexylcarbodiimide (2 g) was added and the mixture was kept at this temperature for 30 minutes. The reaction mixture was allowed to come to room temperature and allowed to stand for 1 day. It was acidified with 1 ml glacial acetic acid. The insoluble urea was removed and 200 ml of ethyl acetate and 300 ml of water were added. The ethyl acetate solution was washed with *N* HCl and water, then dried over anhydrous sodium sulphate. The solvent was evaporated *in vacuo*. Yield: 2.8 g (60%).

Di-(N-*p-nitrocarbobenzoxy-γ-*L-*glutamyl*)-L-*cystinyldiglycine*

The crude product obtained above (2.7 g) was dissolved in methanol (20 ml), and *N* NaOH (2% excess) was added in two portions. The mixture was stirred at 0–5° for a first hour and at room temperature for another. It was acidified with HCl. The crude product, an oil, was dissolved in ethanol. The solvent was evaporated *in vacuo* and the residue was dissolved in dioxane; precipitation with ether yielded 1.9 g of product (74%).

Glutathione (Oxidized) V

Di-(N-*p*-nitrocarbobenzoxy)-γ-L-glutamyl-L-cystinyldiglycine (2 g) was dissolved in 80% ethanol (25 ml). The compound was hydrogenated for 8 hours at room temperature and at atmospheric pressure over 10% palladium on carbon (1 g). After filtration, the catalyst was washed with water and the washings were combined with the first filtrate. The solvent was evaporated *in vacuo* and the residue was triturated with water. The filtrate was concentrated and glutathione (oxidized) was precipitated by addition of absolute ethanol. Yield: 0.7 g (55%); m.p. 175–195°; $[\alpha]_D^{25}$ −92.8 (*c*, 1.2 in water). Literature (12, 13) m.p. 170–195°; $[\alpha]_D^{27}$ −93.9 (*c*, 1.0 in water).

Glutathione VI

Glutathione (oxidized) (0.4 g) was dissolved in 25 ml of water. The compound was hydrogenated for 12 hours at room temperature and at atmospheric pressure over palladium (13) (200 mg). The catalyst was removed by filtration and the filtrate was concentrated *in vacuo*. By addition of ethanol (95%) to the syrupy residue, the glutathione precipitated. Yield: 0.26 g (65%); m.p. 190° decomp., $[\alpha]_D^{25}$ −20.6 (*c* 1.5 in water). (Literature (2) m.p. 190°; $[\alpha]_D^{27}$ −21.3 (*c*, 2% in water).) Anal. Calc. for $C_{10}H_{17}N_3O_6S$: C, 39.08; H, 5.58; N, 13.67. Found: C, 39.00; H, 5.48; N, 13.62%.

THE PHOTOLYSIS OF TRIFLUOROMETHYL CYANIDE[1]

A. BRUCE KING[2] AND E. W. R. STEACIE

ABSTRACT

The photolysis of CF_3CN at 1849 Å has been studied. The major products are hexafluoroethane, cyanogen, and perfluoro-3-methyl-2-aza-2-butene.

The experimental value for $k_3/k_2^{\frac{1}{2}}$ is:

$$10^{-9.08\pm.13}\, e^{-5.00\pm.21 \text{ kcal mole}^{-1}/RT} \text{ molecule}^{-\frac{1}{2}} \text{ cc}^{\frac{1}{2}} \text{ sec}^{-\frac{1}{2}},$$

where:

$$CF_3 + CF_3 \rightarrow C_2F_6, \qquad [2]$$

$$CF_3 + CF_3CN \rightarrow (CF_3)_2CN. \qquad [3]$$

Another product was isolated in smaller amounts and has been tentatively identified as perfluorotrimethyl-aza-2-pentene.

INTRODUCTION

Earlier work on the photolysis of CH_3CN (1) showed the mechanism to be so complex that a unique interpretation was difficult. It was felt that the vulnerability of the C—H bond, both to break in the primary step and to subsequent abstraction, led to the wide variety of reaction paths and products. It was thus hoped that a study of the photolysis of CF_3CN would give information for the interpretation of the CH_3CN studies. In particular the importance of reaction [8]:

$$CN + CF_3CN \rightarrow C_2N_2 + CF_3 \qquad [8]$$

was sought.

EXPERIMENTAL

Photolyses were carried out in a cylindrical quartz reaction vessel 4.8 cm long and 4.7 cm in diameter, which was connected to a mercury-free system with a Hoke No. 413 high-vacuum stainless-steel valve. The windows of the cell were 1.00-mm-thick quartz, each of which transmitted about 75% of the 1849 Å radiation used in this work. The initial pressure in the reaction cell was measured with a quartz spiral Bourdon gauge nulled with a mercury manometer. When a mixture of gases was desired in the reaction cell, the appropriate amounts of the gases were premixed in a 125-cc bulb with a magnetically driven stirrer and then expanded into the reaction cell. The techniques described by McElcheran *et al.* (1) were used; the reaction products were transferred to the analytical system through a silicone oil diffusion pump, a stopcock, and two liquid nitrogen traps to keep the mercury vapor in the analytical system out of the reaction cell.

The cell was placed inside a cylindrical furnace which was mounted on an optical bench. The quartz spiral low-pressure mercury lamp and the platinum photocell were also mounted on the optical bench as part of an airtight system with the furnace tube. This permitted nitrogen to flow through the light path and yet allowed the lamp and photocell to be easily moved for heating the windows of the reaction cell with a torch.

The nitrogen was passed through the system at approximately 200 cc min^{-1} by means of a small heater in a Dewar of fresh liquid nitrogen. Provision was also made to introduce glass plates between the lamp and the reaction cell. A Vycor plate (Corning No. 7910) was inserted when only 2537 Å radiation was desired and several 3-mm-thick quartz plates were inserted to reduce the 1849 Å intensity to about 20% of the usual value.

Because of polymer formation during the photolysis it was necessary at the end of each run to fill the cell with an atmosphere of oxygen and flame both windows to red heat. This removed the polymer from the windows and ends of the cylindrical walls, but after a number of runs some polymer was built up on the walls of the central section of the cell. The relative amount of polymer was determined for each run by the drop in transmitted 1849 Å radiation during the photolysis and this intensity decrease was as high as 50% for some of the higher-pressure experiments.

The photocell consisted of a semicylindrical cathode of platinum (2) mounted in a quartz envelope that had been thinned slightly in front of the cathode to decrease the light absorption by the envelope. Before the photocell was sealed off, it was evacuated overnight at 10^{-6} mm of Hg with the envelope heated to 500° C, and then the cathode was heated with an induction heater (two thin strips of platinum had been spot-welded to the top and bottom of the cathode to complete the loop and give more effective coupling) until the cathode was no longer sensitive to 2537 Å light. This was determined by measuring the photocurrent produced by a low-pressure Hg lamp with a Vycor plate in front of the photocell. The effective area of the photocell was about 4 cm^2 and the operating anode potential was 135 v. Photocurrents of the order of 10^{-9} amp were obtained in this work and were measured with a Keithley electrometer and decade resistance attachment. After more than a year of use, the photocell remained completely insensitive to the 2537 Å radiation of the mercury lamp.

The volatile products were condensed at −195° C and then separated by distillation from a Ward–Leroy still (3). The C_2F_6 and the bulk of the CF_3CN were removed at −150° C and condensed in a liquid nitrogen trap until the distillation pressure had dropped to approximately half the value of the equilibrium pressure during the bulk of the distillation. This procedure removed at least 95% of the CF_3CN, but none of the higher-boiling products. The CF_3CN–C_2F_6 mixture was then reacted in a micro-hydrogenation tube with about 500 mm of hydrogen over a nickel–kieselguhr catalyst (4) at 85° C for 1 to 2 hours. This converted about 95% of the CF_3CN, principally to higher-boiling amines. The excess hydrogen was pumped off at liquid nitrogen temperature, and the products of the hydrogenation were distilled from −140° C to a liquid nitrogen trap. The quantity of this fraction (cut No. 4) was measured in a gas burette and sealed off in a sample tube for mass spectrometric analysis. This cut consisted mainly of the unreacted CF_3CN, the C_2F_6 (from the photolysis only; none was found in a blank hydrogenation), and some ammonia. This procedure thus served to concentrate the C_2F_6 from about 1% of the original fraction to an appreciable component that could readily be measured by mass spectrometry.

Other fractions of the photolysis reaction products were taken at −130° C (cut No. 1), −115° C (cut No. 2), and the residual higher boiling compounds that remained condensed at −115° C were collected as cut No. 3. The total quantity of each of the samples was measured on a gas burette and then the sample was sealed in a tube for mass spectrometric analysis. The total volume of the inlet system of the mass spectrometer was calibrated by expanding samples of known quantities of pure nitrogen (similar sample size to the unknown samples) into the spectrometer, measuring the

m/e 28 peak height, and comparing with the nitrogen sensitivity. Calculation of analyses for two component samples where standards were not available is described in the Appendix.

The CF_3CN was obtained from Peninsular Chemresearch Inc., practical grade, and was purified by several fractionations from −80° C to −195° C. The hexafluoroacetone was obtained by reacting the hydrate (Merck Chemical) with phosphorus pentoxide, followed by several vacuum fractionations. This gas was stored in a blackened bulb until used.

RESULTS

Mass spectrometric analyses indicated that cut No. 1 contained the remaining CF_3CN (pattern given in Table I) and some of the C_2N_2, while cut No. 2 contained the remainder of the C_2N_2 and a fluorinated product. The pattern for this product is listed in Table I and is consistent with the pattern to be expected for perfluoro-3-methyl-2-aza-2-butene ($(CF_3)_2C{=}NCF_3$, hereafter called MAB). This type of compound gives mass spectral patterns with a small parent peak (m/e 233), medium-sized peaks corresponding to loss of one or two fluorine atoms (m/e 214 and 195), a large peak for loss of a CF_3 group (m/e 164), and a large m/e 69 peak. All other peaks are also consistent with the structure of MAB. Further evidence of consistency with the proposed structure is indicated by the metastable transitions observed which are also listed in Table I. In every case they correspond to transitions of the important ions in the spectrum by typical reaction paths found in mass spectral fragmentation patterns, e.g. references 5 and 6.

Because of lack of mass spectral standards for MAB and because of troubles in obtaining a reproducible cyanogen standard (apparently due to absorption problems), the effective sensitivities of the cyanogen m/e 52 peak and the MAB m/e 164 peak were determined by the method described in the Appendix. A typical plot of equation [A-3] for a set of analyses performed on the same day is shown in Fig. 1 with the sensitivities of C_2N_2 and MAB being determined from the slope and the intercept, respectively, of the straight

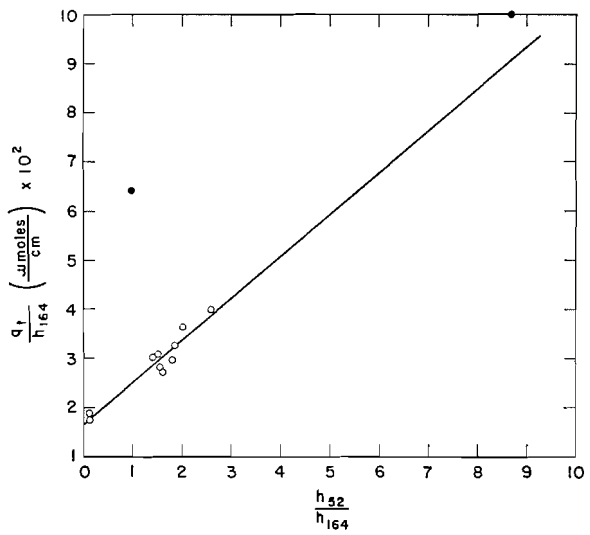

FIG. 1. Plot of equation [*A*-3] for a typical group of cut No. 2 analyses. Open circles used to determine linear plot and closed circles are for points above the line that indicate an additional component present.

line. These sensitivities were used to calculate the absolute amounts of C_2N_2 and MAB in the samples of cut No. 2 as well as samples of cut No. 1 that were analyzed at the same time.

Cut No. 4 was analyzed for C_2F_6 by using the *m/e* 119 peak. Because of absorption of the ammonia and amines in the sample, a complete analysis of the sample was not undertaken. Rather, by expanding the total sample into the calibrated volume on the inlet system of the mass spectrometer, one could relate the partial pressure of C_2F_6 (from the *m/e* 119 peak height) directly to the absolute amount of C_2F_6 in the sample.

The small amount of high-boiling products (cut No. 3) was analyzed on the mass spectrometer and found to contain two major components. One component was distinguished by peaks at *m/e* 96 and 97 (as well as 77, 76, 69, etc.) and is tentatively identified as 2,2,2-trifluoroethylideneimine ($CF_3CH{=}NH$) or a similar partially hydrogenated compound. This compound must arise from reaction of photolytic species or photolysis products with adsorbed water on the walls or with the silicone oil in the diffusion pump, because this compound was not found after a similar fractionation procedure on a sample of CF_3CN that had not been photolysed.

The pattern assigned to the major component of cut No. 3 is shown in Table II. Because of the small quantity of this product in any of the samples, the smaller-sized peaks are subject to considerable scatter and only the major peaks are listed. Many of the lower mass peaks are also omitted because of interference from the other component. The higher mass peaks are consistent with a molecular weight of 383 (loss of one fluorine atom gives *m/e* 364; loss of CF_3 gives *m/e* 314, which is a major peak, etc.). This would indicate a formula of $C_7F_{15}N$ and would probably be either perfluoro-3,4,4-trimethyl-2-aza-2-pentene ($CF_3C(CF_3)_2C(CF_3){=}NCF_3$) or perfluoro-2,4,4-trimethyl-3-aza-2-pentene ($CF_3C(CF_3)_2N{=}C(CF_3)_2$), hereafter called TAP. A plot of equation [*A*-3] for cut No. 3 (Fig. 2) indicates that the amounts of the two major components present are proportional to the *m/e* 314 and 96 peak heights and that there are no other compounds consistently present in significant quantity in these samples (see Appendix).

TABLE II

Mass spectrum of TAP

m/e	Relative peak height	m/e	Relative peak height
31	5.0	196	2.1
50	4.5	214	9.
69	270.	221	2.3
76	4.7	226	11.7
112	3.5	245 and 246	12.
114	2.	259	11.2
131	4.0	264	22.6
138	1.5	271	2.3
145	2.	295	1.4
146	1.	303	0.8
150	2.1	310	3.9
159	3.	314	(100.)
164	9.	322	1.
169	4.3	328	3.
176	3.6	342	4.6
192	2.6	354	1.
195	1.6	364	5.5

The sensitivities for these two components were determined from the graph and were used to calculate the absolute amount of TAP formed.

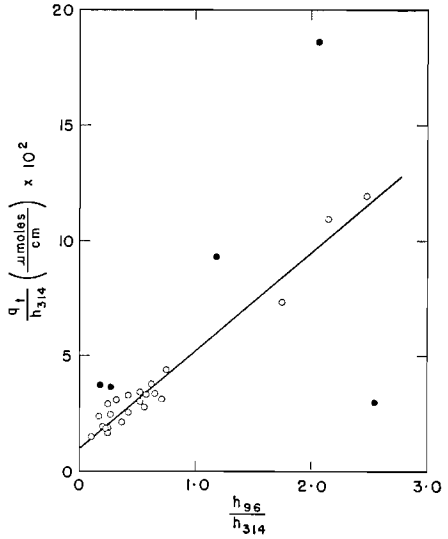

FIG. 2. Plot of equation [*A*-3] for a group of cut No. 3 analyses. Open circles used to determine linear plot and closed circles are for points above the line that indicate an additional component present.

On the basis of the reaction mechanism one might expect perfluorodiisopropylidene hydrazine ($(CF_3)_2C{=}N{-}N{=}C(CF_3)_2$(PDH)), or its isomer perfluoro-3,4-dimethyl-2,5-diaza-2,4-hexadiene ($CF_3N{=}C(CF_3)C(CF_3){=}NCF_3$), as a product. This compound would have a parent peak at *m/e* 328 and significant peaks at *m/e* 309, 290, and 259. Peaks are observed at *m/e* 328, 310, and 259, but the ratio of these peak heights to the *m/e* 314 peak height is reasonably constant (although with more scatter than some of the other peaks in the spectrum of TAP), indicating that traces of PDH may be present, but that the major contribution to these peaks comes from the same compound that gives the *m/e* 314 peak. (A coincidental proportionality between the yields of two different products for all runs under the variety of conditions studied is very unlikely.)

The polymer formation (measured as the decrease in the logarithm of the 1849 Å light transmitted) as a function of irradiation time was found to be linear after an initial induction period. The slope of the linear region was found to be proportional to the square root of the CF_3CN pressure at constant light input (uncorrected for the change in optical density of the CF_3CN) and approximately proportional to the incident intensity at constant pressure. One photolysis was carried out on a mixture of CF_3CN and CF_3COCF_3 with 2537 Å light so that only CF_3COCF_3 would undergo photolysis. No polymer formation was detected with 1849 Å light after the run, although a 20–30% decrease in intensity was observed for runs on CF_3CN alone at 1849 Å at the same pressure and temperature. This indicated that the formation of polymer required reactants in addition to the $CF_3\cdot$ radical and CF_3CN. This fact, and the induction period observed, indicate that the polymer must arise from polymerization of the cyanogen formed during the photolysis.

A blank photolysis of CF_3COCF_3 at 2537 Å in the reaction cell that was partially coated with paracyanogen gave a C_2F_6/CO ratio of about 0.6, indicating an appreciable loss of $CF_3\cdot$ radicals by addition to the unsaturated paracyanogen. This is also confirmed by the observation of the evolution of C_2F_6 on heating the polymer formed in the photolysis of CF_3CN. Because of loss of some of the C_2N_2 product by polymerization and some of the $CF_3\cdot$ radicals by reaction with the polymer, attempts at absolute quantum measurements in order to test the existence of reaction [8] are useless.

The absorption coefficient of CF_3CN at 1849 Å was found to vary with temperature and a statistical analysis of the data taken during the course of this work yielded:

$$\epsilon = 10^{1.483\pm.045}\, e^{-1620\pm70 \text{ cal mole}^{-1}/RT} \text{ mole}^{-1} \text{ l. cm}^{-1}.$$

This rather significant dependence on temperature would seem to indicate that the 1849 Å line coincides with the edge of an absorption band. The same situation occurs for CH_3CN (7), and thus it would appear that the substitution of fluorine atoms on the methyl group of CH_3CN does not shift the absorption band edge very much.

DISCUSSION

The experimental data are summarized in Table III. On the basis of these data and the other results discussed above, the following mechanism is proposed:

$$CF_3CN + h\nu \rightarrow CF_3 + CN, \quad [1]$$

$$CF_3 + CF_3 \rightarrow C_2F_6, \quad [2]$$

$$CF_3 + CF_3CN \rightarrow (CF_3)_2C{=}N\cdot, \quad [3]$$

$$CF_3 + (CF_3)_2CN\cdot \rightarrow (CF_3)_2C{=}NCF_3\,(\text{MAB}), \quad [4]$$

$$CF_3 + \text{MAB} \rightarrow \rightarrow \rightarrow \text{TAP}, \quad [5]$$

$$CN + CN + M \rightarrow C_2N_2 + M, \quad [6]$$

$$C_2N_2 + R(CN?) \xrightarrow{\text{wall?}} \text{paracyanogen}. \quad [7]$$

The formation of MAB proceeds through reactions [3] and [4] with reaction [3] the rate-determining step. An Arrhenius plot of $R_{MAB}/R_{C_2F_6}^{\frac{1}{2}}[CF_3CN]$ is shown in Fig. 3 and gives

$$k_3/k_2^{\frac{1}{2}} = 10^{-9.09\pm.11}\, e^{-5.05\pm.17 \text{ kcal mole}^{-1}/RT} \text{ molecule}^{-\frac{1}{2}} \text{ cc}^{\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}.$$

The mechanism for the formation of TAP is subject to some doubt, but the best kinetic agreement has been found for $R_{TAP}/R_{MAB}R_{C_2F_6}^{\frac{1}{2}}t$ (where t is the reaction time),

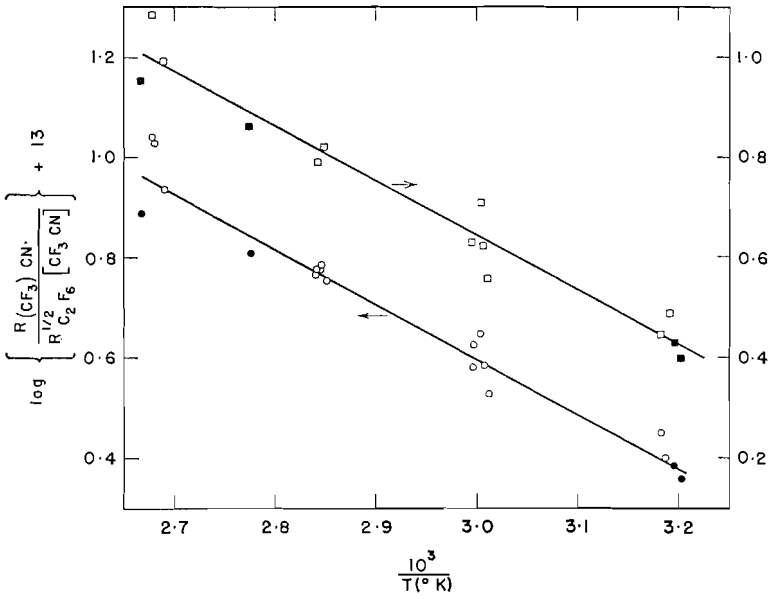

FIG. 3. Arrhenius plot of $k_3/k_2^{\frac{1}{2}}$. Circles (lower plot) represent $R_{(CF_3)_2CN\cdot} = R_{MAB}$. Squares (upper plot) represent $R_{(CF_3)_2CN\cdot} = R_{MAB} + 2R_{TAP}$. Solid circles and squares indicate low-intensity runs.

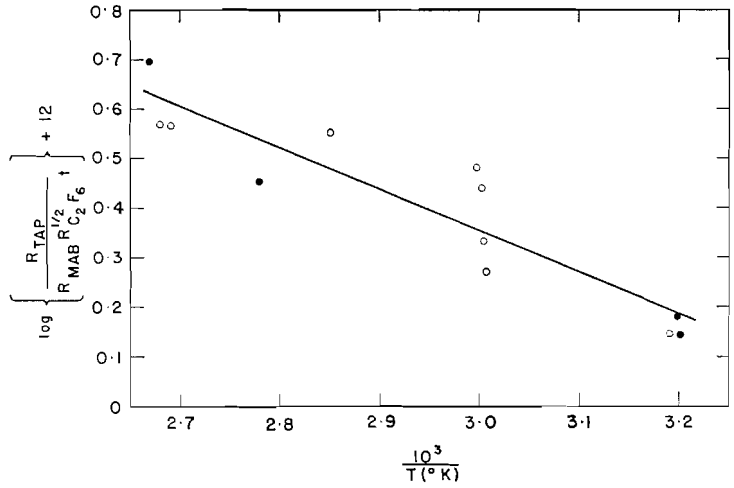

FIG. 4. Arrhenius plot of $k_5/k_2^{\frac{1}{2}}$. Solid circles indicate low-intensity runs.

indicating the rate-determining step for the formation of TAP is the addition of $CF_3\cdot$ to MAB. An Arrhenius plot of this function is shown in Fig. 4 and the lack of effect of intensity on the plot indicates this function represents the rate-determining step for the formation of TAP. From Fig. 4 and assuming the average concentration of MAB is $\frac{1}{2}R_{MAB}t$, one obtains:

$$k_5/k_2^{\frac{1}{2}} = 10^{-8.81\pm.22}\, e^{-3.87\pm.33 \text{ kcal mole}^{-1}/RT} \text{ molecule}^{-\frac{1}{2}} \text{ cc}^{\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}.$$

It is difficult to decide what additional reaction steps following reaction [5] must be involved to explain the formation of TAP. The difficult part is the origin of the perfluoro-

t-butyl group. This may have required breaking a C—N bond, possibly by addition of two CF_3 radicals to MAB and then breaking of the C—N bond due to steric repulsion. If the *t*-butyl radical is an intermediate, one would expect perfluoroneopentane as a detectable product. From the boiling point of this compound (8), one would expect it to appear in cut No. 2 and to give a large *m/e* 219 peak, but none is observed.

Another possibility is that the C—N bond does not break until after 2 molecules of the original CF_3CN are associated in some intermediate compound that contains a number of additional CF_3 groups. This would not require the *t*-butyl radical as an intermediate, but again the absence of any other obvious intermediate is difficult to explain. Still another possibility is that TAP is not the actual product, but rather none of the higher mass peaks (above *m/e* 364) in the pattern of the actual product is stable. Thus the C—N bond has been broken on electron impact of the compound in the mass spectrometer to give a pattern resembling TAP. (It should be emphasized that the kinetic dependence for the formation of the compound giving the *m/e* 314 peak is much better understood from the data available than the structure of the compound.)

If TAP is formed by the reaction of MAB, then $k_3/k_2^{\frac{1}{2}}$ should be corrected for the number of $(CF_3)_2CN\cdot$ radicals or MAB molecules that are consumed in the formation of TAP. If two $(CF_3)_2CN\cdot$ radicals are assumed to be precursors for each molecule of TAP, $k_3/k_2^{\frac{1}{2}}$ would be determined from $(R_{MAB}+2R_{TAP})/R_{C_2F_6}{}^{\frac{1}{2}}[CF_3CN]$. A plot of this function (also shown in Fig. 3) results in a value for $(k_3/k_2^{\frac{1}{2}})_{corr}$ of:

$$10^{-9.08\pm.13}\, e^{-5.00\pm.21 \text{ kcal mole}^{-1}/RT} \text{ molecule}^{-\frac{1}{2}} \text{ cc}^{\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}.$$

It is seen that the uncertainty in the number of precursor $(CF_3)_2CN\cdot$ radicals in the formation of TAP will have only a small effect on the experimental value of k_3.

Using the latter value of $k_3/k_2^{\frac{1}{2}}$, assuming $E_2 = 0$, collision diameters for CF_3, CF_3CN, and MAB as 4.0, 7.0, and 8.0 Å, respectively, and a temperature of 343° K, one calculates $E_3 = 5.0\pm.2$ kcal mole^{-1}, $E_5 = 3.9\pm.3$ kcal mole^{-1}, $p_3/p_2^{\frac{1}{2}} = 2.2\times10^{-5}$, $p_5/p_2^{\frac{1}{2}} = 3.4\times10^{-5}$. If p_2 is taken to be unity, then p_3 and p_5 are about 2×10^{-5} and 3×10^{-5}, respectively.

Reactions [3] and [5] are similar to the addition of CH_3 radicals to simple olefins where the activation energies are about 5–7 kcal mole^{-1} and the steric factors are about 4×10^{-4} (9). The activation energies observed here are about the same, but the steric factors are lower by about a factor of 20. This decrease from the hydrocarbon case is presumably due to the increased size of the fluorinated groups.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Drs. K. O. Kutschke and F. P. Lossing for helpful discussions. They also wish to thank Miss B. Thornton for the mass spectrometric analyses and Mr. G. Ensel for making some of the glassware used in this work.

APPENDIX

Consider the case of a mass spectral analysis on a two-component mixture where each of two peaks in the spectrum can be attributed solely to each component. The total pressure (p_t) is equal to the sum of the partial pressures of the two components and thus:

$$p_t = (h_1/S_1)+(h_2/S_2), \qquad [A\text{-}1]$$

where h refers to the peak height and S the sensitivity of the particular component.

If the total quantity of the sample (q_t) is known and the entire sample is expanded into a volume (V), then:

$$q_t/V = (h_1/S_1)+(h_2/S_2), \qquad [A\text{-}2]$$

and rearranging,

$$q_t/h_2 = (h_1/h_2)(V/S_1)+(V/S_2). \qquad [A\text{-}3]$$

A plot of q_t/h_2 vs. h_1/h_2 for a series of samples of varying relative composition will give the constants V/S_1 and V/S_2 from the slope and intercept, respectively. Since the absolute quantity of each component is:

$$q_1 = h_1(V/S_1), \qquad [A\text{-}4]$$

the absolute quantity can be calculated from the peak height in the individual samples and the constant determined from the plot of equation [A-3] for a set of analyses. No standards are therefore required and the volume (V) need not be known, merely that it is the same for all of the samples. If different volumes have to be used for different sample sizes, only the ratio of volumes needs to be known.

The presence of a third component in all of the samples will cause a scatter of the plot, but an occasional impurity in only a few samples will show up as a few points above the line with the remainder of the analyses giving a good linear plot. Figures 1 and 2 show this latter type of deviation, indicating that there are no significant additional components present in cuts No. 2 and No. 3.

This technique has the added advantage that if one of the components shows preferential absorption on the walls of the inlet system of the mass spectrometer, no effect on the linearity of equation [A-3] will be observed if the fraction of the component absorbed is independent of the total quantity of that component present. The V/S_1 thus obtained is an effective reciprocal sensitivity and the correct absolute quantities will still be obtained when the effective reciprocal sensitivity is used in equation [A-4].

AN ASYMMETRIC SYNTHESIS OF D- AND L-MANNOSAMINE[1]

A. N. O'NEILL[2]

ABSTRACT

The addition of ammonia to the ethylenic bond of D-arabo-tetraacetoxy-1-nitrohexene-1 was stereospecific and formed a crystalline product, 1-nitro-1-deoxy-N-acetyl-D-mannosaminol. Application of the Nef reaction to this compound gave 2-amino-2-deoxy-D-mannose, which was isolated as the crystalline pentaacetate and further characterized as the hydrochloride by deacetylation with hydrochloric acid. In the deacetylation of the pentaacetate with barium methoxide, however, an abnormal epimerization occurred to yield N-acetyl-D-glucosamine.

L-Mannosamine pentaacetate was synthesized in a similar manner from L-arabo-tetraacetoxy-1-nitrohexene-1.

The general chemistry of the simple α-nitroölefins has been investigated extensively. It has been found, in agreement with theoretical considerations, that the α-nitro group, by virtue of its powerful inductive and resonance effects, strongly activates the double bond, thereby facilitating attack in the β-position by nucleophilic reagents. Thus the addition of such reagents as ethyl malonate (7, 8), alcohols (10), thiols (5), ammonia and amines (6), nitroparaffins (11), hydrogen cyanide (2), Grignard reagents (9, 1), and arylacetonitriles (3) to α-nitrostyrene, nitroethylene, α-nitropropylene, etc. has been easily accomplished in the presence of basic catalysts.

Some of the more complex acetylated carbohydrate C-nitroölefins with an olefinic bond in conjugation with the nitro group have been prepared (16), but their reactivities have not been studied other than in the synthesis of 2-deoxy aldoses by selective hydrogenation of the double bond (16, 17). These compounds are readily obtained from the aldoses with one less carbon atom by condensation with nitromethane. This is followed by acetylation and elimination of 1 mole of acetic acid by treatment with a mild base under the conditions of the Schmidt and Rutz reaction (15). The resulting acetylated nitroölefins are obtained in good yield and in general are easily crystallized. As the primary C-nitro group can readily be converted into an aldehyde by the Nef reaction, these compounds should provide excellent starting materials for the synthesis of hexosamines by the addition of ammonia, and branched-chain carbohydrates by the addition of nitroparaffins, malonic ester, or other nucleophilic reagents.

The addition of amines and ammonia to the more simple α-nitroölefins has been studied by Heath and Rose (6), who found the reaction a general one. However the yields were variable, due partly to the instability of the resulting 2-nitroalkylamine in which the basic group caused rapid decomposition of the nitro compound, and partly to the tendency of the nitroölefins to polymerize under the influence of the amine.

In the present investigation both D- and L-arabo-tetraacetoxy-1-nitrohexene-1 were synthesized from D- and L-arabinose by the method of Sowden (16). The addition of ammonia to the olefinic bond was readily accomplished by adding the acetylated nitroölefin slowly to a saturated solution of ammonia in anhydrous methanol at 0°. The product, obtained in 82% yield, was a very stable, white, crystalline solid. Its aqueous solution was neutral. Microanalysis and the infrared spectrum indicated the presence of a N-acetyl group. The absorption spectrum showed the typical bands, types I and II,

of a secondary amide at 1640 and 1550 cm^{-1} respectively. This compound would not undergo the rapid decomposition characteristic of the basic unsubstituted 2-nitroalkylamines because it contains a neutral amide group, which must result from an acyl migration from O to N during the concomitant addition and de-O-acetylation reactions.

From the addition reaction only one of the two possible diastereoisomers was isolated. A search for the second isomer in the mother liquors from the crystallization failed to reveal its presence. The compound isolated was shown to have the *erythro* configuration about carbon atoms two and three by its subsequent conversion into derivatives of mannosamine.

It is reasonable to assume that this addition reaction proceeds through a primary nucleophilic attack by the ammonia or amide ion on the β-carbon atom of the acetylated nitroölefin. If Cram's rule of "steric control of asymmetric induction" (4) can be applied, then the ammonia would enter preferably from the least-hindered side of the double bond when the rotational conformation of the C—C bond is such that the double bond is flanked by H and OAc, the two least bulky groups attached to the adjacent asymmetric center. This should lead to a predominance of the erythroisomer, as was actually obtained (Fig. 1). However, in this case, this simple interpretation is complicated by the possible interaction of the carbonyl carbon atom of the migrating acyl group with the incoming amino group. If the addition of ammonia at the double bond is complete before the

acyl migration takes place, then the acyl group concerned could originate from C_3, with a planar five-membered ring as the intermediate (Fig. 2), or from C_4, with a non-planar six-membered ring as the intermediate (Fig. 3). In each case the nitrogen atom of the amino group can attack the carbonyl carbon atom of the migrating acyl group from either side. In Fig. 3, only one of the two possible configurations for the transient asymmetric center is given.

It is difficult to predict the most favored course of the rearrangement. In each of the above two cases, an intermediate is involved in which there is strong non-bonded repulsion

between fairly large groups, or in which bulky groups are in axial conformations. The addition product VII was treated with sodium hydroxide and the resulting sodium salt of the *aci*-nitro form treated with sulphuric acid under the conditions of the Nef reaction. Acetylation of the crude syrup so obtained yielded a crystalline pentaacetate of which the melting point and specific rotation agreed with values reported by Levene (13) for the β-pentaacetate of epichitosamine (β-D-mannosamine pentaacetate). The compound was further characterized as the hydrochloride by deacetylation with hydrochloric acid when agreement with the reported specific rotation was again obtained (13). Further evidence that XI was indeed D-mannosamine hydrochloride was obtained by a positive Elson–Morgan reaction, and by a degradation to D-arabinose with ninhydrin in pyridine (18).

However, deacetylation of the pentaacetate with barium methoxide gave 80–90% yields of N-acetyl-D-glucosamine (X) and only traces of N-acetyl-D-mannosamine (IX). These compounds were characterized as the hydrochlorides. This is evidence of an unusual epimerization during deacetylation in which a catalytic amount of barium methoxide was used, and is another example of the abnormal behavior of this compound. Thus, as the hydrochloride, it shows no mutarotation, nor is it oxidized by bromine or mercuric oxide. In fact treatment of D-mannosamine hydrochloride with mercuric oxide yields crystalline 2,5-anhydro-D-glucose (14).

For purposes of confirmation and for comparison of physical properties, derivatives of D-mannosamine were synthesized by a modification of Levene's original method (12). D-Glucosamine was oxidized to D-glucosaminic acid and epimerization accomplished in aqueous pyridine to form D-mannosaminic acid. After conversion to the lactone hydrochloride, reduction with sodium amalgam yielded D-mannosamine hydrochloride. The pentaacetate was formed in the usual manner and deacetylated with barium methoxide, when N-acetyl-D-glucosamine was again obtained with only traces of N-acetyl-D-mannosamine. But deacetylation of the pentaacetate with hydrochloric acid gave a quantitative yield of D-mannosamine hydrochloride.

The corresponding enantiomorphs of compounds II to VIII were synthesized by the same method from L-arabinose.

EXPERIMENTAL

All rotations were measured in a 2-dm tube with a Rudolph polarimeter. Melting points were observed on a Kofler micro-melting-point apparatus and are corrected. The infrared spectra were determined in nujol mulls with a Baird double-beam infrared spectrophotometer, model 4-55.

D-*Arabo-tetraacetoxy-1-nitrohexene-1* (VI)

This compound was synthesized from D-arabinose according to the method of Sowden (16), by condensation with nitromethane, acetylation, and elimination of 1 mole of acetic acid from the resulting mixture of acetylated C-nitroalcohols (IV and V). The yield of D-arabo-tetraacetoxy-1-nitrohexene-1 (VI) from 25 g of D-arabinose was 30 g; m.p. 115–116°, $[\alpha]_D^{24}$ +33° (c = 1.0 in chloroform). Main infrared absorption bands: 2900, 1740, 1667, 1530, 1460, 1379, 1220, 1122, 1078, 1050, 972, 953, and 853 cm^{-1}. Anal. Calc. for $C_{14}H_{19}O_{10}N$: C, 46.54; H, 5.30; N, 3.88. Found: C, 46.31; H, 4.87; N, 3.76%.

The corresponding L-arabo-tetraacetoxy-1-nitrohexene-1 prepared in the same manner from L-arabinose had m.p. 114–116°, $[\alpha]_D^{25}$ −34° (c = 1.0 in chloroform), and gave an identical infrared absorption spectrum.

1-Nitro-1-deoxy-N-*acetyl*-D-*mannosaminol* (VII)

Finely powdered D-arabo-tetraacetoxy-1-nitrohexene-1 was added slowly, in portions and with continuous shaking, to 500 ml of absolute methanol saturated with anhydrous ammonia at 0°. Each portion was allowed to dissolve before the next was added. When all of the acetylated nitroölefin was added the solution was left at 5° for 18 hours. Methanol and ammonia were removed by distillation under reduced pressure. This left a crystalline residue. It was recrystallized twice from methanol to give long needles; yield 16 g (82%), m.p. 172–173°, $[\alpha]_D^{24}$ −13.2° (c = 1.1 in water). Anal. Calc. for $C_8H_{16}O_7N_2$: C, 38.09; H, 6.40; N, 11.11. Found: C, 37.99; H, 6.14; N, 11.05%. Main infrared absorption bands: 3330, 2930, 1640, 1570, 1550, 1460, 1379, 1300, 1240, 1122, 1080, 1023, 943, 908, and 855 cm^{-1}.

The enantiomorphous 1-nitro-1-deoxy-N-acetyl-L-mannosaminol had m.p. 172–172.5° and $[\alpha]_D^{24}$ +14.9° (c = 1.5 in water). Its infrared absorption spectrum was identical with that of the D-isomer.

2-Acetamido-2-deoxy-1,3,4,6-tetra-O-*acetyl*-β-D-*mannose* (VIII)

An amount of 10 g of the above crystalline addition product was dissolved in 25 ml of 2 *N* sodium hydroxide at 5° and added dropwise with shaking to 12 ml of sulphuric acid in 15 ml of water also at 5°. During the addition the temperature was maintained at 10–15° by external cooling. The solution was neutralized with warm barium hydroxide solution and filtered. Two drops of acetic acid were added and the filtrate concentrated to a syrup under reduced pressure. It was further dried by the distillation of added ethanol, and finally over phosphorus pentoxide in a vacuum desiccator.

This syrupy material was acetylated for 3 days at 0° with acetic anhydride (125 ml) and pyridine (100 ml). The acetylation mixture was poured into 500 ml of ice and water and extracted with chloroform. The chloroform extract was washed twice with dilute sodium bicarbonate, four times with dilute copper sulphate, four times with water, and dried over anhydrous sodium sulphate. Distillation of the solvent under reduced pressure left a yellow syrup which was crystallized from absolute ethanol and recrystallized from ethanol–ether; yield 13 g (84% from VII), m.p. 162–163°, $[\alpha]_D^{24}$ −17.0° (c = 1.8 in chloroform). Anal. Calc. for $C_{16}H_{23}O_{10}N$: C, 49.35; H, 5.95; N, 3.60. Found: C, 49.44; H, 5.73; N, 3.50%. Levene (13) reported m.p. 158–159° and $[\alpha]_D^{20}$ −18° for his preparation of β-D-mannosamine pentaacetate.

The corresponding compound in the L-series had m.p. 162–163°, $[\alpha]_D^{25}$ +18.0° (c = 1.1 in chloroform).

2-Amino-2-deoxy-α-D-*mannose Hydrochloride* (XI)

β-D-Mannosamine pentaacetate was completely deacetylated by dissolving 200 mg in 4 ml of 2 *N* hydrochloric acid and heating on the steam bath for 4½ hours. After concentration under reduced pressure small amounts of residual water, hydrochloric acid, and acetic acid were removed by co-distillation with ethanol. The resulting dark brown crystalline material was dissolved in a small amount of water, decolorized with charcoal, and, after filtration through a cotton and asbestos plug, crystallized by the addition of ethanol; yield 107 mg. The product reduced Fehling's solution, and gave the characteristic Elson–Morgan reaction for hexosamine hydrochlorides. A small amount when degraded in a sealed tube with ninhydrin and pyridine by the method of Jeanloz (18) gave only D-arabinose as determined by paper chromatography. This compound had an indefinite melting point and showed no mutarotation; $[\alpha]_D^{25}$ −4° (c = 1.0 in 3% hydrochloric acid). Anal. Calc. for $C_6H_{14}O_5NCl$: C, 33.26; H, 6.48; N, 6.50; Cl, 16.44.

Found: C, 33.05; H, 6.36; N, 6.70; Cl, 16.40%. Levene (13) reported no mutarotation for his preparation of D-mannosamine hydrochloride, $[\alpha]_D$ −4.7° in 5% hydrochloric acid.

2-Acetamido-2-deoxy-D-glucose (X)

A portion (10 g) of the syrupy β-D-mannosamine pentaacetate was dissolved in 150 ml of absolute methanol, cooled to 0°, and treated at this temperature for 24 hours with 20 ml of 0.4 *N* barium methoxide. The solution was diluted with an equal volume of water, deionized by shaking with exchange resins Amberlite IR-120 and IR-45, filtered, and the filtrate concentrated to a syrup by distillation under reduced pressure. This was crystallized from ethanol–ether to yield 0.75 g of crystalline material and 5.0 g of syrup. The crystalline material, after recrystallization, had m.p. 193–196° with decomposition starting at 185°; $[\alpha]_D^{26}$ +75.0° (5 minutes), +69.0° (15 minutes), +58.2° (30 minutes), and +43.8° at equilibrium (4 hours); (c = 1.2 in water). Anal. Calc. for $C_8H_{15}O_6N$: C, 43.43; H, 6.84; N, 6.33. Found: C, 43.53; H, 6.79; N, 6.48%.

Both the crystalline material and the syrup gave the characteristic Elson–Morgan reaction for N-acetyl hexosamines. The crystalline material was further deacetylated with hydrochloric acid by dissolving 100 mg in 1 ml of 2 *N* hydrochloric, treating on the steam bath for 2 hours, and working up the material as described in the preceding preparation of D-mannosamine hydrochloride. It was recrystallized from aqueous ethanol; yield 93 mg. It reduced Fehling's solution and gave the Elson–Morgan color reaction for hexosamine hydrochlorides. An $[\alpha]_D^{25}$ of +82.4° at 5 minutes and +73° at 18 hours (c = 0.91 in water) established that the material was D-glucosamine hydrochloride, and that the crystalline N-acetyl hexosamine was N-acetyl-D-glucosamine and not N-acetyl-D-mannosamine.

However, when the syrupy material was treated with hydrochloric acid in the same manner, the product had $[\alpha]_D^{24}$ +18.0° changing to +15.5° after 26 hours (c = 2.2 in water). Fractional crystallization of some of this hydrochloride produced D-glucosamine hydrochloride ($[\alpha]_D^{25}$ +98° (5 minutes), +76° (17 hours; c = 1.1 in water)) and a small amount of D-mannosamine hydrochloride ($[\alpha]_D^{26}$ −4°; c = 1.0 in 2.5% hydrochloric acid). Thus the syrupy N-acetyl hexosamine was a mixture of N-acetyl-D-glucosamine and N-acetyl-D-mannosamine, while the crystalline material was pure N-acetyl-D-glucosamine. Of the total yield of N-acetyl derivative, 80–90% was estimated as N-acetyl-D-glucosamine.

Alternate Preparation of D-Mannosamine Hydrochloride

D-Mannosamine was synthesized by a modification of the method of Levene (12). D-Glucosamine hydrochloride (80 g) was first oxidized in aqueous solution with yellow mercuric oxide (200 g) to give D-glucosaminic acid in 50% yield, $[\alpha]_D^{25}$ −14° (c = 1.3 in 2.5% hydrochloric acid). Epimerization was accomplished by refluxing 40 g of D-glucosaminic acid dissolved in 400 ml water containing 40 ml pyridine on a steam bath for 24 hours. The D-mannosaminic acid was obtained by fractional crystallization from the large amount of starting material. The recovered D-glucosaminic acid was treated twice again with aqueous pyridine in the same manner. Each treatment yielded about 4 g of D-mannosaminic acid which was further purified by many recrystallizations from aqueous ethanol, $[\alpha]_D^{24}$ +10° (c = 1.5 in 2.5% hydrochloric acid). The D-mannosaminic acid was converted into its lactone hydrochloride by treatment with ethanolic hydrogen chloride containing a small amount of benzaldehyde; yield 75%, $[\alpha]_D^{24}$ +45° (c = 1.4 in water). Reduction of the lactone with 2.5% sodium amalgam yielded D-mannosamine hydrochloride; yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

60% from the lactone. Recrystallization from water containing a small amount of methanol gave pure material, $[\alpha]_D^{24}$ −4.0° (c = 2.0 in 2.5% hydrochloric acid).

Acetylation of the hydrochloride with pyridine and acetic anhydride in the usual manner gave β-D-mannosamine pentaacetate, m.p. 161–162°, $[\alpha]_D^{24}$ −18° (c = 1.5 in chloroform). Deacetylation with barium methoxide again yielded predominantly N-acetyl-D-glucosamine. But deacetylation with hydrochloric acid gave a quantitative yield of D-mannosamine hydrochloride.

SYNTHESIS OF SUGARS FROM SMALLER FRAGMENTS

PART XI. SYNTHESIS OF L-GALACTOHEPTULOSE[1]

J. K. N. JONES AND N. K. MATHESON[2]

ABSTRACT

1,3-Dihydroxy-2-propanone phosphate condenses with L-threose in the presence of the enzyme aldolase to yield L-galactoheptulose phosphate, from which the heptose was prepared.

Dihydroxyacetone phosphate (1,3-dihydroxy-2-propanone phosphate) which was formed from D-fructose 1,6-diphosphate has been shown to yield new sugar derivatives when its solution is incubated at pH 6.5 with aldehydes in the presence of crude pea aldolase or purified muscle aldolase (1). The reaction takes place between the aldehyde and an enzyme–substrate complex which involves aldolase and dihydroxyacetone phosphate (2). In particular three of the possible aldotetroses, D-erythrose (3), L-erythrose (4), and D-threose (5) have been shown to condense with dihydroxyacetone phosphate in the presence of aldolase and the resultant heptulose derivatives have the D-*threo* configuration on carbon atoms 3 and 4.

It was considered of interest to examine the behavior of the fourth aldotetrose, L-threose. At pH 6.5, L-threose and dihydroxyacetone phosphate (produced by the cleavage of fructose diphosphate with aldolase) in the presence of aldolase gave a low yield of L-galactoheptulose 1-phosphate which was converted to the crystalline sugar. No other heptulose could be detected chromatographically (an orcinol – trichloroacetic acid spray was used for the detection of heptuloses on chromatograms (6)). The ultraviolet absorption of the product formed on heating the heptulose with cysteine and sulphuric acid (7) was measured at 5080 Å, and its intensity indicated that 1 mole of L-threose had yielded 0.021 mole of heptulose. Thus all the aldotetroses condense with dihydroxyacetone phosphate in the presence of aldolase to yield heptulose derivatives which possess the D-*threo* configuration on carbon atoms 3 and 4.

In view of the results of other workers (8, 9) which indicated that these condensations take place without the intervention of enzymes a reaction mixture which was composed of dihydroxyacetone (1,3-dihydroxy-2-propanone), L-threose, and aldolase at pH 6.5 was studied. The presence of heptulose was determined colorimetrically by the method of Dische (7). The reaction products were also separated on paper chromatograms which were sprayed with orcinol–trichloroacetic acid (6). No heptulose was detected by either method. The formation of heptulose was therefore enzymic and involved dihydroxyacetone as its phosphate.

EXPERIMENTAL

Preparation of L-*Threose*

2,4-*O*-benzylidene-L-threose was prepared by the method of Neish (10). The *O*-benzylidene group was removed by heating the derivative in 10% acetic acid solution at 100° C for 1 hour. The solution was extracted three times with ether and the extracts were evaporated under diminished pressure to half their original volume. This concentration of aldotetrose was used in the enzymic experiments.

D-*Fructose Sodium Diphosphate*

Commercial barium salt was deionized on a column of Amberlite ion-exchange resin IR-120, the acidity of the eluate was neutralized with sodium hydroxide, after which the solution was evaporated to a small volume and the concentrate was cooled to 0° C.

The efflorescent crystalline hydrate which separated was collected on a filter, washed with the cold water, and quickly transferred to a desiccator. The dried salt was a pale yellow powder.

The chromatographic behavior of this substance corresponded to that of authentic D-fructose 1,6-diphosphate.

Reaction of L-*Threose,* D-*Fructose Diphosphate, and Crystalline Muscle Aldolase*

A solution of L-threose (3.0 g) and the sodium salt of D-fructose diphosphate (3.0 g) was adjusted to pH 6.5 with dilute acetic acid. Twice-recrystallized muscle aldolase (50 mg) was added and the volume was adjusted to 150 ml. The solution was kept at 37° C and 1-ml aliquots were taken at intervals (see Table I). Each sample was mixed with an equal volume of 2 *N* sulphuric acid and heated on a boiling water bath for 15 minutes to stop enzyme action. The heptulose content was then estimated by the method of Dische (7) with cysteine hydrochloride and sulphuric acid as follows. One milliliter of the sample was made up to 10 ml, and 1 ml of this solution was treated with 5 ml of sulphuric acid reagent at 0° C. The color at 5080 Å which developed after the solution had been left to stand for 18 hours was measured on a Unicam SP 600 spectrophotometer.

TABLE I

Yield of heptose as determined by the colorimetric procedure of Dische (7)

Time (hours)	Heptulose synthesis: aldolase, D-fructose 1,6-diphosphate, L-threose (log *E* 5080 Å)	Blank experiment: aldolase, dihydroxyacetone, L-threose (log *E* 5080 Å)
0	0.17	0.18
0.5	0.20	0.17
1.5	0.23	0.17
6.0	0.51	0.18
24	0.66	0.17
72	0.76	0.16

A calibration curve made by using D-galactoheptulose as the heptose sugar gave a linear relationship between concentration and intensity of color.

The pH of the reaction solution showed a drop towards lower values with time and this pH was adjusted to the original value by the addition of a few drops of sodium acetate solution. Sulphuric acid (2 *N*, 150 ml) was added to the solution which was heated at 100° C for 6 hours in order to hydrolyze phosphate esters. The sulphuric acid was partially neutralized with barium hydroxide and neutralization was completed with barium carbonate.

The barium salts were removed by centrifugation and the supernatant liquid was passed through a column of Amberlite IR4B (acetate) and IR 120 ion-exchange (H) resins. The eluate was reduced in volume by evaporation under diminished pressure to give a syrup which was separated into three fractions on a column of powdered cellulose using butane-1-ol and water (9:1) as eluent.

Fraction I.—Fraction I (0.030 g) co-chromatographed with dihydroxyacetone and gave the same color with the *p*-anisidine hydrochloride reagent as did dihydroxyacetone.

Fraction II.—Fraction II (0.082 g) co-chromatographed with D-fructose and gave the same color with the orcinol – trichloroacetic acid reagent.

Fraction III.—Fraction III (0.079 g) co-chromatographed with L-galactoheptulose and on trituration with ethanol gave L-galactoheptulose, m.p. and mixed m.p. 100–101°, $[\alpha]_D^{22°}$ −90° → −80° (*c*, 1.1 water).

Reaction of Dihydroxyacetone with L-*Threose and Aldolase at pH 6.5*

A solution of L-threose (0.30 g) and dihydroxyacetone (0.30 g) in water was adjusted to pH 6.5 with acetic acid, crystalline muscle aldolase (5 mg) was then added, the volume made up to 15.0 ml, and the solution kept at 37° C. One-milliliter aliquots were taken at 0, 0.5, 1.5, 6.0, 24, and 72 hours, and the heptulose estimated (7). The absorption at 5080 Å at the elapse of these times is recorded in the table.

The authors thank the National Research Council for grants and for a Postdoctoral Fellowship (to N. K. Matheson).

LYCOPODIUM ALKALOIDS

VIII. LYCOPODINE[1]

D. B. MacLean and W. A. Harrison[2]

ABSTRACT

Information pertaining to the position of the carbonyl group relative to the nitrogen atom and to the size of one of the nitrogen rings in lycopodine has been obtained through a study of the reactions of α- and β-cyanobromolycopodine.

Lycopodine, $C_{16}H_{25}ON$, is the major alkaloid of several species of *Lycopodium*. It is known that it contains a tertiary nitrogen atom, a carbonyl group, and no other functional groups, and it can be inferred that it has a combination of four carbocyclic and/or heterocyclic rings (1).

The first degradative work on lycopodine was carried out by Marion and Manske (2), who dehydrogenated the alkaloid and isolated from the reaction 7-methylquinoline and 5,7-dimethylquinoline along with several other uncharacterized bases. Thus, there may be present in the alkaloid a reduced quinoline ring system. The reaction of lycopodine with cyanogen bromide was studied by MacLean, Manske, and Marion (1) and later by Barclay and MacLean (3). From the cyanogen bromide reaction two isomeric cleavage products, α- and β-cyanobromolycopodine, I and II, respectively, were isolated. The bromo group in I was shown to be primary by its conversion to an acetate, hydrolysis of the acetate to an alcohol, and oxidation of the latter to a carboxylic acid without loss of carbon. An attempt to carry out an analogous series of reactions on II failed in the first step, for, instead of the expected acetate, a different compound III, $C_{17}H_{24}ON_2$, was formed, apparently in a cyclization reaction. The carbonyl group in lycopodine is ketonic and is present in a six-membered or larger ring on the basis of its absorption in the infrared near 1700 cm^{-1} (1). Barclay and MacLean (3) have shown that the carbonyl group is flanked on one side by a methylene group through the formation of a benzylidene derivative from α-cyanolycopodine. In the present study the reactions of α- and β-cyanobromolycopodine have been extended to give information on the size of one of the two nitrogen rings and on the position of the carbonyl group relative to the nitrogen atom.

α-Cyanobromolycopodine I was converted to the carboxylic acid IV reported by MacLean, Manske, and Marion (1). Reduction of the acid IV with sodium borohydride yielded the hydroxy acid V, $C_{17}H_{26}O_3N_2$. This hydroxy acid failed to form a lactone on treatment with catalytic amounts of *p*-toluene sulphonic acid in a boiling benzene solution and a close relationship between the carbonyl and the nitrogen in the direction of the α-cleavage is precluded. Hydrolysis of the acid IV with aqueous alcoholic hydrochloric acid yielded an impure amino acid hydrochloride VI. Treatment of a solution of VI in methanol with a solution of diazomethane in ether yielded a mixture from which the lactam VII, $C_{16}H_{23}O_2N$, was isolated. The lactam had ketonic absorption in its infrared spectrum at 1700 cm^{-1} and lactam absorption at 1635 cm^{-1}. The latter is in the region characteristic of six-membered or larger ring lactams. Reduction of VII with

For personal use only.

lithium aluminum hydride yielded dihydrolycopodine VIII, identified by comparison with an authentic sample prepared by the reduction of lycopodine with lithium aluminum hydride. It can be concluded that no rearrangements in the carbon skeleton occurred in the above reaction sequence.

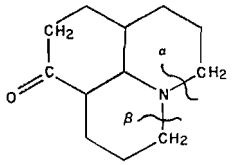
MacLean, Manske, and Marion (1) reported that β-cyanobromolycopodine II reacted with potassium acetate in an unexpected manner and formed compound III in an elimination reaction rather than undergoing displacement to form an acetate. We have confirmed this result. We have found, however, that treatment of II with silver acetate in boiling benzene yielded a mixture of III and an acetate. The presence of the acetate in the reaction mixture was indicated by an examination of the infrared spectrum of the crude reaction product. To facilitate the separation of compound III from the other product of reaction, the mixture was hydrolyzed and then separated by chromatography into two components. The less strongly adsorbed fraction proved to be compound III formed in 82% yield, while the more strongly adsorbed proved to be the β-alcohol, $C_{17}H_{26}O_2N_2$, IX formed in 18% over-all yield from the β-bromide. The crude product IX had absorption bands in the infrared attributable to a carbonyl group and a hydroxyl group. In an alternate method of separation, the crude reaction mixture from the silver acetate reaction was treated directly with sodium borohydride in ethanol. Chromatographic separation of the product of this reduction yielded III in 72% yield and a new compound, $C_{17}H_{28}O_2N_2$, X in 23% yield. Compound X was also obtained by treatment of IX with sodium borohydride. Compound X showed no carbonyl absorption in its infrared spectrum, but had strong hydroxyl absorption as well as the usual cyanamide absorption. The compound X was oxidized by the Oppenauer method to the keto alcohol IX, and in this manner IX was obtained in crystalline form.

The low yield of alcohol in the silver acetate reaction coupled with the difficulty in isolation of the β-bromide II led us to seek an alternative source of the β-alcohol IX. In the reaction of lycopodine with cyanogen bromide, Barclay and MacLean (3) reported that an alcohol fraction was formed in small yield along with the two isomeric bromides. From this alcohol fraction they isolated, after treatment with acetic anhydride, α-cyanoacetoxylycopodine XI, previously reported by MacLean, Manske, and Marion (1). We have treated this alcohol fraction with sodium borohydride and have obtained a mixture from which we have isolated compounds III and X and a new compound XII. Compound XII proved to be identical with the product obtained when α-cyanohydroxylycopodine was reduced with sodium borohydride. In this manner a sufficient quantity of the β-alcohol was obtained for degradative study.

The chromic acid oxidation of IX yielded a non-crystalline acid XIII which was converted to a crystalline methyl ester XIV, $C_{18}H_{26}O_3N_2$, on treatment with diazomethane. The analysis indicated that no loss in carbon had occurred in the oxidation reaction and one can safely conclude that the alcohol IX is a primary alcohol. Reduction of the crude β-acid XIII with sodium borohydride yielded a neutral product XV, $C_{17}H_{24}O_2N_2$, with the properties of a lactone. It had no hydroxyl absorption in its infrared spectrum, but had a strong peak at 1743 cm^{-1} when the spectrum was determined in nujol mull, and at 1761 cm^{-1} when it was determined in a carbon tetrachloride solution. This is a borderline region between five-membered and six-membered lactones and it can be concluded that the carbonyl group is separated from the nitrogen atom by three or four carbon atoms about the periphery of the molecule in the direction of the β-cleavage.

In proposing a model to account for these reactions it is inviting to use the hexahydrojulolidine ring system which is present in annotinine, the only alkaloid of this group of

known structure (4, 5). In making use of this ring system it is convenient to place the carbonyl group in the position shown in the partial formula below.



Those carbon atoms which are definitely known are so indicated, and the α- and β-cleavages are designated. This model is in agreement with the data presented here, namely, that the ring broken in the α-cleavage is six-membered and that the carbonyl group is located close to the nitrogen atom about the periphery of the molecule in the direction of the β-cleavage, but not in the direction of the α-cleavage. The model also accounts for the carbonyl frequency in the infrared spectrum of lycopodine. It does not attempt to account for the fourth ring of lycopodine nor for the C-methyl group which is present in the alkaloid.

EXPERIMENTAL

Lycopodine

The alkaloid was isolated from *L. flabelliforme* by the procedure described by Barclay and MacLean (3). It melted at 116° after recrystallization from petroleum ether. Calc. for $C_{16}H_{25}ON$: one C-methyl, 6.1%. Found: 5.0%.

Reaction of Lycopodine with Cyanogen Bromide

The reaction was carried out and the products isolated according to the procedure of Barclay and MacLean (3).

Oxidation of α-Cyanohydroxylycopodine

α-Cyanohydroxylycopodine (1.9 g), prepared by the method of MacLean, Manske, and Marion (1), was dissolved in 40 ml of 90% acetic acid and the solution added slowly to a solution of 4 g of chromium trioxide in 60 ml of 90% acetic acid. The temperature was maintained at -10 to $-15°$ during the addition, and the mixture was stirred at this temperature for a further 4 hours. The excess chromic acid was destroyed with methanol and the mixture was then evaporated to dryness. Water was added to the residue and the mixture was exhaustively extracted with chloroform. The chloroform solution was extracted with sodium carbonate solution and the carbonate extract acidified and extracted with chloroform. Evaporation of the second chloroform solution yielded 1.2 g of non-crystalline acid. The crude acid crystallized on standing, but a suitable solvent system for its recrystallization was not found. It was characterized as its methyl ester reported previously (1).

Preparation of the Lactam VII

The acid IV (1.2 g) was dissolved in 12 ml of *n*-propanol and treated with 60 ml of 2 *M* hydrochloric acid. The mixture was heated on the steam bath for 15 hours and then evaporated to dryness. The residue was washed several times with warm ether to remove unreacted starting material. There remained a residue of 1.1 g of crude amino acid hydrochloride.

The hydrochloride was dissolved in methanol, an excess of diazomethane in ether was added, and the mixture allowed to stand for 1 hour before it was taken to dryness.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The crude product was dissolved in chloroform and washed with dilute hydrochloric acid. The chloroform solution yielded, on evaporation, 0.5 g of crude product which was purified by chromatography on an alumina column using chloroform as eluant. Practically all the material was eluted in a single band. The chloroform was evaporated and the residue dissolved in low boiling petroleum ether from which it crystallized in needles. Recrystallization from the same solvent gave an analytical sample which melted at 159–161°. Calc. for $C_{16}H_{23}O_2N$: C, 73.6; H, 8.88; N, 5.4%. Found: C, 73.9; H, 9.29; N, 5.2%. The infrared spectrum showed a strong band at 1635 cm^{-1} in the lactam region, as well as the usual carbonyl band at 1700 cm^{-1}. The over-all yield of lactam from α-cyanohydroxylycopodine was about 30%.

The acid washings from the purification of the lactam were worked up and yielded 0.3 g of an amino acid ester. The ester was slowly converted to the lactam by refluxing in xylene. This was shown by the infrared spectrum of the crude product, which exhibited a decrease in the intensity of the ester carbonyl absorption at 1730 cm^{-1} and the appearance of the lactam carbonyl band at 1635 cm^{-1}.

Reduction of the Lactam VII *with Lithium Aluminum Hydride*

A sample of the lactam VII (0.15 g), dissolved in anhydrous tetrahydrofuran, was added with stirring to a solution of lithium aluminum hydride (0.2 g) in tetrahydrofuran. The mixture was heated under reflux for 4 hours and then allowed to stand overnight. The excess hydride was decomposed with wet tetrahydrofuran, the solution filtered, and the precipitated hydroxides extracted thoroughly with chloroform. The combined tetrahydrofuran and chloroform extract was evaporated to dryness and the residue was purified by chromatography on an alumina column using chloroform as eluant. From the chloroform eluant a residue was obtained which crystallized from ether – petroleum ether. This material proved to be identical with a sample of dihydrolycopodine prepared by the reduction of lycopodine with lithium aluminum hydride. The melting point of a mixture of the two samples was not depressed and their infrared spectra were identical.

Reduction of the Acid IV *with Sodium Borohydride*

The acid IV (0.3 g) was dissolved in an aqueous sodium carbonate solution and treated with an excess of sodium borohydride. After the mixture had stood at room temperature for 12 hours, the excess sodium borohydride was destroyed with acetone and the mixture evaporated to dryness. The residue was taken up in water, acidified with hydrochloric acid, and the resulting mixture extracted with chloroform. The chloroform extract was dried and evaporated to yield a crystalline residue in virtually quantitative yield. Recrystallization from ether, in which the compound is only sparingly soluble, gave an analytical sample which melted at 193–194°. The compound analyzed for a monohydrate. Calc. for $C_{17}H_{26}O_3N_2 \cdot H_2O$: C, 62.9; H, 8.70; N, 8.6%. Found: C, 63.0; H, 8.35; N, 8.7%. Loss in weight on drying: Calc., 5.5%; found, 5.8%.

Reduction of α-Cyanohydroxylycopodine with Sodium Borohydride

α-Cyanohydroxylycopodine (0.2 g) was dissolved in ethanol and treated with an excess of sodium borohydride. After a period of 3 hours the excess borohydride was destroyed by the addition of acetone and the mixture evaporated to dryness. Water was added to the residue and the mixture was extracted with chloroform. The chloroform extract was dried and evaporated to dryness to yield a crystalline residue in virtually quantitative yield. Recrystallization from acetone yielded an analytical sample which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

melted at 195–197°. Calc. for $C_{17}H_{28}O_2N_2$: C, 69.8; H, 9.65; N, 9.6%. Found: C, 70.1; H, 9.97; N, 9.2%.

Treatment of β-Cyanobromolycopodine II *with Silver Acetate*

Silver acetate (1.0 g) was added to a solution of 0.82 g of β-cyanobromolycopodine in benzene (80 ml) and the mixture heated under reflux for 5 hours. After the insoluble salts had been removed by filtration, the benzene solution was evaporated to give 0.67 g of non-crystalline material. The infrared spectrum (film) of the crude product showed bands at 1700 and 1735 cm^{-1}, attributed to ketone and acetate carbonyl groups respectively, as well as a strong band at 1675 cm^{-1} characteristic of the cyclized compound III.

To facilitate separation of the cyclized and non-cyclized products, the acetate which had been formed was hydrolyzed to the alcohol by treating the mixture for 2.5 hours with potassium hydroxide (0.8 g) in boiling methanol (20 ml). The methanol was evaporated, water added to the residue, and the mixture extracted with chloroform. The oil obtained on evaporation of the extract was chromatographed on alumina with chloroform as the eluant. The first fractions yielded 0.52 g (82%) of crystalline cyclized compound III, identified by comparison with a sample prepared according to the procedure of MacLean, Manske, and Marion (1). A yellow band which moved more slowly down the column yielded 0.12 g (18%) of an almost colorless oil, the infrared spectrum of which had absorption bands in the hydroxyl, cyanamide, and carbonyl regions. Reduction of this crude keto alcohol IX is described below.

A second silver acetate reaction was carried out using 0.47 g of β-cyanobromolycopodine. In this run the cyclized compound – acetate mixture was reduced with sodium borohydride and the resulting mixture separated by chromatography on alumina with chloroform as the eluant. This procedure yielded 0.26 g (72%) of the cyclized compound III and 0.09 g (23%) of compound X described below.

Reduction of β-Cyanohydroxylycopodine IX *with Sodium Borohydride*

The non-crystalline alcohol IX (0.12 g) obtained by the foregoing procedure was dissolved in 95% ethanol, sodium borohydride (0.1 g) added, and the mixture left overnight at room temperature. When the reaction mixture was worked up in the usual manner a nearly quantitative yield of a crystalline product was obtained which melted at 181–182° after recrystallization from acetone. Calc. for $C_{17}H_{28}O_2N_2$: C, 69.8; H, 9.65; N, 9.6%. Found: C, 69.9; H, 9.43; N, 8.9%.

The infrared spectrum of the compound showed a band at 3360 cm^{-1} in the hydroxyl region, cyanamide absorption at 2195 cm^{-1}, and no absorption in the carbonyl region.

Sodium Borohydride Reduction of the Alcohol Fraction from the Cyanogen Bromide Reaction

An ethanol solution containing the alcohol fractions (3.6 g) from a number of reactions of lycopodine with cyanogen bromide was added to a solution of 1.0 g of sodium borohydride in 95% ethanol. The reaction mixture was allowed to stand overnight at room temperature. The excess hydride was destroyed by the addition of formalin and the solution taken to dryness. Water was added to the residue, the mixture extracted with chloroform, and the chloroform extract washed with dilute hydrochloric acid. The non-crystalline basic material which was recovered from the acid washings weighed 0.22 g. The neutral fraction obtained on evaporation of the chloroform solution was dissolved in acetone. Concentration of the acetone solution yielded 0.31 g of a crystalline com-

For personal use only.

pound, m.p. 193–196°, which was identical with compound XII obtained by borohydride reduction of α-cyanohydroxylycopodine.

The material recovered by evaporation of the mother liquors from the crystallization above was dissolved in chloroform and adsorbed on an alumina column. Elution with 99:1 chloroform–methanol first yielded a fraction containing 0.43 g of cyclized compound III, followed by a brown band (0.43 g) from which no crystalline compounds could be isolated. Evaporation of the next fractions yielded an additional 0.78 g of crystalline compound XII. This diol was closely followed down the column by another compound (0.22 g, m.p. 179–181°) which was found by a mixed melting point determination and comparison of infrared spectra to be identical with that obtained by sodium borohydride reduction of β-cyanohydroxylycopodine. Further elution of the column yielded only non-crystalline material of complex composition. The yields of cyclized compound III, α-cyanohydroxydihydrolycopodine XII, and β-cyanohydroxydihydrolycopodine X were 12%, 30%, and 6%, respectively.

Oppenauer Oxidation of β-Cyanohydroxydihydrolycopodine X

To 0.60 g of β-cyanohydroxydihydrolycopodine X partially dissolved in anhydrous benzene (70 ml) were added 5 ml of acetone and 1.5 g of aluminum isopropoxide. The mixture was heated under reflux for 11 hours and then poured into water. The benzene layer was separated and the aqueous phase extracted with more benzene. The crude product obtained by evaporation of the combined benzene extract was dissolved in chloroform and adsorbed on an alumina column. Evaporation of the fractions collected on elution with chloroform yielded 0.38 g of β-cyanohydroxylycopodine which melted at 123–124° after crystallization from ether – petroleum ether. Calc. for $C_{17}H_{26}O_2N_2$: C, 70.3; H, 9.03; N, 9.7%. Found: C, 69.8; H, 8.82; N, 10.0%.

The infrared spectrum showed absorption bands at 3475 cm^{-1} in the hydroxyl region, 2195 cm^{-1} in the cyanamide region, and 1685 cm^{-1} in the carbonyl region. The spectrum of a non-crystalline film of the compound was found to be identical with that of the non-crystalline alcohol obtained by hydrolysis of the product of the reaction of β-cyanobromolycopodine with silver acetate.

Elution of the column with 95:5 chloroform–methanol gave a fraction containing 0.09 g of unreacted diol.

Oxidation of β-Cyanohydroxylycopodine with Chromic Acid

A solution of 0.15 g of β-cyanohydroxylycopodine (m.p. 123–124°) in 90% acetic acid was added dropwise over 1.5 hours to a stirred solution of chromium trioxide (0.3 g) in 90% acetic acid maintained at −5 to −10°. The reaction mixture was stirred 3 hours longer, during which time the temperature rose to 0°. After the excess chromium trioxide had been destroyed by the addition of methanol, the mixture was evaporated under reduced pressure. Water was added to the residue and the mixture extracted repeatedly with chloroform. The chloroform solution was extracted with aqueous sodium bicarbonate and the bicarbonate solution acidified and extracted with chloroform. Evaporation of the chloroform yielded 0.11 g (70%) of a non-crystalline acid, whose infrared spectrum (film) showed absorption maxima at 1695 (ketone carbonyl), 1710 (acid carbonyl), and 2200 cm^{-1} (cyanamide), and absorption in the hydroxyl region.

A sample of the acid (35 mg) was converted to the methyl ester by dissolving it in methanol and treating it with an excess of an ether solution of diazomethane. After it had stood for 2 hours the solution was evaporated and the residue dissolved in chloro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

form. The chloroform solution was washed with aqueous sodium bicarbonate and then evaporated. The product crystallized readily and melted at 127–129° after recrystallization from ether – petroleum ether. Calc. for $C_{18}H_{26}O_3N_2$: C, 67.9; H, 8.23; N, 8.8%. Found: C, 67.8; H, 8.41; N, 8.9%.

The infrared spectrum of the ester showed absorption at 1700 (ketone carbonyl), 1725 (ester carbonyl), and 2210 cm^{-1} (cyanamide).

Reduction of the Acid XIII *with Sodium Borohydride*

A solution of the non-crystalline acid XIII (70 mg) in aqueous sodium bicarbonate was added to an ethanolic solution of sodium borohydride. After the reaction mixture had stood at room temperature for 2 hours, the excess hydride was destroyed by adding formalin, and the mixture evaporated. The residue was acidified with dilute hydrochloric acid and extracted with chloroform. The chloroform extract was washed with aqueous sodium bicarbonate and then evaporated to give 45 mg (68%) of a crystalline neutral compound. A small amount of starting material was recovered when the bicarbonate washings were acidified and extracted with chloroform, but no hydroxy acid was detected. Recrystallization of the neutral compound from ether yielded colorless needles, m.p. 201–203°. Calc. for $C_{17}H_{24}O_2N_2$: C, 70.8; H, 8.39; N, 9.7%. Found: C, 70.7; H, 8.52; N, 9.8%.

The infrared spectrum of the neutral compound exhibited cyanamide absorption and a single band in the carbonyl region which appeared at 1761 cm^{-1} when the spectrum was determined in carbon tetrachloride solution, and at 1743 cm^{-1} when determined in nujol mull. There was no absorption in the hydroxyl region.

THE CONSTITUTION OF THE SODIUM – ACID PHOSPHATE GLASSES[1, 2]

A. E. R. Westman, M. Joyce Smith, and P. A. Gartaganis

ABSTRACT

The preparation of phosphate glasses containing sodium and hydrogen is described. The over-all composition was calculated from the Na/P ratio of the starting mixture and the hydrogen content determined by a zinc oxide ignition. The chemical constitution was determined paper-chromatographically employing recent improvements in technique.

Close resemblance between the molecular weight distributions of the sodium–acid glasses and the strong phosphoric acids is shown by the results, but it is also shown that there is no sharp transition to the molecular weight distribution shown by the sodium, potassium, and lithium glasses.

The importance of stoichiometry on the constitution of glass is discussed, together with the statistical models from which several theories are derived to predict the distribution of the polymers in a glass. The theories of Van Wazer and Parks, which show the most satisfactory agreement with the experimental results, receive detailed consideration.

INTRODUCTION

Glasses with compositions in the Na_2O–H_2O–P_2O_5 system between the orthophosphate and the metaphosphate compositions were studied, in particular glasses containing both hydrogen and sodium cations. New methods of preparation involved the progressive dehydration of orthophosphate mixtures to give a series of compositions following the lines on Fig. 1. In the preliminary examination compositions on the line $T = 20$ were also studied.

The development of the separation of phosphate anions by paper chromatography has been described by Hettler (1). The latest techniques used in this laboratory, especially a

new method of quantitative estimation of phosphorus, have been described recently (2) and give greater precision and reliability.

The chromatographic separation of the condensed phosphate anions made it possible to determine the constitutions of the soluble glasses, i.e. the proportions of each chain length. The first study of the change in the size distribution with composition was carried out by Westman and Crowther (3) on the Na_2O–P_2O_5 system, the sodium glasses. However, only glasses with a number-average chain length, $\bar{n}$, higher than 3 were obtainable crystal-free. Many attempts to obtain clear sodium glasses of lower $\bar{n}$ have not yet yielded satisfactory results, although experiments are still in progress, notably with the through-flame apparatus originally devised by Haller (4). Secondly, the system H_2O–P_2O_5, the strong phosphoric acids, was studied by Huhti and Gartaganis (5) and also by Thilo and Sauer (6) and Ohashi and Sugatani (7). Some modification of techniques was necessary because these compositions give rise to hygroscopic, syrupy liquids at room temperatures. Certain significant differences were observed between the distributions obtained for the sodium glasses and the acids from these two studies, the principal being the absence of orthophosphate in sodium glasses and the existence of "free-water" in the acids. Two further investigations into the effect of the cation on distribution were begun. The distributions obtained from glasses containing lithium and potassium as cations have already been published (8). They were similar to those of the original sodium glasses, no orthophosphate being detected; however there were differences too large to be ascribed to experimental error alone. The object of the present study was to obtain the distribution patterns of glasses having a sodium–hydrogen ratio of unity, and to determine the effect of the substitution of sodium by hydrogen at one particular cation to phosphorus ratio.

EXPERIMENTAL

Preliminary Works

Attempts to prepare sodium–acid glasses with Na/H = 1 by heating phosphorus pentoxide with sodium hydrogen pyrophosphate in a sealed pyrex flask, as in the case of the strong phosphoric acids, were unsuccessful and dangerous because the pyrex, leached by the phosphate, became brittle and exploded. "Vycor" brand, 96% silica glass was found to be resistant to attack and so small tubes of Vycor were prepared as containers.

Starting materials consisted of $Na_2H_2P_2O_7$ and either P_2O_5 or an equimolecular mixture of Na_2HPO_4 and NaH_2PO_4. (The $Na_2H_2P_2O_7$, Na_2HPO_4, and NaH_2PO_4 were previously dried at 110° C.) The mixtures were homogenized by vigorous shaking, a portion was sealed in a Vycor tube and placed in a furnace at 650° or 800° C. A clear liquid was obtained in 10 minutes. The tube was carefully removed (the worker wearing protective shields) and plunged horizontally into a bath of water. When cool the tube was broken open and a sample of the glass was dissolved in alkaline solution and chromatographed. Tubes were processed singly due to the frequency of explosion, both in the furnace and on quenching.

Despite the difficulties, data were obtained for a range of number-average chain lengths, $\bar{n}$ = 1.1 to 9.0. These were communicated to Van Wazer and Parks to illustrate their distribution theory and were published by them as preliminary values (9). In this laboratory, publication of the detailed results was delayed because an error was detected in the preparation. When the number of molecules per 100 atoms of phosphorus indicated by the chromatographic analysis, "N", was compared with the number derived from the cation to phosphorus ratio of the starting material, the agreement was found to be unsatisfactory at high cation–phosphorus ratios. Appreciable quantities of water had

escaped from the liquid phase and, on quenching, condensed on the upper portion of the tube, leaving the bulk of glass poor in hydrogen and with a correspondingly increased average chain length. This was confirmed by experiment showing that packing the tubes as fully as possible lowered the average chain length again and that the surface layer of the glass with adsorbed water had a very different constitution from the bulk of the glass. The techniques adopted to avoid this error are described later.

The glass prepared by the earlier technique with an average chain length $\bar{n} = 5$ was sufficiently defined to be used in admixture with a sodium glass $\bar{n} = 5$ to examine the effect of a change in cation. The mixtures were melted quickly in a platinum crucible over a burner and quenched between copper blocks. No general increase in average chain length was detected.

Final Preparation of Glasses

Efforts were made to avoid the unknown composition change due to loss of water to the vapor phase. A lowering of the temperature required to give a clear melt was sought in an alternative starting mixture including sodium – acid tetrametaphosphate (10) but no significant improvement in results was observed. Finally, a method was adopted whereby the composition (%) with respect to hydrogen was determined after the glass was made by ignition with zinc oxide. The standard deviation of this determination was 0.12.

Glasses of number-average chain length greater than three were obtained by quenching between copper blocks, at 1-minute intervals, the liquids resulting from melting and partially dehydrating certain mixtures of pure monobasic sodium orthophosphate and standard orthophosphoric acid (85.454%) in a platinum crucible over a Meeker burner. Usually six glasses of decreasing water content resulted from one starting mixture. A second series covering a smaller range of compositions, due to shorter intervals of dehydration, permitted glasses to be obtained with Na/H near unity. Most were clear, brittle, crystal-free glasses, but if insufficient water was removed, very viscous liquids similar to the strong phosphoric acids resulted. The end of a dehydration series was controlled by the formation of fibrous "hypoly" material, as the metaphosphate composition was approached. This appeared crystalline under the petrographic microscope and would not remelt.

The chemical constitution of each glass was determined by dissolving a few fragments in sodium bicarbonate solution maintaining the pH at approximately 8, separating the various molecular species on a filter paper chromatogram, and analyzing by the new technique (2). By adding the other fragments to a weighed, fired crucible containing zinc oxide (approx. 2 g), the water content (in %) was determined from the loss in weight from firing at 550° C for 1 hour.

Glasses having a sodium to phosphorus ratio greater than .83 (i.e. $\bar{n} = 3$ when Na = H) required a starting mixture of mono- and di-basic orthophosphates without orthophosphoric acid. These mixtures lost almost all of their water content before melting. Glasses of these compositions were obtained, however, by returning to a sealed Vycor-tube technique. Mixtures of the correct sodium to phosphorus ratio, but rich in water content (i.e. using $NaH_2PO_4.H_2O$ crystals in part), were sealed into Vycor tubes and heated to 350° C for about one hour. The liquid was homogenized by rolling the tube over the floor of the furnace (with all due precautions) and then removed vertically and allowed to cool to room temperature. The coefficients of expansion of the Vycor and the phosphate glass were sufficiently different to allow the phosphate lump to be lifted cleanly away from the fractured Vycor tube. Carefully avoiding the upper surface layer and possible absorbed water, we chromatographed part of the lump and ignited part to determine the water

For personal use only.

content and thus the composition of the bulk of the phosphate glass. Again, a series of varying composition was obtained by varying the proportion of hydrated and anhydrous NaH_2PO_4; slight variations were also effected by using tubes of various lengths and different temperatures of melting, both of the latter influencing the proportion of the water existing in the vapor phase.

DATA

The constitution of some 150 glasses with compositions located along the solid lines in Fig. 1 were obtained. For these glasses it was found that the Na/H ratio had little effect on the observed constitutions so all of the results, including those for Na = H, could be represented adequately by the curves in Fig. 2 (11). The abscissa "T" is defined by

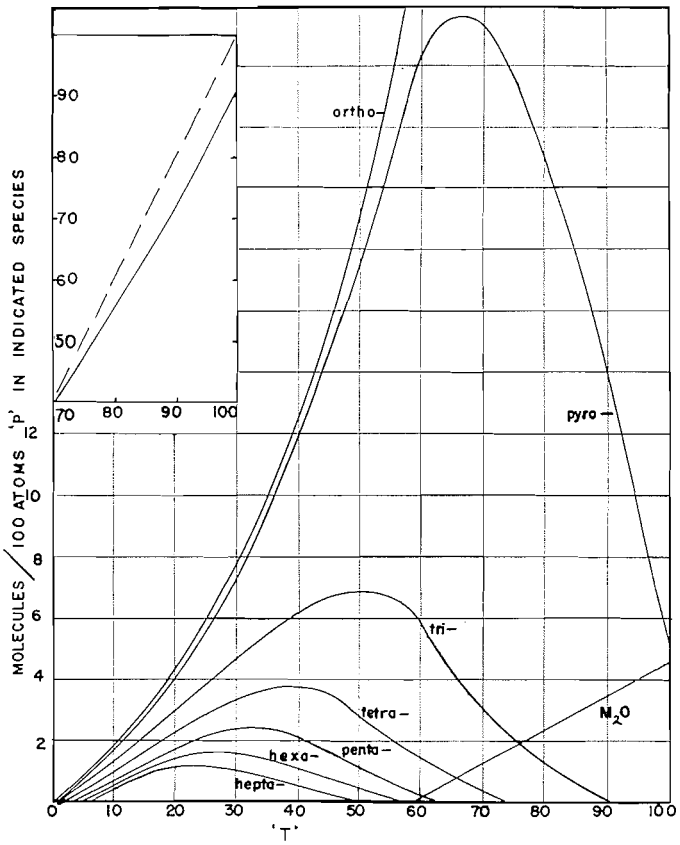

FIG. 2. The variation of distributions with T for the sodium–acid glasses. Inset: solid line, extension of orthophosphate curve; broken line, orthophosphate proportion in a system containing only ortho- and pyro-fractions.

$T = 50(M/P-1)$ where M/P is the cation to phosphorus atomic ratio (see also Stoichiometry later), "T" therefore represents the number of molecules per 100 phosphorus atoms for the particular composition. The ordinate indicates the number of molecules appearing in each fraction for a total of 100 atoms of phosphorus. The value of "T" for each glass was calculated from its water content using the following equation:

[1] $$T = 100/\bar{n} = 50\ (x+w(ax+b)/(1-w)-1)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

where w = % water content/100, $a = Na_2O/H_2O = 3.440$, $b = P_2O_5/H_2O = 7.885$, and x = molecular ratio $Na_2O:P_2O_5$. The curve marked "M_2O", i.e. "free water or sodium hydroxide" in Fig. 2 is derived from the difference between "T" and "N", the latter being the total of the molecules observed in the chromatographic analysis per 100 atoms of phosphorus, i.e. those molecules not detected chromatographically, "hypoly" being negligible. At smaller values of "T" the number-average chain length of the hypoly material can be deduced from $T-N$. A check on the methods of preparation and chromatographic analyses is provided when both M_2O and "hypoly" are negligible.

DISCUSSION

Qualitative Comparisons

The distributions observed in Fig. 2 are similar to those of the strong phosphoric acids in that free M_2O and orthophosphate are present; the latter does not occur in the sodium glasses. When only ortho- and pyro-phosphate are present their proportion is fixed as indicated by the broken line in the insert on Fig. 2, but the experimental points for both the sodium–acid glasses and the strong phosphoric acids tend to follow the lower solid line. This was explained by Huhti and Gartaganis (5) in the case of the acids by assuming "free water" to exist in equilibrium with the phosphoric acids. Their auxiliary experiments and those of other workers (6, 7) confirmed this explanation. In the case of the sodium–acid glasses, free M_2O may again explain the points below the theoretical line. However, it was difficult to prepare bubble-free glasses in this region and it was possible for moisture trapped in the bubbles to result in a higher value of T. This was borne out when the deliberate analysis of specimens containing some bubbles showed values for % total phosphorus as orthophosphate, approximately 5% lower than the samples without bubbles indicated by the solid line in the inset on Fig. 2. More experiments, possibly with other techniques, are needed in this region.

A closer comparison of the curves in Fig. 2 with the corresponding curves for the strong acids and the alkali metal glasses revealed the following differences:

(*a*) The orthophosphate content of the acid glasses was greater than that of either the strong acids or the sodium glasses, the latter being zero. The preliminary experiments at $\bar{n} = 5$ described above showed that as hydrogen replaced sodium as cation, the orthophosphate content of the glasses increased *gradually* to a very flat maximum or plateau over the acid glass compositions before dropping very slightly at the strong phosphoric acid composition. Thus, there was no particular arrangement of hydrogen and sodium atoms necessary for the development of orthophosphate.

(*b*) The maximum in the curve for pyrophosphate in Fig. 2 is to the right of that for the strong acids.

(*c*) The sodium–acid glasses and the acids had much higher hypoly contents than the sodium glasses. At low values of T the sodium–acid glasses contained less hypoly than the acids; at high T values, more hypoly; the hypoly contents being the same at about $T = 20$.

(*d*) Free water occurred in much the same mole percentages and over the same range of T in both the acid glasses and acids.

(*e*) The ring phosphates found in the alkali metal glasses were not found in either the acids or the sodium–acid glasses studied. Studies of compositions closer to the left side of Fig. 1 are indicated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Some of the above comparisons are seen later in Fig. 4 where the agreement between theoretical and experimental results is shown for three of the fractions.

Phase Relations

Morey (12) investigated phase relations in sealed tubes for systems with compositions along a line in Fig. 1 from H_2O to $NaPO_3$. A comparison with the data of this paper is of interest in connection with the much discussed question of the relation of glass constitution to the constitution of the primary phase. The molecules, or molecule-ions, that form the primary phase may exist as such in the glass or may be formed from smaller units as the crystal grows. There is evidence for the first of these possibilities in this case. The cyclic trimetaphosphate crystals (Morey's $NaPO_3I$) grow in glasses containing trimetaphosphate rings near the $NaPO_3$ composition.

STOICHIOMETRY

For a particular cation or combination of cations M, the chromatographic analysis of a properly fused and quenched glass depends solely on the M/P atomic ratio of that glass. This means that stoichiometry is an important factor in determining the constitution of a glass.

Stoichiometric ideas can be introduced in several ways. The method developed in papers from this laboratory starts from the number-average chain length. Other approaches include that of Stevels (13) and Van Wazer and Parks (9).

Number-average Chain Length

If only polymers of the general formula $M_{n+2}P_nO_{3n+1}$ are involved, then the number-average chain length, $\bar{n}$, is related to the M/P atomic ratio by the equation

$$\bar{n} = 2/(M/P-1) \qquad [2]$$

where M and P stand for corresponding numbers of cation and phosphorus atoms respectively. If for a particular $\bar{n}$, we consider 100 phosphorus atoms, then on stoichiometric grounds alone the constitution might be such that all the polymers had the same formula $MO_{\frac{1}{2}}.(MPO_3)_{\bar{n}}.O_{\frac{1}{2}}M$ and there would be $100/\bar{n}$ such polymers. The MPO_3 units, 100 in all, could then be distributed in other ways among the $100/\bar{n}$ polymers. The number of polymers per 100 phosphorus atoms remains the same, depending only on $\bar{n}$, and being given by [1] above.

When ring compounds are formed, the number of linear polymers per 100 phosphorus atoms is unchanged, but there are fewer MPO_3 groups to distribute among them. A single long linear polymer can also rearrange according to equation [5] (following) to form a branched or cross-linked polymer with the same M/P ratio and without altering the above empirical formula so long as the "length" of the new polymer is defined by the number of phosphorus atoms it contains. However, when branching or cross-linking is accompanied by an increase in molecular weight, as when two polymers go together to form the new polymer, splitting off M_2O, then the M/P ratio of the polymer decreases.

When the M/P atomic ratio = 1 the number-average chain length becomes infinite (equation [2]). For M/P atomic ratios < 1, branching or cross-linking accompanied by higher molecular weights, postulated by Van Wazer, creates "ultraphosphates" (14). As the M/P ratio is reduced through unity a sharp change from finite linear polymers to infinite (wall-to-wall) polymers, or cross-linked structures, is unlikely. In the experimental

For personal use only.

data for glasses just below the metaphosphate line there is some indication of branched or cross-linked material.

Bridging and Non-bridging Oxygens

A number of glass technologists, notably Stevels (13), introduce stoichiometric ideas into the discussion of silicate glasses by distinguishing between bridging and non-bridging oxygens.

Stevels defines the number of non-bridging oxygens per silicon atom, X, and the number of bridging oxygens per silicon atom, Y, as follows:

[3] $$X = 2(O/Si) - 4$$

[4] $$Y = 8 - 2(O/Si)$$

where the symbols O and Si stand for numbers of atoms of oxygen and silicon respectively and $X + Y = 4$.

Criteria for finite chains, infinite chains, and cross-linked structures are then given in terms of Y, as $O < Y < 2$, $Y = 2$, and $Y > 2$ respectively. The silicate glasses of commerce have values of Y from 3 to 3.4. Glasses can be made in the laboratory having Y values between 3 and 2 and, by special means, below 2.

When this approach is applied to phosphate glasses it is found to be algebraically equivalent to the methods just given, except that there is no provision for unreacted M_2O or rings. A phosphorus–oxygen tetrahedron is only capable of bonding to three other tetrahedra and cannot form a three-dimensional network, as do the SiO_4 tetrahedra. In its usual crystalline modification P_4O_{10} consists of isolated cage structures each built of four PO_4 tetrahedra. In other forms sheets of PO_4 tetrahedra occur but no three-dimensional networks. Thus, it is interesting to note: (*a*) that the silicate glasses of commerce on this basis have a more cross-linked structure than even P_2O_5 in the phosphate series; (*b*) that bonding a cation to a SiO_4 tetrahedron renders it equivalent to a PO_4 tetrahedron, i.e. NaSi may substitute for P; and (*c*) that, using Stevels' equations [3] and [4], the phosphate glasses with which this paper is concerned are in the range of $O < Y < 2$ or very much below the commercial silicate glasses. Each of these comments is illustrated in Table I.

TABLE I

Stoichiometric comparison of silicate and phosphate compositions

Composition of silicate	X	Y	O/Si or O/P ratio	Composition of phosphate
SiO_2	0	4	2	
$Na_2Si_2O_5$	1	3	2.5	P_2O_5
Na_2SiO_3	2	2	3	$NaPO_3$
	3	1	3.5	$Na_4P_2O_7$
	4	0	4	Na_3PO_4

Parks–Van Wazer Approach

Parks and Van Wazer (9) define chemical groups to which chemical symbols and names are assigned as follows:

Symbol	Name	Symbol	Name
o = M_3PO_4	Ortho group	**b** = $PO_{2.5}$	Branching group
e = $M_2PO_{3.5}$	End group	**u** = MOM	Unreacted M_2O
m = MPO_3	Middle group	(**2e**) = $M_4P_2O_7$	Pyro group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

They also define R as the M/P ratio.

All polymers and molecules envisaged in a glass may be constructed from these building units and are subject to the chemical equations

[5] $$2\mathbf{m} = \mathbf{b}+\mathbf{e}$$

[6] $$2\mathbf{e} = \mathbf{m}+\mathbf{o}$$

[7] $$2\mathbf{o} = 2\mathbf{e}+\mathbf{u}$$

or

[8] $$2\mathbf{o} = (\mathbf{2e})+\mathbf{u}.$$

The compound $\mathbf{u} = M_2O$ is not considered to break down further.

Equilibrium constants designated K_1, K_2, K_3, and K'_3 are written for equations [5], [6], [7], and [8] respectively in terms of mole fractions represented by the corresponding italicized letters. This approach is proving very useful for classifying a wide variety of polymer systems. The choice of the constants K_1, K_2, K_3, K'_3 to fit the experimental results as closely as possible permits deductions concerning the degree of ionization of the cations. Conversely, if previous assumptions regarding ionization are made, the change in ortho and unreacted units with composition (M/P) is forecast. In general the shapes of the curves obtained by calculation agree well with the experimental results. This is clearly shown in Fig. 3 where the solid lines indicate the experimental data for the acid glasses and the broken lines the curves derived from the selection of the constants as $K_1 = 0$, $K_2 = 0.08$, and $K_3 = 0.02$. However, no choice of K values will bring the maximum for ends anywhere but at $R = 2$, which does not agree with the experimental data. One must assume in this case that the K values change slightly with composition.

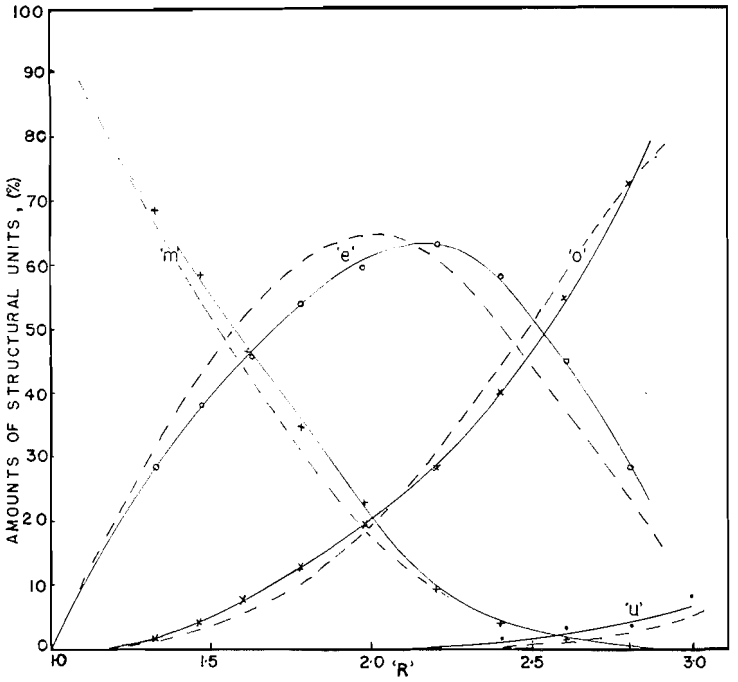

FIG. 3. Comparison of theoretical and experimental amounts of structural units ('*m*', middles; '*e*', ends; '*o*', ortho; '*u*', unreacted M_2O). (Theoretical curves (broken lines) obtained using $K_1 = 0$, $K_2 = 0.08$, and $K_3 = 0.02$.)

Distribution Theories

Since knowledge of the structural units present and their proportions does not define the distribution of polymers to be expected in a glass, various statistical models have been proposed. Van Wazer has discussed a Poisson model; a random reorganization model, based on a flexible chain theory; and, with Parks, a rigid-rod model (9).

The Poisson model has been shown to fit only a limited range of compositions and does not fit the data given in this paper so it will not be discussed further.

It is also possible to invoke mass law theory, which is essentially statistical in origin. This was applied to the chromatographic data for the strong phosphoric acids (5).

Mass Law Theory

This can be applied in as many ways since one can write chemical equations purporting to govern the dynamic equilibrium occurring in the molten glass, or liquid state, etc. In the paper cited, the equilibrium between water, pyrophosphoric acid, and orthophosphoric acid was considered. Thus, unreacted M_2O, i.e. water, was the common factor. This could have been extended to the higher acids present but two difficulties are encountered: (*a*) the number of equilibrium constants involved becomes very large and (*b*) the data required to confirm their validity would have to be very comprehensive and accurate. This is one reason why Van Wazer and Parks worked with structural units, since five or six such units suffice for all polymers.

An alternative method would be to regard orthophosphate as a common factor in all the equilibria since, whatever the mechanism, the polymers gain or lose PO_4 tetrahedra in maintaining an equilibrium. This method has possibilities in the low molecular weight acid glasses and acids, but suffers the two disadvantages already given for the mass law approach and, in addition, when dealing with the non-acid glasses, the difficulty arises that charge density considerations suppress the formation of orthophosphate, as explained by Van Wazer (9). On the other hand, hydrolysis studies indicate that linear phosphate polymers tend to degrade by splitting orthophosphate groups off the end so this approach would have the benefit of starting from chemical knowledge of the polymer properties. One could only hope for some empirical relation relating the equilibrium or other constants with chain length.

Van Wazer–Parks Distributions

Another approach, followed by Van Wazer–Parks, is to set up a statistical model, being guided more or less by the known properties of phosphates and the nature of the distributions to be fitted. They used the results for the strong acids (5) and the authors' preliminary results for the sodium-acid glasses and showed that with some smoothing of the data, a reasonable fit could be obtained using the flexible chain model but not the rigid-rod model. Since the preliminary data do not differ markedly from the more reliable data reported here, a theoretical distribution based on the flexible chain model in the limiting case where there is no branching was computed from

$$[9] \qquad w_n = \frac{n}{\bar{n}(\bar{n}-1)}\left(\frac{\bar{n}-2}{\bar{n}-1}\right)^{n-2}\left(1-\frac{o}{1-u}\right)$$

where n = the chain length of a polymer; w_n = the weight fraction of the total phosphorus in polymers of length n; and $\bar{n}$ = the number-average chain length of the glass, computed by including only the polymers having $n \geqslant 2$. Allowance is made in the equation [9] for "o" and "u", the mole fractions of orthophosphate and unreacted M_2O,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

which are not considered to be polymers but diluents. Their proportion was predicted by the selection of K_1, K_2, and K_3 as shown in Fig. 3.

The comparisons afforded by Table II show that the Van Wazer–Parks distribution (9) fits the observed values remarkably well, considering that the probabilities are introduced from very general physical ideas. The individual chemical properties of the polymers are most likely to influence the system which contains only a few species, especially when these exhibit the striking differences associated with the first members of a homologous series. Thus the ability of statistical models to fit the high molecular weight contributions but not the low ones is understandable. The slight differences between sodium, potassium, and lithium glasses can similarly be attributed to chemical influences.

If the distribution for $T = 10$ is plotted in terms of molecules, it will be seen that, although the number-average chain length is 10, the maximum is still at $n = 2$. Most statistical models result in distributions in which the mode moves away from the origin quickly as the mean is increased.

It will be noted that the observed values for $T = 20$ and $T = 10$ in Table II are practically constant for $n = 2$ or greater. If this holds for the hypoly fraction, it indicates a very flat and long distribution above $n = 7$ which accentuates the difficulty just mentioned.

In Fig. 4 the agreement between distributions derived from the flexible chain model and the results of both the acid – sodium phosphate glasses and the strong phosphoric acids has been indicated in the case of pyro-, tri-, and hypoly-phosphate. Clearly the distributions in the sodium glass system require a modified theory such as that provided by the rigid-rod model.

CONCLUSIONS

Change of Cation

From the discussion of the experimental results in the first part of this paper, it will be evident that a distribution theory which fits the strong acids will give a reasonable fit for glass compositions in the Na_2O–P_2O_5–H_2O diagram, Fig. 2, as far as the center line where Na/H atomic ratio = 1. At higher ratios the effect of the smooth reduction of both orthophosphate and hypoly will have to be taken into account. Also, it has been shown that a shift of cation to K or Li makes a significant but small change in the nature of the distributions.

The postulation of statistical models, however, has served a useful purpose. While not always fitting the data within the experimental error, the fit has been good enough to support the general thesis that some sort of reorganization governed largely by chance encounters is taking place in a molten phosphate glass, that the equilibrium can be frozen in by quick quenching, and that it governs the distributions observed by means of filter paper chromatography as well as by the physical methods used by Van Wazer.

Statistical Models

More than one statistical model plus certain stoichiometrical conditions derived from experiment are necessary in general to give a good fit to the observed molecular weight distributions. However, the most general conclusion is that, despite the differences which have been pointed out, the distributions of molecular weight are much the same over a considerable range of cations.

The relations of the constitution of the phosphate glasses to that of the silicate glasses will be better understood when more work has been done on the silicate glasses having a higher M/Si atomic ratio and on the phosphate glasses with a lower M/P ratio.

More work on the physical properties of the phosphate glasses whose constitution has been established appears to be a logical development.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Anne Mueller for her careful technical assistance and also to the Research Corporation, New York, for their support.

THE PREPARATION OF D-RIBOSE-1-C^{14}, D-ARABINOSE-1-C^{14}, AND D-2-DEOXYRIBOSE-1-C^{14} [1]

D. H. MURRAY AND G. C. BUTLER

ABSTRACT

D-Ribose-1-C^{14} and D-arabinose-1-C^{14} have been synthesized by a modified Sowden–Fischer procedure in which the mixed sodium nitropentitols resulting from the condensation of erythrose and $C^{14}H_3NO_2$ have been submitted to a Nef reaction. The epimeric labelled pentoses were isolated by cellulose column chromatography in an over-all radiochemical yield of 19%.

Mixed nitropentitols-1-C^{14} have been acetylated, partially deacetylated with sodium bicarbonate in a non-polar solvent, and hydrogenated to yield triacetoxy-1-nitropentane-1-C^{14}. The mixture of this material and the accompanying undeacetylated nitropentitols gave rise, via a Nef reaction, to D-2-deoxyribose-1-C^{14} (6.3%), D-ribose-1-C^{14} (3.1%), and D-arabinose-1-C^{14} (2.9%).

INTRODUCTION

The Fischer cyanhydrin (1–4) and the Sowden–Fischer (5, 6, 7) methods of lengthening an aldose chain have both been employed in the preparation of labelled aldoses. The cyanhydrin procedure has generally afforded better radiochemical yields of the desired aldoses but is somewhat tedious. Most of the procedures reported to date employing either method have involved separation of epimeric compounds at an early stage, thus necessitating twice the manipulation of labelled compounds. It is more convenient to carry isomeric materials through one series of reactions and to separate them at a terminal stage. Chromatography on cellulose columns (8) constitutes a convenient method for achieving such separation on a preparative scale.

Rappoport and Hassid (6) have employed a Sowden–Fischer procedure and cellulose column chromatography in preparing L-arabinose-1-C^{14}. Although the yield of labelled pentose reported was only 3% based on the starting C^{14}-nitromethane, the simplicity of the method was attractive. The Sowden–Fischer method has also been adapted to the preparation of deoxyaldoses, and it thus appeared possible that it might be employed for the preparation of the two sugars of nucleic acids, D-ribose and D-2-deoxyribose in Cl-labelled form. Figure 1 shows the routes followed.

D-*Ribose-1*-C^{14} *and* D-*Arabinose-1*-C^{14}

D-Erythrose was condensed with an equimolecular amount of C^{14}-nitromethane in sodium methoxide solution. The mixed sodium nitropentitols formed were submitted to a Nef reaction according to the reaction conditions employed by Mahler (5), with two modifications. First, because of the ready decomposition of sodium nitroalditols in aqueous solutions, the alkaline solution of mixed sodium nitropentitols was added to concentrated acid from a jacketed funnel maintained at 0°. Second, it was to be expected that toward the end of the addition the dilution which had occurred would reduce the concentration of acid to a point where the Nef reaction would not take place. To avoid this possibility, the sodium nitropentitols were dissolved in a minimal volume of ice water and added to a larger amount of concentrated acid than that reported by Sowden (9). The pentoses formed were separated using a cellulose column and aqueous acetone as eluting solvent. The yield of pentose-1-C^{14} based on C^{14}-nitromethane was 19%.

[1]*Manuscript received June 26, 1959.*
Contribution from the Department of Biochemistry, University of Toronto, Toronto, Ontario.

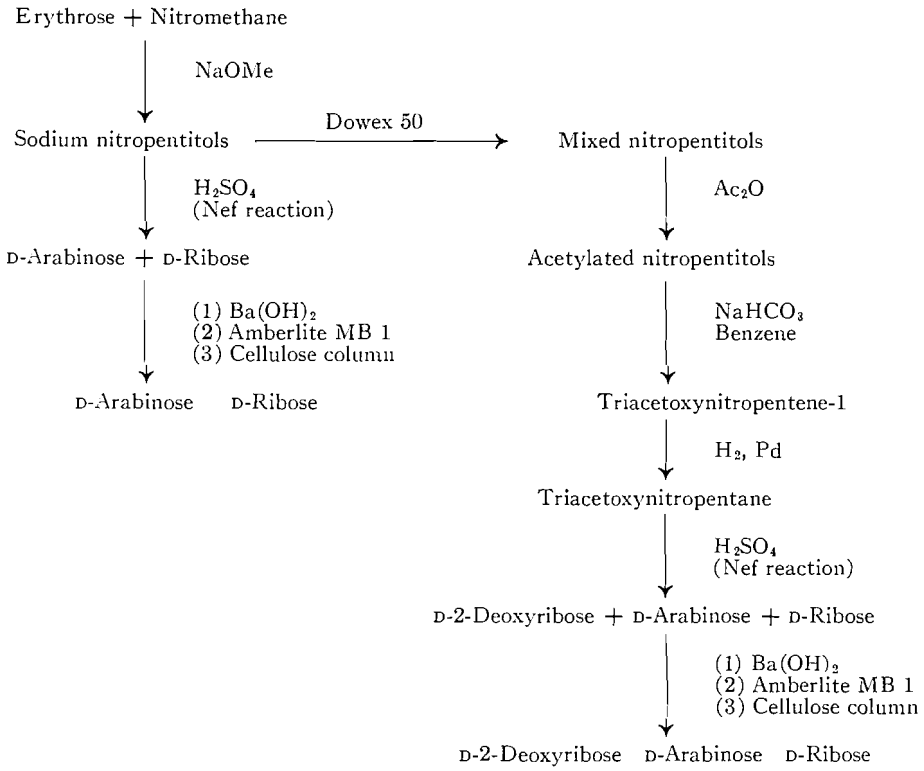

FIG. 1. Scheme of synthesis for labelled pentoses.

A fast-running radioactive fraction containing a small amount of tetrose-1-C^{14} (10) was eluted from the column ahead of the ribose-1-C^{14}. When excess nitromethane was employed in preliminary non-radioactive experiments, a similar small fraction was regularly observed but yields of pentose up to 65% were obtained. With the smaller amounts of C^{14}-nitromethane a reduction in the yield of pentose-1-C^{14} occurred. The reasons for this are discussed in a separate communication (10).

D-*2-Deoxyribose-1*-C^{14}

There seemed to be three potentially feasible routes to deoxyribose-1-C^{14}. Application of a Fischer glycal method (11) starting from D-arabinose-1-C^{14} (1), or a Ruff degradation of the metasaccharinic acids (12) resulting from the alkaline isomerization of D-glucose-2-C^{14} (13) would produce the desired labelled sugar. Both these routes, however, could be anticipated to give low radiochemical yields. On first consideration a Sowden–Fischer procedure starting from erythrose and nitromethane seemed equally unpromising. Although Sowden has prepared D-2-deoxyribose in over-all yield of 21% based on the starting erythrose (14), other workers have obtained less than 1% yields of the deoxy sugar by this route (15). On further examination it appeared that Sowden (9) adequately explained the reasons for this low yield and we therefore undertook the preparation of D-2-deoxyribose-1-C^{14} by his method.

In most cases the erythrose used for the preparation of ribose and arabinose was obtained from 4,6-ethylidene glucose. As discussed elsewhere (10), use of this material in the preparation of the deoxyribose may result in a small but significant contamination

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

of the desired deoxy sugar. By employing benzylidene sorbitol as the source of erythrose this contamination could be avoided.

Erythrose was condensed with an equimolecular amount of C^{14}-nitromethane to yield a mixture of epimeric C-nitropentitols which, after acetylation and subsequent treatment with bicarbonate in a non-polar solvent, gave rise to an acetylated nitroölefin. Partial hydrogenation of this material afforded the 1-nitro-1,2-deoxy-3,4,5-triacetoxypentane.

The intermediate compounds in the above procedure are crystallizable with difficulty (15). However, Sowden has shown (7) that acceptable yields of deoxyribose are attainable without separation of intermediates. Moreover, in the interest of best utilization of carbon-14, advantage was taken of the fact that nitropentitols which were not acetylated, as well as acetylated nitropentitols which were not deacetylated (and would not therefore be available for hydrogenation), would both give rise, via the Nef reaction, to ribose-1-C^{14} and arabinose-1-C^{14}, and the whole preparative procedure could be made to yield these two pentoses in addition to deoxyribose-1-C^{14}.

The total product of the hydrogenation step, in alkaline solution, was submitted to a Nef reaction. After deionization the mixture of pentoses was separated on a cellulose column using aqueous acetone. A radiochemical yield of 12% of pentoses based on nitromethane was obtained.

As in the synthesis of ribose-1-C^{14} and arabinose-1-C^{14} a fast-running fraction carrying significant radioactivity was observed. This was concluded to be 2-deoxytetrose-1-C^{14}, for reasons given in a separate communication (10). As for the ribose–arabinose case, the reactions leading to this by-product, when equimolecular amounts of erythrose and C^{14}-nitromethane were used in the initial condensation reaction, led to a considerable reduction in the yield of deoxyribose-1-C^{14}. In pilot experiments employing excess non-radioactive nitromethane, yields of about 30% of deoxyribose based on the starting erythrose were obtained.

EXPERIMENTAL

D-*Ribose and* D-*Arabinose-1*-C^{14}

D-Erythrose was prepared from 4,6-ethylidene-D-glucose (m.p. 181–183°) by the procedure described for L-erythrose (6). C^{14}-Nitromethane was obtained from Merck and Company, Montreal, and had a specific activity of about 4 mc per g.

Sodium Nitropentitols-1-C^{14}

A sodium methoxide solution (2.4 g of sodium in 50 ml of absolute methanol) was added dropwise, with stirring, to a solution of erythrose (8.3 g) and C^{14}-nitromethane (3.7 ml) in 50 ml of methanol. After 2 hours the reaction mixture was cooled to 0–10° in an ice bath. The cooled mixture was stirred for a further 12 hours, 100 ml of cold anhydrous ether added, and the precipitated sodium nitropentitols collected by filtration. They were washed on the filter with cold methanol – ether (1:1) and ether – petroleum ether (1:1). While still moist the sodium salts were transferred rapidly to a vacuum desiccator containing P_2O_5, which was then evacuated until all solvent had been removed. The yield of dry sodium nitropentitols was 8.28 g (60% based on nitromethane).

Nef Reaction

A solution of the sodium nitropentitols (2.5 g in 15 ml of ice water) was added dropwise, over a 2-hour period, from a cold (0–5°) jacketed dropping funnel to a cold (−20 to −18°) stirred solution of 6 ml of concentrated sulphuric acid and 7.5 ml of water. After the addition was complete, the stirred reaction mixture was allowed to approach 0° slowly over a period of 1 hour.

Deionization and Separation of Pentoses

The resulting solution was diluted by slow addition of 200 ml of ice water and adjusted to pH 4.0 with cold barium hydroxide solution. A few drops of glacial acetic acid were added; the barium sulphate was removed by centrifugation and washed eight times with water. The combined supernatant and washings were concentrated to a small volume at a temperature below 35°, charcoaled, and passed, under suction, through a column of 40 g of Amberlite-MB 1. The column was washed with 200 ml of water, and 0.1 *M* sodium sulphate was passed through the resin until the first faint positive test of sulphate was obtained in the eluate. A few milligrams of resin were added to the eluate, stirred, and removed by filtration. After concentration at reduced pressure (below 35° C), powdered cellulose was added and concentration continued to dryness. To remove the last traces of water, alcohol, and subsequently acetone, were added and removed under reduced pressure. The dry cellulose powder (on which the C^{14}-pentoses were absorbed) was washed with dry acetone on to a cellulose column (5 cm by 50 cm) through which absolute acetone had been passed for 4–6 hours. A pad of filter paper was placed above the cellulose and pressed down firmly. The column was developed with 98% acetone until the fast-running fractions were eluted. Ribose was eluted with 93% acetone and arabinose with 80% acetone. A 40-minute collection time and a flow rate of about 1 ml per minute were used throughout. Pentose was located in the eluate with orcinol reagent (16).

The ribose-containing fractions were combined and concentrated to a syrup at reduced pressure. Alcohol was added and distilled at reduced pressure, twice, to remove the last traces of acetone. The syrup was dissolved in water, charcoaled, and passed through a bacterial filter. The arabinose-containing fractions were combined and treated similarly. No attempt was made to crystallize the pentoses since it was convenient to use aqueous solutions directly in biological experiments. Aliquots of the solutions were taken for determination of pentose and of radioactivity. The pentoses were identified by orcinol reactions and paper strip chromatography with the appropriate authentic samples as markers.

The yields of labelled pentose were: D-ribose-1-C^{14}, 300 mg, 17,400 counts/min mg; D-arabinose-1-C^{14}, 297 mg, 18,100 counts/min mg. The total yield of C^{14}-pentose was 19.1% based on nitromethane.

D-*2-Deoxyribose-1*-C^{14}

D-*Erythrose*

Twenty grams of β-benzyl-4,6-benzylidene-D-glucoside (17, 18) in methanol solution was hydrogenated with 3 g of Raney nickel catalyst, at 3 atmospheres pressure, for 72 hours. After removal of the catalyst, excess of benzene was added to the methanol filtrate. Concentration under reduced pressure removed methanol. Further benzene was added and concentration continued until precipitation occurred. The crude benzylidene sorbitol was collected by filtration, stirred with 50 ml of ethylacetate–chloroform (1:1), refiltered, washed, and dried. One crystallization from ethanol yielded pure benzylidene sorbitol (m.p. 132–134°). From this material D-erythrose was obtained in 85% yield by periodate oxidation as described by Sowden (14).

Acetylated Nitropentitols-1-C^{14}

A solution of 0.85 g of sodium in 40 ml of absolute methanol was added dropwise over a half-hour period to a stirred, cool (10° C) solution of erythrose (3.04 g) and C^{14}-nitromethane (0.5 ml diluted to 1.3 ml with non-radioactive nitromethane) dissolved in 40 ml of methanol. The cool reaction mixture was stirred for a further 15 hours, stored

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

in the cold room overnight, and the sodium nitropentitols collected as described in the procedure for ribose-1-C^{14} and arabinose-1-C^{14}. The sodium nitropentitols were dissolved in 200 ml of ice water and the sodium removed by passage through a cooled column of 40 ml of Dowex 50 (hydrogen form). The eluate and further water washings of the column were charcoaled, filtered, and concentrated to dryness at a temperature below 35°. Alcohol was added to the resulting partly crystalline mass and distilled under reduced pressure. This procedure was repeated three times to remove the last traces of water. After storage over P_2O_5 *in vacuo* the product weighed 2.36 g (51% based on nitromethane). Acetic anhydride (30 ml) and one small drop of concentrated sulphuric acid were added and stirred for 6 hours until the syrupy nitropentitols had dissolved. The reaction mixture was heated at 95° with stirring for 30 minutes, cooled, and 100 ml of ice water added to hydrolyze the excess acetic anhydride. After being stirred for 20 minutes the cold mixture was extracted with three 75-ml portions of chloroform. The combined chloroform extracts were washed twice with ice water, dried over calcium chloride, charcoaled, filtered, and concentrated to a syrup. Benzene was added and removed under reduced pressure. This procedure was repeated eight times to remove the last traces of acetic acid. The product weighed 3.83 g corresponding to an 84% yield of the acetylated nitropentitols.

Deacetylation and Hydrogenation

The acetylated compound, 60 ml of dry benzene and 4.5 g of sodium bicarbonate were refluxed with rapid stirring for $2\frac{1}{2}$ hours, cooled, charcoaled, filtered, and concentrated to a syrup. Alcohol was added and removed under reduced pressure. The syrup was finally completely freed of solvent under high vacuum to yield 2.83 g of presumed triacetoxynitropentene-1. The syrup was dissolved in 50 ml of ethanol, 300 mg of palladium black was added, and hydrogenation carried out at room temperature and atmospheric pressure. After 21 minutes the rate of uptake of hydrogen had become slow and the hydrogenation was terminated. The catalyst was removed by filtration and the ethanol filtrate concentrated to a syrup.

Nef Reaction

The syrup was dissolved in 8 ml of ethanol, cooled to 10°, and 24 ml of 2 *N* NaOH also at 10° was added dropwise with rapid stirring over a 20-minute period. The resulting alkaline solution was employed in a Nef reaction under the same conditions as those for the preparation of ribose-1-C^{14} and arabinose-1-C^{14}. (Eight milliliters of concentrated sulphuric acid and 10 ml of water were used.)

Deionization and Separation of Pentoses

The resulting solution was deionized and the mixture of pentoses transferred to a cellulose column by the same procedure given for the ribose–arabinose case. The column was developed with 99% acetone for 8 hours. (Forty-minute collection time and elution rate of 1 ml per minute.) After 8 hours the eluting solvent was changed to 97% acetone until the deoxyribose-1-C^{14} was eluted; ribose and arabinose were eluted as described previously. The three pentoses were obtained as syrups and, as previously described, dissolved in water for biological experiments. Aliquots were taken for determination of pentose and of radioactivity. The three pentoses were identified by diphenylamine (19) (for the deoxyribose-1-C^{14}) and orcinol (for the ribose-1-C^{14} and arabinose-1-C^{14}) reactions and by paper strip chromatography with the appropriate authentic samples as markers. The yields of labelled pentoses (based on nitromethane) were: D-2-deoxyribose-1-C^{14}, 202 mg (6.3%), 6800 counts/min mg; D-ribose-1-C^{14}, 112 mg (3.1%), 7200 counts/min mg; D-arabinose-1-C^{14}, 106 mg (2.9%), 7100 counts/min mg.

ACKNOWLEDGMENT

The authors are grateful to the National Research Council of Canada for funds which defrayed part of the cost of this study.

NOTES

A RAPID DETERMINATION OF SOME SURFACE PROPERTIES OF SOLIDS

H. P. Schreiber and M. H. Waldman

INTRODUCTION

Among the important properties of a solid used as an adsorbent, catalytic agent, filler, etc., are its specific surface area ($\bar{A}$) and its maximum adsorption capacity ($\bar{V}_{max}$) for a given adsorbate. Standard techniques are available for accurate determinations of these quantities; for example, surface areas can be measured by the B.E.T. method (1) or by electron microscopy (2), adsorption capacities from suitable adsorption isotherms. When routine determinations of such surface properties are required and demands on accuracy are not too stringent, these techniques become overly time consuming. In such cases a rapid method of determination is wanted. To this end, a simplification of the B.E.T. procedure has recently been reported (3). This note is believed to describe a more widely applicable and rapid method of estimating the desired surface properties.

BASIS OF METHOD

The present method relies on a correlation between the surface area and adsorption capacity of a solid on the one hand, and the heat of adsorption in the given system, on the other. For the coverage of any fraction θ of surface per gram of adsorbent,

$$(\bar{A}) = k(\Delta\bar{H}_\theta) \qquad [1]$$

and

$$(\bar{V}_{max}) = k'(\Delta\bar{H}_\theta) \qquad [2]$$

where $(\Delta\bar{H}_\theta)$ denotes the integral heat of adsorption per gram of adsorbent, and k and k' are unspecified proportionality parameters. Thus, provided k and k' are known, an experimental evaluation of $(\Delta\bar{H}_\theta)$ would give an estimate of the required solid characteristic in any specified system.

In this method, a quantity proportional to the heat of adsorption is measured rapidly using apparatus characteristic of differential thermal analysis (d.t.a.). Since results are always comparative, the proportionality between the true and the measured reaction quantity need not be known explicitly.

EXPERIMENTAL

The quantity proportional to the heat of adsorption is measured in apparatus, the essentials of which are shown in Fig. 1. The d.t.a. cell is connected through a manifold system to the usual high vacuum components. Cup A of the cell holds the experimental sample; cup B is the reference arm, containing sintered glass of small specific surface. Chromel–alumel thermocouples (T_1 and T_2) are immersed into the cups, and connected to a Leeds–Northrup Type 9835B d-c. amplifier, the latter to a single pen recording potentiometer. The reservoir R contains the adsorbate, the vapor pressure of which can be read on the constant-volume mercury manometer. Provision was made to append additional d.t.a. cells as indicated. About one gram of adsorbent is weighed into the

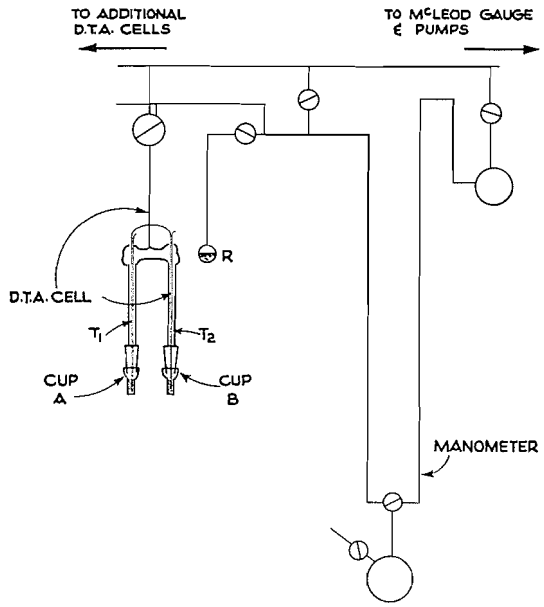

FIG. 1. Sample cell and vacuum system for reaction area determination.

reaction cup. The adsorbent is evacuated for about one hour at room temperature, or sufficiently long to establish a residual pressure of about 10^{-5} mm over the sample. The sample cell is then thermostated at the desired temperature, the dead space volume is exposed to the adsorbate, and the vapor finally admitted to the evacuated sample. The course of the interaction is recorded until no temperature gradient exists between sample and reference arms of the cell. In general, this involves about 10 minutes' operating time. The area under the time–temperature curve is found using a planimeter. This area, divided by the mass of adsorbent involved, is taken to be proportional to the heat of adsorption. Hereafter, the quantity is referred to as the "reaction area".

RESULTS AND DISCUSSION

The procedure for rapid surface area and adsorption capacity measurements was established using commercially available carbon blacks as adsorbents. Water, *n*-butane, and ethyl chloride were chosen as convenient adsorbates. Nine carbon blacks were involved in the water adsorption work, carried out at 25.5° C. Three types of carbon black were used in conjunction with the butane and ethyl chloride, these experiments being done at 0° C. In order to evaluate the parameters k and k', conventional values of $\bar{A}$ and $\bar{V}_{max}$ were needed (equations [1], [2]). Surface areas of the carbon blacks were obtained by the usual nitrogen adsorption technique in a B.E.T. apparatus (1). Maximum adsorption capacities were found only for butane and ethyl chloride adsorption, from the 0° C isotherms.

A description of the carbon black samples, their nitrogen adsorption and various "reaction areas", and the pertinent maximum adsorption capacities, are recorded in Table I. Each "reaction area" is the mean of two separate results. These did not deviate more than 8% about the mean. A correlation seems to exist between the "reaction areas" and the surface areas and maximum adsorption capacities. This is more readily seen by evaluating the proportionality parameters k and k'. In so doing, the pertinent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

"reaction area" was substituted for the heat of adsorption. The values are given in Table II.

TABLE I

Surface areas, adsorption capacities, and reaction areas for adsorption of water, butane, and ethyl chloride on carbon blacks

Sample	Description	N_2 surface areas (m^2/g)	Reaction areas (cm^2/g)			$\bar{V}_{max}$ (cc/g)	
			H_2O (25.5° C)	n-C_4H_{10} (0° C)	EtCl (0° C)	n-C_4H_{10} (0° C)	EtCl (0° C)
1	Fine porous channel	327	88.0	54.2	50.6	470	300
2	Medium porous channel	139	42.0	—	—	—	—
3	Coarse porous channel	106	31.0	—	—	—	—
4	Coarse porous channel	112	35.5	—	—	—	—
5	Medium porous channel	125	36.5	—	—	—	—
6	Medium porous channel	140	38.0	—	—	—	—
7	Fine non-porous furnace	131	15.0	23.2	21.3	205	110
8	Medium non-porous furnace	76	8.8	—	—	—	—
9	Medium non-porous furnace	80	—	13.5	13.0	115	50
10	Coarse non-porous furnace	43	5.5	—	—	—	—

TABLE II

Proportionality parameters for adsorption of water, butane, and ethyl chloride on carbon blacks

Sample	$k \times 10^{-4}$			k' (cm)	
	H_2O	n-C_4H_{10}	EtCl	n-C_4H_{10}	EtCl
1	3.80	6.10	6.50	8.70	5.90
2	3.30	—	—	—	—
3	3.40	—	—	—	—
4	3.20	—	—	—	—
5	3.40	—	—	—	—
6	3.70	—	—	—	—
7	8.70	5.60	6.10	8.80	5.20
8	8.50	—	—	—	—
9	—	5.80	6.10	8.50	4.00
10	7.80	—	—	—	—

The parameter k appears to be constant for each interacting pair. The "reaction area" can therefore serve as a measure of the apparent surface area of the adsorbent in each system. Similarly, the value k' appears to be a constant characteristic of the interacting system, although there is a relatively large spread in the case of ethyl chloride adsorption. Thus, in each specified system an estimate of $\bar{V}_{max}$ is possible from the reaction datum. Provided, therefore, a given adsorbent–adsorbate system has been calibrated by means of a standard determination of surface area or maximum adsorption capacity, the described technique can be used to estimate these characteristics absolutely with an accuracy of some 15%. The total determination time of under two hours constitutes a very pronounced time saving over standard techniques.

A further use of this technique should be in routine control of the surface properties of a given solid. The precision of the "reaction area" determination is about 10–15%, so that changes in the quantity beyond this limit in a selected adsorption process indicate significant changes in the surface characteristics of the adsorbent under consideration. If absolute values are not required, there is no need for prior calibration of the system. If several d.t.a. cells are used, up to 30 or 40 such "surface characterizations" can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

performed per day by a single operator. Although the method had been utilized only in conjunction with carbon blacks, it should be broadly applicable to any adsorbent.

Some further aspects of the data merit brief discussion. Table II shows that k changes only slightly from the butane to the ethyl chloride system. This is reasonable; the apparent surface area is not likely to vary greatly when the probe molecules are approximately equal in size, as is the case here. In the case of water adsorption, the k value is sensitive to differences between channel and furnace blacks, but seems constant in each group. The absence of pore structure in the furnace blacks doubtless lowers the effective number of sites for water adsorption, thus raising the value of k. The water molecule is, presumably, sufficiently small to gain entry into some of the pores of the channel blacks, resulting in a relatively large heat of adsorption, hence a low k value. The apparent constancy of k for ethyl chloride and butane adsorption suggests that little penetration of the pore structure of the channel blacks occurs with these adsorbates.

The proportionality parameter k' is considerably greater for butane than for ethyl chloride. Since the "reaction areas" in these cases are approximately equal (see Table I), a given surface region of the black seems to accommodate greater amounts of butane than ethyl chloride prior to bulk liquefaction. In view of the polar nature of the ethyl chloride molecule, this result seems reasonable.

STEROIDS. CXV. THE SYNTHESIS OF HALOGENATED STEROID HORMONES, 4-CHLORO-19-NOR HORMONE ANALOGS*

O. Mancera and H. J. Ringold

In an earlier paper (1) we noted that halogenation of progesterone at C-4 virtually eliminates progestational activity. It was thus of considerable interest to convert the extremely potent progestational agents (2), 19-nor: 17α-methyl- (3), 17α-ethynyl- (3), 17α-vinyl- (4), and 17α-ethyltestosterone (5) as well as 19-norprogesterone (6) into their 4-chloro analogs for evaluation of gestational activity. This transformation was readily accomplished by converting the parent steroids I into their 4,5-oxides (II) by reaction with alkaline hydrogen peroxide followed by hydrochloric acid treatment to yield directly the 4-chloro-Δ^4-3-ketones (III). This sequence is one first described in the cholesterol series by Shaw and Stevenson (7) and later described in the hormones series by ourselves (1) and by Camerino *et al.* (8). An alternate synthesis involving direct halogenation has been described by Petrow and co-workers (9) while a later paper by a Schering group (10) describes the synthesis of 4-halo hormone analogs by the addition of hypohalous acid to Δ^4-3-ketones.

In the case at hand 17α-methyl-19-nortestosterone (I*a*), 17α-ethynyl-19-nortestosterone (I*b*), and 19-norprogesterone (I*e*) were each reacted for periods of 35 minutes to 1 hour

STEROIDS. CXV. THE SYNTHESIS OF HALOGENATED STEROID HORMONES, 4-CHLORO-19-NOR HORMONE ANALOGS*

O. Mancera and H. J. Ringold

In an earlier paper (1) we noted that halogenation of progesterone at C-4 virtually eliminates progestational activity. It was thus of considerable interest to convert the extremely potent progestational agents (2), 19-nor: 17α-methyl- (3), 17α-ethynyl- (3), 17α-vinyl- (4), and 17α-ethyltestosterone (5) as well as 19-norprogesterone (6) into their 4-chloro analogs for evaluation of gestational activity. This transformation was readily accomplished by converting the parent steroids I into their 4,5-oxides (II) by reaction with alkaline hydrogen peroxide followed by hydrochloric acid treatment to yield directly the 4-chloro-Δ^4-3-ketones (III). This sequence is one first described in the cholesterol series by Shaw and Stevenson (7) and later described in the hormones series by ourselves (1) and by Camerino *et al.* (8). An alternate synthesis involving direct halogenation has been described by Petrow and co-workers (9) while a later paper by a Schering group (10) describes the synthesis of 4-halo hormone analogs by the addition of hypohalous acid to Δ^4-3-ketones.

In the case at hand 17α-methyl-19-nortestosterone (I*a*), 17α-ethynyl-19-nortestosterone (I*b*), and 19-norprogesterone (I*e*) were each reacted for periods of 35 minutes to 1 hour

Paper CXIV, Kincl, F. A. and Garcia, M. Ber. **92, 595 (1959).*

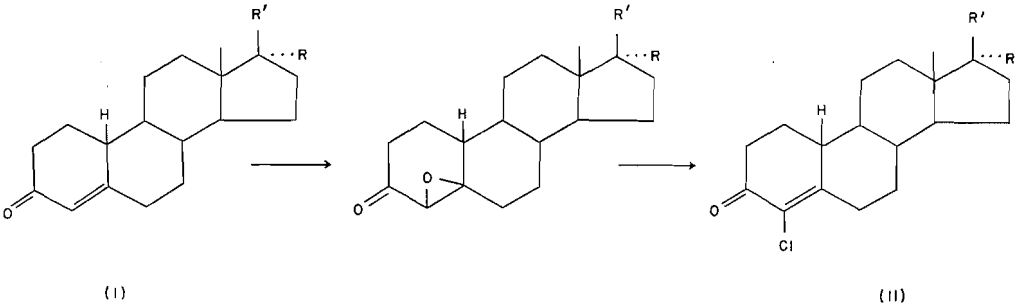
with alkaline hydrogen peroxide in cold methanol solution to give a mixture (1) of the corresponding 4β,5β- and 4α,5α-epoxides. Without purification the epoxide mixtures were treated for 1 hour with concentrated hydrochloric acid in acetone solution (1), thus giving a high yield of the 4-chloro-Δ^4-3-keto compounds II*a*, II*b*, and II*e*.



(I) (II)

(*a*) R = CH_3; R′ = OH
(*b*) R = C≡CH; R′ = OH
(*c*) R = $CH{=}CH_2$; R′ = OH
(*d*) R = CH_2CH_3; R′ = OH
(*e*) R = H; R′ = $COCH_3$

Hydrogenation of 4-chloro-17α-ethynyltestosterone (II*b*) in pyridine (11) over a palladium – calcium carbonate catalyst and interrupted at 1.1 equivalents hydrogen uptake gave 4-chloro-17α-vinyltestosterone (II*c*) in 70% yield, while hydrogenation of II*b* in dioxane (12) with palladium – barium sulphate, interrupted at 2.1 moles uptake, gave the 17α-ethyl compound (II*d*) in 60% yield. When tested* in the Clauberg assay by either the oral or subcutaneous route, compounds II exhibited only a relatively low order of progestational activity.

EXPERIMENTAL

Melting points are uncorrected. Rotations were determined in chloroform and ultraviolet absorption spectra in 96% ethanol.

4-Chloro-17α-methyl-19-nortestosterone (II*a*).—A solution of 17α-methyl-19-nortestosterone (I*a*) (10 g) in methanol (250 ml) was cooled to 0° and then treated dropwise and successively with 35% hydrogen peroxide (40 ml) and 10% sodium hydroxide (16 ml). After it had been left to stand for 35 minutes at 0–5° the solution was poured into water and extracted with ethyl acetate. Evaporation of the washed extract gave 11 g of crude epoxide as a semicrystalline product exhibiting no selective absorption in the ultraviolet. The epoxide without further purification was dissolved in acetone (100 ml), and concentrated hydrochloric acid (10 ml) was added. The solution, after being kept for 1 hour at room temperature, was poured into salt water and the product extracted with methylene chloride. The extract was washed successively with water, sodium carbonate solution, water, and then evaporated. The residue in 200 ml of benzene–hexane (1:1) was adsorbed on 300 g of neutral alumina, whereupon acetone–hexane crystallization of the benzene eluate gave 6.32 g of 4-chloro-17α-methyl-19-nortestosterone (II*a*), m.p. 145–148°. The analytical specimen from acetone–ether exhibited m.p. 148–151°, λ_{max} 255 mμ, log ϵ 4.12, $[\alpha]_D$ +42°.† Anal. Calc. for $C_{19}H_{27}ClO_2$: C, 70.67; H, 8.43; Cl, 10.98. Found: C, 70.68; H, 8.39; Cl, 10.61.

**Bio-assays by T. Endocrine Laboratories, Madison, Wisc.*

†After completion of our work this compound was reported by Camerino et al. (ref. 8b) with m.p. 151–152°, λ_{max} 255 mμ, log ϵ 4.14.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

4-Chloro-17α-ethynyl-19-nortestosterone (II*b*).—17α-Ethynyl-19-nortestosterone (I*b*) (10 g) was epoxidized and then treated with acid as described above for the 17-methyl analog. The residue was chromatographed on neutral alumina and the benzene and benzene–ether 4:1 fractions crystallized from acetone–hexane to yield 5.54 g of II*b*, m.p. 186–188°, λ_{max} 225 mμ, log ε 4.11, $[\alpha]_D$ +7°. Anal. Calc. for $C_{20}H_{25}ClO_2$: C, 72.16; H, 7.57; Cl, 10.65. Found: C, 72.49; H, 7.46; Cl, 10.69.

4-Chloro-19-norprogesterone (II*e*).—19-Norprogesterone (0.8 g) in methanol (100 ml) at 0° was treated with 3.5 ml of 35% hydrogen peroxide and 1.4 ml of 10% sodium hydroxide and stirred for 1 hour at 0–5°. A small amount of insoluble material was removed and the filtrate poured into salt water. The crude epoxide mixture (0.83 g) was isolated by ethyl acetate extraction and then dissolved in 40 ml of acetone, and 1 ml of concentrated hydrochloric acid was added. After the solution had stood for 1 hour at room temperature, water, salt, and ice were added, the precipitate was collected, washed, dried, and recrystallized from acetone–hexane, yielding 0.61 g of II*e*, m.p. 169–172°. Recrystallization from the same solvents afforded the analytical sample, m.p. 174–177°, λ_{max} 256 mμ, log ε 4.11, $[\alpha]_D$ +127°. Anal. Calc. for $C_{20}H_{27}O_2Cl.\frac{1}{2}C_3H_6O$: C, 70.96; H, 8.31; Cl, 9.74%. Found: C, 71.01; H, 7.93; Cl, 9.68.

4-Chloro-17α-vinyl-19-nortestosterone (II*c*).—4-Chloro-17α-ethynyl-19-nortestosterone (5 g) in pyridine (100 ml) was hydrogenated at 25° and 580 mm over 2 g of pre-reduced 2% palladium – calcium carbonate catalyst. When hydrogen uptake reached 1.1 equivalents (2 to 3 hours in general) the reduction was interrupted, the catalyst removed, and the solvent concentrated *in vacuo*. The oily residue was taken up in ethyl acetate, the solution washed with dilute acid, carbonate solution, and then water. Evaporation and crystallization of the product from acetone–hexane gave 3.54 g of the vinyl compound (II*c*), m.p. 115–118°. Two recrystallizations from the same solvent pair produced the analytical specimen, m.p. 124–126°, λ_{max} 255 mμ, log ε 4.13, $[\alpha]_D$ +51°. Anal. Calc. for $C_{20}H_{27}ClO_2$: C, 71.69; H, 8.15; Cl, 10.59. Found: C, 71.42; H, 8.05; Cl, 10.71.

4-Chloro-17α-ethyl-19-nortestosterone (II*d*).—The reduction at 25° and 580 mm of 2 g of 4-chloro-17α-ethynyl-19-nortestosterone (II*b*) in 160 ml of dioxane over 0.8 g of pre-hydrogenated 10% palladium – barium sulphate catalyst was stopped after the uptake of 2.1 equivalents of hydrogen (ca. 3 hours). The catalyst was filtered and the solution concentrated to dryness, whereupon acetone–hexane crystallization of the reduced product gave 1.20 g of 17α-ethyl compound (II*d*), m.p. 122–125°. Repeated crystallization yielded the pure substance, m.p. 126–128° (mixture melting point depression with II*c*), λ_{max} 256 mμ, log ε 4.14, $[\alpha]_D$ +47°. Anal. Calc. for $C_{20}H_{29}O_2Cl$: C, 71.34; H, 8.68; O, 9.50. Found: C, 71.30; H, 8.69; O, 9.58.

THE STREAMING BIREFRINGENCE OF CELLULOSE MICELLES: A CONFIRMATION OF THE THEORY FOR RIGID RODS

D. F. MACLENNAN* AND S. G. MASON

INTRODUCTION

Theories of streaming birefringence have been reviewed by Edsall (1) and by Cerf and Scheraga (2). Peterlin and Stuart (3, 4) have developed a theory for the orientation of rigid ellipsoids of revolution which permits the calculation of particle lengths from streaming birefringence data. Donnet (5) has made a comparison of the lengths of tobacco mosaic virus particles measured directly from electron micrographs and those calculated from flow birefringence measurements using the theory of Peterlin and Stuart. Good agreement between the two methods was obtained.

This note deals with similar measurements on a cellulose sol.

EXPERIMENTAL

Apparatus

The streaming birefringence apparatus, used in this work, is the concentric cylinder type with rotating outer cylinder. A longitudinal section of the cylinders and optical system is shown in Fig. 1.

The outer cylinder, made of stainless steel, has an internal diameter of 3.40 cm and an inside length of 6.35 cm. Four interchangeable stainless steel inner cylinders, 6.30 cm long and having different diameters, make it possible to vary the annular gap from 1.5 mm to 0.2 mm and the velocity gradient up to 10^4 sec^{-1}.

The light source is a General Electric A-H4 100-watt mercury arc with a filter combination to isolate the 546-mμ mercury line.

Cellulose Sol

The sol was prepared (6) by boiling 10 g bleached sulphite wood pulp in 5 *N* sulphuric acid for 3.5 hours, and the residue, after it was washed, was dispersed in 2 l. of distilled water.

To narrow the distribution of particle sizes the sol was then centrifuged at 3500 *g* for 1 hour in a Spinco preparatory ultracentrifuge and the supernatant sol was used for the measurements.

Electron micrographs of the rod-like cellulose particles were made using palladium-shadowed specimens.

RESULTS AND DISCUSSION

The distribution of particle lengths from the electron micrographs is given in Table I. The experimental values of the extinction angle χ over a range of gradients G and using three different stators are plotted in Fig. 2.

The electron micrographs indicate that the cellulose particles range in length from 1500 Å to 6500 Å. From this information a theoretical extinction angle curve, character-

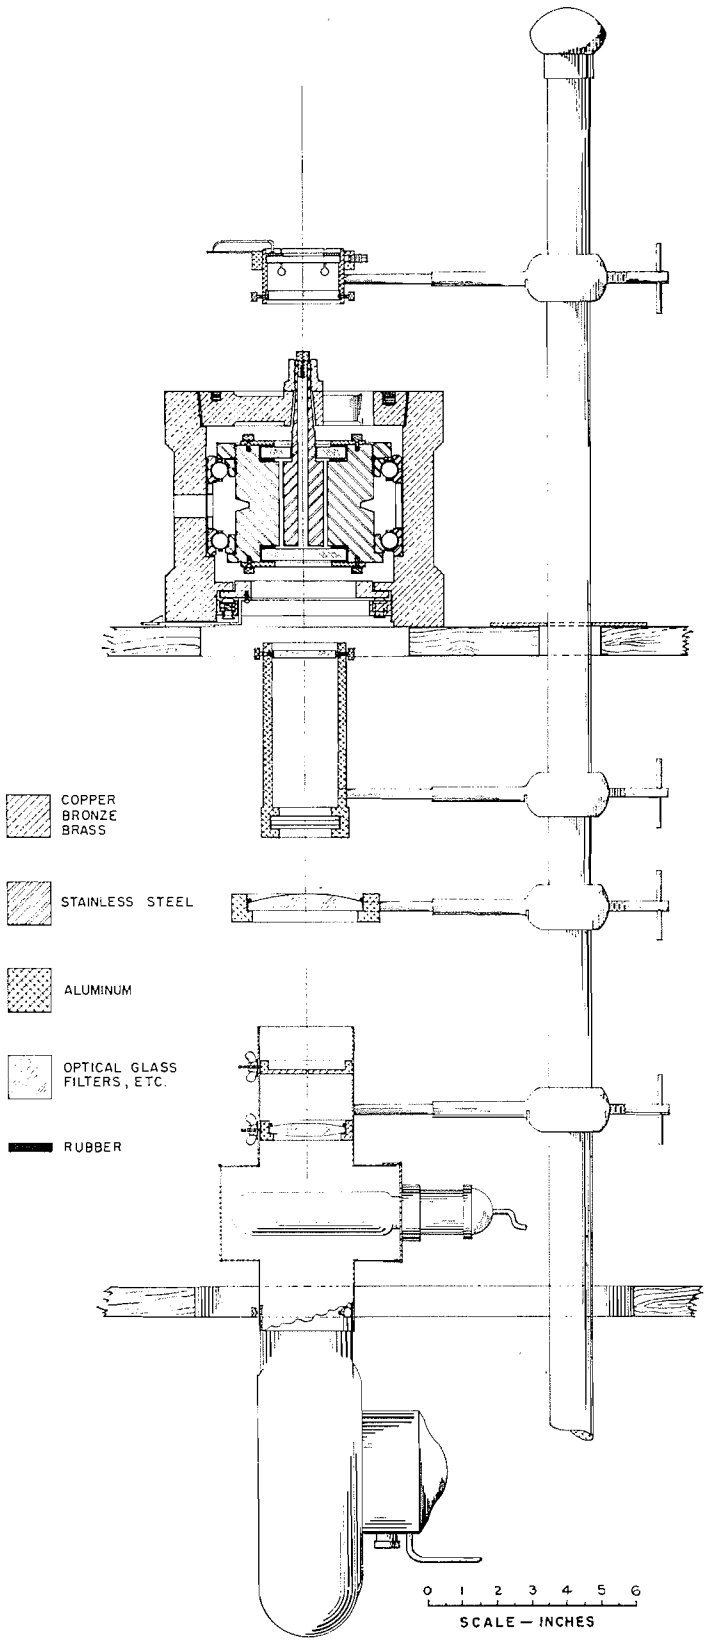

FIG. 1. Sectional view of the streaming birefringence apparatus.

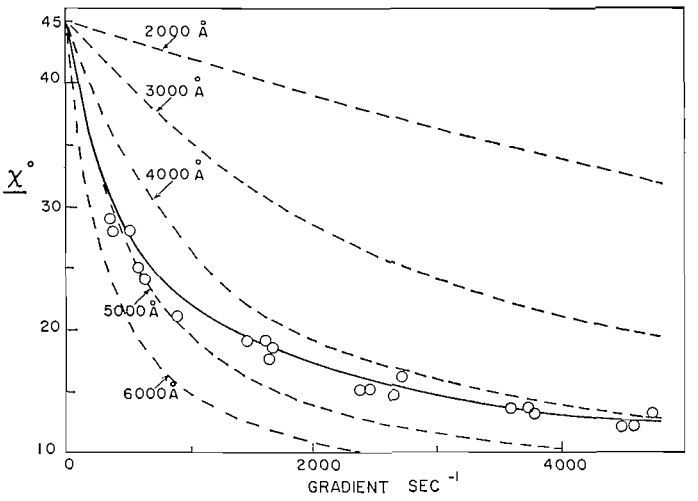

FIG. 2. Extinction angle at various gradients. The points represent experimental values with three different annular gaps in the apparatus. The solid line is calculated from the measured length distribution, and the broken lines are calculated for monodisperse particles of the lengths indicated.

TABLE I
Length distribution from electron micrographs

Range (Å)	Percentage of particles
1500–2500	12
2500–3500	21
3500–4500	27
4500–5500	22
5500–6500	18

istic of a solution of particles having this length distribution, has been calculated.

A rotary diffusion constant, θ, has been calculated for each length range using the Perrin formula (7)

$$[1] \qquad \theta = \frac{3kT}{16\pi\eta a^3}(-1+2\log_e 2p)$$

where k is the Boltzmann constant, T is the absolute temperature, η is the solvent viscosity, a is the length of the semimajor axis, and p is the axis ratio.

Since, as may be seen from eq. [1], θ is much more sensitive to a than to p, the use of an approximate value of p in these calculations is permissible. The latter was taken to be 16, the approximate value estimated from the electron micrographs.

From values of θ and p, theoretical values of χ can be obtained for any velocity gradient from the tables of Scheraga, Edsall, and Gadd (8).

Values for a polydisperse sol, made up of particles of the measured lengths in the proper proportions, have been calculated using the theory of Sadron (9). According to this theory the extinction angle of a polydisperse system is given by

$$[2] \qquad \tan 2\chi = \left(\sum_i \delta_i \sin 2\psi_i\right) \Big/ \left(\sum_i \delta_i \cos 2\psi_i\right)$$

where ψ_i is the extinction angle, and δ_i the birefringence which would be produced by the ith component alone in a given solvent at a given velocity gradient.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

According to Peterlin and Stuart (4) the birefringence Δn of a polydisperse system is given by

$$[3] \qquad \Delta n = \frac{2\pi c}{n_0}(g_1 - g_2) f(\alpha, p)$$

where c is the concentration of the particles expressed as volume fraction, n_0 is the index of refraction of the isotropic solution at rest, $(g_1 - g_2)$ is an optical factor, and $f(\alpha, p)$ is an orientation factor. If $(g_1 - g_2)$ is assumed to be constant, δ_i may be replaced in eq. [2] by $c_i f_i$ where c_i is the concentration and f_i the orientation factor of the ith component of the sol. The relative values of c_i were taken from the distribution (Table I) and f_i and ψ_i were obtained from the tables (8).

The modified equation is

$$[4] \qquad \tan 2\chi = \sum_i c_i f_i \sin 2\psi_i \Big/ \sum_i c_i f_i \cos 2\psi_i.$$

The curve calculated from eq. [4] is shown as the solid line in Fig. 2. Included for comparison as broken lines are the calculated values for monodisperse sols of various lengths. It is seen that the experimental values are in good agreement with the theoretical curve based on the measured length distribution.

NOTE ON THE REACTION OF HYDROGEN ATOMS WITH CYANOGEN*

CATHERINE HAGGART† AND C. A. WINKLER

During a study of the reactions of CN radicals formed in mixtures of cyanogen and active nitrogen, it became of interest to know the extent to which cyanogen was capable of reacting with hydrogen atoms and CN radicals with molecular hydrogen. Using a fast flow system, Geib and Harteck (1) observed that hydrogen atoms react with cyanogen to produce hydrogen cyanide and traces of methylamine and ammonia. Pease and Robertson (2) reported that, in a static system at 550° C, the reaction of cyanogen and molecular hydrogen followed a chain mechanism, initiated by the formation of CN radicals, and they suggested that hydrogen cyanide was formed by the reactions of CN radicals with molecular hydrogen and of hydrogen atoms with cyanogen. The reaction of molecular hydrogen with CN radicals, formed in the sodium flame reaction with cyanogen, was observed by Hartel and Polanyi (3) to produce hydrogen cyanide and to require an activation energy of some 7 kcal.

†*Holder of a C.I.L. Fellowship, 1958–59.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The reaction between hydrogen atoms and cyanogen was studied over a range of temperatures up to 430° C, at various flow rates of cyanogen. Hydrogen atoms were formed in a conventional Wood–Bonhoeffer (4) system. Hydrogen cyanide and unreacted cyanogen were the only substances trapped at liquid air temperature after reaction had occurred and no polymer was formed during the reaction. Analysis for hydrogen cyanide in the presence of cyanogen was made as described by Rhodes (5), by absorbing both products in a known volume of acidified silver nitrate solution, from which cyanogen was quantitatively recovered by slowly drawing nitrogen through the absorber and then into a train of Wallis bubblers (6) containing sodium hydroxide solution. The excess silver nitrate was titrated with potassium thiocyanate using ferrous ammonium sulphate as indicator, and the cyanide content of the bubblers was estimated by titration with silver nitrate with potassium iodide as indicator (7).

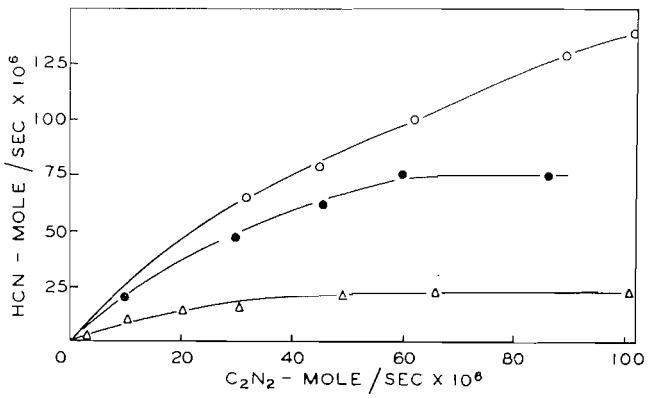

FIG. 1. Production of hydrogen cyanide in the reaction of hydrogen atoms with cyanogen. Temperature in ° C: △, 68; ●, 268; ○, 430.

The relations between the hydrogen cyanide production and cyanogen flow rate at three temperatures are shown in Fig. 1. Even at the lowest temperature used (68° C), the maximum rate of hydrogen cyanide production exceeded by a factor of three the flow rate of hydrogen atoms as determined from the maximum amount of hydrogen bromide that could be decomposed under comparable conditions (8). As the temperature was increased, the maximum production of hydrogen cyanide increased rapidly, until at 430° C it was some twenty times the flow rate of hydrogen atoms from the discharge tube. It seems quite apparent, therefore, that the reaction occurs by a chain mechanism, presumably as follows:

$$(CN)_2 + H \rightarrow HCN + CN \quad [1]$$

$$CN + H_2 \rightarrow HCN + H. \quad [2]$$

Termination of the chain might, of course, occur by recombination of hydrogen atoms or CN radicals, or by the interaction of hydrogen atoms and CN radicals.

THE MERCURY-DISCHARGE REDUCTION OF PHOSPHORUS TRICHLORIDE

ARTHUR FINCH

Little information is available concerning the preparation or properties of simple halogen compounds containing the P—P bond; P_2Br_4 and P_2F_4 are unknown, and only P_2I_4 is well characterized (1). Early work by Besson (2) on the effect of an electrodeless discharge on mixtures of phosphorus trichloride and hydrogen resulted in the production of (presumably) P_2Cl_4, and similar recent work by Gutmann (3) led to unidentified liquid products. Attempts to make the tetrachloride by chemical reactions using P_2I_4 have been unsuccessful (4). The work reported below involves the reduction of phosphorus trichloride vapor by a high-voltage mercury arc, using conditions successfully adopted by Schlesinger and collaborators (5) for the continuous production of unstable boron subhalides.

EXPERIMENTAL

Apparatus and Materials

A "square-four" design discharge tube, similar to that previously used (5) was employed, with a discharge path of about 6 cm. A 2000-volt, 15-ma output transformer was operated under conditions appropriate to give a satisfactory discharge; the potential actually used varied between 1000 volts and 1300 volts, depending on the pressure in the system.

Phosphorus trichloride was redistilled at 74° C, passed into a high-vacuum line of conventional design, and fractionated through a −45.2° bath into a −78° trap. The vapor pressure of the purified compound was 65 mm at about −10°, in agreement with published results (6). Phosphorus trichloride vapor was circulated through the discharge cell either by a circulating pump or by distillation from a −63° bath to a −196° trap.

Results

Extensive decomposition occurred, with the production of dark red and yellow involatile solids on the walls of the discharge tubes, a dark grey scale on the surface of the mercury electrodes, and small quantities of a volatile liquid.

The volatile fraction was transferred to a fractionating system, and condensed as white crystals at −45° after passing a −23° bath. Using the Stock melting-point technique, and a pentane thermometer calibrated at the National Physical Laboratory to ±1°, the crystals were found to melt sharply between −34° and −35° C. The colorless liquid produced on melting the crystals decomposed at room temperature in vacuum, giving yellow involatile solids, and phosphorus trichloride, identified by measurements in a micro vapor-pressure apparatus. The liquid fumed in air, and reacted vigorously with water. Samples were distilled into weighed tubes under vacuum, hydrolyzed, and analyzed for chlorine and phosphorus, using standard procedures. Typical results calculated for P_2Cl_4 (Cl, 69.5%; P, 30.5%) were as follows. Sample 1: weight, 0.3041 g; Cl, 69.3%; P, 29.8%. Sample 2: weight, 0.2520 g; Cl, 69.6%; P, 30.4%. During the hydrolysis some non-condensable gas, presumably hydrogen, was evolved, suggesting the breaking of a P—P bond, though measurement was not possible in the apparatus available. The nature

of the hydrolysis products in the analogous compound P_2I_4 has been studied in detail by Kolitowska (9), who has shown that the final products include HI, H_3PO_2, H_3PO_3, PH_3, ($P_{12}H_6$), and it is expected that similar results obtain for the present compound. Molecular weight determinations by depression of vapor tension of carbon tetrachloride gave the values 191 and 194 for different samples (calculated for P_2Cl_4, 204). Thus the liquid was P_2Cl_4, and exhibited the general appearance and properties described by Besson, though the melting point was 6° lower. Using a single cell, some 200 mg per day were formed by a semiautomatic process.

Lack of volatility at low temperatures, and the rate of decomposition at room temperature, precluded vapor-pressure measurements. By analogy with the fluorination of B_2Cl_4 to form a more volatile and stable compound (7), attempts were made to replace the chlorine by fluorine, using similar Swarts-type reactions. No evidence for volatile compounds other than phosphorus trichloride, and very small amounts of a very volatile gas, presumably phosphorus trifluoride, was obtained. Further experiments to synthesize the tetrafluoro compound are in progress.

The electrode scale was completely soluble in warm nitric acid without apparent evolution of phosphine. Complete analysis, using standard gravimetric techniques, gave the following results. Sample 1: Hg, 86.4%; Cl, 10.7%; P, 2.6%. Sample 2: Hg, 86.2%; Cl, 10.9%; P, 2.6%. Thus in distinction to Gutmann's experiments with copper electrodes, a simple metal phosphide was not formed. It is of interest to note, that mercury tetratritaphosphide Hg_3P_4 is produced by the action of P_2I_4 on mercury at elevated temperatures (8), and the electrode scale is presumably a mixture of this with other mercury phosphides and chlorides.

The colored involatile deposits on the walls of the tubes were pyrophoric, and were similar to the mixture of red and yellow phosphorus described by Gutmann.

Solid ammonia hydrates are known from various investigations (3–5) to be of the molecular, or addition type: $NH_3 \cdot H_2O$, etc. On the other hand, the Raman spectra of the ammonia – hydrogen peroxide compound in the molten state as well as in aqueous solutions (6, 7) show no indication whatsoever of the characteristic bands of the NH_4^+ ion, thereby confirming that under such conditions both component molecules essentially preserve their identity. In view of its relatively high melting point it is conceivable that in the solid state the ammonia – hydrogen peroxide compound is ionic, $NH_4^+O_2H^-$, like the alkali metal hydroperoxides. To answer the question we decided to measure its infrared spectrum. In the meantime we came across a short note by Simon and Kriegsman (8) establishing definitely the ionic nature of crystalline ammonium hydroperoxide from the NH_4^+ ion bands at 3041 and 3152 cm^{-1}. The present results lead to the same conclusion and provide further data on the O_2H^- ion.

Preparation of samples suitable for the infrared spectra presented considerable difficulty due to the marked tendency of the solid to decompose and react with atmospheric moisture. The usual methods of (*a*) grinding of the bulk solid to a fine powder, (*b*) mull in Nujol, (*c*) evaporation of a solution in alcohol, and (*d*) pressing in a KBr disk were tried without success. Satisfactory results could be obtained only by the deposition technique (9) using an evacuated glass absorption cell. First, hydrogen peroxide vapor from a liquid sample 99.9% pure was condensed in a thin film on a rock salt plate cooled with liquid nitrogen. Then a suitable amount of ammonia gas was deposited on top of the solid peroxide film. Mixing of the two vapors before condensation turned out to be unsuitable because of the large difference in the volatility of the two components. As long as the temperature remained in the neighborhood of −180° C no reaction took place between the two solids; when the liquid nitrogen was replaced by acetone – dry ice the compound was formed readily, and the excess ammonia was then pumped off. Traces of water, either from leakage of moisture or from decomposition of the peroxide vapor, yielded complex spectra arising presumably from some ternary compounds, identified since by means of thermal analysis (10).

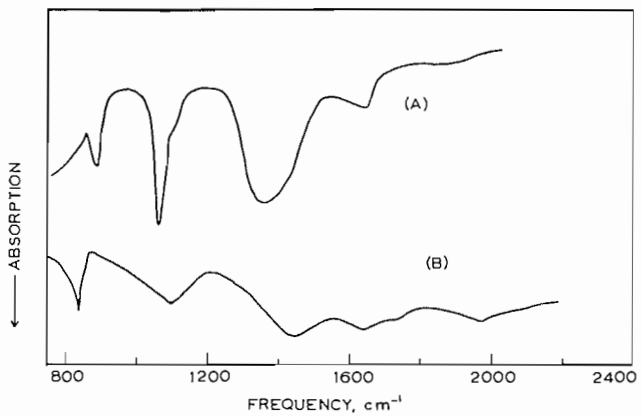

FIG. 1. Infrared spectra of (*a*) unreacted films of anhydrous ammonia and hydrogen peroxide deposited at −180° C, and (*b*) ammonium hydroperoxide.

The infrared spectrum in the rock salt region (Fig. 1) shows the well-known bands of the NH_4^+ ion at 1630 and 1450 cm^{-1} (11), plus a medium-intense band at 1100 cm^{-1} and the sharp O—O stretching band at 836 cm^{-1}. The latter, which coincides exactly with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Raman band, represents an appreciable decrease from the corresponding frequency in hydrogen peroxide, 880 cm^{-1} (12). This implies a lowering of some 10% in the force constant and a lengthening of about 0.02 Å of the O—O bond. Undoubtedly the formal negative charge on the O_2H^- ion is responsible for this effect through (*a*) increase in covalent radius of the terminal O atom and (*b*) repulsion between the latter and the bonding electron cloud. Another example of this is the isocyanate ion (13) the fundamental frequencies of which are noticeably lower that those of isocyanic acid (14). Conversely, the formal positive charge on the hydroxylammonium ion increases the NO stretching frequency and shortens the N—O distance, as shown recently by infrared spectroscopy (15).

The 1100 cm^{-1} band reported here for the first time is not found in the spectra of ammonium salts; therefore it must belong to the O_2H^- ion, most likely to the bending mode. The only other possibility is an overtone or combination involving some lattice frequency, but this seems precluded by its relatively high intensity. Although somewhat low for an OH bending mode (ν_6 = 1380 cm^{-1} in crystalline H_2O_2), the present assignment is reasonable since lengthening of the O—O bond must reduce appreciably the OH bending frequency. Lastly the OH stretching band could not be identified positively in infrared because of strong interference from the NH stretching bands of the ammonium ion. In the Raman spectrum (8) a band at 3112 cm^{-1} has been assigned tentatively to the hydrogen-bonded OH in agreement with the above reasoning. As no X-ray data are available on crystalline hydroperoxides one can only surmise that hydrogen bonds of the type O—H . . . O exist between the neighboring perhydroxyl ions.

It seemed desirable to supplement this work by a study of an alkali metal hydroperoxide. To that effect some NaO_2H was prepared by reacting (in a dry box) pure, reagent grade sodium peroxide with absolute ethanol. The dry solid was ground under an inert atmosphere and the finer particles were allowed to settle on a salt window. The spectra showed bands at 718 (w), 814 (s), 873 (s), 1009 (s), 1325 (s), 1361 (w), 1427 (s), 1555 (w), and 1622 (s) cm^{-1}, indicating that, in spite of all precautions, the sample had reacted with atmospheric carbon dioxide and possibly contained traces of a hydroperoxidate, $2NaO_2H \cdot H_2O_2 \cdot 4H_2O$ (12).

In conclusion it appears that the acid strength of hydrogen peroxide, though greater than that of water (pK = 11.65 at 25°), is not sufficient to ionize ammonia in the liquid state. Only when thermal agitation is reduced on cooling do the strong hydrogen bonds O—H . . . N ionize and the resulting field leads to spatial organization of the ions. On the other hand, with a stronger base like tetramethylammonium, hydrogen peroxide ionizes even in solution (6).

The authors are grateful to the National Research Council for financial help.

VOLUME 37 NOVEMBER 1959 NUMBER 11

SYNTHESIS, REACTIONS, AND PROPERTIES OF SOME HIGHLY HINDERED DIPHENYL ETHERS[1, 2]

MARJORIE ALLEN[3] AND R. Y. MOIR

ABSTRACT

In the Hems synthesis of diphenyl ethers, an ortho-carbonyl offered less obstruction when held in a lactone ring than when present as an ester. Side reactions interfered with the Hems synthesis of highly hindered diphenyl ethers, and the highly hindered, highly activated ethers produced in the synthesis were easily cleaved by nucleophilic reagents, often in a few minutes at room temperature. The latter fact added a lively interest to the transformation of the ethers into other derivatives. Three of these were of special interest: (*a*) methyl 2-(6′-amino-4′-carbomethoxy-2′-nitrophenoxy)benzoate (VI*c*) which existed in remarkably stable dimorphic forms, (*b*) the dibenzoxazepine VIII, and (*c*) the quadruply orthosubstituted, asymmetrical 7-(4′-carbomethoxy-6′-laevo-menthoxyacetamino-2′-nitrophenoxy)metameconine (IX). Attempts to isolate diastereoisomeric substances having the diphenyl ether link as an element of asymmetry failed, the classical explanation of the low configurational stability (due to bending and twisting of bonds) being superior to the quantum mechanical explanation of a tunnelling oscillation of oxygen.

This paper describes the synthesis of diphenyl ethers bearing three or four groups ortho to the ethereal linkage, their conversion into asymmetrical derivatives, and our tentative conclusion that the unsymmetrical derivatives cannot be resolved into optical isomers at room temperature. The most interesting part of the paper describes the synthetic methods that must be used in the face of the very great ease of disruption of the ethereal linkage.

Synthesis of Hindered Diphenyl Ethers

Ullmann's reaction (1, 2) is not very useful for the synthesis of hindered diphenyl ethers[4] (3, 4, 5, 6, 7, 8, 9). A more powerful method is the well-known reaction of a phenol, a base, and an activated aryl halide (10, 11, 12). Considerable activation is required in the aryl halide: with low activation, as with *p*-fluoronitrobenzene, the reaction occasionally fails with as few as two ortho substituents (13), but with greater activation successes with three ortho groups are common, and using the great activation of picryl chloride, Dahlgard and Brewster (14) recently succeeded in making two quadruply orthosubstituted diphenyl ethers. In this method, the large number, position, and similarity of the activating groups required are an embarrassment in further synthetic steps. A more promising synthesis discovered by Borrows, Clayton, Hems, and Long (15) has as its essential step the reaction of a phenol with an activated N-phenylpyridinium salt.

One main advantage of the new method is its lower requirements for activation (9, 15). The discoverers of the reaction felt that at least two nitro groups were required, but

McRae, Moir, Ursprung, and Gibbs (9) and at almost the same time Grundon and Perry (16) showed that activation by one nitro and one carbomethoxy group sometimes sufficed. Constantin and L'Écuyer (17) later showed that one nitro and one formyl group were sufficient in several instances. This theoretically small extension of the limits of activation has already been of considerable service to those interested in the synthesis of cularine and the bis-benzylisoquinoline alkaloids (9, 16, 17, 18).

The new synthesis may produce highly hindered diphenyl ethers with fantastic ease from moderately activated reactants. Thus N-(4-carbomethoxy-2,6-dinitrophenyl)-pyridinium chloride (I*a*) with 7-hydroxymetameconine[5] (III) gave the maximally orthosubstituted ether IV*a*, while the slightly activated N-(4-carbomethoxy-2-

nitrophenyl)pyridinium tosylate reacted easily with III to give the triply orthosubstituted ether V*a* (9). In this paper it is shown that I*a* reacts with methyl salicylate to give the triply orthosubstituted ether VI*a* with ease. Nevertheless, since 1952 we have accumulated many more failures than successes with the method. For example, methyl salicylate, which smoothly reacts with I*a*, has repeatedly failed to react with the less activated N-(4-carbomethoxy-2-nitrophenyl)pyridinium tosylate, which in turn reacts smoothly with III. These examples must closely illustrate the lower limit of activation for ortho-carbomethoxydiphenyl ethers (compare reference 17).

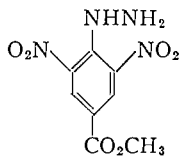
VI*d*: R = NHOAc; R′ = CH_3



VII

One new side reaction is conveniently described here. In the new preparation of VI*a*, as well as in the repetition of the synthesis of IV*a*, the same quaternary salt, N-(4-carbomethoxy-2,6-dinitrophenyl)pyridinium 4′-carbomethoxy-2′,6′-dinitrophenoxide (I*b*) was

[5]*The numbering scheme for the metameconines is that of Chemical Abstracts. A different scheme was used in our previous papers in this journal.*

isolated in considerable yield. Its proof of structure by synthesis and degradation is described in the experimental part. Quaternary salts have previously been isolated from two sources in the synthesis: (*a*) from a simple double decomposition of the ionic reactants, or (*b*) from a nucleophilic attack of pyridine upon an activated diphenyl ether (the reverse of the synthetic reaction) (19). The salt I*b* must have arisen in still a third way, the simplest explanation being that it arose from the hydrolysis of the very unstable reactant I*a*, probably during the isolation of the products. If this explanation is correct, then water attacks I*a* at the 1-position of the benzene ring, while hydroxide ion attacks it at the 2-position of the pyridine ring (see Experimental section) (20), a conclusion that raises the most interesting questions about the mechanism of the synthesis.

Other side reactions will be reported in a later paper, together with the limitations they set upon the scope of the synthesis.

Reactions of Highly Hindered, Highly Activated Diphenyl Ethers

Nucleophilic scissions of the ethers described in this paper occur with remarkable rapidity; apparently a considerable energy of steric compression aids the well-known effects of activation (11). The experimental methods described below were designed to avoid disruption of the sensitive ethereal linkages while (*a*) introducing asymmetry into the molecules or (*b*) hydrolyzing ester groups to free carboxyl groups with a view to possible resolutions.

The ether V*a* is readily cleaved by alkali (9) but careful control of the conditions of saponification has now been found to give the free acid V*b* in very high yield and purity. With the more highly activated ether VI*a*, good yields on saponification were no longer possible. The best yields of the free acid VI*b* were given by 5 minutes' contact of VI*a* with aqueous potassium hydroxide at room temperature; scission of VI*a* was easily detectable after only 1 minute's contact! The conditions which served to give excellent yields in the saponification of V*a* completely degraded VI*a* to the phenolic acid II*b*.

With more nucleophilic reagents it was not possible to prevent nucleophilic attack upon the ether. Methoxide ion (provided by barium hydroxide in methanol) degraded VI*a* *without* saponification to the ester II*c* in 3 minutes at room temperature. (The reagent was shown to be capable of saponifying II*a* to the barium salt of II*b*.) Hydrazine and Raney nickel gave the phenylhydrazine VII without concurrent reduction of the nitro groups.

Selective reduction of one nitro group was achieved with iron and acetic acid. The ether IV*a* was reduced to IV*b*, and the ether VI*a* to VI*c*. These very fortunate reductions provided the asymmetry needed for possible resolvability. Each of the amino esters was characterized through its acetyl derivative (IV*c* and VI*d*, respectively). The amino ester VI*c* exhibits a dimorphism remarkable in that both forms sometimes crystallize together spontaneously from the same mother liquor. The very reproducible double melting point is shown in Plate I.

When the amino ester VI*c* was heated to 210°, it was converted into its lactam (VIII), which was also produced more directly by the reduction of the dinitro ester VI*a* with stannous chloride in the presence of hydrochloric acid. The interesting ring system of VIII (21) is accompanied by substituents well placed for further synthesis. It might be added that the formation of VIII and of the monoacetyl derivatives IV*c* and VI*d*, the scissions of the ethers, and the methods of synthesis provide unequivocal proofs of the structures suggested in this paper and the previous one (9).

The amino ester IV*b* was converted into its N-laevo-menthoxyacetyl derivative IX, the farthest step in our development of the chemistry of metameconine (8, 9, 22), and the most highly hindered asymmetrical diphenyl ether we have yet been able to produce.

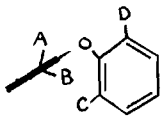
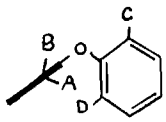
IX

Resolvability of Highly Hindered Diphenyl Ethers

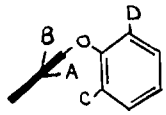
Many years ago it was suggested[6] on the basis of a study of models (9) that suitably hindered diphenyl ethers might be resolvable into optical isomers. During the course of our work, Dahlgard and Brewster (14) reported their failure to resolve an unspecified highly substituted diphenyl ether. They further suggested that such a resolution might be theoretically impossible if there exists a "tunnelling" oscillation of the ethereal oxygen analogous to the oscillation that destroys asymmetry in substituted ammonias. That was not our independent appraisal of the problem, and a study of the models shows that inversion with the allowed rotations converts a diphenyl ether into itself.



X



XI



XII

In compound X, A is behind the plane of the paper, and B is in front. Inversion through oxygen converts X into XI, while concerted rotation of the two benzene rings about the oxygen bonds converts XI into X. Neither X nor XI can be made to coincide with XII, the mirror image of X, unless interfering groups are forced past each other.

However, we have failed to separate into diastereoisomers either the brucine salt of V*b*, or the much more highly hindered amide IX. Moreover, neither of these compounds exhibited any mutarotation in solution, so that apparently even the lower order of configurational stability, observed by Adams and his co-workers (23) for slightly hindered diphenyls, is absent. Dahlgard and Brewster (14) showed that increasing orthosubstitution of diphenyl ethers is accompanied by the gradual disappearance of absorption bands near 3000 Å in the ultraviolet spectra. They felt that this was due to the growing lack of coplanarity between the benzene rings with the consequent loss of quininoid resonance, and they concluded that rotational isomers of diphenyl ethers do exist, though they may not be sufficiently stable to be isolated as such. The triply orthosubstituted ether V*a* showed marked absorption near 2900 Å, while the maximally orthosubstituted ethers VI*c* and IX showed only very weak bands near 3550 Å and 3250 Å, respectively. Accepting the interpretation of Dahlgard and Brewster does lead to the reasonable conclusion that

there is little steric interference with coplanarity in V*a*, but that there is marked interference in VI*c* and IX.

EXPERIMENTAL

Melting points, unless otherwise stated, were determined in an instrument of high precision (24). Melting points followed by (k) were performed on a Koffler Micro Hot Stage and lowered 3–5° to agree with precision capillary melting points within less than 1° up to 250°. Uncorrected melting points were determined in the Fisher–Johns apparatus; comparison with the precision apparatus at one point near the center of the range used here showed the instrument to read about 3° high. Infrared spectra with one exception were done with potassium bromide disks containing 0.8% to 2% by weight of the sample. Ultraviolet spectra were determined with the Beckman recording spectrophotometer. Pyridine was heated under reflux with barium oxide, distilled from the barium oxide, and stored over fresh barium oxide.

7-(4'-Carbomethoxy-2'-nitrophenoxy)metameconine (V*a*)

A repetition of the previous procedure (9) showed that no by-product of the type described below (see under IV*a*) could be isolated.

7-(4'-Carboxy-2'-nitrophenoxy)metameconine (V*b*)

The methyl ester (V*a*) (5.52 g) was mechanically stirred at 76–81° for 30 minutes with a solution of potassium hydroxide (2.9 g) in water (30 ml) and 95% ethanol (30 ml). The solution was immediately cooled and acidified; the fine needles which slowly deposited were recovered, washed, and dried; yield 88%, m.p. 236.0–237.8°. Two recrystallizations from dilute acetic acid gave the analytical sample of V*b*, m.p. 237.4–238.4°, in agreement with the indirectly characterized material previously obtained (9). Found: C, 54.28; H, 3.52%. Calc. for $C_{17}H_{13}O_9N$: C, 54.40; H, 3.49%.

The *brucine salt* of this acid was subjected to three lengthy fractional crystallizations from acetone and from methanol; the salt fractions all showed similar, wide, melting ranges with unsatisfactory upper limits, and their habits varied. A typical fraction of the salt (3.03 g) had m.p. 174.5–177.5° (uncorr.), and $[\alpha]_D^{21} = -7°$ (in chloroform), with no mutarotation at all in the period of 4 to 71 minutes after formation of the solution. Free acid was liberated from the salt by very cautious acidification in the cold of initial, central, and final fractions, but all the acid fractions had zero rotation. Attempts were also made to induce spontaneous crystallization of one enantiomorph of the free acid, using new apparatus free from scratches, great precautions to destroy random seeds, and seeding from single, well-formed crystals with early interruption of the recrystallization process, but all the attempts gave acids of zero rotation.

7-(4'-Carbomethoxy-2',6'-dinitrophenoxy)metameconine (IV*a*)

A repetition of the previous experiments (9) showed the presence of a by-product. Methyl 4-chloro-3,5-dinitrobenzoate (I*a*) (1.65 g) (15) and dry pyridine (10 ml) were warmed on the steam bath for 5 minutes, the pyridinium salt separating as crystals. 7-Hydroxymetameconine (III) (1.35 g, m.p. 158–159°) (9) was added and the heating continued for 90 minutes. The deep red solution was poured onto ice and the product, which soon solidified, was recovered, dried, and recrystallized from acetone to give a mixture of (*a*) pale yellow prisms, and (*b*) long, deep yellow needles. The products were separated mechanically by swirling away the lighter needles in the acetone mother liquor, a process which greatly simplified the subsequent purifications. After a second recrys-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

tallization from acetone the prisms gave 1.4 g of pure 7-(4′-carbomethoxy-2′,6′-dinitrophenoxy)metameconine (IV*a*), m.p. 210–211° (k). Found: N, 6.55%. Calc. for $C_{18}H_{14}N_2O_{11}$: N, 6.45%. The crystals were stable in air (cf. ref. 9), but they were decomposed by light.

The yellow needles, after another recrystallization from acetone, melted at 240–242° (uncorr.). They are shown below to be N-(4-carbomethoxy-2,6-dinitrophenyl)pyridinium 4′-carbomethoxy-2′,6′-dinitrophenoxide (I*b*).

7-(6′-Amino-4′-carbomethoxy-2′-nitrophenoxy)metameconine (IV*b*)

Iron powder (0.27 g) was heated on the steam bath for 1 hour with a solution of 7-(4′-carbomethoxy-2′,6′-dinitrophenoxy)metameconine (IV*a*) (1.0 g) in glacial acetic acid (60 ml). The mixture was evaporated to dryness and the residue thoroughly extracted with water and then with boiling methanol (100 ml). A yellow powder (0.4 g), m.p. 230–233° (k) was thus obtained; two recrystallizations from acetone gave the analytical sample, m.p. 234–235° (k). Found: C, 53.63; H, 3.99; N, 7.18%. Calc. for $C_{18}H_{16}O_9N_2$: C, 53.47; H, 3.96; N, 6.93%.

7-(6′-Acetamino-4′-carbomethoxy-2′-nitrophenoxy)metameconine (IV*c*)

The above amino compound (IV*b*) (0.1 g) was heated 5 minutes with acetic anhydride (2 ml) and concentrated sulphuric acid (1 drop). The solution was poured into water and boiled to decompose the acetic anhydride. White needles, m.p. 197–199° (k) were deposited from the cooled solution. Two crystallizations from 50% aqueous methanol raised their m.p. to 206–207° (k). Found: C, 54.16, 54.14; H, 4.14, 4.02; N, 6.08, 6.50%. Calc. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.04; N, 6.28%.

7-(4′-Carbomethoxy-6′-laevo-menthoxyacetamino-2′-nitrophenoxy)metameconine (IX)

The amino compound IV*b* (0.539 g), laevo-menthoxyacetyl chloride (0.31 g), $[\alpha]_D = -85.75°$ (*c*, 2.13 in chloroform) (25), and chloroform (30 ml) were heated under reflux for 6 hours. The crystals (0.1 g) which separated from the cooled solution had a m.p. of 228–232° (k), undepressed by admixture with authentic IV*b*. Evaporation of the mother liquors and trituration of the oily residue with petroleum ether gave a solid, which was sensitive to light, in a yield of 0.7 g, m.p. 183°. Five successive recrystallizations gave products of the following melting points (k): (from ethanol) 185–190°; (from ethanol) 188–191°; (from methanol) 188–190°; (from benzene – petroleum ether) 188–190°; (from ethanol) 188–189°; thus there was no evidence for the presence of stable diastereoisomers. Stout white needles. Found: C, 60.23; H, 6.08; N, 4.85%. Calc. for $C_{30}H_{36}O_{11}N_2$: C, 60.00; H, 6.00; N, 4.67%.

A solution of the menthoxy-amide (IX) (0.1467 g) in chloroform (solution volume 5 ml) was observed in the polarimeter; nine readings were taken over the period from 5 minutes to 68 hours after the formation of the solution, each reading, as well as the instrument's zero-point, being the mean of 10 observations. The corrected readings varied smoothly from the initial value of −0.85° to the final value of −0.89°; the variation was probably not significant. The initial value gives $[\alpha]_D = -29°$ and a molar rotation of −174°; under approximately the same conditions the molar rotation of purified menthoxyacetic acid was found to be −190°. The lack of mutarotation, and the approximate agreement of the molar rotations, were regarded as significant.

Methyl 2-(4′-Carbomethoxy-2′,6′-dinitrophenoxy)benzoate (VI*a*)

Methyl 4-chloro-3,5-dinitrobenzoate (2.6 g) and dry pyridine (15 ml) were heated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

5 minutes on the steam bath. Methyl salicylate (1.5 ml) was then added and the heating continued for 90 minutes. The dark colored solution deposited a bright yellow gum on being poured onto ice (100 g); when the gum had solidified it was recovered, washed with water, and dried. The crude mixed product was separated into its components in any of three ways.

(*a*) Recrystallization from acetonitrile gave bright yellow needles, m.p. 241–242° (uncorr.) in a yield of 0.4 g, or 11%. Evaporation of the mother liquors followed by recrystallization of the residue from ethanol gave the diphenyl ether VI*a*, m.p. 109.5–110.5°, yield 2.1 g (56%). One more recrystallization from ethanol gave the analytical sample, m.p. 110.6–111.2°. Found: C, 51.12; H, 3.50; N, 7.71%. Calc. for $C_{16}H_{12}O_9N_2$: C, 51.06; H, 3.22; N, 7.45%.

(*b*) Extraction with hot ethanol left the yellow needles undissolved; the ether was recovered by dilution of the ethanol. Further recrystallizations gave the same two products as before.

(*c*) The crude product was washed with dilute hydrochloric acid (which decomposed the yellow needles) and then recrystallized twice from ethanol to give the pure ether, m.p. 110–111°. On a larger scale, 23.3 g (73% of theory) of the twice recrystallized ether VI*a*, m.p. 110–111°, was made in this more convenient way.

The yellow needles are shown below to be N-(4-carbomethoxy-2,6-dinitrophenyl)-pyridinium 4′-carbomethoxy-2′,6′-dinitrophenoxide (I*b*).

Stability of Methyl 2-(4′-Carbomethoxy-2′,6′-dinitrophenoxy)benzoate (VI*a*) *in Pyridine*

The dinitroether VI*a* (0.5 g) and dry pyridine (5 ml) were heated on the steam bath for 30 minutes, poured onto ice, the precipitate recovered and recrystallized from methanol. The product (0.4 g) had m.p. 111°, undepressed by admixture with the original ether. Hence the quaternary salt (I*b*) did not arise from nucleophilic attack upon the diphenyl ether.

Scissions of the Diphenyl Ether Linkage; Preparation of Methyl 2-(4′-Carboxy-2′,6′-dinitrophenoxy)benzoate (VI*b*)

(*a*) *With Hot Potassium Hydroxide*

The dimethyl ester VI*a* (0.3 g) was heated under gentle reflux for 30 minutes with 10% aqueous potassium hydroxide solution. The cooled, acidified solution deposited white crystals, m.p. 254–255° (uncorr.). Analyses were approximately correct for 3,5-dinitro-4-hydroxybenzoic acid (II*b*), and the identification was confirmed by mixture melting point with authentic material (made by saponification of the methyl ester II*a*, and twice recrystallized from ethanol; the melting point of 254–255° (uncorr.) was considerably higher than that (244–246°) observed by Christianson) (26).

(*b*) *With Cold Potassium Hydroxide*

The dimethyl ester VI*a* (3.0 g) was dissolved in hot ethanol and the solution rapidly cooled to give a suspension of very fine crystals. Potassium hydroxide solution (18 ml of 10%) was slowly added and the mixture shaken at room temperature for 5 minutes. Ether (50 ml) was then added, and the mixture acidified, separated, and the aqueous layer extracted with three 50-ml portions of ether. Exhaustive back extraction of the combined ethereal layers with cold sodium bicarbonate solution (each extract being rapidly chilled and acidified after the extraction) followed by re-extraction with ether of the acidified sodium bicarbonate extracts, and evaporation of the final, dried, ethereal extracts, gave a pale yellow oil containing some crystals. Recrystallization of the oily mixture from methanol gave 1.1 g of light-sensitive crystals m.p. 175–185°. Three more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

wasteful recrystallizations from methanol gave the analytical sample of 2-(4′-carboxy-2′,6′-dinitrophenoxy)benzoate, m.p. 214–215° (k). Found: C, 49.81; H, 2.90; N, 7.62%. Calc. for $C_{15}H_{10}O_9N_2$: C, 49.72; H, 2.76; N, 7.74%.

When a similar preparation was acidified after the reaction had proceeded for only 1 minute at room temperature, a strong odor of methyl salicylate could be detected. This observation, together with the isolation of the free dinitro acid (II*b*) in (*a*) part, and the rapid saponification observed in the less activated ether (V*a*) (see above), made it sufficiently clear that it was the less activated ester group which remained in compound VI*b*.

(*c*) *With Acids*

When the dimethyl ester VI*a* was heated under reflux with dilute acetic acid containing a little *p*-toluenesulphonic acid, it was recovered unchanged almost quantitatively. An attempted transesterification with glacial acetic acid and *p*-toluenesulphonic acid gave no detectable methyl acetate in the fractionating column, and again the recovery of unchanged material was almost quantitative. When concentrated sulphuric acid was allowed to react with the ester at room temperature for 14 hours, and the mixture poured into water, recovery of the starting material was lower, and a strong odor of methyl salicylate showed that some rupture of the ethereal linkage had occurred.

(*d*) *With Methoxide Ion*

The dimethyl ester VI*a* (2 g) was dissolved in a methanolic solution of barium hydroxide hydrate (64 ml of a solution containing 18 g of the hydrate per liter) and allowed to react for 3 minutes at room temperature. No precipitate formed. The deep red solution was then acidified, diluted with water, and extracted with ether. The ethereal extracts were dried and evaporated; the yellow oil remaining (1.7 g) had a strong odor of methyl salicylate. Extraction of an ethereal solution of the oil with aqueous sodium bicarbonate, removal of the ether, and recrystallization of the residue from methanol gave white crystals in a yield of 0.6 g, whose m.p. of 54–55° was not depressed by admixture with authentic methyl 3,5-dinitro-4-methoxybenzoate (II*c*) (prepared by the action of diazomethane upon II*a*, and recrystallized from methanol, m.p. 52–53°).

Methyl 3,5-dinitro-4-hydroxybenzoate (II*a*) (1 g) was dissolved in 150 ml of the same solution of barium hydroxide hydrate in methanol, and allowed to stand 3 days at room temperature. The bright orange crystals (1.7 g) of the barium salt were recovered, suspended in water (150 ml), and acidified; the free acid slowly precipitated and on recovery it had a m.p. of 249–250° (uncorr.) undepressed by admixture with authentic II*b*. Thus the scission of the ether had been accomplished by direct nucleophilic attack of methoxide, and not, for example, by hydrolysis followed by methylation of the free phenolic group by the activated methyl ester.

(*e*) *With Hydrazine*

The dimethyl ester VI*a* (1 g) was suspended in absolute alcohol and treated with a solution of hydrazine hydrate (0.4 g) in ethanol (2 ml). A little Raney nickel was added and the mixture heated under reflux for 1 hour, more ethanol being added to keep the product in solution. The hot solution was filtered from the Raney nickel and cooled; the red crystals (0.3 g) which separated were recovered and thrice recrystallized from ethanol to give thick red needles of 4-carbomethoxy-2,6-dinitrophenylhydrazine (VII), m.p. 171° (k). Found: C, 37.58; H, 3.26; N, 22.03%. Calc. for $C_8H_8O_6N_4$: C, 37.51; H, 3.12; N, 21.87%. The phenylhydrazine reacted with benzaldehyde to give a derivative which on purification consisted of orange plates, m.p. 241° (k), not further characterized.

Methyl 2-(6'-Amino-4'-carbomethoxy-2'-nitrophenoxy)benzoate (VI*c*)

The dinitro ester VI*a* (1 g) was dissolved in glacial acetic acid (25 ml) and gently warmed to 30° with iron powder (0.45 g). The temperature then rose spontaneously to 55° and was kept at 50–55° for 15 minutes by external cooling. Allowed to cool by itself during 30 minutes more, the mixture was then filtered from a precipitate which was washed with hot glacial acetic acid. The combined filtrates were evaporated to dryness, the residue thoroughly extracted with ether, the ether evaporated, and the residual oil recrystallized from methanol with charcoal to give 0.5 g of yellow crystals, m.p. 134–138°. Five successive recrystallizations from methanol gave crystals of grossly erratic shape and melting point. In a second preparation, the product was recrystallized once from methanol and then five times from benzene, with the same erratic results (which were therefore not due to solvent of crystallization) (see below). The final analytical sample so obtained consisted of needles, m.p. 135° (k). Found: N, 8.16%; and on another sample: C, 55.67, 55.63%; H, 4.08, 3.92%. Calc. for $C_{16}H_{14}O_7N_2$: C, 55.49; H, 4.08; N, 8.09%.

Dimorphism of Methyl 2-(6'-Amino-4'-carbomethoxy-2'-nitrophenoxy)benzoate (VI*c*)

The analytical sample of the amino ester VI*c* (0.2 g, m.p. 139°) was heated at 150° for 45 minutes to give a clear yellow melt without any signs of decomposition. Allowed to cool slowly, the melt produced crystals of m.p. 141–143°; admixture with the starting material gave an intermediate m.p. of 137–139°. Recrystallization of the solidified material from methanol gave a mixture of crystals of two distinct forms: (*a*) pale yellow "prisms" (*b*) slightly darker yellow "plates". The two forms were separated by hand, and careful examination of the prisms (type "*a*") under the microscope showed them to be perfectly free from crystals of type "*b*". Nevertheless, recrystallization of the prisms from methanol gave plates of type "*b*". Careful heating of these plates on the hot stage of the microscope showed melting to begin at 135°; at 137° crystals of the prism type "*a*" appeared in the melt, and at 139° the sample had solidified entirely into the prism form, which then melted at 144–145°. This sequence, remarkable for its reproducibility, has twice been recorded photomicrographically by Professor J. R. Allen, as shown in Plate I.

Infrared spectra of the solid plates and prisms in potassium bromide disks showed differences in the regions of 1300 to 1375 cm^{-1}, and 3280 to 3300 cm^{-1}, but the infrared spectra of chloroform solutions of the two forms were identical.

Methyl 2-(6'-Acetamino-4'-carbomethoxy-2'-nitrophenoxy)benzoate (VI*d*)

The amino ester VI*c* (0.1 g, m.p. 142°), acetic anhydride (1 ml), and concentrated sulphuric acid (1 drop) were heated together to complete solution, then diluted with water (20 ml) and heated to destroy the acetic anhydride. When cool, the solution deposited pale yellow needles which after four recrystallizations from aqueous ethanol gave the colorless analytical sample m.p. 149–150° (k). Found: C, 55.43, 55.29; H, 4.19, 4.29; N, 7.75%; on another sample: N, 7.14, 7.35%. Calc. for $C_{18}H_{16}O_8N_2$: C, 55.68; H, 4.12; N, 7.22%.

8-Carbomethoxy-6-nitro-11-oxo-10,11-dihydro-dibenz[b,f][1,4]oxazepine (Lactam of 2-(6'-Amino-4'-carbomethoxy-2'-nitrophenoxy)benzoic Acid (VIII)

(*a*) The amino ester VI*c* (0.2 g, m.p. 135°) was heated in an oil bath at 210° for 30 minutes. Decomposition was evident, and the cooled melt was a black tar coated with white crystals. Extraction with hot methanol left the white crystals as an insoluble residue, m.p. 315–316° (k).

(*b*) The dinitro ester VI*a* (0.5 g), dissolved in glacial acetic acid (15 ml), was heated for

30 minutes on the steam bath with a solution of stannous chloride dihydrate (1.0 g) in concentrated hydrochloric acid (2 ml). White needles were recovered from the cooled reaction mixture; one recrystallization from glacial acetic acid gave 0.1 g of fluffy needles, m.p. 289–291° (uncorr.), and two more similar recrystallizations gave the analytical sample, m.p. 315–316° (k). Found: C, 57.75; H, 3.59; N, 8.83%. Calc. for $C_{15}H_{10}O_6N_2$: C, 57.32; H, 3.19; N, 8.92%. The melting point was not depressed by admixture with the product from (*a*), and the infrared spectra of the two preparations were identical.

Supposed N-(*4'-Carbomethoxy-2',6'-dinitrophenyl*)*pyridinium Chloride* (I*a*)

Methyl 4-chloro-3,5-dinitrobenzoate (2.6 g) (15) in dry benzene (20 ml) was treated with dry pyridine (1.5 ml). After 1 hour the slightly sticky yellow crystals were recovered, washed with benzene and then with acetone, dissolved in warm ethanol, and reprecipitated with ether to give white prisms (3.0 g, 88%), m.p. 117–120°. Since they decomposed very rapidly indeed they were characterized indirectly as described below.

N-(*4-Carbomethoxy-2,6-dinitrophenyl*)*pyridinium 4'-Carbomethoxy-2',6'-dinitrophenoxide* (I*b*)

(*a*) The pyridinium chloride I*a* (3.4 g) was dissolved in water (10 ml) and shaken with silver oxide (freshly prepared from 3.4 g of silver nitrate). Filtered from the silver compounds, the solution was slowly added to a suspension of methyl 3,5-dinitro-4-hydroxybenzoate (II*a*) (27) (2.5 g) in boiling water (150 ml). The bright yellow precipitate was recovered, washed with water, and then with acetone (100 ml) to remove unchanged phenol. The initial melting point of 236–237° (decomp.) was raised to 242–243° (k) (decomp.) by two recrystallizations from acetone. Found: C, 46.67, 46.52; H, 2.72, 2.77%. Calc. for $C_{21}H_{15}O_{13}N_5$: C, 46.25; H, 2.77; N, 12.84%.

(*b*) The yellow needles, m.p. 240–242° (uncorr.), obtained as a by-product in the preparation of IV*a* as described above were the same substance as that obtained in (*a*) part (mixture melting point, identical infrared spectra). Found: C, 47.90; H, 2.89; N, 12.88%. The presence of the activated N-phenylpyridinium group was shown by the slow solubility of the crystals in cold dilute potassium hydroxide to give a deep red coloration (20)—a test not given by the diphenyl ethers or dinitrohydroxybenzoic acids of this series. When this preparation of the quaternary salt (0.35 g) was heated for 3 hours on the steam bath with dry pyridine (3 ml) and the mixture poured onto ice, the solid recovered and recrystallized from acetone, unchanged quaternary salt was obtained in a yield of 0.2 g, m.p. 240–242° (uncorr.). Thus the salt is resistant to hydrolysis and to transformation into a diphenyl ether (19).

(*c*) The yellow needles, m.p. 241–242°, isolated from the preparation of VI*a* as above were also identical with those from (*a*) and (*b*) (mixture melting point, infrared spectra). Another sample of the yellow needles from the same source was recrystallized four times from acetonitrile and twice from acetone. Found: C, 46.18, 46.18; H, 2.30, 2.25; N, 12.98, 12.85%. Allowed to stand in the cold with dilute potassium hydroxide solution, the crystals slowly gave the deep red color characteristic of activated N-phenylpyridinium compounds.

Further proof of identity and structure is given in the next section.

Decomposition of the Quaternary Salt I*b*

(*a*) A sample of the quaternary salt I*b* (3.0 g, prepared as in "*a*" above) was stirred 5 minutes with dilute hydrochloric acid. The deep yellow color of the phenoxide was slowly replaced by the cream color of the insoluble decomposition product. This precipitate on recovery was shown to be methyl 3,5-dinitro-4-hydroxybenzoate (II*a*) by melting point and mixture melting point—a demonstration of the anion of the quaternary salt.

For personal use only.

The aqueous filtrates after being neutralized with sodium bicarbonate gradually deposited a yellow solid which was recovered next morning, yield 0.88 g. Four recrystallizations from acetone converted it to long pale yellow needles, m.p. 244–245° (uncorr.) (decomp.).

(*b*) A sample of I*b*, recovered from the preparation of IV*a*, and as described in part (*b*) of the previous section, gave the same results. In particular, the precipitate from the neutralized solution had the same infrared spectrum as that described in part (*a*) of this section. Thus the identity of the two specimens of I*b* had been demonstrated.

ACKNOWLEDGMENTS

The research was made possible by a grant from the National Research Council, and by the grant of a Fellowship to one of us (M. A.) by Canadian Industries, Limited. We wish to thank Miss Shelagh Courtenay for determining the infrared spectra reported in the paper.

GUANIDINE COMPOUNDS

III. THE PREPARATION OF TRIACETYLGUANIDINE AND ITS TRANSFORMATION WITH ALCOHOL[1, 2]

R. GREENHALGH AND R. A. B. BANNARD

ABSTRACT

Triacetylguanidine has been prepared and shown to undergo stepwise deacetylation in the presence of alcohol to guanidine acetate. Diacetylguanidine has been shown to have a m.p. 176–177° and not 166° as previously reported.

Acetylation of guanidine under mild conditions gave a compound m.p. 110–112°, in 82% yield, which had not previously been reported by Korndorfer (1), Grundmann and Beyer (2), Ryabinin (3), or Cockburn and Bannard (4). The substance could be purified by crystallization from acetone or sublimation *in vacuo*. Its ultraviolet spectrum differed from those of model diacetyl- and monoacetyl-guanidine derivatives. The diacetylguanidines showed two bands in the regions 222–229 mμ and 255–265 mμ, and the monoacetylguanidines only one band at 230–236 mμ (5). Analytical data gave an empirical formula $C_7H_{11}O_3N_3$, which together with acetyl and molecular weight determinations showed the compound to be triacetylguanidine.

The most important property of triacetylguanidine is its instability in the presence of hot alcohol. Treatment with ethanol at 75° for 30 minutes or repeated recrystallization from methanol gave a compound, m.p. 176–177°, which sublimed unchanged *in vacuo*. This compound was shown to be different from monoacetylguanidine acetate (m.p. 178–180°), since admixture with an authentic sample depressed the melting point, also the infrared spectra of the two compounds differed. No free acetic acid was present, as indicated by the fact that no sodium hydroxide was consumed on potentiometric titration. The ultraviolet spectrum indicated a diacetylguanidine and the analytical data agreed with this. Confirmation was obtained by the preparation of a picrate m.p. 162–164°, which analyzed for diacetylguanidine picrate. Previously, Ryabinin (3) had obtained a substance, m.p. 166°, which he designated as diacetylguanidine and which gave a picrate, m.p. 162–164°. Since we could also isolate the compound, m.p. 176–177°, by following Ryabinin's procedure for acetylation of guanidine, we concluded his sample was impure. A possible explanation for the failure of previous workers to isolate the triacetyl derivative could be their use of more vigorous conditions. Treatment of triacetylguanidine with acetic acid led to a number of unstable intermediates, which on drying *in vacuo* gave the diacetyl derivative. The acetic acid formed during acetylation under these vigorous conditions could be expected to yield these intermediates, which on drying as Ryabinin did, would give diacetylguanidine.

When diacetylguanidine was treated with ethanol under conditions similar to those used with triacetylguanidine a compound, m.p. 187–189°, was obtained which was shown to be identical with monoacetylguanidine. Monoacetylguanidine in its turn when treated with ethanol gave guanidine acetate. Thus we were able to deacetylate triacetylguanidine

to guanidine acetate in a stepwise manner, each step proceeding with a yield greater than 55%. In acidic methanol, deacetylation occurs even more readily, as can be shown by treatment of diacetylguanidine in methanol with 1 equivalent of acetic acid, when monoacetylguanidine acetate is formed almost instantaneously. On substituting N,N-dimethylformamide for methanol as solvent no deacetylation occurs, although monoacetylguanidine is readily converted to the acetate salt in the presence of 1 equivalent of acetic acid.

No attempt was made to study the kinetics of the stepwise deacetylation, but the high yields obtained would suggest that it is not a simple first-order sequential reaction.

EXPERIMENTAL[3]

Triacetylguanidine

Guanidine acetate (500 mg) was heated for 1 hour on the steam bath with acetic anhydride (5 ml). The solution was taken to dryness *in vacuo* yielding a colorless oil which slowly crystallized. Recrystallization from acetone gave 636 mg (82%) of colorless thick needles, m.p. 110–112°. Calc. for $C_7H_{11}O_3N_3$: C, 45.40; H, 5.99; N, 22.69; CH_3CO, 69.7%; mol. wt., 184. Found: C, 45.47; H, 5.86; N, 22.94; CH_3CO, 68.65%; mol. wt., 182. The compound could also be purified by sublimation *in vacuo* (70–80° at 0.005 mm). Ultraviolet spectrum in ethanol, λ_{max} 214 mμ, ϵ_{max} 15,260; λ_{max} 250 mμ, ϵ_{max} 9712: (concn. 0.8 mg/100 ml).

Conversion of Triacetylguanidine to Diacetylguanidine

Triacetylguanidine (503 mg) was dissolved in ethanol (1.0 ml) and heated for 30 minutes at 75°. When the solution was concentrated, colorless prisms separated. They were recrystallized from methanol–ether, yielding 275 mg (71%) of diacetylguanidine, m.p. 176–177°. Calc. for $C_5H_9O_2N_3$: C, 41.95; H, 6.34; N, 29.36; CH_3CO, 60.15%. Found: C, 41.86; H, 6.33; N, 29.51; CH_3CO, 58.7%. On admixture with an authentic sample of monoacetylguanidine acetate, m.p. 178–180°, the melting point was depressed to 164°. Diacetylguanidine sublimed unchanged at 105–110° at 0.005 mm. Ultraviolet spectrum in ethanol λ_{max} 212 mμ, ϵ_{max} 8921; λ_{max} 248 mμ, ϵ_{max} 16,840: (concn. 1.09 mg/100 ml). The picrate was prepared by adding the theoretical amount of picric acid in methanol to diacetylguanidine in methanol, m.p. 162–164°. Calc. for $C_{11}H_{12}O_9N_6$: C, 35.49; H, 3.25; N, 22.58%. Found: C, 35.73; H, 3.19; N, 22.05%.

Conversion of Diacetylguanidine to Monoacetylguanidine

Diacetylguanidine (250 mg) was treated with ethanol as above. The colorless prisms obtained were recrystallized from methanol–ether, m.p. 188–190°, yield, 103 mg (55%). Identified by mixed melting point and infrared spectrum as monoacetylguanidine.

Conversion of Monoacetylguanidine to Guanidine Acetate

Monoacetylguanidine (250 mg) was treated with ethanol as above. Recrystallization of the crude product from methanol–ether gave 187 mg (74%) of colorless prisms, m.p. 227–229°. Identified by infrared spectrum and no depression of melting point on admixture with a sample of guanidine acetate.

ACKNOWLEDGMENTS

The authors wish to thank J. Helie for the analysis and S. Head and A. Grey for ultraviolet and infrared determinations.

AN ELECTRON DIFFRACTION STUDY OF ELECTROPOLISHED IRON[1]

P. B. SEWELL,[2] C. D. STOCKBRIDGE,[2] AND M. COHEN

ABSTRACT

Iron has been electropolished over a range of voltage and current in the acetic acid–perchloric acid bath. Under optimum conditions an "atomically smooth" surface has been obtained as evidenced by marked refraction effects in the electron diffraction patterns. There is also evidence for a thin film on the electropolished surface which thickens on further exposure to air to form a preferentially oriented cubic iron oxide. Light etching in nitric acid removed the film and formed a surface which, on diffraction, gave the more normal spot pattern of iron.

INTRODUCTION

The behavior of metals in corrosion and oxidation studies is very dependent on the original method of surface preparation. Mechanical polishing leads to plastic deformation of the structure which may penetrate quite deeply into the metal. Some impurities and original oxide film may be introduced into the metal by the polishing agent. Subsequent etching to remove the deformed layer can lead to surfaces with high and variable surface roughness factors. Hydrogen reduction may introduce hydrogen into the metal and roughen the surface. For these reasons there has been a great deal of interest in the use of electropolishing as a method of surface preparation.

Satisfactory electropolishing gives rise to an undulating surface which may best be described as "atomically smooth" (1). During reflection electron diffraction examination, the incident electron beam enters such a surface at varying angles of grazing incidence. Each resulting diffraction image is thus built up of a series of diffracted beams suffering slightly different refraction displacements towards the shadow edge. The over-all effect is the elongated spot pattern commonly found with electropolished surfaces (2).

Pashley (1) indicates that on a flat substrate uniform films of the order of 2 Å thick (monolayers) may be detected by electron diffraction under favorable conditions. Available information suggests that a layer of material 25–50 Å thick completely obscures the low angle diffraction maxima of a flat substrate (3, 4, 5). It follows that marked refraction streaking of the substrate pattern and low background scatter strongly suggest freedom from such extensive contamination.

There have been a number of attempts to produce "clean" and smooth iron surfaces by electropolishing. Recently Ladage (6) has reported the satisfactory electropolishing of iron in an ortho-phosphoric–chromic acid bath. Boswell (7) has electropolished iron in a chromic–acetic acid bath. Both these baths may contaminate the surface with chromium or phosphorus compounds.

Electropolishing polycrystalline iron in the perchloric–acetic anhydride bath (8), Cohen (9) obtained surface films which obscured the substrate. Iron surfaces polished in a bath of different composition (10) were also contaminated by a film estimated to be about 100 Å thick by electron microscopy. Wilman *et al.* (11, 12, 13) have polished iron single crystals in the perchloric–acetic anhydride bath (8) and claim to have produced clean "atomically smooth" surfaces. The somewhat restricted spot elongation that is

[1]*Manuscript received June 24, 1959.*

Issued as N.R.C. No. 5349.
[2]*N.R.C. Postdoctorate Research Fellow. Present address: Bell Telephone Laboratories, Whippany, N.J., U.S.A.*

apparent in their published patterns and the absence of diffuse spots from an air-formed film suggest that much of their surface was etched.

The present paper describes a procedure for preparing an iron surface by electropolishing which, as evidenced by electron diffraction, is a closer approximation to a clean "atomically smooth" condition than has heretofore been achieved.

EXPERIMENTAL

A Ferrovac iron (Al 0.0005%, C 0.007%, Cr 0.002%, Mn 0.0002%, Ni 0.0009%, Si 0.002%, S 0.0015%) sheet, 10 mil in thickness, cut into 1.5×5.0-cm coupons with a 2.5-cm × 2-mm tail was used. As received, this iron contained excessive oxide inclusions, which rendered optical judgment of electropolishing impossible. To remove this oxide, several Ferrovac coupons, mechanically polished down to 4/0's were reduced for 99 hours in wet hydrogen followed by a further 84 hours in dry hydrogen continuously above 1100° C.

Metallographic examination of this iron showed that the oxide inclusions had been largely removed. The slow cooling after the high-temperature treatment led to sufficient grain growth in the polycrystalline sheet to allow diffraction patterns to be obtained from single grains.

The internally clean iron polycrystals were electropolished in a 20/1 glacial acetic acid/70% perchloric acid solution under an optimum bath potential of 105±5 volts d-c. (ripple $\not>$ 300 millivolts). This bath was chosen since the iron surfaces were required for corrosion studies in the absence of avoidable contaminants. Thus complete removal of a perchlorate/acetate anolyte is more likely than a chromium, phosphate, or sulphate anolyte. The "areal average" current density was 0.4–0.5 Å/cm² under proper conditions of stirring in the bath geometry illustrated in Fig. 1. With an initial bath temperature of 17±2° C each coupon was polished for a total period of 3 minutes in 10-second bursts.

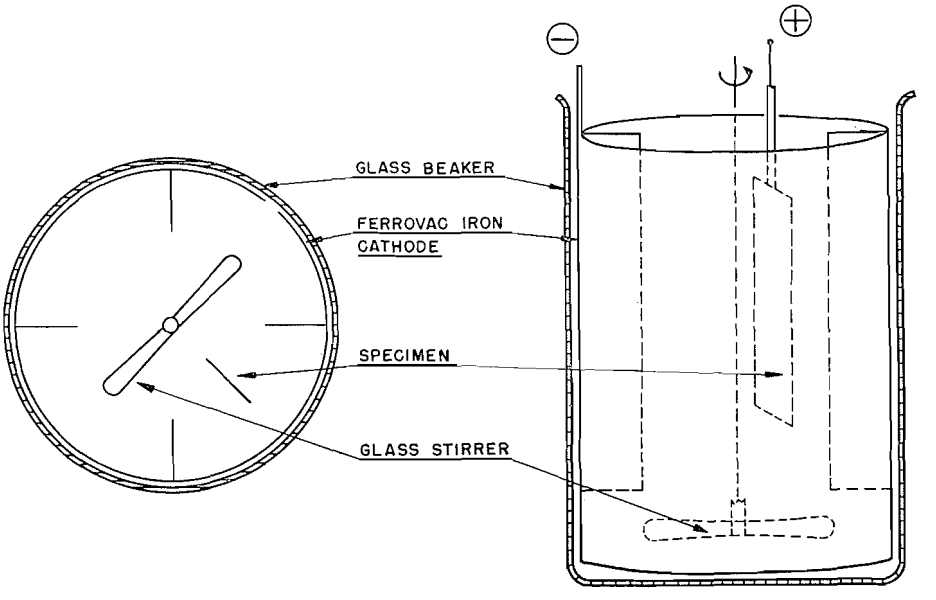

FIG. 1. Schematic diagram of electropolishing cell.

Each 10-second treatment resulted in the removal of iron to a depth of 1.2 μ. While waiting for the bath to cool, we washed the coupon in a jet of anhydrous redistilled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

methyl alcohol and held it inverted. On removal from the final 10- to 15-second electropolish (which was also found to be a sufficient period to eradicate the effects of the subsequent etching employed), the coupon was withdrawn from the bath under potential and washed generously (200 ml) and immediately in a jet of anhydrous methyl alcohol.

At 1000-diameter magnification such coupon surfaces were optically featureless save for sharp steps at the few grain boundaries. These steps, initially present on the iron after reduction, were not removed by prolonged electropolishing.

A number of polishing variables were investigated. The best results were obtained by polishing in fresh solutions. Such coupon surfaces gave the most marked refraction elongation in diffraction patterns and the best optical polish. Coupons polished in solutions which had been used repeatedly gave some degree of refraction elongation until the solution took on a brown coloration. The presence of ferric ion was suspected of having deleterious effects.

Optimum stirring conditions were determined by trial and error. Inadequate agitation of the bath by stirring gave rise to local etching even at optimum polishing conditions, while excessive agitation disrupted the anolyte layer causing irregular polishing.

A cell voltage of less than 100, for example, 80 volts, produced plateaux with flower-like peripheries on an otherwise well-polished surface. Electron diffraction showed relatively weak iron spots with a high background, which indicated a contaminated surface. At cell voltages of greater than 110, for example, 120 volts, a smooth clean surface with microetching just visible at 1000 diameters was obtained and little evidence of refraction elongation of the diffraction spots was observed.

The removal of the coupon with or without disconnecting the applied potential appeared to make no difference provided the anolyte was displaced quickly. Allowing the anolyte to disperse in the polishing solution caused the surface to pick up excess contamination, as evidenced by a higher ratio of background scatter to spot intensity. In contrast, leaving the anolyte on the iron surface after removal from the bath caused sufficient etching within 60 seconds to obliterate refraction elongation of the diffraction spots.

After final rinsing in alcohol the coupons were transferred under methyl alcohol to the specimen chamber of the electron diffraction camera. In subsequent etching experiments the coupon was agitated under 0.05% nitric acid in conductivity grade water, washed generously with an alcohol jet, and returned to the camera while still moist.

All electron diffraction photographs were taken using a camera length of 50 cm and an accelerating voltage of 50 kilovolts.

RESULTS

The results shown are typical of those obtained from large crystals which developed in the coupons during annealing. The crystal chosen for study had a (521) plane almost parallel to the macroscopic surface, and the diffraction pattern observed with the electron beam parallel to the [$\bar{1}$13] zone axis is indexed in Fig. 2. The specimen was bent slightly to allow the electron beam to be incident on the surface of this particular crystal. The resulting lattice distortion prevented the formation of sharp Kikuchi lines. Many orders of reflection were observed at the one setting of angle of incidence.

On electropolishing this specimen under optimum polishing conditions, Fig. 3 was obtained. Figure 3 shows marked refraction elongation of all spots towards the shadow edge, characteristic of an "atomically smooth" surface. A diffuse spot not belonging to the iron pattern is visible below the (220) iron reflection in Fig. 3. This is attributed to an overgrowth film which also contributed to the background scatter. After a 15-second etch

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

in 0.05% nitric acid, the diffuse background was reduced and the iron pattern increased in intensity (Fig. 4). A diffuse spot still appearing below the (220) iron reflection indicates that some oriented overgrowth was again present on the surface. Little change in the spot elongation suggests that most of the substrate metal was unaffected. (Double spots appearing in Figs. 4, 5, and 6 occurred as a result of the unintentional location of a second crystal of similar orientation in the incident beam.) Figures 5 to 8 illustrate the effect of further etching. Refraction elongation of the iron reflections was gradually reduced and the intensity of the spot from the overgrowth diminished. The diffraction spots in Fig. 8 are characteristic of an etched surface where diffraction is a result of transmission through etch structures.

Exposure of an electropolished surface to the atmosphere at 20° C for 17 hours resulted in Fig. 9. The intensity of the overgrowth spot below the (220) iron reflection has greatly increased and numerous other diffuse reflections are visible.

DISCUSSION

(*1*) *Diffraction Pattern from Substrate*

The details of refraction phenomena in electron diffraction have been discussed by a number of authors (14, 15). Relationships between the angle of incidence of the electron beam (ϕ), the Bragg angle of reflection within the crystal (θ), and the inner potential of the specimen (Φ) are developed in the above literature. A discussion of refraction effects on electropolished surfaces has recently been published (16). The gradual change of refraction elongation of the iron reflections may be discussed with reference to the idealized models in Fig. 10.

On an atomically flat surface (Fig. 10(*a*)), the electron beam suffers refraction as it enters and leaves the crystal through the same surface plane SS' by the path $ABCDE$. It may be shown to suffer an angular displacement of $2(\theta-\phi)$ from the direction of the electron beam in the absence of refraction $FBCDG$. For metal crystals, the inner potential giving rise to this refraction effect is generally of the order of 10 to 15 volts positive. The resulting angular displacement of the electron beam may be about 0.017 radian for low orders of reflection and grazing angles of incidence. If the distance between the specimen and the photographic plate in the diffraction apparatus is 50 cm, the displacement is recorded as an 8.5-mm shift of the diffraction spot towards the shadow edge of the photograph. Some symmetrical spot broadening may be expected due to lack of penetration of the beam normal to the surface of the specimen, resulting in diffraction spots of the type illustrated in Fig. 10(*a*). Such discrete spot displacements are observed on cleavage faces of many crystals and are clearly demonstrated by cleaved rock-salt surfaces (17).

Should isolated etch pits develop on an atomically flat surface, the path of the electron beam may be that of $ABCDE$ shown in Fig. 10(*b*). When the facet $S'S''$ makes an angle β greater than about 10° with the surface plane SS', the deviation of the beam CDE passing across the surface $S'S''$ is negligible. Under such conditions the angular displacement of the beam from the direction in the absence of refraction ($FBCDE$) is $(\theta-\phi)$. If the angle β has values between 0 and 10° the beam suffers refraction displacements varying between $2(\theta-\phi)$ and $(\theta-\phi)$.

A more markedly etched surface may be composed entirely of structures of the type Fig. 10(*c*). The electron beam will suffer no apparent change in direction on passing across the facets SS' or $S''S'''$ providing the angles β and β' are greater than about 10°. If the facets $S'S''$, parallel to the surface, are not developed, all refraction effects should

(*a*) Atomically flat surface; (*b*) very lightly etched flat surface; (*c*) heavily etched surface; (*d*) slightly rolling surface characteristic of electropolishing.

be absent. Small circular diffraction spots should appear in the positions calculated from the normal Bragg relationship ($n\lambda = 2d \sin \theta$). The beam suffers a deviation of 2θ from the initial direction ACF (Fig. 10(*c*)).

The current concept of an electropolished or "atomically smooth" surface is illustrated in Fig. 10(*d*). The rolling nature of this surface gives rise to a range of angles of incidence (ϕ), which when considered in conjunction with a mosaic structure in the crystal, results in elongated diffraction spots of the type illustrated. The displacement of the region of maximum intensity in the spot from the normal Bragg position has been shown to be a function of the mean angle of slope (δ) of the rolling surface, the inner potential of the crystal, and the electron-accelerating voltage (16).

This explanation of refraction elongation of spots from electropolished surfaces is found to be at fault when considered in detail. The concept of a smooth rolling structure on a surface parallel to a major crystallographic plane becomes questionable when the mean angle of slope (δ) is of the order of 0 to 10°. These problems will be discussed more fully in a note to be published elsewhere.

For the present, an "atomically smooth" surface (Fig. 10(*d*)) would account for the shape of the diffraction spots observed from the electropolished surface of an iron single

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

crystal (Figs. 3 and 4). With etching, pits developing in the metal enable effects of the type Fig. 10(*b*) to contribute more strongly to the spot intensity. The observed spot elongation due to refraction is thus reduced (Figs. 5, 6, 7). Further etching covers the surface with structures of the type Fig. 10(*c*). If a suitable etchant is chosen so that no facets parallel to the surface are developed, no evidence of spot elongation should be apparent (Fig. 8).

At present it is not possible to determine from the shape of the diffraction spots the relative areas of the specimen surface giving rise to the separate effects Figs. 10(*a*), (*b*), (*c*), and (*d*). The change in spot elongation observed during etching serves only as an indication that intermediate states exist between that of an electropolished (Fig. 10(*d*)) and the completely etched state (Fig. 10(*c*)). It is hoped that the correlation of electron micrographs and electron diffraction photographs from such surfaces will enable a more accurate assessment of the surface microstructure.

(*2*) *Overgrowth*

The overgrowth material giving rise to the diffuse spot below the (220) iron reflection in Fig. 3 is probably an oxide film formed during electropolishing. The identification of this material is being attempted using similar results obtained from iron surfaces parallel to other crystal planes. On exposure of an electropolished surface to air for 17 hours at 20° C, the overgrowth thickens, resulting in Fig. 9. The diffuse spots due to the overgrowth in this pattern are in good agreement with either of the cubic oxides Fe_3O_4 or γ-Fe_2O_3, confirming the results of Nelson (18) and Haase (19). The (111) plane of the oxide is parallel to the (110) of the metal, and the $[11\bar{2}]$ azimuth of the oxide is parallel to the $[\bar{1}13]$ azimuth in the metal. This corresponds to an orientation of the close-packed oxygen planes in the oxide on the closest-packed (110) planes in the b.c.c. iron. A more complete investigation of this epitaxial relationship is in progress. Figure 9 illustrates the suitability of the electropolished surface for the investigation of thin oxide films. Cathodic reduction of such an air-formed film of oxide on iron shows it to be of the order of 10 to 20 Å thick.

After etching of the electropolished surface, a diffuse spot is still visible below the (220) iron reflection (Figs. 4 to 8). This spot is due to an overgrowth material developed during rinsing and air exposure as the specimen was loaded into the diffraction apparatus and the instrument evacuated. The film should develop to the same thickness on each exposure after etching. The observed decrease in intensity of the spot due to this material in Figs. 4 to 8 resulted from the decreased ratio of film to substrate which was traversed by the electron beam on the etched surface.

(*3*) *Electropolishing*

Electropolishing is generally considered to take place by the anodic dissolution of metal through a thin film of conversion product. During the process both metal and film dissolve. The composition of the film probably depends on both the current density and potential and is probably different from the film formed on air exposure. At voltages and current densities below the optimum there appears to be a thick polishing film which is uneven in thickness or conductivity and leads to both uneven polishing and high scattering of the electron beam. At higher than the optimum voltage and current density the polishing film is too thin to prevent etching of the metal by the highly acid polishing solution. Due to different activities of the different crystal planes some very light etching was occasionally observed on some grains even under good polishing conditions. This etching takes place first on grains with a (110) plane parallel to the specimen surface.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The strong refraction effect on the smooth electropolished surface results in broad banding in the electron diffraction patterns of randomly oriented polycrystalline specimens. It would appear that the assessment of electropolished surfaces by the use of electron diffraction should be made using large-grained polycrystals or single crystals.

CONCLUSION

Iron can be electropolished in the acetic–perchloric bath to give an "atomically smooth" surface with a very small amount of overgrowth. The film formed during electropolishing can be removed by treatment in dilute nitric acid. This treatment also etches the metal, thus changing the character of the diffraction pattern. On exposure to air, the film present after electropolishing thickens to form a cubic iron oxide with preferred orientation. On the basis of the electron diffraction evidence, the electropolishing and etching procedure developed above should serve as a proper method of specimen preparation for corrosion and oxidation studies.

OXIDATION OF D-GALACTURONIC ACID WITH SOME DELIGNIFYING AND BLEACHING AGENTS[1]

R. H. ZIENIUS[2] AND C. B. PURVES

ABSTRACT

D-Galacturonic acid was oxidized with decreasing ease, and in the approximate order shown, by excess of the following agents: sodium chlorite near pH 2.8 and 75°; sodium hypochlorite at pH 10–11 and 25°; chlorine dioxide, pH 1.3 or 5 at 75°; chlorine near 0° and pH 5 (slight); and hydrogen peroxide at pH 10–11 and 25° (negligible). Some uronic acid was always recovered unchanged, even from conditions that would have oxidized glucose quantitatively to gluconic acid. The only other products were mucic acid, together with DL-tartaric acid and tartronic acid presumably derived therefrom. Chlorine dioxide, however, never produced tartronic acid. Methyl-α-D-galacturonoside methyl ester yielded some galacturonic acid when exposed to alkaline hypochlorite or peroxide, and this cleavage of the glycosidic group was tentatively attributed to the oxidants rather than to the alkalinity of the systems.

Anhydrous bromine degraded the silver salt of methyl-α-D-galacturonoside in poor yield to a syrup which was probably L-arabotrihydroxyglutaric dialdehyde.

INTRODUCTION

In connection with a study of the action on pectic acid of agents used for delignifying wood and for bleaching cellulose, it seemed desirable to conduct some preliminary experiments with D-galacturonic acid and its methyl-α-glycoside methyl ester. The presence of the carboxyl group in the sixth position of these substances would be expected to make the fifth position more readily oxidizable than the corresponding position in non-acidic carbohydrates. As Link and his collaborators pointed out (1), oxidation of uronic acids with periodic acid yielded a dialdehyde in which the fifth position lay between an aldehyde and the carboxyl group. Such enhancement of the effect produced by the carboxyl group alone probably explained why the fifth position was then oxidizable even by an agent as mild as periodic acid. This assumption received solid support from later work on the overoxidation of uronides (2, 3), and the oxidation of the methylene group in malonic acid (4) by periodate; also from the oxidation of acetylacetone by lead tetraacetate (5). D-Galacturonic acid was, of course, oxidized by many agents to mucic acid, and could also be degraded in high yield to L-araboglutaric acid even by oxygen in aqueous barium hydroxide (6).

In the present experiments, a solution of pure galacturonic acid in a 10-fold molar amount of aqueous sodium chlorite buffered near pH 2.8 was kept at 70–75° for 150 minutes. These conditions resembled those used for delignifying wood meals by Wise's method (7). After excess oxidant and all cations were removed by appropriate methods described below, the solution was concentrated and the mucic acid that separated was removed. The concentrate was then resolved into its components by passage through a column of anion-exchange resin followed by paper partition chromatography. Galacturonic acid, DL-tartaric acid, and tartronic acid were recovered in pure crystalline form, the identities of the last two being confirmed by preparing the crystalline di-*p*-nitrobenzyl ester, and the crystalline dimethyl ester, respectively. The recovery of unchanged galacturonic acid was unexpected, because the conditions of the oxidation would have oxidized the aldehyde group in glucose (8) or in veratraldehyde (9) swiftly and almost quantitatively to carboxylic acid.

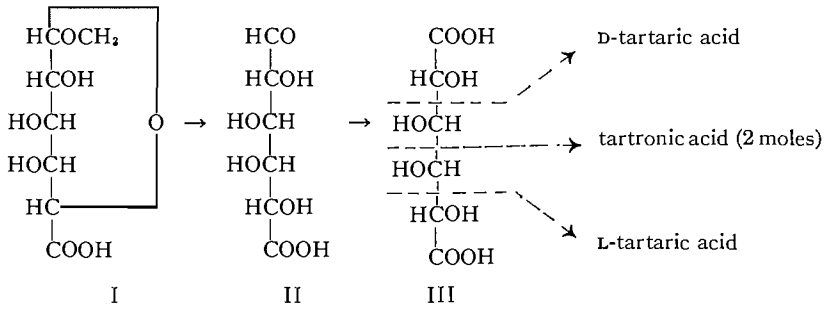
A similar oxidation employed a 10-fold molar amount of aqueous chlorine dioxide, buffered near pH 2.7 and kept at 70–75° for 150 minutes. Some unchanged galacturonic acid was recovered, as might have been expected from the resistance of glucose to oxidation with chlorine dioxide at 20° (8); also some mucic acid and DL-tartaric acid, but tartronic acid was absent. The pure, crystalline methyl ester of methyl-α-D-galacturonoside, when oxidized for 2 hours at 25° with a 3-fold molar amount of sodium hypochlorite at pH 11.5, yielded DL-tartaric acid and tartronic acid, but, in addition, acidic methyl-α-D-galacturonoside and galacturonic acid itself, all of which were crystallized and carefully identified. Mucic acid was absent. The appearance of galacturonic acid in this experiment was attributed to oxidation, since small amounts of glucose were isolated from methyl-β-D-glucopyranoside (10) and cellulose (11) oxidized with hypochlorite at pH 4–4.5. When the methyl ester methyl glycoside of galacturonic acid was kept at 25° for several hours in 1% sodium hydroxide (pH 12), free galacturonic acid formed only if traces of air were present. This observation contrasted sharply with the relatively great resistance of uronosides to acid hydrolysis (12) and with the claim that methyl-α-D-galacturonoside and its methyl ester were both non-reducing to Fehling's solution (13). Although the methyl ester of methylglucopyranuronoside was also non-reducing and required the proper amount of alkali when saponified, the 3,6 lactones of methyl-β-D-glucofuranoside and 1,2-di-*O*-isopropylidene glucofururonic acid both reduced Fehling's solution and slowly neutralized more than the theoretical amount of alkali (14). The instability toward alkali of methyl pectate was discussed in the review by Whistler and BeMiller (15). In the present case, the action of alkali alone on galacturonic acid, its methyl glycoside, and methyl glycoside methyl ester, could well be the subject of a separate research. After treatment with 1% sodium hydroxide, the product from the methyl glycoside methyl ester, for example, yielded paper chromatograms showing only the spots characteristic of the acidic methyl glycoside and of galacturonic acid, and there was no clear evidence of either saccharinic acids or Lobry de Bruyn inversion products derived from galacturonic acid. Chromatographic evidence of such inversion products would be expected if an aldohexose had been submitted to the same conditions.

Since the only tartaric acid isolated in the above three oxidations was the DL-isomer, whose purity and optical inactivity were always carefully checked, it followed that the galacturonic acid or its methyl glycoside had been cleaved at equal rates at the 2,3- and 4,5-positions. Such symmetrical cleavage suggested that one of the initial products of oxidation was mucic acid, whose symmetry made it inevitable that the 2,3- and 5,6-positions would be equally liable to further oxidation. Oxidative cleavage at the 3,4-position would give the tartronic acid found. Mucic acid, when oxidized with chlorine dioxide, did, in fact, yield paper chromatograms with the spot characteristic of DL-tartaric acid; oxidation with chlorite and with alkaline hypochlorite yielded traces of tartronic acid, as well as of DL-tartaric acid. Structures I, II, and III illustrate these suggestions. Parallel test oxidations with glucurone showed that the phenomena discussed above were probably valid for uronic acids in general, though, of course, the products from glucurone were not the same as those from galacturonic acid.

When butanol – formic acid – water was the solvent in paper chromatography, the R_F values for galacturonic acid, its methyl-α-glycoside, DL-tartaric acid, and tartronic acids were well spaced at 0.04, 0.11, 0.21, and 0.38–44, respectively, and these compounds were easily distinguished from each other. A series of small-scale oxidations of galacturonic acid yielded chromatograms with spots at one or more of the four positions but no chromatogram contained additional spots at other R_F values. The chromatograms



I II III

were also sprayed with *o*-aminodiphenyl to detect any carbonyl compounds formed, but the results were uniformly negative. Although all of the oxidants tried thus yielded one or more of the same acids, and no others, it should be emphasized that the yields were small, and that any non-reducing, non-acidic products would not have been detected. As before, mucic acid was isolated directly from the concentrated liquors.

The results (Table I) showed that the behavior of chlorine dioxide depended to some extent on the hydrogen ion concentration of the solution. The production of some mucic acid near pH 1.3 agreed with the slow conversion of aldoses to aldonic acids by this

dioxide had no effect on sugars and polysaccharides thus did not apply strictly to galacturonic acid. Attempts to oxidize galacturonic acid at room temperature in a sodium borate buffer at pH 9, in 1% ammonium hydroxide (pH 10.5), or by continuously bubbling the gas through an ammonium hydroxide – sodium hydroxide solution kept near pH 12, yielded little or no mucic acid, and only traces of tartaric acid. As expected (8, 9), sodium chlorite readily oxidized the aldehyde group in galacturonic acid to give mucic acid as a major product, but the other major product was tartronic acid, no trace of which had been observed at any pH when the oxidant was chlorine dioxide. The result supported the opinion (8, 9) that sodium chlorite was an oxidant in its own right, and its effects could not be completely attributed to by-product chlorine dioxide. The possibility that the latter was exclusively responsible for the trace of DL-tartaric acid formed was not investigated.

Only traces of oxidation were observed when chlorine gas was bubbled through a solution of galacturonic acid kept near 0° and pH 5, conditions reminiscent of those used to delignify wood by one or other of the chlorination processes (17, 18). At pH 10–12 and 25°, however, hypochlorite produced relatively extensive oxidation to mucic and tartronic acids, with lesser amounts of DL-tartaric acid, and thus resembled acidified sodium chlorite in its action. The resemblance included the survival of some of the galacturonic acid in circumstances where glucose would have been rapidly and almost quantitatively oxidized to gluconic acid. Alkaline hydrogen peroxide appeared incapable of oxidizing galacturonic acid at 25°, although some of this acid was produced from the corresponding methyl-α-glycoside methyl ester. As in the case of alkaline hypochlorite, the loss of the glycosidic methyl group was tentatively attributed to the oxidant rather than to the alkalinity.

Kleinberg (19) reviewed the degradation of the anhydrous silver salts of many organic acids to the lower halides by elemental chlorine, bromine, or iodine,

$$RCOOAg + Br_2 \rightarrow RBr + CO_2 + AgBr,$$

and the reaction was extended to alginic acid, penta-*O*-acetyl gluconic acid, and an oxycellulose acetate by Rice and Johnson (20). A mixture of the anhydrous acid chloride and silver oxide could be substituted for the silver salts in these reactions (20). Since salts of simple uronic acids had apparently not been degraded in this way, a few preliminary experiments were carried out with galacturonic acid and its methyl glycoside. Little or no action occurred when dry calcium galacturonate was suspended in carbon tetrachloride containing an equimolar amount of bromine. The same reagent, however, caused the quick evolution of carbon dioxide from the silver salt of methyl-α-D-galacturonic acid. Extraction of the product with water gave a neutral, strongly reducing solution, free of silver and bromide ions, from which a clear syrup was isolated by paper chromatography. This syrup was free of methoxyl groups and yielded a crystalline phenylhydrazone melting at 128–129°. By analogy with the earlier work, the methyl galacturonide (I) would first be degraded to an acetobromo derivative (IV), which probably decomposed during isolation to yield the methoxyl-free dialdehyde (V). The yield of the crystalline di-phenylhydrazone, however, was only 8–10% of theory, the compound was not pure, and the work was discontinued. The product appeared to be of the same type as the xylotrihydroxyglutardialdehyde bis-phenylhydrazone derived from the oxidation of 1,2-*O*-isopropylidene-D-glucofuranose with lead tetraacetate (21) or sodium periodate (22, 23).

IV V

EXPERIMENTAL

All solutions and eluents were concentrated in a rotatory film evaporator under diminished pressure at not more than 50°. Melting points were corrected and analyses were quoted as the mean of concordant determinations.

Materials and Methods

The methyl ester of methyl-α-D-galacturonopyranoside monohydrate was prepared by boiling crystalline D-galacturonic acid, 25 g, in methanolic hydrogen chloride (13, 24), and after recrystallization from water had m.p. 142–144°, and specific rotation in water $[\alpha]_D^{20}$ +122° (*c*, 1.0%).

To prepare the silver salt, 1.1 g of the methyl ester was saponified by solution for 1 hour at room temperature in 50 ml of 0.1 *N* sodium hydroxide in a nitrogen atmosphere. Silver acetate, 0.72 g dissolved in 50 ml of hot water, was then added and a few minutes later the solution was filtered. Evaporation of the filtrate to small volume caused the white salt to separate. Yield, 0.7 g or 67%. Found: Ag, 33.5%. Calc.: Ag, 34.3%.

Di-(*p*-nitrobenzyl)-DL-tartrate, prepared from the crystalline disodium salt and *p*-nitrobenzyl bromide (25), after recrystallization from 63% ethanol melted correctly at 146–148°. The dimethyl ester of tartronic acid, also required for reference purposes, was prepared by boiling 0.1 g of the free acid under reflux for 2 hours in 3% methanolic hydrogen chloride. After removing halide ions as the silver salt and any residual cations by an ion-exchange resin, the liquid was concentrated and chilled. The crystalline dimethyl ester separated, and its melting point was correct at 43–45° (26).

Chlorine-free, 0.25–0.35 *M* solutions of chlorine dioxide were prepared from Schacherl's mixture of potassium chlorate, oxalic acid, and 33% sulphuric acid with the precautions noted elsewhere (27) and were standardized iodometrically. Chlorine dioxide was assumed to have five oxidizing equivalents in this standardization, whereas sodium chlorite had only four (27). Solutions of sodium hypochlorite were standardized either iodometrically or by the method employing arsenite.

Paper partition chromatography, employing Whatman No. 1 paper, and 10 lambda (10^{-2} ml) aliquots, was carried out by conventional methods. The solvent system was butanol – formic acid – water (500:115:385 vol.) (28), and the chromatograms after being dried *in vacuo* at 115° were sprayed with bromphenol blue in 90% ethanol (29). This spray gave yellow spots with sugar acids, and was stable indefinitely if stored in the dark at −10°. Residual traces of hydrochloric and chloric acids were retained at or near the starting line in these chromatograms. The best separations by column chromatography were obtained with a 50–100 mesh Dowex 1-4X anion-exchange resin which was converted from the chloride to the acetate form by washing in succession with 5% sodium hydroxide, water, *N* acetic acid, and water.

Oxidations of D-*Galacturonic Acid*

(*a*) *With Chlorine Dioxide*

Galacturonic acid, 18 g (93 mmole), was dissolved in a 10-fold molar amount of aqueous 0.3 *M* chlorine dioxide adjusted to pH 5 with acetic acid and kept at 70–75°. After 150 minutes the solution was cooled, and excess chlorine dioxide was removed by the passage of nitrogen gas. Concentration then caused the separation of crystalline mucic acid, decomp. 214–217°, and a paper chromatogram of the filtrate showed it to contain only unchanged galacturonic acid, R_F 0.04, a tartaric acid, R_F 0.21, and traces of inorganic acids.

A few grams of Dowex 1-4X anion-exchange resin (acetate form) was dispersed in the concentrate, and several hours later the resin with the absorbed acids was recovered and added to the top of a 102 cm × 5 cm column of the same resin. Elution of the column with water, and then with increasing concentrations of acetic acid, failed to remove any sugar acids until *N* acetic acid was used. Twelve 1-liter fractions then contained the galacturonic acid, which crystallized when the combined fractions were concentrated and chilled. After recrystallization, the galacturonic acid had the correct m.p., 158–159°, and the correct initial specific rotation of $[\alpha]_D^{20}$ +97° in 1% aqueous solution. The sample when oxidized with nitric acid gave mucic acid, decomp. 215–217°.

More concentrated acetic acid, *N* to 3 *N*, failed to remove sugar acids from the column, but elution with 0.5 *N* trifluoroacetic acid, 100 ml fractions being collected, removed both DL-tartaric acid and inorganic acids. These eluates were combined, concentrated to a very small volume, and spotted on sheets of Whatman No. 3MM chromatography paper, 50 mg being in each spot. The portions of paper containing the tartaric acid were extracted with water, and the product crystallized from the concentrate. After recrystallization, the m.p., 203–204°, the neutralization equivalent, 75, and the optical inactivity in water (*c*, 1%) were correct for DL-tartaric acid. A mixed melting point with an authentic sample was undepressed, and the m.p., 146–148°, of the crystalline di-(*p*-nitrobenzyl)-DL-tartrate was also satisfactory.

Several experiments with 0.35-g samples of galacturonic acid were carried out at room temperature and different pH values, and the results were assessed by paper chromatograms (Table I). A larger quantity of acetic acid was used to maintain pH 1.3. The buffer for pH 5 consisted of acetic acid and 3.2% aqueous sodium acetate, the sodium ions being afterwards removed by Amberlite IR-120 cation-exchange resin. In an experiment at pH 9, 0.35 g of galacturonic acid was dissolved in 70 ml of a potassium chloride – boric acid – sodium hydroxide buffer (30), but as soon as 20 ml of 0.27 *M* chlorine dioxide was added the pH decreased and more sodium hydroxide had to be added. Two further additions of the same amount of chlorine dioxide were made at intervals of 30 minutes, with additions of alkali to maintain pH 9, and after 2 hours the solution was shaken with silver carbonate. Insoluble silver salts were removed, and the filtrate was evaporated to dryness. The residue was taken up in 100 ml of acidified methanol and the solution was evaporated to dryness; several such cycles sufficed to remove all boric acid as the volatile methyl ester. An aqueous solution of the residue was then prepared for chromatography by passage through Amberlite IR-120 cation-exchange resin. An experiment that yielded only a trace of tartaric acid, R_F 0.21, consisted of adding a solution of 0.35 g of galacturonic acid in 100 ml of 1% ammonium hydroxide to 50 ml of 0.21 *M* chlorine dioxide (6-fold amount). After 2 hours at 70–75° the solution was colorless, but on acidification to pH 2–3 with acetic acid the characteristic odor and color of chlorine dioxide reappeared. A similar ammonia solution was kept at pH 12 by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

the continuous addition of sodium hydroxide while chlorine dioxide was bubbled through it, but little or no oxidation of the galacturonic acid occurred.

(*b*) *With Sodium Chlorite*

A solution of galacturonic acid, 5.5 g, and 18.7 g of sodium chlorite (10-fold molar amount) in 1430 ml of 10% acetic acid (pH 2.7–2.9) was kept at 70–75° for 150 minutes. By-product chlorine dioxide then was expelled by the passage of nitrogen gas, and any remaining oxidizing agents were destroyed by the addition of a little cold, 48% hydriodic acid, the liberated iodine being promptly extracted with ether. After the removal of halides as the silver salts, the filtered solution was passed through a column of Amberlite IR-120 cation-exchange resin, and was concentrated. Mucic acid, decomp. 215–218°, separated, and after further concentration the filtrate was separated on a 91.5 cm × 5 cm column of Dowex 1-4X resin (acetate form) as described in the oxidation with chlorine dioxide. Galacturonic acid again crystallized from the *N* acetic acid eluates and after recrystallization had the correct melting point and specific rotation. Oxidation with nitric acid yielded mucic acid.

DL-Tartaric acid and tartronic acid occurred together in the 0.5 *N* trifluoroacetic acid eluates, and were separated by paper chromatography. After recrystallization, the DL-tartaric acid was optically inactive, melted correctly at 204–205°, had the correct neutralization equivalent, and yielded the crystalline di-(*p*-nitrobenzyl) derivative with the proper melting point. The tartronic acid solution was evaporated to dryness because no crystallization occurred on cooling of the concentrated liquor. A solution of the residue in water was evaporated to dryness several times to eliminate formic acid, and the tartronic acid then crystallized. After recrystallization from water, the product had the correct m.p., 141–143°, and neutralization equivalent, 61.0, and was optically inactive (water, *c*, 1%). Its identity was confirmed by conversion to dimethyl tartronate, m.p. 44–45°.

(*c*) *With Chlorine*

A solution of 0.35 g of galacturonic acid in 100 ml of water buffered to pH 5 with acetic acid – sodium acetate was kept near 0° while chlorine gas was bubbled through it for 10 minutes. Most of the gas was removed by the passage of nitrogen, and any residual oxidant was destroyed by the addition of a small amount of hydriodic acid, liberated iodine being extracted with ether. After neutralization with silver carbonate, the clarified liquor was passed through Amberlite IR-120 resin, and the cation-free effluent was concentrated. A small amount of mucic acid, decomp. 215–216°, separated, and after its removal the concentrate was chromatographed on paper.

(*d*) *With Sodium Hypochlorite*

Galacturonic acid, 0.35 g, was dissolved in 50 ml of water and the solution was adjusted to pH 11.7 with aqueous sodium hydroxide. After 8 ml of 0.75 *M* sodium hypochlorite (3-fold molar amount) had been added the mixture was kept at 25° for 2 hours, during which period the pH decreased to 11.3. The solution was acidified, treated with dilute hydriodic acid and silver carbonate, and freed of cations as described above. A large amount of mucic acid, decomp. 214–216°, was removed prior to chromatography.

(*e*) *With Hydrogen Peroxide*

A solution of 0.35 g of galacturonic acid in 100 ml of water, adjusted to pH 9.9 with aqueous sodium hydroxide, was mixed with 2 ml of 0.98 *M* hydrogen peroxide (1.1 molar amount), and kept at 25° for 90 minutes. After acidification with acetic acid, the excess oxidant was reduced by the addition of a little 48% hydriodic acid, 30 minutes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

being required for this reaction to become complete. The iodine formed was extracted with ether. Neutralization, the removal of cations, and concentration yielded a solution containing unchanged galacturonic acid.

Methyl-α-D-galacturonoside Methyl Ester and Sodium Hypochlorite

Five grams of the crystalline methyl glycoside methyl ester monohydrate was oxidized at pH 11.7 and 25° with a 3-fold molar amount of aqueous sodium hypochlorite, and the products were recovered, as in the parallel oxidation of galacturonic acid. These products were: acidic methyl galacturonoside, m.p. 112–114°, $[\alpha]_D^{20}$ +130° in water (*c*, 1.0%); galacturonic acid, m.p. 158–159°, initial $[\alpha]_D^{20}$ +97° in water (*c*, 1.0%); optically inactive DL-tartaric acid (1% aqueous solution), neutralization equivalent, 75.8, and m.p. 203–204°; and optically inactive tartronic acid, m.p. 142–144°, and neutralization equivalent 61.0. All these constants were in good agreement with those of authentic samples.

Attempted Decarboxylations with Bromine

In a typical experiment, 1 g of the dry silver salt of methyl-α-D-galacturonoside, dispersed in 100 ml of anhydrous carbon tetrachloride, was treated with 0.3 ml, or the equimolar amount, of bromine (31). A rapid reaction occurred initially, with the evolution of some heat and carbon dioxide. After the mixture had been warmed for 10 minutes at the end of this reaction, the insoluble portion was washed with carbon tetrachloride and dried over silica gel. The yellow-white solid, 0.9 g, was extracted with three 75-ml volumes of water to remove insoluble silver salts. The combined extracts were free of silver and bromine ions, and gave a negative test for carboxylic acid groups, but a strongly positive test for aldehydic groups. No solid separated when the extracts were concentrated, but a small aliquot when chromatographed on paper yielded a single spot of R_F 0.84 (butanol – formic acid – water system, *o*-aminodiphenyl spray).

An orange precipitate immediately formed when the above concentrate was mixed with 5 ml of water containing 0.5 g of phenylhydrazine hydrochloride and 0.8 g of sodium acetate. After being dried, this precipitate weighed 0.1 g (10%), and melted at 129–130°. Found: OCH_3, 0.0; N, 23.7%. Calc. for the bis-phenylhydrazone of a trihydroxyglutardialdehyde, $C_{17}H_{20}N_4O_3$: OCH_3, 0.0; N, 17.1%.

When the molar ratio of bromine to the silver salt of the methyl galacturonoside was doubled, the yield of the crystalline phenylhydrazone was 8%. Found: OCH_3, 0.0; N, 20.5%.

THE EXCHANGE OF OXYGEN-18 BETWEEN CELLULOSE, ADSORBED WATER, AND WATER VAPOR[1]

A. R. G. LANG AND S. G. MASON

ABSTRACT

The adsorption on regenerated cellulose of water at vapor pressures of 0 to 40 μ Hg has been measured by an oxygen-18 dilution technique. The results showed that cellulose may be dried to less than 0.04% moisture by evacuation at 70° C. The adsorption isotherm was compared with that of Taylor for viscose rayon.

It was also shown that oxygen-18 does not exchange between cellulose and water.

INTRODUCTION

The experiments described in this note provided supplementary information for a study of the exchange of tritium between cellulose and water vapor described elsewhere (1). In order to correct the experimental data for the exchange occurring between the water vapor and the water adsorbed on the cellulose even after prolonged evacuation, it was necessary to know the amount of water adsorbed under the conditions of the experiments.

The published values for the amount of adsorbed water present on cellulose at very low vapor pressures (2–5) actually represent the incremental adsorption above a certain minimum defined by the method of drying; there still exists, however, some doubt as to whether cellulose can be completely freed from adsorbed water. In the usual method of drying by heating to 105–110° C, in an air oven, up to 0.5% by weight of water remains as a result of the small but nevertheless significant water vapor pressure (6, 7). On the other hand, it is generally considered that cellulose is completely dried by prolonged desiccation over phosphorus pentoxide at room temperature (6) or at elevated temperatures (8), by heating in a stream of dry gas (8), or by extended evacuation (2–5, 7). However, in all these measurements the sole criterion of dryness was that the mass of cellulose had reached a minimum value. Recently it was reported from the direct titration of cellulose by the Karl Fischer reagent that 1% adsorbed water remained on cellulose dried over phosphorus pentoxide (9).

In the present experiments, these uncertainties were eliminated by measuring the dilution of oxygen-18 when oxygen-18-enriched water was mixed with the adsorbed water *in situ*. The method requires, however, that the oxygen atoms of cellulose do not exchange with those of water, and it was therefore first necessary to determine whether or not such exchange was taking place.

Oxygen-18 generally does not exchange between alcohols and water (10). However, only one author (11) has studied the system cellulose/water and a critical study of his data showed that less than 6% of the cellulose oxygens reacted. Since this precision was inadequate for the present work, it was necessary to extend the measurements.

PROCEDURE

In the method used, known quantities of dried cellulose and O^{18}-enriched water were reacted together, the water recovered, and the dilution of the O^{18} measured mass spectrometrically. Dilution could be caused both by exchange with the oxygen atoms of the

[1]*Manuscript received July 6, 1959.*
Contribution from the Physical Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Que., and the Department of Chemistry, McGill University, Montreal, Quebec.

cellulose molecules, and by mixture with adsorbed water. The quantities were chosen so that an adsorption of 1 mg water per g cellulose would cause a 10% change in the concentration of O^{18}.

Figure 1 shows the apparatus. It was made of brass and copper, except for the Pyrex glass jacket (F) of the trap and the tared recovery tube (H). The train could be broken at E so that the reaction vessel could be connected directly to the vacuum system, which

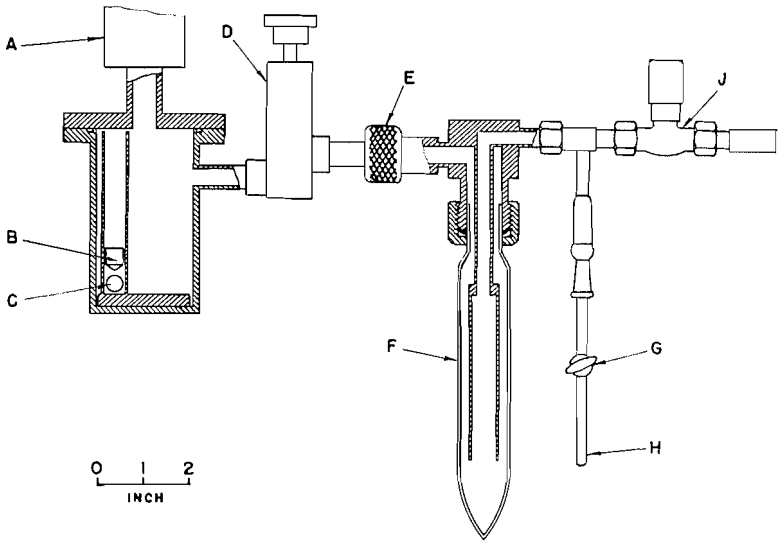

FIG. 1. Apparatus. A, Pirani gauge; B, plunger; C, ampoule; D, valve; E, vacuum coupling; F, trap; G, stopcock; H, tared glass tube; J, valve.

consisted of a mechanical pump, a two-stage oil diffusion pump, and a liquid-air trap.

Air-dried gel cellulose film was used, made from viscose and neither plasticized nor coated. This sample was identical with sample *c* used previously (1). For each experiment, strips 7.5 cm wide by 23 μ thick and weighing 2 g on a dry basis (oven-dried at 105° C) were folded backwards and forwards on themselves and placed in the reaction vessel together with a thin-walled Pyrex ampoule (C) containing 0.02 g of water having an O atom content of 9.4% O^{18}. The masses of cellulose and water (with the necessary correction for buoyancy of the evacuated ampoule) were determined within 1%.

The cellulose was dried to various degrees by evacuating the reaction vessel. In one case the reaction vessel was heated to about 70° C during the reaction; in all other cases the temperature was about 25° C. Details including times of evacuation are given in Table I. After the evacuation, the cellulose was isolated by closing valve D, and the gas pressure was measured at intervals for a total time of up to 3 hours with an Edwards Pirani gauge, Type MA-5 (A, in Fig. 1), which had been calibrated against a McLeod gauge. Since the empty reaction vessel leaked air (0.071 μ Hg per minute), the equilibrium water vapor pressure was obtained as follows: The pressure was plotted against time to yield curves illustrated in Fig. 2. When the slope of a curve reached the constant value of 0.071 μ Hg per minute, measurements were discontinued; the linear part of the graph was then extrapolated back to zero time and the intercept on the pressure axis taken as the equilibrium water vapor pressure.

To bring about the exchange the reaction vessel was shaken until the stainless steel plunger (B, Fig. 1) broke the ampoule of water (C). The reaction continued for 8 to 8.5

TABLE I

Adsorption of water on cellulose at low vapor pressures

Experiment	Sample	Evacuation: Time, hours	Evacuation: Temp., °C	P equilibrium H_2O, μ Hg	Oxygen-18 in recovered water, atom fraction	m/M*	Water adsorbed at P, mg/g
1	Blank	21	25	0	0.0941	—	0
2	Cellulose	59	70	< 0.1	0.0932	0.0089	0.10
3	Cellulose	47	23	4	0.0815	0.0104	1.61
4	Cellulose	40	24	6.5	0.0693	0.0099	3.52
5	Cellulose	35	25	16	0.0681	0.0104	3.95
6	Cellulose	23	27	41	0.0589	0.0108	6.46

*m/M = (mass of water in ampoule, g)/(mass of dry cellulose, g).

hours at 23 to 27° C, and then the water was collected by evacuating the reaction vessel through the trap (F) cooled with a Dewar flask of liquid air. Valves D and J were then closed and the Dewar of liquid air moved from the trap to the lower end of the tared tube (H) so that the water distilled into it. Stopcock G was then closed and the tared tube (H) removed from its matching ground-glass joint and weighed. Between 50 and 60% of the total water reacted with the cellulose was recovered. The isotope effect in this distillation is negligible: calculations assuming the extreme case of equilibrium distillation (1) and using the values of the vapor pressures of the H_2O^{18} and H_2O^{16} given by Huffman and Urey (12) show that the concentration of O^{18} in the distillate after 50% recovery is the same (within 0.6%) as before distillation.

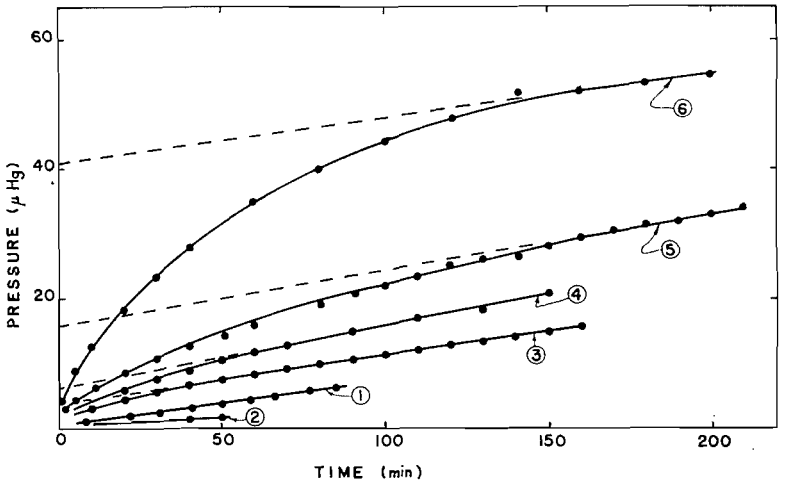

FIG. 2. Estimation of equilibrium pressure. Circled figures are experiment numbers.

The concentration of the O^{18} in the water in tube H was determined by the method of Dostrovsky and Klein (13). The water was exchanged with carbon dioxide, then the ratio of the 44/46 mass peaks of the carbon dioxide was measured four times in a mass spectrometer. The concentration of the O^{18} in the water was calculated from relationships given by Dostrovsky and Klein.

RESULTS AND DISCUSSION

The results are summarized in Table I.

When the sample was evacuated until the vapor pressure was practically zero (experi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

ment 2), almost no dilution of the O^{18} occurred. This experiment showed simultaneously that no exchange occurred between the oxygen atoms of the water and the cellulose (less than 0.08% of the cellulose oxygens), and that no water (less than 0.4 mg per g) remained adsorbed in the cellulose. The amount of adsorbed water on the cellulose for experiments 2 to 6 was therefore given from an O^{18} balance as:

$$A = \frac{m}{M}\{(N_i/N_f)-1\}$$

where A is the adsorbed water (milligrams per gram of cellulose), m the mass of water in the ampoule (milligrams), M the mass of cellulose on an oven-dry (105° C) basis (grams), and N_i and N_f the initial and final atom fractions of O^{18}.

The zero adsorption of water in experiment 2 removed any reasonable doubt that cellulose can be completely dried by evacuation with heat. Since this fact was assumed in the low-pressure adsorption studies of Taylor (2, 3, 4) and Neale and Springfellow (5) its establishment adds reliance to their experimental values.

Figure 3 shows the relationship between the amount of adsorbed water and the estimated vapor pressure. Except for the zero value the vapor pressures were probably less

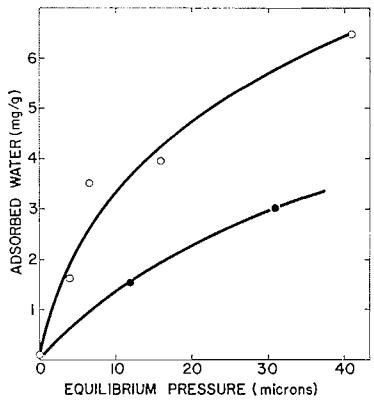

FIG. 3. Graph of adsorbed water on cellulose versus water vapor pressure. —○— Oxygen-18 dilution method (desorption branch). —●— Results of Taylor (2) for viscose rayon (reproducible adsorption branch).

than the true equilibrium values, because, although it takes several days to reach equilibrium (2), in the present experiments only 3 hours were allowed. The sorption values reported here are, therefore, upper limits for the desorption branch of the sorption cycle. This is supported by the comparison with the somewhat lower "reproducible adsorption" values for viscose rayon reported by Taylor (2), who also demonstrated that appreciable sorption hysterisis occurred at these low pressures.

ACKNOWLEDGMENT

The authors are indebted to Dr. H. I. Schiff, Chemistry Department, McGill University, for performing the mass spectrometric analyses.

THE MERCURY-PHOTOSENSITIZED DECOMPOSITIONS OF PROPANE AND ETHANE[1]

R. A. BACK[2]

ABSTRACT

The mercury-photosensitized decompositions of propane and ethane have been studied at pressures of 300 and 600 mm, at 24° C, at very low conversions. Hydrogen was the only product identified and measured. The hydrogen yield fell rapidly at first, with increasing time of irradiation, and finally became constant. This behavior is attributed to the accumulation in the system of propylene or ethylene formed by the disproportionation of propyl or ethyl radicals, and the constant rate of hydrogen production finally achieved is thought to correspond to a steady-state concentration of the unsaturate. Previous values of the quantum yields of these decompositions were probably measured in this steady-state region, and must be corrected upwards.

Relative values have been estimated for the various rate constants involved in this mechanism. There is some evidence that energy-rich radicals, formed by the addition of hydrogen atoms to the unsaturates, tend to disproportionate rather than dimerize.

INTRODUCTION

In a previous study of the mercury-photosensitized decomposition of *n*-pentane at very low conversion, the hydrogen production decreased rapidly at first, then more slowly, and finally became constant after about 0.5% reaction (1). This was attributed to the accumulation in the system of pentene, formed by disproportionation of pentyl radicals, and the final constant rate of hydrogen production was thought to correspond to a low, steady-state concentration of pentene. The hydrogen yield was reduced, and pentene consumed, by the addition of hydrogen atoms to pentene. Similar behavior has been observed with the cyclo-alkanes (2), and more recently with *n*-butane (3). Previous studies of the mercury-photosensitized decomposition of propane and ethane did not show this effect, as hydrogen production was independent of time (4). However, rough calculations from the relative rates of the reactions concerned suggest that even the smallest conversions achieved in these experiments were probably much too large for the initial behavior to be observed. It was decided to study these reactions at very low conversions to see whether they behaved in the same way.

EXPERIMENTAL

The apparatus, a conventional static system, and the method were essentially similar to those described previously (1). Two reaction vessels, of 38- and 180-cc volume, were used in the course of the work, the larger volume permitting measurements to be made at lower conversion. After irradiation, gases non-condensable at −210° C were removed and analyzed, and the hydrocarbon, together with any condensable products, was returned to the reaction vessel for further irradiation. In this way, the hydrogen yield could be studied as a function of total irradiation time, using a single sample of hydrocarbon. Concentrations of hydrogen and unsaturates produced in the system were always low enough so that all quenching of the excited mercury atoms was by the hydrocarbon alone. Measurements were made with propane at 300- and 600-mm pressure, and with ethane at 305-mm pressure, all at 24° C. In some experiments, unsaturates (propylene or ethylene) were added.

[1]*Manuscript received July 17, 1959.*

Phillips Research-grade propane was used without further purification. A sample treated with $HgSO_4$–H_2SO_4 solution to remove unsaturates gave the same results as the untreated gas. Phillips Research-grade ethane was found to contain appreciable amounts of methane and ethylene. The former was removed by repeated trap-to-trap distillation and prolonged pumping at −210° C. The latter was removed by condensing the ethane onto charcoal previously treated with bromine.

RESULTS

Propane

The non-condensable gas was never less than 99.5% hydrogen, measured by diffusion through a Pd thimble at 300° C. Careful analysis with a low temperature still failed to detect any C_2 hydrocarbons, so that hydrogen was the only product detected and measured. Hydrogen yield is shown as a function of total time of irradiation in Figs. 1 and 2 for propane at 600- and 300-mm pressure respectively. The effect of adding propylene to the system is shown in Fig. 3.

Ethane

When care was taken to remove all the methane present initially, the non-condensable gas produced was never less than 99% hydrogen, and this was again the only product detected and measured. The hydrogen yield is shown in Fig. 4 as a function of total time of irradiation for ethane carefully purified to remove ethylene. For comparison, the hydrogen yield from Research-grade ethane, used without purification, is shown in the same figure.

Under conditions of high pressure, low light intensity, and low temperature, and consequent absence of hydrogen atom "cracking" reactions and other complicating processes, the simple mechanism suggested previously (1) seems to account adequately for the observed behavior of both compounds.

$$h\nu + Hg \longrightarrow Hg^* \quad [1]$$

$$Hg^* + RH \xrightarrow{\text{rate} = K} \dot{R} + H + Hg \quad [2]$$

$$H + RH \xrightarrow{k_3} H_2 + \dot{R} \quad [3]$$

$$\dot{R} + \dot{R} \xrightarrow{k_4} R_2 \quad [4]$$

$$\dot{R} + \dot{R} \xrightarrow{k_5} RH + R' \quad [5]$$

RH is an alkane, $\dot{R}$ is an alkyl radical, and R′ is an olefin. As the olefin accumulates in or is added to the system, the following additional reactions may become important.

$$H + R' \xrightarrow{k_6} \dot{R} \quad [6]$$

$$H + R' \xrightarrow{k_7} H_2 + \dot{R}' \quad [7]$$

$$\dot{R} + R' \xrightarrow{k_8} \dot{R}_2 \quad [8]$$

$$\dot{R} + \dot{R}' \xrightarrow{k_9} R'_2 \quad [9]$$

where $\dot{R}'$ is an unsaturated radical, $\dot{R}_2$ is a dimer radical, and $\dot{R}'_2$ is an unsaturated dimer. From the mechanism, it may be shown that

$$[1] \qquad dH_2/dt = K(k_3[RH]+k_7[R'])/(k_3[RH]+(k_6+k_7)[R']).$$

Thus dH_2/dt is equal to K initially, decreases as R′ accumulates, and becomes constant if R′ attains a steady-state concentration before depletion of RH becomes appreciable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

This behavior was shown by propane and ethane, Figs. 1, 2, and 4, and the reduction of the hydrogen yield in the steady state may be taken as a measure of the extent of reaction 6. Furthermore, if loss of R′ via reaction 8 is neglected, the reduction of the hydrogen yield is also a measure of the rate of disappearance of R′, and since it is a steady state, of the rate of formation of R′ by reaction 5. Thus we may obtain the relative rates of reactions 4 and 5 directly from Figs. 1, 2, and 4, as shown.

Interesting confirmation that the plateaux do represent steady-state concentrations of

unsaturates is seen in the behavior of the impure Research-grade ethane (Fig. 4). Upon repeated irradiation, the ethylene in excess of the steady-state value was slowly used up, until finally the hydrogen yield rose to the same steady-state value as before. In another experiment, a sample of pure ethane was irradiated until the hydrogen yield had attained the plateau value. At this point, a small amount (0.02%) of ethylene was added, whereupon the hydrogen yield was reduced to 0.0042 micromoles/minute. Upon repeated

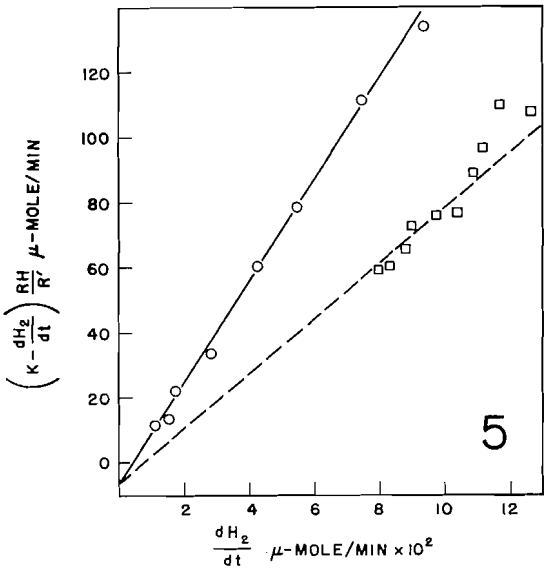
irradiation, the hydrogen yield slowly increased, following the same curve as the sample of impure ethane, and again attained the same limiting value. Thus the same steady state, which is a function only of the ratio k_4/k_5, was approached in three different ways.

Equation 1 may be rewritten as

$$[2] \qquad (K-d\mathrm{H}_2/dt)\,[\mathrm{RH}]/[\mathrm{R}'] = A(d\mathrm{H}_2/dt)-BK$$

where $A = (k_6+k_7)/k_3$ and $B = k_7/k_3$. Plots of this equation for the experiments with propane–propylene mixtures are shown in Figs. 5 and 6. Ratios of rate constants calculated from the slopes and intercepts of these plots are shown in Table I, together with values of k_5/k_4.



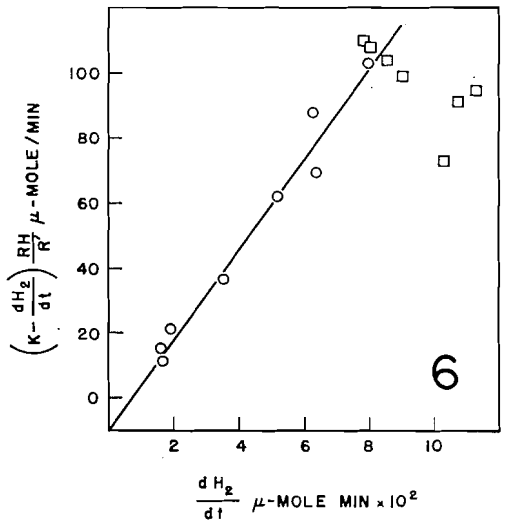


FIG. 5. A plot of equation 2 for propane at 300-mm pressure; □ pure propane, ○ added propylene.
FIG. 6. A plot of equation 2 for propane at 600-mm pressure; □ pure propane, ○ added propylene.

The same ratios of rate constants may be calculated in a different way from the experiments with pure propane and ethane. If one assumes a constant rate of formation of R′ by reaction 5, and a loss of R′ equal at any time to the net decrease in hydrogen production (thus neglecting reaction 8), it may be shown that the net rate of production of R′ is given by

$$[3] \qquad dR'/dt = d_2H/dt - (dH_2/dt)_S$$

where $(dH_2/dt)_S$ is the rate of production of hydrogen in the steady state. R′ may then be evaluated as a function of time by a graphical integration of this equation, represented by the shaded areas in Figs. 1, 2, and 4. Using values of R′ obtained in this way, the data were plotted according to equation 2 and are shown in Figs. 5 and 6, for propane, and Fig. 7 for ethane. A similar graphical integration of the data for the impure ethane,

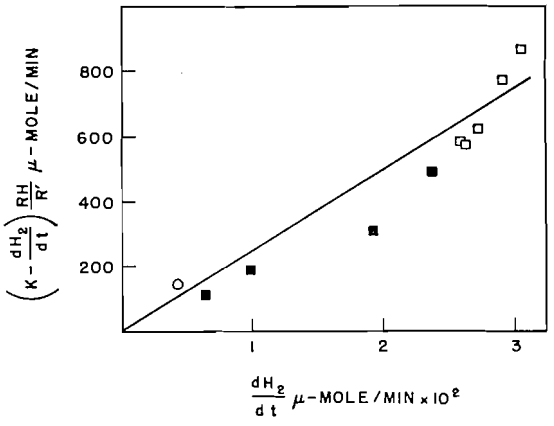

FIG. 7. A plot of equation 2 for ethane at 305-mm pressure; □ pure ethane, ■ Research-grade ethane, ○ added ethylene.

integrating backwards from the steady state, permitted calculation of ethylene concentrations in this system. These data are also plotted in Fig. 7, together with a single point obtained in the experiment, mentioned previously, when ethylene was added to ethane already irradiated until the steady state had been reached. From the pure ethane data, a rough value of $k_6/k_3 = 25{,}000$ was estimated from a straight line drawn through the origin (since k_7 is zero for ethylene). All ratios of rate constants are summarized in Table I.

DISCUSSION

The mercury-photosensitized decompositions of propane and ethane both show the same initial behavior that has been observed with *n*-pentane (1), *n*-butane (3), and some cyclo-alkanes (2). Because of the larger values of k_6/k_3, this was observed only at very low conversions (shown as upper abscissae in Figs. 1, 2, and 4). This was especially true for ethane, with which the steady state was attained after about 0.05% reaction, with an estimated steady-state concentration of ethylene of one part in 80,000. All previous studies of these reactions, in which hydrogen production was observed to be linear with time, were undoubtedly made in the steady-state region, and the measured quantum yields must be corrected upwards by the factor $(k_4+k_5)/k_4$, as indeed the authors anticipated. Bywater and Steacie reported a pressure-independent quantum yield of 0.50

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

For personal use only.

for hydrogen production from propane at high pressures and room temperature (4), from which values of the initial quantum yield of 0.90 and 0.77 at 300 and 600 mm, respectively, may now be estimated. It may be noted that while the steady-state hydrogen yields at the two pressures are almost identical, confirming the pressure independence observed by Bywater and Steacie, the initial quantum yield appears to decrease with increasing pressure, suggesting, perhaps, the intermediate formation of an excited propane molecule of appreciable lifetime in the primary process. The quantum yields for the ethane decomposition reported by Darwent and Steacie (4), which tended towards unity at high pressure, should be revised upward in a similar way, although the correction here is smaller than for propane.

Values of k_5/k_4 for both ethyl and propyl radicals appear to be rather higher than those observed for thermally equilibrated radicals (5, 6, 7, 8). Some of this discrepancy may be attributed to inaccuracy in the extrapolation to zero time. However, it should be noted that in the steady-state region, where this ratio is estimated, a fraction $k_5/2(k_5+k_4)$ of the radicals in the system were formed via reaction 6, and would be vibrationally excited until stabilized by collisions. It has clearly been shown by several authors that such "hot" radicals tend to disproportionate rather than dimerize, and that these effects can persist to quite high pressures (9, 10, 11). The decrease in k_5/k_4 for propane in going from 300- to 600-mm pressure lends support to such an explanation. It might be noted, incidentally, that the "propyl" radicals in the present study are very probably isopropyl radicals (9).

Values of k_6/k_3 obtained from the experiments with propane–propylene mixtures (Table I) are in fair agreement with a value of about 3000 which may be estimated

TABLE I

Ratios of rate constants

Hydrocarbon	k_6/k_3	$k_7/(k_6+k_7)$	k_5/k_4
Propane, 300 mm	1515	0.032	0.08
Propane, 600 mm	1304	0.061	0.54
Ethane, 305 mm	25000	—	0.31

from separate measurements of the two rate constants by Schiff and Steacie (12), and Bradley, Melville, and Robb (13). The values of $k_7/(k_6+k_7)$, the fraction of hydrogen atoms reacting with propylene which abstract hydrogen (Table I), are rather lower than previous estimates of this ratio (14). The variation with pressure is probably not significant, considering the relatively long extrapolation which is involved.

The data from the experiments with pure propane at 300 mm, plotted in Fig. 5, using calculated values of the propylene concentration, lie considerably below the data from the experiments with added propylene, and, taking the same intercept, would lead to values of k_6/k_3 about half as large. A similar behavior was previously observed with *n*-pentane at 300 mm, which was tentatively attributed to the formation of 2-pentene in the disproportionation reaction (1). Such an explanation is impossible with propylene, and another cause must be sought. The values of the propylene concentration were calculated assuming, first, disappearance of propylene by reaction 6 only, and secondly, a constant rate of formation of propylene equal to that in the steady state. If propylene disappeared by other reactions, such as 8, or by direct photosensitized decomposition, the calculated values of propylene concentration would be too high, and k_6/k_3 would be low, as observed. It is doubtful, however, that reaction 8 would occur to such an extent,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

and the very low concentrations of propylene eliminate the possibility of direct decomposition. It may be noted that the reaction sequence, 7+9, would merely substitute hexene for propylene, which would not have a large effect.

The second assumption, that the rate of production of propylene is constant, is more likely at fault. The high value of k_5/k_4 noted previously was attributed to preferential disproportionation of "hot" propyl radicals formed by reaction 6. Initially, however, all the propyl radicals were formed by reactions 2 and 3, and reaction 6 only becomes important as propylene accumulates in the system. Thus if "hot" propyl radicals were the cause of the high values of k_5/k_4 in the steady state, the rate of formation of propylene may have been much lower in the earlier stages of the reaction, and the graphical integration may have thus overestimated the concentration of propylene quite considerably. In support of this explanation is the improved agreement of the two sets of data at 600-mm pressure, where a lower value of k_5/k_4 was observed, and, presumably, "hot" radical reactions were less important. It seems that a similar explanation is probably valid for *n*-pentane. With ethane, at 305 mm, only one experiment was done with added ethylene, and it again lies somewhat above the data for pure ethane using calculated concentrations of ethylene. It should be noted, finally, that all these data for low concentrations of unsaturates lie in an inherently inaccurate region for the plot of equation 2, towards the right-hand side of Figs. 5, 6, and 7.

The value of k_6/k_3 of 25,000, calculated from the data obtained with pure ethane, may also be compared with values calculated from the literature. Berlie and LeRoy measured k_3 over a range of temperature, and from their data a collision yield of 4.5×10^{-8} at 24° C may be estimated (15). Bradley, Melville, and Robb estimated a collision yield of 9.3×10^{-5} for reaction 6 (13), which, assuming similar collision numbers, gives $k_6/k_3 = 2100$, an order of magnitude lower than found in the present study. Pursuing the discrepancy further, the collision yield of 4.5×10^{-8} for reaction 3, with ethane, is almost identical with the value 4.6×10^{-8} found by Schiff and Steacie for the same reaction with propane (12). From the results of Darwent and Roberts, however, a ratio k_3(propane)/k_3(ethane) of about 19, at 24° C, may be calculated (14). Taking a value of the ratio k_6(propylene)/k_6(ethylene) of 1.5 (13), from the present results a value of k_3(propane)/k_3(ethane) of about 25 may be estimated, in fair agreement with Darwent and Roberts, but much higher than the value of about 1 indicated from the combined results of Berlie and LeRoy, and Schiff and Steacie. One would expect the reaction of hydrogen atoms with the primary hydrogen atoms of ethane to be considerably slower than with the secondary hydrogen atoms of propane, and it would appear that the values of k_3 (ethane) found by Berlie and LeRoy may be too high, as has been suggested elsewhere (16), although perhaps the discrepancies are simply an indication of the rather unsatisfactory knowledge of accurate absolute values for the rates of hydrogen atom reactions.

It may be noted that all the relative rate constants measured in the present work are dependent upon the values chosen for K, the initial rate of hydrogen production. The sharply rising nature of the curves (Figs. 1, 2, and 4) makes this extrapolation to zero time inherently inaccurate, while the presence of even minute amounts of unsaturates initially present in the hydrocarbon could seriously reduce the observed value of K. The reasonable agreement between values of k_5/k_4 observed, and those measured by other methods suggests that the initial extrapolations were not grossly in error. The value of 0.9 for the initial quantum yield estimated for propane at 300 mm puts an upper limit on the possible value of K for that particular system. The reaction

$$H + R + M \rightarrow RH + M \qquad [10]$$

may be of some importance, especially with ethane (6), and probably accounts for the decrease in quantum yield with decreasing ethane pressure observed by Bywater and Steacie (4). The occurrence of this reaction would not seriously affect the kinetics and rate constants observed in the present study, since for a given pressure and light intensity, it may be regarded, to a first approximation, simply as a constant factor reducing the extent of reaction 2.

A careful measurement of initial quantum yields of the mercury-photosensitized decompositions of the simple alkanes would be of obvious value in determining the exact nature of the primary process, and it is perhaps worth while to note briefly the conditions essential for such measurements as indicated by the present study. These are: (1) very low conversions, preferably 10 or 100 times lower than in the present work, in order to improve the accuracy of the extrapolation to zero time; (2) rigorous purification of hydrocarbons to eliminate trace amounts of unsaturates; and (3) low light intensities, sufficiently low to make reaction 10 negligible.

The author wishes to thank Miss M. Cooper and Miss M. Bilevicius, summer research assistants in 1957 and 1958 respectively, who performed some of the experimental work. The author also gratefully acknowledges tenure of a National Research Council of Canada postdoctoral fellowship.

THE ABSOLUTE CONFIGURATION OF (+)-DES-(OXYMETHYLENE)-LYCOCTONINE HYDRIODIDE MONOHYDRATE AND (+)-DEMETHANOLACONINONE HYDRIODIDE TRIHYDRATE[1]

MARIA PRZYBYLSKA AND LÉO MARION

ABSTRACT

By X-ray analyses it has been possible to derive the absolute configuration of (+)-des-(oxymethylene)-lycoctonine and that of (+)-demethanolaconinone. These are shown in Figs. 2 and 3.

The detailed X-ray analyses of (+)-des-(oxymethylene)-lycoctonine hydriodide monohydrate (1) and (+)-demethanolaconinone hydriodide trihydrate (2) showed that these compounds have the same carbon–nitrogen ring structure (Fig. 1). The determinations of absolute configuration have since been carried out in order to establish whether the skeleton in Fig. 1 or its mirror image represents the ring structure of these compounds.

The principle on which it is possible to distinguish between optical isomers by means of X-rays in the case of anomalous dispersion was outlined by Bijvoet (3) and since then the absolute configuration of several compounds has been established (4, 5, 6).

The equi-inclination Weissenberg films were indexed taking into account the rotation of the crystal, the translation of the film, the position of the film, and the direction of the inclination of the camera (7). On the examination of Weissenberg films eight reflections corresponding to a right-handed set of axes were chosen for each compound and the intensities I_H and $I_{\bar{H}}$ were estimated by visual comparison with an intensity strip. In each case the shortened and lengthened diffraction spots were measured and then averaged.

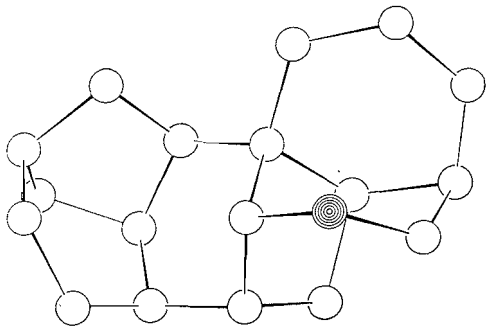

FIG. 1. The carbon–nitrogen skeleton of des-(oxymethylene)-lycoctonine and demethanolaconinone.

The intensities $I_H = KF_H.F_H^*$ and $I_{\bar{H}} = KF_{\bar{H}}.F_{\bar{H}}^*$ were calculated using the refined atomic co-ordinates obtained from the X-ray analyses. They corresponded to molecular models in right-handed sets of axes, the photographs of which were already published (1, 2). Their carbon–nitrogen skeleton is shown in Fig. 1. The contribution made by the hydrogen atoms was not taken into account, but it would certainly be small and considering large differences observed in intensities between I_H and $I_{\bar{H}}$, it could safely be neglected.

Issued as N.R.C. No. 5360.

The values for the real and imaginary dispersion corrections were those given by Dauben and Templeton (8). For the scattering factor for the iodine atom and CuK_α radiation they were $\Delta f' = -1.1$ e.Å^{-2} and $\Delta f'' = 7.2$ e.Å^{-2}.

(+)-Des-(oxymethylene)-lycoctonine Hydriodide Monohydrate

(+)-Des-(oxymethylene)-lycoctonine hydriodide monohydrate, $C_{24}H_{39}O_6N.HI.H_2O$, crystallizes in the space group $P2_1$. The authenticated sample was kindly provided by Dr. O. E. Edwards, who found the optical rotation of the anhydrous compound to be: $[\alpha]_D^{28}$ +6±2° (*c*, 1.0 in absolute ethanol). The *b* axis was taken as unique, polar axis and therefore the reflections which showed the violation of Friedel's law were *hkl* and $h\bar{k}l$ ($I_{h\bar{k}l} = I_{\bar{h}\bar{k}\bar{l}}$). They were obtained by inclining the Weissenberg camera in opposite ways with respect to the X-ray beam. The films were exposed for identical periods of time and developed simultaneously. The crystal used was very small, roughly cylindrical in shape, about 0.06 mm in diameter, hence absorption corrections were not applied. The observed and calculated ratios of intensities are given in Table I.

TABLE I

(+)-Des-(oxymethylene)-lycoctonine hydriodide monohydrate

hkl	$I_{hkl}/I_{h\bar{k}\bar{l}}$, calculated	$I_{hkl}/I_{h\bar{k}\bar{l}}$, observed
$11\bar{2}$	1.7	2.2
213	0.4	0.5
510	1.2	1.2
$31\bar{4}$	1.5	1.6
$41\bar{4}$	0.6	0.6
610	0.8	0.7
$51\bar{4}$	2.0	2.4
$61\bar{4}$	1.3	1.3

The agreement is satisfactory and it can be concluded that the molecular model used for calculation represents the absolute configuration of this compound. The structural formula emphasizing the diterpenoid character of the (+)-isomer is therefore as shown in Fig. 2. It should be noted that if the mirror image of that molecule was used for calculation, the ratio $I_H/I_{\bar{H}}$ would be inverted.

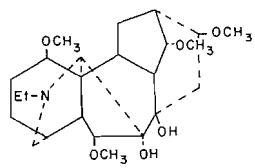

FIG. 2. (+)-Des-(oxymethylene)-lycoctonine.

(+)-Demethanolaconinone Hydriodide Trihydrate

The crystals of (+)-demethanolaconinone hydriodide trihydrate, $C_{24}H_{35}O_8N.HI.3H_2O$, were prepared and authenticated by Dr. H. Mayer, who found the rotation was $[\alpha]_D^{25}$ +59.2±1.5° (*c*, 1.04 in water) (9). The space group of this compound is $P2_12_12_1$. The three axes of the unit cell are polar and therefore $I_{\bar{h}kl} = I_{h\bar{k}l} = I_{hk\bar{l}} = I_{\bar{h}\bar{k}\bar{l}}$.

The crystal used was cylindrical in shape, about 0.12 mm in diameter, and the absorption corrections were not applied.

For personal use only.

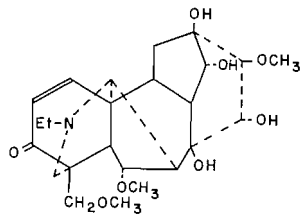

FIG. 3. (+)-Demethanolaconinone.

The results in Table II indicate that the (+)-isomer can be represented by the formula in Fig. 3 and its carbon–nitrogen skeleton by Fig. 1.

It is of interest to note that Dvornik and Edwards have concluded on molecular rotation grounds that the *Aconitum* alkaloid atisine (10) and the *Delphinium* alkaloid

TABLE II

(+)-Demethanolaconinone hydriodide trihydrate

hkl	$I_{hkl}/I_{\bar{h}kl}$, calculated	$I_{hkl}/I_{\bar{h}kl}$, observed
511	1.8	2.2
513	0.5	0.5
611	0.4	0.3

821	5.7	3.2
822	1.6	1.5
912	0.6	0.7

ajaconine (11) also bear mirror image relationship to the common diterpenes. The biosynthesis of the lycoctonine family of alkaloids undoubtedly proceeds via intermediates with the atisine-type skeleton (12, 13) and the above correspondence of absolute configuration is in agreement with this.

THERMAL DECOMPOSITION OF 1-HEXANETHIOL[1]

PAUL E. GAGNON, JEAN L. BOIVIN,[2] AND DONALD C. WATSON[3]

ABSTRACT

The uncatalyzed thermal decomposition of 1-hexanethiol was studied at temperature varying from 300 to 700° C and was observed to give 42% of olefinic hydrocarbons at 600° C. Dialkyl sulphides were also obtained at 550° C with a maximum yield of 13.3% at 650° C. The effect of sulphide catalyst was investigated and nickel sulphide was found to be the most effective: at low temperature (150–450° C) dihexylsulphide was produced and at higher temperature (450–600° C) olefinic hydrocarbons were obtained. Very little catalytic effect was observed with molybdenum and cadmium sulphides.

INTRODUCTION

The thermal decomposition of aliphatic mercaptans has been extensively studied by several investigators (1 to 12), but it appears from the various results obtained that additional studies of this pyrolysis should be made in the absence or presence of catalysts at temperature of 150 to 750° C using 1-hexanethiol.

EXPERIMENTAL

1-Hexanethiol was distilled and the fraction boiling at 153–154° C was used in the pyrolysis. Other materials had to be prepared for purpose of identification and analysis: dihexyl sulphide (13), dihexyl disulphide (14), and 1-hexene (15).

The apparatus used in the thermal decomposition of 1-hexanethiol was essentially the same as the one described in an earlier paper (12), together with the general procedure.

The liquid pyrolyzate was analyzed for mercaptan by the method of Kimball, Kramer, and Reid (16) and also by an amperometric method (17, 18) and for the olefinic material by an iodine method (19). Dialkyl sulphide was estimated by the bromide–bromate reagent (20), dialkyl disulphide by the Kolthoff method (21), and sulphur by a colorimetric method using sodium cyanide (22).

The gaseous pyrolyzate was analyzed by the Orsat apparatus (12).

For the uncatalyzed thermal decomposition, the pyrolysis tube was filled with Pyrex glass helices forming a column 40 cm high in the reaction zone; then 1-hexanethiol was dropped into the vaporizing flask at the rate of 0.5 g per minute. The liquid and gaseous pyrolyzates were analyzed and sampled for infrared measurements. Tables I and II show the composition of the liquid and gaseous products as a function of the temperature. Elemental sulphur could not be detected in the pyrolyzate residue until the pyrolysis temperature had risen to 500° C. At 550° C, the pyrolyzate contained 0.1% sulphur and only 0.3 at 650° C.

In the metal sulphide catalyzed decompositions, the pyrolysis tube was packed as follows: a 2-cm-thick plug of glass wool was placed in the pyrolysis tube at the lower end of the decomposition zone. A 3-cm layer of 8-mm glass helices was placed on top of the plug, followed by a 3-cm layer of the metal sulphide catalyst. The placing of alternate layers of glass helices and catalyst was continued until a column 40 cm high was built up

in the decomposition tube. This type of packing was used in preference to a solid column of metal sulphide catalyst in order to prevent channeling and hence loss of catalyst contact of the vaporized mercaptan. The results obtained are shown in Tables I and II for the composition of liquid and gaseous pyrolyzates. With the sulphide catalysts, elemental sulphur was not detected in pyrolyzate liquids at temperatures below 400° C. At a decomposition temperature of 550° C, the sulphur content was only 0.1% with NiS and 0.2 with MoS_3 and CdS.

DISCUSSION

There is a general agreement that the thermal decomposition of an aliphatic mercaptan will result in the formation of a dialkyl sulphide and an unsaturated hydrocarbon. Several investigators (1, 2, 12) have pointed out that at a high decomposition temperature, the mercaptan undergoes loss of hydrogen sulphide, which results in the formation of an unsaturated hydrocarbon as the main product. At a lower decomposition temperature, there is only partial desulphurization, and a dialkyl sulphide is the major product formed. As a result of the present investigation, this generalization has been found to be true only under certain conditions.

In the thermal decomposition of 1-hexanethiol without catalyst, it was found that unsaturated hydrocarbons were produced at lower temperatures than the dialkyl

sulphides. Olefinic hydrocarbons were first detected at 450° C, and reached a maximum concentration of 42.3% at a decomposition temperature of 600° C. On the other hand, dihexyl sulphide was not formed until 550° C, and the maximum content of 8.1% was obtained at a decomposition temperature of 600° C.

These observations were not found true of the subsequent catalytic studies. With nickel sulphide as catalyst, dialkyl sulphide formation began as low as 200° C and increased to give a maximum pyrolyzate concentration of over 35% at 250° C to 300° C, the temperature range at which olefinic hydrocarbon formation began. In the case of the molybdenum and cadmium sulphide catalysts, analysis of the liquid residues indicated that sulphide and unsaturated hydrocarbons were both formed at the same decomposition temperature range, i.e., between 300 and 350° C.

It then appears that in non-catalytic decompositions, unsaturated hydrocarbons are produced at a lower temperature than the dialkyl sulphides. A very active catalyst like nickel sulphide reverses this, causing sulphides to be produced at the lower temperature. Molybdenum and cadmium sulphides, on the same basis, are classed as possessing only moderate catalytic activity, in that sulphides and olefins are produced at the same temperature.

The effect of the catalyst on the decomposition of 1-hexanethiol is also indicated by the residual thiol content of the liquid samples. As noted from the analytical results, 1-hexanethiol undergoes marked decomposition without catalyst in a very narrow temperature range of 100° C, i.e., between 500 and 600° C. In the studies with nickel sulphide, decomposition took place in two stages. The first decomposition, which was accompanied by considerable sulphide formation, was determined as catalytic, extending from 150 to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

450° C. The second stage was determined to be thermal, extending from 450 to 600° C. However, in molybdenum and cadmium sulphide decompositions, thiol decomposition is considered as a one-stage process, due mainly to a thermal effect. The decomposition range extended over a much wider temperature zone, from about 300 to 600° C.

Similar conclusions regarding the activities of the different catalysts were indicated from dialkyl disulphide formation. During the non-catalytic decompositions, very little disulphide was produced. The disulphide content did not rise above 3% of the total pyrolyzate, and therefore could not be considered as a major decomposition product. However, in nickel sulphide decomposition studies, disulphide was formed in moderate quantities in the 450 to 600° C temperature range. With the sulphides of molybdenum and cadmium, the disulphide content accounted for over 10% of the total only in the final 50° C decomposition range studied, i.e., from 550 to 600° C.

From the analytical results, it should be noted that there were a number of liquid and gaseous samples obtained during the pyrolysis of 1-hexanethiol, in which the known components, analyzed by chemical means, constituted less than 75% of the total sample weight. In most cases, these were obtained from high temperature decomposition studies, both with and without catalyst. Infrared analysis indicated the formation of many decomposition products containing less than six carbon atoms. These smaller fragments included the saturated hydrocarbon gases, methane, ethane, propane, and butane, as well as the olefinic hydrocarbons, ethylene, propylene, and butylene. A number of sulphur-containing compounds such as thiophene and carbon disulphide were also identified by infrared examination.

The formation of hydrogen sulphide could be considered as a function of carbon–sulphur cleavage whereas gaseous hydrocarbon formation would indicate carbon–carbon cleavage. The relative quantities of these two components in any given sample indicated the major point of cleavage at a particular decomposition temperature. In non-catalytic pyrolysis, hydrogen sulphide was produced at 450° C, and remained the main gaseous component until a temperature of 600° C had been reached. In the 600 to 700° C range, hydrocarbons formed the greater part of the effluent gas, indicating that the above 600° C cleavage of the carbon chain occurred more readily than that of the carbon–sulphur bond. From the results of gas analysis with the sulphide catalysts, the same generalization holds true, with the exception that lower temperatures were required. Hydrogen sulphide was produced at about 350° C and carbon–carbon cleavage did not become the predominant reaction until a decomposition temperature of 500° C had been reached.

One final difference between catalytic and non-catalytic decomposition was indicated by the hydrogen content of the effluent gas. In non-catalytic decomposition, less than 3% hydrogen was produced throughout the temperature range studied. Sulphide catalysts, however, gave an increased hydrogen content of the effluent gas. With nickel sulphide, 15% hydrogen was produced at 500° C; approximately half this quantity was obtained with molybdenum and cadmium sulphide catalysts.

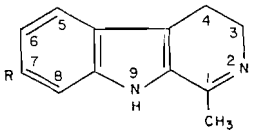
A SYNTHESIS OF HARMALINE[1]

IAN D. SPENSER

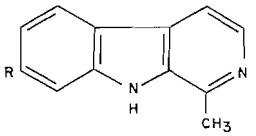
ABSTRACT

The synthesis of 1-methyl-3,4-dihydro-β-carboline (harmalan) and of two of its derivatives by dehydration of the corresponding 1-hydroxymethyl-1,2,3,4-tetrahydro-β-carbolines is described. Harmalan was also obtained by oxidative decarboxylation of 1-methyl-1,2,3,4-tetrahydro-β-carboline-1-carboxylic acid.

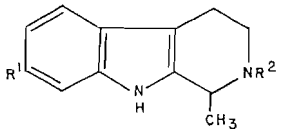
Harmalol (I), isolated from *Peganum harmala* L. (1), and the corresponding methyl ether harmaline (II), obtained from the same plant (1), as well as from *Banisteria caapi* Spruce (2), are the only 3,4-dihydro-β-carboline derivatives hitherto found to occur in nature. All other naturally occurring compounds containing the β-carboline ring system are either fully aromatic (IV) or contain a 1,2,3,4-tetrahydro-structure (VI) (3*a*). Amongst the structurally analogous isoquinoline alkaloids only two, psychotrine and O-methyl-psychotrine (3*b*) have so far been recognized as 3,4-dihydro-derivatives. The 3,4-dihydro-structure thus represents a rare oxidation state in these plant bases.



I R = OH
II R = OCH_3
III R = H



IV R = H
V R = OCH_3



VI $R^1 = R^2 = H$
VII $R^1 = H$, $R^2 = CH_3$
VIII $R^1 = OCH_3$, $R^2 = H$

Although the biosynthesis of the β-carboline alkaloids has not so far been investigated, it has long been assumed (4) that the nucleus arises in the plant by a Mannich-type condensation of tryptamine or oxytryptamine with an aldehyde to yield a tetrahydro-β-carboline derivative. Such condensations have been carried out in vitro under mild conditions of temperature and pH (e.g. (5)), and a number of tetrahydro-β-carbolines have been found in plants (e.g. 1-methyl-1,2,3,4-tetrahydro-β-carboline (eleagnine) (VI) (6, 7, 8), 1,2-dimethyl-1,2,3,4-tetrahydro-β-carboline (leptocladine) (VII) (9), and 1-methyl-7-methoxy-1,2,3,4-tetrahydro-β-carboline (tetrahydroharmine) (VIII) (2, 8)).

Partial dehydrogenation of these tetrahydro-derivatives has been postulated (4, 7, 10) to account for the origin of the dihydro-derivatives harmaline (II) and harmalol (I), and further loss of hydrogen for that of the β-carbolines (e.g. 1-methyl-β-carboline (harman) (IV) (3*a*) and its 7-methoxy-derivative (harmine) (V) (3*a*)).

If this stepwise oxidation sequence were indeed to represent the biosynthetic origin of dihydro-β-carbolines and β-carbolines, the former might be expected to accompany the latter frequently in the plant. The comparative rarity of the dihydro-derivatives is thus puzzling and led us to consider other possible biogenetic routes.

Neither of the reported syntheses of harmaline (II) can be regarded as models for in vivo formation. The synthetic base was first obtained (11) by cyclization of 1-acetyl-2-

[1]*Manuscript received July 2, 1959.*

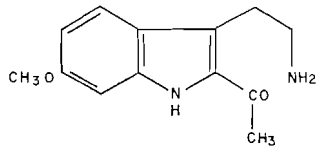
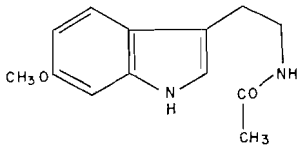
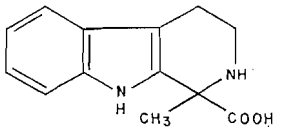
aminoethyl-6-methoxyindole (IX), and later by Bischler–Napieralski ring closure of



(IX)



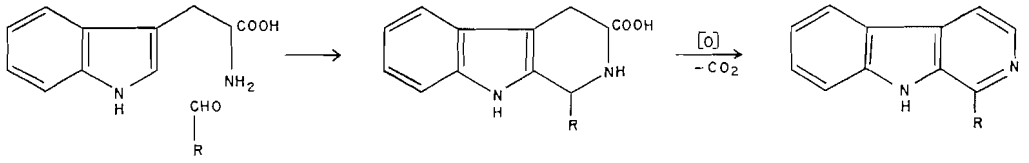
(X)



(XI)

N_β-acetyl-6-methoxytryptamine (X) (12). Much earlier Perkin and Robinson (4) had obtained the compound by oxidation of tetrahydroharmine (VIII) with permanganate in acetone. Under nonacidic conditions dihydro-β-carbolines thus appear to be stable to oxidizing agents. This stability has now been confirmed: 1-methyl-3,4-dihydro-β-carboline (III) (harmalan) was obtained in good yield both by oxidation of 1-methyl-1,2,3,4-tetrahydro-β-carboline (VI) (13) in acetone with permanganate, and also by oxidative decarboxylation of 1-methyl-1,2,3,4-tetrahydro-β-carboline-1-carboxylic acid (XI) (5) with silver oxide in aqueous solution. This latter synthesis of a dihydro-β-carboline was modelled on our studies of oxidative decarboxylation of amino acids (14).

Under acid conditions (nitric acid (15), chromic acid (16), acid permanganate (12, 17)) dihydro-β-carbolines are oxidized to β-carbolines. Oxidation of tetrahydro-β-carbolines under similar conditions does not take place as readily (12) and leads to β-carbolines in poor yield (18). β-Carbolines are obtained in good yield by acid dichromate oxidation of tetrahydro-β-carboline-3-carboxylic acids (XII), decarboxylation accompanying the reaction (19). The biogenetic origin of β-carbolines, without intermediate formation of dihydro-β-carbolines, has been proposed in analogy to this reaction sequence (20).



(XII) (IV)

In the present synthesis harmaline was obtained in two physiologically possible steps, the C=N double bond being introduced by dehydration, rather than oxidatively: 6-Methoxytryptamine (21)[2] was condensed with glycolaldehyde to give (±)-1-hydroxymethyl-7-methoxy-1,2,3,4-tetrahydro-β-carboline (XIV) in good yield. This step involves the usual Mannich reaction between a biogenetic amine and an aldehyde. The latter, glycolaldehyde, is known to arise enzymically *inter alia* by decarboxylation of hydroxypyruvic acid (22), a metabolic precursor of serine (23).

In a similar manner tryptamine gave (±)-1-hydroxymethyl-1,2,3,4-tetrahydro-β-carboline (XIII), and *dl*-tryptophan yielded the corresponding 3-carboxylic acid (XV) (24).

[2]*I am grateful to Dr. R. A. Abramovitch, University of Saskatchewan, for a specimen of this material.*

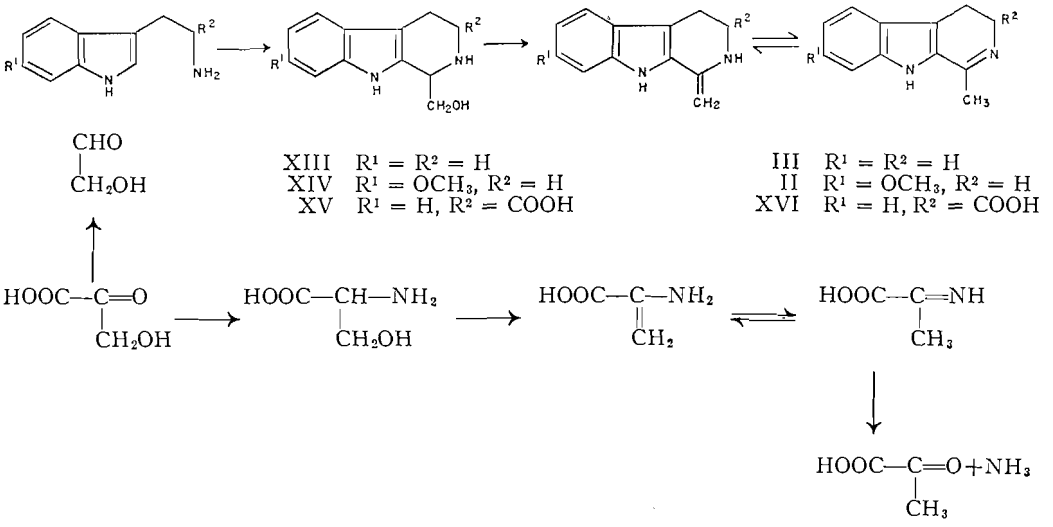
For personal use only.



Dehydration of these tetrahydro-derivatives gave the corresponding 3,4-dihydro-β-carbolines. Harmaline (II) was obtained in 70% yield with 90% w/w phosphoric acid, harmalan (III) in 75% yield with phosphoric acid and in 25% yield with 50% w/v sulphuric acid. In each instance the product was indistinguishable from an authentic specimen.[3] 1-Methyl-3,4-dihydro-β-carboline-3-carboxylic acid (XVI) was obtained in moderate yield with 50% w/v sulphuric acid. The course of the dehydration reaction was followed in each case by observing the change in ultraviolet absorption (Figs. 1 and 2).

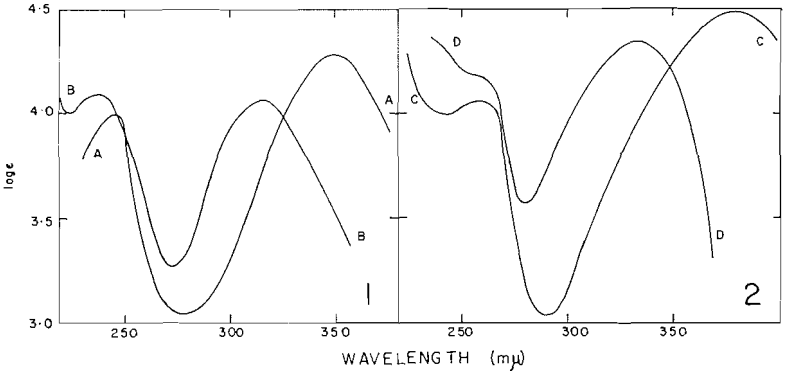


FIG. 1. 1-Methyl-3,4-dihydro-β-carboline (harmalan). Curve A, in 0.1 *N* HCl in aqueous ethanol; curve B, in 0.1 *N* NaOH in aqueous ethanol.
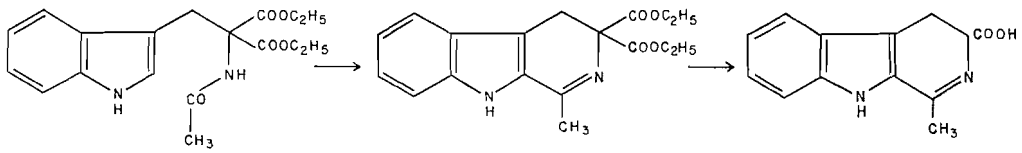
FIG. 2. 1-Methyl-7-methoxy-3,4-dihydro-β-carboline (harmaline). Curve C, in 0.1 *N* HCl in aqueous ethanol; curve D, in 0.1 *N* NaOH in aqueous ethanol.

The dihydro-β-carboline (XVI) derived from tryptophan had not hitherto been described. Another synthetic route was therefore sought to confirm its identity. Bischler–Napieralski ring closure of N_β-acetyltryptophan was not suitable since it has proved unsuccessful with classical dehydrating agents (24, 25) while with polyphosphoric acid

[3]*I am greatly indebted to Dr. T. M. Sharp, Wellcome Laboratories, London, England, for a sample of natural harmaline.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

it was accompanied by decarboxylation and aromatization (26) to yield 1-methyl-β-carboline (IV) instead of the desired product. However, cyclization of ethyl α-acetamido-α-carbethoxy-β-(3-indolyl)-propionate (XVII) (27) gave 1-methyl-3,3-dicarbethoxy-3,4-dihydro-β-carboline (XVIII) (28) and the latter was saponified and decarboxylated, to give a 65% yield of the desired compound (XVI), identical with a specimen obtained by dehydration.



(XVII) (XVIII) (XVI)

A second, as yet unidentified material, differing in infrared and ultraviolet absorption from the main product was also isolated in this reaction.

The dehydration step in the present harmaline synthesis parallels the catabolic pathway of serine (29), enzymatic dehydration to α-aminoacrylic acid, and rearrangement to α-iminopropionic acid. Whereas this compound spontaneously hydrolyzes to pyruvic acid and ammonia, the imino-linkage in harmaline is stabilized by conjugation with the indole system. In vitro this dehydration of serine requires strong acid (30).

The synthesis of harmaline here described is put forward as a possible biogenetic route and an alternative to the oxidative pathway postulated by earlier authors (4, 7, 10). The recent confirmation (31) of the structure of calycotomine as 1-hydroxymethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline, analogous to the intermediate in the present synthesis, lends additional interest to this hypothesis.

EXPERIMENTAL

1-Methyl-3,4-dihydro-β-carboline (harmalan) (III)

(1) By Dehydration of 1-Hydroxymethyl-1,2,3,4-tetrahydro-β-carboline (XIII)

(±)-1-Hydroxymethyl-1,2,3,4-tetrahydro-β-carboline

Tryptamine hydrochloride (5.9 g, 0.03 moles) was dissolved in 250 ml warm water containing 15 ml 2 *N* HCl (1.095 g, 0.03 moles) and the solution was filtered. To the cold solution was added an aqueous solution of 1.90 g (0.032 moles) glycolaldehyde (32) and the mixture was kept on the steam bath (2 hours) until a sample no longer gave a precipitate with dinitrophenylhydrazine. The cooled solution was then treated with charcoal, filtered, extracted with ether to remove nonbasic impurities, concentrated, and treated with excess of 20% NaOH, when the product precipitated as an oil which crystallized on standing. It was taken up in ether, and the solution was dried with KOH and concentrated to yield an oil which crystallized on digestion with warm water to give the trihydrate of 1-hydroxymethyl-1,2,3,4-tetrahydro-β-carboline (6.25 g, 81%) melting at 138–139° after sintering below 100°. Recrystallization from aqueous ethanol did not raise the melting point. Distillation of a small sample at 2.10^{-2} mm and 140–150° gave an oil, crystallizing into a white solid, melting at 144–145°, which still retained water of crystallization. (Found: H_2O, 19.18. $C_{12}H_{14}ON_2,3H_2O$ requires H_2O, 21.10%. After drying at 120° found: C, 71.5; H, 6.8. $C_{12}H_{14}ON_2$ requires C, 71.5; H, 7.0%.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The hydrochloride, recrystallized from ethanol, melted at 215–216° after darkening from 205°. (Found: C, 56.3; H, 6.8; N, 10.5. $C_{12}H_{15}ON_2Cl,H_2O$ requires C, 56.1; H, 6.7; N, 10.9%.)

Harmalan

(*i*) *90% w/w* H_3PO_4.—The above tetrahydro-β-carboline trihydrate (3.37 g, 0.013 moles) was wetted with 10 ml water, 100 ml 90% H_3PO_4 was added, and the suspension was kept on the steam bath until the absorption band at 280 mμ, characteristic of the indole chromophore of the starting material, had disappeared. The reaction was complete after 2 hours. The dark brown solution was diluted with water, extracted with ether, treated with charcoal, and made alkaline with 20% NaOH. The precipitate was collected, dried in air, and extracted in the Soxhlet extractor with 70–100° petroleum ether, from which harmalan crystallized in fluffy needles, melting at 178–179° in a total yield of 1.80 g (75%). For analysis a sample was sublimed at 1.10^{-3} mm and 90° C. (Found: C, 77.9; H, 6.4; N, 15.1. Calc. for $C_{12}H_{12}N_2$: C, 78.2; H, 6.6; N, 15.2%.) Infrared absorption (Nujol) (cm^{-1}): 1622 (m), 1605 (m), 1570 (m), 1550 (s). Ultraviolet absorption (Fig. 1) (λ_{max}, mμ (log ε)); in 0.1 *N* HCl: 245 (4.04); 350 (4.28); in 0.1 *N* NaOH: 240 (4.09), 315 (4.06).

(*ii*) *50% w/v* H_2SO_4.—The tetrahydro-β-carboline (0.11 g, 0.00043 moles) was treated with an ice-cold mixture of 2 ml 95% H_2SO_4 and 4 ml water. After 2 hours on the steam bath and standing overnight, the solution showed a strong dihydro-β-carboline peak at 350 mμ, but the indole peak at 280 mμ was still apparent. The latter had disappeared after a further 2 hours on the steam bath with an additional 1 ml of 95% H_2SO_4. The solution was diluted with water, treated with charcoal, and the product precipitated by addition of a little 20% NaOH, when harmalan, melting at 176–177°, was obtained in poor yield (25%). When the experiment was carried out at room temperature, even after 1 week unchanged starting material was recovered.

(*2*) *By Oxidation of 1-Methyl-tetrahydro-β-carboline* (VI)

1-Methyl-1,2,3,4-tetrahydro-β-carboline (13) (0.186 g, 0.001 moles) was dissolved in acetone. To the ice-cold solution was added 0.11 g (0.0007 moles) powdered $KMnO_4$. When reaction was complete, MnO_2 was filtered off, the solution evaporated, the residue taken up in ether, dried over NaOH, the solvent removed, and the residual solid extracted with boiling ligroin, from which harmalan (0.11 g, 65%), melting at 176–178°, crystallized.

(*3*) *By Oxidative Decarboxylation of 1-Methyl-1,2,3,4-tetrahydro-β-carboline-1-carboxylic Acid* (XI)

1-Methyl-1,2,3,4-tetrahydro-β-carboline-1-carboxylic Acid

Cooled aqueous solutions of tryptamine hydrochloride (0.98 g, 0.005 moles) and pyruvic acid (0.48 g, 0.0055 moles) were mixed and left at 37° overnight when the product had separated in 85% yield (0.96 g) as colorless crystals, melting with decarboxylation at 217–219°. Recrystallization from dilute aqueous ammonia did not raise the melting point, which is reported as 220° (5).

Harmalan

The above amino acid (0.115 g, 0.0005 moles) in 20 ml water was refluxed 24 hours with freshly precipitated Ag_2O (0.23 g, 0.001 moles). Metallic silver deposited, and the solution gave an ultraviolet absorption curve characteristic of a dihydro-β-carboline. The mixture was filtered hot. On cooling a solid precipitated, which on recrystallization from boiling petroleum ether gave 0.079 g (85%) of harmalan, melting at 178–180°.

The products obtained from each of the above experiments were compared with a sample of harmalan prepared from N_β-acetyltryptamine (12) and were found to have identical ultraviolet (Fig. 1) and infrared (Nujol) spectra, melting points, and mixed melting points.

1-Methyl-7-methoxy-3,4-dihydro-β-carboline (harmaline) (II)

6-Methoxytryptamine (21) (0.033 g, 0.00017 moles) was dissolved in 3.5 ml 0.1 *N* HCl (0.00035 moles) and heated on the steam bath with 0.011 g (0.00019 moles) glycolaldehyde, until a sample no longer gave a precipitate with dinitrophenylhydrazine (1½ hours). The solution was filtered, concentrated, washed into a continuous extractor, overlayered with ether, and made alkaline with 10 ml 0.5 *N* NaOH. Eighteen hours' extraction, drying over KOH and removal of solvent, gave 50 mg of a white crystalline solid, melting at 170–175°, after sintering at 85°, presumably a hydrate of 1-hydroxymethyl-7-methoxy-1,2,3,4-tetrahydro-β-carboline (XIV). (Ultraviolet absorption (λ_{max}, mμ (log ε)): 225 (4.37), 275 (3.53), 295 (3.65) in ethanol.) Without further purification, this base was treated with 2.5 ml 90% H_3PO_4 and kept on the steam bath for 2 hours, when the solution gave an ultraviolet curve identical with that of natural harmaline (footnote 2). The solution was diluted with water, placed in a continuous extractor, made alkaline with 20% NaOH, and the product was extracted into ether. The ether extract was dried, the solvent removed, and the product distilled at 10^{-3} mm and 120–140° to yield 27 mg (72%) harmaline, melting at 235–237°, identical with an authentic specimen in infrared and ultraviolet absorption (Fig. 2), R_f value (0.89) in 95% ethanol/.880 ammonia (99:1), melting point and mixed melting point. (Found: C, 72.6; H, 6.6; N, 13.1. Calc. for $C_{13}H_{14}ON_2$: C, 72.8; H, 6.6; N, 13.1%.) Infrared absorption in (Nujol) (cm^{-1}): 1620 (s), 1600 (m), 1570 (m), 1535 (s). Ultraviolet absorption (Fig. 2) (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 260 (4.07), 380 (4.49); in 0.1 *N* NaOH: 260 (4.18) (shoulder), 335 (4.34).

A portion was converted to the picrate, orange needles, melting at 228–229° after sintering at 215°, after recrystallization from aqueous ethanol, identical with the picrate derived from the authentic sample.

1-Methyl-3,4-dihydro-β-carboline-3-carboxylic acid (XVI)

(*1*) *By Dehydration of 1-Hydroxymethyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic Acid* (XV)

1-Hydroxymethyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic Acid

dl-Tryptophan (1.02 g, 0.005 moles) was dissolved in *N* HCl (5 ml, 0.005 moles), 0.33 g glycolaldehyde (0.0055 moles) was added, and the mixture was kept on the steam bath for 2 hours when a sample no longer gave a precipitate with dinitrophenylhydrazine. The dark solution was treated with charcoal, the pH of the filtrate was adjusted to pH 7, and a small amount of precipitate was removed by filtration. On concentration the product crystallized, and on recrystallization from boiling water was obtained in 51% yield (0.63 g) as long needles, decomposition 256–257° after darkening from 235°. No attempt was made to separate the diastereoisomers. A melting point of 234° was reported (24) for the product derived from *l*-tryptophan. (Found: C, 63.1; H, 5.7; N, 11.6. Calc. for $C_{13}H_{14}O_3N_2$: C, 63.4; H, 5.7; N, 11.4%.)

1-Methyl-3,4-dihydro-β-carboline-3-carboxylic Acid

The above amino acid (0.37 g, 0.0015 moles) was treated with an ice-cold solution of 2 ml 95% H_2SO_4 in 5 ml H_2O. After keeping this solution at room temperature for 48 hours no absorption at 355 mμ was observed. The solution was then kept on the steam bath for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

2 hours, when absorption at 355 mμ appeared, but since the ultraviolet absorption band at 280 mμ was still strong, a further 1 ml 95% H_2SO_4 was added. After 2 hours the reaction was complete. The solution was diluted with water, absorbed on a Zeocarb cation exchange resin in the acid form, and eluted with ammonia. The eluate was concentrated and the residue taken up in aqueous ethanol, treated with charcoal and allowed to stand at 0°, giving 88 mg (26%) of yellow crystals, melting at 189–190° after darkening at 185°, of the dihydrate of 1-methyl-3,4-dihydro-β-carboline-3-carboxylic acid. (Found: H_2O, 14.0. $C_{13}H_{12}O_2N_2,2H_2O$ requires H_2O, 13.6%. After drying at 100° found: C, 68.2; H, 5.4; N, 12.0. $C_{13}H_{12}O_2N_2$ requires C, 68.4; H, 5.3; N, 12.3%.) Infrared absorption (Nujol) (cm^{-1}): 1655 (m), 1632 (m), 1615 (m), 1592 (s), 1570 (s), 1523 (m), 1445 (s). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 245 (3.97), 355 (4.29); in 0.1 *N* NaOH: 235 (4.10), 315 (4.07).

(2) By Malonic Ester Synthesis

Ethyl α-Acetamido-α-carbethoxy-β-(3-indolyl)-propionate (XVII)

This was prepared by the pyridine method of Howe, Zambito, Snyder, and Tishler (27) which was found more satisfactory than their other methods. It was obtained as colorless crystals, melting at 142–144°.

1-Methyl-3,3-dicarbethoxy-3,4-dihydro-β-carboline (XVIII) (*cf.* (*28*))

Ethyl α-acetamido-α-carbethoxy-β-(3-indolyl)-propionate (1.04 g, 0.003 moles) was gently warmed with 5 ml $POCl_3$ for 45 minutes, when the band at 280 mμ in the ultraviolet spectrum of the original solution had been completely replaced by the band at 355 mμ. The reaction mixture had become dark brown. Excess $POCl_3$ was distilled off at room temperature at 10^{-3} mm, and the brown tarry residue triturated with excess NH_3. On standing overnight the tarry salt had been converted into the solid, crude base, which was filtered off and taken up in ether. The ether solution was washed with dilute NH_3 and H_2O, and the product then extracted into 0.02 *N* HCl. The acid solution was immediately treated with dilute ammonia, and the product re-extracted into ether and dried over Na_2SO_4. Removal of solvent gave a yellow solid which was dissolved in acetone. Addition of 70–100° petroleum ether and cooling gave the product as long yellow needles, melting at 154–156°, which was identical in infrared and ultraviolet absorption with the product described by Hardegger and Corrodi (28), melting at 147–149°[4] (yield 0.45 g, 44%). (Found: C, 65.6; H, 6.3; N, 8.7. Calc. for $C_{18}H_{20}O_4N_2$: C, 65. 8; H, 6.1; N, 8.5%.) Infrared absorption (cm^{-1}) 1725 (s), 1612 (w), 1595 (m), 1570 (w), 1540 (m), 1500 (w). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 245 (4.11), 355 (4.40); in 0.1 *N* NaOH: 240 (4.18), 318 (4.22).

1-Methyl-3,4-dihydro-β-carboline-3-carboxylic Acid

1-Methyl-3,3-dicarbethoxy-3,4-dihydro-β-carboline (0.2 g, 0.00061 moles) was wetted with a little ethanol, suspended in 1.22 ml *N* NaOH (0.00122 moles), and warmed for 2 hours. A small quantity of tarry material was filtered off and the filtrate acidified by addition of 19 ml 0.982 *N* HCl (0.00183 moles) and decarboxylation accelerated by keeping the mixture on a steam bath for 30 minutes. A small amount of solid was filtered off. The solution was applied to a column of Dowex 50, was washed free of chloride ion, and the product eluted with *M* NH_3. Concentration gave a small amount of a substance, crystallizing as long needles and melting at 188–190°, which gave an infrared spectrum ((Nujol) (cm^{-1}): 1620 (m), 1545 (m), 1510 (w)) different from that of the expected product (*vide supra*) and an ultraviolet absorption which even after repeated recrystallization of

PHYSICAL PROPERTIES OF ALKYL PYRROLES AND THEIR SALTS[1]

R. J. ABRAHAM,[2] E. BULLOCK,[2] AND S. S. MITRA[2]

ABSTRACT

The structures of the ions formed by several alkyl pyrroles in hydrochloric acid are deduced from proton resonance spectra. Basicity values for three alkyl pyrroles are determined from ultraviolet spectra of their salts in buffer solutions. An attempt is made to estimate the basicity of other pyrroles from the variation of the —OD stretching frequency of methanol-*d* in solution in the pyrroles. Variations of the free and bonded NH frequencies of alkyl pyrroles are shown to be a simple function of the positions and number of the substituents.

INTRODUCTION

The basic nature of substituted pyrroles has been emphasized recently (1, 2, 3, 4, 5) and suggestions made about the structures of the protonated forms (3, 4, 5, 6). Proton magnetic resonance seemed to present a good method for defining these structures, which are probably the activated forms of pyrroles in acid (3, 4, 6).

The proton magnetic resonance spectra of pyrrole and some substituted pyrroles have been given in a previous publication (12) and the frequencies completely assigned. The spectra of the methyl-substituted pyrroles given here can be interpreted on the same basis and need not be discussed in detail. However, the pyrrole hydrochlorides give much more complex spectra and these will be discussed here. The striking differences between the spectra of the hydrochlorides and of the parent compounds show immediately that the methyl pyrroles in acid solution do not form merely loose addition complexes, but true salts, and the structure of the cations can be found from the interpretation of the proton magnetic resonance spectra.

Basicity constants for two substituted pyrroles have been reported (5) and in addition to a redetermination of these values, two further pyrroles have been examined. Since the application of the ultraviolet method is very limited (by instability of the solutions) in the pyrrole series, a correlation with infrared measurements was desirable (7, 8). In view of a possible relationship between hydrogen-bonding and basicity, the NH frequencies of the pyrroles were examined.

Materials

Substituted pyrroles were synthesized by standard methods (9) or recent variations on these methods (10, 11). Pyrrole was a commercial sample (Fisher) repeatedly redistilled to give a fraction of 1° boiling range; other liquid compounds were distilled similarly. Tetramethyl pyrrole was crystallized from heptane.

The hydrochlorides were prepared as described earlier (5). 2,3,4,5-Tetramethyl pyrrole hydrochloride forms deliquescent white needles of low melting point and regenerates the parent base (melting point and mixed melting point) on treatment of the salt with sodium acetate. The salt slowly decomposed when stored *in vacuo*; the decomposition is not obvious from the condition of the solid but is observed by a slow decrease in the intensity of the ultraviolet absorption.

Infrared spectrum of II*b* ($R_2 = R_3 = R_4 = CH_3$, $R_5 = H$) (fluorolube mull): 2860, 2810, 2680, 2610 (broad), 1755, 1650, 1574, 1478, 1446, 1412, 1382 cm^{-1}.

Infrared spectrum of II*b* ($R_n = CH_3$) (nujol mull); 2680, 2490 (broad), 1780, 1655, 1580, 1415 cm^{-1}.

CH_3OD and DCl in D_2O were kindly provided by Dr. L. C. Leitch.

EXPERIMENTAL

The NMR spectrometer has been described previously (12). The spectra were measured at 60 Mc/s and the chemical shifts are given in c.p.s. from an internal dioxane reference, high field being positive. The internal reference was used in order to remove bulk susceptibility corrections. However, the position of the dioxane reference may change with the change in the acidity of the medium. This change would be expected to be only of the order of a few c.p.s. but must be taken into account in any correlation of the chemical shifts of the parent compound and the hydrochloride.

Most of the ultraviolet measurements were made on a Beckmann DU spectrometer, the remainder being determined on a Cary Model 11M instrument.

Buffer solutions, pH 2.2, 2.8, 3.4, and 4.0 were McIlvaine's citric acid – phosphate standards.

Solutions of the solid hydrochlorides containing 0.8–2.5 mg/25 ml were used.

A Perkin–Elmer model 12C infrared spectrometer equipped with LiF prism was used. Very dilute solutions in carbon tetrachloride were used for the determination of the free NH stretching mode of the pyrroles. The condition of infinite dilution was attained by increasing the dilution until the frequency was unaffected by further dilution. To determine the extent of association, a few drops of the liquids were pressed between rock salt plates and the spectrum of the thin film was taken.

In an attempt to measure the basicity of the different pyrroles, a solution of methanol-*d* was made in each pyrrole and the —OD stretching frequency was examined at 'infinite dilution' to ensure the absence of solute–solute interaction (8).

RESULTS

(*i*) *NMR Spectroscopy*

The chemical shifts for the parent compounds are shown in Table I. The spin coupling constants are observed only in two cases. In 3,4-dimethyl pyrrole $J_{12} = J_{15} = 2.3$ c.p.s.

TABLE I

The chemical shifts of methyl pyrroles

		Ring protons		Methyls	
Compound	N–H	α	β	α	β
2,4-Dimethyl pyrrole	−220	−166	−138	80	84
3,4-Dimethyl pyrrole		−161			95
2,3,4-Trimethyl pyrrole*	−221	−155		92	96, 100
2,3,5-Trimethyl pyrrole			−127	91, 94	96
2,3,4,5-Tetramethyl pyrrole*				94	104

*In carbon tetrachloride solution; all the others were pure liquids.

and in 2,3,5-trimethyl pyrrole $J_{14} = 2.1$ c.p.s. In the other ring proton peaks, this interaction is obscured by the additional interactions of the ring protons with the nitrogen nucleus and the methyl protons. The couplings of the methyls to the ring protons are known to be very small (~1 c.p.s.) and are not observed in these spectra. The chemical shift values serve as reference points for the shifts in the hydrochlorides and the coupling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

constants are also useful in assigning the various lines. Note that the α-methyl groups and the α-ring protons always come to low field of the corresponding β-positions.

The most probable structures for the pyrrole hydrochlorides are shown in Fig. 1. The structure formed by a loose association of the pyrrole ring with a bare proton is not shown and need not be considered as it does not explain the observed spectra. The structures shown, therefore, are formed by the attachment of the proton to I, the nitrogen atom; II*a* and *b*, the α-carbon atoms; III*a* and *b*, the β-carbon atoms. The chemical evidence supports structures I or II (3, 4, 5); however, we include III for completeness.

2,3,4,5-Tetramethyl Pyrrole

This is the simplest case to consider. Here all the R groups in Fig. 1 are methyl groups and thus structures II*a* and *b* are equivalent as are also III*a* and *b*. Thus we need to

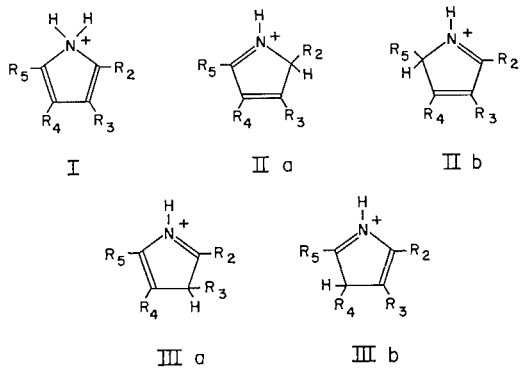

FIG. 1. Possible structures for pyrrole hydrochloride ion.

consider only three possible structures for the hydrochloride. Due to its symmetry the free base has only two methyl resonances, of the α- and β-methyl groups, at +94 and +104 c.p.s. respectively. If the hydrochloride had structure I this symmetry would be preserved and there would be only two peaks corresponding to the methyl groups, with possibly some fine structure.

The observed spectrum (Fig. 2*a*) is much too complex to be explained by this structure, which therefore is eliminated. In the observed spectrum, it is difficult to distinguish chemical shift separations from those due to spin interactions. In order to resolve this uncertainty the pyrrole was dissolved in DCl/D_2O. Any spin interaction with an exchangeable proton (i.e. all protons except those on the methyl groups) will now be reduced by a factor of six. The spectrum of the deuterated pyrrole salt (Fig. 2*b*) has the same methyl resonances, apart from a spurious peak due to some acetic acid impurity, but the original doublets at +71 and +138 are now broad single lines, proving conclusively the existence of four distinct methyl resonances, two of which are doublets due to spin–spin interaction.

Consider now structures II and III. Both structures would be expected to give rise to four different methyl peaks, one of which (the 2-methyl in II and the 3-methyl in III) will lie to high field, as it is attached to a saturated carbon atom, and give a doublet pattern of separation around 8 c.p.s. due to interaction with the nearest proton. This doublet is seen in the observed spectrum (at +134, +141 c.p.s.) and is strong support for one of these structures. The remaining peaks of the spectrum are less clearly assigned.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

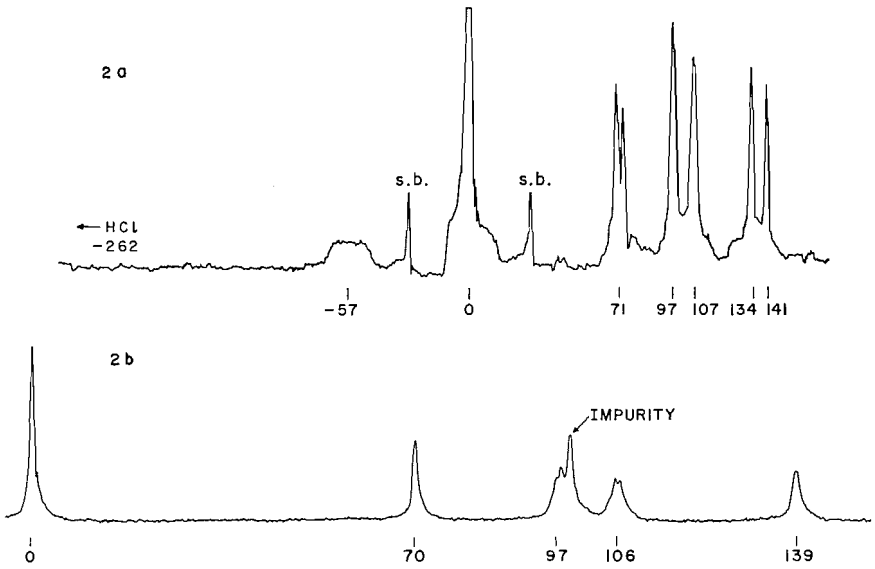

FIG. 2. The NMR spectrum of (*a*) 2,3,4,5-tetramethyl pyrrole in concentrated HCl, (*b*) 2,3,4,5-tetramethyl pyrrole in concentrated DCl.

In structure II either of the 3- or 5-methyl peaks could be the low field signal at +71 c.p.s., the 3-methyl as it is now in an α-position in the ring, and the 5-methyl as it is adjacent to a positively charged nitrogen atom, whilst in structure III it would be expected to be due to the 2-methyl peak. The remaining methyl peaks will be essentially unchanged. Thus from the chemical shift data both structures are possible. However, the doublet fine structure of this signal does provide a further clue. The spin coupling constants in these types of compound are not completely known, but for planar molecules, the methyl ring proton interactions are very small (less than 1 c.p.s. (12)). Thus the 3-c.p.s. splitting of this low field methyl peak is very likely the result of the interaction of the methyl protons with a ring proton which is not in the plane of the ring, i.e. proton 2 or 3, in structure II and III respectively.

However, in structure III, the 3-proton will couple equally with the methyl groups in positions 2 and 4, and thus two of the methyl peaks should be doublets. This is not observed and thus structure III may be discarded.

Thus the ion is very probably structure II. The assignment of the spectrum is then that the low field methyl peak (at +71 c.p.s.) is due to the 3-methyl group, and the remaining methyl peaks at 97 and 107 c.p.s. are assigned to methyls 5 and 4 respectively. The broad hump at −57 is the 2-proton. This has a complex fine structure which would not be expected to be resolved. The N–H proton signal is not observed and the interaction with the nitrogen quadrupole moment would be expected to broaden the peak to such an extent that it would not be observed. The spectrum of the hydrochloride is unchanged on dilution and is given on dissolving the pyrrole hydrochloride in dilute hydrochloric acid. Thus this salt is quite stable in acid solution, in agreement with the chemical evidence.

2,3,4-Trimethyl Pyrrole

The free base has three distinct methyl peaks at 92, 96, and 100 c.p.s. which can be reasonably assigned to the methyl groups in positions 2, 4, and 3 respectively, the 3-methyl being the most shielded. The spectrum of the hydrochloride in concentrated hydrochloric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

acid is shown in Fig. 3. The striking feature of this spectrum is the triplet of 2.8-c.p.s. separation given by the low field methyl group.

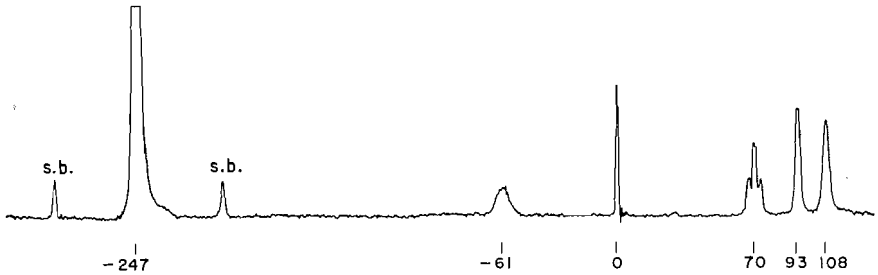

FIG. 3. The NMR spectrum of 2,3,4-trimethyl pyrrole in concentrated HCl.

Consider the possible structures for this ion (Fig. 1). In this case R_2, R_3, and R_4 are methyl groups whilst R_5 is a proton. Structures II*a*, III*a*, and III*b* can be eliminated immediately as they would all give the high field doublet observed in the tetramethyl pyrrole hydrochloride. The two remaining possibilities (structures I and II*b*) are very similar. Both structures may be expected to give a low field triplet methyl resonance (from the 2-methyl in I and the 4-methyl in II*b*), and the other methyl resonances will not differ appreciably from those in the free base; however, the structures can be differentiated by considering the chemical shifts of the ring protons. The resonances of ethylenic protons and protons attached to a positive nitrogen atom are known to lie at very low fields; on the scale used here, at around -150 c.p.s. (Table I) and -260 c.p.s (13) respectively. Thus there are no protons in structure I which would explain the broad peak at -61 c.p.s. However, this can be assigned very simply on structure II*b* as due to the CH_2 protons. The peak is in the correct region (compare the tetramethyl pyrrole hydrochloride in which the corresponding proton is found at -57 c.p.s.), and a further check is provided by the intensity of the peak. The three methyl peaks in Fig. 3 have intensities, in arbitrary units, of 216, 239, and 227 respectively giving an average of 227 ± 12. The intensity of the low field peak in the same units is equal to 157, which corresponds almost exactly to two-thirds of the intensity of the methyl, i.e. to two protons. The remaining peaks at $+93$ and $+108$ c.p.s. can be assigned to the 2- and 3-methyl groups respectively. Their fine structure can arise from coupling between themselves or with the nitrogen hydrogen, in any case it is expected to be small.

Thus the proton magnetic resonance spectrum strongly supports structure II*b* in which, as in the case of the tetramethyl pyrrole hydrochloride, the extra proton adds on to an α-carbon atom in the ring. The spectrum of this salt also does not change appreciably in different solutions, but in very concentrated solutions the individual line widths increase until eventually all the fine structure is obscured. This is probably due to intermolecular interactions rather than to any changes in the structure of the ion.

2,3,5-Trimethyl Pyrrole

The free base has again three distinct methyl peaks at 91, 94, and 96 c.p.s. which can be assigned to the 5-, 2-, and 3-methyl groups, the 3-methyl being the most shielded. The spectrum of the hydrochloride in concentrated hydrochloric acid (Fig. 4) is almost identical with that of the tetramethyl pyrrole hydrochloride with one methyl group missing. This is strong support for the proposed structure of the tetramethyl hydrochloride, as it is the 4-methyl peak in the tetramethyl case which should be missing here

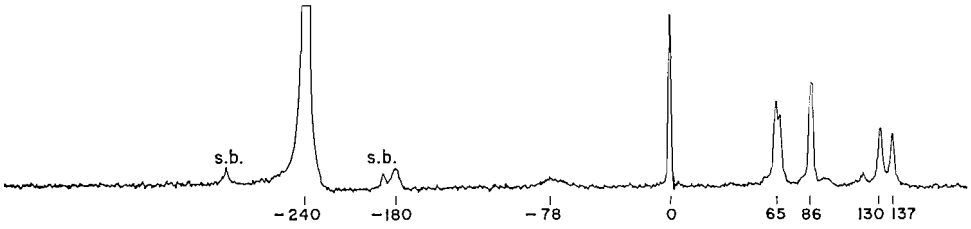

FIG. 4. The NMR spectrum of 2,3,5-trimethyl pyrrole in concentrated HCl.

(if the trimethyl hydrochloride has the same type of structure), and this is what is observed. Thus we may conclude that this structure has again the additional proton on the α-carbon atom. There are now two possible structures II*a* and II*b*, i.e. the additional proton is on either the 2- or 5-position. These can be differentiated. The doublet methyl peak at +65 c.p.s. cannot be explained on structure II*b*, assuming the values of the ring coupling constants mentioned earlier, but finds a reasonable assignment on structure II*a* as the 3-methyl group. The rest of the spectrum is assigned as follows. The 2- and 5-methyl resonances occur at +134 and +86 c.p.s. respectively, the 2-proton is at −78 c.p.s. and the 4-proton at −180 c.p.s.

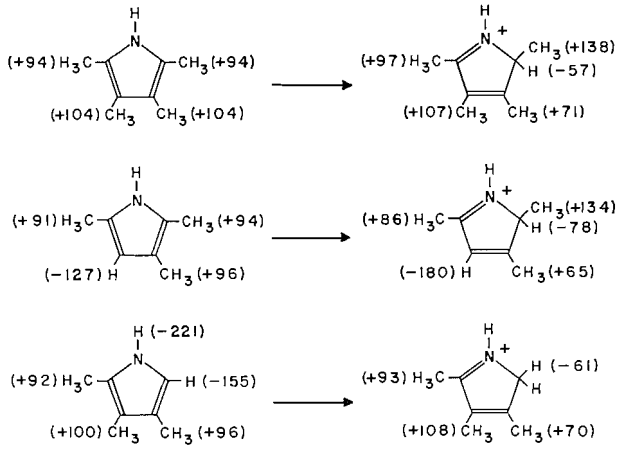

FIG. 5. The chemical shifts and assignments of the protons in the proton magnetic resonance spectra of 2,3,4- and 2,3,5-trimethyl and 2,3,4,5-tetramethyl pyrrole and their hydrochloride ions.

The structures of the remaining pyrrole hydrochlorides studied cannot be determined from their proton magnetic resonance spectra with the same certainty. However, before giving these results, the results for the tri- and tetra-methyl pyrroles are summarized in Fig. 5. Here the chemical shifts and assignments for the free bases and the hydrochlorides are given. The 2,3,4-trimethyl pyrrole formula has been written reversed in the figure so that the similarity with the other structures is more obvious. The figure shows that the differences in chemical shift on going from free bases to hydrochlorides are consistent in these compounds (allowing for the small chemical shift differences in concentration of the solutions and any shift in the internal standard), and these results can now be used to obtain some idea of the structures of the remaining pyrroles studied.

2,4-Dimethyl Pyrrole

The spectrum of the hydrochloride in concentrated hydrochloric acid is shown in Fig. 6 (note that the methyl groups are given on a different field scale from the rest of the

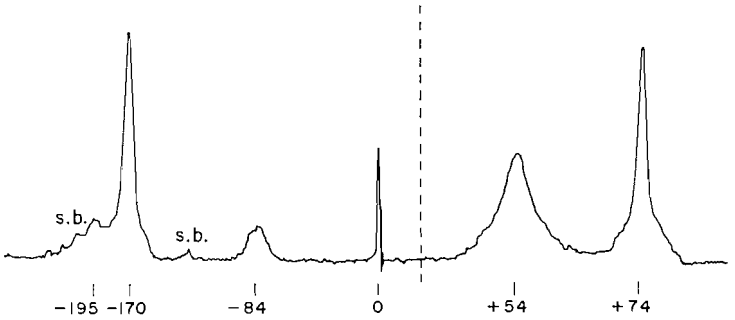

FIG. 6. The NMR spectrum of 2,4-dimethyl pyrrole in concentrated HCl.

spectrum, but that the vertical scale is the same throughout). By exactly similar reasoning to that used in the 2,3,4-trimethyl pyrrole case, it can be shown that the observed spectrum, and in particular the absence of a doublet methyl peak to high field, the breadth of the methyl peak at +54 c.p.s., and the broad peak of intensity two at −84 c.p.s., is explained only by structure II*b*, and is inconsistent with any of the other structures. The other dimethyl pyrroles give very different spectra in acid solution. Pyrrole itself is known to trimerize in acid solution (6), and the spectra of the acid solutions of 2,5- and 3,4-dimethyl pyrrole suggest that some reaction has occurred other than the formation of a positive ion. In particular, both compounds give many peaks in the methyl region, 3,4-dimethyl pyrrole gives four broad peaks at +82, 99, 109, and 125 c.p.s. and 2,5-dimethyl pyrrole three main peaks with a considerable amount of fine structure. This suggests that a reaction has occurred with the formation of compounds in which the environment of the methyl groups has changed radically. However, the spectra are difficult to interpret without further chemical evidence.

(*ii*) pK_a *Values*

The method reported previously (5) suffers from two disadvantages: (*a*) The difficulty of ensuring complete solution of the base in the very dilute hydrochloric acid used, and (*b*) the very limited pH range available, which prevents any check on the values obtained.

The solid salts of the tri- and tetra-substituted pyrroles were dissolved in phosphate–citric acid buffers at pH 2.8, 3.4, and 4.0. The results given in Table II are the average of at least nine determinations per compound (several concentrations). The 'error' quoted represents the spread of values obtained and is not a standard deviation. 2,4-Dimethyl pyrrole was checked by the former method at five different concentrations.

TABLE II
pK_a's of alkyl pyrroles

Pyrrole	λ_{max} (mμ)	pK_a
2,4-Dimethyl pyrrole	249	$1.9_8 \pm .14$
Cryptopyrrole	260	$3.5_4 \pm .14$
2,3,4-Trimethyl pyrrole	261	$3.9_4 \pm .07$
2,3,4,5-Tetramethyl pyrrole	265	$3.7_7 \pm .16$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

It is clear from these values that the incorrect figure reported previously for cryptopyrrole (5) is due to the fact that at the pH used the degree of dissociation being measured was comparable with the error in the method.

(iii) OD *Stretching Frequency for Methanol-d Dissolved in the Pyrroles*

Having established reference pK_a values by the ultraviolet method, an attempt was made to determine at least the order of the pK_a's for other substituted compounds.

The —OD bonding method of Gordy (7) is known to give reasonable agreement within a series of closely related compounds (8). The results recorded in Table III include the

decrease in ν_{OD} with respect to the value in CCl_4. The range of frequency from pyrrole to 2,3,4-trimethyl pyrrole is only 11 cm^{-1} and since the OD peaks often coincided with solvent peaks and were found by manual plotting, it is not likely that the accuracy obtained ($\sim \pm 1$ cm^{-1}) permits any conclusion to be drawn about the relative basicities; indeed, the $\Delta\nu_{OD}$ appears to be quite unrelated to the substitution of the pyrrole.

(iv) Free and Bonded —NH *Stretching Frequencies*

In view of the inconclusive results above, the extent of association in the substituted pyrroles was determined by measurement of the —NH stretching frequencies in two extreme cases. Table IV gives NH stretching frequencies for the pyrroles at infinite

TABLE IV

dilution in carbon tetrachloride (free molecules) and in the pure liquid (fully associated molecules). The separation $\Delta\nu_{NH}$ between the free and bonded values is large enough,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

according to the Sutherland (28) criterion of $\Delta\nu/\nu \geqslant 3\%$, to show the existence of hydrogen bonding. The values of $\Delta\nu_{NH}$, which are considered to be a measure of the strength of the hydrogen bond, are included in Table IV.

The NH stretching frequencies of the free molecules and the $\Delta\nu_{NH}$ values can be expressed as linear functions of the numbers of α- and β-substituents. The values are well reproduced by the following formulae

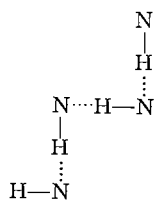
$$[1] \qquad \nu_{NH\ str} = 3497 - 10n_\alpha + 2n_\beta$$

$$[2] \qquad \Delta\nu_{NH} = 102 + 5n_\alpha + 4n_\beta$$

where n_α and n_β are the numbers of α- and β-substituents respectively.

$\Delta\nu_{NH}$ for 2,5-dimethyl pyrrole is considerably greater than that of pyrrole and the value for 2,3,4,5-tetramethyl pyrrole is the highest of all. Since the strength of the hydrogen bond must increase with $\Delta\nu_{NH}$ it seems that steric hindrance by α-methyl groups has no appreciable inhibitory effect on the strength of the hydrogen bond. This point is emphasized by the fact that the linearity relation (2) is obeyed almost exactly (within the limits of experimental accuracy).

Many suggestions have been made concerning the nature of the association in pyrrole (15–27) and the latest work (27) proposes a zigzag polymer form.



This proposal is also consistent with the results given here for the alkyl pyrroles.

DISCUSSION

The ions formed from all four pyrroles which remained as monomers in the aqueous acid are shown to be very probably ions in which the new proton is attached at an α-carbon in the ring.*

In a series of experiments using pyrroles which were activated by formation of a Grignard derivative, it has been shown (29) that alkylation by an alkyl halide always occurs at an α-position. In these cases the new alkyl group could be inserted at a substituted α-position about as easily as at an unsubstituted one when both were available on the same pyrrole. In the protonation reaction, the new proton always adds to the unsubstituted α-position when the choice exists.

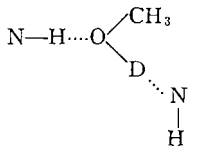
The mull spectra of three hydrochlorides in the crystalline state are so similar in the region 3000–1400 cm^{-1} as to leave no doubt that the ring structures are identical. The assignments of infrared bands made earlier (5) are still valid, however, and it must be considered possible that the solid phase salts are different in orientation from the salts in solution. In this connection one chemical observation is pertinent. Thus, treatment of 2,3,4,5-tetramethyl pyrrole hydrochloride with water gives an immediate precipitate of the *free base* (melting point) which slowly redissolves in the acid solution. Although this does not prove the hypothesis, it indicates at least that a two-step process involving dissociation and reassociation occurs on dissolution of this salt.

**Professor G. W. Kenner has kindly informed us that he has also reached this conclusion by similar methods.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

This structural assignment gives strong support to the reaction mechanism proposed by Treibs and his co-workers (*inter alios*, 2, 3, 4) by confirming the initial postulate of salt formation.

It was expected that the mechanism of hydrogen bonding in the liquid pyrroles and between methanol-*d* and pyrrole molecules would be very similar, since energetically the processes are presumably almost equivalent. The methanol-*d* solution probably represents the insertion of CH_3OD units into the pyrrole chains, i.e.,



The small range of $\Delta\nu_{NH}$ (Table IV) and $\Delta\nu_{OD}$ (Table III) agrees with this hypothesis. Thus $\Delta\nu_{OD}$ should show the same regular variation with substitution as does $\Delta\nu_{NH}$ and it is probably the inaccuracy inherent in the former measurement which prevents this correlation.

It is found that for three pyrroles, the pK_a versus $\Delta\nu_{OD}$ plot is approximately linear and

$$\Delta\nu_{OD} = 2.3\ pK_a + 168. \qquad [3]$$

Interpolation of other $\Delta\nu_{OD}$ values into this equation gives values of pK_a which are apparently unrelated to the substitution and do not follow any logical additive principle such as is found for the methyl pyridines (14).

From the known structure of the pyrrole ions, it is reasonable to suggest that a mono-α-substituted pyrrole would form an ion more readily than would a di-α-substituted compound, since the latter involves displacement of a methyl group from the plane of the ring. Thus two distinct series of pK_a variations would be expected. This expectation is borne out by the measured pK_a values for 2,3,4- and 2,3,4,5-substituted compounds. The $\Delta\nu_{NH}$ measurement, which should also reflect basicity, does not show any steric effect of this type and hence does not relate to the basicity measured in solution.

The variations in absorption maximum of the salts with increasing methyl substitution are unusual. Thus (Table II) the addition of the 3-methyl to 2,4-dimethyl pyrrole changes the λ_{max} by 12 mμ whilst adding the fourth methyl produces a bathochromic shift of only 4 mμ (cf. 30). The large increment in pK_a accompanying the addition of the third methyl group is also unusual, and the relative positions of substituents, therefore, has a great influence on the salts and also on the ease of salt formation.

The results recorded here add another limit to the value of the hydrogen bonding method for determination of basicity, i.e., that it is necessary to be certain that the hydrogen bond formation is not a radically different process from the salt formation.

ACKNOWLEDGMENTS

The authors are indebted to Dr. S. F. MacDonald and Dr. H. J. Bernstein for their interest and helpful suggestions, and to Mr. R. Lauzon for the solid phase infrared spectra.

SYNTHESES IN THE TERPENE SERIES

VIII. SYNTHESIS OF THE *CIS*- AND *TRANS*-ISOMERS OF 7,7,10-TRIMETHYLDECAL-1-ONE. A CONVENIENT MODIFICATION OF THE BROWN HYDRATION REACTION[1, 2]

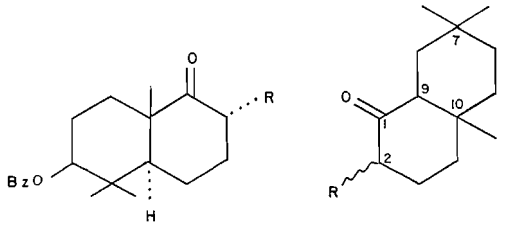
FRANZ SONDHEIMER AND SAUL WOLFE[3]

ABSTRACT

7,7,10-Trimethyl-$\Delta^{1(9)}$-octal-2-one (VII) was converted to the cycloethylenedithioketal (VIII), which on Raney nickel reduction yielded 7,7,10-trimethyl-$\Delta^{1(9)}$-octalin (IX). Oxidation with perbenzoic acid led to the corresponding oxide (X), which could be rearranged in low yield to an equilibrium mixture of 7,7,10-trimethyldecal-1-one consisting essentially of the *trans*-isomer (XI).

A convenient modification of the Brown hydration reaction is described, whereby the necessity of generating diborane or of using diglyme is avoided. 7,7,10-Trimethyl-$\Delta^{1(9)}$-octalin (IX) on Brown hydration using this modification stereospecifically furnished 7,7,10β-trimethyl-*cis*-decal-1β-ol (XII), which was oxidized to 7,7,10-trimethyl-*cis*-decal-1-one (XIII). Isomerization resulted in the above-described equilibrium mixture containing at least 90% of the *trans*-isomer (XI). Similarly, the previously described 10-methyl-$\Delta^{1(9)}$-octalin (XVI) yielded a mixture of the *cis*- and *trans*-isomers of 10-methyldecal-1-one (XIX). Syntheses of 2-methylene-7,7,10-trimethyl-$\Delta^{1(9)}$-octalin (XIV) and of 7,7,10-trimethyl-*cis*-decal-2,3-dione 3-dithiotrimethylene ketal (XXII) are also described.

In Part V of this series (1) stereospecific syntheses of the bicyclic ketones (I*a*) and (I*b*) were described, compounds which could become rings A and B of triterpenes of the β-amyrin (III) type. For the construction of rings D and E, ketones of type (II)



(Ia) R = H
(Ib) R = Me

(IIa) R = H
(IIb) R = Me

(III)

are required which are to be joined to the ketones (I) by a two-carbon unit, probably best introduced as acetylene. In this connection a study of the synthesis and stability of 10-methyldecal-1-one has already been carried out (2).

The substances of particular interest are the ketones (II*a*) and (II*b*) of the *cis*-configuration. Conformational considerations show that the derived acetylenic carbinols on dehydration should give vinyl-acetylenes with the double bond at the required $\Delta^{1(2)}$-position, whereas the corresponding *trans*-ketones would be expected to give vinyl-acetylenes with the double bond at the less desirable $\Delta^{1(9)}$-position. In this paper we

[1]*Manuscript received July 13, 1959.*

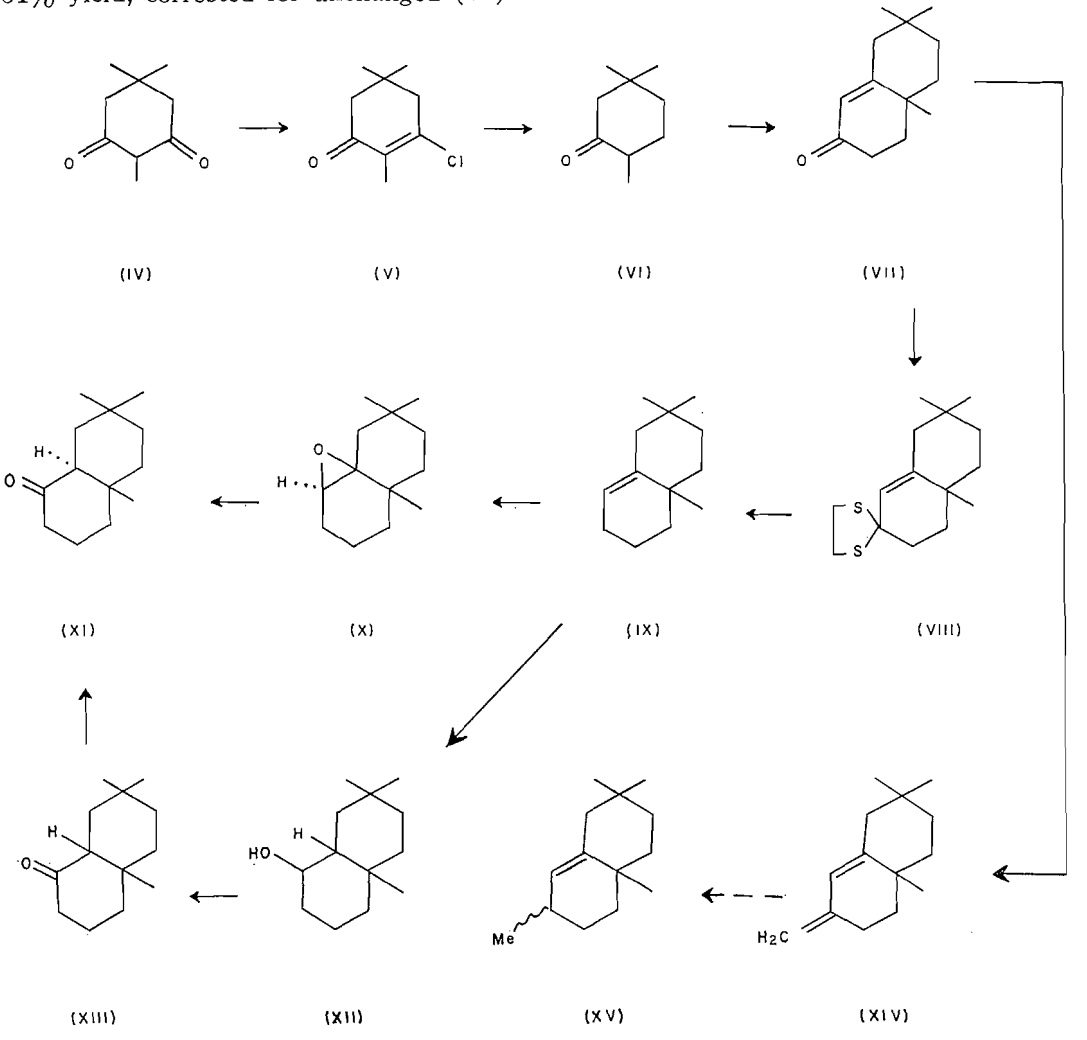
describe a synthesis in good yield of the key intermediate 7,7,10-trimethyl-*cis*-decal-1-one (*cis*-II*a* = XIII) as well as its inversion to the corresponding *trans*-isomer (*trans*-II*a* = XI).

The starting material for our work was 7,7,10-trimethyl-$\Delta^{1(9)}$-octal-2-one (VII), obtained by Halsall and Thomas (3) by the route (IV) → (V) → (VI) → (VII). The conversion of 2,5,5-trimethylcyclohexane-1,3-dione (IV) to 2,5,5-trimethylcyclohexanone (VI) has been carried out by two methods (3), the preferred one involving conversion to the enol chloride (V) and subsequent reduction with lithium in ammonia–ethanol and reoxidation. The hydrogenation of the enol chloride (V) over palladium – calcium carbonate in the presence of pyridine (cf. (4)) was reported not to yield (VI). However, in our hands the corresponding reaction when carried out over palladium–charcoal in the absence of pyridine smoothly produced 2,5,5-trimethylcyclohexanone (VI) in 75% yield and this was found to be the best preparative method for obtaining the latter compound. It was found further that the condensation between the ketone (VI) and 4-diethylaminobutan-2-one methiodide could be effected conveniently by the potassium *tert*-butoxide-*tert*-butanol method (2, 5), whereby the octalone (VII) was obtained in 34% yield, corrected for unchanged (VI).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Our first experiments designed to convert the octalone (VII) to 7,7,10-trimethyl-*cis*-decal-1-one (XIII) were modelled after those which led to the successful transformation of 10-methyl-$\Delta^{1(9)}$-octal-2-one (VII without the 7,7-dimethyl group) to a mixture of the *cis*- and *trans*-isomers of 10-methyldecal-1-one (XIX) (2). Thus, treatment of (VII) with ethanedithiol in the presence of boron trifluoride etherate gave in 91% yield the cycloethylenedithioketal (VIII), m.p. 71°, which on reduction with Raney nickel produced over 80% of 7,7,10-trimethyl-$\Delta^{1(9)}$-octalin (IX). It has been shown that no shift of the double bond occurs in this type of transformation (6).

Oxidation of the octalin (IX) with perbenzoic acid gave a liquid oxide. A model of the olefin (IX) reveals the double bond to be considerably more hindered from the α- than from the β-side[4] and the oxide is therefore most probably largely, if not completely, the β-oxide (X). The rearrangement of this oxide with boron trifluoride etherate was investigated under a variety of conditions, but in all cases the yield of ketonic material was rather unsatisfactory. Under the optimum conditions (see Experimental) about a 10% yield of a liquid ketone was obtained after chromatography on alumina, Girard separation, conversion to the semicarbazone, and pyruvic acid regeneration. This ketone, the infrared spectrum of which is reproduced in Fig. 1, is an equilibrium mixture of 7,7,10-trimethyldecal-1-one containing at least 90% of the *trans*-isomer (XI) (see below). The material appeared to be reasonably homogeneous, as evidenced by the fact that it yielded directly the pure semicarbazone on being reconverted to this derivative. This is in contrast to the situation which was observed with 10-methyldecal-1-one (XIX) (2).

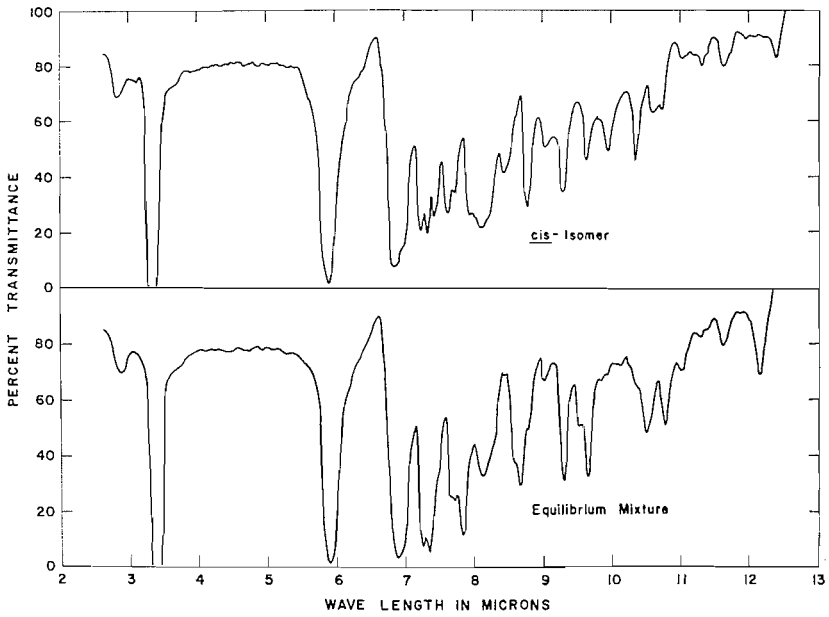

FIG. 1. Infrared spectra of 7,7,10-trimethyldecal-1-ones (in chloroform).

This route to 7,7,10-trimethyldecal-1-one suffers from two disadvantages. Firstly, the yield is poor. Secondly, it has been shown that the rearrangement of oxides to ketones

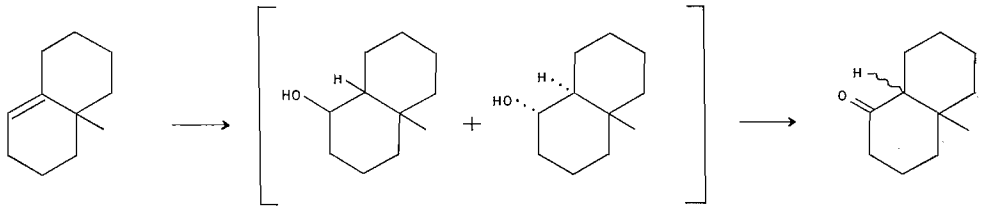
[4]*It may be noted that a model of 10-methyl-$\Delta^{1(9)}$-octalin* (XVI) *shows the double bond to be about equally hindered from both sides, and, in fact, hydrogenation proceeds about equally from the α- and the β-side (2). In 7,7,10-trimethyl-$\Delta^{1(9)}$-octalin* (IX), *the additional equatorial 7β-methyl group appears to make little difference, whereas the axial 7α-methyl group would be expected effectively to block attack from the α-side.*

proceeds by *cis*-shift of hydrogen (7). The β-oxide (X) will therefore produce the *trans*-decalone (XI) directly, even if care were taken to avoid equilibration of the product during its isolation. This fact, taken together with the apparent stability of the *trans*-ketone (XI), indicates that the more desirable *cis*-isomer (XIII) cannot be obtained by the present method. For these reasons another route to ketones of type (XI) and (XIII) was worked out, as described in the sequel.

An excellent method for the hydration of double bonds has recently been described by H. C. Brown and co-workers. This involves the conversion of the olefin dissolved in an ether to the corresponding trialkylborane by passing in diborane (generated from sodium borohydride and boron trifluoride etherate in diglyme) (8, 9), or alternatively allowing the olefin in diglyme solution to react *in situ* with sodium borohydride and aluminum chloride (10) or with sodium borohydride and boron trifluoride (11). The trialkylborane without purification is then oxidized with alkaline hydrogen peroxide to the borate ester, which under the reaction conditions is hydrolyzed to the corresponding alcohol. The hydration has been shown to proceed by over-all *cis*-addition of water from the less hindered side of the molecule,[5] the hydroxyl function being introduced at the less substituted position (anti-Markownikoff).

Application of the Brown hydration method to $\Delta^{1(9)}$-octalins of type (IX) seemed to offer a simple route to ketones of type (XI) and (XIII). However, since no diglyme (diethylene glycol dimethyl ether) was available to us and since the ether-soluble lithium aluminum hydride with boron trifluoride is known also to produce diborane (12), the following modification was made, as exemplified with cyclohexene (for a preliminary communication, see (13)). The latter olefin in ether solution was treated with boron trifluoride etherate and then gradually with an ethereal lithium aluminum hydride solution. The product on oxidation with alkaline hydrogen peroxide then gave cyclohexanol in over 80% yield. Similarly 1-octene was converted to 1-octanol in excellent yield. In this way the necessity of generating diborane separately or of using the high-boiling diglyme (b.p. 160–162° (740 mm)) *in situ* is avoided.

Application of this modification to 10-methyl-$\Delta^{1(9)}$-octalin (XVI) (2) gave 85% of an alcohol, which judging from our experience in the steroid series (13) and the known



(XVI) (XVII) (XVIII) (XIX)

course of hydrogenation of (XVI) (2) is most probably a mixture of 10β-methyl-*cis*-decal-1β-ol (XVII) and 10β-methyl-*trans*-decal-1α-ol (XVIII). Oxidation of this material with chromium trioxide – pyridine then smoothly yielded 10-methyldecal-1-one (XIX),

[5]*The experiments of Brown, H. C. and Zweifel, G. (J. Am. Chem. Soc.* **81**, *247 (1959)) do not provide unequivocal proof that this mode of addition operates in all cases, since they involve flexible monocyclic systems and lead to alcohols in all of which the hydroxyl group is presumably equatorial. Rigid proof for over-all cis-addition from the less hindered side (involving cis-addition of diborane, followed by oxidation and hydrolysis with retention of configuration) was provided by the demonstration that Δ5-cholestene derivatives on Brown hydration yield the corresponding axial 6β-hydroxycoprostane as well as the equatorial 6α-hydroxycholestane derivatives (Wechter, W. J. Chem. & Ind. 294 (1959); Wolfe, S., Nussim, M., Mazur, Y., and Sondheimer, F., J. Org. Chem.* **24**, *1034 (1959)).*

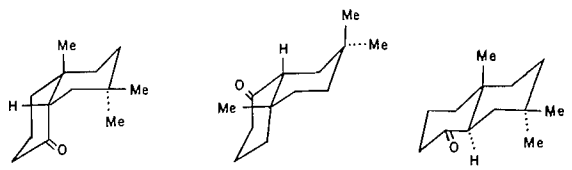
For personal use only.

probably as a mixture of the *cis*- and *trans*-isomers, which gave the same semicarbazone as obtained previously from the equilibrium mixture (2).

Finally our modification of the Brown hydration method was applied to 7,7,10-trimethyl-$\Delta^{1(9)}$-octalin (IX). A crystalline alcohol, m.p. 83°, was readily obtained in 80% yield, which must be 7,7,10β-trimethyl-*cis*-decal-1β-ol (XII) in view of the known steric course of the reaction (9, 13) and the fact that the α-side of (IX) is considerably more hindered than the β-side.[6] Oxidation of the alcohol (XII) with chromium trioxide – pyridine and direct crystallization of the product then gave 80% of 7,7,10-trimethyl-*cis*-decal-1-one (XIII), m.p. 43°. The infrared spectrum of this ketone, reproduced in Fig. 1, is considerably different from that of the 7,7,10-trimethyldecal-1-one obtained by the first method.

Adsorption of the crystalline *cis*-ketone (XIII) on alkaline alumina resulted in isomerization and yielded the equilibrated product, which was identified with the ketone obtained by the first method in view of the complete identity of the infrared spectra (Fig. 1) and of crystalline derivatives. Comparison of the infrared spectrum of the equilibrated product with that of the crystalline *cis*-ketone (XIII) shows that no more than about 10% of the latter can be present and consequently that it consists essentially of the *trans*-ketone (XI).

Of the two conformations A and B which can be written for the *cis*-ketone (XIII), the latter is undoubtedly the preferred one. It contains three methyl–hydrogen and three methylene – hydrogen 1,3-diaxial interactions, whereas the *trans*-ketone (XI) (conformation C) contains five methyl–hydrogen interactions. The observed greater stability of the latter isomer is therefore in keeping with expectation.



A B C

The methylation of the *cis*- and *trans*-isomers of 7,7,10-trimethyldecal-1-one (type II*a*) to the corresponding 2,7,7,10-tetramethyl-ketones (type II*b*) is now being studied. Some experiments designed to obtain the latter directly have also been carried out and are briefly reported in the sequel, although the desired objective was not reached.

Thus, 7,7,10-trimethyl-$\Delta^{1(9)}$-octal-2-one (VII) on being subjected to the Wittig reaction (14) with triphenylphosphinemethylene yielded 70% of 2-methylene-7,7,10-trimethyl-$\Delta^{1(9)}$-octalin (XIV). This diene proved to be rather unstable and it was not possible to effect its partial hydrogenation to the corresponding 2-methyl compound (XV), which we intended to hydrate by the Brown reaction.

Hydrogenation of 7,7,10-trimethyl-$\Delta^{1(9)}$-octal-2-one (VII) with palladium–charcoal in ethanol gave the known 7,7,10-trimethyl-*cis*-decal-2-one (XX), m.p. 68° (3). The 3-position of this compound was blocked through conversion to the 3-hydroxymethylene-ketone (XXI),[7] which with the toluene-*p*-thiosulphonate of propane-1,3-dithiol yielded

[6]*See footnote 4.*

[7]*The formulation of this compound as* (XXI) *follows from the fact that condensation of cis-decal-2-one with ethyl oxalate is known to occur at the 3-position (Stork, G. and Hill, R. K. J. Am. Chem. Soc.* **79**, *495 (1957)), and in the case of 7,7,10-trimethyl-cis-decal-2-one* (XX) *even normal alkylation and bromination takes place at this position (3).*

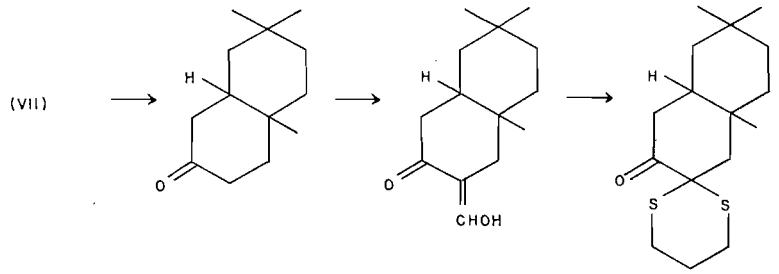
the dithioketal (XXII), m.p. 121° (method of Woodward *et al.* (15)). This thioketal appears to be a useful substance for further synthetic studies.



(XX) (XXI) (XXII)

EXPERIMENTAL

Melting points and boiling points are uncorrected. The alumina used for all chromatograms was prepared from Alcoa activated alumina, grade F-20 (Aluminum Co. of America, Pittsburgh, Pa.) through neutralization by means of ethyl acetate and reactivation for 4 hours at 200° (35 mm). Ultraviolet spectra were measured in 95% ethanol solution on a Unicam model S.P. 500 spectrophotometer and infrared spectra in chloroform solution on a Baird double-beam recording spectrophotometer. Analyses were carried out in our microanalytical department under the direction of Mr. Erich Meier.

2,5,5-Trimethyl-3-chlorocyclohex-2-en-1-one (V)

2,5,5-Trimethylcyclohexane-1,3-dione (IV) was prepared by the methylation of dimedone (3, 16, 17). The reaction of (IV) with phosphorus trichloride was best carried out on a 30–35 g scale under the conditions described by Halsall and Thomas (3). The yield could be improved by azeotropic distillation with dry chloroform of traces of moisture in the ketone (IV) before the addition of the phosphorus trichloride. By taking this precaution, there were obtained from a total of 165 g of IV a total of 125 g (68%) of 2,5,5-trimethyl-3-chlorocyclohex-2-en-1-one, b.p. 78–80° at 2 mm, n_D^{22} 1.4963; reported (3): b.p. 76–78° at 5 mm, n_D^{20} 1.4962.

2,5,5-Trimethylcyclohexanone (VI)

A solution of 15 g of 2,5,5-trimethyl-3-chlorocyclohex-2-en-1-one (V) in 165 ml of absolute methanol was shaken with 2 g of a 5% palladium–charcoal catalyst in hydrogen at 22° and 758 mm. The absorption of hydrogen had become very slow after 1 hour, by which time 2.09 molar equivalents of gas had been absorbed. The catalyst was removed and washed well with ethanol. Most of the solvent was removed by fractional distillation through a 12-inch Vigreux column. The residue was dissolved in ether and the solution was washed with water, dried, and evaporated. Distillation of the residue yielded 9.1 g (75%) of 2,5,5-trimethylcyclohexanone, b.p. 79–80° at 21 mm, n_D^{24} 1.4458; reported (3): b.p. 71–73° at 12 mm, n_D^{20} 1.4460. The semicarbazone showed m.p. 179–180°; reported (3): m.p. 173–177°.

7,7,10-Trimethyl-$\Delta^{1(9)}$-octal-2-one (VII)

A solution of potassium *tert*-butoxide in *tert*-butanol (1000 ml of 0.86 *N*) was added all at once to a boiling solution of 120 g (0.857 mole) of 2,5,5-trimethylcyclohexanone in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12

For personal use only.

200 ml of dry *tert*-butanol under nitrogen. The mixture was boiled for 1 hour under nitrogen and the resulting clear orange solution was allowed to cool to room temperature during the next 2 hours. During this time a solution of 4-diethylaminobutan-2-one methiodide in *tert*-butanol was prepared by the addition of 236 g (1.64 moles) of 4-diethylaminobutan-2-one (18) in 200 ml of dry *tert*-butanol to 230 g (1.62 moles) of methyl iodide in 150 ml of *tert*-butanol, followed by stirring under nitrogen at 0° for 1 hour. The resulting non-viscous two-phase system was added gradually during 1 hour to the solution of the enol, with stirring, whereby the temperature rose to 60° and a reddish suspension resulted. The mixture was stirred in nitrogen at room temperature for 70 hours. It was then poured onto cracked ice containing 180 ml of concentrated hydrochloric acid, and the mixture was well extracted with ether. The organic layer, containing ether and *tert*-butanol, was evaporated, the residue was diluted with ether, and the solution was washed with water, dried, and evaporated. The dark residue was distilled through a small column under reduced pressure. The first fraction after redistillation gave 55 g (46%) of unreacted 2,5,5-trimethylcyclohexanone (b.p. 62–64° at 10 mm; semicarbazone, m.p. 177–179°, undepressed on admixture with an authentic sample). The next fraction (60.5 g) consisted of the crude ketone VII, b.p. 120–125° at 0.7 mm, λ_{max} 241 mμ (ε 9800). This fraction was converted to the semicarbazone in the usual way. The crude derivative after being filtered and dried weighed 46 g and showed m.p. 208–212°. The derivative could be purified by crystallization, but in practice it was found wasteful and unnecessary to do so. The total crude derivative was therefore boiled under reflux for 30 minutes with 52 g of fused sodium acetate and 40 g of freshly distilled pyruvic acid in 1 l. of glacial acetic acid containing 200 ml of water. Most of the solvent was removed by distillation at 30 mm and ether and water were added to the residue. The ether extract was washed with sodium bicarbonate solution and water, dried, and evaporated. Distillation of the residue yielded 30.2 g (34%, corrected for recovered starting material) of the ketone (VII), b.p. 122–124° at 3 mm, n_D^{22} 1.5068, λ_{max} 241 mμ (ε, 16,400); reported (3): b.p. 110–115° (bath) at 0.5 mm, n_D^{20} 1.5070, λ_{max} 243 mμ (ε, 17,000). The semicarbazone after crystallization from ethanol showed m.p. 226–227°. Anal. Calc. for $C_{14}H_{23}N_3O$: C, 67.43; H, 9.30. Found: C, 67.22; H, 9.35.

7,7,10-Trimethyl-$\Delta^{1(9)}$*-octal-2-one Cyclоethylenedithioketal* (VIII)

Boron trifluoride etherate (2 cc) was added to a mixture of 5 g of the unsaturated ketone VII and 4.25 cc of ethanedithiol, with ice-cooling, and the mixture was then allowed to stand at 0° for 30 minutes. The crystalline mass was diluted with 25 cc of dry methanol, cooled, and filtered. This procedure yielded 6.38 g (91%) of the dithioketal (VIII), m.p. 67–69°, which was used in the next step. Crystallization of a small sample from methanol led to the analytical specimen, m.p. 70.5–71°, no high-intensity absorption in the ultraviolet. Anal. Calc. for $C_{15}H_{24}S_2$: C, 67.10; H, 9.01. Found: C, 66.86; H, 8.84.

7,7,10-Trimethyl-$\Delta^{1(9)}$*-octalin* (IX)

The dithioketal (VIII) (6.3 g), W-2 Raney nickel (ca. 50 g), and absolute ethanol (450 cc) were boiled under reflux for 14 hours. The nickel was removed, washed with absolute ethanol, and the solvent was evaporated through a 12-inch Vigreux column. Pentane was added to the residue, the mixture was filtered, and the filtrate evaporated. Distillation of the residue at 120–130° (bath temperature) at 30 mm yielded 3.40 g (81%) of the olefin (IX), n_D^{22} 1.4951, infrared band at 6.00 and 12.44 μ (trisubstituted double bond). Anal. Calc. for $C_{13}H_{22}$: C, 87.56; H, 12.44. Found: C, 87.42; H, 12.20.

The olefin could also be purified by chromatography on alumina and elution with pentane.

1β,9β-Oxido-7,7,10-trimethyldecalin (X)

7,7,10-Trimethyl-$\Delta^{1(9)}$-octalin (IX) (2 g) (0.0112 mole) in benzene (40 ml) was added during 15 minutes to a solution of perbenzoic acid (0.0123 mole) in benzene (40 ml) cooled to 5°. The solution was then allowed to reach room temperature. Aliquots (0.1 cc each) were removed at intervals and titrated against standard sodium thiosulphate solution. After 15, 30, and 150 minutes the extent of reaction was 88, 95, and 104%, respectively. After the last titration, the solution was washed with 2 *N* potassium hydroxide solution and water and was then dried and evaporated. Evaporation of the solvent yielded 2.16 g (99%) of the crude oxide (X), which was used for the next step. A small sample was purified by chromatography on alumina, followed by elution with pentane and pentane–benzene (9:1) and finally distillation at 120° (bath temperature) at 23 mm. The purified oxide showed n_D^{18} 1.4868, no infrared band in the 6-μ region. Anal. Calc. for $C_{13}H_{22}O$: C, 80.35; H, 11.41. Found: C, 80.30; H, 11.53.

Rearrangement of 1β,9β-Oxido-7,7,10-trimethyldecalin (X) *to 7,7,10-Trimethyl-trans-decal-1-one* (XI)

Boron trifluoride etherate (1.78 g) in dry chloroform (25 ml) was added to a solution of the crude oxide (X) (2.0 g) in dry chloroform (25 ml) kept at 0° by ice-cooling. The solution, which rapidly turned orange, was maintained at 0° for 30 minutes and was then poured into 100 ml of a saturated sodium bicarbonate solution. Ether was added and the organic extract was washed with water, dried, and evaporated. The residue (2.02 g) was chromatographed on 80 g of alumina, a procedure which showed it to be a complex mixture. The only ketonic fraction (0.84 g; strong infrared band at 5.84 μ) was eluted with pentane–ether (3:1). This fraction did not yield a crystalline semicarbazone. It was therefore boiled under reflux for 1 hour with 2 g of Girard reagent P in 40 cc of absolute methanol containing 4 g of glacial acetic acid. The solution was cooled and added to 5.05 g of sodium bicarbonate dissolved in 250 ml of ice-cold water. The mixture was extracted with ether, and the aqueous layer was then acidified with dilute hydrochloric acid, allowed to stand for 30 minutes, and extracted well with ether. The latter extract was washed with water, dried, and evaporated. The resulting ketone (0.29 g; 14.5%) was converted in about 80% yield into the semicarbazone of the ketone XI, which after crystallization from ethanol showed m.p. 221–222°. Anal. Calc. for $C_{14}H_{25}N_3O$: C, 66.89; H, 10.03. Found: C, 66.81; H, 10.21.

The ketone was regenerated from the semicarbazone in over 80% yield with pyruvic acid as described above for the octalone (VII). It showed b.p. 84–86° at 0.1 mm, n_D^{22} 1.4905. The infrared spectrum is reproduced in Fig. 1. Anal. Calc. for $C_{13}H_{22}O$: C, 80.35; H, 11.41. Found: C, 80.51; H, 11.43.

Reconversion to the semicarbazone, followed by one crystallization from ethanol, yielded the pure derivative, m.p. 220–222°. The 2,4-dinitrophenylhydrazone after crystallization from ethanol formed orange needles, m.p. 197–198°. Anal. Calc. for $C_{19}H_{26}N_4O_4$: C, 60.94; H, 7.00. Found: C, 61.10; H, 6.92.

Conversion of Cyclohexene to Cyclohexanol with Lithium Aluminum Hydride and Boron Trifluoride

Boron trifluoride etherate (3.4 g; 0.024 mole) was added to a solution of cyclohexene (4 g; 0.049 mole) in 100 ml of dry ether. A solution of lithium aluminum hydride (0.7 g; 0.018 mole) in 70 ml of ether was then added dropwise during 20 minutes, under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

nitrogen, with stirring and ice-cooling. The mixture was stirred at room temperature under nitrogen for a further 2 hours, when 20 ml of acetone were added carefully to destroy excess reagent. A saturated solution of sodium sulphate was added, followed by solid sodium sulphate. The mixture was filtered, the precipitate was washed with ether, and the clear filtrate was evaporated. The residue was dissolved in 30 ml of 90% ethanol containing 0.8 g of sodium hydroxide, and 10.2 ml of 20% aqueous hydrogen peroxide was then added during 5 minutes with stirring, whereby the mixture heated spontaneously to about 70°. The temperature was maintained at this point for 5 minutes longer by external heating and the flask was then cooled. Water and ether were added, the ether extract was washed with water, dried, and evaporated through a Vigreux column. Distillation of the residue yielded 4.0 g (82%) of cyclohexanol, m.p. 20–23°, b.p. 161–162°, n_D^{22} 1.4656, identified with an authentic sample through non-depression of the melting point on admixture and by the complete identity of the infrared spectra.

In exactly the same way, 1-octene was converted in 80% yield to *n*-octanol (b.p. 194–196°, n_D^{25} 1.4295) identified through the infrared spectrum with an authentic sample.

Conversion of 10-Methyl-$\Delta^{1(9)}$*-octalin* (XVI) *to cis- and trans-10-Methyldecal-1-one* (XIX) *by the Diborane Reaction*

A solution of 0.45 g (0.0032 mole) of boron trifluoride etherate in 5 ml of ether was added to 0.5 g (0.0033 mole) of 10-methyl-$\Delta^{1(9)}$-octalin (XVI) (2) in 15 ml of ether. A solution of 0.2 g (0.005 mole) of lithium aluminum hydride in 20 ml of ether was then added during 10 minutes under nitrogen with stirring and the mixture was stirred at room temperature for 3 hours more. The product, isolated as before, was dissolved in 15 ml of 90% ethanol containing 0.4 g of sodium hydroxide. The solution was heated to 70° and 1 ml of 20% aqueous hydrogen peroxide was added dropwise. Heating at 70° was continued for 5 minutes and the product was then isolated as above. The resulting material (0.52 g) was chromatographed on 25 g of alumina. Elution with pentane yielded 0.08 g (16%) of unchanged octalin (XVI), while elution with pentane–ether (3:1) gave 0.40 g (71%; 85% corrected for recovered starting material) of a liquid mixture of the carbinols (XVII) and (XVIII), showing a strong hydroxyl band in the infrared.

This material was dissolved in 12 ml of dry pyridine and added dropwise during 10 minutes to a mixture of 0.6 g of chromic acid and 12 ml of pyridine, with stirring and ice-cooling. The mixture was allowed to stand overnight and was then diluted with water and extracted repeatedly with ether. The organic extract was filtered through Celite and evaporated. Distillation of the product at 90–100° (bath temperature) at 3 mm yielded 0.33 g (83%) of a mixture of the *cis*- and *trans*-isomers of 10-methyldecal-1-one (XIX), the infrared spectrum of which was almost identical with that of the previously described equilibrium mixture (2). Conversion to the semicarbazone gave about an 80% yield of derivative, m.p. 198–204°, which after several crystallizations from ethanol rose to 209–210°. The melting point was undepressed on admixture with an authentic sample (m.p. 209–211°) (2).

7,7,10β-Trimethyl-cis-decal-1β-ol (XII) *from 7,7,10-Trimethyl-*$\Delta^{1(9)}$*-octalin* (IX)[8]

Boron trifluoride etherate (5 ml) was added to a solution of 2 g of the octalin (IX) in 40 ml of ether. A solution of 1.1 g of lithium aluminum hydride in 70 ml of ether was then added during 45 minutes, with stirring under nitrogen, and the mixture was stirred for another 2 hours at room temperature. The product, isolated as before, was dissolved in 30 ml of 90% ethanol containing 1.2 g of sodium hydroxide. Hydrogen peroxide (7 ml

For personal use only.

of a 20% solution) was added, and the mixture was allowed to stand at room temperature for 1 hour. Isolation with ether then gave 2.1 g of a product which was chromatographed on 80 g of alumina. Elution with pentane gave 0.12 g (6%) of unchanged octalin (IX), while elution with pentane–ether (4:1) gave 1.65 g (75%; 80% corrected for recovered starting material) of the crystalline alcohol (XII), m.p. 78–81°. Crystallization from pentane gave the analytical sample, m.p. 82–83°, strong hydroxyl band in the infrared. Anal. Calc. for $C_{13}H_{24}O$: C, 79.53; H, 12.32. Found: C, 79.87; H, 12.32.

7,7,10-Trimethyl-cis-decal-1-one (XIII) *from 7,7,10-Trimethyl-cis-decal-1β-ol* (XII)

A solution of 2.4 g of the carbinol (XII) in 20 ml of dry pyridine was added during 10 minutes to a mixture of 3 g of chromic acid and 40 ml of pyridine, with stirring and ice-cooling, and the mixture was then allowed to stand at room temperature for 24 hours. The product, isolated as described above, on crystallization from pentane yielded 1.54 g of the *cis*-ketone (XIII), m.p. 40–42°. Distillation of the mother liquors at 120–130° at 25 mm and subsequent crystallization from pentane gave another 0.36 g (total yield, 80%), m.p. 39–42°. Further crystallization from pentane gave large plates, m.p. 42–43°, with the infrared spectrum shown in Fig. 1. Anal. Calc. for $C_{13}H_{22}O$: C, 80.35; H, 11.41. Found: C, 80.36; H, 11.23.

Isomerization of 7,7,10-Trimethyl-cis-decal-1-one (XIII) *to the trans-Isomer* (XI)

The crystalline *cis*-ketone (XIII) (0.5 g) dissolved in 10 cc of pentane was absorbed on a column of 50 g of alkaline alumina (Grade F-20, Aluminum Co. of America, Pittsburgh, Pa.), prepared with pentane. The column was then allowed to stand for 12 hours. Elution with pentane and then with pentane–benzene (2:3) yielded 0.47 g (94%) of the liquid equilibrated product, consisting essentially of the *trans*-ketone (XI). The infrared spectrum was identical in every respect with that of the ketone obtained by the boron trifluoride isomerization method. The semicarbazone after crystallization from ethanol formed needles, m.p. 221–222°. The 2,4-dinitrophenylhydrazone formed orange needles from ethanol, m.p. 196–197°. Neither of these melting points were depressed on admixture with the corresponding derivatives of the ketone (XI) obtained from the oxide (X).

2-Methylene-7,7,10-trimethyl-$\Delta^{1(9)}$*-octalin* (XIV)

An ethereal solution of *n*-butyllithium (35 ml of 0.68 *N*; 0.024 mole) was added to a suspension of 10 g (0.028 mole) of methyltriphenylphosphonium bromide (prepared from methyl bromide and triphenylphosphine (14)) in 160 ml of dry ether, with swirling under nitrogen. The mixture was stirred in nitrogen for 1½ hours and a solution of 0.96 g (0.005 mole) of the octalone (VII) in 50 ml of ether was added. Stirring at room temperature was continued for 20 hours and 200 ml of dry tetrahydrofuran were then added at the same time as most of the ether was removed by distillation. The resulting mixture was boiled under reflux for 10 hours, cooled, and diluted with water. The product was extracted with ether and the ether layer was washed with dilute hydrochloric acid and water, dried, and evaporated. The orange oily residue was heated with 500 ml of dry pentane, the mixture was cooled, and the triphenylphosphine oxide which had precipitated was removed. Evaporation of the solvent and distillation of the residue gave 0.67 g (71%) of the diene (XIV), b.p. 130–140° (bath temperature), at 23 mm n_D^{24} 1.5100, infrared bands at 6.08 and 11.35 μ. Anal. Calc. for $C_{14}H_{22}$: C, 88.35; H, 11.65. Found: C, 88.60; H, 11.42.

The diene polymerized on attempted chromatographic purification on alkaline alumina and also on being allowed to stand for 1 week in light and air at room temperature.

7,7,10-Trimethyl-cis-decal-2,3-dione 3-Dithiotrimethylene Ketal (XXII)

7,7,10-Trimethyl-$\Delta^{1(9)}$-octal-2-one (1 g) in 200 ml of absolute ethanol was shaken in hydrogen over 0.6 g of a 10% palladium–charcoal catalyst at 755 mm and 25°. After 20 minutes, 1.01 molar equivalents of hydrogen had been absorbed and uptake stopped. The catalyst was removed, the filtrate was evaporated, and the resulting crystalline residue on sublimation at 60° (bath temperature) at 23 mm gave 7,7,10-trimethyl-*cis*-decal-2-one (XX) (0.74 g) as needles, m.p. 65–67°, infrared band at 5.83 μ; reported (3): m.p. 67.5–68°.

A solution containing 0.62 g of the *cis*-ketone (XX) and 0.75 ml of freshly distilled ethyl formate in 15 ml of dry benzene was stirred in nitrogen with 0.4 g of sodium hydride at room temperature for 65 hours. Excess hydride was then destroyed by the dropwise addition of methanol, and ether and cold 3% sodium hydroxide solution was added. The aqueous layer was separated, acidified with cold 5% hydrochloric acid, and again extracted with ether. The latter ether extract on being washed with water, dried, and evaporated yielded 1.13 g of the crude hydroxymethylene-ketone (XXI), admixed with formic acid, λ_{max} 282 mμ (ϵ, 5500). This material was dissolved in 25 ml of absolute ethanol, 1.67 g of propane-1,3-dithiol toluene-*p*-thiosulphonate was added, and then a solution of 2.4 g of freshly fused potassium acetate in 10 ml of ethanol. The resulting mixture was boiled under reflux for 5 hours and then evaporated nearly to dryness. Ether and water were added, the organic layer was washed with water, dried, and evaporated. The residue was chromatographed on 30 g of alumina. Elution with benzene yielded 0.42 g (44%) of the dithioketal (XXII) as a crystalline solid, m.p. 100–110°. Two crystallizations from methanol gave the analytical sample as long needles, m.p. 120–121°. Anal. Calc. for $C_{16}H_{26}OS_2$: C, 64.38; H, 8.78. Found: C, 64.08; H, 8.59.

MYCOCHRYSONE

II. CARBON SKELETON, PRINCIPAL CHROMOPHORE, AND OXYGEN FUNCTIONS[1]

G. READ[2] AND L. C. VINING

ABSTRACT

A mono- and di-methyl ether and two diacetates of mycochrysone have been prepared. Elemental analyses of these derivatives and of the purified pigment itself are consistent with a revised $C_{20}H_{12}O_7$ formula for mycochrysone.

The formation of a leucohexaacetate suggests that the molecule contains two hydroxyl or potential hydroxyl oxygen functions in addition to the quinonoid and phenolic (or enolic) groups already shown to be present. The infrared spectra of mycochrysone and derivatives provide evidence that the remaining oxygen atom is ketonic. The principal chromophore of mycochrysone is related to 8-hydroxy-1,2-naphthoquinone. Hydrogenation experiments indicate that the pigment has a perylene carbon skeleton.

INTRODUCTION

In part I of this series (1) it was proposed that mycochrysone is a $C_{20}H_{14}O_7$ peri-hydroxylated orthoquinone containing a second, more acidic, hydroxyl, and since perylene was formed on zinc – zinc chloride fusion, it was concluded that the carbon skeleton was that of either perylene or 1,1′-dinaphthyl.

Several derivatives of the pigment have now been prepared and repeated analyses have given lower hydrogen values than expected for a parent compound of the above formula. Re-examination of the purity of the pigment preparations used in earlier work has now shown that a persistent minor contaminant, not removed by recrystallization from cold chloroform, is responsible for this inconsistency. Recrystallizing the pigment from cold aqueous acetone or by concentrating an ethereal solution at room temperature, or chromatographic purification on silicic acid, has given material analyzing for $C_{20}H_{12}O_7$, the molecular formula expected from the analysis of derivatives. The best solvent for purification was cold aqueous acetone. Low and variable carbon analyses had been obtained for the quinoxaline derivative crystallized from methanol (1) and preparations from ethyl acetate give similar results. The derivative is hygroscopic and it appears that complete dessiccation cannot be obtained.

Methylation of the pigment with silver oxide and methyl iodide at room temperature gave two crystalline compounds, separable by chromatography on silicic acid. The minor product was shown to be a monomethyl ether with properties indicating methylation of the more acidic hydroxyl. The second compound, a dimethyl ether, showed a pronounced hypsochromic shift of the quinonoid absorption band, and tests indicated that in this product the *peri*-hydroxyl group had also been methylated. The monomethyl ether could be readily converted to the dimethyl ether by refluxing with silver oxide in methyl iodide. The incomplete substitution in the cold is not surprising for methylation of *peri*-hydroxyl groups is frequently difficult (2). Both methyl ethers formed quinoxaline derivatives, providing additional evidence for the orthoquinonoid group in mycochrysone. Methylation of mycochrysone quinoxaline at room temperature gave a single

[1]*Manuscript received July 10, 1959.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1957–59. Present address: The Dyson Perrins Laboratory, Oxford University, England.*

product shown to be identical with the quinoxaline of the monomethyl ether, a result consistent with the presence of a *peri*-hydroxyl group.

Acetylation by standard techniques failed to yield solid derivatives, and examination of the reactions by paper chromatography indicated that extensive decomposition of the pigment had taken place. The use of silver carbonate with acetic anhydride, however, gave two principal products (mycochrysone acetates I and II) which were separated on a silicic acid – Celite column and found to be isomeric diacetates. Re-examination of the products from acetylation with acetic anhydride and sodium acetate at room temperature by paper chromatography showed that, under these conditions, some mycochrysone acetate I was formed.

Paper chromatographic examination of the crude product from reductive acetylation showed a large number of components. The ultraviolet spectrum of the material indicated that a perylene chromophore was present in low concentration, and in view of the relatively mild reaction conditions this suggested a perylene skeleton in the starting material. The major product, separated by countercurrent distribution, was a hexa-acetate. The hydrogen values favored a $C_{32}H_{28}O_{13}$ formula, but in view of the slightly high carbon analyses and the difficulty experienced with the parent pigment, the compound may be the simple acetylated leucomycochrysone, $C_{32}H_{26}O_{13}$. If so the parent compound should contain four hydroxyl groups. The seventh oxygen atom is most probably present in a ketone group since the carbonyl stretching region of the infrared spectra of mycochrysone and all of the derivatives described above contain maxima at or near 1690 cm^{-1} (s). Should the $C_{32}H_{28}O_{13}$ formula be correct, it is possible that one or both of the hydroxyl groups not revealed by methylation may have been generated during reduction.

The ultraviolet absorption spectrum of the leucoacetate resembles that of naphthalene, and the principal chromophore of the pigment is therefore similar to that of diosquinone (I),* isolated from the shrub *Diospyros tricolor* Hiern (Ebenaceae) (3). A comparison between the absorption spectra of these two compounds is shown in Fig. 1. The authors

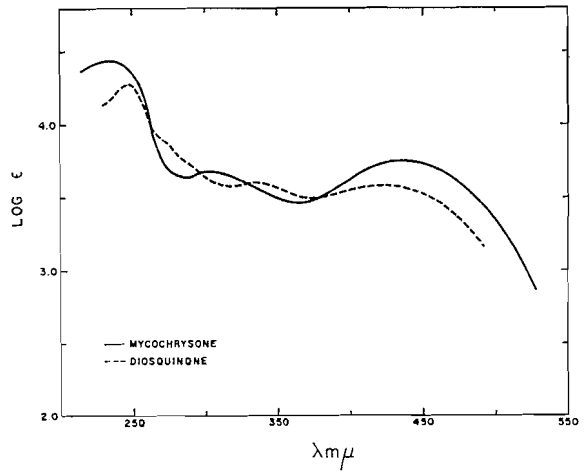

FIG. 1. Absorption spectra in ethanol of mycochrysone and diosquinone (redrawn from (4)).

have observed that the ultraviolet spectral properties of a sample of diosquinone changed over a period of several months. Some reservations should therefore be made in accepting

This structure has not yet been confirmed by synthesis.

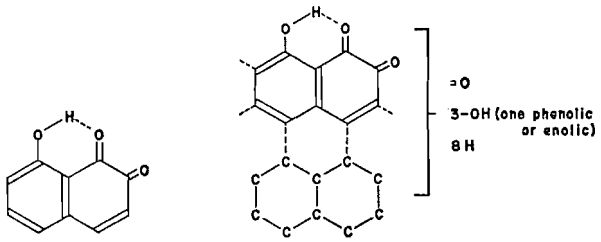
the data obtained by Prista (4), and reproduced here, as an accurate spectrum of this sensitive pigment. Although the two spectra are alike, a closer similarity might have been expected if the naphthaquinone system were the only chromophore present in mycochrysone. In view of the unsaturation in the remainder of the molecule, the differences may be due to an extension of the conjugated system or to an independent chromophore.

The formation of perylene from the pigment by zinc – zinc chloride fusion (1) did not exclude the possibility that mycochrysone is a derivative of 1,1′-dinaphthyl. The identification of the carbon skeleton by a series of reactions less likely to result in cyclized artifacts was therefore sought. It could be expected that hydrogenation followed by dehydration would remove most of the oxygen atoms so that subsequent dehydrogenation of the product might proceed unambiguously to yield the parent hydrocarbon (5). When the pigment was hydrogenated in ethanol or dioxane over Raney nickel, a dark red tarry product was obtained and it was evident that decomposition had occurred. However, under similar conditions mycochrysone dimethyl ether reduced smoothly to a colorless oil which yielded a small amount of solid product on trituration with methanol. The solid proved to be tetradecahydroperylene, obtained in 12.5% yield and identified by comparison with an authentic sample. This unexpected result in itself provided convincing evidence for the perylene skeleton, while the production of considerable quantities of perylene from the residual oil on dehydration and dehydrogenation supported the finding. From the dimethyl ether, under somewhat milder conditions, there was obtained a complex mixture of products, some of which appeared to retain the quinol system. Dehydration and dehydrogenation again gave perylene but in lower yields. On no occasion could 1,1′-dinaphthyl be detected.

From a consideration of the results given above, II is suggested as the most probable partial structure for mycochrysone, although the hydroxylic character of two oxygen functions requires confirmation.



(I) (II)

EXPERIMENTAL

Unless otherwise indicated, the petroleum ether referred to in this section has a 60–80° C boiling range.

Whatman No. 1 filter paper disks (32 cm diameter), impregnated with formamide (adjusted with formic acid to pH 6.0), were used for paper chromatograms.

Melting and decomposition points were determined on a Leitz hot stage instrument. Figures given in cases of slow decomposition refer to the first appearance of decomposition. This temperature is largely dependent on the crystal size and is of little diagnostic value.

Mycochrysone

The following purifications gave satisfactory products.

(*a*) Crude mycochrysone, isolated by chloroform extraction (1), was dissolved in acetone and filtered free from a trace of dark impurity. Water was added to the filtrate until it became faintly cloudy and crystals began to form. The solution was refiltered and, on standing overnight at 4° C, gave the bulk of the compound as fine red needles. The crystallization was repeated to give a product slowly decomposing above 195° C. Found: C, 66.00, 66.04%; H, 3.47, 3.37%. $C_{20}H_{12}O_7$ requires: C, 65.94%; H, 3.32%. Ultraviolet absorption spectrum in ethanol showed λ_{max} 236, 303, 438 mμ; log ε 4.49, 3.75, and 3.80, respectively.

(*b*) A solution of crude mycochrysone dissolved in "analar" chloroform was filtered and concentrated. The product, which was slowly deposited as orange microcrystals, was redissolved in a large volume of ether. Filtration and concentration of the ethereal solution at room temperature gave mycochrysone as short orange-brown rods, decomposing slowly above 200° C. Found: C, 66.00, 66.27%; H, 3.45, 3.49%.

(*c*) Crude mycochrysone was adsorbed on a silicic acid column from benzene–chloroform (1:1) and the pigment slowly eluted with chloroform containing 2% ethanol. The product was dissolved in a small volume of acetone and rapidly precipitated with petroleum ether to give mycochrysone as a red amorphous powder decomposing slowly above 175° C. Found: C, 65.92, 65.60%; H, 3.71, 3.69%.

Mycochrysone Quinoxaline

The derivative was prepared as in (1); the crude product (100 mg) dissolved in chloroform was applied to a silicic acid column (2.2×6.0 cm). Elution with chloroform – 4% ethanol gave the quinoxaline which was crystallized twice from a small volume of ethyl acetate as prisms, slowly decomposing above 228° C.

A sample dried for 16 hours at 140° C and cooled to room temperature under high vacuum was observed to increase steadily in weight while being weighed for analysis. Found: C, 70.68%; H, 3.86%. $C_{26}H_{16}O_5N_2 . 1/3H_2O$ requires: C, 70.61%; H, 3.80%. A sample (590.08 mg), dried as above, gained 3.26 mg in weight on standing in an open sample tube for 24 hours. Ultraviolet absorption spectrum in ethanol – 4% dioxane showed λ_{max} 240, 266.5, 443, λ_{infl} 330 mμ; log ε 4.64, 4.70, 4.17, and 3.95, respectively.

Methylation (Typical Run)

Mycochrysone (0.25 g) was shaken for 12 hours at room temperature with silver oxide (0.25 g) and methyl iodide (30 ml) free from hydrogen iodide. The products were washed into chloroform (100 ml Analar), filtered from silver iodide and excess silver oxide, and the filtrate applied to a silicic acid column (4×15 cm). The chloroform eluate gave mycochrysone monomethyl ether (35 mg), deep red needles decomposing slowly above 170° C after three crystallizations from methanol. Found: C, 66.43, 66.74, 66.83%; H, 3.98, 3.86, 3.63%; CH_3O, 8.79, 9.28%. $C_{21}H_{14}O_7$ requires: C, 66.67%; H, 3.73%; CH_3O, 8.21%. Ultraviolet absorption in ethanol showed λ_{max} 235, 301, 443 mμ; log ε 4.50, 3.78, and 3.80, respectively. The monomethyl ether was readily soluble in acetone, dioxane, chloroform, ether, and benzene. In concentrated sulphuric acid, ferric chloride, and sodium hydroxide or sodium carbonate solutions it gave blue, brown, and purple colorations, respectively. It was not extracted from chloroform by sodium bicarbonate solution, and gave a purple solution but no precipitate with methanolic lead acetate.

Development of the column with chloroform containing 3% ethanol eluted mycochrysone dimethyl ether (135 mg), obtained as small, yellow needles, m.p. 251–252° C

(decomp.) after three crystallizations from acetone. Found: C, 67.31, 67.41, 67.47%; H, 4.03, 4.06, 4.16%; CH_3O, 15.08, 15.95%. $C_{22}H_{16}O_7$ requires: C, 67.34%; H, 4.11%; CH_3O, 15.82%. Ultraviolet absorption in ethanol containing 4% dioxane showed λ_{max} 234, 330, 419 mμ; log ε 4.58, 3.70, and 3.85, respectively. The dimethyl ether gave a blue solution with concentrated sulphuric acid, dissolved slowly with decomposition in sodium hydroxide, and gave a colorless solution with concentrated ammonia.

Mycochrysone monomethyl ether, mycochrysone dimethyl ether, and mycochrysone had R_f values of 0.42, 0.20, and 0.07, respectively, when chromatographed on paper by the circular technique using benzene–chloroform (3:1) as mobile phase.

Mycochrysone Monomethyl Ether Quinoxaline

The quinoxaline of mycochrysone monomethyl ether was prepared in ethanol, purified by elution from a silicic acid column with chloroform, and crystallized from methanol–chloroform (1:1) as needles, m.p. 276–277° C (decomp.). Found: C, 71.69, 71.95%; H, 4.09, 4.07%; N, 6.19%. $C_{27}H_{18}O_5N_2$ requires: C, 71.99%; H, 4.03%; N, 6.22%. Ultraviolet absorption in ethanol containing 4% dioxane showed λ_{max} 237.5, 266, 443, λ_{infl} 330 mμ; log ε 4.65, 4.71, 4.11, and 4.00, respectively. The quinoxaline was sparingly soluble in ether, ethyl acetate, benzene, methanol, and ethanol.

Methylation of mycochrysone quinoxaline as above gave a monomethyl ether as needles, m.p. 275–277° C (decomp.). Found: C, 71.75%; H, 4.27%. The ultraviolet and infrared spectra and R_f of this product were indistinguishable from those of the quinoxaline obtained from mycochrysone monomethyl ether.

Mycochrysone Dimethyl Ether Quinoxaline

The quinoxaline of mycochrysone dimethyl ether was prepared in glacial acetic acid and purified on a silicic acid column developed with chloroform. The compound was very soluble in common solvents with the exception of ether and petroleum ether and was precipitated from chloroform by petroleum ether as a bright yellow powder, m.p. 175° C. Found: C, 72.26%; H, 4.57%; N, 6.16%. $C_{28}H_{20}O_5N_2$ requires: C, 72.40%; H, 4.34%; N, 6.03%. Ultraviolet absorption in ethanol showed λ_{max} 232, 265.5, 423, λ_{infl} 324 mμ; log ε 4.68, 4.73, 4.17, and 4.02, respectively.

The quinoxalines of mycochrysone monomethyl ether, mycochrysone dimethyl ether, and mycochrysone had R_f values of 0.64, 0.34, and 0.08, respectively, when developed on circular paper chromatograms using petroleum ether – benzene (2:1).

Acetylation with Silver Carbonate and Acetic Anhydride

Silver carbonate (100 mg) was added to a refluxing solution of mycochrysone (0.5 g) in acetic anhydride (15 ml). After 0.25 hour the solution was cooled, filtered, and poured onto ice. When the acetic anhydride had decomposed, the product (440 mg) was separated by extraction into chloroform and evaporation to dryness under reduced pressure. It showed two main components, acetate I (R_f 0.37) and acetate II (R_f 0.61), when developed on paper chromatograms with petroleum ether – benzene (1:1). The product was dissolved in benzene and adsorbed on a column (38×2.3 cm) of silicic acid – Celite (1:1). Benzene–chloroform (2:1) eluted acetate II which, upon evaporation of the solvent, was left as a brown viscous gum, unstable in hot solvents. Since it could not be crystallized even after further chromatography, it was dissolved in chloroform (5 ml), passed through a fine sintered glass filter, and precipitated by the addition of petroleum ether as a yellow powder (65 mg), m.p. 127–129° C. Found: C, 64.45, 64.50%; H, 3.79, 3.83%; acetyl (Kuhn Roth), 18.52%. $C_{24}H_{16}O_9$ requires: C, 64.29%; H, 3.60%; $(OAc)_2$, 19.2%. Ultraviolet absorption in ethanol showed λ_{max} 244, 296.5, 442 mμ; log ε 4.37, 3.85, and 3.76, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Elution of the silicic acid – Celite column with benzene–chloroform (1:1) gave additional acetate II followed by acetate I. After rechromatography on silicic acid the latter product, which was also thermolabile and could not be obtained crystalline, was precipitated as above to give a yellow powder (205 mg), m.p. 142–144° C. Found: C, 64.42, 64.23%; H, 3.74, 3.79%; acetyl (Kuhn Roth), 19.54%. Ultraviolet absorption in ethanol showed λ_{max} 245, 292, 443 mμ; log ϵ 4.39, 3.79, and 3.75, respectively.

Reductive Acetylation

A solution of mycochrysone (0.4 g) in acetic anhydride (60 ml) was shaken with zinc dust (5 g) for 30 minutes, when it became pale yellow with a bright green fluorescence. Sodium acetate (5 g) was added, the mixture shaken for 30 minutes, and then heated for 40 minutes on a water bath. After cooling and filtration, the solution was poured onto ice and, on decomposition of the acetic anhydride, extracted with chloroform (4×50 ml) and the extract evaporated to dryness under reduced pressure. Paper chromatography using petroleum ether – benzene (2:1) showed eight fluorescent bands detected under ultraviolet light in addition to two principal non-fluorescent bands detected by alkali spray.

Countercurrent fractionation through 200 transfers in the solvent system, water – ethanol – benzene – petroleum ether (2:6:5:3), gave the main component (252 mg) in tubes 66 to 92, with peak concentration in tubes 77 and 78. The material in tubes 76 to 79 (83 mg) was considered pure and was precipitated with petroleum ether (100–120° C) as a colorless powder. It could not be crystallized but melted at 133–135° C. Found: C, 62.14, 62.12%; H, 4.68, 4.63%; acetyl, 43.3, 42.0%. $C_{32}H_{26}O_{13}$ requires: C, 62.14%; H, 4.24%; $(OAc)_6$, 41.7%. Ultraviolet absorption in ethanol showed λ_{max} 227, 292, λ_{infl} 326 mμ; log ϵ 4.95, 4.12, and 3.57, respectively.

Hydrogenation of Mycochrysone Dimethyl Ether

Mycochrysone dimethyl ether (1 g) was hydrogenated in ethanol (60 ml) with Raney nickel for 10 hours at 2000 lb/sq. in. and 200° C. Evaporation of the solvent yielded a colorless viscous oil which on trituration with methanol deposited a solid (85 mg). Crystallization from methanol and sublimation (110° C; 0.05 mm) raised the melting point from 155° to 170° C. Found: C, 89.99%; H, 9.96%. $C_{20}H_{26}$ requires: C, 90.16%; H, 9.84%. Ultraviolet absorption spectrum in heptane showed λ_{max} 274 mμ; log ϵ 3.07. The melting point of this product was undepressed on admixing with an authentic sample of tetradecahydroperylene obtained by hydrogenating perylene (100 mg) under the same conditions. Found: C, 90.35%; H, 9.89%. The ultraviolet and infrared absorption spectra of the two materials were indistinguishable. Literature gives m.p. 175–177° C (6) and λ_{max} 270 mμ; log ϵ 3.38 for the ultraviolet absorption in hexane (7).

The residual oil from the reaction was refluxed for 2 hours with a small amount of cymene over freshly fused and powdered potassium hydrogen sulphate at 180° C. On cooling, the products were freed from inorganic salt by extraction into benzene and chromatographed on an alumina column (45×2.3 cm). In addition to cymene, four fractions were collected: (*a*) 145 mg and (*b*) 86 mg in the benzene eluate, (*c*) 74 mg in the chloroform–ethanol (1:1), and (*d*) 80 mg in the ethanol eluates, respectively. Fractions (*a*) and (*b*) gave perylene (78 and 40 mg, respectively) on heating for 3 hours with selenium powder at 290° C, while (*c*) and (*d*) yielded small amounts of perylene together with unidentified oils under the same conditions. The perylene was isolated by column chromatography and identified by melting point and ultraviolet absorption (1).

CONDUCTANCES OF DILUTE SOLUTIONS OF POTASSIUM IODATE IN WATER AND WATER–DIOXANE MIXTURES AT 25° C[1]

E. Bock

ABSTRACT

Conductances of dilute solutions of potassium iodate in water and water–dioxane solutions, extending over the dielectric constant range from $D = 78.54$ to $D = 29.71$, have been measured over the concentration range from zero up to $Ka < 0.2$ at 25.00° C. By applying the Fuoss–Onsager treatment to the data obtained, the association constants for the electrolyte in the various solvents, as well as $\mathring{a}$, the distance of closest approach of the ions, have been determined.

INTRODUCTION

In the literature are recorded several attempts at calculating association constants of a number of moderately strong electrolytes by means of conductance data. According to the latest refinement of the electrolytic conductance theory by Fuoss and Onsager (1) all these earlier attempts have yielded erroneous association constants, since in their derivation an incomplete equivalent conductance function was used. More specifically, the early association constants were forced to carry transcendental as well as linear terms of the conductance function, terms which have now become calculable. The Fuoss–Onsager conductance equation provides a means of determining all three parameters usually encountered in conductance work, viz. the limiting equivalent conductance Λ_0, the association constant K_A, and $\mathring{a}$ the distance of closest approach of the ions.

The assumption that salts of the oxyacids belong to the class of moderately strong electrolytes is of long standing. Thus T. Shedlovsky (2) in 1932 interpreted the anomalous course of the phoreograms of $AgNO_3$ and KNO_3 by assuming ion association. More recently Monk (3), Krieger and Kilpatrick (4), and especially Spiro (5) have addressed themselves to the problem of determining the extent of ion-association of potassium iodate in aqueous solution. However, since, as already pointed out above, in all these efforts the incomplete conductance function was used, it was thought worth while to reinvestigate the potassium iodate problem, and as it was apparent from the papers of the above workers as well as from results of experiments carried out in this laboratory (6) that the association constant of potassium iodate in aqueous solution is of the order of unity, it was necessary to obtain conductance data in solvents of varying dielectric constants. Moreover as rather reliable dielectric constants (7) as well as viscosity and density (8) data for water–dioxane mixtures were available in the literature, it was decided to study the conductance of potassium iodate in these media.

EXPERIMENTAL

The experimental technique employed has been recorded elsewhere (9), with the exception that instead of preparing dilute solutions by weight dilution these were prepared by direct addition of dry salt in platinum cups, to the solvent, contained in a Shedlovsky-type conductance cell. The salt, dried in a vacuum oven at 80° C for 36 hours, was weighed out on a Mettler M-5 Grammatic micro-balance having a 2-μg sensitivity.

The dioxane of spectro quality was further purified according to the scheme proposed

[1]*Manuscript received July 13, 1959.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.

by Hess and Frahm (10). After purification the dioxane had a melting point of 11.75° C and a refractive index of $n_D^{20} = 1.42246$. In each and every preparation of a water–dioxane mixture only dioxane freshly distilled from sodium was used. The water–dioxane mixtures were prepared by first passing a stream of nitrogen, which was purified by passage through alkaline pyrogallol, sulphuric acid, ascarite, and two tall water saturators (the latter situated in the same bath in which the conductance measurements were carried out), through conductance water, contained in the conductance cell, for several hours until a steady low conductance value was obtained, usually of the order of 2.5–3 $\times 10^{-7}$ mho. Then dioxane freshly distilled from sodium was added to the water by means of a container similar in design to that described by Martel and Kraus (11). The dielectric constants were interpolated from the work of Critchfield, Gibson, and Hall (7), and the viscosities and densities, the former corrected for the latest value of the viscosity of water (12), from the work of Geddes (8).

The conductances were measured on a Jones conductivity bridge, an oscilloscope serving as a detector. The cell constant was determined using the equation for conductances of dilute aqueous solutions of KCl, proposed by Fuoss *et al.* (13).

The temperature was read on a platinum resistance thermometer calibrated by the National Research Council of Canada.

RESULTS AND DISCUSSION

The experimental results are summarized in Table I. Figure 1 shows the plots of y vs. x,

NOTE: These data were taken from a previous publication, see ref. 9.

In Figs. 2 to 6 are shown the graphs of Λ_J vs. $C\gamma_0$ where

$$\Lambda_J = \Lambda + Sc^{\frac{1}{2}}\gamma_0^{\frac{1}{2}} - Ec\,\gamma_0 \log C\,\gamma_0 + K_A\,C\,\gamma_0 f^2\,\Lambda \quad [4]$$

and γ_0 the degree of association is given by

$$\gamma_0 = \frac{\Lambda}{\Lambda_0 - (S(\Lambda c)^{\frac{1}{2}}/\Lambda_0^{\frac{1}{2}})}. \quad [5]$$

Figure 7 shows the plot of log K_A vs. $1/D$, where K_A is the association constant for the equilibrium

$$A^+ + B^- \rightleftarrows AB. \quad [6]$$

Lastly Table II summarizes the derived values of K_A, Λ_0, and $\mathring{a}$; also included are the values of $\mathring{a}$ and the corresponding dielectric constants, as well as the weight per cent composition of the solvent, and the Walden product.

As is apparent from Fig. 7, log K_A is a linear function of $1/D$, a behavior first predicted on theoretical grounds by Denison and Ramsay (14) and later verified experimentally by Kraus *et al.* (15). The linear character of the log K_A vs. $1/D$ plot of course means, as one would expect, that the chief forces involved in ion-pair formation are electrostatic in nature.

57.12	29.71	775	3.60	36.8	44.32_0	87.94

The graph of log K_A vs. $1/D$ was constructed from the values of K_A for the five lower dielectric constant media, viz. for mixtures containing 29.91% to 57.12% dioxane. The latter were derived according to the procedure recommended by Fuoss (16) from the slope of the y vs. x plot. Only mixtures containing more than 29.91% dioxane yielded a graph of y vs. x with a reasonable slope; for a mixture poorer in dioxane than 29.91 the

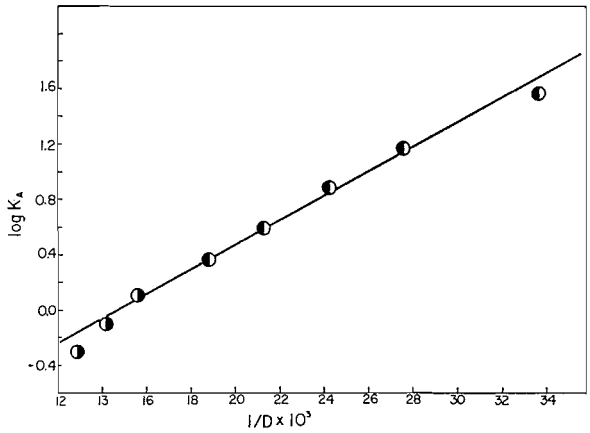

FIG. 7. log K_A vs. $1/D \times 10^3$. ◐ From Λ_j vs. $c\gamma_0$ plots. ◑ From y vs. plots assuming an $\mathring{a}$ of 3.2 Å.

slope of the y vs. x plots were so nearly horizontal that no reliable value of K_A could be obtained. In these latter cases the K_A's were obtained by an alternative procedure, viz. first obtaining the value of $y(0)$ through extrapolation of the y vs. x curve. Then, since at $x = \Lambda_0 y = y(0) = (J(\mathring{a}) - K_A\Lambda_0)$, K_A could be calculated by assuming a value for $\mathring{a}$ and calculating $J(\mathring{a})$. The selection of $\mathring{a}$ was in turn guided by the series of $\mathring{a}$ values derived from the slope of the Λ_j vs. $C\gamma_0$ curve for the five lower dielectric constant mixtures. The limiting equivalent conductances were also derived from these plots. When the logarithms of the association constants thus calculated are plotted vs. $1/D$ the points fall reasonably close to the straight line of log K_A vs. $1/D$ drawn through the log K_A points for the five lower dielectric constant solvents.

From a perusal of Table II it will be noticed that $\mathring{a}$, the distance of closest approach of the ions, is not constant for the various dielectric constant mixtures, but exhibits a slow increase with decreasing dielectric constant. A similar behavior was noticed by Fuoss and Kraus (17) for $NaBrO_3$ (although the increase for this salt was slight it was still noticeable), tetrabutyl ammonium iodide, tetrabutyl ammonium bromide, and tetraisoamyl ammonium nitrate. The change in $\mathring{a}$ in the latter three cases was attributed by the above authors to the disparity of the cationic and anionic sizes. In the case of Bu_4NI it was further suggested that additional induction forces on the periphery of the cation as well as possible specific interactions with the solvent molecules were also causing $\mathring{a}$ to increase in the low dielectric constant region.

Whether similar effects are causing an increase in $\mathring{a}$ in the present case is difficult to say. From an examination of the origin of the $\mathring{a}$ term it would seem that one would expect a change in the magnitude of $\mathring{a}$ with change in the composition of the solvent medium, since $\mathring{a}$ arises out of specifying a boundary condition which demands equality of electrical potential and intensity originating inside and outside a sphere of radius $\mathring{a}$, on the surface of this sphere. Thus $\mathring{a}$ measures, in a sense, the electrical influence of an ion, an influence which one would expect to change with a change in dielectric constant. The present investigation is of course too incomplete to permit a definite determination of the causes of the increase of $\mathring{a}$ with changing solvent composition, if only because of the fact that all calculations presented in this paper were carried out manually and no second and third approximations in γ_0 and Λ_0 were attempted. Moreover, $\Lambda\eta = \Lambda(1+Fc)$ was approximated to Λ by neglecting the Fc term for lack of viscosity data but this latter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

approximation should not prove too serious in the present case since as suggested by Fuoss (16), for relatively small inorganic ions the Fc term is unimportant. From the slope of log K_A vs. $1/D$, $\mathring{a}$ results as 2.8 Å; a value which seems to be unrealistically small. But if as suggested by Fuoss and Kraus, the internal dipole of the iodate ion is taken into account then the steepness of the log K_A plot becomes more understandable. Since, if an internal dipole moment is present in one of the ions K_A should be written as

$$K_A = K_0 \exp (U_1 + U_2)/kT,$$

where $U_1 = e^2/aD$ is the electrostatic energy of ion-pair dipole in the absence of an internal dipole in one of the ions and $U_2 = \mu/d^2D$ is the additional energy term resulting from the interaction of the cation with μ the internal dipole of the anion. Here d is the distance from the center of the cation to the electrostatic center of the anion dipole.

There still remains, however, the difficulty of interpreting the equally small $\mathring{a}$ values derived from the y vs. x plots, and the gradual increase of $\mathring{a}$ with decrease in dielectric constant. Thus the average value of $\mathring{a}$ derived from y vs. x plots results as 3.2 Å which is some 0.3 Å smaller than the sum of the crystallographic radii of the potassium ion (1.33 Å), and the iodate ion (2.2 Å). This latter value was calculated on the assumption that iodate ion has the shape of a regular tetrahedron of edgelengths 3.35 Å (18).

CONCLUSION

In conclusion it may be said that the present paper certainly bears out the predictions of the Fuoss–Onsager conductance equation. There is some difficulty, however, in interpreting the rather small magnitude of $\mathring{a}$. If some sort of interpenetration of ionic shells takes place, a possibility which does not seem too inconceivable in the case of the iodate ion considering its tetrahedral or perhaps more correctly, pyramidal structure, then the small value of $\mathring{a}$ would find an explanation, but this of course is mere conjecture. Further studies of potassium iodate conductances especially in other than water–dioxane mixtures should prove interesting.

Concerning the change of the size of $\mathring{a}$ with change in dielectric constant of the mixture, attention should be drawn to the fact that the Walden product, almost constant in the region of higher dielectric constants, drops more or less sharply in lower dielectric constant mixtures. Now an increase in $\mathring{a}$ would of course result in a lowering of the ionic mobility which in turn would result in a decrease of the Walden product. This correlation seems to suggest that the increase of $\mathring{a}$ in the lower dielectric constant region is perhaps real and does not arise out of some inaccuracies in the experimental data, or the theoretical treatment thereof.

SENSITIVE VIBRATIONAL FREQUENCIES

IV. MASS EFFECTS[1]

J. K. WILMSHURST[2]

ABSTRACT

The correlation of vibrational frequencies with atomic properties of substituent atoms in the molecular system is critically examined for reality in the light of possible mass effects. The general rule is formulated that only frequencies continuously characteristic of a grouping in the mass–frequency plot can be used in such correlations. Calculated mass–frequency plots are presented for the systems XC≡N, XC≡CX, XC≡CY, $X_2C{=}CX_2$, $X_2C{=}O$, $X_3P{=}O$, XCH_3, X_2CH_2, X_3CH.

A number of empirical relations between molecular vibrational frequencies and some property of a substituent atom or radical in the molecular system have recently been reported (1–18), the most common properties used being Hammett's σ-constant (1–7), electronegativity (10–17), and ionization potential (18). However, since all these properties decrease down any column of the periodic table, while any vibrational frequency (for example, ν_{CO} in the system $X_2C{=}O$) will decrease as a substituent (X) in the molecular system is altered down the periodic table, due only to the increasing mass, care must be taken when expressing these empirical relations to ensure that they are indeed real. Ideally, of course, force constants should be evaluated and used (15), but, unfortunately, this is often impracticable for most systems of interest. However, in the absence of force constant data, the characteristic frequency of a bond or group can be used in the empirical correlations provided that firstly its dependence upon the mass of the substituent it is intended to vary is checked. This can be done simply by choosing a potential energy function for the molecular system and plotting the vibrational frequencies as a function of the mass of the substituent which is to be varied. Any significant variation in the slope of the plot of the experimental frequencies from that calculated would then indicate some change in the potential energies of the systems and would hence justify some attempt at a correlation.

In the present investigation calculated plots of frequency versus mass are given for a number of common systems assuming a simple valence force field. These plots show the mass sensitivity of the molecular vibrations and illustrate the phenomenon of "vibrational coupling". Rules are derived to permit rapid qualitative estimates of the mass insensitiveness of vibrations and the types of vibrational coupling that may occur in the general case.

Secular Determinants

The secular determinants usually encountered in normal co-ordinate calculations are of the form (19):

$$[1] \qquad \begin{vmatrix} A_{11}-\lambda, & A_{12}, & \cdots\cdots & A_{1_n} \\ A_{12}, & A_{22}-\lambda, & \cdots\cdots & A_{2_n} \\ \vdots & \vdots & & \vdots \\ A_{1_n}, & A_{2_n}, & \cdots\cdots & A_{nn}-\lambda \end{vmatrix} = 0$$

[1]*Manuscript received August 5, 1959.*
Contribution from the Department of Chemistry, Auckland University College, Auckland, New Zealand. This work was performed in part at the University of Auckland with financial assistance from the New Zealand University Research Grants Committee.

[2]*Present address: Research Laboratories, National Carbon Company, Division of Union Carbide Corporation, P.O. Box 6116, Cleveland 1, Ohio.*

where the A_{ii} are functions of the force constant and masses of a diparticle system (2 atoms for stretching, two bonds for bending, etc.) and $\lambda = 4\pi^2c^2M\nu^2$ ($= 5.8894\times10^{-2}\nu^2$) (19). The A_{ij} are also functions of the masses and force constants, but are in general smaller than the corresponding A_{ii} or A_{jj}.

It is a general property (20) of such symmetrical determinants that the roots of the nth order determinant are separated by the roots of the diagonal $(n-1)$th order determinants which roots are again separated by those of the diagonal $(n-2)$th order determinants, and so on. In particular, for the second order determinant:

$$\begin{vmatrix} A_{11}-\lambda & A_{12} \\ A_{12} & A_{22}-\lambda \end{vmatrix} = 0$$

having roots λ_1, λ_2 ($\lambda_1 > \lambda_2$), then

$$\begin{aligned} &\lambda_1 > A_{11} > \lambda_2 \\ &\lambda_1 > A_{22} > \lambda_2. \end{aligned} \qquad [2]$$

Thus, in a symmetry species containing only two vibrational modes, the vibrational frequencies are separated by the frequencies of the two diatom modes. Further, if the frequency–mass plots of the two diatom modes cross (e.g., σ-frequencies in Fig. 1*a*), then the pair of frequencies of the system cannot cross, but instead change their vibrational character and in this cross-over region can no longer be defined as approaching a particular diatom mode, but rather are only characteristic of the system as a whole. This is commonly called "vibrational coupling".

If a third order secular equation has roots λ_1, λ_2, λ_3 ($\lambda_1 > \lambda_2 > \lambda_3$) then these are separated by the roots of the three diagonal second order determinants σ_1, σ_2 ($\sigma_1 > \sigma_2$); τ_1, τ_2 ($\tau_1 > \tau_2$); and ω_1, ω_2 ($\omega_1 > \omega_2$) which are in turn separated by the roots of the first order determinants, giving the following set of inequalities:

$$\begin{aligned} &\lambda_1 > \sigma_1, \tau_1, \omega_1 > \lambda_2 > \sigma_2, \tau_2, \omega_2 > \lambda_3 \\ &\sigma_1 > A_{11}, A_{22} > \sigma_2 \\ &\tau_1 > A_{22}, A_{33} > \tau_2 \\ &\omega_1 > A_{11}, A_{33} > \omega_2. \end{aligned} \qquad [3]$$

As with two vibrations in a symmetry species, so in this case with three vibrations it is seen that non-crossing rules apply in the mass–frequency plots. This can be easily extended to higher order determinants and inequality relations similar to eq. [2] and [3] obtained. These inequalities afford a very quick qualitative estimate to be made of the mass–frequency plot and the regions in which vibrational coupling will occur.

Using secular equations derived elsewhere (19, 21, 22, 23, 24) mass–frequency plots have been calculated[3] for a number of simple systems which appear most amenable to empirical correlations, and these are shown in Fig. 1 (XC≡N, XC≡CX, XC≡CY); Fig. 2 ($X_2C{=}CX_2$, $X_2C{=}O$, $X_3P{=}O$); and Fig. 3 (XCH_3, CH_2X_2, HCX_3).

DISCUSSION

A comparison of the data calculated here with the published empirical correlations shows that in every case the experimental "sensitive" frequency chosen for the empirical correlation varies by a much larger extent than if it were only dependent on mass. Thus,

[3]*Though more theoretical significance is attached to the plot of frequency versus* $1/\sqrt{M_X}$, *in order to obtain a better magnification of the curves the frequency was plotted against log* M_X *in the present work. In the symmetry species containing a bending mode the term* $1/r^2_{CX}$ *appears and in the calculation of the curves in Figs. 1 and 2a, this has been varied as* M_X *varies the standard curve for its variation being obtained by plotting* r_{CX} *for the bonds* C—H, C—F, C—Cl, C—Br, C—I *against the mass of* X.

in every case it appears the variation of the sensitive frequency with substituent is reflecting a change in potential energy of the system. However, although the variation of vibrational frequency in these systems can then be considered as expressing a variation of potential energy, one fundamental consideration must be remembered before starting any correlations. The region of vibrational coupling in the mass–frequency plot is a cross-over region in which the two interacting frequencies mix, losing their initial characters and emerging with the opposite characters (e.g. Fig. 1*a*, ν_3 is a C—X stretching vibration for $M_X = 1$ and a C≡N stretching vibration for $M_X > 10$, while ν_1 is a C≡N stretching vibration for $M_X = 1$ and a C—X stretching vibration for $M_X > 10$). If these frequencies are the only two in the symmetry species, or if no interaction with other frequencies in the symmetry species occurs, then they must lie on opposite sides of the corresponding diatom plots (Fig. 1*a*). In other systems where additional interactions occur, this is modified, but the following general rule still applies. *A frequency characteristic of a particular grouping can only be used in an empirical correlation in that region of the mass–frequency plot where it is continuously characteristic of the vibrational mode.* Thus, in the system XC≡N any correlation of $\nu_{C\equiv N}$ with some property of X cannot plot $\nu_{C\equiv N}$ for HCN on the same curve as $\nu_{C\equiv N}$ for systems with $M_X > 10$ (Fig. 1*a*).

This rule has been overlooked in some cases and plots of characteristic frequency versus some atomic property have been constructed using frequencies which are not continuously characteristic of the vibrational mode (10, 11, 12). The apparent agreement of these "improper" points must be considered in these cases as fairly fortuitous, e.g. in the series $X_2C{=}O$, $\nu_{C=O}$ for $H_2C{=}O$ or for $HXC{=}O$ should not be included on the plots of $\nu_{C=O}$ derived for $X_2C{=}O$ and $XYC{=}O$ where M_X, $M_Y > 10$. The agreement in this case fortuitously arises from the additional interaction of $\nu_{C=O}$ with δ_{HCH} shifting $\nu_{C=O}$ to higher frequencies.

In other systems such as the benzonitriles where $\nu_{C\equiv N}$ is correlated with Hammett's σ-constant of meta- and para-aromatic ring substituents (1, 7) the secular equation virtually factorizes due to the smallness of the interaction (off diagonal) terms between the nitrile group and the ring substituents. In this case the vibrational coupling between $\nu_{C\equiv N}$ and the frequencies of the ring substituent will be extremely small and while the non-crossing rule will still apply, both branches of the nitrile curve in the mass–frequency plot will approximate the same straight line for virtually all masses of the substituent and the correlation can be made for all masses of ring substituent. This state of affairs will occur in most cases where the group whose characteristic frequency is being considered is placed a number of atoms away (and is away in space also) from the group whose atomic property is to be correlated. However, since the effect of any group on the characteristic frequency of a vibrating unit decreases rapidly as the group is separated from the vibrating center by atoms in a chain or by space, this approximate factorization is only of interest in conjugated or aromatic systems. In other systems the group affecting the frequency of the vibrating center must be either closely bonded to the center or close in space to it to actually produce any effect on the frequency, and in both cases vibrational coupling will, in general, need to be considered. In the case of orthosubstituted benzonitriles, for instance, the nitrile frequency is not only affected by effects transmitted through the atomic chain, but also because the ortho substituent is close in space to the nitrile group it is affected by the field effect across space. Thus, the approximate factorization will not apply here, as a strong interaction or central force will exist between the nitrile group and the substituent and vibrational coupling will need to be considered in any empirical correlation.

(*a*) CH_3X ($k_{C-X} = 3.6\times10^5$, $k_{CH} = 4.58\times10^5$, $\delta_{XCH}/r^2_{CH} = \delta_{HCH}/r^2_{CH} = 0.46\times10^5$ dynes cm^{-1}).

(*b*) CH_2X_2 ($k_{C-X} = 3.6\times10^5$, $k_{CH} = 3.6\times10^5$, $\delta_{HCH}/r^2_{CH} = \delta_{XCX}/r^2_{CX} = \delta_{HCX}/r^2_{CH} = 0.36\times10^5$ dynes cm^{-1}).

(*c*) HCX_3 ($k_{C-X} = 3.6\times10^5$, $k_{CH} = 3.6\times10^5$, $\delta_{HCX}/r^2_{CX} = \delta_{XCX}/r^2_{CX} = 0.36\times10^5$ dynes cm^{-1}).

FIG. 3. Calculated mass–frequency curves for:

In conclusion it should be pointed out that while any variation of a vibrational frequency with changing atomic substituents in a molecular system in excess of that predicted, assuming it were dependent only on mass alone, does reflect a real change in potential energy of the system, any correlation of this sensitive frequency with an atomic property cannot, in general, be verified regardless of how good the correlation appears. In fact, it may quite possibly be fortuitous. As an example, consider the series (13) of methyl derivatives, CH_3X, where the squares of the rocking and symmetrical deformation frequencies for X = F, Cl, Br, and I, were each found to be linearly dependent on the electronegativity of the halogen. It can be quickly seen on comparison (19) of the experimental data with Fig. 3*a* that these frequencies in these molecules are varying by a much greater extent than if they were dependent on mass changes alone and are, therefore, reflecting a real variation in potential energy. However, whether this real variation in potential energy is dependent on the electronegativity of X as suggested (13) is not established. Fitting other sensitive methyl frequencies to these empirical relations produced estimates of group electronegativities, but the meaning of such group electronegativities is open to the original question of the reality of the relation between potential energy and electronegativity. However, the fact that group electronegativities were later calculated (25) by a completely unrelated method and were found to be in good agreement with those predicted from the empirical frequency versus electronegativity relations does give more credulence to the reality of the empirical relations in this case, but it by no means proves them. Although similar uncertainty must be placed on all data obtained from such empirical relations, there is still considerable value in these relations.

As another example, a number of frequency–frequency plots have been obtained (9, 11, 26) and these are often of considerable use to the spectroscopist. However, in setting up these plots care must be taken to obey the non-crossing rule while in using them it must be remembered that an assumption is involved, namely, that the frequencies concerned each depend on the same atomic or molecular properties. This assumption cannot in general be proven and may or may not be valid, a point which should not be forgotten in using these types of relations.

CATALYSIS OF THE *CIS-TRANS* ISOMERIZATION OF AZOBENZENE BY ACIDS AND CUPRIC SALTS[1]

STEFANIA CICCONE AND J. HALPERN

ABSTRACT

The catalytic effects of various acids and metal salts on the *cis–trans* isomerization of azobenzene in aqueous ethanol were examined kinetically. The effect of perchloric acid is apparently due to H^+ ions and is interpreted in terms of a catalytic mechanism involving the conjugate acid of azobenzene. The much greater catalytic effect found for hydrochloric acid is attributed to an additional path involving catalysis by the undissociated acid. Acetic acid was found to be inactive. Of the metal salts examined only those of Cu^{++} showed pronounced activity which was attributed to co-ordination with the azo group. Kinetic evidence was obtained for a catalytic path involving Cu^{++} and H^+ simultaneously.

INTRODUCTION

It has been reported (1, 2) that the *cis–trans* isomerization of azobenzene, which proceeds spontaneously in solution, is susceptible to catalysis by acids, certain metal salts, and a variety of other inorganic and organic substances. However, while the kinetics of the uncatalyzed isomerization have been examined extensively (1, 3), few quantitative measurements have been made on the catalyzed reactions whose mechanisms are thus for the most part unresolved. This paper describes a kinetic study of the catalysis of the isomerization of azobenzene in aqueous alcohol solution by acids and cupric salts and an attempt is made to elucidate the mechanisms of the catalytic effects in these systems.

EXPERIMENTAL

Cis-azobenzene was prepared by the method of Hartley (1) and recrystallized from petroleum ether to a constant melting point of 70°. Distilled water and ethanol, redistilled from KOH, were used as solvents. Cupric perchlorate (G. F. Smith Reagent) was recrystallized from perchloric acid. The acids and other reagents were of reagent grade.

The kinetics of the isomerization reaction were measured using the procedure described earlier (3). The absorption spectra of *cis*- and *trans*-azobenzene were determined in each of the media used and were found to be substantially unaffected by the added acids and metal salts. Solutions of azobenzene were prepared, and all experiments performed, in the dark to prevent photochemical isomerization.

RESULTS AND DISCUSSION

All the kinetic experiments were made at 60°. The solvent was generally aqueous alcohol in which both azobenzene and the catalysts were conveniently soluble. A few experiments were also made in benzene solution.

Typical rate plots for the uncatalyzed and catalyzed reactions are shown in Fig. 1. The kinetics were generally first order in *cis*-azobenzene yielding a pseudo first order rate constant, k, which contained contributions from both the uncatalyzed (k_0) and catalyzed

(k_{cat}) paths, i.e.

[1] $$-d\,[cis\text{-A}]/dt = k\,[cis\text{-A}]$$

where

[2] $$k = k_0 + k_{cat}\,,$$

k_0 was measured separately and k_{cat} determined by difference.

Deviations from first order kinetics were sometimes observed at high catalyst concentrations (particularly with perchloric acid), possibly due to side reactions of azobenzene with the catalyst. In such cases only the region of first order behavior was investigated and the range of results reported below reflects this limitation.

Table I summarizes some of the observed catalytic effects. Of the three acids examined in aqueous alcohol, namely $HClO_4$, HCl, and CH_3COOH (selected as typical strong, intermediate, and weak acids), the first two showed pronounced catalytic activity while the last was inactive. The unimportance of ionic strength effects is indicated by the observation that 0.5 *M* $NaClO_4$ or 0.2 *M* NaCl, either alone or in the presence of equivalent concentrations of the corresponding acid, were substantially without effect.

Since it seemed likely that the acid catalysis was associated with protonation of the azo group, salts of a number of metal ions (Cu^{++}, Co^{++}, Ag^{+}) with known tendency to coordinate with nitrogen were also examined for catalytic effects. Of these only the cupric salts showed pronounced activity, which was further enhanced in the presence of acids. These effects are discussed further below.

Perchloric Acid

The results for this acid, in solvents of various compositions, are summarized in Fig. 2. The range of catalyst concentrations in each case is that for which the kinetics remained first order in *cis*-azobenzene. In this region the catalytic effect conforms to the rate law,

[3] $$k_{cat} = k_{H^+}\,[HClO_4]$$

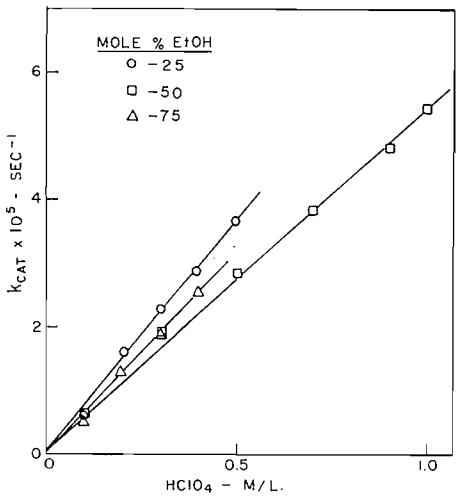

FIG. 2. Catalytic effect of perchloric acid at 60°.

where the values of $10^5k_{H^+}$ are 7.4, 5.1, and 6.5 l. $mole^{-1}$ sec^{-1} in 25, 50, and 75 mole per cent EtOH, respectively.

It seems likely that $HClO_4$ is completely dissociated in these solutions and hence that the observed catalytic effect is due to H^+ (i.e. H_3O^+ or $EtOH_2^+$) ions. A plausible mechanism, depicted below, assumes that the catalyzed isomerization proceeds through the conjugate acid of azobenzene (AH^+), formed in a rapid pre-equilibrium step, i.e.

$$cis\text{-A} + H^+ \rightleftharpoons cis\text{-AH}^+ \text{ (fast)} \quad [4]$$

$$cis\text{-AH}^+ \rightarrow trans\text{-AH}^+ \text{ (slow)} \quad [5]$$

$$trans\text{-AH}^+ \rightleftharpoons trans\text{-A} + H^+ \text{ (fast).} \quad [6]$$

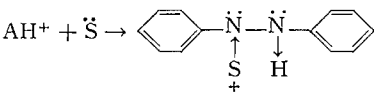
The protonation equilibrium of azobenzene in acidic solutions is well known (4, 5) although, because of the rapid isomerization, it can be studied only for the *trans* isomer. Spectrophotometric measurements have yielded values of -2.5 (4) and -1.6 (5) for pK_a of AH^+ at 25°. The equilibrium concentration of AH^+ in our solutions is thus very small ($\sim$1% at 1 *M* H^+) and is not detected spectrophotometrically.

The structure of AH^+ has not been conclusively established. Klotz (4) has proposed structure (I) in which the proton is localized on one of the N atoms through a bond involving lone pair electrons. On the other hand Jaffé (5, 6), on the basis of convincing evidence, favors the non-classical structure (II) in which H is attached to both N atoms through

(I) (II)

delocalized bonds. Enhanced ease of isomerization is more readily explained in terms of the first model where some reduction in the degree of double bond character of the azo bond might be expected through polarization. It is less obvious why structure (II) should lead to enhanced isomerization particularly if, as suggested by Jaffé (5, 6), the *cis*-conformation of this structure is the more stable one.

An alternative description of the slow isomerization step, which we are inclined to favor, involves the attack of a solvent molecule (S) on AH^+ to give an intermediate (III) in which free rotation about the N—N bond is possible, i.e.



[7]

(III)

This mechanism is readily consistent with either structure (I) or (II) for AH^+.

Zucker and Hammett (7, 8) have suggested a criterion for distinguishing between a mechanism of the type represented by equations [4], [5], and [6] and one in which the rate-determining step [5] is replaced by step [7] involving attack on the conjugate acid by a solvent molecule. This is based on the expectation of a linear dependence of k_{cat} on h_0 (related to the Hammett acidity function H_0 (9, 10) by $H_0 = -\log h_0$) in the first case and on $[H^+]$ in the second. Unfortunately this criterion is not readily applicable here in view of the limited acidity range accessible to kinetic measurement and of the absence of h_0 data for mixed solvents. In aqueous solution the dependence of h_0 on $[H^+]$ does diverge appreciably from linearity even below 1 *M* $HClO_4$ and this divergence is not reflected in plots in Fig. 2. On the other hand the dependence of k_{cat} on solvent composition appears to follow h_0 which, at least for HCl, has been shown to pass through a minimum in the vicinity of equimolar concentrations of H_2O and EtOH (11). Because of their conflicting nature, and because of the questionable theoretical validity of the Zucker–Hammett hypothesis (8), these indications are considered as inconclusive. An alternative kinetic interpretation, namely that the protonation step [4] is rate determining, also leads to an expected h_0, rather than $[H^+]$, dependence but is considered unlikely in view of the low rates.

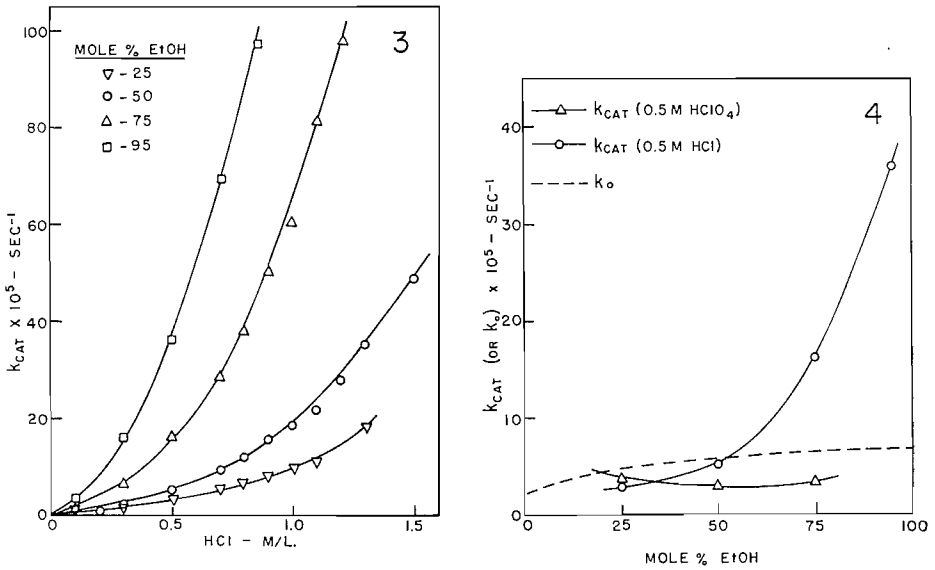

FIG. 3. Catalytic effect of hydrochloric acid at 60°.
FIG. 4. Solvent dependence of the catalytic effects of perchloric and hydrochloric acids at 60°. The broken line depicts the solvent dependence of the uncatalyzed rate (k_0).

Hydrochloric Acid

The results for this acid are depicted in Figs. 3 and 4. Attention is directed to the following features.

(1) Except at very low concentrations, the catalytic activity of HCl is greater than that of $HClO_4$.

(2) the kinetic dependence of k_{cat} on the total HCl concentration, $[HCl]_0$, is apparently greater than first order.

(3) The catalytic effect increases markedly with the EtOH content of the medium. At low EtOH content it approaches that of $HClO_4$.

This behavior can be interpreted in terms of a catalytic contribution due to undissociated HCl in addition to that due to H^+. The predicted rate law is then

$$[8] \qquad k_{cat} = k_{H^+}[H^+] + k_{HCl}[HCl]$$

$$[9] \qquad = k_{H^+}[H^+] + (k_{HCl}/K)[H^+][Cl^-],$$

where K is the dissociation constant of HCl. If the fraction of undissociated HCl is small, $[H^+] \sim [Cl^-] \sim [HCl]_0$, and equation [9] becomes

$$[10] \qquad k_{cat} = k_{H^+}[HCl]_0 + (k_{HCl}/K)[HCl]_0^2$$

or

$$[11] \qquad k_{cat}/[HCl]_0 = k_{H^+} + (k_{HCl}/K)[HCl]_0.$$

The linear plots of $k_{cat}/[HCl]_0$ vs. $[HCl]_0$ in Fig. 5 are, on the whole, in accord with this, although their intercepts yield values of k_{H^+} which are somewhat lower than those obtained with $HClO_4$ (like the latter, however, these pass through a minimum at 50 mole per cent EtOH). Again this may be due to the fact that the H^+-catalyzed reaction follows h_0 rather than $[H^+]$ and that in these media the former is appreciably lower for HCl than for $HClO_4$ even at low concentrations.

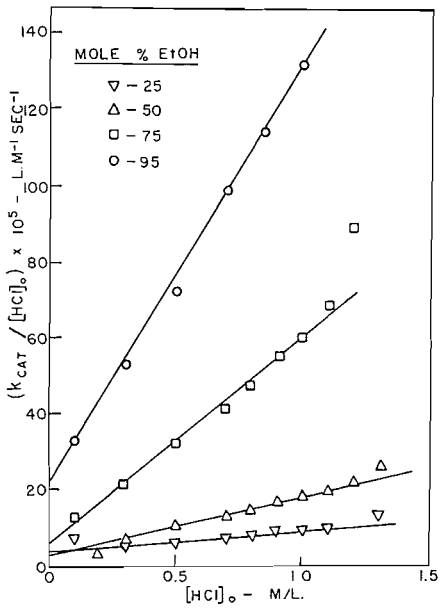

FIG. 5. Concentration-dependence of HCl catalysis plotted according to equation [11].

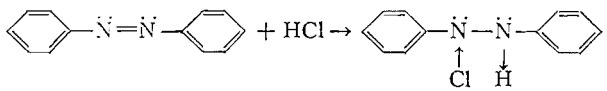
A plausible mechanism for the catalysis by undissociated HCl involves protonation, coupled with simultaneous co-ordination of Cl^-, to give an intermediate (IV), analogous to (III), in which the role of the solvent molecule is effectively assumed by Cl^-.



[12]

(IV)

A similar mechanism may account for the combined catalytic effect of H^+ and thiourea on the *cis–trans* isomerization of azobenzene, observed by Schulte-Frohlinde (2). This has the kinetic form, $k_{cat} = [H^+]$ [thiourea] and may involve a reaction analogous to equation [12] between azobenzene and the conjugate acid of thiourea.

It is also of interest that the above pattern of catalytic effects for $HClO_4$ and HCl resembles that found by Nozaki and Ogg (12) for the *cis–trans* isomerization of maleic acid. In the latter case also a mechanism involving simultaneous co-ordination of H^+ and Cl^- (although not at adjacent positions) was proposed to account for the higher activity of HCl. Analogous mechanisms have also been proposed (13, 14) for the catalysis by secondary amines of the *cis–trans* isomerization of diethyl and dimethyl maleate.

Cupric Salts

Figure 6 depicts the catalytic effect due to cupric perchlorate. The kinetic dependence of k_{cat} on the cupric perchlorate concentration is greater than first order (approximately 1.5) implying some contribution from a path involving more than one Cu^{++} ion. As for H^+, it seems plausible to interpret the catalytic effect of Cu^{++} in terms of a mechanism involving co-ordination of Cu^{++} with the azo nitrogen atoms to give intermediates analogous to (III). The significance of the higher order path is not clear but a plausible interpretation is in terms of a complex, azobenzene.$2Cu^{++}$, in which Cu^{++} ions are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

co-ordinated to both N atoms of the azobenzene molecule. The existence of an analogous cuprous complex of azomethane (azomethane.$2Cu^+$) has been reported (15).

A similar complex, involving simultaneous co-ordination of H^+ and Cu^{++} with the two N atoms of azobenzene, may account for the unexpected and very marked enhancement of the catalytic activity of cupric perchlorate by perchloric acid shown in Fig. 7. Over a considerable range of concentrations the combined effect of the two catalysts is much greater than the sum of their separate effects and the predominant contribution to k_{cat} is of the kinetic form, k $[H^+]$ $[Cu^{++}]$, implying a catalytic path involving H^+ and Cu^{++} simultaneously.

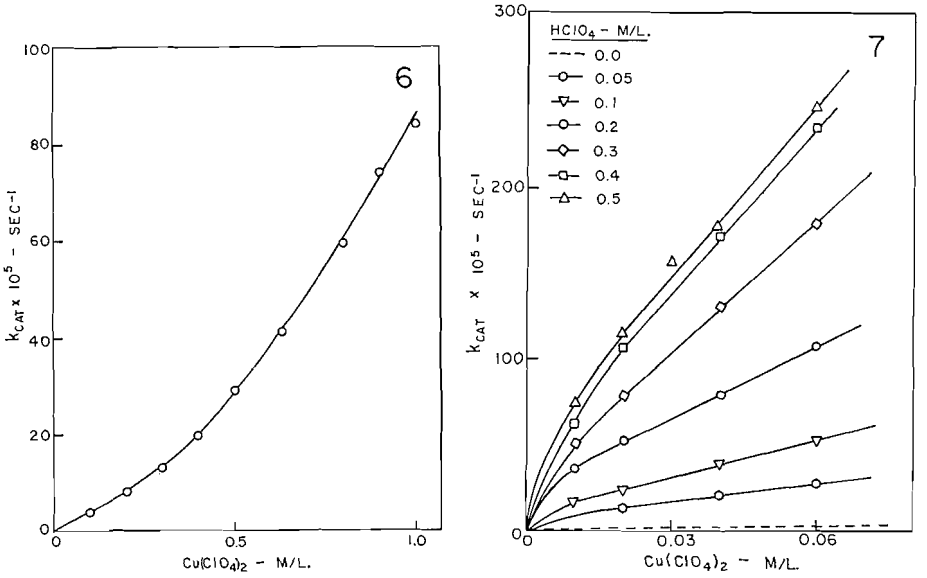


FIG. 6. Catalytic effect of cupric perchlorate in 50 mole% EtOH at 60°.
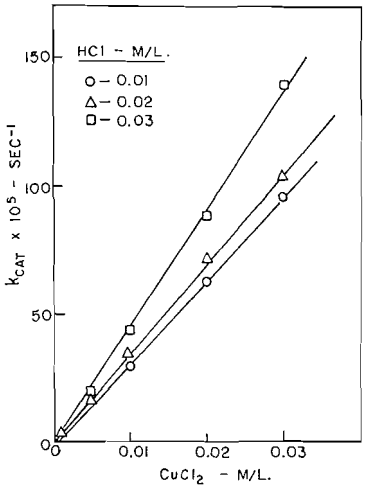
FIG. 7. Combined catalytic effects of cupric perchlorate and perchloric acid in 50 mole% EtOH at 60°.

Because of solubility limitations the effect of $CuCl_2$ in aqueous ethanol could be examined only in the presence of HCl. The results are shown in Fig. 8 and again reveal a



Catalytic effect of cupric chloride in 50 mole% EtOH at 60°.

tendency, although less marked than for cupric perchlorate, for the catalytic activity to be enhanced by the acid. At low HCl concentrations k_{cat} is first order in $CuCl_2$ and is much greater than for $Cu(ClO_4)_2$ at comparable $HClO_4$ concentrations.

Cupric acetate in aqueous ethanol and cupric heptanoate in benzene (in each case in the presence of the corresponding acid which by itself was without effect) were also found to catalyze the isomerization reaction (Table I), but their effects were not examined quantitatively.

Co-ordination of the catalyst to the azo nitrogen atoms appears to be a common feature of all the catalytic effects described and the low catalytic activities of Co^{++} and Ag^{+}, relative to Cu^{++} (Table I), may be related to their much smaller tendencies to form complexes with nitrogen ligands in general.

ENTROPY PRODUCTION IN A SPONTANEOUS, ADIABATIC (NON-ISOTHERMAL) CHEMICAL REACTION[1]

D. H. EVERETT[2]

ABSTRACT

When a chemical reaction occurs spontaneously and isothermally the loss of useful work is equal to the decrease in free energy of the system. If the same reaction, supposed for example to be exothermic, occurs adiabatically the temperature rises and the system can be used as a source of heat to operate a heat engine: as heat is withdrawn the temperature of the system falls and eventually returns to its initial value. Part of the free energy of the reaction has been recovered as useful work, part lost in the spontaneous irreversible step. Expressions are derived for the loss of useful work and the entropy production in the adiabatic irreversible step, and it is shown that the work lost is equal to $T_0\times$(entropy produced) where T_0 is the temperature *of the surroundings*. Some consequences of these ideas in relation to the definition of the efficiency of internal combustion engines are considered briefly.

When a chemical reaction proceeds spontaneously under isothermal conditions the irreversible production of entropy in a finite change ($\Delta_i S$) is related both to the "loss of useful work" and to the "decrease in free energy" (1). For a reaction which proceeds spontaneously at a temperature T,

$$T\Delta_i S = \Delta W(\text{rev.}) - \Delta W(\text{irrev.}) = -\Delta F, \qquad [1]$$

where ΔW(rev.) is the work which can be obtained if the process takes place reversibly and ΔW(irrev.) the work done by the system in an irreversible change between the same initial and final states. F is the Helmholtz free energy.

However, as pointed out by Prigogine and Defay (2), these equations cannot be applied immediately to a non-isothermal process, and a more general relationship involves the affinity of reaction (**A**). For an infinitesimal process:

$$Td_i S = \mathbf{A}d\xi, \qquad [2]$$

where

$$\mathbf{A} = -(\partial F/\partial \xi)_{T,V} \qquad [3]$$

and ξ is the extent of reaction.

In practice, we often have to deal with reactions which occur more or less adiabatically (e.g. in an internal combustion engine) so that it is instructive to see whether an equation of the form [1] can be derived for this case, and whether Prigogine and Defay's objection to this equation can be overcome.

Consider, for the sake of simplicity, an exothermic reaction

$$\mathrm{A} \rightarrow \mathrm{B}$$

whose equilibrium position lies far to the right. We start with 1 mole of A at a temperature T_0 (state α), and allow it to react spontaneously at constant volume in an adiabatic container, whose heat capacity is negligible compared with that of A or B. The final equilibrium state of the system (β) is one in which ξ_e moles of A have reacted to form

[1]*Manuscript received May 13, 1959.*

B, while the temperature has risen from T_0 to T_1. Again, for simplicity, we suppose that the molar heat capacities of A and B are equal (c) and that the heat of reaction at constant volume ($u^0_{T,V}$) is independent of ξ; it will also be independent of T. The temperature rise is then given by

$$T_1-T_0 = (-u^0_{T,V}/c)\xi_e; \qquad [4]$$

or since we suppose $\xi_e \rightarrow 1$,

$$T_1-T_0 = -u^0_{T,V}/c. \qquad [5]$$

The entropy produced in this process may be obtained by integrating [2].

$$\Delta_1 S \text{ (chem. adiab.)} = \int_0^{\xi_e} \frac{\mathbf{A}}{T} d\xi \text{ (adiabatic conditions)} \qquad [6]$$

where

$$\mathbf{A} = \mathbf{A}^0 + RT \ln (1-\xi)/\xi,$$

and

$$\mathbf{A}^0 = -u^0_{T,V} + Ts^0_{T,V}.$$

Here $\mathbf{A}^0$ is the standard affinity of reaction and $s^0_{T,V}$ the standard entropy of reaction at constant volume, which is also independent of T. Remembering that $(-u^0_{T,V})d\xi = cdT$ under adiabatic conditions, it is readily shown that subject to the above assumptions

$$\Delta_1 S \text{ (chem. adiab.)} = \xi_e s^0_{T,V} + c \ln (T_1/T_0) - \mathbf{R}[\xi_e \ln \xi_e + (1-\xi_e) \ln (1-\xi_e)]. \qquad [7]$$

When $\xi_e \rightarrow 1$, this reduces to

$$\Delta_1 S \text{ (chem. adiab.)} = s^0_{T,V} + c \ln (T_1/T_0). \qquad [8]$$

The same equation is obtained from the consideration that, since the process is adiabatic, the only way in which the entropy of the system can change is by the internal production of entropy which must therefore be equal to the difference between the total entropy of final and initial states.

The system in state β can now be cooled to T_0 (state γ) in two ways. First consider reversible cooling using the system as the source of entropy working a reversible heat engine whose sink temperature is T_0: the source temperature is initially T_1 but falls eventually to T_0. It may then be shown (3) that the work obtainable in this way is given by

$$\Delta^\gamma_\beta W(\text{rev.}) = c(T_1-T_0)\left[1-\frac{T_0}{T_1-T_0}\ln\frac{T_1}{T_0}\right], \qquad [9]$$

which, from [4], reduces to

$$\Delta^\gamma_\beta W(\text{rev.}) = -u^0_{T,V} - cT_0 \ln (T_1/T_0). \qquad [10]$$

On the other hand, if $\beta \rightarrow \gamma$ is carried out irreversibly, i.e. by placing the system in thermal contact with the surroundings at T_0 so that thermal equilibrium is established by heat conduction, then it can be shown that the entropy produced in this process, $\Delta_1 S$ (heat cond.), is given by

$$\Delta_1 S(\text{heat cond.}) = \Delta^\gamma_\beta W(\text{rev.})/T_0, \qquad [11]$$

$$= -(u^0_{T,V}/T_0) - c \ln (T_1/T_0). \qquad [12]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

We now compare this two-stage path between α and γ with the reversible isothermal path, e.g. using a van't Hoff equilibrium box, or a reversible electrochemical cell, in which the amount of work done by the system is

$$[13] \qquad \Delta_\alpha^\gamma W(\text{isothermal rev.}) = \int_0^{\xi_e} \mathbf{A} d\xi = \xi_e \mathbf{A}^0 - \mathbf{R}T[\xi_e \ln \xi_e + (1-\xi_e) \ln (1-\xi_e)].$$

Here ξ_e is the equilibrium extent of reaction at T_0 rather than T_1, but since we suppose $\xi_e \to 1$, we do not have to elaborate the argument to take account of this. Equation [13] thus reduces to

$$[14] \qquad \Delta_\alpha^\gamma W(\text{isothermal rev.}) = \mathbf{A}^0(T_0).$$

We may now identify the "loss of useful work" associated with the irreversible step $\alpha \to \beta$ with the difference between the work done by the system in the reversible, isothermal change $\alpha \to \gamma$, and that done when the process follows the path $\alpha \overset{\text{irrev.}}{\to} \beta \overset{\text{rev.}}{\to} \gamma$.

Thus:

[Loss of useful work in adiabatic, spontaneous chemical reaction]

$$= \Delta_\alpha^\gamma W(\text{isothermal rev.}) - \Delta_\beta^\gamma W(\text{rev.})$$

$$= \mathbf{A}^0(T_0) + u^0_{T,V} + cT_0 \ln (T_1/T_0)$$

$$[15] \qquad = T_0 s^0_{T,V} + cT_0 \ln (T_1/T_0)$$

which, from [8],

$$[16] \qquad = T_0 \Delta_t S \text{ (chem. adiab.)}.$$

Hence, the first number of equation [1] can be generalized to a non-isothermal process by identifying T not with the temperature of the system but with T_0, that of the surroundings. We note in passing that if both $\alpha \to \beta$ and $\beta \to \gamma$ are carried out irreversibly, then the entropy production (and the loss of useful work) is the same as when the process $\alpha \to \gamma$ is allowed to proceed spontaneously at constant temperature.

As an example of the above discussion we consider the irreversible freezing of supercooled water. This process, carried out isothermally, is a frequently quoted example in standard texts on chemical thermodynamics. When carried out adiabatically the freezing process is accompanied by a rise in temperature until the equilibrium freezing point is reached. To the approximation employed here, the fraction (ϕ) of the liquid which solidifies for a given degree of supercooling ($T_f - T$) is

$$[17] \qquad \phi = c(T_f - T)/\Delta_f h$$

where $\Delta_f h$ is the heat of fusion. It is then readily shown that the entropy production in this irreversible process is

$$[18] \qquad \Delta_i S = -\phi \Delta_f s + c \ln (T_f/T).$$

The entropy produced per mole of ice formed is thus

$$[19] \qquad \frac{\Delta_i S}{\phi} = -\Delta_f s + \frac{c}{\phi} \ln \frac{T_f}{T}$$

$$= -\Delta_f s + \frac{\Delta_f h}{T_f - T} \ln \frac{T_f}{T}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

which tends to zero as $T \rightarrow T_t$. $\Delta_i S/\phi$ is shown as a function of the degree of supercooling in Fig. 1.

The present considerations are also relevant to the question of the efficiency of internal combustion (or more generally, chemical reaction) engines. Thus the processes $\alpha \overset{\text{irrev.}}{\rightarrow} \beta \overset{\text{rev.}}{\rightarrow} \gamma$ may be regarded as the basic steps in the operation of an "ideal internal combustion engine", and the work derivable from this series of changes is the maximum which can be obtained from any engine involving a spontaneous chemical reaction. The magnitude of this work depends not only on the heat of reaction, but also upon the

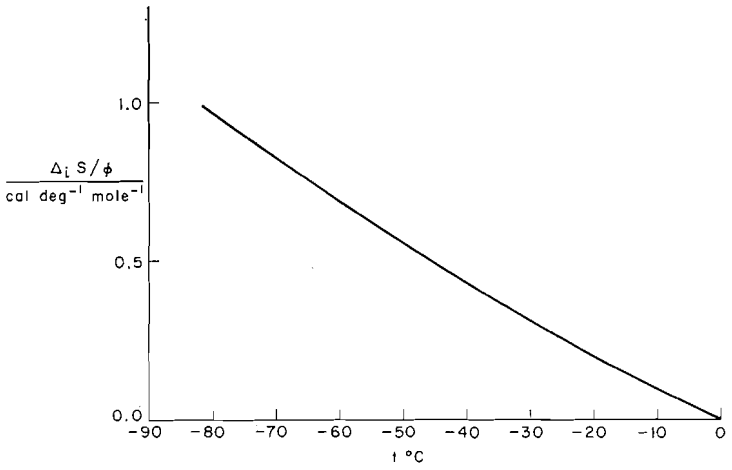

FIG. 1. Entropy production per mole of ice formed when water cooled to $t°$ C freezes spontaneously under adiabatic conditions.

heat capacities of the components: it therefore takes a much more specific account of the nature of the chemical reaction than do other treatments. In discussions of the Otto and Diesel cycles, for example, the only characteristic of the reaction which enters specifically is the heat of reaction. Conventionally, the efficiency of an internal combustion engine may be defined in relation to the heat of reaction

$$\theta_H = \frac{\Delta_\beta^\gamma W(\text{rev.})}{(-u^0_{T,V})} = 1-\frac{T_0}{T_1-T_0}\ln\frac{T_1}{T_0} \qquad [20]$$

$$= 1-\left(\frac{cT_0}{-u^0_{T,V}}\right)\ln\left[1+\left(\frac{-u^0_{T,V}}{cT_0}\right)\right].$$

A more fundamental definition of efficiency (θ_A) is the ratio of the work obtained to that which could be obtained in an isothermal, reversible process (e.g. in an ideal reversible fuel cell):

$$\theta_A = \frac{\Delta_\beta^\gamma W(\text{rev.})}{\mathbf{A}^0} = \frac{-u^0_{T,V}}{\mathbf{A}^0}\left\{1-\left(\frac{cT_0}{-u^0_{T,V}}\right)\ln\left[1+\left(\frac{-u^0_{T,V}}{cT_0}\right)\right]\right\} \qquad [21]$$

$$= \frac{-u^0_{T,V}}{\mathbf{A}^0}\theta_H.$$

The two efficiencies are equal when the standard entropy of reaction is zero. Alter-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

native equations are

$$\theta_A = 1 - \frac{T_0 \Delta_1 S(\text{chem. adiab.})}{\mathbf{A}^0}; \quad [22]$$

$$\theta_A = 1 - \frac{T_0}{\mathbf{A}^0}\left[s^0_{T,V} + c \ln \frac{T_1}{T_0} \right]. \quad [23]$$

θ_A may be regarded, therefore, as the ratio of the maximum fuel cell efficiency to the maximum efficiency of converting chemical energy to work via an engine involving a spontaneous chemical reaction. To illustrate the way in which the nature of the chemical reaction determines the maximum efficiency, the following table gives the results of calculations (making the approximations mentioned above) of θ_H and θ_A for some typical reactions, when $T_0 = 300°$ K. We notice that in the highly exothermic combination of H atoms, which because of low heat capacities involved leads to a large temperature rise, only 1% of the available "chemical energy" is lost in the irreversible step.

TABLE

Reaction	$-u^0_{T,V}$ kcal	c_V cal deg^{-1}	θ_H	θ_A
$2H \rightarrow H_2$	103	5.5	0.934	0.990
$H_2 + \frac{1}{2}O_2 \rightarrow H_2O$	57.5	6.6	0.883	0.930
$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$	191.8	17	0.914	0.915

In the above discussion, consideration has been limited to exothermic reactions. For an endothermic reaction similar arguments apply, except that $T_1 < T_0$, and in the step $\beta \rightarrow \gamma$ the system is used as the sink of the heat engine whose temperature rises steadily from T_1 to T_0. A chemical reaction for which $u^0_{T,V} = 0$ cannot form the basis of an internal combustion engine: in this case $\mathbf{A}^0 = T_0 \Delta_1 S$ (chem. adiab.) and $\theta_A = 0$.

In the present note, we have not elaborated the argument by taking account of incomplete reaction ($\xi_e \neq 1$) or of the variation of heat of reaction with temperature, although there would be no difficulty in doing so for the purposes of more precise calculations.

THE INFLUENCE OF TEMPERATURE ON THE KINETICS OF CHEMISORPTION OF HYDROGEN ON ZINC OXIDE[1]

MANFRED J. D. LOW

ABSTRACT

The kinetics of hydrogen adsorption by ZnO have been measured at constant pressures of 403 mm Hg over temperatures from 0° C to 257° C. Two distinct consecutive kinetic stages occur at all temperatures, each stage being precisely expressed by the Elovich equation. The rates and extents of adsorption increase in the temperature ranges 0–80° C and 110–200° C and decrease in the range 80–110° C. The change with temperature of the constants a and $1/\alpha$ of the Elovich equation parallels changes in the amount adsorbed with temperature.

INTRODUCTION

It has been found (1) that the kinetics of many chemisorption processes can be described by the Elovich equation,

$$(dq/dt) = a\, e^{-\alpha q},$$

where q is the amount of gas adsorbed at time t. The parameters a and α were found (1–5) to be affected by changes in initial gas pressure and in temperature. It was suggested (2, 3, 4) that the direction of change of the parameters with temperature might be bound up with a similar change of the isobar. Previous investigations were made mainly over temperature regions corresponding to increasing or to decreasing regions of the isobar, and it was consequently thought desirable to measure chemisorption kinetics in a temperature region in which an adsorption maximum or minimum existed. The system hydrogen – zinc oxide was chosen because two maxima and one minimum were known to exist (7, 8, 9) in the chemisorption region of about 0°–300° C.

EXPERIMENTAL DETAILS

The course of hydrogen adsorption was followed by measuring the disappearance of gas in a constant pressure system of the type described by Taylor and Strother (8). The electrolysis cell of that system was modified by addition of a water jacket in order to cool the electrolyte. The latter consisted of a concentrated solution of sodium acetate in glacial acetic acid and was electrolyzed by a current of 5–8 amps at 40–60 v a-c. Gold electrodes of $\sim$ 300 mm^2 area, about 3 cm apart, were used. Electrolytic tank hydrogen was purified by passage over palladized asbestos, Ascarite, Drierite, and glass wool at the temperature of liquid nitrogen. Helium, used for measurement of dead space in the usual fashion, was purified by passage over charcoal at the temperature of liquid nitrogen. During an adsorption experiment the catalyst was kept at the described temperature to within ± 0.1° C by the vapor of a boiling liquid. A Wheelco Amplitrol Model 152 was used to regulate temperatures to within about 5° C during degassing. Two sets of experiments were made. The first, set A, is incomplete because experiments became irreproducible, probably due to accidental exposure of the catalyst to air. Except where specifically noted, all reference is to the data of the second set, B.

The adsorbent was prepared by decomposing zinc oxalate *in vacuo* by heating at the following schedule: 20–100° C, 1 hour; 100–200°, 1 hour; 200–300°, 1.5 hours; at 400°,

[1]*Manuscript received July 24, 1959.*
Contribution from the Texaco Research Center, Beacon, N.Y.

4 hours; at 450°, 15 hours. Evolution of gas began at about 150°, and continued until 400° had been reached. After the 450° treatment the catalyst was cooled *in vacuo*. For set B, a 19.76-g sample of the preparation was placed in a tube which was then sealed to the adsorption system. This catalyst was degassed at 450° for 2 days, was then cooled to 300°, and exposed to hydrogen at $\frac{1}{2}$ atm for about 30 minutes. The catalyst was then degassed at 420° C for 20 hours. This "activation" procedure was repeated twice. Residual pressures $\leqslant 10^{-6}$ mm Hg were attained. Between runs the catalyst was degassed at 420° C overnight. The adsorbent had a nitrogen B.E.T. surface area of 16 m^2/g. Experiments were made at constant pressure of 403 mm Hg.

EXPERIMENTS, RESULTS, AND DISCUSSION

Kinetics of Chemisorption

At the lower temperatures the plots of q vs. t showed the characteristics of "normal" adsorption, namely a rapid adsorption at short times that quickly decelerated. Each of the q–t curves of runs at the higher temperatures, however, shows a distinct "dip", or change in rate, after some 20 to 80 minutes, shown in the plots of Fig. 1. Similar dips

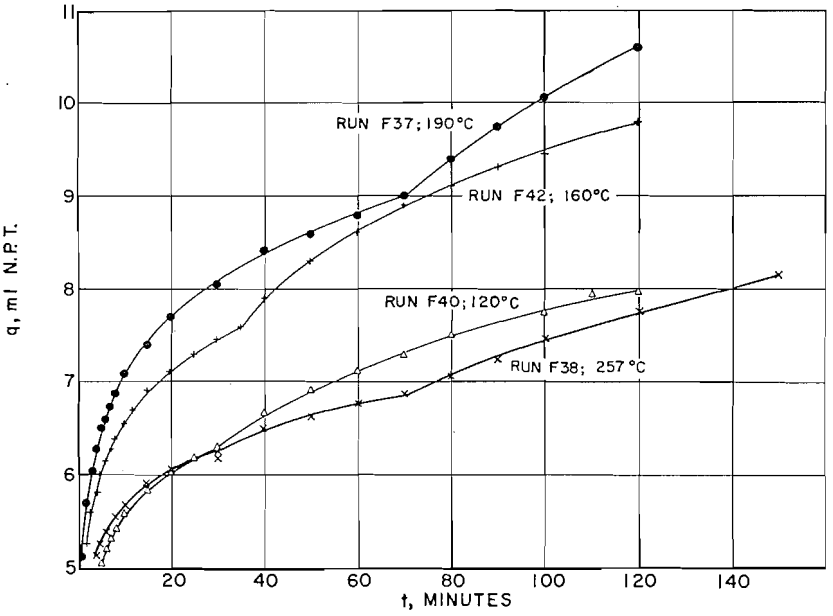

FIG. 1. Adsorption rate data: typical runs. The points of F42, F38, and F40 are displaced by 1, 4, and 5 minutes, respectively.

are noticeable in the q–t data of hydrogen adsorption on ZnO of Taylor and Sickman (6) and Taylor and Strother (8). These authors drew smooth curves through the data, ignoring the dip. Indeed, on cursory examination the dips might be ascribed to experimental scatter, especially in the plots of data at the lower temperatures. However, as shown by Fig. 2, plots of q vs. $\log_{10}t$ show the presence of two distinct kinetic stages. After some time the q–$\log_{10}t$ line changes in slope, and such discontinuities, or "breaks", are present in the data of all runs, and are also found in the q–$\log_{10}t$ plots of the data of other studies (6, 8). Each linear portion of a q–$\log_{10}t$ plot can be described by the Elovich equation (1).

Isobars

Plots of amounts adsorbed after a specific time, q_t, against temperature reveal the double-humped isobars first described by Taylor and Strother (8). Figure 3 shows curves

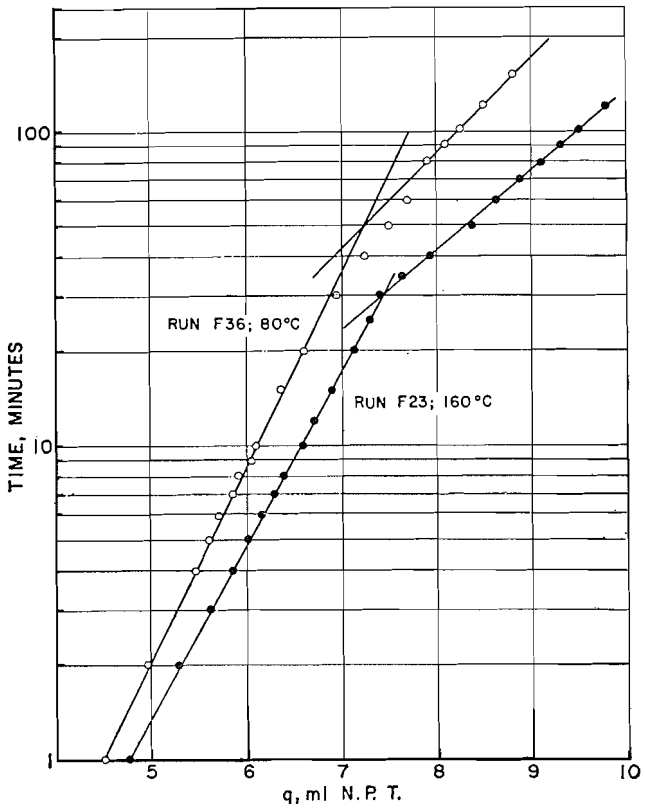

FIG. 2. Adsorption rate data: Elovich plots.

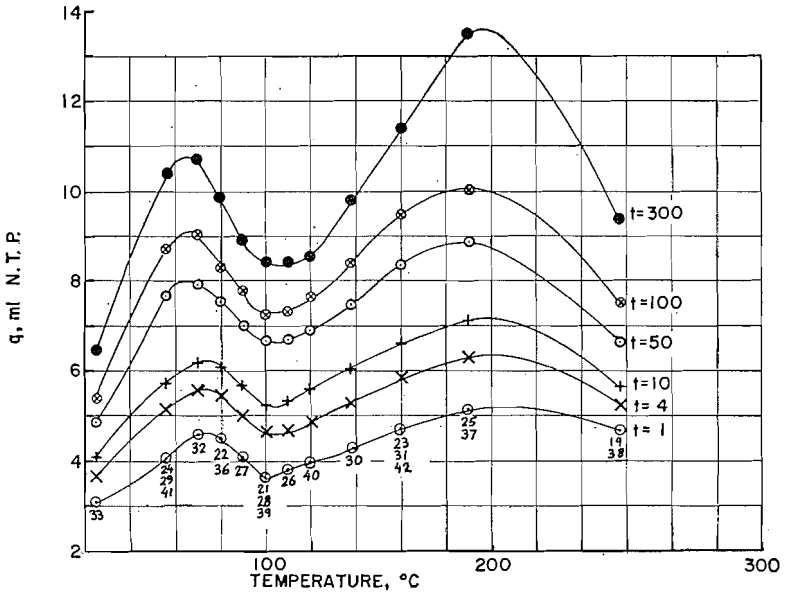

FIG. 3. H_2–ZnO isobars. The numbers next to points of the $t = 1$ curve are those of the experiments, which were numbered consecutively in order of their execution.

representing amounts adsorbed after 1, 4, 10, 50, 100, and 300 minutes at each temperature. Adsorption maxima appear at about 70° and 200°, and a minimum appears at about 105°. Inspection of Table I reveals small temperature differences in isobar positions. Cimino, Cipollini, and Molinari (9) were able to displace the position of their isobar by about 20° by sintering their adsorbent at 900°. The relatively small differences in isobar positions of pure ZnO suggests that the maxima are not very sensitive to catalyst preparation variables, although it has been shown (9) that the structure of the isobar is severely affected by doping the ZnO.

TABLE I
Temperatures of occurrence of the maxima and the minimum of the adsorption isobar of hydrogen on zinc oxide

Investigation*	Maximum, ° C	Minimum, ° C	Maximum, ° C
(*a*) Taylor and Strother (8)	80	97	218
(*b*) Wicke (7)	70	100	260
(*c*) Cimino *et al.* (9)	50	105	—
(*c, d*) Cimino *et al.* (9)	70	135	190
(*e*) Present experiments	70	105	200
(*f*) Present experiments	80	110	200

*(*a*) Measured after 1000 minutes; pressure: 1 atm.
(*b*) Measured after 600 minutes; pressure: 1 atm.
(*c*) Measured after 900 minutes; pressure: 1 atm.
(*d*) After sintering the catalyst at 900° C.
(*e*) Set B measured after 300 minutes.
(*f*) Set A measured after 500 minutes.

Effect of Temperature on Rate Constants

Values of the constants a and α were calculated (10) for each linear portion of an Elovich plot, and are given graphically as functions of temperature in Figs. 4, 5, and 6.

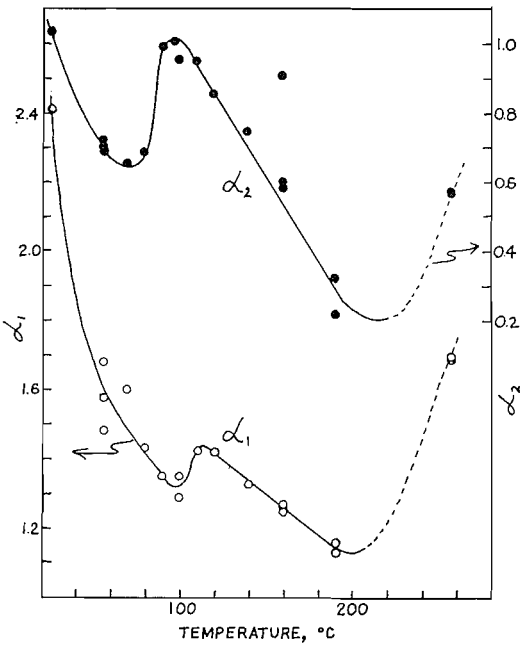

FIG. 4. The effect of temperature on α.

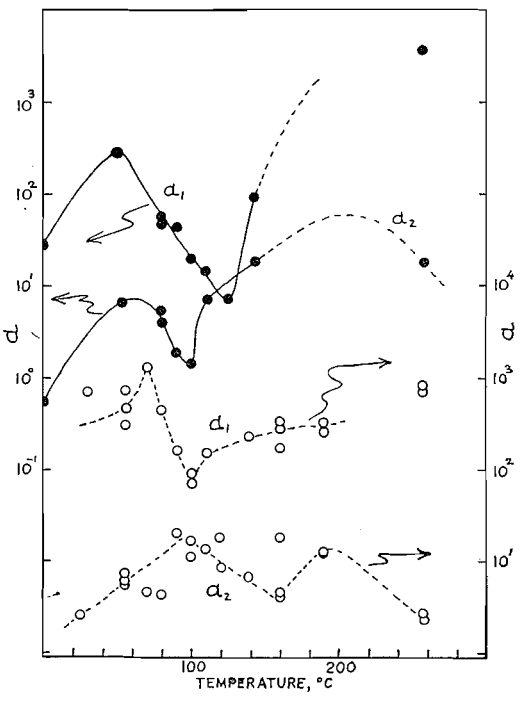

FIG. 5. The effect of temperature on a. ●, Data of set A. ○, Data of set B. The catalyst of set A consisted of 31.30 g ZnO ex oxalate.

For personal use only.

The subscripts 1 and 2 refer to the constants for the first and second lines of Elovich plots, respectively. The structure shown by the α–T plots of Fig. 4 is similar but inverse of that of the isobar. The plots of Fig. 5 of the more sensitive (2, 3, 4) values of a against temperature similarly reflect the isobar structure, but show more scatter. In Fig. 5 the lower two curves formed by open circle refer to the data of set B, while the upper two curves refer to the incomplete set A, shown here to illustrate the trends in a–T relations. The ratio of the rate of the second kinetic process to that of the first process is α_1/α_2. Figure 6 shows the α_1/α_2–T relation: undulations similar to those of the isobar are apparent, so that the effect of temperature on the second kinetic process is greater than that on the first process. Figure 7 shows values of the co-ordinates q_b and t_b of the break

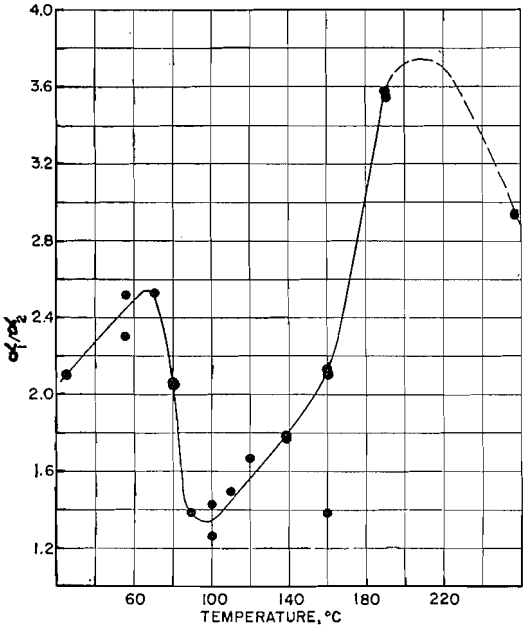

FIG. 6. The effect of temperature on (α_1/α_2).

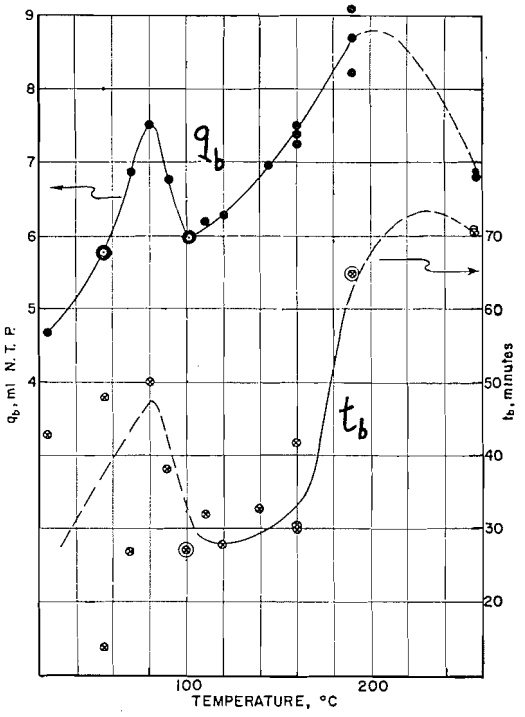

FIG. 7. The variation of the co-ordinates of the break with temperature.

of Elovich plots at various temperatures. The q_b–T plot shows structures similar to that of the isobar. The t_b–T plot shows some variations but, because of the exponential effect of scatter of a values on those of t_b, the trends are not well defined. In general, then, in the present system of H_2–ZnO, the rates of adsorption vary with temperature in a fashion similar to the variation of the extents of adsorption after long times.

It is obvious that the temperature dependencies of the rate parameters can be more complex than had been previously believed. Earlier studies (1–4) show simple relations

$$\alpha = A+B/T$$
$$\log a = C+D/T \qquad A, B, C, D = \text{constants}$$

to hold over ranges of temperatures covering about 200° C. Such studies, however, had been made in a temperature region of continuously increasing or decreasing adsorption. Such linear equations can be constructed for the present data. The constants α_1 and α_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

over the range 120–190° C, for example, vary inversely with temperature. In view of the undulations of the isobar, however, such equations are pointless in this case. Similarly pointless are calculations of activation energies of adsorption, particularly in the region 80–110° C, where negative activation energies are obtained. By analogy one may expect similar undulant variations of rate parameters with temperature to occur with the adsorption of hydrogen on iron synthetic ammonia catalyst (11), the only other system known to exhibit the double-humped isobar. Also, a consistent reversal of temperature coefficients in the vicinity of a normal adsorption isobar maximum seems plausible. However, because no adequate general explanation of these phenomena is apparent, the sign and magnitude of the temperature coefficients in both the ascending and the descending portions of the isobar cannot be predicted.

The Effect of Continuously Changing Temperature

Taylor and Liang (12) found that if the temperature of a sample of ZnO almost saturated with hydrogen was suddenly increased, a desorption followed by a readsorption of gas occurred. When the temperature was decreased, increased adsorption was found. It was thought of interest to perform several experiments in order to determine if similar results would be obtained when (*a*) the temperature was changed relatively slowly and in continuous fashion; (*b*) the adsorbent was in a state relatively far removed from complete coverage.

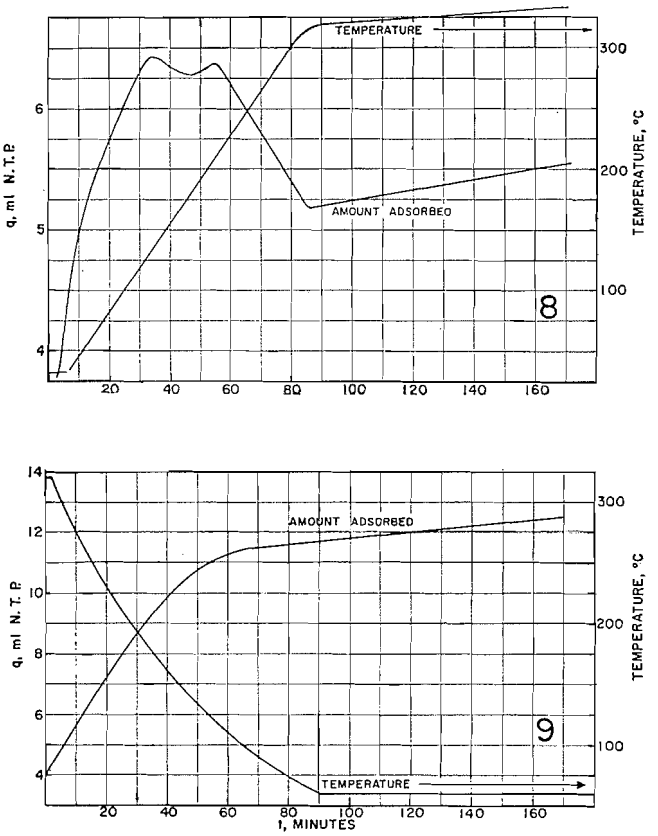

FIG. 8. The effect of continuously increasing temperature.
FIG. 9. The effect of continuously decreasing temperature.

For personal use only.

Run F34 was started in normal fashion, with the catalyst degassed, at a temperature of 33° C. However, instead of keeping the temperature constant as in a normal run, the temperature was raised at a rate of about 4°/minute to about 314° C. Readings were made every minute except after 85 minutes. The numerous q data as well as the prevailing furnace temperature are shown in Fig. 8 as smoothed plots as functions of time. Adsorption ceases to increase at about 130°, and a continual decline in q is found after about 205° C. The significance of the small dip in the q–t curve at about 180° is not clear: the decline in q between 140° and 180° is only about 0.15 ml. Further, it may be expected that the temperature of the catalyst will not be uniform and will be at a slightly lower temperature than that of the furnace.

Run F35 was started at 323° C in normal fashion, but the temperature was allowed to fall to 69° C. In Fig. 9 the smoothed q–t plot of the numerous data shows continuous increase in adsorption with time. The rate of adsorption declines slowly and becomes roughly constant in the constant temperature region after 100 minutes. The results of the two experiments are thus comparable to those of the experiments of Taylor and Liang. Apparently quite drastic departures from the techniques of those authors will not bring about significantly different results.

THE THIRD LAW ENTROPY AND STRUCTURE OF IRON PENTACARBONYL[1]

A. J. LEADBETTER[2] AND J. E. SPICE[3]

ABSTRACT

The heat capacity of solid and liquid iron pentacarbonyl has been measured from 20° to 290° K. The heat of fusion was also measured and found to be 3161±3 cal/mole. From an investigation of the change of temperature of the sample during melting the triple point of iron pentacarbonyl was estimated to be 253.15° K and the purity of the sample 99.9 mole%. An anomalous absorption of energy amounting to 4.8 cal/mole was observed at about 230° K; this is shown to be due to an unknown impurity in the sample. The vapor pressure of the liquid was measured in the vicinity of room temperature and from these results the heat of vaporization at 25° C was estimated to be 9.1±0.1 kcal/mole.

The entropy of iron pentacarbonyl as an ideal gas at 1 atm pressure and 25° C computed from the thermal measurements is 106.4±0.8 cal/mole deg. Comparison of this quantity with values calculated from spectroscopic data indicates that the iron pentacarbonyl molecule has the form of a trigonal bipyramid rather than that of a square pyramid.

INTRODUCTION

The iron pentacarbonyl molecule, one of the few of type AX_5, might on general grounds be either a trigonal bipyramid or a square pyramid. An electron diffraction study (1) indicated a trigonal bipyramid structure but this does not appear to be consistent with the reported dipole moment of 0.8 Debye (2). An attempt has been made to use nuclear resonance techniques to determine the structure but the results were inconclusive (3).

Many spectroscopic investigations have been reported but the photosensitivity of iron pentacarbonyl has made it difficult to obtain the Raman spectrum which is necessary for an unambiguous frequency assignment. However, the weight of spectroscopic evidence favors the bipyramidal structure (3, 4, 5, 6) although O'Dwyer (7) has recently claimed that his infrared results can best be interpreted on the basis of the square pyramid structure.

It has thus not been possible to establish conclusively the structure of the iron pentacarbonyl molecule from spectroscopic data alone. A comparison of the Third Law entropy with the statistical value calculated on the basis of the two possible structures and the corresponding frequency assignments might therefore help to decide between the two structures.

EXPERIMENTAL

The Material

We are grateful to the Mond Nickel Co. Ltd. for supplying the sample of iron pentacarbonyl. It was supplied in the form of the pure liquid, and an analysis of the freezing curve by the method of Taylor and Rossini (8) indicated the purity to be 99.9 mole%. The sample was therefore used without further purification; a subsequent study of the melting curve confirmed the above value for the purity.

The Calorimetric Method

The cryostat contained a miniature hydrogen liquefier of the type used by Jones[4]

(9). The calorimetric measurements were made with a conventional vacuum adiabatic calorimeter by standard methods. All of the measurements were made with a White double potentiometer. Time of energy input was determined with a Venner mechanical stop clock, the solenoid switching mechanism of which was coupled directly to the switch controlling the heater current. The clock was calibrated by comparison with the B.B.C. time signals. The platinum resistance thermometer was calibrated on the International Temperature Scale above 90° K and on the thermodynamic scale below this temperature. The calorimetric apparatus and the establishment of the temperature scale below 90° K will be fully described elsewhere (10).

The copper calorimeter vessel, weighing 240 g, was filled with 0.5906 mole of sample in a dimly lit, dry atmosphere. It was sealed by pinching shut and sealing with solder a short length of thin-walled nickel tubing previously soldered into the neck of the vessel. The heat capacity of the calorimeter amounted to 17% of the total at 20° K and to 39% at 290° K. Temperature increments of between 4° and 8° were generally used except in the region of 230° K, where smaller increments were used in order to investigate the anomalous energy absorption.

The Vapor Pressure Measurements

The vapor pressure of the liquid was measured between 20° and 33° C using a mercury manometer of 17-mm-bore tubing. Pressures were measured using a comparator telescope and a glass scale, etched in 0.5-mm divisions, which was freely suspended between the arms of the manometer; the accuracy of pressure measurement is estimated to be ±0.05 mm. The temperature of the sample was maintained constant to ±0.02° for each pressure determination, by means of a water thermostat. The vapor space was always maintained at a slightly higher temperature than the liquid. Temperatures were measured to ±0.02° with a mercury-in-glass thermometer, the ice point reading of which had been found correct within these limits. In order to prevent photochemical decomposition light was excluded from these portions of the apparatus containing the iron pentacarbonyl; as a check against possible decomposition, measurements were made after both warming and cooling the sample.

RESULTS

The Heat Capacity

The experimental results are given in Table I (the ice point was taken as 273.16° K and the calorie as 4.1840 absolute joules). The maximum deviation of any point from a smoothed curve is 0.4% and the average deviation ±0.1%, except in the anomalous region where the measurements were somewhat less precise. The accuracy of the results is estimated to be ±0.5% for $20° K < T < 50° K$ and ±0.3% for $T > 50° K$. The heat capacity curve shows a quite regular behavior except for a very small peak at about 230° K, associated with the absorption of an "extra" energy of 4.8 cal/mole over a narrow temperature range. A preliminary investigation of the heat capacity of iron pentacarbonyl, made in this laboratory by McGowan (11), had indicated the presence of a much larger anomaly in the heat capacity curve. It was shown in the present work, by determination of the heat capacity after cooling through the anomalous region at different rates and to different temperatures, that the size of the anomaly was independent of the previous history of the sample. The data obtained on the apparent anomaly in the two investigations are compared in Table II. T_{max} is the temperature at which the heat capacity in the anomalous region reaches its maximum value. The amount of impurity in each specimen was estimated from the depression of the melting point.

TABLE II

The apparent anomaly in $Fe(CO)_5$ at 230° K

T_{max} (° K)	ΔH (cal/mole)	Impurity (mole%)	
229.9±0.1	4.84±0.05	0.1	This work
229.7±0.3	124 ±1	3.4	McGowan

Within the limits of experimental uncertainty the size of the anomaly is directly related to the amount of impurity in the specimen, showing that the anomaly must be caused in some way by the impurity and is not an intrinsic property of pure iron pentacarbonyl. The most probable explanation of the anomaly is that it is due to the melting of an eutectic mixture present in a small amount. Unfortunately, the nature of the impurity is not known but the most likely impurities in iron pentacarbonyl are nickel carbonyl and $Fe_2(CO)_9$ formed in the photochemical decomposition of the pentacarbonyl. Since both samples were obtained from the same source it seems unlikely that they initially contained such differing amounts of impurity and this would suggest that $Fe_2(CO)_9$ is the most likely impurity. However, without additional experimental data further speculation would appear to be of little value. In addition, it should be noted that the entropy associated with the anomaly (0.02 cal/mole deg) is quite negligible in the determination of the standard entropy.

The Triple Point and Heat of Fusion

The equilibrium temperatures as a function of the fraction of the sample melted are shown in Table III. From these results the calculated triple point of iron pentacarbonyl is 253.15° K.

TABLE III

The melting point of $Fe(CO)_5$

% Melted	T° K
31	253.018
50	253.062
67	253.084
84	253.097
100	253.11

NOTE: Impurity: 0.1 mole%. Triple point: 253.15° K.

The heat of fusion was determined in the usual manner, the premelting energy being included in the heat of fusion. Two determinations gave respectively 3158.7 and 3162.6 cal/mole, or a mean value of 3161±3 cal/mole. The only previously published value for the heat of fusion is 3250±40 cal/mole reported by Mittasch (12).

The Vapor Pressure

The experimental results are given in Table IV. Pressures are expressed in terms of the height of a column of mercury under standard gravity at 0° C. The results may be represented within their experimental uncertainty by the formula

$$\log P \text{ (mm)} = 8.514 - (2105/T)$$

as is shown in Table IV.

TABLE IV

The vapor pressure of $Fe(CO)_5$

Temp. (° K)	P_{obs} (mm)	P_{calc} (mm)	Temp. (° K)	P_{obs} (mm)	P_{calc} (mm)
293.47	21.95	21.90	301.44	34.00	33.89
294.36	23.01	23.02	302.71	36.38	36.25
295.99	25.38	25.21	302.91	36.65	36.64
296.94	26.45	26.56	303.48	37.88	37.77
297.98	28.05	28.12	304.01	38.70	38.83
298.30	28.68	28.62	305.24	41.37	41.41
299.60	30.56	30.70	305.30	42.73	41.53
300.26	31.67	31.82	306.32	43.60	43.78

The above formula has been compared with vapor pressure data reported by Dewar and Jones (13) between −7° and 78° C, Eyber (14) between −15° and 20° C, and Trautz and Badstübner (15) between 46° and 104° C. The results of Dewar and Jones appear to be too high below about 40° C, while those of Eyber are in excellent agreement with the present work. The results of Trautz and Badstübner are higher by about 1% at 46° C and the deviation increases with temperature. This, however, may only represent the inadequacy of a two-constant expression for log P over any but a restricted temperature range.

The heat of vaporization at 25° C was calculated by means of the Clausius–Clapeyron equation, the Berthelot equation of state being used to correct for gas imperfection. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

values of the critical constants used were $T_c = 560°$ K and $P_c = 29.6$ atm (13). The heat of vaporization of iron pentacarbonyl was found to be $9.6_0 \pm 0.1$ kcal/mole.

DISCUSSION

The Third Law Entropy of $Fe(CO)_5$

The computation of the entropy of iron pentacarbonyl as an ideal gas at 1 atm pressure and 25° C is summarized in Table V. The extrapolation of the heat capacity from 22.59° to 0° K was carried out by means of a Debye function with 18 degrees of freedom and $\Theta = 155°$ K.

TABLE V

The Third Law entropy of $Fe(CO)_5$

	cal/mole deg	
ΔS (0° to 22.59° K) Debye extrapolation	2.7 ±0.2	
ΔS (22.59° to 253.15° K) solid	56.3 ±0.2	
$\Delta S_{253.15}$ (3161/253.15) fusion	12.49±0.02	
ΔS (253.15° to 298.16° K) liquid	9.26±0.03	
$\Delta S_{298.16}$ (960_0/298.16) vaporization	32.2 ±0.3	
Entropy of real gas at 28.4 mm and 298.16° K		$112.9_5 \pm 0.7_5$
$\Delta S_{\text{compression}}$ R ln (28.4/760)	−6.53±0.01	
Correction for gas imperfection	0.01	
Entropy of the ideal gas at 1 atm and 298.16° K		106.4±0.8

The Statistical Entropy of $Fe(CO)_5$

The standard entropy of iron pentacarbonyl has been calculated from spectroscopic data by standard methods, using the rigid rotator – harmonic oscillator approximation. The values of the fundamental constants were taken from the tables of Kaye and Laby (16).

The computation was carried out for both the trigonal bypiramid model (symmetry D_{3h}) and the square pyramid model (symmetry C_{4v}) and in both cases the following interatomic distances were used (1): Fe—C, 1.84 Å and C—O, 1.15 Å; the Fe—C—O groups were assumed linear. The D_{3h} model was precisely that proposed by Ewens and Lister (1) on the basis of their electron diffraction studies, while for the C_{4v} model the four equivalent CO groups were assumed coplanar with the Fe atom and the remaining CO group perpendicular to the plane. This is a reasonable assumption since the C—Fe—C angle would not be expected to differ greatly from 180° and numerical values of entropy are not sensitive to small changes in bond angles. In fact, the difference in the moments of inertia of the D_{3h} and C_{4v} models contributes less than 0.01 cal/mole deg to the difference in the rotational entropies of the two structures; almost the whole difference is due to the change of symmetry number from 6 to 4.

A serious deficiency in the frequency assignments of King and Lippincott (4, 5), Murata and Kawai (6), Edgell and Wilson (see ref. 5), and O'Dwyer (7) is the lack of experimental data on the low frequency C—Fe—C deformation modes, to which the thermodynamic properties at normal temperatures are most sensitive. Only one of these fundamentals was directly observed, the remainder being obtained from infrared combination bands or by comparison with similar molecules. Very recently, however, Cotton Danti, Waugh, and Fessenden (3) have reported the observation of these low frequency fundamentals. They conclude that these and other (unpublished) results at higher frequencies are more consistent with the D_{3h} than the C_{4v} model and have accordingly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

assigned the observed fundamentals on this basis. The various assignments proposed for the C—Fe—C deformation modes on the basis of both molecular models are given in Table VI, where the numbering is taken from the original papers.

TABLE VI

C—Fe—C deformation frequencies

	D_{3h}					C_{4v}	
		Frequency (cm^{-1})					
	Symmetry	King and Lippincott	Murata and Kawai	Edgell and Wilson	Cotton *et al.*	Symmetry	Frequency (cm^{-1}), O'Dwyer
ν_9	A_2''	100	100	115	93	ν_6 A_1	79
ν_{14}	E'	110	110	92	72	ν_{11} B_1	185
ν_{15}	E'	100	63	102	104	ν_{13} B_2	146
ν_{18}	E''	110	95	110	112	ν_{19} E	103
						ν_{20} E	71

The vibrational entropy for the D_{3h} model has been calculated using each of the proposed frequency assignments, first as published and then corrected to include the observed low frequency fundamentals reported by Cotton *et al.* For the C_{4v} model O'Dwyer's assignment has first been used to calculate the vibrational entropy, but in order to provide a fair comparison of the two models it is necessary to correct his assignment to incorporate the new spectroscopic results for the low frequency fundamentals and calculate the entropy on this basis also. This may be done most reasonably by assigning the observed fundamentals to ν_6 (93 cm^{-1}), ν_{13} (112 cm^{-1}), ν_{19} (104 cm^{-1}), and ν_{20} (72 cm^{-1}) but it must be emphasized that such an assignment does not appear to be consistent with the spectroscopic results. The results of the entropy calculations are summarized in Table VII, the final column contains the entropies calculated using the frequency assignments corrected to incorporate the observed values for the low frequency fundamentals.

TABLE VII

The statistical entropy of $Fe(CO)_5$

	Moments of inertia (g cm^2 $\times 10^{40}$)		$S°_{trans+rot}$ (cal/mole deg)		$S°_{vib}$ (cal/mole deg)	$S°$ (cal/mole deg)	$S°_{corr}$ (cal/mole deg)
Model	I_A	$I_B = I_C$		Frequency assignment			
C_{4v}	1220	861	69.5_4	O'Dwyer	35.5_2	105.1	105.2
D_{3h}	915	1067	68.9_0	King and Lippincott*	35.4_7	104.4	106.0
				Murata and Kawai	34.5_2	103.4	102.6
				Edgell and Wilson	36.0_1	104.9	106.1
				Third Law entropy		106.4±0.8	

*The values of $S°$ and $-(F°-E_0°)/T$ quoted by King and Lippincott (4) are too high at all temperatures by 1.9 cal/mole deg.

The comparison of the Third Law entropy with the statistical value, calculated using the new results of Cotton *et al.* for the C—Fe—C deformation frequencies, provides strong support for the D_{3h} rather than the C_{4v} model for the iron pentacarbonyl molecule. In view of the evidence from electron diffraction and spectroscopic studies, which alone were not conclusive, and the new evidence presented here from thermodynamic studies, it can now be concluded with reasonable certainty that the structure of the iron pentacarbonyl molecule is a trigonal bipyramid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The above comparison cannot help to resolve the details of the frequency assignment since the entropies calculated on the basis of the assignments of King and Lippincott and Edgell and Wilson are very close, while the frequency assignments differ considerably in detail. However, it can be concluded that the assignment proposed by Murata and Kawai based on the same experimental data as that of King and Lippincott, must be seriously in error.

ACKNOWLEDGMENT

CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES
VIII. SYNTHESIS OF α-D-MANNOPYRANOSYL- AND α-L-RHAMNOPYRANOSYL-DISACCHARIDES BY THE KÖNIGS–KNORR REACTION*

P. A. J. Gorin and A. S. Perlin

6-*O*-β-D-Mannopyranosyl-D-glucose was required for studies on oligosaccharide structure. A synthesis of the octa-*O*-acetyl derivative of this disaccharide via the Königs–Knorr reaction (1) has been reported by Talley, Reynolds, and Evans (2), who condensed 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose in the presence of silver oxide. The procedure of these earlier workers has now been repeated, and the disaccharide fraction produced was deacetylated and isolated by column chromatography on cellulose (3). The amorphous material, which contained a major and a minor component (chromatographic evidence), showed an unexpectedly strong dextrorotation ($[\alpha]_D$ +64°). Examined by the periodate oxidation procedure described in Part I of this series (4), it yielded a product ($[\alpha]_D$ +63°) which corresponded in optical rotation much more closely to that (I, free trialdehyde form) given by (1 → 6)-α-D-aldohexopyranosyl disaccharides (for example, No. 1, Table I), than by the β-D-anomers

[a]Based on the assumption that the compound on oxidation yields the corresponding di- or tri-aldehyde in quantitative yield (4).

[b]Present work.

[c]Prepared in low yield as a chromatographically pure syrup from 6-*O*-α-D-galactopyranosyl-D-glucose, via a series of reactions utilized commonly for preparation of ω-deoxy sugars and derivatives (cf. (28)), i.e., tritylation, acetylation, detritylation, tosylation, iodination, reduction, deacetylation; intermediate products were not isolated.

[d]Obtained as the β-hepta-*O*-acetate (m.p. 175–176° C; $[\alpha]_D^{25}$ −2° (*c*, 1.4, chloroform). Calculated for $C_{26}H_{36}O_{17}$: C, 50.32%; H, 5.85%. Found: C, 50.35%; H, 5.93%) by condensation of 2,3,4-tri-*O*-acetyl(6-deoxy-α-D-glucopyranosyl)-bromide ((m.p. 152–155° C; $[\alpha]_D^{25}$ +268° (*c*, 1.3, chloroform). Calculated for $C_{12}H_{17}O_7Br$: C, 40.81%; H, 4.85%. Found: C, 40.98%; H, 4.95%)) with 1,2,3,4-tetra-*O*-acetyl β-D-glucose, according to the procedure of Talley, Reynolds, and Evans (2).

(for example, No. 3, Table I). A sample of the disaccharide octaacetate† prepared by Talley, Reynolds, and Evans was deacetylated and oxidized as described previously (4)

*Issued as N.R.C. No. 5354.

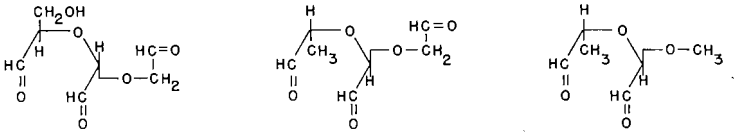
†*Obtained through the kindness of Professor M. L. Wolfrom.*

for isomaltose octaacetate. The rotatory power of the oxidation product (No. 2, Table I) showed that the disaccharide possesses the α-D-linkage, rather than the β-D-linkage assigned (2).

A (1 → 6)-mannobiose octaacetate (designated (1 → 6)-β-D-) was synthesized in the same manner by these earlier workers (2), and examination of this disaccharide* (No. 4, Table I) showed that it too must be assigned the α-D-linkage. This disaccharide has been obtained by acid reversion of D-mannose and partial hydrolysis of yeast mannan (5), its configuration having been confirmed earlier by the periodate oxidation method (4).

Two trisaccharides have been synthesized by Talley and Evans (6) through condensation of the α-acetobromo derivative of their 6-*O*-D-mannopyranosyl-D-glucose with 1,2,3,4-tetra-*O*-acetyl-D-glucose or -D-mannose. These trimers may now be redesignated, therefore, *O*-α-D-mannopyranosyl-(1 → 6)-β-D-glucopyranosyl-(1 → 6)-D-glucose, and *O*-α-D-mannopyranosyl-(1 → 6)-β-D-glucopyranosyl-(1 → 6)-D-mannose. The trisaccharides were thought (6) to be isomeric, or identical, with two oligosaccharides prepared (7) by acetolysis of the glucomannan from *Amorphophallus konjac*. Recently, however, it has been shown that the parent polysaccharide contains (1 → 4)-, but not (1 → 6)-, glycosidic linkages (8).

Reducing disaccharides which contain L-rhamnopyranose(6-deoxy-L-mannopyranose) as the non-reducing end unit have also been prepared by the Königs–Knorr reaction. Rutinose, the sugar moiety of the flavone glycoside, rutin, has been synthesized (9) from 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose in the presence of mercuric acetate (the Zemplen modification (10)) and its linkage assigned a β-configuration. Similarly, the related disaccharide robinobiose, a component of the flavonoid robinin, has been synthesized and designated 6-*O*-β-L-rhamnopyranosyl-D-galactose (11). On periodate oxidation these disaccharides theoretically should yield a trialdehyde (II, α-L-anomer) which is closely related structurally to that (I) produced from (1 → 6)-linked aldohexose disaccharides, or to the dialdehyde produced from the corresponding methyl L-rhamnopyranoside (III, α-L-anomer). Examined by the oxidation procedure, rutinose† afforded a strongly levorotatory product (No. 5, Table I) which, by comparison with the products prepared from methyl 6-deoxy-α- and β-L-glycopyranosides (13) (Nos. 8 and 9, Table I), was to be expected for the α-L-isomer. Confirmation of this possibility was provided by the fact that 6-*O*-(6-deoxy-



I II III

α-D-galactopyranosyl)-D-glucose (No. 6, Table I) on oxidation yielded a product having a specific rotation approximately equal and opposite to that produced from rutinose. In addition, the oxidation product derived from 6-*O*-(6-deoxy-β-D-glucopyranosyl)-D-glucose (No. 7, Table I) possessed a negative specific rotation of much smaller magnitude than that shown by the α-L- (or α-D-) isomers, which parallels the properties of the corresponding methyl β-D- and β-L-glycosides (Nos. 9 and 10, Table I). These findings

Obtained through the kindness of Professor M. L. Wolfrom.

show, therefore, that rutinose is an α-L- (rather than a β-L-) rhamnoside and, by analogy, that robinobiose most probably also is an α-L-rhamnoside.*

In most applications of the Königs–Knorr reaction it has been found that a Walden inversion accompanies replacement of the halide group, and the glycosidic linkage formed thus possesses a configuration opposite that of the parent glycosyl halide (16, 17, 18, 19, 20). Several reactions have been reported, however, in which the anomeric configuration of the product is the same as in the glycosyl halide used (for example, 21, 22, 23, 24, 25). Syntheses of the oligosaccharides considered above, using poly-*O*-acetyl-α-D-mannopyranosyl- or α-L-rhamnopyranosyl-bromide, clearly represent yet other examples in which configuration is retained. The latter two glycosyl halides may also undergo replacement with inversion, nonetheless, since on methanolysis the respective β-glycosides (together with orthoesters) have been obtained (24, 26, 27). These conflicting results are related possibly to the fact that different reaction conditions have been used in preparing the two classes of compounds. For methyl glycoside formation, the methanol served also as the reaction medium (24, 26, 27), whereas a less polar solvent (benzene or chloroform) was used in synthesis of the disaccharides (2, 9, 11). Isbell and Frush have shown (24) that use of a diluent (for example, benzene or ether) alters the course of the methanolysis of tetra-*O*-acetyl-α-D-mannopyranosyl bromide, promoting synthesis of the α-D-glycoside and a lower yield of the β-D-glycoside and orthoacetate. They suggested that the diluent interacts with an orthoester-type intermediate, formed with participation of the 2-*O*-acetyl group, permitting the reaction with methanol to proceed without a Walden inversion.† In the light of these observations, therefore, the formation of α-D-mannosyl- and α-L-rhamnosyl-disaccharides by the Königs–Knorr reaction is understandable.

The authors are grateful to Professor M. L. Wolfrom and Drs. G. L. Talbot and F. J. Simpson for the gift of samples, and to J. W. L. C. Christ and Sheila Lubin for technical assistance. Microanalyses were performed by M. Mazurek.

**The specific rotation of rutinose, when correlated with Hudson's observations on the configuration of disaccharides (14), suggests that the compound possesses the α-L-linkage (15). Similarly, the specific rotations of the D-mannopyranosyl disaccharides considered above, are much more in accord with assignment of the α-D-linkage, rather than the β-D-linkage, to these bioses.*

†*Alternatively, retention of configuration has been ascribed (20) to formation initially of a cyclic orthoester ion (17, 19) which undergoes further solvolysis, so that two successive Walden inversions occur. However, this mechanism does not account for the solvent effects noted above.*

CATALYTIC ACTIVATION OF MOLECULAR HYDROGEN IN SOLUTION BY CHLORORHODATE(III) COMPLEXES

J. F. HARROD AND J. HALPERN

We have found that rhodium (III) chloride, in aqueous solutions containing hydrochloric acid, activates molecular hydrogen homogeneously. Its behavior is qualitatively very similar to that observed earlier (1) for palladium (II) chloride and the same procedure (i.e. determination of the rate of catalytic reduction of ferric chloride by measuring the volume of hydrogen taken up at constant pressure) was employed to study the kinetics. The results are summarized in Table I.

The kinetics of the catalyzed reduction of ferric chloride were found to be of the form

$$-d\,[H_2]/dt = k\,[H_2]\,[Rh(III)].$$

Typical hydrogen uptake rate plots are shown in Fig. 1. Simultaneous spectrophotometric measurements confirmed that the hydrogen taken up is consumed in the reduction of

Fe(III) to Fe(II) and that the concentration of Rh(III) remains constant. The reaction under these conditions is clearly homogeneous (providing the HCl concentration exceeded 3 *M*, the reduction of Rh(III) to metallic Rh, a powerful heterogeneous catalyst, did not commence until the reduction of Fe(III) to Fe(II) was nearly complete), and since the concentrations of Rh(III) and of H_2 remain constant, the kinetics are of pseudo-zero order. Values of k are listed in Table I and are seen to be substantially independent of the concentrations of Fe(III), H_2, and Rh(III). The slight dependence on the HCl concentration and the effects of added electrolytes follow much the same pattern as found for Pd(II) and are attributable to variations in the solubility of hydrogen (1). Measurements of k over the temperature range 61.5° to 85.0° (Table I) yielded a good Arrhenius plot fitted by,

$$k = 2.3 \times 10^{15} \exp[-25{,}200/RT] \text{ l. mole}^{-1} \text{ sec}^{-1}$$

corresponding to an entropy of activation of +9 e.u.

[a]Based on solubility of hydrogen in 3 *M* HCl estimated as described earlier (1).

The insensitiveness of the rate to the HCl concentration in the region where $RhCl_6^{---}$ is the predominant species (2, 3) suggests that the major catalytic contribution is due to this species, although it is not possible to rule out some contributions also from lower chloro complexes (particularly $RhCl_5(H_2O)^{--}$ which is probably present in appreciable concentrations). It seems likely that the mechanism is of the same type as proposed earlier (1, 4) for kinetically analogous reactions of hydrogen involving other metal ions and complexes (including $PdCl_4^{--}$) as catalysts. This involves heterolytic splitting of hydrogen by the catalyst in the rate-determining step with formation of a catalyst–hydride complex (in this case $HRhCl_5^{---}$) which is reoxidized in subsequent rapid reactions with the substrate.

The abnormally high frequency factor of the present reaction is in contrast to the "normal" values ($\sim10^{11}$ l. mole^{-1} sec^{-1}) found for $PdCl_4^{--}$ (1) and for most of the other catalytic species previously examined (5), and its significance is not clear. It may reflect the higher charge of the present catalytic species and imply some spreading out of the charge (resulting in a decrease in the electrostriction of the surrounding solvent) in the activated complex, such as would result from separation of one of the Cl^- ligands. This

is consistent with earlier suggestions concerning the configuration of the activated complex in reactions of this type (4).

PROFILES AND AREAS OF INTERFACES IN THE DU NOÜY RING METHOD[1]

F. VAN ZEGGEREN, C. DE COURVAL, AND E. D. GODDARD

ABSTRACT

Profiles and areas of interfaces subjected to interfacial tension measurements by the du Noüy ring method, were calculated with the aid of a digital computer. The computations were based on a solution of a set of two simultaneous, first order, ordinary differential equations. Area corrections amounted to from 5 to 17% of the total area calculated on the assumption of planar contact. These corrections permit more precise evaluation of the molecular area of monolayers spread at such interfaces. Two interfaces, viz. benzene–water and hexane–water, were taken as examples. Profiles of curves around the rings were also determined experimentally by means of an electrical contact micromanipulator method. Theoretically computed and measured profiles show very good agreement.

INTRODUCTION

Of the procedures available for investigating insoluble monolayers at the oil/water interface, that developed by Alexander and Teorell (1) is the most satisfactory. This utilizes the ring method for determination of the interfacial tension. For calculation of the area per molecule of the monolayer, it is necessary to allow for the fact that the interface is not completely planar; corrections must be made for the increase in interfacial area around the ring and also for that at the walls of the containing vessel. By using a vessel of large cross-sectional area, the correction for contours around the ring can be made relatively small, but even with a vessel of area 300 cm², Crisp (2) has estimated that the over-all correction to the planar area can be greater than 10%.

The shape of a surface between two fluids is given by the Laplace equation:

$$[1] \qquad (1/R_1)+(1/R_2) = P/\gamma$$

where R_1 and R_2 are the radii of curvature in vertical and horizontal directions, respectively, P is the hydrostatic pressure difference, and γ is the interfacial tension.

Thomas (3) has given a solution to this equation for flat-walled vessels; here R_2 is infinite and the equation becomes quite simple. Bashforth and Adams (4) have used an approximate Taylor expansion of the equation, but their publication is very old and almost inaccessible on this continent. Also, it only applies to drops. Freud and Freud (5) in their theory of the ring method, have used a Taylor expansion of the Laplace equation to calculate the total volume of liquid raised by the ring. However, their publication does not give many details about the manner in which profile calculations were performed. As far as we can determine, no treatment has been presented for the calculation of the area of interface raised by the ring, and it is the purpose of this paper to present a treatment which will allow both this calculation and also that of the area increase due to curvature of the interface at the walls of the containing vessel.

THEORETICAL DERIVATION OF EQUATIONS

The Laplace equation [1] can be written in the form:

$$[2] \qquad \frac{d \sin \phi}{dx} + \frac{\sin \phi}{x} = \frac{P}{\gamma}$$

where x is the horizontal distance from the center of cylindrical symmetry to any point on the surface, and ϕ is the angle that the tangent to the surface makes with the horizontal plane. Now $P = \pm g(d_2 - d_1)y$, where g is the constant of gravity (980.6 cm/sec^2), d_2 and d_1 are the densities of the two liquids under study, and y is the vertical distance from the planar contact region to the point on the surface. With $\sin \phi = u$ the equation becomes:

$$[3] \qquad \frac{du}{dx} + \frac{u}{x} = \pm\frac{g(d_2 - d_1)y}{\gamma}$$

or

$$\frac{du}{dx} + \frac{u}{x} = \pm By$$

where B is a constant for a certain interface of two fluids.

It is readily shown that the expression for the interfacial area, A, is given by

$$[4] \qquad A = 2\pi \int \frac{x dx}{\sqrt{1-u^2}}.$$

The boundary values of the integral depend on whether the area inside the ring, outside the ring, or at the wall is desired.

In equation [3] x, y, and u are interrelated variables. Hence, this equation cannot be solved unless one of the variables can be expressed explicitly as a function of the other two. The obvious choice for such an expression is:

$$[5] \qquad \frac{dy}{dx} = \pm \tan \phi = \frac{\pm u}{\sqrt{1-u^2}}.$$

The importance of this equation has only been assessed before by Lohnstein (6) who used a Taylor expansion of the expression for the calculation of profiles and volumes of drops.

The set of equations [3] and [5] can be combined into one second order differential equation with two variables.

Differentiating equation [3] with respect to x gives:

$$[6] \qquad \frac{d^2u}{dx^2} + \frac{1}{x}\frac{du}{dx} - \frac{u}{x^2} = \pm B\frac{dy}{dx}.$$

Combining [5] and [6] and rearranging terms yields:

$$[7] \qquad x^2\frac{d^2u}{dx^2} + x\frac{du}{dx} + u\left(-1 - \frac{Bx^2}{\sqrt{1-u^2}}\right) = 0.$$

This equation has the general appearance of a Bessel equation but for the awkward term $\sqrt{1-u^2}$. No solution for an equation of this type could be found in the literature, nor could we arrive at an analytical solution.

However, a numerical solution to the problem can be obtained. Bashforth and Adams

have used Taylor's theorem to calculate approximate solutions for equation [3]. We have attempted to use a more exact method to find u (and y) at distinct values of x.

Equations [3] and [5] are a set of two simultaneous first order ordinary differential equations.

For the inside of the ring the equations are:

$$\left.\begin{aligned} \frac{du}{dx} + \frac{u}{x} &= +By \\ \frac{dy}{dx} &= \frac{+u}{\sqrt{1-u^2}} \end{aligned}\right\} \quad [8]$$

outside the ring they are:

$$\left.\begin{aligned} \frac{du}{dx} + \frac{u}{x} &= -By \\ \frac{dy}{dx} &= \frac{-u}{\sqrt{1-u^2}} . \end{aligned}\right\} \quad [9]$$

At the walls of a circular vessel the set of equations [8] holds; if the vessel is flat-sided $u/x = 0$.

In each case the equations can be written:

$$\left.\begin{aligned} \frac{dy}{dx} &= f(u) \\ \frac{du}{dx} &= g(x, y, u). \end{aligned}\right\} \quad [10]$$

These equations may be solved by the Runge–Kutta method (see, e.g., ref. 7), and this method has been used in the present work.

Boundary values x_0, y_0, and u_0 for the starting point of the calculations were the values of the variables x, y, and u at the ring or wall, depending on the interfacial region being considered. In the former case x_0 is the radius of the ring; y_0 is the height to which the ring is pulled up in the interfacial tension measurements; and u_0 is the sine of the angle ϕ at the ring surface. The value of u_0 is not known in advance, but it is determined by the boundary conditions.

For the inside of the ring the calculation proceeds as follows: A value of u_0 between 0 and 1 is chosen, and the region between $x = x_0$ and $x = 0$ is divided into 10 equal intervals. Corresponding to each of these x values, values of y and u are computed. After 10 of these steps at the point where $x = 0$, i.e. the ring center, the value of u should be zero. If u does not become zero, the value chosen for u_0 is incorrect, and another value must be estimated. Usually it is not necessary to go through all 10 steps before the correctness of u_0 can be evaluated. After two or three steps u either increases again (it should decrease) or it decreases too fast. Suitable interpolation between extreme values of u_0 chosen leads to an accurate value in about six or seven estimates (accurate to four decimal places). The u value at the ring center is then usually less than ± 0.005.

Then, 11 correct values of u at 10 intervals of x are obtained and the integral in equation [4] can be evaluated numerically using a simple Simpson's one-third rule.

For the area outside the ring the calculation proceeds very similarly with the aid of equations [9], but now both y and u have to go to zero as x increases. If one of these variables becomes zero while the other remains positive, the chosen u_0 value was wrong, and another value has to be estimated. Six or seven successively closer estimates normally lead to an initial u_0 value correct to four decimal places.

For the area at the walls of a circular vessel, equations [8] are used, and the above described procedure is followed.

CALCULATIONS

Hand calculations of the equations as outlined in the preceding section would undoubtedly be a very laborious and time-consuming undertaking. The time required for the calculation of one curve for the inside of the ring, for instance, would take about six hours. However, the Runge–Kutta procedure can be handled extremely well on a digital computer. All calculations described below were performed on a Burroughs E-101 digital computer. Although this machine is relatively slow, it computed a curve inside the ring in approximately twenty-five minutes, which indicates a time saving factor of about fifteen.

The computations were carried out for a number of different parameters.

(*a*) *Various Liquids*

Benzene–water (B = 3.308) and hexane–water (B = 6.462) were studied.

(*b*) *Various Ring Sizes*

The platinum rings supplied for the du Noüy tensiometer usually have a circumference of 4 or 6 cm, corresponding to radii of 0.6366 and 0.954 cm, respectively. Alexander and Teorell (1) published results of tension measurements with a ring radius 1.501 cm. Our calculations were carried out for these three ring sizes.

(*c*) *Various Ring Heights*

The heights ($y_0 = h_2$) to which the rings are raised from the heavier liquid (water)

in the tension measurements are dependent upon the monolayer present at the interface. For future reference, we have compiled data for various heights (five for each set of the other parameters) from which the value for a particular measured height can be obtained by interpolation, provided the change in interfacial tension due to the presence of the monolayer is not too great. See (*ii*) under Discussion.

(*d*) *Various Elevations at the Wall*

For the same reasons as mentioned under (*c*) we proceeded with calculations at the wall, using five different heights of elevation of the interface at the vessel wall.

Typical results of profile calculations are shown in Fig. 2 for a curve outside the ring. (Tables and curves for other sets of parameters can be obtained from the authors upon request.)

The results of the area calculations are given in Tables I and II.

EXPERIMENTAL

For a particular oil/water interface there are three heights which require experimental determination for present purposes. These are the height of the interface at the wall of the vessel, h_1; and at the position of maximum pull on the ring, the height of the ring, h_2, and the lowest point of the interface drawn up inside the ring, h_3 (see Fig. 1). Heights h_1 and h_2 can be determined optically, but because of the complex

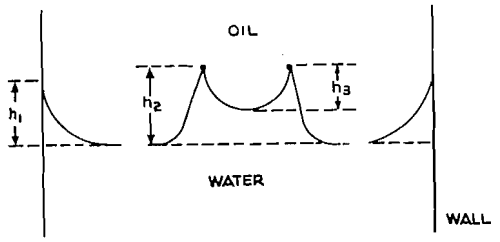

FIG. 1. Diagram showing the heights requiring experimental determination.

curvature around the ring, optical determination of h_3 appeared difficult if not impossible. After experimenting with photographic methods, the use of a cathetometer, and simple observation with a scale placed in contact with the outside wall of the vessel, it was concluded that determination of h_1 is best carried out by the simple scale method. This method can also be used fairly reliably for h_2, but in the present work the more convenient and accurate method developed for the determination of h_3 was used for

For personal use only.

h_2 as well. This makes use of an electrical probe and depends on the fact that the electrical conductivity of distilled water is much greater than that of a hydrocarbon liquid. The device was as follows: a platinum electrode (1 cm × 1 cm) was placed in the water in the bottom of the vessel and connected through a 20-v dry cell to one terminal of

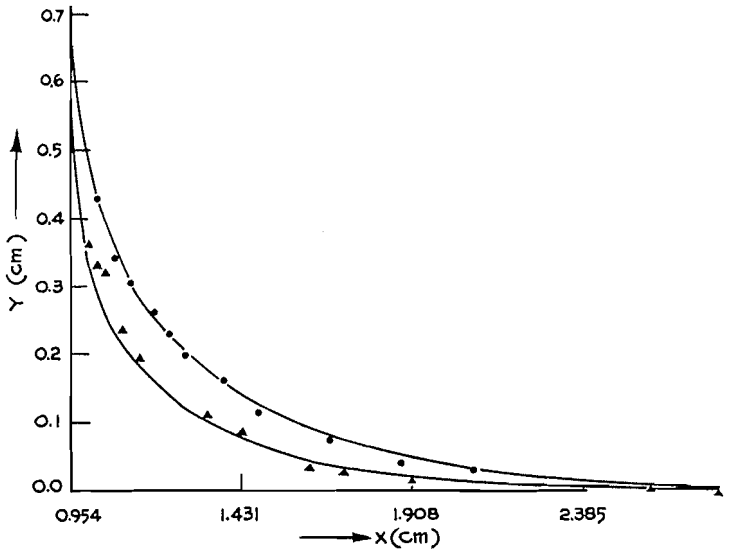

FIG. 2. Calculated and experimentally determined profiles of the interface outside the ring. The solid lines were computed. The dots are experimental points for a benzene/water interface, the triangles for a hexane/water interface.

an electrometer-type vacuum tube voltmeter (Keithley, VTVM, input impedance ca. 10^{14} Ω). A second electrode, the probe, in the form of a fine platinum wire, was connected to the other terminal of the voltmeter. The probe was attached to a micromanipulator which permitted movement in three perpendicular directions, each movement being equipped with a scale and vernier. The system was found to be very sensitive; when the probe was in the oil, no movement of the electrometer needle was detectable, but at the instant contact was made with the water interface, the instrument registered a reading of 20 v. This method was suitable not only for determining heights h_2 and h_3 but could be used for mapping the profile of the interface; this was done for the region just outside the ring, see Fig. 2.

TABLE III

	Heights (cm)		
Liquids	h_1	h_2	h_3
Benzene–water	0.68±0.04	0.72±0.02	0.40±0.02
Hexane–water	0.54±0.04	0.55±0.02	0.41±0.01

The water used in the determinations was distilled and then passed through a mixed bed ion exchange column; the organic solvents, benzene and *n*-hexane, were Fisher reagent and were distilled just before use; measured interfacial tensions against water agreed with published values. The dimensions of the Cenco platinum–iridium ring were: circumference of ring 5.998 cm, circumference of wire .1118 cm. The glass vessel used had a diameter of 14.60 cm.

The results of the determinations are given in Table III.

DISCUSSION

From Fig. 2 it can be seen that the theoretically computed and experimentally determined curves more or less coincide, so that it may be assumed that the calculated results represent the Laplace equation quite well and that any deviations will be due to experimental inaccuracies rather than to computational errors.

Computing errors that may have arisen are due to the following.

(*a*) *The Interval Size Taken*

For the region inside the ring the interval was chosen as one-tenth of the radius of the ring. In one case ($x_0 = 0.954$, $y_0 = 0.45$ cm, $B = 6.462$) the region was split up in 20 intervals, and it was found that the curve obtained was almost identical to the one obtained from the 10-interval calculation, and that the area increase was 0.4317 cm², as compared to 0.4367 cm² for the double interval size. For the region outside the ring, using the parameters, $x_0 = 0.954$, $y_0 = 0.5$, $B = 3.308$, an area increase of 1.199 cm² was calculated for the small interval computation, whereas for twice as large intervals it was 1.156 cm². Thus, the finer division only affected the corrections by 1 to 4%, i.e. about 0.04% of the total area of the interface in a vessel of radius 7.30 cm, which is quite negligible.

(*b*) *The Accuracy of the Iterated u_0 Value*

In some cases the u_0 value chosen leads to a y value of zero before u reaches zero, or vice versa, particularly at the wall of the vessel. This means that the initial u_0 value was in error by about 0.0001. The effect of such an error has been studied for one case at the wall ($x_0 = 7.30$ cm, $y_0 = 0.5$ cm, $B = 3.308$), and it was found that for $u_0 = 0.7872$ the area increase was 5.157 cm², whereas for $u_0 = 0.7874$ the area increase was 5.175 cm². For one case outside the ring ($x_0 = 0.954$, $y_0 = 0.45$, $B = 6.462$) the following results were found: for $u_0 = 0.9810$, $\Delta A = 1.3792$ cm²; for $u_0 = 0.9808$, $\Delta A = 1.3698$ cm². In both cases a difference of 0.0001 in u_0 amounted to a difference of about 0.004% of the total area.

(*c*) *The Value of B*

For a benzene–water interface the value of B was taken to be 3.308 and for a hexane–water interface 6.462 at a temperature of 18° C. These values were calculated from

$$B = \frac{g(d_2 - d_1)}{\gamma}$$

where $g = 980.6$ cm/sec², d_2 = density of water, d_1 = density of benzene or hexane, and γ is the interfacial tension; d_2 and d_1 and γ are dependent upon the temperature. For a 1° increase in temperature B(benzene) increases by about 0.6%, and B(hexane) by about 0.2%. The effect of small changes in B on the area increments has been investigated, and it was found that area increases augmented by 0.6–1.0% for benzene–water interfaces and by 0.2–0.6% for hexane–water interfaces, which indicates that the corrections expressed as a percentage of the total area amount to about 0.005–0.01% per degree for both interfaces. This may be quite a considerable correction for an operator working far outside the ordinary temperature range, but it is felt that for most purposes the correction is negligible.

Thus all possible corrections amount to a negligible change in the ΔA values given in the tables.

The corrections for oil–water interfaces can be obtained from the tables by means

of suitable interpolation for the heights h_1 and h_2 determined; e.g. for the heights observed by us with a 0.954-cm radius ring, and 167.5-cm² area dish:

Benzene–water	$h_1 = 0.68$ cm	$\rightarrow \Delta A = 11.24$	total correction 14.74 cm², i.e. 8.82%
	$h_2 = 0.72$, $h_3 = 0.40$	$\rightarrow \Delta A = 3.50$	
Hexane–water	$h_1 = 0.54$	$\rightarrow \Delta A = 11.61$	total correction 14.65 cm², i.e. 8.75%.
	$h_2 = 0.55$, $h_3 = 0.41$	$\rightarrow \Delta A = 3.04$	

These percentage increases come close to the 10% estimated by Crisp (2) for vessels of area 300 cm². It is likely that above 100 cm² the percentage increase will decrease only very slightly with increasing vessel size.

It is interesting to compare the computed values for $h_2 - h_3$ with the experimental ones. For benzene–water the values are 0.342 and 0.320, respectively, for hexane–water 0.144 and 0.140, respectively. In view of the experimental inaccuracies (see Table III) this is very satisfactory agreement.

A few points of general interest may be reported here.

(*i*) The size of the vessel can influence the elevation of the ring. For the particular vessel used by us, radius 7.30 cm, the interface at the wall curves downward to reach the planar part asymptotically. At a distance of 2.04 cm the elevation has become negligibly small. At a distance of 2.86 cm from the ring outward the elevation of the interface is negligibly small as well. As $2.04+2.86 < 7.30-0.954$, the two curves will not overlap. However, when the radius of the vessel becomes smaller than 5.85 cm, the curves will overlap, and the ring height will be affected. Thus it is advisable to use vessels of radius larger than 5.85 cm, with a ring of radius 0.954 cm.

(*ii*) If, as a result of the presence of an interfacial monolayer, the lowering of the interfacial tension becomes too great, it will no longer be permissible to use the data tabulated in this paper, as these were obtained using the capillary constant characteristic

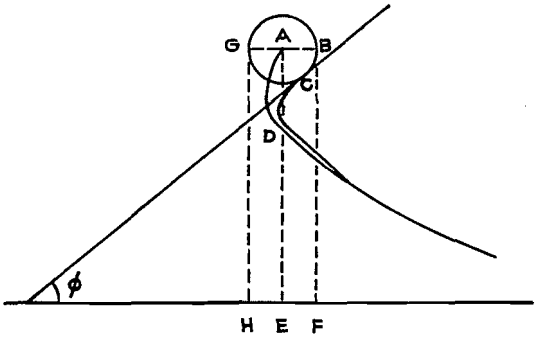

FIG. 3. Diagram illustrating the curving effect at the ring surface, for finite wire diameter (observed in experiments) and for zero wire diameter (indicated by Freud and Freud).

of the uncontaminated interface between the two liquids. For interfacial pressures up to about 5 dynes/cm, the tabulated area values would probably be acceptable for most purposes; however, in cases where the lowering of the interfacial tension is considerable, further computation using a program similar to that described in this paper, would be necessary. The measured value of the interfacial tension would be required for calculation of the constant B, see equation [3].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

(*iii*) The peculiar effect found by Freud and Freud (5) that the interface at the ring can curve inwards beyond AE (see Fig. 3), cannot be explained from considerations of the Laplace equation alone. For such behavior the equation $dy = -udx/\sqrt{1-u^2}$ should yield a finite negative value for dy (AD) when dx becomes infinitely small. This can only be the case when u becomes 1 as dx goes to zero. But $u = \sin\phi$ and hence ϕ should become 90°. This in turn indicates that the tangent should be vertical, and this means that the curve cannot extend beyond AE. Also in no instance was an angle of 90° computed, i.e. u_0 was always smaller than 1.

The fact that there can be a region where the interface around the ring curves inwards beyond AE, i.e. where $\phi > 90°$, can only be explained on the basis of the finite wire diameter of the ring, a constant which has not been considered in the present treatment. Thus, if the curve starts at the point C, where the interface leaves the wire, and the contact angle is small or zero, it is apparent that the interface can curve inwards. Such curvature has in fact been observed in the present studies, but it was noted that the interface did not curve in beyond the vertical line GH.

(*iv*) The equations could have been solved with the center of symmetry as a starting point, but then the boundary value of u/x becomes doubtful. It may be assumed that the value is given by l'Hopital's rule:

$$\frac{u}{x} = \frac{B(h_2-h_3)}{2}$$

but since h_2-h_3 is even less accurate than h_2 alone, and since small errors in h_2-h_3 lead to wide spreads in the curves obtained, this method of approach was abandoned in favor of the one reported here.

ACKNOWLEDGMENT

MECHANISM OF FORMATION OF ANTHOCYANIDINS FROM FLAVAN-3,4-DIOLS[1]

A. V. ROBERTSON[2]

ABSTRACT

Conversion by hydrochloric acid in 2-propanol of 5,7:3′,4′-tetramethoxyflavan-3,4-diol (I; R = OMe) into cyanidin chloride 5,7:3′,4′-tetramethyl ether is examined. The diol is wholly changed into the anthocyanidin. The over-all reaction mechanism must therefore be oxidative, since the alternative of disproportionation is excluded. Fading of this anthocyanidin in solution is studied. Attempts to synthesize flavan-3-one derivatives are briefly described.

Interest in the mechanism of conversion of flavan-3,4-diols (e.g. I; R = OH) into anthocyanidins (e.g. II; R = OH) arises from the possible biogenetic relation between natural leucoanthocyanins and anthocyanins and the need for satisfactory analytical procedures for leucoanthocyanins in plant materials. The usual qualitative test for leucoanthocyanins depends on the production of anthocyanidins by treatment with hot hydrochloric acid, and as late as 1953 the leuco-compounds had to be defined as colorless substances giving this reaction (1). Since then several leucoanthocyanins have been structurally identified as flavan-3,4-diol derivatives (2). An important feature of the chemistry of the leucoanthocyanins is that the anthocyanidins produced from them have lost the 4-hydroxyl and retained the 3-hydroxyl group, and Bauer, Birch, and Hillis suggested that the mechanism is an initial acid-catalyzed dehydration to a flavan-3-one (e.g. III) (3). The mechanism for the required direction of dehydration has been discussed by Birch for the corresponding tetrahydronaphthalenes (4). Flavan-3-ones, like flavan-3,4-diols, are in the same oxidation state as dihydroanthocyanidins so that the flavylium salt must be produced by oxidation. Over-all mechanistic possibilities are direct oxidation and disproportionation (3, 5). Production of anthocyanidins from leucoanthocyanins seems independent of the presence of oxygen in some cases, but not in others (6, 7). The reduced substance from disproportionation of a flavan-3-one would be at the catechin (e.g. IV; R = OH) level of oxidation. The detection of catechins among the products from the action of acid on cacao leucocyanidin (8) is no longer support for the disproportionation hypothesis (3, 5, 9), since Forsyth and Roberts (10) have shown that this leucoanthocyanin contains an epicatechin unit bound as a semiacetal

to what is probably a flavan-2-ol-3-one. Roux and Bill (11) have recently obtained evidence for the initial dehydration step by demonstrating that increased yields of anthocyanidins result when treatment of several flavan-3,4-diols with acid is conducted under anhydrous conditions. The low yield of anthocyanidins from leuco-compounds is generally considered to be due to a competing reaction leading to condensed tannins. This is explicable if flavan-3-ones are intermediates for, by analogy with the naphthalene analogues (β-tetralones), they would be very unstable, polymerization occurring by aldol-type condensations of the ketone group with the phloroglucinol nucleus (3). Direct polymerization of flavan-3,4-diols can also be expected to occur by routes similar to the acid-catalyzed self-condensations of catechins, suggested mechanisms for which have been reviewed by Freudenberg and Weinges (12). Much higher yields of anthocyanidins have recently been obtained by Laumas and Seshadri (13), who first converted the flavan-3,4-diols into flav-3-en-3-ol acetates (e.g. V). In such flavan-3-one derivatives competing self-condensations are inhibited because of the lowered reactivity of the acetylated phenolic rings. Other products may also be produced by acid treatment of leucoanthocyanins, and some of these have been identified as flavonols and more highly condensed leucoanthocyanins (14, 15). The reaction is thus most complex, since different kinds and ratios of flavonoid substances can be formed depending on the precise experimental conditions and the particular leucoanthocyanin being studied.

This paper reports a study of the action of acid on the tetramethoxyflavan-3,4-diol (I; R = OMe) and of attempts to synthesize certain flavan-3-ones. Birch has briefly described some of these experiments (16).

The diol (I; R = OMe) was prepared by reduction of taxifolin tetramethyl ether (VI) with either lithium aluminum hydride or sodium borohydride. The crystalline product was considered to be a mixture of stereoisomers because of the melting range (175–190°; compare Swain (14)) of analytically pure material, and because spots of the compound on paper chromatograms were always somewhat streaked (chromatographic examination by Mr. W. E. Hillis). Ganguly and Seshadri have recently separated two isomers of m.p. 172° and 198° from this reduction (17). The proportions and ease of separation of the isomers may depend on the optical purity of the starting material as well as the exact experimental conditions. The present taxifolin tetramethyl ether had $[\alpha]_D$ −14° (2.5% in chloroform) and the recrystallized diol was optically inactive (polarimetric examination by Dr. J. W. Clark-Lewis).

The action of hydrochloric acid in 2-propanol on the diol gave cyanidin tetramethyl ether (II; R = OMe), which could be separated from the other product of the reaction, a neutral polymer, by normal partition methods. The flavylium salt was obtained as the crystalline dihydrate and its identity was proved by analysis and comparison of the ultraviolet and visible spectrum, color reactions, and paper chromatographic behavior with these properties for a synthetic specimen. The neutral by-product was reddish-purple and produced more flavylium salt on further acid treatment. The salt was separated and the neutral fraction was again heated with acid. After the third acid treatment no more anthocyanidin was formed, and the combined yield of cyanidin tetramethyl ether amounted to about 40% (percentage yields have been calculated throughout for this reaction by assuming a diol:anthocyanidin stoichiometry of 1:1). Neutral material remaining at this stage was quite intractable and attempts to prepare crystalline derivatives were unsuccessful.

The anthocyanidin is unstable under the conditions of its formation: the yield (12%) after 5 hours' refluxing with the reagent with free exposure to air was slightly lower

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

than that (15%) after 1 hour under the same conditions and, more significantly, the neutral fraction no longer produced a red color with acid. Production of the anthocyanidin is dependent on the presence of oxygen for only a trace (3%) was isolated after 1 hour in an atmosphere of nitrogen.

Failure to obtain more than 50% of the diol as anthocyanidin is therefore a result of decomposition of the product and not evidence for disproportionation. In any case, disproportionation would lead to one or more of the stereoisomeric catechin tetramethyl ethers (IV; R = OMe), but no evidence for their presence in the reaction products was obtained. (+)-Catechin tetramethyl ether is also unstable under the reaction conditions, but the rate of decomposition is sufficiently slow to allow isolation of the compound if it were present.

It is possible that considerably greater yields of anthocyanidin could be obtained by frequent interruption of the reaction, but such preparative experiments are tedious and lead to inaccuracies due to losses during extraction and isolation of products. Spectrophotometric examination appeared to offer a more convenient and accurate method of measuring the yield of anthocyanidin. In practice, complications arose through fading of the anthocyanidin but the results confirm the conclusion from the preparative experiments.

When the flavan-3,4-diol (I; R = OMe) was refluxed in the acid solvent in diffuse daylight, the anthocyanidin concentration at first rapidly increased but fell off as the rate of decomposition became greater than the rate of formation. The maximum intensity occurred at 30 minutes and corresponded to a 25% yield of anthocyanidin. The spectrum of the solution was recorded when the optical density at the visible absorption peak had become constant (Fig. 1, curve D). Under the same conditions pure tetramethylcyanidin gave a nearly identical spectrum (curve C). A trace of color remained in each solution after prolonged boiling. After similar treatment (+)-catechin tetramethyl ether had the spectrum shown in curve E. The spectrum of pure tetramethylcatechin closely resembles that of pure diol (I; R = OMe) (curve B). The high intensity absorption of curves C

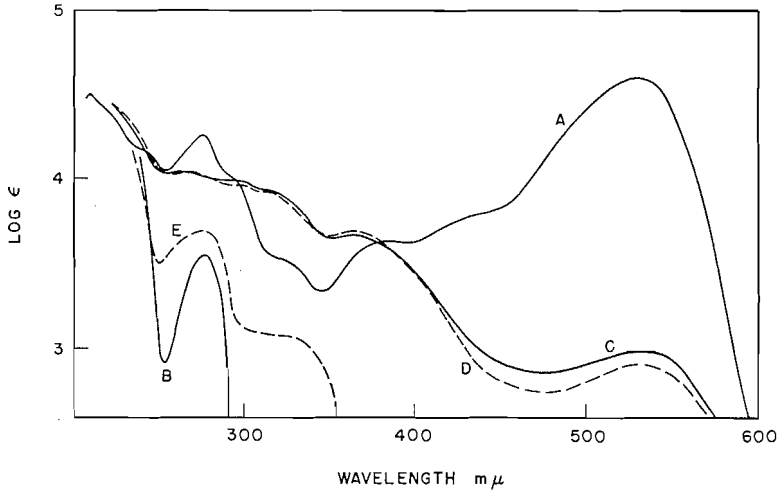

FIG. 1. (A) Tetramethylcyanidin chloride (II; R = OMe) in acidified 2-propanol. (B) Tetramethoxyflavan-3,4-diol (I; R = OMe) in ethanol. (C) (II; R = OMe) after 15 hours' refluxing in acidified 2-propanol. (D) (I; R = OMe) after 15 hours' refluxing in acidified 2-propanol. (E) Tetramethylcatechin (IV; R = OMe) after 15 hours' refluxing in acidified 2-propanol.

and D is unresolved and due to mixtures. Disproportionation of the diol into tetramethylcyanidin and tetramethylcatechin would lead to a mixture of decomposition products whose spectrum would be the sum derived from curves C and E at halved concentrations. The only reasonable conclusion from the fact that curves C and D are essentially superposable is that they represent the same mixture of decomposition products. In other words the diol must be wholly converted into anthocyanidin which then decomposes into unknown products. The possibility of any disproportionation of this flavan-3,4-diol under these conditions is clearly excluded. The conclusion from the earlier preparative scale experiments is supported: the final neutral material was largely a decomposition product of anthocyanidin already formed, and no weight should be attached to the failure to isolate more than 50% of anthocyanidin, since this value merely represents the quantity isolable when the reaction mixtures were worked up at the arbitrary times used.

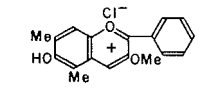
The degree to which these conclusions may be extrapolated to the reactions of phenolic flavan-3,4-diol is difficult to assess. The tetramethyl ether used in the present work is deactivated towards competing side reactions such as self-condensations involving active methylene groups. Nevertheless, the yield of flavylium salt as determined spectrophotometrically may not measure the total conversion of leucoanthocyanins into anthocyanidins, and the need for blank fading experiments with the latter compounds is obvious.

It is generally known that solutions of anthocyanidins are unstable, and fade particularly under the influence of light. The phenomenon has not been studied extensively although Spaeth and Rosenblatt (18), Nordström (19), and Hillis (15) have investigated the matter in order to establish satisfactory analytical methods for anthocyanidins and leucoanthocyanins. Nordström found that solutions of cyanidin chloride (II; R = OH) in 0.1–2.0 *N* hydrochloric acid were stable in the dark at room temperature or 100°, but on 6 hours' exposure to diffuse light the intensity of color decreased by 10%, and by 95% in sunlight. Slightly less fading occurred under nitrogen. Hillis reports somewhat faster fading for 3,7,8:3′,4′-pentahydroxyflavylium chloride in acidified 2-propanol. The presence of other materials can greatly influence the rate of fading. For example, after reduction of quercetin penta-acetate in tetrahydrofuran with lithium aluminum hydride (3), a 50% yield of cyanidin chloride (compare King and White (20)) can be obtained by partition between hydrochloric acid, amyl alcohol, and light petroleum if the acidified reaction mixture is worked up immediately; when the aqueous acid fraction is left for 3 hours in diffuse light, the cyanidin chloride decomposes and leaves a light orange solution.

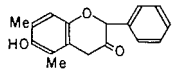
Cyanidin tetramethyl ether (II; R = OMe) in acidified 2-propanol was stable in the dark at room temperature. Nevertheless, at reflux temperature (80°) in darkness the color faded only slightly more slowly than at 80° in duffuse daylight. Fading was only slightly faster under oxygen and only slightly slower under nitrogen. In sunlight the anthocyanidin solution was decolorized very rapidly and the process was considerably slower under nitrogen. The rate of fading in sunlight at room temperature was faster than the rate at 80°. Cyanidin chloride and 3,7,8:3′,4′-pentahydroxyflavylium chloride behaved similarly in the above tests, but qualitative comparisons showed that the free phenols fade at a noticeably slower rate than tetramethylcyanidin chloride.

It was hoped to obtain further information about the conversion by acid of flavan-3,4-diols into anthocyanidins by examination of the properties of synthetic flavan-3-

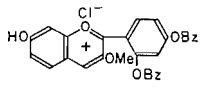
ones. Such information has added interest in view of the recent work by Laumas and Sheshadri on flavan-3-one enol acetates (e.g. V) (13). There are few other reports of syntheses in this field. Karrer and Fatzer claimed to have prepared the flavan-3-one (VIII) by catalytic reduction of the anthocyanidin (VII) (21). Fonsenka hydrogenated



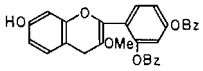
(VII)



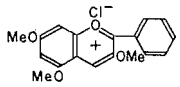
(VIII)



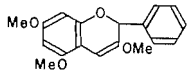
(IX)



(X)



(XI)



(XII)

the flavylium salt (IX) over platinum and obtained a crystalline compound to which he assigned the structure of the enol ether (X) on the basis of scanty evidence (22). Karrer and Seyhan reduced three 3-methoxyflavylium salts (e.g. XI) with lithium aluminum hydride and obtained crystalline dihydro products which were allotted structures of the corresponding flavan-3-one enol ethers (e.g. XII) (23). Elementary analysis and analogy with the reduction of quinolinium and isoquinolinium salts (24) were the only pieces of evidence used to support these formulations.

We have been unable to prepare crystalline flavan-3-ones or corresponding enol ethers. Reduction of flavylium salts (XI), (II; R = OH) and (II; R = OMe) with complex metal hydrides, hydrogen in the presence of catalysts, or combinations of these methods, gave oils or gums from which the flavylium salts were sometimes regenerated by the action of acids. Oxidative methods were also unsuccessful. The tetramethyl ethers (IV; R = OMe) of (+)-catechin and (−)-epicatechin resisted oxidation by the methods of Oppenauer and Sarett. Details of these unfruitful experiments are given below.

EXPERIMENTAL

Absorption spectra were measured with a Hilger Uvispek spectrophotometer. The term "acid reagent" is used to describe the solvent mixture 2-propanol:10 *N* hydrochloric acid (9:1).

5,7:3′,4′-Tetramethoxyflavan-3,4-diol (I; R = OMe)

Taxifolin tetramethyl ether (3.0 g) in tetrahydrofuran (100 ml) was added dropwise to a stirred slurry of lithium aluminum hydride (0.5 g) in tetrahydrofuran (50 ml) at 0°. Excess of reagent was decomposed with water after 1 hour and the mixture was poured into dilute hydrochloric acid at 0°. The mixture was immediately extracted with chloroform and after removal of solvent the slightly pink product (2.8 g) was recrystallized three times from ethanol to give the diol (I; R = OMe) as white feathery needles having m.p. 175–190° after drying *in vacuo* at 100°. (Found: C, 62.7; H, 6.3; OMe, 34.5%; *M* (Rast), 390. Calc. for $C_{19}H_{22}O_7$: C, 63.0; H, 6.1; 4OMe, 34.3%; *M*, 362.) The diol is moderately soluble in alcohol, but is very difficult to dissolve. For recrystallization it was convenient to add ethanol (50 ml) to a solution of the compound (1 g) in hot acetone (10 ml) and reduce the volume to 30 ml by boiling.

5,7:3′,4′-Tetramethylcyanidin Chloride (II; R = OMe)

Karrer and his co-workers (25) claimed to have prepared this compound by methylation of cyanidin, but Hayashi (26) obtained a compound having different properties by condensation of the appropriate phloroglucinaldehyde and acetophenone derivatives. Hayashi's work has been substantiated in this laboratory and, as his paper was available only in abstract, the synthesis is reported in full.

Phloroglucinaldehyde 2,4-dimethyl ether was prepared from phloroglucinol dimethyl ether (27), by the method of Gruber (28). ω-Acetoxyacetoveratrone (29) was prepared from acetoveratrone (30) via ω-bromoacetoveratrone (31). A solution of phloroglucinaldehyde 2,4-dimethyl ether (2.7 g) and ω-acetoxyacetoveratrone (3.6 g) in ethyl acetate (50 ml) and ethanol (10 ml) was saturated at 0° with hydrogen chloride and left in the refrigerator. Three days later the precipitate (2.5 g) was collected, recrystallization from ethanol:10 *N* hydrochloric acid (1:1) giving cyanidin tetramethyl ether dihydrate, after drying to constant weight *in vacuo* at room temperature, as red-brown microcrystals having a golden luster. (Found: C, 55.0, 55.0; H, 5.5, 5.6; Cl, 8.5; OMe, 25.1, 24.8; MeCO, 0. Calc. for $C_{19}H_{19}O_6Cl.2H_2O$: C, 55.0; H, 5.6; Cl, 8.6; 4OMe, 29.9%.) Light absorption in ethanol:10 *N* hydrochloric acid (9:1): λ_{max} 209 (log ε 4.50), 276 (4.25), 381 (3.63), and 532 mμ (4.59). Dilution with ether of the mother liquors from the reaction mixture gave further crude flavylium salt (2 g). Attempts to prepare the anhydrous anthocyanidin by drying the dihydrate *in vacuo* at elevated temperatures were unsuccessful owing to general decomposition. The pure dihydrate sintered at 140°, softened at 170°, but was not completely molten until 200° (decomp.), on a Kofler block. The structure of the compound was confirmed by reduction to tetramethylepicatechin.

(±)-*Epicatechin 5,7:3′,4′-Tetramethyl Ether*

Tetramethylcyanidin chloride dihydrate (0.41 g) in ethanol (30 ml) was hydrogenated at room temperature and pressure over platinum black (0.3 g). When reduction was complete (1 hour), the catalyst was removed and the filtrate was evaporated at reduced pressure. The residue, dissolved in ether, was washed with aqueous sodium hydroxide and water. Removal of the ether left a light yellow gum (0.35 g) which was chromatographed in benzene on alumina. Elution with benzene:ether (4:1) gave (±)-epicatechin 5,7:3′,4′-tetramethyl ether (0.118 g, 34%) which after recrystallization from aqueous methanol had m.p. 136–139°. (Found: C, 65.7; H, 6.4. Calc. for $C_{19}H_{22}O_6$: C, 65.9; H, 6.4%.) The infrared absorption spectra in Nujol of the (±)-compound and authentic (−)-epicatechin tetramethyl ether showed an exact correspondence.

Stability of 5,7:3′,4′-(+)-Catechin Tetramethyl Ether to Acid Reagent

Tetramethylcatechin (50 mg) was refluxed for 1 hour in acid reagent (25 ml). The colorless solution was evaporated to dryness under reduced pressure and the partly crystalline residue was chromatographed in benzene on alumina. Elution with benzene–ether (4:1) gave starting material (27.5 mg, 55% recovery).

Reactions of Flavan-3,4-diol (I; R = OMe) *with Acid Reagent*

A typical experiment is described. The flavandiol (200 mg) was dissolved in boiling 2-propanol (90 ml) in a flask shaded from direct light, and concentrated hydrochloric acid (10 ml) was added. An immediate red coloration was observed which became more intense as the solution was refluxed (1 hour). Most of the solvent was removed *in vacuo* and, after addition of amyl alcohol (10 ml) and light petroleum (100 ml; b.p. 60–80°), the flavylium salt was extracted into 2 *N* hydrochloric acid (4×25 ml). The antho-

cyanidin (35 mg, 15%) was purified by further partitioning in the usual way between amyl alcohol, light petroleum, and dilute hydrochloric acid, and was finally obtained as the dihydrate of tetramethylcyanidin (II, R = OMe) by crystallization and drying as for the synthetic sample above. (Found: C, 55.4; H, 5.6; Cl, 9.0.) The light absorption, color reactions, and paper chromatographic behavior were identical with those for the synthetic specimen; R_F 0.69 in 2 *N* hydrochloric acid:acetic acid (7:3) (lit., (14) 0.62), and 0.93 in water:acetic acid:10 *N* hydrochloric acid (10:30:3) (lit., (19) 0.82). The material that remained in the first light petroleum layer was a reddish-purple amorphous solid (160 mg) which yielded further flavylium salt on repetition of the above treatment. The neutral fraction (125 mg) which was separated still furnished tetramethylcyanidin, but after a third treatment as above the neutral fraction (93 mg) gave no red color on heating with the acid reagent. It was a brown gum which resisted crystallization and could not be purified by chromatography on alumina, or by acetylation. The total yield of crude flavylium salt was 88 mg. Other reactions with slight experimental modifications gave much the same results. In one experiment, the neutral fraction after the first hour's heating was chromatographed, but no crystalline compounds were obtained. When the initial heating was continued for 5 hours, 12% of anthocyanidin was isolated, but the dark neutral fraction no longer gave a red color on heating with the acid reagent. When a moderate stream of oxygen was passed through the reaction mixture the yield of anthocyanidin in 1 hour was 18%. Under purified nitrogen, the yield in 1 hour was 3% in either a sealed flask, or with a stream of gas through the solution; the solvents in each case were freed from oxygen by refluxing for 1 hour with passage of purified nitrogen before the diol was added.

Spectrophotometric and Fading Experiments

Beer's law was valid within ±2% for cyanidin tetramethyl ether over the range of optical densities 0.1–2.0 at the visible absorption peak. The reactions with tetramethyl cyanidin, the diol (I; R = OMe), and tetramethylcatechin were performed by refluxing 1- to 2-mg samples, accurately weighed, in 40 ml of acid reagent. The volumes were finally made up to 50 ml to eliminate solvent evaporation errors. Log ϵ values of decomposition products were calculated using molar concentrations of starting materials. The rate of fading of refluxing tetramethylcyanidin solution in diffuse daylight was: 40% in 1 hour; 60% in 2 hours; 70% in 3 hours; 90% in 6 hours; and 98% in 12 hours. The last trace of color remained even after the solution was heated a further 12 hours. In sunlight, the anthocyanidin solution in a pyrex tube was completely decolorized in 20 minutes at room temperature and 45 minutes at reflux temperature. When oxygen was passed through the cold solution in sunlight fading was complete in 6 minutes, but under nitrogen 80 minutes were required.

Reduction of Anthocyanidins

Karrer and Seyhan prepared the enol ether (XII) by treating a suspension of 3,5,7-trimethoxyflavylium chloride (XI) (27) in ether with lithium aluminum hydride (23). In our hands no reaction occurred under these conditions, presumably because of the complete insolubility of the anthocyanidin which was recovered by acid extraction and the usual partition methods after decomposing the excess of reagent. The anthocyanidin was soluble in tetrahydrofuran, but numerous reduction experiments with lithium aluminum hydride gave yellow or red oils which resisted crystallization and which darkened rapidly on exposure to air. Treatment of these oils with aqueous or alcoholic hydrochloric acid, or acetic acid gave the original flavylium salt having R_F 0.80 in 2 *N* hydrochloric acid:acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

acid (7:3). Color developed after a few minutes in the cold and very rapidly on heating. These properties were not changed under nitrogen. 3,5,7-Trimethoxyflavylium ferrichloride was formed when the oils were treated with anhydrous ferric chloride in glacial acetic acid. The compound had m.p. 176–178° (lit., (27) 174°) after recrystallization from acetic acid. (Found: C, 43.8; H, 3.2. Calc. for $C_{18}H_{17}O_4Cl_4Fe$: C, 43.7; H, 3.4%.) The melting point was not depressed by admixture with an authentic specimen. Similar oils were obtained when the anthocyanidin in tetrahydrofuran was reduced with sodium borohydride in water. When the flavylium salt in ethanol was treated with sodium borohydride in water, 3,5,7-trimethoxyflavylium pseudo base ethyl ether was obtained as white prisms of m.p. 90–91° after recrystallization from aqueous alcohol. (Found: C, 69.4; H, 6.4. $C_{20}H_{22}O_5$ requires C, 70.2; H, 6.5%.) This compound regenerated the anthocyanidin (XI) immediately with cold acid.

At room temperature and pressure, solutions in ethanol of flavylium salts (XI), (II; R = OH) and (II; R = OMe), were decolorized by 1 mole of hydrogen over Adam's catalyst or platinum black, but only unstable red gums were isolated. An attempt to provide evidence for the fugitive existence of the flavan-3-ones from cyanidin and tetramethylcyanidin was made by adding sodium borohydride to solutions in ethanol which had absorbed 1 mole of hydrogen over platinum and then been neutralized. Only dark amorphous material was isolated even after acetylation or methylation, and no indication of the presence of catechin derivatives was obtained.

Attempted Oxidation of Catechins

(+)-Catechin 5,7:3′,4′-tetramethyl ether (1 g) was unchanged after being refluxed (40 hours) with aluminum isopropoxide (2 g) and cyclohexanone (5 ml) in toluene (50 ml). The tetramethyl ether (1 g) in pyridine (10 ml) was treated with chromic oxide (1 g) in pyridine (10 ml) according to the method of Sarett and his co-workers (32). The substance isolated (0.7 g) was starting material. (−)-Epicatechin 5,7:3′,4′-tetramethyl ether behaved similarly toward these reagents; no ketonic fraction was obtained when the material isolated was treated in each case with Girard P reagent.

ACKNOWLEDGMENTS

I am indebted to Professor A. J. Birch and Dr. E. Ritchie for advice; to Monsanto Chemicals (Australia) Ltd. for the award of a scholarship; and to Dr. E. F. Kurth, Dr. W. G. C. Forsyth, and Mr. W. E. Hillis for samples of natural taxifolin, epicatechin, and catechin respectively. Microanalyses were performed by Miss B. Stevenson and the C.S.I.R.O. Microanalytical Service.

THE SYNTHESIS OF 5-*O*-METHYL-L-ARABINOSE[1]

G. G. S. DUTTON, Y. TANAKA, AND K. YATES

ABSTRACT

5-*O*-Methyl-L-arabinose is thought to occur in the hydrolysis products of methylated wheat bran hemicellulose. This sugar has now been synthesized from ethyl 2,3-di-*O*-acetyl-5-*O*-trityl-α-L-arabinoside by detritylation, methylation, and hydrolysis. The free sugar was obtained as a sirup and was characterized by periodate oxidation together with the preparation of a crystalline osazone and a crystalline lactone.

In 1955 Adams (1) reported the probable occurrence of 5-*O*-methyl-L-arabinose, together with another monomethylarabinose, in the hydrolysis products of methylated wheat bran hemicellulose. It was not possible to separate these compounds and no constants for 5-*O*-methyl-L-arabinose were available so that positive identification was not possible.

We have now synthesized this compound from L-arabinose diethylmercaptal in 16% over-all yield by the following series of reactions:

L-arabinose diethyl mercaptal (I) → ethyl α-L-arabofuranoside (II) → ethyl 2,3-di-*O*-acetyl-5-*O*-trityl-α-L-arabinoside (III) → ethyl 2,3-di-*O*-acetyl-α-L-arabinoside (IV) → ethyl 2,3-di-*O*-acetyl-5-*O*-methyl-α-L-arabinoside (V) → 5-*O*-methyl-L-arabinose (VI).

Tritylation and acetylation of (II), which was readily obtained from (I) by the action of ethanol, mercuric chloride, and mercuric oxide, afforded (III) in high yield as a sirup. Although detritylation of (III) with hydrogen bromide in acetic acid was not satisfactory and gave positively rotating sirups the use of 80% acetic acid gave (IV) in high yield. Two treatments with Purdie's reagents gave a sirup which showed no hydroxyl band in the infrared. Successive hydrolyses with alkali and acid gave a sirup which showed a strong *p*-anisidine positive spot with R_f 0.30 (butanone–water azeotrope) and several weak spots which were not further examined. By chromatography on a column of cellulose–hydrocellulose (2) the component of R_f 0.30 was obtained pure.

A sample of this compound was oxidized with sodium metaperiodate and rapidly consumed 3 moles of periodate yielding 3 moles of formic acid. These results can be expected only from the 5-*O*-methyl derivative. Confirmation of this structure was obtained from the infrared spectrum of the lactone obtained by bromine oxidation. It has been reported that γ-lactones of aldonic acids show their C=O band in the range of 5.59–5.68 μ while for δ-lactones this is in the range of 5.68–5.79 μ (3). The C=O band of our mono-*O*-methyl-L-arabonolactone was at 5.62 μ, in agreement with the assigned structure of 5-*O*-methyl-L-arabinose. This was further supported by the fact that the lactone showed no change in rotation in aqueous solution after 20 hours.

It may be noted that the 5-*O*-methyl ether has a much higher R_f value than the corresponding 2-*O*-methyl derivative and that this is consistent with sugars which can only exist in the furanose form. Although sugar acetates may undergo acetyl migration even in the presence of such a weak base as silver oxide (4, 5) there was no indication of such migration in the preparation described here. It is obvious that this preparation might be shortened

by starting from an equilibrium mixture of arabofuranosides but we preferred to use a pure anomeric form in the hope that any intermediates would be crystalline. This hope was not realized. The ethyl furanoside was preferred to the methyl because of the hygroscopic nature of the latter (6, 7).

The related 2- and 3-*O*-methyl-L-arabinoses have been known for some time and only the 4-isomer remains to be synthesized.

EXPERIMENTAL

Ethyl α,L-Arabofuranoside (6)

L-Arabinose diethylmercaptal (4.90 g) was shaken for 4 hours at room temperature in absolute ethanol (50 ml) with mercuric chloride (11 g), yellow mercuric oxide (4.7 g), and drierite (1.5 g). The inorganic salts were removed by filtration and the filtrate was concentrated *in vacuo* to sirup. The sirup was dissolved in chloroform (60 ml) to remove inorganic salts and evaporation of the solution gave a light yellow sirup (3.05 g, 90%) which crystallized slowly on standing after seeding. R_f values of the sirup were 0.042 (very weak), 0.386 (very weak), and 0.543 (strong) (butanone–water azeotrope). M.p. 66–69° C, $[\alpha]_D^{25}$ −114.1° (*c*, 0.918 in water). Lit. (6) m.p. 68–69° C, $[\alpha]_D^{20}$ −116.0° (*c*, 7.055 in water).

Ethyl 2,3-Di-O-acetyl-5-O-trityl-α,L-arabinoside (8)

Ethyl α,L-arabofuranoside (3.05 g, 0.0172 mole) was dissolved in dry pyridine (20 ml) and the solution was kept at room temperature for 24 hours after addition of trityl chloride (5.25 g, 0.0188 mole). During this period pyridine hydrochloride precipitated out of the solution. Acetic anhydride (20 ml) was added and the solution was kept at room temperature for a further 24 hours. The acetylated solution was poured into ice water and extracted with chloroform (20 ml × 5). The chloroform solution was washed with aqueous sodium bicarbonate solution, washed with water, dried over anhydrous sodium sulphate, and evaporated *in vacuo* to give a yellow sirup (8.30 g, 96%), $[\alpha]_D^{25}$ −82.9° (*c*, 0.362 in chloroform).

Ethyl 2,3-Di-O-acetyl-α,L-arabinoside (8)

To ethyl 2,3-di-*O*-acetyl-5-*O*-trityl-α,L-arabinoside (8.30 g) were added water (62 ml) and glacial acetic acid (250 ml) and the mixture was heated for 1 hour in boiling water. The solution was concentrated *in vacuo* to give a mixture of tritanol and yellow sirup. The mixture was dissolved in chloroform (10 ml) and adsorbed on an alumina column (3.5×20 cm) which was washed with benzene. Tritanol was eluted first with benzene (800 ml) and the detritylated compound was eluted with chloroform (1500 ml). Evaporation of the eluate gave a yellow sirup (3.59 g, 83%) $[\alpha]_D^{25}$ −58.8° (*c*, 0.218 in chloroform). Lit. (8) $[\alpha]_D^{20}$ −30° (*c*, 1.7 in chloroform). Infrared spectrum of the sirup showed complete lack of aromatic character.

Ethyl 2,3-Di-O-acetyl-5-O-methyl-α,L-arabinoside

Ethyl 2,3-di-*O*-acetyl-α,L-arabinoside (3.59 g) and drierite (5 g) were stirred under reflux in methyl iodide (50 ml) for 6 hours. Silver oxide (10 g) was added in 10 portions at about 30-minute intervals. Excess methyl iodide was removed by distillation and the residue was extracted five times with 50 ml each of chloroform. Evaporation of the solvent gave a yellow sirup (2.99 g).

The procedure was repeated again under the same conditions and the yellow sirup (2.48 g, 65.5%), $[\alpha]_D^{25}$ −49.0° (*c*, 0.306 in chloroform), showed no free hydroxyl band on the infrared spectrum.

Hydrolysis of Ethyl 2,3-Di-O-acetyl-5-O-methyl-α,L-arabinoside

Ethyl 2,3-di-*O*-acetyl-5-*O*-methyl-α,L-arabinoside (2.48 g) was heated in a mixture of 2 *N* sodium hydroxide (20 ml), water (20 ml), and methanol (40 ml) for 1 hour in boiling water, and then neutralized with IR-120 resin (Rohm and Haas). The neutral solution was concentrated *in vacuo* to a volume of 65 ml and 1 *N* hydrochloric acid (65 ml) was added. The mixture was heated in boiling water and the hydrolysis was followed polarimetrically. The initial rotation (−1.440° in 1-dm tube) changed after 4 hours to a constant value (−0.155° in 0.5-dm tube). The acidic solution was neutralized with Duolite A-4 resin (Chemical Process Co.) and then concentrated *in vacuo* to a sirup (1.10 g, 74%). Paper chromatography (butanone–water azeotrope) of the sirup showed a strong spot of R_f 0.30 and weak spots of R_f's 0.64, 0.53, 0.22, and 0.12.

Separation of 5-O-Methyl-L-arabinose by Chromatography

The hydrolysis product (1.1 g) was dissolved in methanol (2 ml) and was chromatographed on a cellulose–hydrocellulose column (3×40 cm) using butanone–water azeotrope as developing solvent (rate of flow, 10 ml/30 minutes). Each fraction (10 ml) was checked by paper chromatography. In tubes No. 13–23 a compound with R_f 0.30 was found with others having R_f 0.64 and R_f 0.53, but in tubes No. 24–40 only the compound with R_f 0.30 was observed. On evaporation of the fractions No. 24–40 a colorless sirup (387 mg) was obtained. Rechromatography of fractions No. 13–23 under the same conditions gave a further quantity of sirup (120 mg). Both were chromatographically pure (R_f 0.30) and the total yield of the sirup was 507 mg (46%). Anal. calc. for $C_6H_{12}O_5$: OMe, 18.9%. Found: OMe, 18.8, 19.0%. $[\alpha]_D^{25}$ −32.0° (*c*, 0.484 in water). The R_f value in butan-1-ol–ethanol–water–ammonia (40:11:19:1) was 0.48.

Periodate Oxidation of 5-O-Methyl-L-arabinose

All reactions were carried out in the dark and at 5° C.

(*i*) *Determination of periodate consumed.*—5-*O*-Methyl-L-arabinose (7.5 mg) was dissolved in water (10 ml), and 0.23 *M* sodium metaperiodate solution (1 ml) was added to the solution. A blank was run concurrently. Aliquot portions (1 ml) were withdrawn at intervals and the consumption of periodate was determined by means of the arsenite method (8). The results are shown in Table I.

(*ii*) *Estimation of formic acid produced.*—After reacting overnight, an aliquot was titrated with 0.01 *N* sodium hydroxide solution using methyl red as an indicator. The results are shown in Table I.

TABLE I

Periodate oxidation of the mono-*O*-methyl-L-arabinose

	Periodate consumption					Formic acid production
Time, hour	0	1	2	3	Overnight	Overnight
Moles	1.97	2.68	2.70	2.86	2.86	3.09

5-O-Methyl-L-arabinose Phenylosazone

5-*O*-Methyl-L-arabinose (111 mg) was dissolved in 20% acetic acid (5 ml), and sodium bisulphite (110 mg) and phenylhydrazine (1 ml) were added. The solution was kept for 1 hour at 80° C and then at room temperature overnight. The precipitated yellow crystals (50 mg) were filtered and recrystallized from aqueous acetone, m.p. 154.5°, $[\alpha]_D^{25}$ −16.6°

(*c*, 0.4 in methanol). Dilution of the filtrate with water gave a further 70 mg of the crystals which showed m.p. 154.5° after recrystallization from aqueous acetone. Total yield of the phenylosazone was 120 mg (52%). Anal. calc. for $C_{18}H_{22}O_3N_4$: C, 63.1; H, 6.5; N, 16.4; OMe, 9.1%. Found: C, 62.9; H, 6.4; N, 16.3, 16.6; OMe, 9.0, 9.2%. (C, H, and N by Drs. Weiler and Strauss, Oxford).

*5-O-Methyl-*L*-arabonolactone*

5-*O*-Methyl-L-arabinose (120 mg) was dissolved in water (2 ml) and kept at room temperature in the dark, after addition of bromine (10 drops). The oxidation was complete after 30 hours (paper chromatography) and water (10 ml) was added. Excess bromine was removed by aeration, and the solution was treated with silver carbonate and centrifuged. After hydrogen sulphide was passed through the solution and after centrifugation, the solution was concentrated *in vacuo* to dryness to give a solid (77 mg) which by recrystallization from acetone–petroleum ether gave colorless needles, m.p. 135° C, $[\alpha]_D^{25}$ −76.2° (*c*, 0.22 in water) (no change after 20 hours); $[\alpha]_D^{25}$ −43.7° (*c*, 0.27 in acetone); γ Nujol max. 5.62 μ. Anal. calc. for $C_6H_{10}O_5$: OMe, 19.2%. Found: OMe, 19.1, 19.3%.

TRANSFERENCE NUMBERS AND CONDUCTANCES IN CONCENTRATED SOLUTIONS: SILVER NITRATE AND SILVER PERCHLORATE AT 25.00° C[1]

A. N. Campbell and K. P. Singh[2]

ABSTRACT

The transference numbers, equivalent conductances, densities, and viscosities of aqueous solutions of silver nitrate and of silver perchlorate have been determined from a concentration of 0.1 *M* up to 7.6 *M*, for silver nitrate, and up to 5.6 *M* for silver perchlorate. In both cases the cation transference number increases considerably with increasing concentration. Certain anomalies in the results for silver perchlorate raise the possibility of complex ion formation here. Similar anomalies appear in the behavior of equivalent conductance with respect to concentration.

The results of the conductance measurements have been compared with the values calculated from the equations of Wishaw and Stokes and of Falkenhagen and Leist.

Little experimental work has been done on transference numbers in concentrated solution. Elementary textbooks make such statements as, "They [transference numbers] vary somewhat with concentration, but the variation is in general not large. As a rule, the transference numbers that are large in dilute solution increase with rise in concentration, while those which are small decrease." (1). This statement seems to rest principally on the results of Longsworth, which extend only to a concentration of 0.2 *M* (2); a few results from other sources extend to 1.0 *M*. Apart from the present work, the only references to work in really concentrated solutions are those of Stokes and Levien (3), who determined the transference numbers of the ions of zinc perchlorate, by the E.M.F. method, between the concentration limits 0.1 *M* to 4 *M*; of Lee and Millen (4), who determined the data for nitric acid, between the concentrations 0.1 *M* to 1.8 *M*, by a form of the Hittorf method; and Fritz and Fuget (5), who measured the transference numbers of copper sulphate, by the moving boundary method, between 0.1 and 0.5 *M*.

EXPERIMENTAL

Two years of work with the moving boundary method, using both sheared and autogenic boundaries, and both rising and falling boundaries, convinced us that this method is not suitable for measurements in concentrated solution. The E.M.F. method rests on a not completely satisfactory theoretical basis and, in any case, for accurate results calls for a very high degree of precision in E.M.F. measurements. We were therefore forced to make use of the Hittorf method.

It is sometimes claimed that the Hittorf method cannot be used in concentrated solution because the relative change of concentration becomes inappreciable with respect to the high concentration of electrolyte. This statement, however, is the result of careless thinking. It would be true if the same cell were used both for dilute and concentrated solutions. In dilute solutions, it is true that anode and cathode compartments must be relatively large, and widely separated, in order to preserve the necessary constancy of concentration in the middle compartment. If, however, one considers the well-known equation used in determining transference numbers by the moving boundary method, viz.

$$t_+ = (V \times C \times F)/1000\,Q$$

[1]*Manuscript received July 24, 1959.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.
[2]*N.R.C. Postdoctorate Fellow, 1957–59.*

and solves this for V, the volume swept out by the moving boundary, i.e.

$$V = t_+ 1000\, Q/CF,$$

one sees that for a fixed Q the volume through which the boundary moves is inversely proportional to the concentration of the electrolyte. It is therefore only necessary to reduce the volumes of anode and cathode chambers as the concentration increases, in order to preserve constant the relative change in concentration. We therefore built Hittorf cells with smaller and smaller chambers. A limit is of course set to this by the necessity of having a chamber sufficiently large to hold the electrode. About 8 ml was the smallest volume of electrode chamber used by us.

Other modifications of the usual method were as follows: Since the coulometer has been virtually abandoned as an instrument for measuring quantity of electricity in the moving boundary method, we saw no reason for retaining what is in practice a rather clumsy instrument. When working with the moving boundary method we were accommodated, thanks to the kindness of Dr. G. Ballard and his associates of the National Research Council, with a constant current source which yielded constant current (maximum variation equal to $\pm 0.02\%$) within the limits 1.5 ma to 15 ma, the potential at the same time altering between 1 and 500 v. Time was measured by means of a railway watch, whose maximum variation was 15 seconds in a week. In short, our determination of the quantity $Q = Ct$ is practically without error. In some of our experiments, the experiment continued as long as 20 hours. In all cases, the central compartment was analyzed and absence of change there demonstrated.

As a means of analysis we used the specific conductance. The contents of the anode and cathode chambers were run into separate containers and weighed and the specific conductance determined. As a preliminary, curves of specific conductance versus concentration were determined, for silver nitrate and for silver perchlorate. Since it was now only necessary to determine, in addition to the above data, the density of the solutions, in order to obtain the equivalent conductance, this was done. It should be added that anode and cathode chambers were washed out and titrated with potassium thiocyanate to determine the silver salt adhering to the walls of the chamber.

While the measurements with silver nitrate were pushed with ease up to a concentration of 7.640 molar, great discrepancies at first appeared in our results for silver perchlorate. These discrepancies were traced to the presence in the silver perchlorate (supplied as pure) of free acid, presumably perchloric acid. It was found quite easy to free the silver perchlorate from adhering acid by recrystallization from benzene. Examination of the purified product with a series of indicators showed it to be neutral. (The pH meter gives wavering and uncertain results with silver perchlorate.) The results with the purified product were consistent and reproducible but we found a certain lack of agreement between the results from anode and cathode chambers, in the more concentrated solutions, an effect we did not observe with silver nitrate.

While the silver nitrate solutions were made up by direct weighing, it was not possible to do this with silver perchlorate because of its extremely hygroscopic nature. Accordingly, a very concentrated stock solution was made up and analyzed gravimetrically in quadruplicate, by precipitation of silver as silver chloride, a method known for its accuracy. From this stock solution other solutions were prepared by weight dilution.

EXPERIMENTAL RESULTS

The results of the transference number experiments are contained in Table I.

DISCUSSION

When transference numbers are plotted against concentration the transference number of silver ion in silver nitrate is seen to increase continuously from about 0.46 at zero concentration to about 0.56 at 7.5 molar, while the transference number of silver ion in silver perchlorate starts with a value of about 0.47 at zero concentration, passes through a minimum value of 0.46 at about 0.5 molar and then increases continuously and rather rapidly to a value of 0.61 at 4.0 molar. The increase in the transference number of silver ion in silver nitrate with increasing concentration is in agreement with the result of Laity and Duke (6), who found that in molten silver nitrate the cation carries three-quarters of the current. The behavior of silver perchlorate points to some abnormality in the structure of silver perchlorate solutions, possibly complex anion formation. This hypothesis would also account for our inability to obtain agreement in the results from anode and cathode for this salt.

The graph of equivalent conductance versus concentration (Fig. 1) is perfectly normal for silver nitrate, i.e. the curve flattens out towards a constant value as saturation is

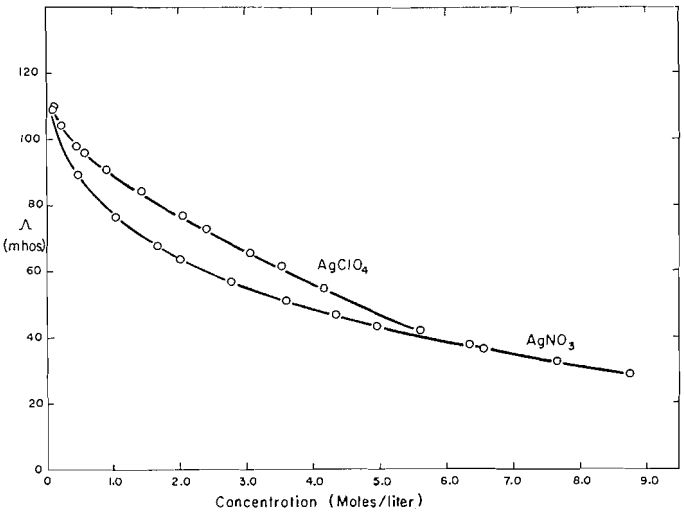

FIG. 1.

approached and the curve is convex towards the axis of concentration. The curve for silver perchlorate, on the other hand, is much less convex to the axis of concentration; indeed, the curve becomes actually concave if, instead of concentration, the square root of concentration is used as abscissa. This may be connected with our postulated complex ion formation.

As usual, in work proceeding from this laboratory the conductance results have been compared with the results calculated from the equations of Wishaw and Stokes and of Falkenhagen. The results are given in Table III. The agreement is good up to a concentration greater than 1 *M*. In order to obtain this correspondence, it has been necessary to assume an $\mathring{a}$ value of 4.5 (Stokes) and 3.7 (Falkenhagen) for silver perchlorate, as against 2.18 and 1.88 for silver nitrate, and this is in harmony with the belief that the radius of the perchlorate ion must be greater than that of the nitrate ion. The common device of introducing 1 solvent molecule between anion and cation in the ion-pair is obviously not applicable to silver nitrate, since $\mathring{a}$ is so small, but it might well be done

with silver perchlorate. The fact that agreement between observed and calculated results is poorer for silver perchlorate is again in agreement with the assumption of the existence of complex anion in the more concentrated solutions of silver perchlorate.

Despite the contention that the Debye–Hückel–Onsager concepts cannot apply to concentrated solutions, and that therefore the above conductance equations can only be considered empirical equations, the fact that the $\mathring{a}$ values which it is necessary to assume for these equations are always in at least qualitative agreement with the sums of the crystallographic radii (with a certain allowance for ionic hydration) inclines us to believe that there is more than a measure of truth in these equations. Perhaps the full story will refer to effects not yet accounted for but the final treatment may be of the same form. At least, this is possible.

It is common practice to express the product of equivalent conductance and viscosity as a function of concentration. It is not very obvious why this is done, since there is no reason why the product should be constant; it never is and usually passes through a minimum. This is the behavior observed here, for both electrolytes.

1′,2;3,6;3′,6′-TRIANHYDROSUCROSE[1,2]

R. U. Lemieux and J. P. Barrette

ABSTRACT

The "trianhydrosucrose" obtained on treatment of amorphous "sucrose tritosylate" with sodium methoxide was found to be 1′,2;3,6;3′,6′-trianhydrosucrose.

The preparation of two "trianhydrosucroses" was reported (1) in a previous publication. The compound which was obtained on the alkaline alcoholysis of 1′,4,6′-tri-*O*-tosyl sucrose was shown (1) to be 3,6-anhydro-α-D-galactosyl 1,4;3,6-dianhydro-β-D-fructoside. The purpose of this communication is to present evidence that 1′,2;3,6;3′,6′-trianhydrosucrose (II) is formed on the alkaline alcoholysis of 6,1′,6′-tri-*O*-tosyl sucrose (I). Compound I is a component of the so-called tri-*O*-tosyl sucrose which is obtained on reaction of sucrose with 3 moles of tosyl chloride in pyridine (2, 3, 4).

The trianhydride (II), m.p. 163–164.5°, $[\alpha]_D$ +117°, R_f value = 0.42–0.48 (butanol–water), was extremely sensitive to acid hydrolysis (about 200 times more rapid in 0.01 *N* hydrochloric acid at 25° than sucrose (5), measured polarimetrically). The initial rapid hydrolysis led to a reducing (Fehling's solution) compound (III) (R_f = 0.32–0.38 (butanol–water)), which resisted crystallization. The chromatographically pure compound (III) very rapidly consumed 2 moles of periodate without formation of either formic acid or formaldehyde. Since the trianhydride (II) resisted periodate oxidation at pH 7 or higher, it was evident that the acid hydrolysis liberated two isolated α-glycol groups. Furthermore, the lack of formation of formic acid or formaldehyde showed the absence of —CHOH—CH_2—OH, —CHOH—CHO, or —CO—CH_2OH groups. Since acid hydrolysis of II produced readily only one compound (III), it was apparent that the anhydrization had produced an ether linkage between the glucose and fructose residues. It seemed likely that this linkage would be between the 2- and 1′-positions of sucrose, since Helferich and Werner (6) have shown that reaction of both the α- and β-anomers of 2-chloroethyl-D-glucopyranoside with alkali proceed with participation of the 2-oxygen atom to form 1,2-*O*-ethylene derivatives of D-glucopyranose.

The compound III was reduced with sodium borohydride to a non-reducing substance (IV) (R_f = 0.20–0.24 (butanol–water)) which, like III, very rapidly consumed 2 moles of periodate. Again no formaldehyde nor formic acid was liberated in the oxidation.

The acetolysis and subsequent deacetylation of substance IV gave a crystalline dihexitol ether (V), m.p. 110–114° (dimorphic), $[\alpha]_D$ −12.6 (in water), which on periodate oxidation produced 2 moles of formaldehyde, 5 moles of formic acid, and an aldehydic residue (VI) (7) which was reduced with sodium borohydride to 2-(β-hydroxyethoxy)-1,3-propanediol (VII). The identity of VII was proved from its synthesis through periodate oxidation and subsequent sodium borohydride reduction of polygallitol (VIII) (1,5-anhydro-D-glucitol). These results established the existence of the 1′,2 aliphatic-type ether linkage between the anhydrohexopyranose and the anhydroketohexofuranose residues of II.

The infrared spectrum of II gave no indication of unsaturation and the absence of epoxide ring was indicated by the substance's resistance to prolonged treatment both with 25% alkali and hydrazine at 100°. The ditosylate of II, m.p. 164.5–166° (decomp.), was unaffected by either sodium iodide in acetone or hydrazine at 100°. It could then be concluded that neither of the two free hydroxyl groups in II were at the 6- or 6′-position (2).

The extremely rapid periodate consumption by compounds III and IV (90% uptake, 2 minutes in 0.025 *M* sodium metaperiodate at 0°) was clearly indicative of *cis*-α-glycols (8, 9) situated on five-membered rings. Consequently, these results require structures III and IV to possess free *cis*-glycol groups at the 4,5- and 4′,5′-positions. Compound III showed no absorption in the infrared characteristic of carbonyl groups. It seems probable that the carbonyls were masked through the formation of a hydrate as shown in the formula for III.

The results require that both the glucose and fructose residues of II possess 3,6-anhydro rings. In view of these rings, the fact that the configurations at the 5- and 5′-positions were in all likelihood not affected in the formation of II, and the fact that the 4- and 4′-hydroxyl groups are in *cis*-relationship to the 5- and 5′-oxygens, respectively, it can be concluded that configurations at the positions 3, 4, 5, 3′, 4′, and 5′ in II are the same as in sucrose. Although methyl 3,6-anhydro-α-D-glucopyranoside is known readily to undergo both α-to-β anomerization (10) and pyranoside-to-furanoside ring contraction (10) under acid conditions, there can be no doubt that such isomerizations would not

For personal use only.

occur under the alkaline conditions used to prepare the trianhydride II. Therefore, only the configuration at the 2-position of the glucose residue was reasonably in need of verification. Information on this point of structure was provided by the nuclear magnetic resonance spectrum for the di-*O*-acetyl derivative of II. Our experience with the nuclear magnetic resonance spectra of sugar derivatives (11) enables us to assign the doublet of total intensity 1 at 76.9 and 79.5 c.p.s. (60 Mc/s) (the lowest field signal in the spectrum) to the anomeric hydrogen of the glucose residue. The spacing for the doublet was found to be 2.9 ± 0.1 c.p.s. both at 40 Mc/s and 60 Mc/s. This requires that the spacing represents a true spin–spin coupling constant. The magnitude of the coupling is that characteristic for two neighboring hydrogens in gauche or skewed relationship (11). In view of the 3,6-anhydro ring, the glucose residue must reside in that conformation which possesses the anomeric hydrogen in axial orientation. It follows, therefore, that the 2-hydrogen is in equatorial orientation since if it were in axial orientation, the coupling with the anomeric hydrogen would have been two to three times stronger (11) than that observed. It follows that the sucrose trianhydride (II) possesses the configuration of sucrose and must have formed from 6,1′,6′-tri-*O*-tosyl sucrose (I). All attempts to obtain 4-*O*-methyl-D-hexose by acetolysis of the methyl ether of the trianhydride (II) met with failure because of the high resistance of the 1′,2 ether linkage to acetolyzing reagents.

It is of interest to note that titration of the solution obtained on the periodate oxidation of III suggested that 1 mole of acid was liberated in the periodate oxidation. However, *no* formic acid could be detected in the mixture. The details of the effort to characterize the formic acid are reported since they provide a convenient method for the estimation of formic acid and formaldehyde produced in periodate oxidations. Our results render obvious the need for the application of such a technique in experiments designed to elucidate points of structure in carbohydrates through a measure of the formic acid produced in a periodate oxidation.

EXPERIMENTAL

All melting points are uncorrected. The rotations were measured at room temperature, 20–25°, using the D-line of sodium. Infrared spectra were obtained with a Perkin–Elmer single beam double pass instrument. Optical densities for colorimetric determinations were obtained from a Coleman Junior spectrophotometer. Microanalysis for carbon and hydrogen were carried out by Geller Laboratories, West Englewood, N.J. The n.m.r. spectra were measured with Varian Associates' high resolution spectrometers and the chemical shifts are from the signal for chloroform as an internal standard.

Acid Hydrolysis of II

1′,2;3,6;3′,6′-Trianhydrosucrose (II) (1), 53 mg, m.p. 163–164.5°, $[\alpha]_D$ +117° (*c*, 0.92 in chloroform), was dissolved in 5 ml of 0.01 *N* hydrochloric acid at 25°. The change in rotation of this solution was observed at intervals and the rotation became constant after 8 hours. The final specific rotation, based on the concentration of II at the start of the hydrolysis was +87.0 (*c*, 1.063 in 0.04 *N* HCl). Sucrose in 0.05 *N* hydrochloric acid at 25° requires about 1600 hours (6) for 99.99% inversion.

The solution was deionized by percolating through a small column of Dowex 1X8 anion exchange resin (quaternary ammonium type) and evaporated *in vacuo* to a syrup (54.6 mg). Paper chromatography (butanol–water) of this syrupy product showed only one major component, $R_f = 0.36$, when examined with aniline phthalate spray reagent (12). A faint streak appeared from the origin to $R_f = 0.45$. The material was chromatographed on a 25-g Celite column in the manner described by Lemieux, Bishop, and

Pelletier (13). The main band was obtained in 39.1 mg yield, $[\alpha]_D$ +87 (c = 0.69 in water), R_f value 0.36 (butanol–water), and reduced Fehling's solution. The chromatographically pure compound (III) resisted crystallization. Periodate oxidation of III in 0.025 N sodium metaperiodate at 0° consumed 1.73, 1.85, 1.88, 1.90, and 1.92 moles of the oxidant per mole, after 2, 10, 60, 120, and 720 minutes. Titration of the reaction mixture, after destroying the excess periodate with ethylene glycol, suggested the formation of 1 mole of carboxylic acid per mole of III oxidized. However, no formic acid or formaldehyde could be detected using the following procedures.

A weighed sample of the compound, ca. 0.05 mmole, is dissolved in 2 ml of 0.2 M sodium metaperiodate and left to oxidize for the required time. When the oxidation has progressed to the desired extent, the oxidation mixture is quantitatively transferred into the "microvacuum distillation" apparatus described by Grant (14), and the solution is frozen in an acetone – dry ice mixture. The apparatus is then evacuated to less than 1 mm. The arm of the apparatus which contains the frozen reaction mixture is then removed from the freezing mixture and the other arm is kept in the freezing mixture until all the volatile components have sublimed to the cold portion of the apparatus. The distillate, after thawing, is quantitatively transferred to a 25-ml volumetric flask and aliquots are titrated with standard 0.01 N sodium hydroxide to estimate the total amount of acid present in the distillate. The acid can be conveniently characterized by converting a suitable aliquot to sodium salt, 1–2 mg, and dissolving the salt in 4 ml of 10% aqueous potassium bromide, freeze-drying, and pressing the residue into a window in the usual manner (15). The formaldehyde content is conveniently determined using the chromotropic acid reagent (16).

Compound IV

The trianhydride (II), 100 mg, was hydrolyzed in 0.001 N hydrochloric acid to constant rotation in order to obtain crude compound III. The solution was neutralized with 0.05 N sodium hydroxide and then treated with a twofold excess of sodium borohydride at 0° for 36 hours. The excess sodium borohydride was destroyed with acetic acid and the resulting solution was evaporated *in vacuo* to dryness. The dry residue was acetylated using 5 ml acetic anhydride, and 5 ml pyridine. The acetylated product, 92.4 mg, was isolated in the usual manner and deacetylated in dry methanol, 10 ml, saturated at 0° with ammonia. Paper chromatography of the crude product (IV), 60 mg, indicated a main component with R_f value = 0.26 (butanol–water). There was a faint streak from the origin to R_f = 0.28. This syrupy product was chromatographed on a 25-g column of Celite in the usual manner (13). The resulting product (IV) did not reduce Fehling's solution and failed to crystallize. Periodate oxidation of IV in 0.025 N sodium metaperiodate at 0° consumed 1.8, 1.85, 1.91, 1.95, and 1.96 moles of the oxidant per mole after 2, 15, 30, 60, 120, and 720 minutes. No formic acid nor formaldehyde was produced in this oxidation.

Periodate oxidation of erythritan (8), (1,4-anhydroerythritol) in 0.025 N sodium metaperiodate at 0° consumed 0.95, 0.97, 0.99, 0.99, 0.99, and 0.99 mole of the oxidant per mole after 2, 5, 10, 30, 60, and 120 minutes. However, oxidation of threitan (8) (1,4-anhydrothreitol) in 0.025 N sodium metaperiodate at 0° consumed 0.135, 0.153, 0.168, 0.210, 0.434, 0.930, and 0.99 mole of the oxidant after 2, 5, 15, 70 minutes and 2.5, 11, and 22 hours.

Dihexitol Ether V

The crude acetyl derivative of IV, 96 mg (prepared as described above from a 100 mg of the trianhydride (II)), was treated with acetic anhydride, 1 ml, and concentrated

sulphuric acid, 0.08 ml, at 0° for 3 days. The resulting acetolysis products were isolated in the usual manner and deacetylated by percolating through a column of Dowex 1X8 anion exchange resin to yield 63.8 mg of syrupy polyol. This was chromatographed on a 25-g Celite column (butanol–water) (13). The main band, $R_f = 0.24$, gave 39.7 mg of crystalline dihexitol ether (V), m.p. 105–109°. After two recrystallizations from ethanol the melting point was 110–114° (dimorphic), $[\alpha]_D^{25} - 12.6°$ (c, 0.48 in water). The periodate oxidation of V produced 5 moles of formic acid and 2 moles of formaldehyde per mole, based on the assumption that the compound corresponds to structure V and using the above described lyophilization procedure. The elementary analyses were unsatisfactory, probably because of solvent of crystallization. The following experiment together with the periodate oxidation can leave no doubt as to the structure of V.

2-(β-Hydroxyethoxy)-1,3-propanediol (VII)

The dihexitol ether (V), 20.2 mg, was dissolved in 2 ml of 0.11 *M* sodium metaperiodate and left to oxidize to a final rotation of 0°. Excess sodium borohydride, 250 mg, was added to reduce the oxidation products (VI) and the solution was left for 18 hours before acidification with acetic acid to destroy the excess sodium borohydride. The resulting solution was evaporated *in vacuo* to a dry cake, which was acetylated with acetic anhydride in pyridine in the usual manner to yield 12.1 mg of syrupy acetate. This syrupy acetate was distilled at a bath temperature of 125–135° and 0.3 mm pressure to yield 8.2 mg of yellowish syrup. The infrared spectrum of this syrupy acetate was almost identical with that of 2-(β-hydroxyethoxy)-1,3-propanediol triacetate prepared by an identical treatment of polygallitol (VIII) (1,5-anhydrosorbitol). The syrupy triacetate was then deacetylated in absolute methanol, 3 ml, saturated with ammonia. The resulting syrupy triol was chromatographed on Celite in the usual manner (13). The main product, 2-(β-hydroxyethoxy)-1,3-propanediol (VII), had the same $R_f = 0.48$ (butanol–water) and identical infrared spectrum as the authentic specimen prepared in similar manner from polygallitol. Reacetylation of VII, produced a substance with a spectrum identical with that of the authentic triacetate prepared from polygallitol.

Stability of Trianhydrosucrose (II) *and its Ditosylate Derivative toward Nucleophilic Reagents*

Substance II remained unchanged when heated at 100° in 25% potassium hydroxide for 24 hours as well as in 85% hydrazine at 100° for 36 hours. Similarly the ditosylate of II, m.p. 164.5–166°, when heated to 100° with sodium iodide in acetone or with hydrazine in sealed tubes for 24 hours, remained unchanged.

4,4′-Di-O-methyl-1′,2;3,6;3′,6′-trianhydrosucrose

The trianhydride (II), 200 mg, was methylated using the procedure described in a previous communication (1), to yield 147 mg of di-*O*-methyl trianhydrosucrose, m.p. 179–181°, $[\alpha]_D^{24} +140°$ (c, 1.9 in chloroform). Anal: Calc. for $C_{14}H_{20}O_8$: methoxyl, 19.62%. Found: methoxyl, 19.78, 20.05%.

VOLUCRISPORIN

ISOLATION, STRUCTURE, AND SYNTHESIS OF THE METHYL ETHER[1]

P. V. DIVEKAR,[2] G. READ,[3] L. C. VINING, AND R. H. HASKINS

ABSTRACT

A new pigment, volucrisporin, has been isolated from shaken cultures of the Hyphomycete *Volucrispora aurantiaca* Haskins, and characterized as 2,5-(*m*-hydroxyphenyl)-1,4-benzoquinone. The structure has been confirmed by synthesis of the dimethyl ether.

Volucrispora aurantiaca Haskins (1), a new genus and species of Hyphomycete, produces a red pigment which has been named "volucrisporin" (2). This represents approximately two per cent of the dry weight of mycelia from cultures grown in shaken flasks in a suitable liquid medium and could be readily obtained by hot extraction of the dried culture solids with acetone. Subsequent crystallization from pyridine afforded the pigment as red rhombic plates. Preliminary defatting with petroleum ether yielded a product which was shown to contain ergosterol in the non-saponifiable fraction.

Elemental analyses of the pigment together with analyses and molecular weight estimations on derivatives indicated a molecular formula $C_{18}H_{12}O_4$. Neither C-methyl nor O-methyl groups were present. A quinone group in the substance was considered likely since reduction with zinc and acetic acid gave a colorless unstable dihydro compound which could be readily reoxidized to the original pigment with chromic acid in acetic acid. Acetylation of volucrisporin gave a yellow diacetate and reductive acetylation of this derivative or of the original pigment yielded a colorless dihydrotetraacetate. With methyl iodide and silver oxide a yellow dimethyl ether was obtained. These results provided further evidence for the presence of a quinone group and indicated that both remaining oxygen atoms were present as hydroxyls.

Distillation of volucrisporin with zinc dust yielded *p*-terphenyl, thus establishing the carbon skeleton of the pigment. The ultraviolet absorption spectrum of the leucoacetate was similar to those of acetoxylated *p*-terphenyls (3, 4), and the position of the single absorption maximum at 258.5 mμ was consistent with a terphenyl quinone structure containing no further substituents in either the central quinone ring or in the ortho positions of the phenyl rings. From the lack of solubility of volucrisporin in sodium carbonate, failure to react with diazomethane, and negative tests for chelation with ferric chloride or lead acetate, it was evident that the quinone ring did not contain a vinylogous acid group.

Oxidation of volucrisporin with alkaline peroxide yielded *m*-hydroxybenzoic acid, which was shown by paper chromatography to be the only hydroxybenzoic acid formed. Structure (I, R = H) was therefore assigned to the pigment.

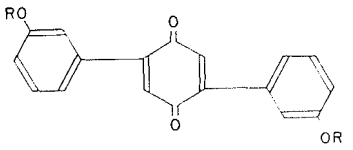
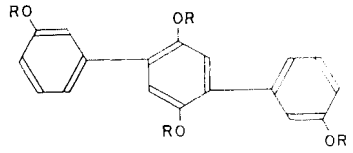
The infrared spectrum of the dimethyl ether in potassium bromide showed the carbonyl maximum at 1649 cm^{-1} (s) expected for a 2,5-disubstituted *p*-benzoquinone (5). In the pigment itself intermolecular hydrogen bonding was evident, since the carbonyl region showed a split peak at 1630 (s) and 1637 (s) cm^{-1} and the hydroxyl absorption occurred at 3280 cm^{-1} (s).

Unsuccessful attempts were made to synthesize the dimethyl ether of volucrisporin by a single-step arylation of *p*-benzoquinone with 2 moles of diazotized *m*-anisidine. Failure was attributed to the instability of the diazonium salt, particularly in the organic solvents which it was necessary to use to overcome the low solubility of the intermediate monosubstituted quinone. In aqueous solution (6) the diazonium salt of *m*-anisidine was sufficiently stable to give the 2-(*m*-methoxyphenyl)-1,4-benzoquinone in a yield of 37%, but attempts to introduce the second aryl ring into the quinone again met with difficulty. Paper chromatographic examination of the products from reactions carried out under a variety of conditions established that in aqueous acetone at low temperature, as recommended by Brassard and L'Écuyer (7), detectable amounts of a material with the desired R_f value were formed. Chromatography failed to separate this completely from other reaction products but a fraction was isolated which contained the compound contaminated only with a large amount of unreacted monoaryl derivative. The starting material was removed by sublimation leaving a product which, after purification, was indistinguishable from the dimethyl ether of volucrisporin (I, R = CH_3).



(I)



(II)

Volucrisporin is the first terphenyl quinone to be found in a hyphomycetous fungus, and differs from those isolated from Basidiomycetes and lichens (8) in the absence of hydroxyl groups on the quinone ring and in the unusual metasubstitution of the outer rings. It is accompanied in the mold by the leuco form (II, R = H) which was occasionally found to crystallize from the pyridine mother liquors after the separation of volucrisporin. The occurrence of atromentin in both oxidized and reduced forms has already been noted in *Paxillus atrotomentosus* (Batsch) Fr. (9), and the substituted quinols of aurantiacin (10) and leucomelone (11) occur with the corresponding quinones in *Hydnum aurantiacum* Batsch and *Polyporus leucomelas* Pers. ex Fr., respectively.

Derivatives of meta-hydroxybenzoic acid are rare in nature and, to the authors' knowledge, have been found only in the beaver castor (12), the urine of animals (13, 14), and recently in cultures of *Penicillium griseofulvum* Dierckx (15). Their appearance in urine was associated with the administration of 3,4-dihydroxyphenyl derivatives and was suggested to result from removal of the *p*-hydroxy group (16), a mechanism which may also be of significance in the biosynthesis of volucrisporin.

Solutions of volucrisporin in dilute aqueous sodium hydroxide are very unstable and when neutralized after only a few minutes yield a mixture of products. One of these has been isolated and appears to be 3-hydroxy-2,5-(*m*-hydroxyphenyl)-1,4-benzoquinone. This ease of hydroxylation emphasizes the need for caution when isolating quinones, particularly terphenylquinones, by treatment of the fungus or crude extracts with sodium hydroxide solution (9).

EXPERIMENTAL

Medium

The medium used for production runs consisted of distilled water 2000 ml, soil extract 200 ml, peptone 10 g, soluble starch 2 g, and glucose 100 g. The soil extract incorporated in the medium was prepared in the following manner. A beaker, two-thirds full of garden soil, was filled with tap water. The contents were stirred well and the mixture was autoclaved for an hour at 15 lb per square inch pressure. On cooling, the liquid was decanted, mixed with Celite, and filtered.

The medium was dispensed in 25-ml aliquots into 250-ml conical flasks which were then plugged and sterilized in the usual manner. While the medium is obviously not a precise one, its use resulted in yields exceeding those obtained from a number of others tested.

Inoculation

The initial inoculum was prepared by blending in sterile distilled water in Waring blendors several 3-week-old cultures of *Volucrispora aurantiaca* Haskins growing on Difco potato dextrose agar. Inoculum was added to the growth medium at the rate of 5% volume for volume, and the inoculated flasks were shaken for 6 days at 28° C on a rotary shaker operating at 220 r.p.m. describing a radius of motion of 1 inch. The organism also grew well in stirred aerated tank fermentors, but under the conditions tested, the growing mycelium collected in the foam at the surface of the liquid and yields of the pigment were considerably less than in shake flasks.

Subsequently the inoculum was prepared by blending 6-day-old shake flask cultures from production runs with an equal volume of sterile, distilled water. By always selecting flasks showing the greatest pigment production for use as inoculum, yields of pigment have been increased considerably.

Isolation of Volucrisporin

At the end of 6 days' incubation, the cultures were bulked and filtered. The orange-colored mycelium obtained by filtration was freeze-dried and pulverized in a Wiley mill.

In a typical isolation procedure, the pulverized mycelium (40 g obtained from 270 flasks), packed in a hot extractor, was defatted (16 hours) with petroleum ether (35–50° C), and then extracted (6 hours) with ether, which removed a small quantity of colored impurities. The bulk of the pigment was subsequently extracted from the mycelium with acetone (40 hours), the mycelium becoming practically colorless.

The acetone extracts (350 ml), on concentration *in vacuo* to about 50 ml and cooling, deposited an amorphous brick-red precipitate (2.1 g). This was crystallized twice from pyridine to give volucrisporin as rhombic plates (0.85 g) which did not melt below 300° C. Found: C, 74.3%; H, 4.1%; active H (Zerewitinoff), 0.57%; no N, methoxyl, or C-methyl. Calculated for $C_{18}H_{12}O_4$: C, 74.0%; H, 4.1%; two active H, 0.68%. Ultraviolet maxima in dioxane at 281.5 and 329 mμ, inflexions at 234 and 377 mμ; log ε 4.00, 3.90, 4.47, and 3.45, respectively. Infrared maxima (KBr disk) at 3280 (s), 1637 (s), 1630 (shoulder, s), 1590 (s), 882 (s), 790 (s), 727 (m), and 683 (s) cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

Volucrisporin is sparingly soluble or insoluble in most common organic solvents with the exception of pyridine or dioxane. It is insoluble in cold sodium carbonate solution but dissolves readily in dilute sodium hydroxide giving a purple color.

Isolation of Ergosterol

The petroleum ether extract of the mycelium was evaporated to dryness. A portion of the dried extract (1 g) was boiled for 3 hours with 100 ml of 10% methanolic potash, the reaction mixture concentrated, diluted with water, and extracted with two 50-ml portions of ether. The crystals obtained by evaporation of the ethereal extract were washed with petroleum ether and crystallized from ethanol to give colorless plates (20 mg), m.p. 160–162° C, undepressed on admixture with an authentic sample of ergosterol. The color reaction with the Liebermann–Burchard reagent and wavelengths of the ultraviolet absorption maxima were also identical with those of ergosterol.

Leucovolucrisporin

(*i*) When the mother liquors of the initial crystallization of volucrisporin were allowed to evaporate slowly, a crop of colorless needles was obtained. These were recrystallized from pyridine to give a product m.p. 253–255° C which was stable as a solid but slowly converted in solutions exposed to air to volucrisporin. Found: C, 73.2%; H, 5.0%. Calculated for $C_{18}H_{14}O_4$: C, 73.5%; H, 4.8%.

(*ii*) Volucrisporin (30 mg) was boiled for 20 minutes with 3 ml of glacial acetic acid and zinc dust when the pigment slowly dissolved giving a colorless solution. This was filtered and poured into ice water. The precipitate was collected and crystallized from pyridine as colorless needles (20 mg), m.p. 253–255° C, undepressed on admixture with a sample of leucovolucrisporin isolated from *V. aurantiaca*. Found: C, 73.2%; H, 4.8%.

The dihydro compound was reoxidized to volucrisporin by brief warming with CrO_3 in glacial acetic acid.

Volucrisporin Diacetate

A mixture of volucrisporin (50 mg) and acetic anhydride (3 ml) was boiled for 15 minutes, when a clear solution resulted. When the mixture was cooled, yellow crystals were obtained. They were filtered and recrystallized from glacial acetic acid as glistening yellow needles (45 mg), m.p. 223° C, insoluble in sodium hydroxide. Found: C, 70.3%; H, 4.5%; CH_3CO, 24.0%; mol. wt. (Rast), 312. Calculated for $C_{22}H_{16}O_6$: C, 70.2%; H, 4.3%; $2CH_3CO$, 22.8%; mol. wt., 376. Ultraviolet absorption in dioxane shows λ_{max} 236 and 330 mμ; log ϵ 4.51 and 3.99, respectively.

When the compound was hydrolyzed by boiling for 2 hours with methanol containing a drop of concentrated sulphuric acid, volucrisporin was obtained.

Dihydrovolucrisporin Tetraacetate

Volucrisporin (50 mg) was boiled for $\frac{1}{2}$ hour with acetic anhydride (3 ml) and zinc dust giving a colorless solution which was filtered and poured into ice water. The precipitate was collected and crystallized from methanol as colorless plates (40 mg), m.p. 161–162° C, showing bright green fluorescence under ultraviolet light. Found: C, 67.4%; H, 5.1%; CH_3CO, 35.9%; mol. wt. (Rast), 438. Calculated for $C_{26}H_{22}O_8$: C, 67.5%; H, 4.8%; $4CH_3CO$, 37.2%; mol. wt., 462. Ultraviolet absorption maximum in dioxane at 258.5 mμ; log ϵ 4.42.

Volucrisporin Dimethyl Ether

A mixture of volucrisporin (60 mg), methyl iodide (4 ml), and silver oxide (500 mg) was refluxed for 2 hours. The resulting orange solution was filtered and evaporated to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

dryness. The crude product thus obtained was crystallized twice from glacial acetic acid as glistening orange cubes (40 mg), m.p. 172–174° C. The analytical sample was sublimed in high vacuum at 120° C. Found: C, 75.0%; H, 5.3%; OCH_3, 18.3%. Calculated for $C_{20}H_{16}O_4$: C, 75.0%; H, 5.0%; $2OCH_3$, 19.4%. Ultraviolet absorption in ether shows λ_{max} at 279 and 326, λ_{Infl} at 235 and 371 mμ; log ε 4.22, 4.16, 4.82, and 3.72, respectively. Infrared maxima (KBr disk) at 1649 (s), 1580 (s), 871 (s), 860 (s), 809 (s), 778 (s), 730 (m), and 688 (s) cm^{-1}.

Zinc Dust Distillation

Volucrisporin (100 mg) was mixed intimately with zinc dust (6 g) and the mixture divided into 10 parts. Each was distilled in an open test tube and the distillates collected and crystallized from glacial acetic acid as colorless plates (10 mg). This product was purified by repeated sublimation in high vacuum at 120° C to give *p*-terphenyl, m.p. 209° C, undepressed on admixture with an authentic sample. Found: C, 93.4%; H, 6.4%. Calculated for $C_{18}H_{14}$: C, 93.9%; H, 6.1%. Ultraviolet absorption spectrum in ether showed λ_{max} 277 mμ, log ε 4.44, and was identical with that of an authentic sample of *p*-terphenyl. The infrared spectrum of the product was also identical with that given by *p*-terphenyl.

Alkaline Peroxide Oxidation

Three per cent hydrogen peroxide (1.5 ml; 7.3 moles) was added to a solution of volucrisporin (50 mg) in 0.1 *N* NaOH (10 ml). After 14 hours at room temperature in the dark the solution was neutralized with 1 *N* HCl and excess hydrogen peroxide decomposed with a small amount of palladized charcoal. An aliquot was spotted onto paper (Whatman No. 1) together with samples of the monohydroxybenzoic acids and the chromatogram developed in *i*-propanol – concentrated NH_4OH – water (8:1:1) (17). After the paper was dried and sprayed with diazotized *p*-nitraniline (18), the principal spot from the reaction mixture was found to correspond in R_f value (0.45) and color to that of *m*-hydroxybenzoic acid. Of the minor spots present, none corresponded to *o*- or *p*-hydroxybenzoic acids.

The aqueous solution was evaporated to dryness and the product (9.2 mg) sublimed directly from the mixture at 110–120° C/0.05 mm. Resublimed material melted at 199–201° C. Found: C, 60.9%; H, 4.6%. Calculated for $C_7H_6O_3$: C, 60.9%; H, 4.4%. The compound was indistinguishable from a sample of *m*-hydroxybenzoic acid in ultraviolet and infrared spectra and the melting point, on admixture with an authentic sample, was undepressed.

Sodium Hydroxide Treatment

Volucrisporin (100 mg) was dissolved in normal sodium hydroxide (5 ml) and the dark purplish solution filtered, neutralized with normal hydrochloric acid (5 ml), and extracted with ether until the aqueous layer became colorless. The reddish brown ethereal solution was extracted three times with 5% $NaHCO_3$. The purple bicarbonate extract was acidified with hydrochloric acid and left overnight in the refrigerator. The precipitate was filtered, dried, and crystallized three times from aqueous methanol as small reddish brown plates, (42 mg), m.p. 294–296° C. Found: C, 69.8%; H, 3.5%. Calculated for $C_{18}H_{12}O_5$: C, 70.1%; H, 3.9%.

An alcoholic solution of the compound gave a light green color with alcoholic $FeCl_3$. Distillation with zinc dust yielded *p*-terphenyl. The leucoacetate, prepared by boiling with zinc and acetic anhydride, crystallized from aqueous methanol as colorless needles,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

m.p. 78° C. Found: C, 65.0%; H, 4.9%. Calculated for $C_{28}H_{24}O_{10}$: C, 64.6%; H, 4.7%. Attempts to crystallize the bicarbonate-insoluble fraction which was obtained by evaporation of the ethereal layer failed.

2-(m-Methoxyphenyl)-1,4-benzoquinone

m-Anisidine (12.3 g), prepared by the method of Meldola and Stephens (19) and dissolved in concentrated hydrochloric acid (25 ml) and water (50 ml), was diazotized at 0° C by dropwise addition, under vigorous stirring, of a solution of sodium nitrite (7.0 g) in water (25 ml). This solution was then added at 10° C to a well-stirred suspension of *p*-benzoquinone (13 g) in water (1 liter) containing sodium acetate (18 g). After 1 hour the temperature was allowed to rise slowly to ambient, and after all evolution of nitrogen had ceased (approximately 4 hours), the residue was filtered off, washed well with water, and dried. (Yield of crude product, 17.4 g.) This was extracted in a Soxhlet with petroleum ether (b.p. 30–60° C) and, after cooling, the supernatant solution was decanted onto a short column (4 cm × 8 cm) of activated alumina. The partially crystalline residue was dissolved in benzene and applied to the same column. Elution of the yellow product was continued with fresh benzene until impurities giving a dark red zone reached the bottom of the column. The eluate was then evaporated to dryness and the residual solid crystallized from acetone as yellow needles, m.p. 115–115.5° C. Concentration of the mother liquor to half volume yielded a second crop of crystals of the same melting point. (Total yield, 9.3 g = 37%.) Found: C, 73.0%; H, 4.8%; OCH_3, 14.0%. Calculated for $C_{13}H_{10}O_3$: C, 72.9%; H, 4.7%; $1OCH_3$, 14.5%. Ultraviolet spectrum in ether shows λ_{max} 273 and 362, λ_{Infl} at 230 and 303 mμ; log ε 3.64, 3.27, 4.17, and 3.14, respectively. Infrared spectrum (KBr disk) shows maxima at 1650 (s), 1593 (s), 1575 (s), 873 (s), 837 (m), 769 (s), and 687 (s) cm^{-1}.

2,5-Bis-(m-methoxyphenyl)-1,4-benzoquinone

2-(*m*-Methoxyphenyl)-1,4-benzoquinone (2.72 g) in acetone (85 ml) cooled to −5° C was poured into a well-stirred solution of *m*-anisidine (1.75 g) in concentrated hydrochloric acid (3.5 ml) and water (7.5 ml) which had been diazotized as above with a solution of sodium nitrite (1 g) in water (4.5 ml). Stirring was continued and the reaction mixture kept at −8° C during the addition of sodium acetate (3.5 g) in 10 equal portions over a period of 20 minutes. Water (10 ml) was then added to avoid a separation into two phases and the mixture allowed to warm up very slowly to room temperature. After all evolution of nitrogen had ceased, the reaction mixture was diluted with water and extracted several times with benzene. The benzene solution was evaporated to dryness and applied in chloroform to a column (4.5 cm × 30 cm) of silicic acid (Mallinckrodt 2847). Development with chloroform eventually eluted a bright red zone which was shown, by circular paper chromatography using formamide impregnated Whatman No. 1 filter disks (32 cm diameter) and petroleum ether (b.p. 100–120° C) as mobile phase, to contain a mixture of the desired product (R_f 0.70) together with unreacted monosubstituted benzoquinone (R_f 0.45). This fraction was concentrated to dryness and the residue (1.29 g) sublimed for 12 hours at 80° C in high vacuum. The unsublimed residue (0.36 g) was washed with benzene and crystallized from glacial acetic acid and then chloroform – carbon tetrachloride (1:2) to give yellow needles (99 mg), m.p. 175–176° C. Mixed melting point with dimethylvolucrisporin 173–174.5° C. Found: C, 75.0%; H, 5.1%; OCH_3, 18.9%. The ultraviolet and infrared spectra were identical with those of the dimethyl ether prepared from the natural pigment.

LIGHT ABSORPTION STUDIES

PART XVI. THE ULTRAVIOLET ABSORPTION SPECTRA OF FLUOROBENZENES[1]

W. F. FORBES[2]

ABSTRACT

The ultraviolet absorption spectra of a series of fluorobenzenes are determined. It is found that as a first approximation a fluoro substituent does not appreciably affect the benzenoid absorption. The spectra are discussed on the assumption that the mesomeric effect of the fluorine atom is small.

INTRODUCTION

It has previously been noted in studies of the ultraviolet absorption spectra of a number of *p*-substituted halobenzenes that the implied order of the over-all electron release for the halogens is I (greatest release) > Br > Cl > F (1, 2, 3, 4, 5). This order is difficult to reconcile with the currently accepted order of the relevant mesomeric effects, which is F > Cl > Br > I (cf. refs. 1, 3 and see also Ingold, C. K. Structure and mechanism in organic chemistry. Cornell Univ. Press, Ithaca, New York. 1953. p. 75). One attempt to reconcile the conflicting orders has been made by Burawoy, Schubert, and co-workers (1, 2, 3), who do not use the concept of the mesomeric effect but instead interpret the spectra in terms of what is known as an inductomeric effect. The order of the inductomeric effect is I > Br > Cl > F and in this way the spectral results are not at variance with the conclusions deduced from reactivity measurements, which suggest the reverse order for the mesomeric interactions.

In our own studies, on the other hand, it was found helpful to correlate spectral changes in the main ultraviolet absorption band primarily with mesomeric and steric effects. Mesomeric effects were defined in general terms as associated with electron mobility acting along systems of conjugated bonds, and classical resonance structures were found to account satisfactorily for a large number of the spectral changes. For example, the spectral changes for a number of disubstituted benzene derivatives are consistently greatest in the *p*-isomers. Two difficulties became apparent in our approach. First, it was found necessary to postulate that frequently, for steric or other reasons, absorption spectra are determined by what have been termed locally excited states. For example, the main absorption band of phenol has been interpreted as being caused predominantly by locally excited states involving only the benzene ring, with the hydroxy group exerting merely a secondary effect (6). Secondly, it was found necessary to postulate that the mesomeric effect of the halogen atoms is in the order I > Br > Cl > F, that is, not in the order generally accepted. This implies that the activated complexes involved in the chemical reactions (cf., for example, ref. 7 and references cited there), which differ from the excited states involved in electronic absorption spectra, are also affected in a different manner by the halogen atoms. This hypothesis is evidently not entirely satisfactory but it is preferred since at least it provides a consistent explanation of a variety of different spectral effects. The purpose of the present paper is to show how the spectra of fluorobenzenes can be interpreted on the basis of our general hypotheses.

*Values in italics represent inflections in this and the subsequent table.
†For band nomenclature used, see previous parts of this series of papers.
‡Intensities not determined.
§See "Experimental" concerning the accuracy of maximal wavelengths below 210 mμ.

The similarity of the *C*-bands for fluorobenzene and benzene in inert media has previously been noted (8), and Fig. 1 now records both *B*- and *C*-bands as also the *B*- and *C*-bands of iodobenzene.

Table I shows that the *B*-band location of fluorobenzene is not appreciably affected by solvent changes. Figure 1 indicates that any effect which the fluorine atom has on the benzene spectrum is less than the effect of the other halogens since the latter all cause appreciable spectral changes particularly on the *B*-band as illustrated, for example, by the spectrum of iodobenzene. The small wavelength displacement caused by the fluorine atom on the benzene *B*-band (*ca.* 2 mμ) is ascribed to secondary interaction (cf. ref. 6), and this displacement is similar to the effect which the fluorine atom has on a number of other benzenoid spectra in the absence of appreciable mesomeric interaction (see next sections). Both *B*- and *C*-bands of fluorobenzene appear to be less intense in ether or aqueous solutions.

THE SPECTRA OF PARASUBSTITUTED FLUOROBENZENES

The spectra of substituted fluorobenzenes are listed in Table II.

Table II shows that the maximal locations of the *B*-bands of *p*-substituted fluorobenzenes are all similar to the locations of the *B*-bands of the corresponding non-fluoro-substituted analogues as a first approximation (cf. also ref. 5). However, closer inspection

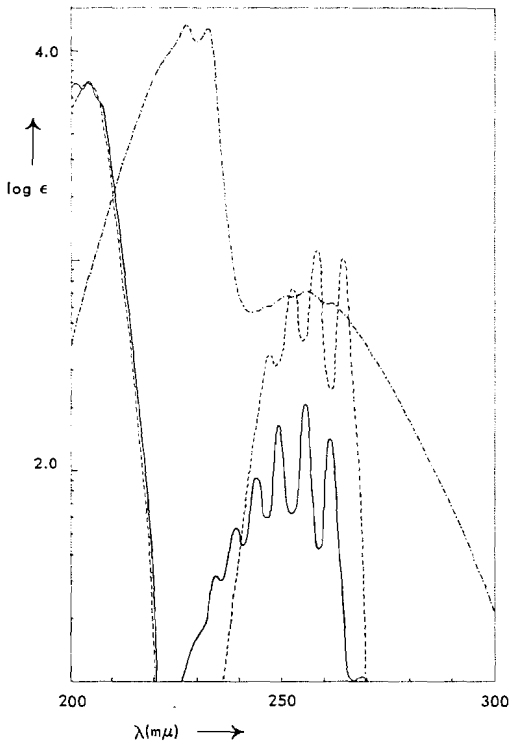

FIG. 1. The ultraviolet absorption spectra of benzene (——) in *n*-heptane solution, and of fluorobenzene (– – –) and of iodobenzene (—·—·) in cyclohexane solution.

allows a subdivision into two classes:

(i) If the *p*-substituent is electron-donating, a *hypsochromic* wavelength displacement is frequently observed in the *B*-band with respect to the non-fluorosubstituted parent compound. For example, in hexane solution Burawoy and Thompson (3) report the wavelength changes in the *B*-band for *p*-fluoroaniline, *p*-fluoroanisole, and *p*-iodofluorobenzene to be -3.5, -3.5, and -3.8 mμ compared with the *B*-bands of aniline, anisole, and iodobenzene respectively. To explain these wavelength displacements it may be assumed that resonance forms of type I contribute predominantly to the electronic excited state. These resonance forms represent locally excited states, in the example shown that of aniline, and the fluorine atom is assumed to exert only a secondary effect. Since the fluorine atom may be expected to withdraw electrons from the neighboring carbon atom, and since further this electron withdrawal will hinder the formation of a negative charge on the carbon atom, the secondary effect may be anticipated to raise the transition energy and in this way the observed slight hypsochromic wavelength displacement in the *B*-band can be rationalized.

**B*-Band assignment doubtful; cf. also "Experimental". †Reference 10 (in isooctane solution). ‡These bands are concentration dependent; values quoted are those at relatively small solute concentrations.

(ii) If, on the other hand, the non-fluoro substituent is electron-withdrawing, the reverse effect would be expected. That is, resonance forms of type II would be favored by the electron-withdrawing effect of the fluorine atom and this may cause a slight *bathochromic* wavelength displacement. Examples to support this suggestion are provided by the data of Burawoy and Thompson (3), who report bathochromic displacements in hexane of 3.1 and 5.6 mμ for the *B*-bands of the spectra of *p*-fluorobenzaldehyde and *p*-fluoronitrobenzene compared with the spectra of benzaldehyde and nitrobenzene respectively. It might be noted that the small wavelength displacement from benzene to fluorobenzene in inert media (see previous section) can similarly be explained.

In addition to the wavelength displacement of the *B*-band caused by the fluorine atom, the fluorine atom also generally appears to decrease the extinction coefficient (ϵ_{max}) of the *B*-band of the fluorosubstituted benzene derivative compared with the ϵ_{max} value of the *B*-band of the non-fluorosubstituted parent compound (see Table II and refs. 3 and 5). This effect may again be ascribed to the electron-withdrawing ability of the fluorine atom which may be assumed to decrease the proportion of available π-electrons in the benzene ring and in this way decrease the over-all absorption probability of the transition involving the benzene ring.

Significant spectral changes between the *p*-substituted fluorobenzene and the non-fluorosubstituted parent compound are also observed in the *C*-band; for example, the fine structure is frequently increased characteristically. This is shown by the data in Table II and is further illustrated by Fig. 2 which records the spectra of phenol and *p*-fluorophenol. Figure 2 shows that while the *B*-bands remain similar, the *C*-band fine structure in *p*-fluorophenol is appreciably increased.

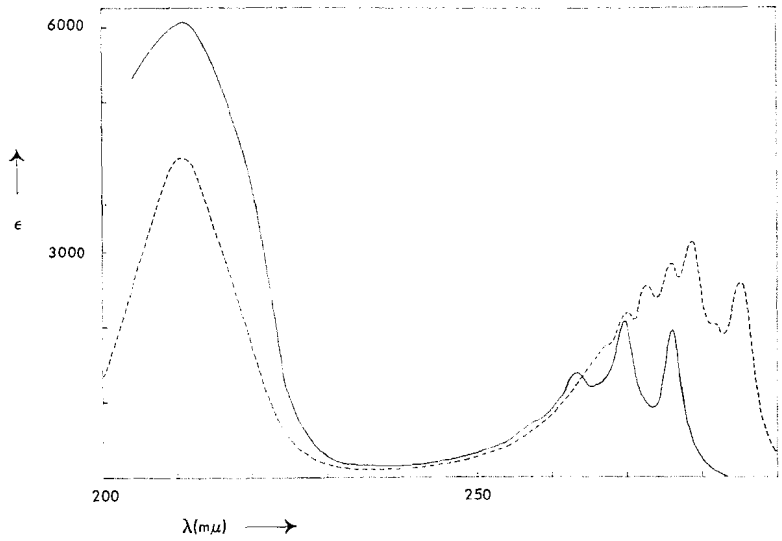

FIG. 2. The ultraviolet absorption spectra of phenol (——) and *p*-fluorophenol (– – –) in cyclohexane solution.

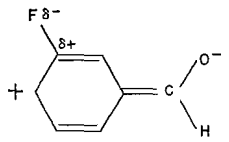
THE SPECTRA OF METASUBSTITUTED FLUOROBENZENES

The spectra of *m*-substituted fluorobenzenes, as other previously discussed spectra of *m*-disubstituted benzene derivatives, might be expected to show two *B*-bands corresponding to the two monosubstituted parent compounds. Unfortunately, the fluorobenzene *B*-band cannot usually be identified with any degree of confidence, because it occurs at a wavelength at which it is not readily identified.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

The location of the maximal absorption of the second, non-fluorobenzene, *B*-band again does not appear to be appreciably affected by the fluorine atom as a first approximation. More careful examination of the data, however, indicates that the second *B*-band is frequently *hypsochromically* displaced if the non-fluoro substituent is *electron-withdrawing*. For example, *m*-fluorobenzaldehyde absorbs at shorter wavelength than benzaldehyde (9), and *m*-fluoronitrobenzene absorbs at shorter wavelength than nitrobenzene (10, 11). These slight hypsochromic displacements are in a different direction from the displacements observed in the corresponding *p*-isomers (see previous section), but this is not unexpected if resonance forms of type III are assumed to be predominantly



(III)

involved in the transitions leading to the observed absorption. This follows because the electron-withdrawing effect of the fluorine atom will now favor the formation of a positive charge on a *different* carbon atom (cf. the related resonance form II in the previous section), which in turn will tend to hinder the positive charge formation associated with resonance forms II and III.

Conversely, if the non-fluoro substituent is *electron-donating* a slight *bathochromic* wavelength displacement is usually observed for the *m*-substituted fluorobenzenes (see Table II, and previous parts of this series for the relevant *B*-bands of the non-fluoro-substituted parent compounds). It may also be noted that opposite wavelength displacements in the meta and para isomers are sometimes observed in the infrared spectra. For example, Krueger and Thompson (12) report that the amino group stretching vibrations of *p*-fluoroaniline occur at *lower* frequency than for aniline, but that those of *m*-fluoroaniline occur at *higher* frequency compared with the stretching vibrations of aniline.

The extinction coefficient (ϵ_{max}) of the second *B*-band is again generally decreased compared with the *B*-band of the corresponding non-fluorosubstituted parent compound (see Tables I and II).

Whereas, with the exception of the above-mentioned minor spectral changes, the *B*-band remains essentially unaltered, the *C*-bands of *m*-substituted fluorobenzenes are frequently profoundly altered on introducing a substituent (see Table II and cf. also ref. 13 for a discussion of the fluorobenzene band). For example, in *m*-fluorobenzaldehyde compared with benzaldehyde, the *C*-band is bathochromically displaced and the extinction coefficient is almost doubled (see Table II and ref. 9). The *C*-band in the *o*-isomers incidentally appears frequently to undergo similar spectral changes.

THE SPECTRA OF ORTHOSUBSTITUTED FLUOROBENZENES

In the absence of direct mesomeric interaction two *B*-bands are again possible (see previous section), but again the *B*-bands associated with fluorobenzene absorption can only be identified with difficulty. As a first approximation, the second *B*-band is only slightly altered because of the fluorine atom.

Closer inspection of the data shows that this second *B*-band, compared with the same *B*-band in the *m*-isomer, usually occurs at slightly shorter wavelength and with slightly

reduced absorption intensity. Since this effect appears to be more pronounced when the non-fluoro substituent is large and electronegative, it seems reasonable to ascribe this secondary spectral effect to electrostatic repulsions and/or steric interactions between the fluorine atom and the *o*-substituent. This is illustrated by the data in Table II for the relevant *B*-bands (see also refs. 14, 15, and 16 for the spectra and a full discussion of diphenyl, fluorosubstituted diphenyls and related compounds). The effect of the size of the substituent may be deduced from the aniline spectra where an *o*-fluoro substituent causes an increased extinction coefficient, whereas an *o*-fluoro substituent in the larger N,N-dimethylaniline is reported to cause a reduced extinction coefficient (ϵ_{max} 11,600) compared with the relevant extinction coefficient in N,N-dimethylaniline (ϵ_{max} 13,750) (cf. Klevens and Platt (17), who assume a certain degree of non-planarity for *o*-fluoro-N,N-dimethylaniline). Likewise the spectra of *o*-fluorobenzaldehyde and *o*-fluoroacetophenone, which may be assumed to possess similar conformations,* indicate that *o*-fluoroacetophenone is less planar because the characteristic hypsochromic wavelength displacement and ϵ decrease only occur in the *B*-band of the acetophenone.

The data also again show that the *B*-band spectral changes can be explained as a first approximation without taking into account the effects of intramolecular hydrogen bonding or of inductive effects involving the fluorine atom. For example, compounds like *o*-fluorophenol and *o*-fluorobenzoic acid, which are believed to form an intramolecular hydrogen bond (19, 20), possess spectra similar to those of the corresponding *m*-isomers (see Table II). This is illustrated in Fig. 3, which shows that the *B*-band of *o*-fluorobenzoic acid is not very different from the *B*-bands of either *m*-fluorobenzoic acid or even benzoic acid itself.

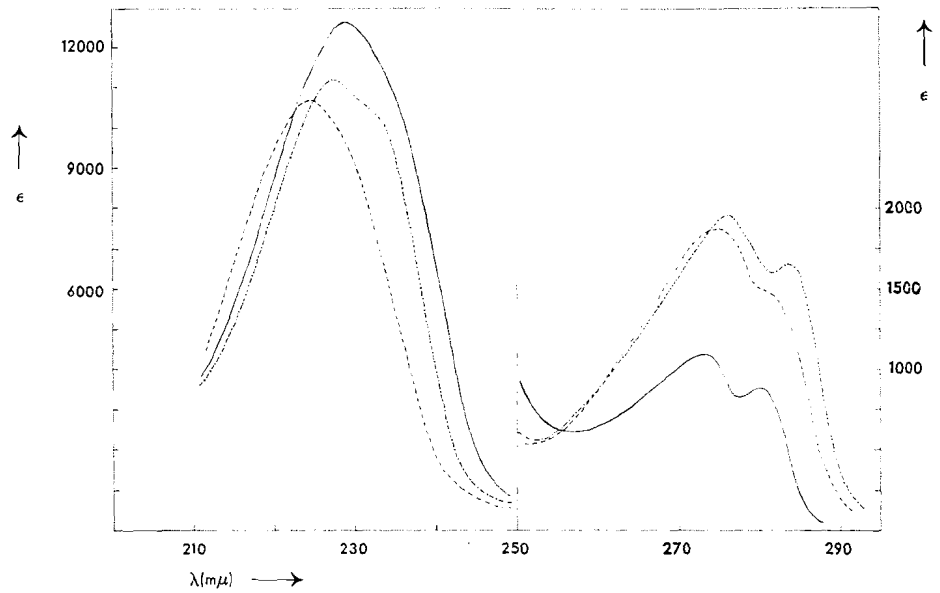

FIG. 3. The ultraviolet absorption spectra of benzoic acid (——), *o*-fluorobenzoic acid (– – –), and *m*-fluorobenzoic acid in cyclohexane solution.

**The infrared carbonyl band of o-fluorobenzaldehyde in carbon tetrachloride solution showed only one intense peak at 1701 cm^{-1}. By analogous reasoning as employed in the interpretation of the infrared carbonyl band of o-fluoroacetophenone at 1692 cm^{-1} (18), we assume that both compounds exist predominantly in one conformation with the C=O and C—F dipoles aligned in opposite directions. Since on the basis of steric considerations alone o-fluorobenzaldehyde might be expected to exist in two s-cis, s-trans conformations, this further suggests that the electrostatic repulsive forces associated with the fluorine atom are sufficiently important to tend to maintain the molecule predominantly in only one conformation.*

This then provides additional evidence that, as a first approximation, *B*-bands of the type discussed in this paper are determined predominantly by mesomeric and steric interactions (cf. refs. 4 and 21).

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP500 or a Beckman Model DU spectrophotometer. For each compound at least two independent sets of observations were made. Some of the spectra have previously been described in this series. The Unicam SP500 instrument was calibrated against a didymium filter and wavelength readings obtained on the Unicam and Beckman instruments were found to be within 1 mμ of each other. The values given in this paper should replace earlier wavelength values (6) which were determined on an uncalibrated SP500 spectrophotometer. Difficulty was encountered in obtaining maximal absorptions below 210 mμ since on both instruments the location of the maximal absorption frequently changed with concentration. The values quoted were determined in 1-mm cells for absorption maxima below 210 mμ but otherwise in 1-cm cells. Apart from the maximal wavelengths below 210 mμ, the accuracy of λ_{max} values is estimated to be ± 0.5 mμ, and the precision of ϵ_{max} values $\pm 5\%$ or better. Values were reproducible in most cases to $\pm 2\%$.

The infrared spectrum was determined on a Unicam SP100 instrument, using a NaCl prism and a diffraction grating.

The fluorobenzenes were either prepared by standard methods or were commercially available; they were purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) or other commercially available spectroanalyzed solvents.

ACKNOWLEDGMENTS

The author is greatly indebted to Miss Florence Jackman for very competent technical assistance in the determination of the spectral data. Thanks are also due to Mr. D. L. Coffen for determining the infrared spectrum and to Mr. J. C. Dearden, who prepared the diagrams and also obtained some of the spectral data.

The financial assistance of the National Research Council is again gratefully acknowledged.

THE NATURE OF THE SPECIFICITY OF ADSORPTION OF ALKYL ORANGE DYES ON SILICA GEL[1]

JOHN L. MORRISON,[2] M. WORSLEY,[3] D. R. SHAW,[4] AND G. W. HODGSON[5]

ABSTRACT

The properties of silica gels sensitized by methyl orange and its homologues were critically examined in order to decide between the alternative hypotheses of a lock and key mechanism and an association mechanism to explain the enhancement of adsorption. Evidence appears to favor an association mechanism in which the unextractable dye particles act as centers to attract their own kind more strongly than one of their homologues. Nitrogen area measurements show that less than 0.5% of the gel surface area is used in adsorbing dye molecules. The dye series from methyl to butyl orange have a very sharp increase in solubility from ethyl to propyl when dissolved in 5% aqueous acetic acid solution (pH = 2.3).

INTRODUCTION

The preparation of solid adsorbents specific to predetermined substances has both theoretical and practical interest (1). Dickey (2, 3) has reported the preparation of silica gels that specifically adsorb their sensitizing alkyl orange dyes. Haldeman and Emmett (4) attempted to correlate dye adsorption with nitrogen area measurements.

In his original communication (2), Dickey compared his adsorbents by making single adsorption measurements from solutions of the same *initial* concentration; this magnified any differences in adsorption. He interprets the phenomenon in terms of a "lock and key" or "footprint" mechanism.

There is, no doubt, a production of some specificity in adsorption, but our experiments show that an alternative explanation of the specificity may be found in the fact that a relatively appreciable amount of the sensitizing dye is permanently retained by the adsorbent.

EXPERIMENTAL

Preparation of Silica Gels

Following Dickey (2, 3), silica gels were prepared by the acetic acid and the oxalate methods. In each case, sodium silicate solution (J. T. Baker Chemical Co., Technical, 40°–42° Bé) with and without a sensitizing dye was acidified by an acid to produce a gel.

Two modifications were made in the procedure: one, the mixture of sodium silicate solution and dye was heated nearly to boiling before adding the acid. This was necessary to ensure more complete solution of the dyes. When the acid was added, there was a precipitation of much of the methyl orange, less of the ethyl orange, and the propyl and butyl orange solutions gave clear gels.

The other modification was to wash the gel thoroughly with distilled water after it had been dried, ground, and sieved. It was found that methanol extraction alone did not

remove all of the residual sodium acetate in the acetic acid method. As a result, in the absence of water washing, both the weight of the gel and the concentration of dye solutions used in the subsequent adsorption experiments were in doubt. The pH of these solutions shifted from 2.3 (5% acetic acid solution) to about 4 with an indeterminate effect on the concentration measurements by the spectrophotometer (Beckman model DU).

A similar washing procedure was used for the oxalate gels.

Adsorption Measurements with Dye Solutions

The alkyl orange dyes were prepared by the method of Slotta and Franke (5). The dyes were purified (6) and analyzed by a semimicro Nesslar method. Purity of 98–100% was obtained, and the extinction coefficients were similar to those reported by Klotz *et al.* (7).

Dye solutions for adsorption measurements were prepared in 5% acetic acid, pH 2.3. At this pH, the absorption maxima at about 510 μ for the four dyes were used for analysis. In some of the later experiments, corrections were made for small deviations from Beer's Law.

For the series A acetic acid gels, each adsorption measurement was made on a separate gel sample (1 g). As a result, there was a considerable sampling error which for this method could only be overcome by using larger samples.

For the series B acetic acid gels and the oxalate gels, the same gel sample was used with each dye (4). Thus, for example, 100 ml of 1×10^{-5} molar dye solution was added to 1 g silica gel, and equilibrated with occasional shaking at 25.0° C for 3 days. After centrifugation, 80 ml of supernatant was removed and analyzed, and 80 ml of the next higher concentration (2×10^{-5}) was added. A repetition of this procedure for 3 and 5×10^{-5} molar solutions completed the adsorption measurements. A much smoother adsorption isotherm curve was obtained by this serial procedure than by the batch method.

Acid-washing of the Gels

The effect of acid(HCl)-washing (3) was determined by dividing the gel samples into two parts, one part which was immersed in 1 *N* HCl for 1 day, then carefully washed with distilled water, and the other part washed with distilled water only.

Residual Dye Content

Following Haldeman and Emmett (4), the residual dye content of each gel was determined by dissolving a weighed sample in 1 *N* NaOH solution. The sample was neutralized, adjusted to pH 2.3 and analyzed spectrophotometrically.

Nitrogen Areas

Nitrogen adsorption isotherms were measured at −195° C on all samples of series B acetic acid gels and oxalate gels. The Brunauer–Emmett–Teller equation (8) was applied to determine the amount of nitrogen adsorbed in a monolayer. In contrast to Haldeman and Emmett (4), who heated their gels to 200° C for 1 hour, a temperature and time which "would be sufficient to destroy the specificity of the sample . . .", we evacuated the gels at room temperature for at least 16 hours to remove adsorbed gases. The measurements were made as soon as possible after the gels were prepared.

Dye Solubilities

The solubilities of the alkyl orange dyes in 5% acetic acid at 25° C were determined spectrophotometrically, and are given in Table I. In each case, excess solid dye was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

added to the acetic acid solution at 75° C, then cooled to the bath temperature and kept in contact, with occasional shaking, for 3 days.

TABLE I

Dye solubilities in 5% aqueous acetic acid at 25° C

Dye	Concentration of saturated solution (moles/liter)
Methyl orange	8.17×10^{-5}
Ethyl orange	7.75×10^{-5}
Propyl orange	22.5×10^{-5}
Butyl orange	34.8×10^{-5}

RESULTS AND DISCUSSION

Adsorption Isotherms

The adsorption isotherms are reversible (4) as illustrated in Fig. 1 by the batch measurements for ethyl orange on an ethyl-orange-sensitized gel.

In general, the adsorption isotherms of the dyes on sensitized gels are concave to the concentration axis and then they increase approximately linearly. The isotherms of methyl and ethyl orange dyes on control gels are approximately linear from zero concentration (3). However, propyl and butyl orange dyes also show concavity on control gels.

The isotherms increase approximately linearly up to saturated solutions of adsorbate. This is illustrated by Figs. 1 and 2. In the latter case, an equilibrium concentration of 17×10^{-5} molar was achieved.

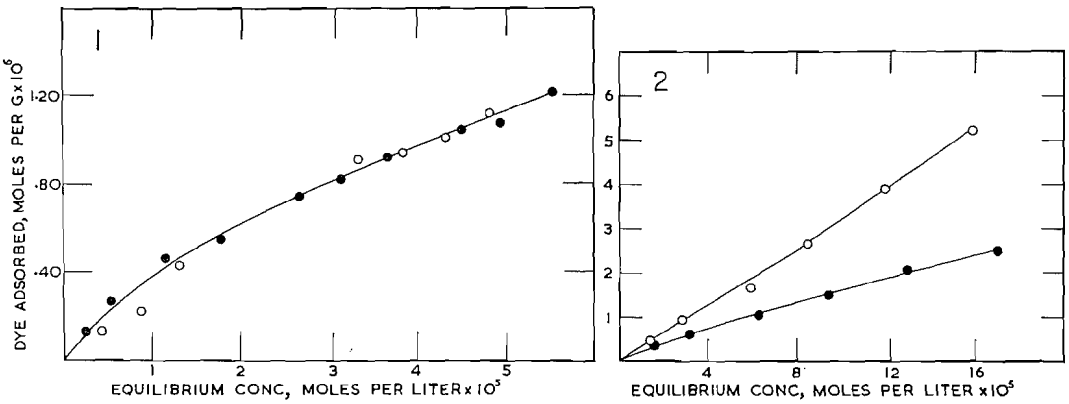

FIG. 1. The sorption isotherm of ethyl orange dye on an ethyl orange silica gel (series A, acetic acid, water-treated). ● Adsorption. ○ Desorption.

FIG. 2. Adsorption isotherms of propyl orange dye extended to relatively high concentrations. ○ A methyl orange, acetic acid, water-treated gel. ● A propyl orange, oxalate, HCl-treated gel.

Absolute Amounts Adsorbed

The absolute magnitudes of adsorption are given in Table II for 1.5×10^{-5} molar equilibrium concentration as interpolated on the isotherms.

It is not possible to determine the absolute magnitudes from Dickey's original paper (2), but more recently (3) he reported absolute measurements for methyl and ethyl dyes and gels. Our results are very similar to his for the dye-sensitized gels, and much higher for control gels. Thus, we conclude that our modification of heating the dye – sodium

silicate solutions before adding the acid is not a significant one insofar as specific effects are concerned.

Relative Adsorption Power

The relative adsorption powers given in Table II are defined as the ratio of the adsorptions for the sensitized and control gels at 1.5×10^{-5} molar equilibrium concentration.* Dickey (3) used 0.5×10^{-5} molar and Haldeman and Emmett (4) used 1×10^{-5}. The value 1.5×10^{-5} was chosen here because it was in a region of greater accuracy, although it is recognized that it tends to give somewhat lower values for the relative adsorption power.

Specificity of Adsorption

In general, the sensitizing process enhances adsorption by $1\frac{1}{2}$ to 2 times compared with the control gels. Higher degrees of enhancement are more apparent than real. For example, a relative adsorption power of 9.7 for ethyl orange on ethyl orange oxalate (HCl) gel arises from an extremely low value for the adsorption on the control. The absolute value (0.32×10^{-6} mole per g) on this ethyl orange gel is lower than the absolute values on all of the other ethyl orange gels except the oxalate (H_2O) gel.

The specificity is so low that it can be masked by gel fluctuations. It was found that two controls when prepared under identical conditions from the same batch of sodium silicate may differ by as much as 25% and two sensitized gels also identically prepared may differ by as much as 50%.

Nitrogen Areas

Nitrogen area measurements were made to test the postulate by Dickey that the specificity of adsorption was due to footprints or imprints left in the gel structure by the dye molecules.

The nitrogen areas of a number of our gels are given in Table III. Haldeman and

TABLE III

Nitrogen surface areas, square meters per g

	Series B acetic acid gels		Oxalate gels	
Silica gel	(H_2O)	(HCl)	(H_2O)	(HCl)
Control	715	746	484	457
Methyl	(*a*) 574	(*a*) 702	695	471
	(*b*) 574	(*b*) 631	674	
Ethyl	574	662	674	461
Propyl	584	675	492	550
Butyl	588	649	554	588

NOTE: Basis: N_2 molecular adsorption area = 16.2 Å^2.

Emmett also measured the nitrogen areas of a number of Dickey's silica gels (4). They obtained the same area, 980 sq. m per g, for all the gels. Our gel areas are significantly lower, and are very similar to those obtained by Sing and Madeley (10). The latter workers used freshly prepared gels, but, like Haldeman and Emmett, they heated the

**Dickey in his original paper and Haldeman and Emmett in some of their measurements have used the same initial concentration. This misleadingly magnifies the specificity, and the more so, the lower the initial concentration. Dickey acknowledges this magnifying effect (ref. 3, p. 698), but he and Bernhard (9), and also Haldeman and Emmett, continue to accept the original announcement and perpetuate the misleading method. Dickey (Table I in ref. 4) confuses the problem even further by using a variety of initial concentrations for the different dye solutions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

gels to 200° C for 1 to 2 hours. It would appear that the gel gradually disintegrates in time to produce a larger surface area.

It is questionable that nitrogen area measurements will reveal anything concerning the *specificity* of adsorption on sensitized silica gels. What they do show is that the fraction of gel surface used in the adsorption of the alkyl oranges is very small.

For example, the highest adsorption we observed, which was for propyl orange approaching saturation concentration, was 5.2×10^{-6} mole dye per g gel. Assuming like Haldeman and Emmett that the molecular adsorption area of each dye molecule is 100 Å^2, and that they adsorb in a monolayer, we find that in this case only 0.4% of the surface is covered by dye molecules.

Nitrogen area measurements on the same sample vary by as much as 1% and the variations observed here from one gel preparation to another, and even from water to acid washing on the same gel are as much as 40%. Obviously, it would be very difficult to distinguish by means of nitrogen areas between the presence of "footprints" in a sensitized gel and their absence in a control gel, and even more so, the difference of the "imprints" of two methylene groups in gels sensitized to two successive dye homologues.

Unextractable Dye

The residual dye content of two series of sensitized gels, both water- and acid-washed, are given in Table IV. Acid-washing does not alter the amount of residual dye.

TABLE IV

Unextractable dye contents, moles $\times10^8$ per g

	Series B acetic acid gels		Oxalate gels	
Silica gel	(H_2O)	(HCl)	(H_2O)	(HCl)
Methyl	3	8	8	7
Ethyl	15	10	24	26
Propyl	31	29	70	72
Butyl	23	21	67	75

In general, contrary to Dickey's statement "that more than one hundred times as much dye may be specifically adsorbed as is unextractably retained" (ref. 3, p. 705), we find that the amount of residual dye is an appreciable fraction of the amount of dye specifically adsorbed.

For example, in Fig. 3, the amount of propyl dye *specifically* adsorbed on a propyl

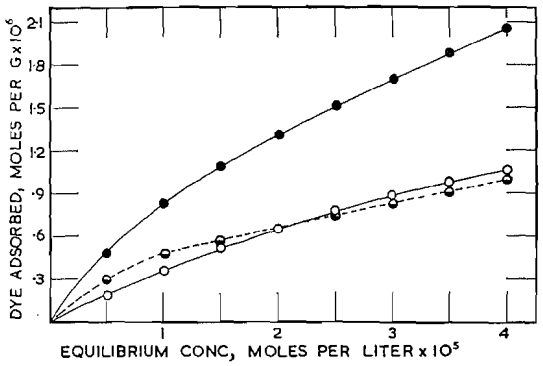

FIG. 3. Specifically adsorbed propyl orange dye. ● Propyl orange gel (series B, acetic acid, HCl-treated). ○ Control gel (same type). ◒ Difference between the two curves. All points are from smoothed curves.

gel is given as the difference between the amounts actually adsorbed on the propyl gel and on the control gel. The extrapolated value of the linear portion of the resultant isotherm at zero equilibrium concentration is 0.3×10^{-6} moles per g gel, which practically coincides with the amount of residual dye. Of course, this is an accidental coincidence but it serves to emphasize the fact that the amount of unextractable dye is not negligible.

Acid-washing of the Gel

Dickey claims that acid-washing (with HCl) is "found to preserve the specific adsorption property". Included in Table II are the acetic acid B series and the oxalate series of gels in each of which one part was water-washed and the other part HCl-washed and then water-washed.

Acid-washing does not have much effect on the adsorption of dyes on the oxalate gels. Similarly, the nitrogen areas of the oxalate gels show no general trend as a result of acid-washing (Table III).

The effect of acid-washing is more definite for the acetic acid gels. In general, dye adsorption is enhanced on the dye-sensitized gels and reduced on the control gels. Acid-washing noticeably enhances nitrogen adsorption on the dye-sensitized gels, but only slightly affects that on the control gel.

It is difficult to account for an *enhancement* of adsorption by acid-washing in terms of "footprints" left by the dye. A more plausible explanation could be given in terms of the effect of acid-washing on the unextractable dye. It was already noted that acid-washing does not extract any dye. Possibly this treatment exposes more dye to the external surface by corroding the gel; concomitantly, the control gel becomes somewhat less active by the same corroding action.

Although there is much more unextractable dye in the oxalate gels than in the acetic acid gels, it appears that this dye is either more deeply buried or in a less active form (the oxalate gels are prepared at a significantly higher pH value than the acetic acid gels). Thus, the oxalate gels have lower absolute dye adsorptions and they are almost totally insensitive to the action of acid-washing.

The Nature of the Dyes as Adsorbates

It was generally observed that the adsorption of the orange dyes on the control gels increased with increasing molecular weight; moreover, methyl and ethyl were grouped together followed by a gap after which propyl and butyl were grouped. This grouping is also largely maintained among the sensitized gels.

A similar grouping occurs for the amounts of unextractable dye retained by the sensitized gels (Table IV) and for the solubilities of the dyes in 5% aqueous acetic acid solutions (Table I).

It is very unusual to find that the more soluble adsorbates of a homologous series are the ones adsorbed in the larger amounts. For example, Hansen and Craig (11) found that the adsorptions of slightly soluble homologues were congruent functions of their *reduced* concentrations (equilibrium concentration divided by saturation concentration). They reported on the adsorption of the monobasic aliphatic acids on non-porous carbons.

When the same method was applied to one of our sets of isotherms on a single gel, the isotherms became more divergent (Fig. 4).

Hansen and Craig point out that congruency of the adsorption isotherms is to be expected if the adsorbent acts on the same functional group of the adsorbate. Apparently, in the present case, one must use an entirely different mechanism to account for the

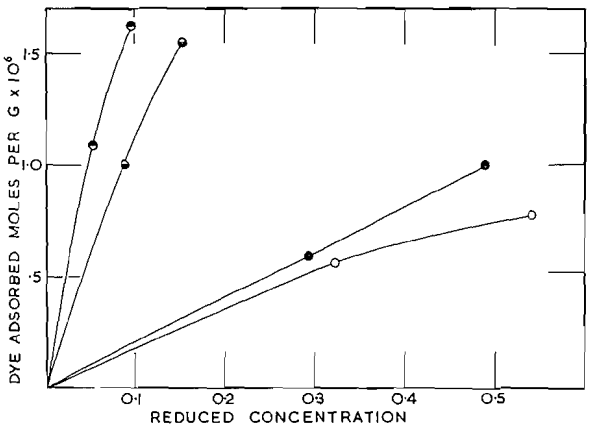

FIG. 4. Adsorption on a methyl orange gel plotted against reduced concentration (methyl orange gel, series B, acetic acid, water-treated); ● methyl, ○ ethyl, ◒ propyl, and ◓ butyl orange dyes.

adsorption of the methyl orange homologues on silica gel. Our results suggest that such a mechanism will be very dependent on properties of the adsorbate molecules.

The striking increase in solubility from ethyl to propyl orange recalls a rule of Blitz and Herzog (12) that the diffusibility of dyes with more than 45 to 50 atoms suddenly decreases in comparison with those of less than this number of atoms. We are suggesting that the sudden increase in solubility is due to a sudden increase in the degree of association of the propyl and butyl orange dye molecules in comparison with the methyl and ethyl orange molecules.

Such an increase could largely account for the greater adsorbability of these two dyes compared with their methyl and ethyl homologues. The adsorption of the larger aggregates of propyl and butyl oranges would thus partially mask any specificity.

Moreover, a general tendency for association would be one way of accounting for the unextractable dye playing a role as attraction centers in specific adsorption.

A similar explanation for specific adsorption is the suggestion of Singer (ref. 3, footnote, p. 702) that the unextractable dye molecules act as centers for a phenomenon akin to crystallization.

The Effect of Other Unextractable Substances

Dickey (3) rejects the suggestion that the unextractable dye plays a role in the enhancement of adsorption; his rejection is largely based on a single experiment, in which decolorizing of the unextractable dye by ozone did not alter the amount of adsorption. He suggests that the dye "has been destroyed" without altering the footprints.

However, this experiment does not ensure the *removal* of the decolorized molecules from the gel, and these may still act as centers for adsorption.

Bernhard (9) and Beckett and Anderson (13) have shown that the sensitization of the gel by similarly structured molecules gave similar adsorptive properties.

We prepared gels in the presence of sulphanilic acid and of *p,p'* diaminodiphenyl and compared their adsorptive properties to methyl and ethyl orange dyes by measuring complete isotherms. The adsorptions at 1.5×10^{-5} molar equilibrium concentration are given in Table V. It is quite apparent that both these substances, and particularly sulphanilic acid, enhance the adsorption as much as do the two orange dyes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

TABLE V

Adsorption on various gels at 1.5×10^{-5} molar equilibrium concentration

	Adsorbate dye	
Sensitized silica gel	Methyl orange	Ethyl orange
Control	0.25	0.19
Methyl orange	0.40	0.25
Ethyl orange	0.50	0.51
p,p' diaminodiphenyl	0.38	0.42
Sulphanilic acid	0.50	0.55

We have concluded from these experiments that unless the unextractable dye is completely removed, and not merely decolorized, one cannot unequivocally reject its role in enhancing adsorption. Unfortunately, it does not appear possible to remove the dye completely without destroying the gel. Moreover, the drastic treatments necessary to decolorize the unextractable dye bring into question the survival of "footprints".

CONCLUSION

According to Martin (1) the "finding of stationery phases of high specificity . . . " is "an extremely difficult field, as difficult as it is obviously rewarding". Therefore, much care should be taken particularly in the interpretation of any observations of specificity; for, a correct interpretation should be more fruitful than an incorrect one in developing new specific adsorbents.

In the present case, neither of the participants in the specific adsorption phenomena is a simple substance.

Silica gel is extremely complex; in its formation under the present conditions it undergoes about a 30-fold shrinkage. It is very difficult to envisage the survival of matching structures to the dye molecules in such a gel. However, some of the dye particles remain trapped within the gel structure during this shrinkage and become unextractable. Until the effect of such unextractable material has been unequivocally disproved, one must, we believe, follow the simpler hypothesis that the specificity arises from the retained dye.

The methyl orange homologues have been found to be complex substances. For example, Burkhard, Burgert, and Levitt (14) have shown in connection with dye–protein interactions that, at pH 6.8 and 7.3, methyl orange does not form micelles whereas butyl orange does so. We are reporting the unusual solubility behavior of the dye series, and it is interesting to note that Dickey in his second paper has only dealt with methyl and ethyl orange dyes (3).

If the specificity in the silica gels is due to unextractable substances, then the development of tailor-made adsorbents might follow a different path from that suggested by the "footprint" hypothesis.

HYDROXYLYCOCTONINE[1]

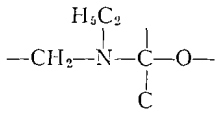
O. E. Edwards, M. Los,[2] and Léo Marion

ABSTRACT

The structures of isolycoctonine and hydroxylycoctonine salts have been shown to be VII and X respectively. These structures and the δ-lactone character of the products of lead tetraacetate cleavage of hydroxylycoctonam are in harmony with structure XI for hydroxylycoctonine.

Most of the chemistry of the alkaloid lycoctonine (1, 2, 3) has been accounted for on the basis of structure I (R = CH_2OH).[3] However, one of the remaining sets of facts not readily reconciled with this structure centered around the base hydroxylycoctonine.

This product of silver oxide (5) or lead tetraacetate (1, 6) oxidation of lycoctonine contained one more oxygen than the parent alkaloid, and had many characteristics of a carbinolamine. The marked drop in pK_a in going from lycoctonine to hydroxylycoctonine (3.3 units) indicated that the extra oxygen was close to the nitrogen. The fact that the base could be oxidized to a lactam, which on acid hydrolysis gave ethylamine (1), proved the presence of the system:



Suginome (7) treated hydroxylycoctonine with methanolic hydrogen chloride and obtained what appeared to be a carbinolamine ether. In addition, when hydroxylycoctonine was heated in mildly alkaline solution formaldehyde, acetaldehyde, lycoctonine, and des(oxymethylene)-lycoctonine were among the compounds formed (1). The aldehydes obviously arose from the carbinolamines II (R = CH_2OH) and III. Since only a trace of lactam was produced it was suggested (1) that II (R = CH_2OH) was reduced by the above aldehydes in a crossed Cannizzaro reaction to lycoctonine, while the carbinolamine II (R = H) formed by retroaldol fission was similarly reduced to des(oxymethylene)-lycoctonine (I, R = H).

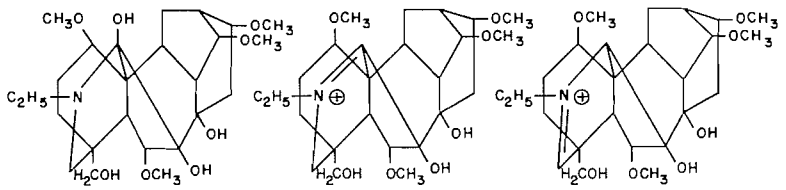
Finally, the presence of a vicinal diol in hydroxylycoctonam was demonstrated, suggesting that the original lycoctonine skeleton was intact. On this basis, structure IV was advanced for hydroxylycoctonine (1). This structure is consistent with the above facts provided it is possible for the immonium salt V to exist as a transient intermediate in the formation of IV. This assumption would also be required to account for the rearrangement of IV to the immonium ion VI which must be the precursor of II, and for the comparable formation of III. However, four pieces of evidence were not readily reconcilable with structure IV for hydroxylycoctonine.



IV V VI

(*a*) The salts of hydroxylycoctonine were anhydronium salts (i.e. involved loss of a molecule of water), and these salts had unusual ultraviolet and infrared spectra (1, 6) (see below). The corresponding anhydronium salt structure V is extremely strained.

(*b*) A solution of hydroxylycoctonine in acetic acid over platinum rapidly absorbed 1 mole of hydrogen, giving an isomer of lycoctonine "isolycoctonine" (5), which proved to be a ketone. Lithium aluminum hydride reduced hydroxylycoctonine salts[4] to dihydroisolycoctonine[5] (carbonyl reduced to the secondary alcohol).

(*c*) Although structure IV contains a vicinal triol system, glycol cleavage reagents failed to cleave more than one vicinal diol in the molecule (1). The main products gave monoacetates whose infrared spectra contained no hydroxyl absorption bands.

(*d*) A marked change in saponification rate exists between methyl lycoctonamate and methyl hydroxylycoctonamate (1).

In an attempt to account for these observations we undertook the study of the structure of isolycoctonine. This base had a pK_a' of 6.7 (0.9 unit higher than hydroxylycoctonine), was inert to nitrous acid, and gave no amide with acetic anhydride. It thus appeared to be a simple tertiary amine. Its infrared spectrum demonstrated the presence of a carbonyl in a six-membered or larger ring.

Permanganate oxidation of isolycoctonine gave a neutral compound without loss of carbon. Since vigorous hydrolysis of this compound yielded no acetic acid or volatile amine it was a lactam (named isolycoctonam), and hence the nitrogen was flanked by two skeletal carbons as in lycoctonine itself.

The environment of the carbonyl was next proved by a series of experiments. The action of lead tetraacetate in wet acetic acid on isolycoctonam resulted in the consumption of 1 mole of reagent and the production of a keto acid. This spontaneously cyclized on handling giving a lactone, which in view of this ease of formation and its infrared absorption at 1737 cm^{-1} was undoubtedly a δ-lactone. The keto lactone lost the elements of methanol when heated with dilute mineral acid, giving rise to a compound containing the lactone ring and a lightly substituted α-β unsaturated ketone

[4]*Leonard and co-workers showed that immonium salts are reduced by this reagent to the tertiary amine (8).*
[5]*We cordially thank Dr. D. K. R. Stewart, who performed this experiment.*

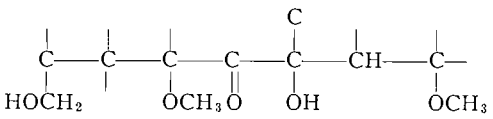
For personal use only.

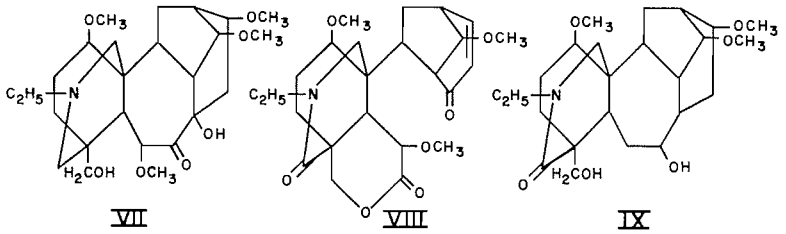
(λ_{Infl} 225 mμ). 17-Desoxylycoctonine (I, R = CH_3) gave an exactly parallel series of reactions, except that no lactone formed. The lactone formation thus indicates a 1,5 relation between the primary hydroxyl and the carbonyl.

Zinc and refluxing acetic anhydride removed the tertiary hydroxyl α to the carbonyl in isolycoctonam. When the product was hydrolyzed and then treated with 5% sodium amalgam in ethanol one methoxyl was removed and the ketone carbonyl reduced. Since isolycoctonam is stable to base, this reaction proved that a methoxyl was α to the carbonyl.[6]

The above evidence defines the sequence



in isolycoctonine. This sequence is present in lycoctonine if the C(7)–C(15) bridge is ruptured. In view of the gentle conditions under which lycoctonine can be transformed into isolycoctonine, it seems unlikely that a deep-seated skeletal rearrangement takes place, hence VII is a very plausible structure for isolycoctonine. The α-β unsaturated keto-δ-lactone must then be VIII, and the product of the successive Zn–Ac_2O and $Na(Hg)_x$ treatment of isolycoctonam is IX.



VII VIII IX

The infrared spectrum of salts of hydroxylycoctonine had two absorption bands at 1670 cm^{-1} and 1712 cm^{-1}. The former correspond to the $\rangle C{=}N^{\oplus}\langle$ stretching vibration (9, 10), but the latter was not easily accounted for. Solution of the salts in alcohol, or of the base in acetic acid, had a carbonyl absorption band in the ultraviolet at the abnormally long wavelength of 330 mμ. The very rapid catalytic reduction of hydroxylycoctonine in acid solution to VII, and the course of the lithium aluminum hydride reduction of hydroxylycoctonine salts, coupled with the above spectroscopic evidence, led to the conclusion that the salts must have structure X. Thus the IR band with ν_{max} 1712 cm^{-1} is the $\rangle C{=}O$ stretching absorption and the catalytic hydrogenation reduces the immonium bond.

While the above results prove the structure of isolycoctonine and hydroxylycoctonine salts, acceptance of structure IV for hydroxylycoctonine still demands the invoking of the highly strained immonium ion of V as a transient intermediate (see above), and no explanation of points (*c*) and (*d*) above is provided. While the preliminary communication of the above results (11) was in press, Professor G. Büchi suggested to us that

[6]*The reductive removal of a methoxyl α to a ketone carbonyl has been used previously in lycoctonine chemistry (2). In this case, and in the original work of Kondo, the carbonyl was not reduced. However, in the present work it was not found possible to avoid reduction to the secondary alcohol.*

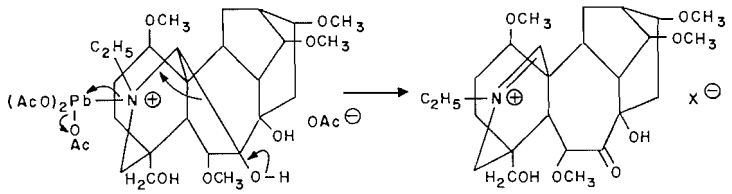
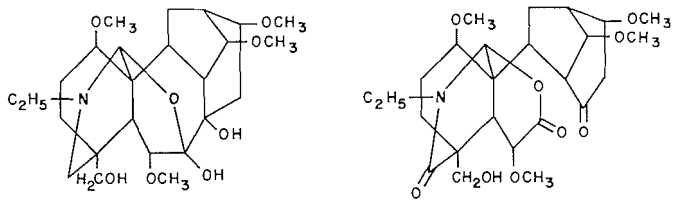
an initial complex between the nitrogen of lycoctonine and $Pb(OAc)_4$ led directly to the "open" structure X(X = OAc) as shown. Hydroxylycoctonine would then be XI and the product of lead tetraacetate cleavage of hydroxylycoctonam would be XII. In



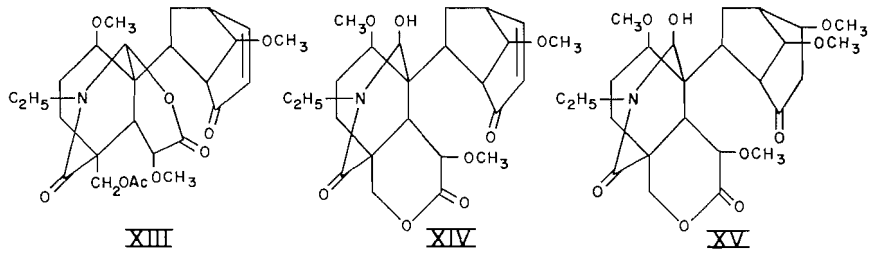
X



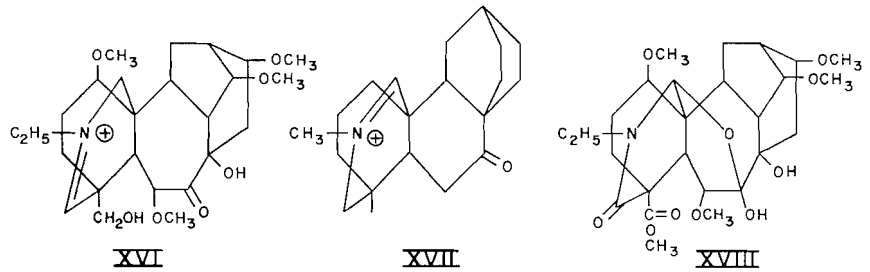
XI XII

a recent communication (12) Valenta has drawn the same conclusion about the structure of hydroxylycoctonine and its salts. These very convincing rationalizations were quickly established to be correct by alkaline hydrolysis of the compound XIII which we had called desmethanol *seco*hydroxylycoctonam diketone monoacetate.[7] A nearly quantitative yield of acid was obtained, which spontaneously cyclized to a new crystalline lactone, presumably XIV.

In view of the new structure for hydroxylycoctonine it appeared that the more strongly adsorbed compound lacking the primary hydroxyl (not acetylatable) produced in the



XIII XIV XV



XVI XVII XVIII

[7]*By mistake this compound was called des(oxymethylene) hydroxysecolycoctonam diketone monoacetate in several places in reference 1.*

For personal use only.

lead tetraacetate cleavage of hydroxylycoctonam (1) might have structure XV. The compound even after 8 hours' drying at 100° in high vacuum still gave carbon values 0.5% low for this possibility. However, the compound was shown to be a lactone by alkaline hydrolysis to an acid. Flash pyrolysis of the compound *in vacuo* gave a mixture from which XIV was obtained by crystallization. Thus structure XV is confirmed.

N-Bromosuccinimide (13) rapidly oxidized isolycoctonine. The product gave a hydrochloride which appeared to be a mixture of the salt of N-desethyl isolycoctonine (ν_{max} 2680, 2470, and 1602 cm^{-1}, ascribable to $\rangle\overset{\oplus}{N}H_2$) and of immonium salt XVI (ν_{max} 1673 cm^{-1}). Attempts to rearrange the immonium salt to the readily crystallizable hydroxylycoctonine salts by heating the mixture in dimethylformamide failed, although the corresponding transformation in the atisine series is facile (14). This gives some support to our contention that hydroxylycoctonine salts represent a high energy state (see below).

Considerable driving force for the formation of hydroxylycoctonine must come from the relief of non-bonded interaction between the ring A hydrogens and the ethyl group in going from lycoctonine to X. Examination of Courtauld's models, however, suggested that this was offset by an increase in other non-bonded interactions and in ring strain[8] in going from lycoctonine to X. The expected course of the lead tetraacetate oxidation by analogy to the attack of other oxidizing agents on the lycoctonine (5, 15), atisine (16, 17), and garrya (18) groups of alkaloids would lead to initial formation of the immonium ion VI. This ion is strain free, has no serious non-bonded interactions, and gives the same relief of crowding of the N-ethyl group as the formation of X. Hence it is not clear why the oxidation goes rapidly and nearly quantitatively to X. The possibility exists that VI is the primary product, which rearranges rapidly to X, but this still leaves the question unsettled as to why X is formed.

The low basicity of hydroxylycoctonine is more readily understood. The basic strength of carbinolamines (13, 19) and oxazolidines (9, 16, 19) derived from tertiary bases is 2 to 4 units greater than that of the parent saturated bases.[9] The higher values pertain when the salt formation relieves strain or reduces non-bonded interaction (19). In the case of hydroxylycoctonine, salt formation relieves the interaction of the ethyl group with ring A hydrogens, hence we might expect a pK_a' at least 3 units greater than that of the saturated analogue. However, the presence of the carbonyl should lower the basicity by approximately 1 unit,[10] leaving a net increase of 2 pK_a units. Using dihydroisolycoctonine XVI as the reference base (pK_a' 7.4) we would thus expect a pK_a' of hydroxylycoctonine of at least 9.4. (The pK_a' of base XVII (20) derived from ajaconine which has very similar N to CO distance and orientation is 11.7 in aqueous alcohol.) Thus a discrepancy of a minimum of 3 units exists between the actual pK_a' (5.8) and the estimated value. Since inductive effects must be negligible we attribute this difference to the ring strain and increased non-bonded interactions in the salt[11] relative to the hemiketal structure of hydroxylycoctonine (XI), thus destabilizing the salt.

[8]*The hydrogen on* C-*6 was very crowded and there was serious interaction between the* C-*15 and* C-*12 hydrogens. In addition, considerable distortion of bond angles was necessary to form the skeleton.*

[9]*This is only true if there is no violation of Bredt's rule or no introduction of new serious non-bonded interaction in forming the anhydronium salts.*

[10]*The difference in pK_a' between the azomethine ketone from which* XVII *is derived and the corresponding alcohol is 0.9 unit. In this case the carbon of the carbonyl is slightly closer to the nitrogen than in hydroxylycoctonine salts. The nitrogen lies close to the axis of the carbonyl and on the positive end of the dipole, conditions that should favor the maximum field effect. Isolycoctonine* (VII) *is weaker (pK_a' 6.7) than the corresponding alcohol dihydroisolycoctonine (pK_a' 7.4) by 0.7 unit.*

[11]*See footnote 8.*

Comparison of Courtauld models of lycoctonine and hydroxylycoctonine showed increased crowding of the C-6 hydrogen and methoxyl against the functions on C-17 in the latter. This gave a possible explanation of the fact that methyl hydroxylycoctonamate (XVIII) was hydrolyzed much more slowly than methyl lycoctonamate (point (*d*) above).

The mechanism of the oxidation of lycoctonine to hydroxylycoctonine by silver oxide remains obscure. The fact that silver ammonium ion did not oxidize the base suggested that here, too, a silver–amine complex is a necessary intermediate. However, the way in which two silver atoms participate to accept the pair of electrons is not clear.

The transformation of hydroxylycoctonine salts (X) to lycoctonine etc. suggests an alternative to aldol condensation (21, 22) for the formation of the C-7:C-15 bridge in the biosynthesis of lycoctonine from diterpenoid precursors.

EXPERIMENTAL

Isolycoctonine (VII)

Adams' catalyst (25 mg) in 3 ml of acetic acid was prereduced and 105 mg of hydroxylycoctonine added. One mole of hydrogen was absorbed in 4 minutes, after which the reduction was stopped. The catalyst was removed by filtration, the solvent evaporated, and the residue dissolved in methylene chloride. This was washed with dilute sodium carbonate solution, dried, and evaporated to give 90 mg of syrup. Crystallization from aqueous methanol gave plates identical in melting point, mixed melting point, and rotation with isolycoctonine previously described (5). ν_{max} (Nujol): 3470 and 3420 (OH), 1713 (ketone).

Dihydroisolycoctonine

Isolycoctonine (97 mg) in 5 ml of acetic acid was hydrogenated in the presence of 25 mg of Adams' catalyst. One mole of hydrogen was absorbed in 16 hours. The catalyst was removed by filtration and the filtrate concentrated under reduced pressure. The residue was dissolved in methylene chloride, washed with dilute sodium carbonate solution, dried, and evaporated. Four crystallizations from acetone gave 50 mg of colorless plates, m.p. 176–179° C. pK_a 7.35 in 50% aqueous methanol, $[\alpha]_D^{23}$ −21° (*c*, 1.07). Found: C, 63.98; H, 9.20; OCH_3, 26.14. Calc. for $C_{25}H_{43}O_7N$: C, 63.94; H, 9.23; $4OCH_3$, 26.42.

Dihydroisolycoctonine could be obtained more readily by the reduction of isolycoctonine with sodium borohydride in 50% aqueous methanol for ½ hour at room temperature.

Reduction of Hydroxylycoctonine Hydriodide by $LiAlH_4$[12]

Hydroxylycoctonine hydriodide (120 mg) was dissolved in hot purified dioxane. $LiAlH_4$ ether solution (15 cc) was added and the temperature raised until the ether evaporated. The solution was refluxed for ½ hour. Excess $LiAlH_4$ was destroyed using methanol and the solvent removed *in vacuo*. The residue was suspended in saturated Rochelle salt solution and extracted with methylene chloride yielding 89 mg of clear glass. This crystallized from aqueous methanol giving 50 mg, m.p. 164–171°. After two recrystallizations the product melted at 174–177° and had $[\alpha]_D$ −21° (*c*, 1.25). It did not depress the melting point of dihydroisolycoctonine, described above, and the infrared spectra of the two compounds were identical.

Isolycoctonam

Isolycoctonine (3.23 g) was dissolved in 130 ml of acetone containing 1 ml of acetic acid and 1 ml of water. Powdered potassium permanganate (1.94 g) was then added portionwise over a period of 3 hours. The last portion persisted for ¾ hour. Sulphur dioxide was then passed into the solution to destroy excess permanganate, and the solution filtered and evaporated. The residue was dissolved in methylene chloride, washed first with dilute H_2SO_4, and then with dilute Na_2CO_3 solution. After drying (Na_2SO_4) the methylene chloride was removed to give 2.40 g of neutral product. Crystallization from acetone–hexane gave 2.02 g of white crystalline material m.p. 181–184°. Recrystallization from the same solvent raised the m.p. to 182–184°. Found: C, 62.21; H, 7.99. Calc. for $C_{25}H_{39}O_8N$: C, 62.35; H, 8.16%. $[\alpha]_D^{24}$ +45.2° (*c*, 0.93 in ethanol); ν_{max} (Nujol): 3410 (OH), 1702 (ketone), 1620 and 1640 (lactam). The dilute sulphuric acid solution when made alkaline and extracted with methylene chloride yielded 0.346 g of isolycoctonine (melting point and mixed melting point).

Isolycoctonam Acetate

When prepared using acetic anhydride – pyridine, this compound crystallized from acetone–hexane as blades, m.p. 180–181°. Found: C, 61.79; H, 7.77. Calc. for $C_{27}H_{41}O_9N$: C, 61.93; H, 7.89.

17-Desoxyhydroxylycoctonine

A solution of 310 mg of 17-desoxylycoctonine (I, R = CH_3) in 10 ml of acetic acid and 20 ml of a saturated solution of lead tetraacetate in acetic acid was allowed to stand at room temperature for ¾ hour. Excess tetraacetate was then destroyed with a saturated aqueous solution of sodium bisulphite and lead salts precipitated by the addition of a saturated aqueous solution of sodium sulphate. The precipitate was removed by centrifugation. The precipitate was thoroughly washed with acetic acid and the solutions combined and evaporated. The residue was then dissolved in methylene chloride and washed with dilute sodium carbonate solution and water. After the methylene chloride solution was dried, (Na_2SO_4) it was evaporated leaving a froth (313 mg). The base was not obtained in the crystalline form but its perchlorate crystallized readily from acetone – ethyl acetate as colorless prisms (283 mg) m.p. 199–209°. Three recrystallizations raised the melting point to 203–207° C. Found: C, 54.67; H, 7.2. Calc. for $C_{25}H_{40}O_{10}NCl$: C, 54.55; H, 7.23. Infrared spectrum (Nujol): 3410 (OH), 1715 (ketone), 1673 ($\rangle C{=}\overset{\oplus}{N}\langle$).

17-Desoxyisolycoctonine

17-Desoxyhydroxylycoctonine (220 mg) was reduced with hydrogen and prereduced PtO_2 (120 mg) in acetic acid (18 ml). One mole of hydrogen was absorbed in 20 minutes. After the solvent was removed the residue was dissolved in methylene chloride and washed with dilute sodium carbonate solution and water. Evaporation of the solution after drying (Na_2SO_4) gave a syrup (231 mg) which crystallized as colorless prisms from acetone–hexane, m.p. 155–161° C. Two further crystallizations gave a pure product (184 mg), m.p. 162–164° C. Found: C, 66.54; H, 8.97. Calc. for $C_{25}H_{41}O_6N$: C, 66.49; H, 9.15%. $[\alpha]_D^{27}$ +41.7° (*c*, 0.96). Infrared spectrum (Nujol): 3425 (OH), 1715 (ketone).

17-Desoxyisolycoctonam

17-Desoxyisolycoctonine (320 mg) was dissolved in pyridine (5 ml) and to this was added at 0° C the complex derived from chromic anhydride (321 mg) and pyridine (5 ml).

After standing at room temperature for 24 hours, sulphur dioxide was bubbled through the solution, the solution evaporated, and the residue dissolved in 3 *N* sulphuric acid. This was extracted with methylene chloride, the methylene chloride washed with dilute sodium carbonate solution, dried, and evaporated. The neutral material (254 mg) was chromatographed on alumina (3 g, activity II). Benzene (150 ml) and 5% $CHCl_3$–benzene eluted material (220 mg) which crystallized from acetone–hexane in colorless prisms, m.p. 145–148° C. Two recrystallizations raised the melting point to 147–149° C. Found: C, 64.55; H, 8.15. Calc. for $C_{25}H_{39}O_7N$: C, 64.49; H, 8.44. Infrared spectrum (Nujol): 3410 (OH), 1707 (ketone), 1649 (lactam).

Environment of the Nitrogen

(*a*) Isolycoctonine was recovered quantitatively after 1 hour in aqueous nitrous acid solution.

(*b*) Desoxyisolycoctonine was recovered in 84% yield after 4 hours' heating at 100° with 50% acetic anhydride – pyridine mixture.

(*c*) Desoxyisolycoctonam (75 mg) in 1 ml of methanol and 4 ml of 1 *N* sulphuric acid was heated for 24 hours at 100° C and 24 hours at 160° C in a sealed tube. The filtered solution was basified and distilled until approximately 1 ml remained. Picric acid (70 mg) was added to the distillate and the solution evaporated. Extraction of the dry residue with ether left no residue of ethylamine picrate.

The residue after the initial distillation was acidified with sulphuric acid and again distilled. The distillate was neutral showing the absence of acetic acid.

Lead Tetraacetate on Isolycoctonam Monoacetate

A solution of 12.6 mg of the acetate in 10 ml of a saturated solution of lead tetraacetate in glacial acetic acid to which had been added 0.5 ml of water was titrated at intervals. The mole ratio of lead tetraacetate consumed was 0.31 (28 hours), 0.68 (73 hours), 0.94 (96 hours).

Lead Tetraacetate Cleavage of Isolycoctonam

Isolycoctonam (200 mg) was dissolved in 40 ml of a saturated solution of lead tetraacetate in glacial acetic acid containing 2.4 ml of water. After 120 hours at room temperature, hydrogen sulphide was passed into the solution until the precipitation of lead sulphide was complete. The solution was filtered through Hyflo Supercel, the acetic acid removed, and the residue taken up in dilute sodium carbonate. After the carbonate solution was washed with chloroform, it was acidified with dilute H_2SO_4 and extracted with chloroform. Evaporation of the dried extract gave 195 mg of a white froth. This crystallized from benzene–hexane as white prisms m.p. 162–172°. ν_{max} ($CHCl_3$), 1737 (lactone), 1704 (ketone), 1670 (α-β unsaturated ketone), 1635 (lactam). Found: C, 63.91; H, 7.76. Calc. for $C_{25}H_{37}O_8N$: C, 62.61; H, 7.78. This indicates the product to be a mixture of the expected *seco*ketolactone and its desmethanol derivative VIII.

Desmethanol Keto Lactone (VIII)

Crude acidic material (500 mg) as obtained above was dissolved in 1 ml of ethanol, 20 ml of 6 *N* H_2SO_4 was added, and the solution heated at 90° C for $\frac{1}{2}$ hour. After extraction with $CHCl_3$, washing with water, and drying (Na_2SO_4), the extract yielded 477 mg of froth. Crystallization from acetone–hexane gave 376 mg of crystalline material. After three recrystallizations it had a melting point of 255–258°. Found: C, 64.87; H, 7.29; OCH_3, 20.64. Calc. for $C_{24}H_{33}O_7N$: C, 64.41; H 7.43; $3OCH_3$, 20.8. $[\alpha]_D^{24}$ −104°; ν_{max} ($CHCl_3$), 1738 (lactone), 1671 (α-β unsaturated ketone), 1635 (lactam); λ_{infl} 225 mμ (ϵ 8230), λ_{max} 305 mμ (ϵ 57).

Action of Lead Tetraacetate on 17-Desoxyisolycoctonam

17-Desoxyisolycoctonam (556 mg) was treated with lead tetraacetate in the same manner as described for isolycoctonam. Separation of the product into neutral and acidic fractions gave 320 mg of starting material and 120 mg of acidic material.

The acidic material (100 mg) was heated at 70° C for ½ hour with 6 *N* sulphuric acid (5 cc). Extraction of the cold solution with chloroform followed by washing with water, drying (Na_2SO_4), and evaporation of the chloroform yielded 38 mg froth which crystallized from acetone–hexane as colorless plates, m.p. 248–252°. Two further recrystallizations gave material of m.p. 251–253 (decomp.). Found: C, 63.99; H, 7.69. Calc. for $C_{24}H_{35}O_7N$: C, 64.12; H, 7.85. Infrared spectrum (Nujol): no OH, 1732 (—COOH), 1677 (α-β unsaturated ketone), 1597 (lactam), 692 (*cis*-disubstituted double bond).

8-Deoxyisolycoctonam

Isolycoctonam (302 mg) in a mixture of acetic acid and 10 ml of acetic anhydride was heated under reflux, and then zinc dust (15 g) was added portionwise over a period of 1½ hours. The cold solution was filtered and evaporated. Methanol was added and the solution evaporated. The residue was then dissolved in methylene chloride, washed with dilute sodium carbonate solution, dried (Na_2SO_4), and evaporated to give 327 mg of a colorless oil.

Hydrolysis of this material was accomplished by refluxing for 1 hour a solution of the above oil in 3% potassium hydroxide in 60% aqueous methanol. After most of the methanol was removed, water (15 ml) was added and the solution extracted with methylene chloride. Evaporation of the dried extract gave 273 mg of a colorless froth which was chromatographed on alumina (8.2 g activity III). Chloroform and chloroform–methanol eluted 192 mg of material which crystallized from ether. Recrystallization from ether–hexane gave colorless prisms, m.p. 110–125°. Found: C, 64.62; H, 8.44; OCH_3, 26.46. Calc. for $C_{25}H_{39}O_7N$: C, 64.49; H, 8.44; $4OCH_3$, 26.63. Infrared spectrum (Nujol): 3360 (OH), 1695 (ketone), 1645 (lactam).

Action of Sodium Amalgam on 8-Deoxyisolycoctonam

8-Deoxyisolycoctonam (50 mg) was dissolved in 5 ml absolute ethanol, and 5% sodium amalgam (600 mg) added. After the solution was shaken for 1½ hours it was filtered, evaporated to 1 ml, diluted with water, and extracted with methylene chloride. The dried extract yielded 38 mg of froth. This crystallized from ether as plates, m.p. 176–189°. Two recrystallizations from acetone–ether raised the melting point to 197–199°. $[\alpha]_D^{24}$ −29.1° (*c*, 0.79 in ethanol). Found: C, 66.08; H, 8.83; OCH_3, 21.63. Calc. for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98; $3OCH_3$, 21.27%. Infrared spectrum (Nujol): 3365 and 3480 (OH), 1605 (lactam).

Desmethanol secohydroxylycoctonam Ketolactone Isomer (XIV)

A solution of 37 mg of desmethanol *seco*hydroxylycoctonam "diketone" monoacetate (1) in a mixture of 5 ml of methanol and 5 ml of 2.5% aqueous potassium hydroxide was refluxed for 40 minutes. After the methanol was removed, the solution was extracted with chloroform. This extract, after drying, yielded 1 mg of material. The aqueous solution was acidified (H_2SO_4), extracted with chloroform, the extract washed with water, dried, and evaporated. The residue, 34 mg, crystallized from acetone–hexane and after two recrystallizations had m.p. 235–242° C. Its infrared spectrum (1745 (lactone), 1708 (ketone) (weak), 1675 (α-β unsaturated ketone), 1650 (lactam)) showed this to be predominantly an α-β unsaturated keto-δ-lactone. The compound was dried

for 7 hours at 140°, 1×10^{-3} mm. Found: C, 60.61; H, 7.66. Calc. for $C_{24}H_{33}O_8N.\frac{1}{2}H_2O$: C, 61.01; H, 7.25.

Strongly Adsorbed Lead Tetraacetate Cleavage Product

(*a*) A solution of 13 mg of the compound (dried for 10 hours at 100°, 1×10^{-3} mm; found: C, 60.07; H, 7.40; calc. for $C_{25}H_{37}O_9N$: C, 60.59; H, 7.53) in 2 ml of 2.5% potassium hydroxide solution was heated on the steam bath for 55 minutes. The yellow solution was extracted thoroughly with chloroform and the chloroform extracts backwashed with dilute alkali. The combined aqueous layers were acidified and extracted with chloroform giving 11 mg of acid which could not be induced to crystallize.

(*b*) Adsorption of the compound on a 25-fold ratio of acid-washed alumina, activity 3, failed to eliminate cleanly the elements of methanol.

(*c*) The compound was subjected to flash pyrolysis at 220°, 1×10^{-3} mm in 5-mg lots. The colorless glass which distilled out of the hot zone crystallized readily from acetone–ether giving a first crop, m.p. up to 220°. After two recrystallizations the compound melted at 235° with sintering at 225°, ν_{max} 3440, 1745, 1673, 1650 cm^{-1}. This did not depress the melting point of the 242° lactone (XIV) and the two gave identical X-ray powder patterns.

Action of N-*Bromosuccinimide on 17-Desoxyisolycoctonine*

A solution of 18 mg N-bromosuccinimide in 3 ml of dry ethanol-free chloroform was added to a solution of 37 mg of 17-desoxyisolycoctonine in 1 ml dry, ethanol-free chloroform. An immediate yellow color developed which slowly faded and was replaced by a slight pink coloration. After 5 minutes no N-bromosuccinimide remained (starch–iodide test), and the solution was diluted with chloroform, washed with dilute Na_2SO_3 solution, dried, and evaporated. The residual 42 mg of oil was converted to its perchlorate, which could not be induced to crystallize. The corresponding hydrochloride had ν_{max} 2680, 2470, 1602 cm^{-1} ($\rangle\overset{\oplus}{N}H_2$) and 1673 cm^{-1} ($\rangle C{=}\overset{\oplus}{N}\langle$).

The product obtained by refluxing a solution of the amorphous hydrochloride in dimethylformamide for more than 1 hour failed to crystallize or give a crystalline perchlorate. Isoatisine hydrochloride was 50% isomerized (by rotation) on refluxing for $\frac{1}{2}$ hour in this solvent.

Parallel experiments using osmium tetroxide as oxidizing agent were similarly unsuccessful.

ACKNOWLEDGMENTS

The authors are grateful to Professor G. Büchi for informing us of his conclusions regarding the structure of hydroxylycoctonine. We thank Mr. R. Lauzon for obtaining the infrared spectra, Mr. H. Seguin for the analyses, Mr. M. Lesage and Mr. Allan Knoll for technical assistance, and Dr. M. Przybylska for the comparison of X-ray powder patterns.

THE CARBONYL STRETCHING BANDS IN THE INFRARED SPECTRA OF UNSATURATED LACTONES[1]

R. N. JONES, C. L. ANGELL,[2] T. ITO,[2] AND R. J. D. SMITH[3]

ABSTRACT

Certain types of unsaturated lactones exhibit two bands in the region of the spectrum associated with the C=O stretching vibrational mode. This is observed both in the infrared and Raman spectra.

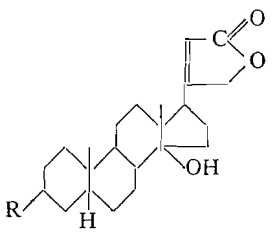
The infrared spectra of 23 simple saturated and unsaturated lactones have been examined in an attempt to determine the structural features with which this carbonyl band splitting is associated. It appears to be common to most unsaturated five- and six-membered ring lactones in which the double bond is conjugated with the carbonyl group, though one well-established exception has been observed. The relative intensities of the two bands are extremely sensitive to changes in the polarity of the solvent; they also vary reversibly with temperature but are independent of concentration.

The splitting of the C=O stretching band is attributed to an intramolecular vibrational effect similar to that which occurs in cyclopentanone and in certain Δ^2-cyclopentenone derivatives. Its possible dependence on Fermi resonance with the overtone of a lower lying fundamental vibration is discussed.

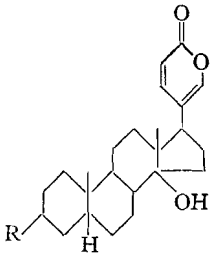
Similar effects occur in other types of carbonyl compounds, such as benzoyl chloride and cyclic five-membered ring anhydrides, and care is needed to distinguish carbonyl band splitting of this kind from that associated with equilibria between conformational isomers.

INTRODUCTION

In the course of a systematic survey of the infrared spectra of steroids, it was observed (1, 2) that compounds containing the unsaturated lactone rings of I and II show anomalous absorption in the region of the carbonyl stretching bands. The single absorption band



I



II

expected for the stretching vibration of the lactone carbonyl is replaced by two bands, the relative intensities of which are extremely sensitive to the solvent polarity.

The steroids in which the effect was first observed contained hydroxy and acetoxy groups in addition to the lactone ring; this complicated study of the lactone carbonyl absorption and suggested that the bands might involve inter- or intra-molecular hydrogen bonding, or some other interaction between the lactone and the functional groups of the ring system. The spectra of a series of simple model compounds have therefore been

investigated. These compounds show the same anomalies as the steroid lactones, and the effects of solvent, temperature, and small structural changes on the carbonyl stretching band system have been investigated.

EXPERIMENTAL

The compounds examined have the structures III–XXV; they include four saturated γ-lactones (III–VI), 13 unsaturated γ-lactones (VII–XIX), one saturated δ-lactone (XX), and five unsaturated δ-lactones (XXI–XXV). The majority of these compounds were synthesized specifically for this investigation, and the preparative details and structural characterization are noted briefly below.

Synthesis and Characterization of Compounds

III. *β-n-Hexyl-butanolide.*—Prepared by hydrogenation of VIII with 5% Pd on charcoal in methanol at 1 atm H_2.

IV. *γ-Methyl-butanolide.*—Prepared from XIII by hydrogenation under the same conditions as III, b.p. 83° (10 mm).

V. *γ,γ-Dimethyl-butanolide.*—Prepared as III from XIV, b.p. 80° (10 mm).

VI. *trans-Cyclohexanol-2-acetic acid lactone.*—Prepared as described by Newman and VanderWerf (3), b.p. 142° (20 mm).

VII. *$\Delta^{\alpha\beta}$-Butenolide.*—Prepared as described by Smith and Jones (4), b.p. 86–87° (12 mm). Found: C, 57.03%; H, 4.94%. Calc.: C, 57.14%; H, 4.80%.

VIII. *β-n-Butyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as described by Rubin, Paist, and Elderfield (5); the product was repeatedly distilled until free from bromine, b.p. 101–101.5° (1 mm) n_D^{20} 1.4715.

IX. *β-n-Hexyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as VIII, b.p. 120–121° (2 mm). Found: C, 70.99%; H, 9.63%. Calc.: C, 71.40%; H, 9.59%.

X. *β-Cyclopentyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as VIII, b.p. 120–121° (2 mm). Found: C, 70.18%; H, 8.00%. Calc.: C, 71.02%; H, 7.95%.

XI. *β-Cyclohexyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as VIII, b.p. 143–144° (5 mm). Found: C, 72.36%; H, 8.61%. Calc.: C, 72.28%; H, 8.43%. Ultraviolet spectrum: λ_{max} 2215 Å log ϵ_{max} 3.33 (*n*-heptane solution).

XII. *β-Phenyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as VIII. Recrystallized five times from 75% aqueous methanol, m.p. 94°. Ultraviolet spectrum: λ_{max} 2020 Å log ϵ_{max} 4.34; λ_{max} 2070 Å log ϵ_{max} 4.24; λ_{max} 2530 Å (broad) log ϵ_{max} 4.37 (*n*-heptane solution).

XIII. *β-Angelica lactone.*—Prepared by isomerization of the α-isomer with triethylamine (6). Some residual α-isomer was removed by hydrolysis and redistillation (7) but the product still contained 7–10% of the α-isomer as estimated from the infrared spectrum, b.p. 83° (10 mm).

XIV. *γ,γ-Dimethyl-$\Delta^{\alpha\beta}$-butenolide.*—Prepared as described by Haynes and Jones (8) and purified by chromatography on a neutralized alumina column from petroleum ether – benzene (2:1), b.p. 80° (10 mm).

XV. *(2-Hydroxy-1-cyclohexylidine)-acetic acid lactone.*—Prepared as described by Newman and VanderWerf (3), b.p. 130° (5 mm); m.p. 30°. Ultraviolet spectrum: λ_{max} 2215 Å log ϵ_{max} 3.26 (*n*-heptane solution).

XVI. *Phthalide.*—Commercial sample recrystallized twice from water, m.p. 72°.

XVII. *5,6-Dimethoxyphthalide.*—Sample provided by Dr. O. E. Edwards. Recrystallized twice from water, m.p. 156–157°.

XVIII. *α-Angelica lactone.*—Commercial sample purified by distillation, b.p. 52° (10 mm); m.p. 18°.

XIX. *2-Hydroxy-(Δ^1-cyclohexenyl)-acetic acid lactone.*—Prepared as described by Newman and VanderWerf (3), b.p. 110° (5 mm).

XX. *δ-Valerolactone.*—Prepared by hydrogenation of XXI under the same conditions as III, b.p. 107° (7 mm).

XXI. *5,6-Dihydro-α-pyrone.*—Prepared as described by Haynes and Jones (8), b.p. 105° (7 mm). Ultraviolet spectrum: λ_{max} 2195 Å log ϵ_{max} 2.87 (*n*-heptane solution).

XXII. *α-Pyrone.*—Prepared as described by von Pechmann (9), m.p. 5°.

XXIII. *5-Methyl-α-pyrone.*—Prepared as described by Fried and Elderfield (10), m.p. 17–19°.

XXIV. *Coumarin.*—Commercial sample purified by vacuum sublimation, m.p. 70°.

XXV. *γ-Pyrone.*—Sample supplied by Dr. O. E. Edwards, m.p. 32°.

Spectroscopic Measurements

Most of the infrared spectra were measured in carbon tetrachloride, carbon disulphide, or chloroform solution on a Perkin–Elmer 112 spectrometer. A calcium fluoride prism was used above 1300 cm^{-1} and a sodium chloride prism below. After correction for background and solvent absorption the spectra were plotted as apparent molecular extinction coefficient against wave number (11). Several of the spectra were also determined as thin liquid films on a Perkin–Elmer Model 21 spectrophotometer with sodium chloride prism. The estimated precision of the carbonyl band positions reported in Tables I and II is ± 2 cm^{-1}. Only portions of selected spectra are shown here, but the complete series of spectra will be published separately (12). A standard Perkin–Elmer heated cell was used to obtain the spectra of liquid films at elevated temperatures, and the spectrum of β-phenyl-$\Delta^{\alpha\beta}$-butenolide at liquid nitrogen temperature was measured on equipment kindly made available to us by Dr. H. J. Bernstein.

have measured the ultraviolet absorption spectra of $\Delta^{\alpha\beta}$-butenolides in ethanol solution, and under these conditions the maximum occurs near 2100 Å. The band is displaced bathochromically to 2200–2215 Å in *n*-heptane, where it is more easily observed and more precisely measured. A representative ultraviolet spectrum in *n*-heptane has been published elsewhere (4).

Molecular Weight Measurements

Molecular weights in solution were kindly determined for us by Dr. A. F. Sirianni of the Applied Chemistry Division of the National Research Council by measurement of the depression of the solvent vapor pressure, using the technique developed by Puddington (14).

RESULTS

The typical doublet carbonyl absorption of the conjugated unsaturated γ- and δ-lactones is illustrated by the infrared spectra of $\Delta^{\alpha\beta}$-butenolide (VII), β-cyclopentyl-$\Delta^{\alpha\beta}$-butenolide (X), and 5-methyl-α-pyrone (XXIII) in Figs. 1–3. It is characteristic of this absorption that the high frequency component (Band *A*) is more intense in carbon tetrachloride, and the relative intensities tend to reverse in chloroform solution. This is identical with the behavior of the lactone carbonyl bands of the steroids I and II. The positions and intensities of these bands for all lactones exhibiting the doublet absorption are given in Table I, while the carbonyl bands of lactones showing normal behavior are summarized in Table II.

Before discussing this absorption it will be convenient first to record some additional experiments that illustrate the effect of various environmental factors on these bands.

FIG. 2. Infrared spectrum of β-cyclopentyl-$\Delta^{\alpha\beta}$-butenolide in the region of the C=O stretching absorption.
FIG. 3. Infrared spectrum of 5-methyl-γ-pyrone in the region of the C=O stretching absorption.

Most of these measurements were made with β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide (IX), as this was the lactone in most plentiful supply. The phenyl derivative (XII) with melting point 94° was used for solid phase studies since most of the other lactones are liquids or low melting solids. We are satisfied, however, that these effects are general to all the lactones exhibiting the split carbonyl bands.

Solvent Effects

In carbon disulphide the spectrum of β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide in the region of the carbonyl bands is similar to that in carbon tetrachloride, while the spectrum of the pure liquid is similar to that in chloroform. The spectrum in acetonitrile and methanol also resembles the spectrum of the chloroform solution, but the inversion of the band intensities is more accentuated (Table III). These band intensity changes are reversible when the same sample of lactone is examined successively in a series of different solvents.

In the last two columns of Table III are given the dipole moments and dielectric constants of the solvents. Although the relative intensity of the low frequency band (Band *B*) increases with the solvent polarity, the relationship is not a simple one. This, however,

†Percentage by weight.

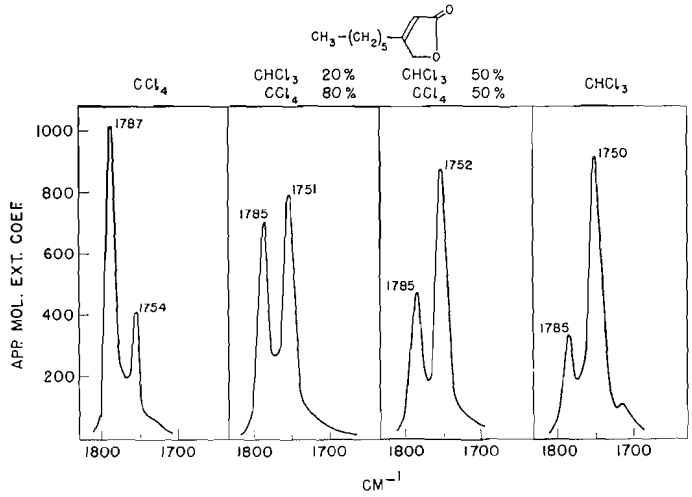

FIG. 4. Effect of solvent on the C=O stretching absorption of β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide.

would hardly be expected in the light of recent studies of solvent effects (15). The sensitivity of the bands to the solvent polarity is illustrated by the curves for mixed carbon tetrachloride/chloroform solvents shown in Fig. 4. With increase in the chloroform concentration the relative intensities of the bands change progressively; the position of Band *A* remains unchanged while Band *B* shifts slightly from 1754 cm^{-1} to 1750 cm^{-1}. Saturation of either solvent with dry hydrogen chloride, which might catalyze a chemical bond shift, has no effect on the band positions or intensities.

Concentration Effects

The spectrum of β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide in the region of the carbonyl stretching bands was measured both in carbon tetrachloride and in chloroform solution over a concentration range from 0.001 *M* to 0.03 *M*, and no significant change in the ratios of the band intensities was observed. When this is considered in conjunction with the similarity of the spectrum of the pure liquid to that of the dilute solutions in chloroform, it strongly suggests that we are not dealing with an association phenomenon; this is borne out also by the molecular weight measurements discussed below.

For personal use only.

Temperature Effects

The effect of temperature increase on the spectra of liquid films of β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide and 5-methyl-α-pyrone is shown in Figs. 5 and 6. In both cases there is a pronounced enhancement of the relative intensity of the high frequency component as the temperature rises. This effect is reversed on cooling. The decrease in the absolute intensity in the heated film in Fig. 5 is a secondary consequence of the decrease in the thickness of the capillary film layer.

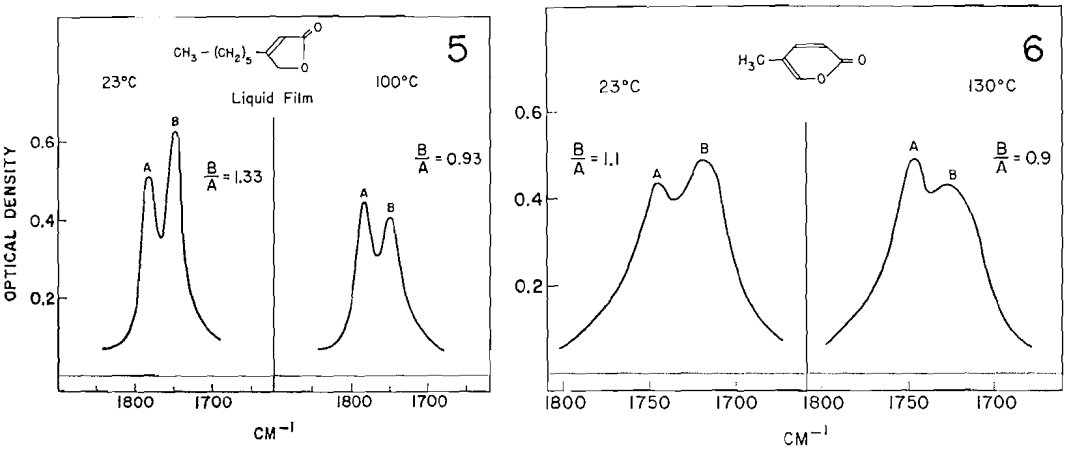

FIG. 5. Effect of temperature on the C=O stretching absorption of a liquid film of β-*n*-hexyl-$\Delta^{\alpha\beta}$-butenolide.

FIG. 6. Effect of temperature on the C=O stretching absorption of a liquid film of 5-methyl-γ-pyrone.

The spectrum of β-phenyl-$\Delta^{\alpha\beta}$-butenolide, measured as a crystalline film at room temperature and when cooled with liquid air, is shown in Fig. 7. Both spectra show the doublet carbonyl peaks. The minor bands and inflection may be due to incomplete compensation for water vapor absorption.

Raman Spectra

The Raman spectra of $\Delta^{\alpha\beta}$-butenolide and its β-*n*-butyl derivative have been determined for the pure liquids and for solutions in carbon tetrachloride and chloroform. The

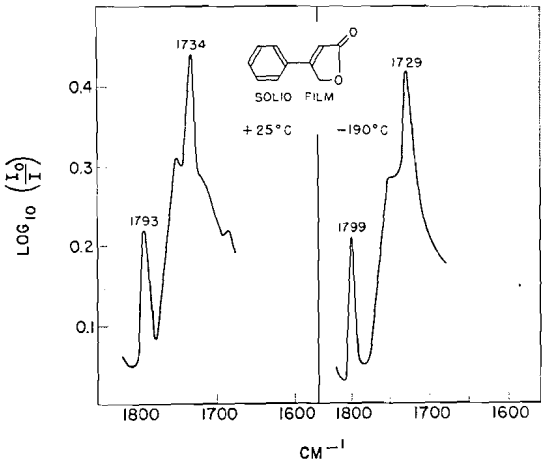

FIG. 7. Effect of temperature on the C=O stretching absorption of a solid crystalline film of β-phenyl-$\Delta^{\alpha\beta}$-butenolide.

Raman spectrum of β-phenyl-$\Delta^{\alpha\beta}$-butenolide was also measured in both solvents. These spectra show the same doublet carbonyl bands as do the infrared spectra with intensity variations in the same sense. The C=C stretching bands are relatively more intense than in the infrared spectrum, as is normally the case. A representative pair of Raman spectra is shown in Fig. 8.

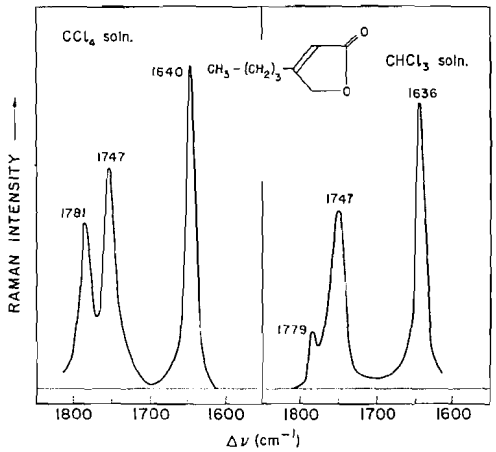

FIG. 8. Effect of solvent on the C=O stretching bands in the Raman spectrum of β-*n*-butyl-$\Delta^{\alpha\beta}$-butenolide.

Molecular Weights in Solution

Accurate molecular weight determinations on solutions of the lower melting and liquid lactones could not be obtained because of their finite vapor pressure. Measurements are reported in Table IV for β-phenyl-$\Delta^{\alpha\beta}$-butenolide (m.p. 74°) and for digitoxigenin acetate (I) (R = —OAc) (m.p. 217°). Although these data all indicate some degree of association in solution, there is no significant difference between the measurements in the more polar and less polar solvents that might reasonably be correlated with the spectral changes. The spectrum of β-phenyl-$\Delta^{\alpha\beta}$-butenolide in benzene shows the typical non-polar solvent pattern with strong reversal of the band intensity in ethanol. These molecular weight measurements therefore exclude any explanation of the carbonyl band splitting based on dimeric or polymeric association.

DISCUSSION

The infrared literature contains numerous examples of monocarbonyl compounds that exhibit two or more prominent bands between 1900 and 1650 cm^{-1}. In the absence of other acceptable explanations, both bands are usually assigned to vibrations involving the carbonyl group. In a number of cases these doublet carbonyl peaks have been attributed to equilibria between conformational isomers.

This interpretation is usually based on the demonstration that the relative intensities of the two peaks are temperature- and solvent-dependent, but are independent of the concentration. It must also be possible to write a pair of conformationally isomeric structures that are plausible on both thermodynamic and spectroscopic grounds. This requires that the energy difference between the two forms will be small enough to allow a significant concentration of the less stable form to exist in equilibrium at room temperature, while the energy barrier to interconversion must be small enough to permit rapid attainment of the equilibrium. It is also necessary that the inductive, mesomeric, and field effects on the carbonyl group must differ sufficiently in the two forms to induce a significant displacement of the two carbonyl frequencies.

The doublet carbonyl peaks of the lactones considered here do show the necessary solvent and temperature dependence and concentration independence, but for them it is not possible to write pairs of stable conformationally isomeric structures within the framework of current views of molecular structure. A similar situation occurs for cyclopentanone (16), which also exhibits a split carbonyl band, and for certain Δ^2-cyclopentenones that have been studied by Yates and his collaborators (17, 18). In both the latter cases it has been shown that the splitting of the carbonyl band must involve an intramolecular vibrational property of the molecule, since it disappears when certain of the hydrogen atoms are exchanged for deuterium. So far our attempts to introduce deuterium into the αβ-unsaturated-γ-lactone ring have been unsuccessful, but there can be little doubt that the nature of the carbonyl band splitting is similar to that in cyclopentanone and in the Δ^2-cyclopentenones.

Assuming that an intramolecular vibrational effect is involved, it must depend on some form of coupling between the carbonyl stretching mode and another vibration. This would seem to require an accidental degeneracy between the C=O stretching mode and an overtone or combination band, i.e. a Fermi resonance. We have come to accept this explanation for the lactone spectra with some reluctance, since, a priori, it seemed highly unlikely that such accidental degeneracy would occur through such a wide range of different types of structure. Thus it is necessary that the overtone or combination band must be entirely uninfluenced by the nature of the substituent on the

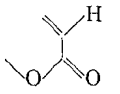
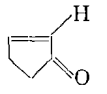
β-carbon atom. The lack of coupling between the vibrations in the ring and in the β-side chain of the $\Delta^{\alpha\beta}$-butenolides is demonstrated in the spectrum of the β-phenyl derivative. The carbonyl bands of this compound show practically no shift from those of compounds containing β-alkyl groups (cf. VIII and XII in Table I). Models demonstrate that in β-phenyl-$\Delta^{\alpha\beta}$-butenolide there is no steric hindrance to a structure in which the aromatic and lactone rings are coplanar, but nevertheless there must be negligible π-electron flow between the rings in the ground state of the molecule.

In terms of a Fermi resonance hypothesis, it is also surprising that the perturbation effects on the five- and six-membered ring lactones should be identical (cf. Figs. 2 and 3). In looking for common structural features among the compounds in Table I we do observe that all contain the partial structure XXVI, and this closely resembles XXVII which Yates and Williams have demonstrated to be necessary for carbonyl band splitting in Δ^2-cyclopentenones (18). On the other hand it must also be noted that the $\alpha\beta$-un-



XXVI



XXVII

saturated-δ-lactone XXI which does contain the partial structure XXVI shows the normal singlet carbonyl maximum. The possibility must be considered that an element of fortuitousness exists in the seemingly similar behavior of the γ- and δ-lactones, and this will arise again when numerical relationships with possible low-lying fundamental vibrations are considered. In γ,γ-dimethyl-$\Delta^{\alpha\beta}$-butenolide (XIV) the doublet is also rather poorly resolved.

In the infrared spectra of the saturated five-membered ring lactones (III–VI) the singlet carbonyl peak occurs at 1795–1785 cm^{-1} in carbon tetrachloride solution. In the absence of vibrational perturbation effects, this frequency would be expected to fall by about 20 cm^{-1} on introduction of the conjugated double bond to form the $\Delta^{\alpha\beta}$-butenolide ring. This would place the "normal" $\Delta^{\alpha\beta}$-butenolide carbonyl band in the range 1775–1765 cm^{-1}. However, the shortening of the $\alpha\beta$-bond will reduce the internal ring angles, and this will have a secondary effect, changing the hybridization to put more sp^2 character into the external bonds, and raising the carbonyl frequency slightly, perhaps to 1780–1770 cm^{-1}.

A survey of the complete spectra of the $\Delta^{\alpha\beta}$-butenolides (12) shows that there is usually a band (ν_2) in the region 900–875 cm^{-1}, the first overtone of which ($2\nu_2$) might couple with the carbonyl stretching mode to provide the postulated Fermi resonance split. These frequency relationships are summarized in Table V. In most of the compounds ν_2 is one of the strongest bands in this region of the spectrum. It might be identified with the out-of-plane deformation vibration of the hydrogen atom on the α-carbon atom, and this would be consistent with the presence of structure XXVI. In some of the compounds, however (notably XIII and XIV), the band is weak.

From Table V it will be seen that ν_2 is displaced upwards with change from carbon tetrachloride to chloroform solvent, while ν_1, the arithmetical mean of the two carbonyl frequencies, moves in the opposite direction. In the last column of Table V the difference $\nu_1 - 2\nu_2$ is given. In the absence of anharmonicity, the Fermi resonance coupling should depend inversely on the numerical value of this difference, irrespective of the sign. This might be changed if $2\nu_2$ is lowered below ν_1 by a strong anharmonicity term. $\Delta^{\alpha\beta}$-Butenolide itself is an exception, and for this compound stronger coupling would be expected

*Where the carbonyl frequency is measured in CCl_4 the value of ν_2 was taken from measurements in CS_2. For the measurements in $CHCl_3$ ν_2 was determined in the same solvent at a higher concentration in an 0.1-mm cell; these measurements were made through regions where the solvent is also absorbing, and the band positions may be displaced slightly on this account.

†These bands are weaker than those designated ν_2 in the spectra of the other compounds and their appearance suggests they are of a different origin (see reference 12).

in chloroform. The spectra in Figs. 1 and 2 give no indication of different behavior from the substituted $\Delta^{\alpha\beta}$-butenolides.

If we are indeed dealing with a Fermi resonance effect, the anharmonicity of the overtone vibration must be a major factor in connection with the sensitive solvent effects. The differential solvent displacements of the two unperturbed combining frequencies will influence the magnitude of the coupling, but in addition the resonance involves a perturbation function (designated w_{n1} by Herzberg (19)) which depends on the cubic and quartic terms of the potential energy. These terms may be considerably modified by the force fields in the solvent–solute complex, particularly in polar media. In regard to the effect of temperature on the resonance coupling, it will be noted from Figs. 4–6 that an increase in temperature alters the band intensities in the same sense as a decrease in solvent polarity. The temperature effect on the spectrum may therefore be an indirect consequence of the reduction of the polarity of the molecular environment at the higher temperature.

Additional difficulties appear when the δ-lactones are considered. Comparisons of the curves for β-cyclopentyl-$\Delta^{\alpha\beta}$-butenolide in Fig. 2 and 5-methyl-α-pyrone in Fig. 3 can leave little doubt that essentially the same phenomenon is involved in both cases. However, in the δ-lactone infrared spectra the bands that might reasonably be assigned to the out-of-plane C—H deformation of the α-hydrogen are displaced to 850–820 cm^{-1}. This would place the pure harmonic overtone at 1700–1640 cm^{-1}, and it would be necessary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

to invoke a large negative anharmonicity to raise this sufficiently to allow Fermi resonance with the carbonyl frequency. In the infrared spectra of the unsaturated δ-lactones there are no suitable infrared active bands nearer to the required position. It is of course possible that combination bands rather than overtone bands may be involved, or bands inactive in the infrared, as probably occurs in cyclopentanone (16). As yet we have had no opportunity to look for such bands in the Raman spectra.

Similar Effects in Other Compounds

A survey of other compounds has shown that this type of carbonyl band splitting may be much more widespread than is generally recognized.

In open chain acid anhydrides, the appearance of two carbonyl stretching bands is well known and, although probably a vibrational resonance phenomenon, it is distinct from the effect we are considering here. In five-membered ring cyclic anhydrides, however, it was noted first by Cooke (20) that the carbonyl band of lower frequency can itself be resolved into a doublet if the spectrum is measured with good dispersion. We have studied this band in maleic anhydride, phthalic anhydride, and naphthalene-1,2-dicarboxylic anhydride, and observe that the two components of the low frequency carbonyl band of these compounds show an intensity reversal with solvent change identical with that of the unsaturated lactones. This is illustrated for maleic anhydride in Fig. 9. This is not observed with the open chain anhydrides, and the cyclic structure seems to be essential.

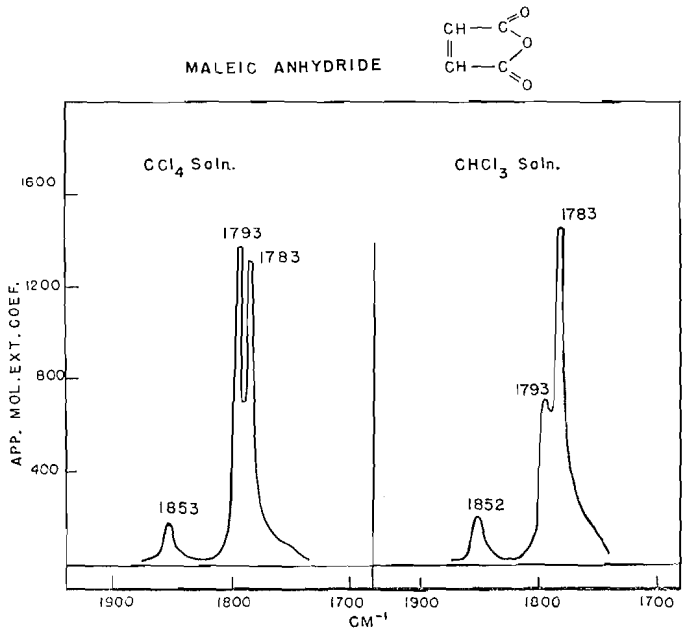

FIG. 9. Effect of solvent on the C=O stretching absorption of maleic anhydride.

The doubling of the carbonyl band in benzoyl chloride and some of its derivatives was first noted in the Raman spectrum by D. D. Thompson and J. F. Norris (21) in 1936, and subsequently by Flett in the infrared spectrum (22). We have confirmed Flett's observation, and it will be seen from Fig. 10 that with change of solvent from carbon tetrachloride to chloroform the low frequency "carbonyl" band of benzoyl chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

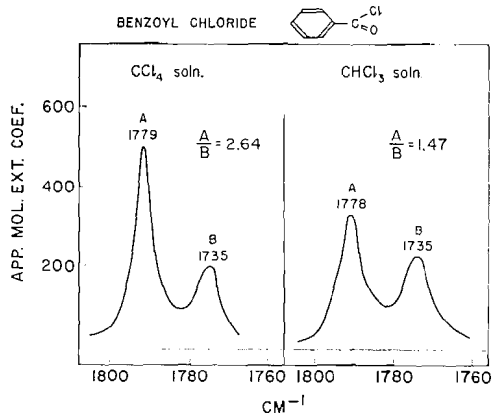

FIG. 10. Effect of solvent on the C=O stretching absorption of benzoyl chloride.

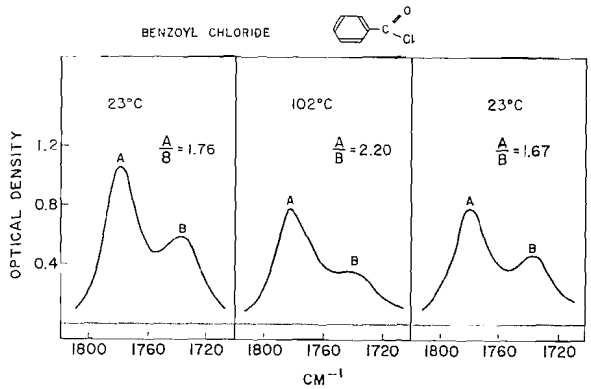

FIG. 11. Effect of temperature on the C=O stretching absorption of a liquid film of benzoyl chloride. The first spectrum at 23° C was determined before heating, and the second one after heating.

gains in intensity at the expense of the high frequency band. In both solvents the relative intensities of the "carbonyl" bands of benzoyl chloride have been shown to be independent of concentration over a 200-fold range. The two bands in the spectrum of the pure liquid show a reversible temperature effect, the high frequency band increasing relative to the low with rising temperature (Fig. 11). This also parallels the behavior of the unsaturated lactones. For benzoyl chloride one cannot write conformational equilibria involving *cis* $\rightleftharpoons$ *gauche* or *s-cis* $\rightleftharpoons$ *s-trans* forms, unless stable structures differing only in the angle between the chlorocarbonyl group and the benzene ring are considered; these are highly unlikely and here again we must resort to an interpretation based on an intramolecular vibrational phenomenon. It should be added that the possibility of the second carbonyl peak in the benzoyl chloride spectrum resulting from partial hydrolysis to benzoic acid has been disproved by the observation that on addition of small quantities of benzoic acid to liquid benzoyl chloride a third band appeared at 1695 cm^{-1}.*

We wish to thank Dr. K. Noack for making these measurements.

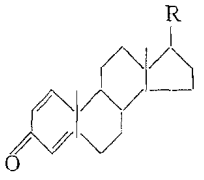
CONCLUSIONS

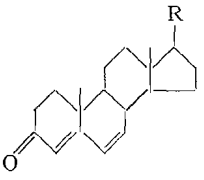
It will be apparent from the above discussion that we are not satisfied that the Fermi resonance hypothesis provides a full explanation of these effects, though there can be little doubt that some type of intramolecular vibrational effect is involved. It is to be hoped that experimental work of this kind will stimulate a more detailed theoretical study of vibrational resonance effects in complex molecules, with particular respect to the influence of solvent–solute interactions and other intermolecular force fields in the liquid phase.

The organic chemist, who is making increasing use of infrared spectra in the study of conformational isomerism and intermolecular association, must be on his guard for effects of the type discussed here. Even where it is possible to explain solvent- and temperature-dependent changes in spectra in terms of plausible conformational equilibria, such interpretations should not be accepted without further investigation. The demonstration that temperature- and concentration-dependent spectral changes can be observed in several widely separated regions of the spectrum will strongly substantiate an interpretation based on conformational isomerism. If, on the other hand, the spectral anomalies can be removed by selective deuteration, it must indicate that they have their origin in an intramolecular vibrational effect.

Finally, we must recognize that cases may arise where this type of vibrational resonance effect may be insufficient to induce a complete splitting of a band, but may broaden the band and modify its intensity and contour. This may explain the marked difference



XXVIII



XXIX

in the contours of the carbonyl bands associated with the steroid structures XXVIII and XXIX which are illustrated in Fig. 99 of reference 29.

It has been shown recently (23, 24) that the various kinetic "σ-constants" of Hammett, Taft, and Roberts can be evaluated from measurements of the intensities, positions, and half-widths of infrared absorption bands associated with vibrations localized in the reactive functional group (23, 24). As work of this kind is extended, it will be particularly important to watch for small perturbation effects of vibrational resonance which would probably have little if any effects on the chemical reactivity of the group, and may cause discrepancies between σ-constants derived from spectrographic and kinetic measurements.

ACKNOWLEDGMENTS

We wish to thank Mr. R. Lauzon and Mrs. M. A. MacKenzie for technical assistance with the measurement of the spectra. We are also grateful to Dr. A. F. Sirianni and Dr. I. E. Puddington of the Applied Chemistry Division of the National Research Council for the molecular weight measurements, Dr. O. E. Edwards for samples of 5,6-dimethoxyphthalide and γ-pyrone, and Mr. H. Seguin for carbon and hydrogen analyses.

ALIPHATIC CHEMISTRY OF FLUORENE

PART I. DERIVATIVES OF 9-BENZOYLFLUORENE[1]

P. M. G. Bavin

ABSTRACT

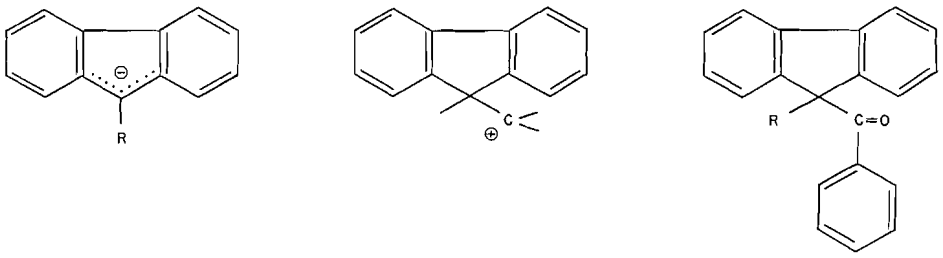
Several C-alkylation products of 9-benzoylfluorene have been prepared. 9-Methyl-9-benzoylfluorene has been transformed into 9-methyl-10-phenylphenanthrene, 9-phenylphenanthrene-10-carboxylic acid, and 1,2:3,4-dibenzfluorenone.

Phenyl-9-allyl-9-fluorenylmethanol has been cyclized and rearranged in one step to 14-methyl-13,14-dihydrodibenz[a,c]phenanthrene.

Phenyl-9-methyl-9-fluorenylmethyl chloride readily decomposes to 9-methyl-10-phenylphenanthrene when heated alone or in formic acid, but reacts with silver or mercuric acetates to give unrearranged acetate.

This series of papers will be concerned with reactions of fluorene anions (I), particularly where R is an electron-demanding group, and with systems potentially capable of forming cations (II), the products being utilized in the synthesis of complex polycyclic systems.

We have shown that methyl fluorene-9-carboxylate anion (I, R = CO_2CH_3) reacts rapidly with a very wide range of alkyl halides (1, 2). Of particular interest was the formation in good yield of the 9-*t*-butyl derivative (1). Experiments with 9-benzoylfluorene anion (I, R = $CO \cdot C_6H_5$) are now reported.



(I) (II) (III)

The keto form of 9-benzoylfluorene crystallizes from acetone as colorless needles which are insoluble in aqueous sodium hydroxide. The enol has been reported only as an oil which rapidly passes into the keto form. Solutions of either tautomer in alcoholic sodium alkoxide are deep orange, with the color attributed to the anion (I, R = $CO \cdot C_6H_5$) (3, 4), also referred to as the enolate ion.

Initial attempts to alkylate the anion (I, R = $CO \cdot C_6H_5$) with methyl or isopropyl iodides gave very low yields of the desired products, even when only 1 equivalent of methoxide ion was used to generate (I). The low yields were attributed to facile cleavage by strong base of the non-enolizable ketonic products, the cleavage being facilitated and its direction controlled by the formation of the mesomeric anion (I, R = alkyl), Fig. 1. These conclusions found support in the isolation of methyl benzoate and 9-methylfluorene among the products of attempted methylation.

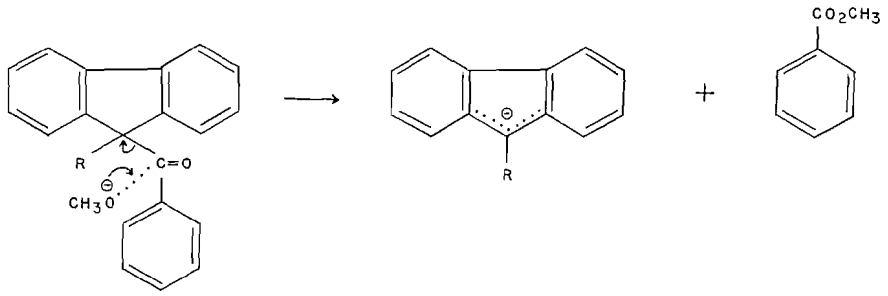

FIG. 1.

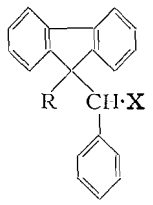
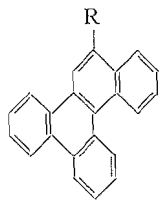
Weaker bases were next examined. Pyridine, piperidine, and triethylamine generated the anion (I) from 9-benzoylfluorene as shown by the color of methanolic solutions, but apparently formed quaternary salts too rapidly to permit C-alkylation. Suitable conditions were eventually found in the mixed solvent acetone–methanol containing a little water, with potassium carbonate as base. The 9-alkyl-9-benzoylfluorenes (III, R = alkyl) prepared in this way were methyl, ethyl, isopropyl, allyl, benzyl, and cyclohexyl, all in satisfactory yields. The reaction with *t*-butyl chloride followed a different course and will be discussed in a later paper.

The structures of the products were shown by their lack of color (the enol ethers would be yellow like other 9-fluorenylidene compounds, e.g. see (5)) and by the presence of carbonyl stretching absorption bands in their infrared spectra. In particular, the 9-methyl derivative formed an oxime in pyridine solution, was cleaved by strong base to 9-methylfluorene, and was reduced to an alcohol by lithium aluminum hydride.

Compounds of structure (IV) are potential phenanthrene intermediates through the cation (II). The transformations of 9-methyl-9-benzoylfluorene are summarized for clarity in Fig. 2. Reduction to the alcohol (IV, R = methyl; X = OH) followed by dehydration–rearrangement brought about by phosphorus pentoxide in boiling xylene gave 9-methyl-10-phenylphenanthrene, which was oxidized* by aqueous sodium dichromate at 250° to a mixture of 9-phenylphenanthrene-10-carboxylic acid (5–10%) and 1,2:3,4-dibenzfluorenone (70–80%). The acid cyclizes particularly readily, even in cold thionyl chloride. Although 1,2:3,4-dibenzfluorenone becomes readily available by this route, insufficient of the acid was obtained to allow synthesis of the phenol (V, R = OH), a potential carcinogen.



(IV)



(V)

The chloride (IV, R = CH_3; X = Cl), prepared from the alcohol by the action of warm thionyl chloride, proved to be particularly interesting. It melted with slow decomposition in the range 90–100°, varying with the sample. The decomposition was rapid at 150° and gave 9-methyl-10-phenylphenanthrene in essentially quantitative yield. Related toluenesulphonates also melt with decomposition to phenanthrene derivatives

The author is indebted to Dr. D. Fishel of the State University of South Dakota for details of this oxidation procedure (6).

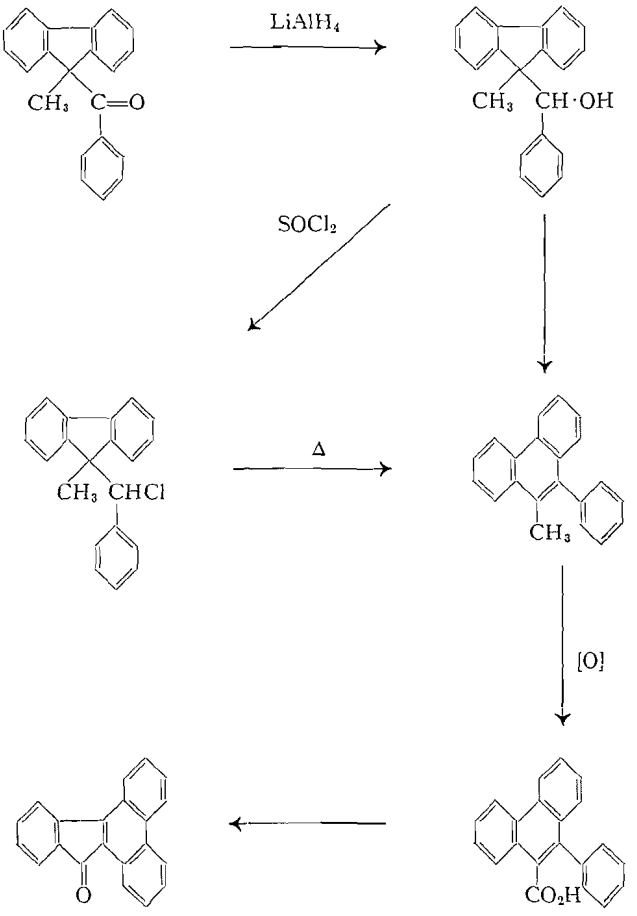

FIG. 2.

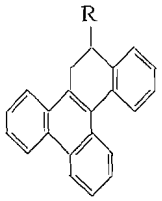
(1), but attempts to prepare the toluene- or methane-sulphonate of (IV, R = CH_3; X = OH) were not successful. The formate and acetate have been prepared. The chloride was recovered essentially unchanged after heating with methanol, acetic acid, pyridine, or quinoline and did not react with sodium iodide in acetone. Decomposition to 9-methyl-10-phenylphenanthrene in hot formic acid was complete in 2 hours. It reacted rapidly with silver or mercuric acetates in dry acetic acid to give the *unrearranged acetate* (IV, R = CH_3; X = $O\cdot CO\cdot CH_3$), the structure of which has been confirmed by esterification of the alcohol with acetic anhydride and by reduction of the acetate with lithium aluminum hydride back to the alcohol. Under similar conditions neopentyl chloride reacts with silver acetate to give the *rearranged* *t*-amyl acetate (7). The difference in behavior is tentatively attributed to stabilization of the cation (II) by the phenyl group. Experiments designed to test this postulate are under way.

When heated with phosphorus pentoxide and xylene, the allyl derivative (IV, R = $CH_2CH{=}CH_2$; X = OH) underwent dehydration–rearrangement and cyclization in one step to 14-methyl-13,14-dihydrodibenz[a,c]phenanthrene (VI, R = CH_3), isolated as the picrate in almost 90% yield. Like Bradsher and Rapoport (8) and despite rigorous purification procedures the hydrocarbon was not obtained crystalline. Dehydrogenation gave 14-methyldibenz[a,c]phenanthrene (V, R = CH_3) of m.p. 115–116°. Through the

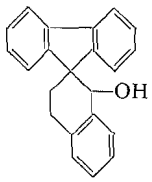
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

kindness of Professor Bradsher it has been established beyond doubt that this is a metastable form, the stable form showing m.p. 150–151° (see Experimental for details). The ultraviolet spectrum showed good agreement with that of dibenz[a,c]phenanthrene having the bathochromic shift of approximately 3 mμ associated with the introduction of a methyl group.

The spiro-alcohol (VII) undergoes dehydration–rearrangement under the action of phosphorus pentoxide to give 13,14-dihydrodibenz[a,c]phenanthrene (VI, R = H) (2). Consequently the reaction of (IV, R = $CH_2CH{=}CH_2$; X = OH) may follow either of the sequences rearrangement–cyclization or cyclization–rearrangement. Cyclization must proceed through the cation $R\cdot CH_2\overset{+}{C}HCH_3$ and it is surprising that the mesomeric ion $R\cdot\overset{+}{C}HCH_2CH_3$ is not formed, leading to a derivative of 1,2:3,4-dibenzfluorene.



(VI)



(VII)

Oxidation of (V, R = CH_3) with aqueous sodium dichromate at 250° gave the pale yellow very sparingly soluble acid, characterized as its methyl ester.

The transformations of (IV, R = $CH_2CH{=}CH_2$; X = OH) are summarized in Fig. 3. The corresponding chloride (IV, R = $CH_2CH{=}CH_2$; X = Cl) failed to yield decomposition products useful for the synthesis of (V, R = OH).

EXPERIMENTAL

9-Methyl-9-benzoylfluorene

To a boiling solution of 9-benzoylfluorene (20 g) (9) in acetone (200 ml) were added successively hot methanol (200 ml), a solution of potassium carbonate (15 g, anhydrous) in hot water (30 ml), and methyl iodide (25 g). The mixture was boiled gently under an efficient reflux condenser for 1 hour during which time the initial deep orange color faded to pale yellow. The mixture was diluted with water (800 ml) and a rapid stream of air passed through overnight. Next day the crystalline *ketone* was collected, washed, and crystallized from acetone–methanol, from which it separated as large colorless tablets (17 g, 81%), m.p. 99–101°, raised to 101–102° by two further crystallizations. Found: C, 89.48; H, 5.72%. Calculated for $C_{21}H_{16}O$: C, 88.70; H, 5.67%. Carbonyl stretching frequency: 1665 cm^{-1}.

The ketone was first obtained by alkylating 9-benzoylfluorene (2.7 g) in cold methanol containing sodium methoxide (from sodium, 0.23 g, 1 equivalent) with methyl iodide (3 g). The product crystallized from chloroform–hexane as colorless prisms (0.4 g), m.p. and mixed m.p. 99–101°. Methyl benzoate and 9-methylfluorene (see below) were obtained by distilling the mother liquors.

The *oxime*, prepared in pyridine, crystallized from chloroform–hexane as colorless needles, more rarely as prisms, m.p. 206–207°. Found: C, 84.66; H, 5.66%. Calculated for $C_{21}H_{17}NO$: C, 84.25; H, 5.73%.

After the ketone (2 g) was warmed for a few minutes with potassium hydroxide (2 g) in 95% alcohol (10 ml), isolation and distillation of the neutral product gave 9-methylfluorene as a rapidly crystallizing oil, which formed bipyramidal prisms from methanol, m.p. 45–47°. (Lit. m.p. 45–47° (10).)

Phenyl-9-methyl-9-fluorenylmethanol

Reduction of the ketone with ethereal lithium aluminum hydride gave an almost quantitative yield of the *alcohol*, which crystallized from hexane as colorless needles, m.p. 100–101°. Found: C, 87.60; H, 5.90%. Calculated for $C_{21}H_{18}O$: C, 88.08; H, 6.33%. Hydroxyl stretching frequency: 3350 cm^{-1}.

Phenyl-9-methyl-9-fluorenylmethyl Chloride

The alcohol was warmed for a few minutes with four times its weight of thionyl chloride. After excess reagent was destroyed with water, a solution of the product in hexane was passed through a column of activated alumina. The *chloride* crystallized from the eluant as massive colorless prisms (70–85%), melting point with decomposition in the range 91–99°, varying with the sample. Found, for two preparations: C, 83.03, 82.60; H, 5.70, 5.36%. Calculated for $C_{21}H_{17}Cl$: C, 82.74; H, 5.62%.

The chloride was recovered essentially unchanged after the solution was boiled with moist methanol, acetic acid, pyridine, or quinoline, or with a solution of sodium iodide in acetone. More fruitful experiments are recorded below.

9-Methyl-10-phenylphenanthrene

(*i*) The alcohol (10 g) and phosphorus pentoxide (10 g) were boiled under reflux for 3 hours with xylene (100 ml). The *hydrocarbon*, isolated in the usual way, crystallized from acetone–methanol as colorless blades (8.7 g), m.p. 98–99°, depressed to 84–90° by addition of the alcohol. Found: C, 93.73; H, 6.01%. Calculated for $C_{21}H_{16}$: C, 93.99; H, 6.01%.

The *1,3,5-trinitrobenzene complex* crystallized from methanol as bright yellow silky

needles, m.p. 126–128°. Found: C, 67.62; H, 4.15%. Calculated for $C_{27}H_{19}N_3O_6$: C, 67.35; H, 3.98%.

(*ii*) The chloride (1 g) was carefully pyrolyzed over a microburner until evolution of hydrogen chloride ceased. Crystallization of the residue from acetone–methanol gave blades (0.7 g), m.p. and mixed m.p. 97–99°.

(*iii*) The chloride (0.2 g) was boiled under reflux for 2 hours with 98% formic acid (100 ml). The product crystallized from hexane as blades (0.15 g), m.p. and mixed m.p. 96–98°.

Phenyl-9-methyl-9-fluorenylmethyl Acetate

(*i*) The chloride (1 g) was boiled for 5 minutes with silver or mercuric acetate (2 g) in anhydrous acetic acid (100 ml). The *acetate* slowly crystallized from hexane as colorless prisms, m.p. 80–81° after three crystallizations. Found: C, 84.06; H, 5.98%. Calculated for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%. No trace of the easily crystallized 9-methyl-10-phenylphenanthrene could be found.

(*ii*) The alcohol (0.2 g) was warmed for 12 hours with acetic anhydride (4 ml) containing 1 drop of concentrated sulphuric acid. The colorless prisms obtained by crystallization from hexane had m.p. and mixed m.p. 78–80°.

Reduction of the acetate with ethereal lithium aluminum hydride gave the original alcohol, identified by melting point and mixed melting point.

Phenyl-9-methyl-9-fluorenylmethyl Formate

Attempts to esterify the alcohol with *p*-toluenesulphonyl or methanesulphonyl chloride in pyridine under a range of conditions were unsuccessful. Boiling the crude products with 98% formic acid usually gave only unchanged alcohol but occasionally the *formate* was obtained, which slowly crystallized from cyclohexane as massive colorless prisms, m.p. 126–128°. Found: C, 84.24; H, 5.83%. Calculated for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

9-Phenylphenanthrene-10-carboxylic Acid and 1,2:3,4-Dibenzfluorenone

In a typical experiment, 9-methyl-10-phenylphenanthrene (13.4 g) was heated at 250–260° for 8 hours with technical sodium dichromate (25 g) and water (250 ml) in a 500-ml, rotating autoclave. After the container was cooled and opened, the contents were heated to boiling with the addition of 1250 ml water. Chromium sesquioxide was removed by filtration, acidification of the filtrate with dilute sulphuric acid precipitating the *phenanthroic acid* (5–10%). It formed colorless prisms from benzene–hexane, m.p. 192–193° after two crystallizations. Found: C, 84.65; H, 4.85%. Calculated for $C_{21}H_{14}O_2$: C, 84.54; H, 4.73%.

The acid dissolved in cold thionyl chloride to give an orange solution, dilution of which with water precipitated 1,2:3,4-dibenzfluorenone, orange needles from heptane, m.p. 185–187° (Lit. m.p. 185–186° (11).)

The chromium sesquioxide formed in the oxidation was contaminated with an orange gum, removed by percolation with methylene chloride. The extracted material formed orange rods from benzene–hexane (10.1 g), m.p. and mixed m.p. 184–186°.

The following ketones were prepared as described for the methyl analogue:

9-Ethyl-9-benzoylfluorene, white needles from hexane, m.p. 129–130°. Found: C, 88.34; H, 5.91%. Calculated for $C_{22}H_{18}O$: C, 88.56; H, 6.08%. Carbonyl stretching frequency: 1663 cm^{-1}.

9-Isopropyl-9-benzoylfluorene, small colorless prisms from acetone–methanol, m.p. 226–227°. Found: C, 88.17; H, 6.40%. Calculated for $C_{23}H_{20}O$: C, 88.42; H, 6.45%. Carbonyl stretching frequency: 1630 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

9-Benzyl-9-benzoylfluorene, white prisms from acetone–methanol, m.p. 134–135°. Found: C, 89.81; H, 5.78%. Calculated for $C_{27}H_{20}O$: C, 89.97; H, 5.59%. Carbonyl stretching frequency: 1665 cm^{-1}.

9-Cyclohexyl-9-benzoylfluorene, colorless prisms from methanol, m.p. 121–122°. Found: C, 88.33; H, 6.78%. Calculated for $C_{26}H_{24}O$: C, 88.60; H, 6.86%. Carbonyl stretching frequency: 1675 cm^{-1}.

9-Allyl-9-benzoylfluorene, long colorless needles from acetone–methanol, m.p. 91–92°. Found: C, 89.11; H, 6.00%. Calculated for $C_{23}H_{18}O$: C, 89.00; H, 5.84%. Carbonyl stretching frequency: 1670 cm^{-1}.

Phenyl-9-allyl-9-fluorenylmethanol crystallized as irregular prisms from benzene–hexane, m.p. 132–134°. Found: C, 88.46; H, 6.33%. Calculated for $C_{23}H_{20}O$: C, 88.43; H, 6.45%.

Phenyl-9-allyl-9-fluorenylmethyl chloride formed lustrous plates from methanol, m.p. 81–82°. Found: C, 83.49; H, 5.78%. Calculated for $C_{23}H_{19}Cl$: C, 83.50; H, 5.79%. Decomposition of the chloride by pyrolysis or by boiling with formic acid gave only gums, from which nothing useful was obtained by oxidation.

14-Methyl-13,14-dihydrodibenz[a,c]phenanthrene

The allyl alcohol (20 g) and phosphorus pentoxide (30 g) were boiled under reflux for 1 hour with xylene (100 ml). The product was a pale yellow viscous oil which formed a *1,3,5-trinitrobenzene complex*, crystallizing as vermilion rods from methanol, m.p. 194–195°. Found: C, 68.48; H, 4.23%. Calculated for $C_{29}H_{21}N_3O_6$: C, 68.63; H, 4.17%. This complex was not decomposed by passing a hexane solution through a column of activated alumina.

The *picrate* crystallized from ethanol as maroon needles, m.p. 174–175°. (Lit. m.p. 170.5–171.0°, corr. (8).) Decomposition of the picrate by passing a benzene solution through a column of alumina and evaporation of the eluant gave a colorless oil which has defied prolonged attempts to induce crystallization (cf. (8)).

14-Methyldibenz[a,c]phenanthrene, (9-Methyl-1,2:3,4-dibenzphenanthrene)

Prepared in almost quantitative yield by dehydrogenating the preceding hydrocarbon at 280–300° over 10% palladium-on-charcoal, 14-methyldibenz[a,c]phenanthrene slowly crystallized from benzene–methanol as large colorless prisms, m.p. 115–116°, not raised by further crystallizations. Subsequently, recrystallization with seeding by Bradsher's preparation gave small prisms, m.p. 150–151°. (Lit. m.p. 150.5–151.5°, corr. (8).)

The ultraviolet spectrum showed excellent agreement with that of dibenz[a,c]phenanthrene (12, 13); with peaks at:

Dibenzphenanthrene	276.5	286	308	321	334	352	371 mμ
Methyl derivative	278	288	311	323	337	354*	373 mμ

The *picrate* crystallized from ethanol as bright red needles, m.p. 212–213°. (Lit. m.p. 207.5–208.5°, corr. (8).)

The *1,3,5-trinitrobenzene complex* formed slender orange needles from methanol, m.p. 234–235.5°. Found: C, 68.91; H, 3.81%. Calculated for $C_{29}H_{19}N_3O_6$: C, 68.91; H, 3.79%.

An impure sample of Professor Bradsher's original preparation was converted to the picrate (m.p. and mixed m.p. 212–213°) from which the hydrocarbon was regenerated on alumina. Crystallization from benzene–methanol gave small prisms, m.p. 149–150°, not depressed by either the low or high melting forms described above.

**Inflexion.*

Methyl Dibenz[a,c]phenanthrene-14-carboxylate

14-Methyldibenz[a,c]phenanthrene (5 g) was oxidized with sodium dichromate (20 g) as described for the methylphenylphenanthrene. The pale yellow acid (4.6 g) was very sparingly soluble but was esterified by boiling with methanol (1500 ml) for 4 hours while dry hydrogen chloride was bubbled in. A solution of the crude product in benzene–hexane (5:1) was passed through a short column of alumina to remove traces of tar. Crystallization of the eluted material from acetone–methanol gave pale orange elongated prisms, m.p. 155–156°. Found: C, 85.75; H, 5.04%. Calculated for $C_{24}H_{16}O_2$: C, 85.69; H, 4.80%.

ACKNOWLEDGMENTS

The author is grateful to Professor N. B. Chapman for his interest and encouragement and to the University, Kingston-upon-Hull, for the award of an I.C.I. Fellowship. He is indebted to Dr. G. W. Gray for taking the infrared spectra and to Dr. K. Clarke for criticizing the manuscript. Sincere thanks are offered to Professor C. K. Bradsher for his sample of 14-methyldibenz[a,c]phenanthrene.

STEROIDS AND RELATED PRODUCTS

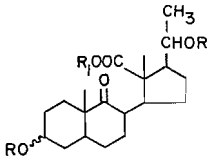
XI. THE SYNTHESIS OF 3,9,12,20-TETRAOXYGENATED 9,12-*SECO*-STEROIDS. PART I[1, 2]

CH. R. ENGEL[3] AND W. W. HUCULAK[4]

ABSTRACT

The synthesis of 3α,20β-dihydroxy-9-oxo-9,12-*seco*-12-pregnanoic acid (XV) and some of its derivatives, from 3α,12α-diacetoxy-20-oxopregnane, is described. The fission of ring C was achieved by ozonolysis of a 9,11-unsaturated 12-ketone. In the course of this work evidence was found that the rearrangement of certain 11-hydroxy-12-ketones to 12β-hydroxy-11-ketones, under the influence of alkali, can occur in high yield, even at room temperature.

For synthetic experiments which will be described at a later date, we needed 3,20-dioxygenated pregnane derivatives in which ring C of the original steroid nucleus had been opened in such a manner as to give a 9,12-*seco*-9-keto-12-acid derivative of the following general formula I:



I, R = H, acyl; R_1 = H, alkyl

Wieland *et al.* (2, compare also 3) had already obtained a similar 9,12-*seco* derivative, but without oxygen functions in positions 3 and 20, in the course of their elucidations of the structure of bile acids. The German authors brominated 12-oxocholanic acid (partial formula II) and hydrolyzed the resulting bromoketone (III)[5] with methanolic potassium hydroxide at reflux temperature. Since it is known that, under these relatively vigorous conditions, 11-hydroxy-12-ketones of structure IV rearrange to 12β-hydroxy-11-ketones (7, 8), one has to assign to the hydrolysis product structure V, in contrast to Wieland's original formulation as IV. Oxidation led Wieland and his co-workers to the 11,12-diketo derivative VIII, which they enolized to VII; treatment with potassium permanganate or chromic acid resulted in the 9-oxo-9,12-*seco*-12-acid derivative of cholanic acid (partial formula VI).

We wished to investigate the possibility of using this method for preparative purposes and, in particular, of employing it for the synthesis of 3,20-dioxygenated 9,12-*seco*-steroids. Since we intended to prepare a product with alcohol functions in positions 3 and 20, it seemed important to isolate in our series the unrearranged ketol of type IV. We considered that this would allow us to acetylate positions 3 and 20 selectively,

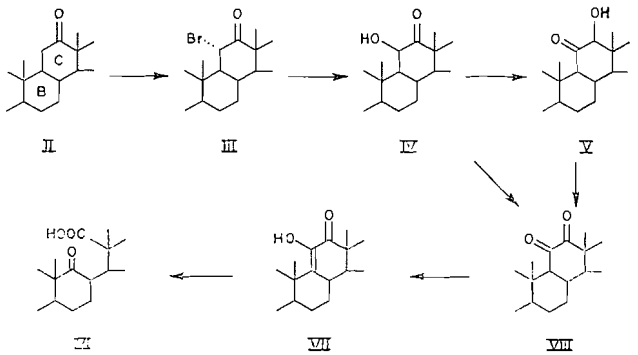
[4]*This paper is abbreviated from a portion of the M.Sc. thesis of W. W. Huculak, presented to the Faculty of Graduate Studies of the University of Western Ontario in April, 1959.*
[5]*In accordance with the now-accepted stereochemical course of brominations of 12-ketones (4, 5, 6), one has to assign the α-configuration to Wieland's main bromination product.*



since it is known that an 11β-hydroxy group generally resists acetylation with acetic anhydride in pyridine under mild conditions, and to oxidize subsequently the 11-hydroxy group without affecting the protected alcohol functions in 3 and 20.

The readily available bile acid derivative, 3α,12α-diacetoxy-20-oxopregnane (IX*a*), served as starting material. Reaction with an excess of lithium aluminum hydride afforded predominantly 3α,12α,20β-trihydroxypregnane (X), further characterized by its triacetate X*a*. The configuration in position 20 of the main reduction product was assigned on the basis of molecular rotational analysis. Upon acetylation of X to the triacetate X*a* we observed an increment in the molecular rotation of +435°; since a computation of the data available in the literature indicates that the increment due to diacetylation in positions 3α and 12α lies between 230 and 360°, the contribution of acetylation in position 20 to the observed increment lies between +75 and +205°. Sarett (9) has shown that acetylation of a 20β-hydroxy function produces an increment of molecular rotation of the same order of magnitude, whereas acetylation of a 20α-hydroxy function is accompanied by a decrease of the molecular rotation.

Succinylation of the triol X afforded in good yield a dihemisuccinate (X*b*), readily methylated to the bis-methylsuccinate X*c*. The assignment of structures X*b* and X*c* to the disuccinates is legitimate because, under the succinylation conditions employed, a 12α-hydroxy group remains unchanged (compare for instance 10 and 11), as also confirmed by the monosuccinylation of 3α,12α-dihydroxy-20-oxopregnane (IX) to the 12α-hydroxy derivative IX*b*.

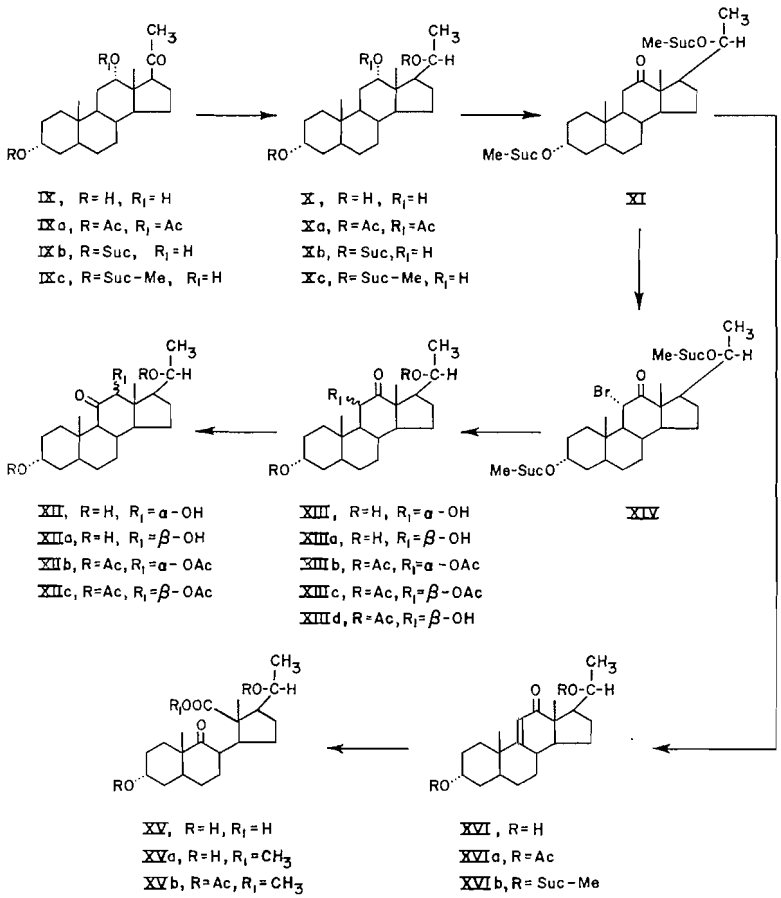
Oxidation of the bis-methylsuccinate X*c* with chromic acid in acetic acid gave in high yield the monoketone XI, which was brominated with 1 equivalent of bromine in acetic acid, at 55°. The amorphous reaction product, presumably containing predominantly the 11α-bromoketone XIV (compare 4, 5, 6), was hydrolyzed directly with aqueous ethanolic potassium hydroxide, at room temperature. The neutral reaction product was acetylated with acetic anhydride in pyridine at room temperature; instead of a mixture containing mainly the desired 3,20-diacetate XIII*d*, a product composed predominantly of a triacetate (M_D +235°) was obtained.

Gallagher (7, compare also article 8, by Wintersteiner *et al.*) proved that, under the influence of hot aqueous alcoholic potassium hydroxide, 11α- and 11β-hydroxy-12-ketones rearranged to 12β-hydroxy-11-ketones. We assumed that such a rearrangement must have occurred in our case at room temperature, as otherwise no appreciable amount of triacetate should have been obtained; it seemed indeed improbable that the 11β-hydroxy function would have been acetylated smoothly under the conditions employed. Furthermore, even if this had been the case, the reaction product should also have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

contained some 3α,11α,20β-triacetoxy ketone XIII*b*, since it is known that bromination of a 12-keto group does not proceed stereospecifically and since the crude bromination product, containing some 11β-bromide, had been hydrolyzed with potassium hydroxide. We were, however, unable to isolate a second triacetate. The homogeneity of the triacetate obtained can be explained by a rearrangement of the originally formed ketols XIII*a* and XIII to ketol XII*a*, as it has been established (7) that both 11α- and 11β-hydroxy-12-ketones can be rearranged to the same 12β-hydroxy-11-ketone.

Recently, Schindler (12) reported a case in the etianic acid series where, under the influence of a 12-keto group, an 11β-hydroxy function was acetylated with acetic anhydride in pyridine at room temperature; this could weaken our argument in favor of



structure XII*c* for the triacetate. However, Baumgartner, Tamm, and Schindler (12, 13) also showed that the constitution and configuration of 11,12-ketol acetates can be determined with the help of ultraviolet and molecular rotational analyses. Thus Schindler (12) tabulated the molecular rotational differences between ring C-acetoxylated and ring C-unsubstituted 11- and 12-ketones of the cholanic acid series; he used these values for calculating the expected molecular rotations of 11,12-ketol acetates of the 3β-hydroxy-etianic acid series from the known rotations of the corresponding non-acetoxylated ketones. Schindler further demonstrated that a definite assignment of constitution and con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

figuration of ring C ketol acetates was, in general, not possible by molecular rotational analysis alone, but that conclusive deductions could be made by also determining the position of the weak ultraviolet maximum of the keto function.

According to the literature, the molecular rotations of methyl 3α-acetoxy-11-oxoetianate (12, 14) and of 3α,20β-diacetoxy-11-oxopregnane (9) are 385° and 340° respectively; if one assumes a similar relationship between the molecular rotations of methyl etianates and 20β-acetoxypregnanes in the 12-keto series, one can calculate, from the known molecular rotation of methyl 3α-acetoxy-12-oxoetianate (595°) (12, 15), the molecular rotation of 3α,20β-diacetoxy-12-oxopregnane to be approximately 550°. If one now adds to this value the decrement, respectively increment, for additional 11α- and 11β-acetoxy substituents (12, 13) and accordingly to the molecular rotation of 3α,20β-di-

TABLE I

Calculated molecular rotations and expected ultraviolet maxima of 11,12-ketol acetates

Substance		$[M]_D$ calc.	λ_{max} (theor.)

acetoxy-11-oxopregnane (9) the increment and decrement of additional 12α- and 12β-acetoxy groups (12, 13), one obtains calculated approximate values for the molecular rotations of the four isomeric ketol acetates XII*b*, XII*c*, XIII*b*, and XIII*c* (cf. Table I).[6] It can be seen from Table I that the molecular rotation of our triacetylated hydrolysis product of the crude 11-bromo-12-ketone XIV can correspond only to structure XII*c* or XIII*b*. On the other hand, the position of the weak maximum of ketol acetates of type XII*c* should be at 292–294 mμ and that of ketol acetates of type XIII*b* at 285 mμ (compare Table I). Since the corresponding absorption maximum of our triacetylated hydrolysis product of the crude bromoketone XIV was at 293 mμ, our original assignment of structure of this product as 3α,12β,20β-triacetoxy-11-oxopregnane (XII*c*) is confirmed and we must assume that, even under the mild reaction conditions employed, the mixture of 11-hydroxy-12-ketones (containing presumably mostly the 11β-hydroxy-12-ketone XIII*a*) formed initially by hydrolysis of the 11-bromo-12-ketone was rearranged extensively to the 12β-hydroxy-11-ketone XII*a*.[7]

It thus appeared that the preparation in good yield of the intermediate 3α,20β-diacetoxy-11β-hydroxy-12-oxopregnane (XIII*d*) would present serious difficulties, and we therefore abandoned Wieland's pathway to 9,12-*seco*-steroids of type I.

We now decided to effect the cleavage of ring C to the desired 9,12-*seco* derivatives (compare I and XV) by ozonolysis of a 9,11-unsaturated 12-ketone (compare XVI), in analogy to the successful cleavage of ring A of Δ^4-3-keto steroids with ozone, yielding 3,5-*seco*-5-oxo-3-acid derivatives (compare 16–23). The 9,11-double bond was introduced in good yield by dehydrogenating the saturated 12-ketone XI with selenium dioxide, according to a modification by McKenzie *et al.* (24) of Schwenk and Stahl's method (25). Treatment of XVI*b* with approximately twenty equivalents of ozone at $-15°$ for 70 minutes in acetic acid – ethyl acetate, followed by reaction with hydrogen peroxide, was not successful, the majority of the starting material being recovered. When approximately a hundred equivalents of ozone were used at 0° there was obtained, after partial purification and complete hydrolysis of the reaction product, an acidic fraction in approximately 25% yield. However, it was not possible to obtain the acid in a crystalline state; neither could its methyl ester and acetylated methyl ester be crystallized.

We considered it more promising to employ the diacetate XVI*a*, instead of the bismethylsuccinate XVI*b*, for the reaction with ozone. Hydrolysis of XVI*b* with potassium hydroxide readily gave the diol XVI, which was easily acetylated to XVI*a*. Treatment with 22–27 equivalents of ozone at $-10°$, over a period of 5–7 hours, afforded in approximately 25% yield a crude acidic material (compare XV) which, upon methylation with diazomethane and reacetylation, gave, in an over-all yield of 2–4% from XVI*a* (10%, considering the recovery of starting material), crystalline methyl 3α,20β-diacetoxy-9-oxo-9,12-*seco*-pregnane-12-oate (XV*b*). Its structure was substantiated by combustion analysis and by its infrared spectrum, as well as by the infrared spectra of the intermediates XV and XV*a*, which all showed very clearly the absorption band of a 6-membered ring ketone.

[6]*Molecular rotations are calculated to the nearest 5° and are based on median values of specific rotations. Relatively large errors are introduced into the calculations because some of the rotations reported in the literature were not taken in chloroform.*

[7]*Baumgartner and Tamm (13) recently reported the presence of the rearranged ketol in the product of hydrolysis at room temperature of methyl 11α-bromo-3α-acetoxy-12-oxocholanate. In the 3β-hydroxy-etianic acid series Schindler (12) found that at room temperature the hydrolysis of an 11-bromo-12-ketone led predominantly to the unrearranged ketol (type* IV*) only when the reaction time did not exceed 20 minutes; otherwise the rearranged ketol (type* V*) constituted the major component of the mixture. These observations are in good accord with our above-discussed finding.*

EXPERIMENTAL[8, 9, 10]

3α,12α-Dihydroxy-20-oxopregnane-3α-methylsuccinate (IX*c*)

A quantity of 591 mg of 3α,12α-diacetoxy-20-oxopregnane (IX*a*) was refluxed for 2 hours with 25 cc of a 5.4% methanolic potassium hydroxide solution. The usual working up gave 486 mg of crude *3α,12α-dihydroxy-20-oxopregnane* (IX) (27), m.p. 150–156°, which upon recrystallization from ether–hexane afforded 380 mg (81%) of pure dihydroxy ketone IX, m.p. 168–169°. The analytical sample melted at 169–170°, $[\alpha]_D^{20}$ +158° (*c* 0.50 in $CHCl_3$). Anal. Calc. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.31; H, 10.17.

A solution of 240 mg of IX, m.p. 168–169°, in 5 cc of pyridine, was heated with 560 mg of succinic anhydride to 90° for 2 hours, with the exclusion of moisture, and then allowed to stand overnight at room temperature. Ice was added and the mixture was poured after 30 minutes into 400 cc of water. The precipitate was extracted with ether and the organic extract was washed with iced hydrochloric acid and water and dried over sodium sulphate. Upon removal of the solvent, 305 mg of crude amorphous *3α,12α-dihydroxy-20-oxopregnane-3-hemisuccinate* (IX*b*) was obtained, which was dissolved in 10 cc of absolute ether and treated with 16.5 cc of a 0.6% ethereal diazomethane solution. The mixture was kept for 20 minutes at room temperature, the excess diazomethane was decomposed with acetic acid, and the solvent was removed *in vacuo*. The amorphous residue (320 mg) was chromatographed on 6.5 g of aluminum oxide. Petroleum ether – benzene, benzene, benzene–ether, ether, and ether – ethyl acetate (4:1) elutions gave 250 mg of crystalline *3α,12α-dihydroxy-20-oxopregnane-3α-methylsuccinate* (IX*c*), m.p. 118.5–122°. A sample was recrystallized three times from ether–hexane for analysis; m.p. 126–128°, $[\alpha]_D^{23}$ +139° (*c* 1.00 in $CHCl_3$). Anal. Calc. for $C_{26}H_{40}O_6$: C, 69.61; H, 8.99. Found: C, 69.53; H, 8.85.

3α,12α,20β-Trihydroxypregnane (X)[11]

To a slurry of 11 g of lithium aluminum hydride in 700 cc of absolute tetrahydrofuran was added over a period of 50 minutes, dropwise and with stirring, 10.02 g of 3α,12α-diacetoxy-20-oxopregnane (IX*a*) in 500 cc of absolute tetrahydrofuran. The mixture was refluxed for 1 hour with stirring and then allowed to stand overnight. There was added, at 0°, 25 cc of ethyl acetate and a small quantity of ice. After addition of 150 cc of 2 *N* sulphuric acid, the volume of the solution was reduced *in vacuo*, at 40°, to 600 cc and the mixture poured into 2 l. of water. The steroid was extracted with ether, and the organic solution was washed with dilute sulphuric acid, sodium bicarbonate solution, and water, and dried over sodium sulphate. During the removal of the solvent, crystals formed, which were repeatedly removed from the mother liquors. Thus there was obtained a batch of 3.86 g of crystals melting at 236–238° and another batch of 4.857 g of less pure material, m.p. 226–229°. The latter was recrystallized from acetone–hexane and afforded another 2.502 g of crystals, melting at 236–238° (total yield 78%). A sample was recrystallized for analysis; m.p. 236°, $[\alpha]_D^{24}$ +31° (*c* 1.06 in $CHCl_3$). Anal. Calc. for $C_{21}H_{36}O_3$: C, 74.95; H, 10.78. Found: C, 74.72; H, 10.49. In another run, 10 g of IX*a* gave various fractions (6.152 g, 76% yield) of X, melting between 230 and 236°. From the mother liquors, 470 mg of another substance, m.p. 97–98°/218–219°, representing probably the 20α-isomer, was isolated. This product was not further investigated.

[8]*The melting points were taken in evacuated capillaries and the temperatures were corrected.*

[9]*The microanalyses were performed by Mr. J. F. Alicino, Metuchen, N.J., to whom we express our appreciation.*

[10]*The aluminum oxide used for chromatography was treated as described under footnote 31 of reference 26. We thank Messrs. Merck and Co., Montreal, for their kindness in providing us with their activated aluminum oxide.*

[11]*This product was first prepared by Mr. George Montandon, in this laboratory.*

Acetylation (*Triacetate* X*a*)[12]

A solution of 300 mg of triol X in 10 cc of pyridine was refluxed with 5 cc of acetic anhydride for 1.5 hours. The usual working up gave an amorphous product crystallizing from ethanol. Recrystallization afforded 260 mg (63%) of pure *3α,12α,20β-triacetoxypregnane*, m.p. 193–195°, and 70 mg (17%) of less pure crystals, m.p. 177–187°. A sample was recrystallized three times for analysis; m.p. 199–200°, $[\alpha]_D^{23}$ +116.7° (*c* 0.556 in $CHCl_3$). Anal. Calc. for $C_{27}H_{42}O_6$: C, 70.10; H, 9.15. Found: C, 70.40; H, 9.06.

3α,12α,20β-Trihydroxypregnane-3α,20β-bis-methylsuccinate (X*c*)[13]

A solution of 3.636 g of dried triol X, m.p. 236–238°, in 31.6 cc of absolute pyridine was heated with 8.32 g of succinic anhydride for 2 hours at 90° and subsequently left overnight at room temperature. Ice was added, and after 45 minutes the mixture was poured into 1 l. of water. The precipitate was extracted with ether, and the ethereal solution was washed repeatedly with cold dilute sulphuric acid and with water and was dried over sodium sulphate. During the removal of the ether, 3.54 g of crude, crystalline *3α,12α,20β-trihydroxypregnane-3α,20β-bis-hemisuccinate* (X*b*), m.p. 175–176°, was separated. The greatest part of the mother liquors (2.38 g) crystallized upon trituration with acetone–hexane. Repeated recrystallizations of both batches from acetone–hexane afforded 4.225 g of pure bis-hemisuccinate X*b*, m.p. 182–184°, and 1.5 g of mother liquors. The latter were subjected anew to succinylation under the conditions described above, and 1.58 g of crude bis-hemisuccinate X*b* was obtained.

The two batches of bis-hemisuccinate X*b* were methylated in the usual fashion with diazomethane. Separate recrystallizations of the reaction products from ether–hexane afforded 5.144 g (84.5% from X) of pure *3α,12α,20β-trihydroxypregnane-3α,20β-bis-methylsuccinate* (X*c*), m.p. 95–98°. A sample was recrystallized three times from ether–hexane and pure hexane for analysis; m.p. 95–96°, $[\alpha]_D^{22}$ +71° (*c* 1.01 in $CHCl_3$). Anal. Calc. for $C_{31}H_{48}O_9$: C, 65.93; H, 8.57. Found: C, 66.02; H, 8.54.

When the crude bis-hemisuccinate X*b* was methylated without having been purified, comparable results were obtained but, in general, chromatography of the product was necessary and the over-all yield was slightly lower.

3α,20β-Dihydroxy-12-oxopregnane-3,20-bis-methylsuccinate (XI)[14]

To a solution of 7.262 g of 3α,12α,20β-trihydroxypregnane-3α,20β-bis-methylsuccinate (X*c*) in 250 cc of glacial acetic acid was added 1.419 g of chromic acid in 14 cc of 90% acetic acid at 17°. After 15 hours, 5 cc of methanol was added and the product stirred into 3.5 l. of water. Filtration afforded 6.507 g of colorless leaflets, m.p. 107–108.5°; extraction of the filtrate afforded 605 mg of crude product, which upon recrystallization from ether–hexane gave 395 mg of XI, m.p. 105.5–106.5° (total yield 95%). A sample was recrystallized three times from ether–hexane for analysis; m.p. 113–114°, $[\alpha]_D^{25}$ +107.5° (*c* 0.975 in $CHCl_3$). Anal. Calc. for $C_{31}H_{46}O_9$: C, 66.17; H, 8.24. Found: C, 66.14; H, 8.34.

Bromination of 3α,20β-Dihydroxy-12-oxopregnane-3,20-bis-methylsuccinate (*Bromide* XIV)

To a solution of 2.002 g of ketone XI, m.p. 110–111°, in 30 cc of acetic acid, were added 2 drops of a hydrogen bromide solution in acetic acid and subsequently, at 55–60°, 8.6 cc of a 0.75 *M* bromine solution in acetic acid. The solution was kept at the same temperature for 5.5 hours and then allowed to cool to room temperature. The product was decolorized with a few drops of sodium thiosulphate solution and poured into 600 cc

[12]*See footnote 11.*

[13]*With the co-operation of Mr. K. D. Burell, whose contribution towards this project represented part of his B.Sc. thesis, submitted to the Department of Chemistry of the University of Western Ontario in May, 1955.*

[14]*See footnote 13.*

of water. The precipitate was extracted with chloroform, and the organic layer was washed with water, iced sodium bicarbonate solution, a small quantity of cold 1% sodium hydroxide solution, and with water, and was dried over sodium sulphate. The solvent was removed *in vacuo* and 2.243 g of an amorphous residue, representing crude XIV, was obtained.

Debromination

To a solution of 278 mg of the above-described crude bromo ketone (compare XIV) in 6 cc of 90% acetic acid was added, in small amounts and with repeated shaking, at 80°, 583 mg of zinc dust. The mixture was heated for another 45 minutes to 90°, with repeated shaking. The zinc was removed by filtration, and the filtrate extracted with ether. The ethereal solution was washed with water, cold dilute hydrochloric acid, cold bicarbonate solution, and with water, and was dried over sodium sulphate. Removal of the solvent afforded 224 mg of crude ketone XI, giving no depression of melting point upon admixture of authentic material.

Hydrolysis of the Bromination Product

To a solution of 1.387 g of the above-described bromide (compare XIV) in 55.4 cc of ethanol was added a solution of 2.16 g of potassium hydroxide in 10 cc of water and 20 cc of ethanol. The mixture was allowed to stand at room temperature for 48 hours. The usual working up afforded 634 mg of neutral material and 95 mg of an acidic product.

Acetylation

The above-described neutral hydrolysis product of bromide XIV (634 mg) was dissolved in 4.5 cc of pyridine and treated with 3.5 cc of acetic anhydride at room temperature. After 18 hours, the mixture was worked up in the usual fashion and afforded 776 mg of a product which was chromatographed on 22 g of aluminum oxide. Petroleum ether – benzene elutions afforded, after recrystallization, 477 mg of *3α,12β,20β-triacetoxy-11-oxopregnane* (XII*c*), m.p. 172–174.5°, and 70 mg of crystals melting between 158 and 166° which gave no depression of melting point upon admixture with XII*c*. From the latter crystals another batch of 22 mg of pure XII*c*, m.p. 172–174.5°, was obtained by recrystallization.

A sample was recrystallized three times for analysis; colorless needles, m.p. 179–180.5°, $[\alpha]_D^{22}$ +49° ($CHCl_3$) λ_{max}^{EtOH} 293 mμ (log ε 1.2). Anal. Calc. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 68.14; H, 8.42.

$\Delta^{9,11}$-3α,20β-Dihydroxy-12-oxopregnene-3α,20β-bis-methylsuccinate (XVI*b*)

To a solution of 2.583 g of 3α,20β-dihydroxy-12-oxopregnane-3α,20β-bis-methylsuccinate (XI), m.p. 105–106.5°, in 26 cc of an 0.0006 *N* hydrogen chloride solution in acetic acid was added 1.505 g of selenium dioxide. The mixture was refluxed for 20 hours, cooled, diluted with 2 l. of ether, and filtered over sodium sulphate. The filtrate was further diluted with ether and the solution was washed with water, iced dilute hydrochloric acid, cold sodium bicarbonate solution, and with water, and was dried over sodium sulphate. Removal of the solvent gave 2.498 g of a yellow oil which yielded, upon recrystallization from ether, 455 mg of $\Delta^{9,11}$-3α,20β-dihydroxy-12-oxopregnene-3α,20β-bis-methylsuccinate (XVI*b*), m.p. 94–95°. The amorphous mother liquors (1.966 g) were dissolved in 23.5 cc of a mixture composed of 80% chlorobenzene and 20% acetic acid. To this was added 9.6 g of chromic acid in 9.6 cc of water. The mixture was shaken for 2 hours at room temperature; then 4.8 g of chromic acid in 4.8 cc of water was added and the flask was shaken again for another 2 hours. The product was diluted with 2 l.

of ether and filtered over sodium sulphate. The filtrate was washed with water, iced sodium bicarbonate solution, and water, and was dried over sodium sulphate. Removal of the solvent afforded 1.941 g of crystalline XVI*b*, m.p. 90–93° (total yield of crystalline XVI*b*, 91%). The batch melting at 90–93° was chromatographed on 58 g of aluminum oxide. Recrystallization of the petroleum ether – benzene (1:4) and benzene fractions yielded 1.027 g of pure XVI*b* (m.p. 94.5–95.5°; total yield of highly purified XVI*b*: 58%). A sample was recrystallized twice from ether for analysis; m.p. 95.5–96.5°, $[\alpha]_D^{22}$ +155° (*c* 1.0 in $CHCl_3$) λ_{max}^{EtOH} 239 mμ (log ε 4.1). Anal. Calc. for $C_{31}H_{44}O_9$: C, 66.40; H, 7.91. Found: C, 66.30; H, 7.87.

$\Delta^{9,11}$-3α,20β-Dihydroxy-12-oxopregnene (XVI)

To a solution of 3.509 g of $\Delta^{9,11}$-3α,20β-dihydroxy-12-oxopregnene-3α,20β-bis-methylsuccinate (XVI*b*) in 70 cc of methanol was added 4.39 g of potassium carbonate in 50 cc of water. The mixture was refluxed for 17 hours, cooled to room temperature, and extracted with 2 l. of ether. The ethereal solution was washed with water and dried. The solvent was removed and 1.992 g (95.5% yield) of crystalline dihydroxy ketone XVI, m.p. 232–234.5°, was obtained. Recrystallization from ether afforded 1.487 g of fine needles, m.p. 238–240°. A sample was recrystallized twice for analysis; m.p. 242–243°, λ_{max}^{EtOH} 242 mμ (log ε 4.04). Anal. Calc. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.65; H, 9.74.

Acetylation

The dihydroxy ketone XVI (2.253 g, m.p. 238–240°) was acetylated overnight at room temperature with 152 cc of acetic anhydride in 225 cc of pyridine. The usual working up afforded 2.8 g of crystalline *$\Delta^{9,11}$-3α,20β-diacetoxy-12-oxopregnene* (XVI*a*), m.p. 179–183°. Recrystallization and chromatography of the mother liquors yielded 1.976 g of broad needles, m.p. 180–200°. A sample was recrystallized twice for analysis; m.p. 200.5–201.5°, λ_{max}^{EtOH} 244 mμ (log ε 4.02). Anal. Calc. for $C_{25}H_{36}O_5$: C, 72.10; H, 8.71. Found: C, 72.01; H, 8.90.

Ozonolysis of $\Delta^{9,11}$-3α,20β-Dihydroxy-12-oxopregnene-3α,20β-bis-methylsuccinate (XVI*b*)

(*a*) At −15°, a stream of oxygen containing 8% of ozone was passed over a period of 70 minutes through a solution of 1.194 g of $\Delta^{9,11}$-3α,20β-dihydroxy-12-oxopregnene-3α,20β-bis-methylsuccinate (XVI*b*), m.p. 94.5–95.5°, in 15 cc of glacial acetic acid and 15 cc of ethyl acetate (40 equivalents of ozone). Subsequently, 4.5 cc of water and 0.45 cc of a 30% hydrogen peroxide solution were added and the mixture was allowed to stand for 19 hours at room temperature. The product was extracted with ether, the ethereal solution was washed repeatedly with water and subsequently extracted with 2 *N* sodium hydroxide solution. The remaining ethereal solution was washed to neutral and dried over sodium sulphate. Evaporation of the solvent gave 950 mg (80%) of starting material XVI*b*, m.p. 91–93°, not depressed upon admixture of an authentic sample. The sodium hydroxide extract was acidified and worked up in the usual way to give 98 mg of an amorphous product.

(*b*) A solution of 950 mg of XVI*b* in 13 cc of acetic acid and 13 cc of ethyl acetate was flushed for 5 hours, at 0°, with an oxygen stream (flow rate 180 cc per minute) containing 8.3% of ozone (100 equivalents). After treatment of the product with 4 cc of water and 0.5 cc of a 30% hydrogen peroxide solution for 18 hours, the product was worked up as described above, yielding 300 mg of neutral material and 412 mg of a crude acid fraction. A quantity of 348 mg of the latter was treated for 24 hours with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

30 cc of a 5% aqueous sodium hydroxide solution. The usual working up afforded 20 mg of neutral material and 210 mg of an acidic product, the infrared spectrum of which was in agreement with structure XV but which resisted all attempts of crystallization.

The product was dissolved in 7 cc of absolute benzene and methylated in the usual fashion with an ethereal diazomethane solution. After 17 hours, the product was worked up and there was obtained 214 mg of a methyl ester (compare XV*a*), which could not be crystallized. A solution of this product in 5 cc of pyridine was treated overnight with 2.5 cc of acetic anhydride. The crude reaction product (234 mg) was chromatographed on 6.9 g of aluminum oxide but none of the fractions could be induced to crystallization.

Methyl 3α,20β-Diacetoxy-9-oxo-9,12-seco-pregnane-12-oate (XV*b*) *from* XVI*a*, *via the Intermediates* XV *and* XV*a*

At −10°, a current of oxygen (180 cc per minute) containing 8.3% of ozone was passed for 5 hours and 22 minutes through a solution of 3.611 g of $\Delta^{9,11}$-3α,20β-diacetoxy-12-oxopregnene (XVI*a*) in 50 cc of glacial acetic acid and 50 cc of absolute ethyl acetate (22 equivalents of ozone). Water (15 cc) and a 30% hydrogen peroxide solution (1.8 cc) were added and the mixture was allowed to stand at room temperature overnight. The usual working up afforded 2.431 g of an amorphous neutral material and 1.041 g of a crude amorphous acidic fraction which resisted crystallization. This product was dissolved in 35 cc of absolute benzene and treated with 20 cc of a 2.5% ethereal diazomethane solution at 0° for 15 hours. The usual working up gave 1.061 g of an amorphous product which was dissolved in 8 cc of pyridine and acetylated in the usual fashion with 5 cc of acetic anhydride. There was obtained 1.07 g of an amorphous product which was chromatographed on 31 g of aluminum oxide. Benzene and benzene–ether (4:1) gave 51 mg (1.3% yield from XVI*a*) of methyl 3α,20β-diacetoxy-9-oxo-9,12-*seco*-pregnane-12-oate (XV*b*), m.p. 125–128.5°. Recrystallization for analysis afforded very fine needles, m.p. 126–127°, $[\alpha]_D^{22}$ +30° (*c* 0.891 in $CHCl_3$), weak ultraviolet absorption maximum at 282 mμ, ν_{max}^{KBr} 1242 cm^{-1} (acetate absorption), 1701 cm^{-1} (9-ketone), 1722 cm^{-1} (12-methyl ester). Anal. Calc. for $C_{25}H_{38}O_7$: C, 66.64; H, 8.50. Found: C, 66.60; H, 8.27.

The major portion (2.39 g) of the neutral reaction product from the ozonolysis was dissolved in 64 cc of a 1:1 mixture of acetic acid and ethyl acetate, and ozonized at −10° over a period of 7 hours and 52 minutes with an oxygen stream (160 cc per minute) containing 7.9% of ozone (27 equivalents). The product was worked up as described above, and there was obtained 93 mg of XV*b*, m.p. 124–126° (3.7% yield), identical with the above-described XV*b*.

ACKNOWLEDGMENTS

We wish to acknowledge with sincere thanks the valuable co-operation of Mr. G. Montandon and Mr. K. D. Burell; the expert technical assistance of Mrs. J. Capitaine and Mr. R. Heckadon; and the highly appreciated help of Mr. R. W. White, Science Service Laboratory, London, Ontario, with the infrared analyses. We are greatly indebted to the Federal–Provincial Departments of National Health and Welfare, Ottawa and Toronto; to Ayerst, McKenna and Harrison Limited, Montreal; and to the Canadian Life Insurance Officers Association, for financial support; and to CIBA Limited, Basle, for kindly providing us with starting materials. Dean J. B. Collip's active interest and Dr. J. Gunton's kindness in making the facilities of his department available were highly appreciated.

SOME CARBOXYLIC ACIDS PRESENT IN ROYAL JELLY[1]

WILLIAM H. BROWN[2] AND ROBERT J. FREURE[3]

ABSTRACT

Only one carboxylic acid, 10-hydroxy-2-decenoic acid, has previously been isolated from royal jelly. Small amounts of two additional acids, sebacic and 2-decendioic acid, have now been found in the ether-soluble portion of this special bee foodstuff. Evidence is presented in favor of the *trans*-configuration for naturally occurring 10-hydroxy-2-decenoic acid. Chromic acid oxidation of the hydroxy acid yields 2-decendioic acid.

The chemical nature of the components of royal jelly has received considerable attention over the past 20 years. Townsend and Lucas (1) reported the isolation of a carboxylic acid, $C_{10}H_{18}O_3$, from the mixture of acids obtained from royal jelly by extraction with ether. Abbott and French (2) and Abbott (3) confirmed this finding and attempted by oxidative means to establish a structure for the acid. However, their efforts were unsuccessful. More recently Butenandt and Rembold (4) have characterized the compound as 10-hydroxy-2-decenoic acid (I).

This year Barker, Foster, and Lamb (5) have independently confirmed the structure proposed by Butenandt and Rembold for I and have speculated on the olefinic configuration.

In view of the increasing interest in royal jelly from a therapeutic standpoint and the findings recently reported by Townsend, Morgan, and Hazlett (6) on the activity of I against experimental leukaemia and ascitic tumors we are reporting the results of our investigation into the chemical nature of additional carboxylic acids which we have discovered in royal jelly.

Besides 10-hydroxy-2-decenoic acid (I) we have isolated, by chromatographic means, sebacic acid (II) and 2-decendioic acid (III) from the mixture of acids obtained from lyophilized royal jelly by ether extraction.

$$HO—CH_2—(CH_2)_6—CH=CH—COOH \qquad I$$
$$HOOC—(CH_2)_6—CH_2—CH_2—COOH \qquad II$$
$$HOOC—(CH_2)_6—CH=CH—COOH \qquad III$$

Barker *et al.* (5) have reported that I comprises approximately 70% of the mixture of ether-soluble acids and approximately 15% of royal jelly. We find that I is present to a greater extent in the mixture of ether-soluble acids, 90%, whereas it is present only in the amount of 3% in whole royal jelly (7% of lyophilized royal jelly). A variety of melting points have been reported for this compound: 46–58° (1); 61–62° (3); 54–56° (4); 52° (5). When I is separated chromatographically from the other ether-soluble acids with which it is associated in royal jelly and subsequently crystallized from water, the pure material has m.p. 62.0–62.5°.

Only Barker *et al.* (5) have considered the olefinic configurations of I but were unable to make a firm assignment. We have found that I, when irradiated in acetone solution, is converted slowly to another isomer (IV). This latter compound, m.p. 43–46°, slowly reverts to I when allowed to stand at room temperature even in the solid state. In the case of IV, absorption is strong in the region 300–340 mμ while I is relatively transparent

[1]*Manuscript received June 29, 1959.*

[2]*Associate Professor of Chemistry, Ontario Agricultural College, Guelph, Ontario.*
[3]*Graduate student, Department of Chemistry, Ontario Agricultural College, Guelph, Ontario.*

over the same range. Both I and IV show strong end absorption (220–290 mμ) in the ultraviolet. Infrared absorption spectra of I and IV were run on mineral oil mulls and are summarized in Table I.

TABLE I

Infrared spectra of 10-hydroxy-2-decenoic acid

Peaks, cm^{-1}	
Naturally occurring (I)	Irradiated with sunlight (IV)
3390	3390
1710	1710
1658	1658
976	976
—	830

The medium peak observed at 830 cm^{-1} in the spectrum of IV is not present in that of I. Allan, Meakins, and Whiting (7) have determined the infrared absorption spectra of a number of α,β-unsaturated carboxylic acids and have established that a peak in the region 830 cm^{-1} indicates an olefinic C—H out-of-plane bending for *cis*-α,β-unsaturated acids. The presence of a peak at 976 cm^{-1} in the spectra of both I and IV indicates that IV is contaminated with I (incomplete conversion). A peak in this latter region has been well established as being characteristic of *trans*-substituted ethylenic structures (8). Based on these observations we postulate that naturally occurring 10-hydroxy-2-decenoic acid exists in the *trans*-form.

The presence of sebacic acid (II) in royal jelly is interesting since its occurrence in other natural foodstuffs is limited to the fat portion of milk from buffalo and cow (9). It has been reported by Stählin and Blievernicht (10) that the free sebacic acid content of rape and turnip seed rises as it becomes moldy.

The third acid, 2-decendioic acid (III), found in royal jelly, has previously been reported only twice. It was synthesized by English (11), who was investigating homologues of traumatic acid ($HOOC-(CH_2)_8-CH=CH-COOH$). The latter compound is a factor involved in plant growth phenomena.

Cram and Tishler (12) isolated III from the acetone-soluble fraction of clinical penicillin. Chromic acid oxidation of 10-hydroxy-2-decenoic acid (I) readily yields III. This reaction was originally reported by Abbott (3), but no structures were known at that time.

It is significant that the three acids in royal jelly are all closely related, 10-carbon compounds. The concentration of each acid is given in Table II.

TABLE II

Acid	Conc. (p.p.m.) (basis lyophilized royal jelly)
I	70,000
II	200
III	300

The chemotherapeutic value of II and III is being investigated by our co-workers, Townsend, Morgan, and Hazlett (6) and will be reported elsewhere.

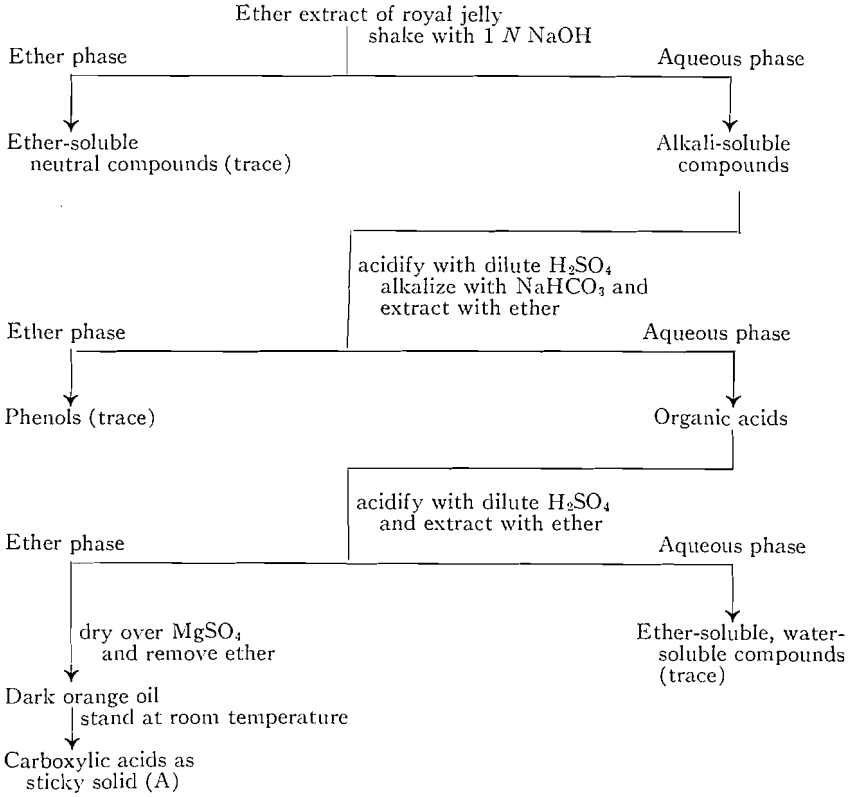
EXPERIMENTAL

(All melting points have been corrected against reliable standards.)

Isolation of Carboxylic Acids (A) from Royal Jelly

Lyophilized royal jelly was placed in a Pyrex 3885 Soxhlet extractor in 2-inch layers alternated with glass wool and was extracted with ether for 26 hours. The resulting straw-colored extract, approximately 2 l. in volume, was concentrated to 200 ml and processed as shown in the following flowsheet.



The final ether extract was dried over anhydrous magnesium sulphate, filtered, and the ether removed in a current of air. The residue, (A), a dark orange oil, crystallized after standing overnight at 25°.

A number of samples of lyophilized royal jelly extracted with ether and the ether extract processed as already described showed an average of 7% ether-soluble organic acids. This represents 3% of whole royal jelly which averages 65% moisture and 35% solids.

Isolation and Identification of Sebacic Acid (II) *as the p-Bromophenacyl Ester*

The crystalline mixture of acids, (A), (7.7 g), was taken up in hot hexane–ether and refrigerated to 5°. While the solution was cooling, seeds of 10-hydroxy-2-decenoic acid were introduced. The resulting white crystalline solid, 3.8 g, was removed by filtration, m.p. 43–46°. A further crystallization of the solid gave 2.8 g (36% by wt.) of impure 10-hydroxy-2-decenoic acid, m.p. 55–59°. The mother liquor from the first crystallization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

was concentrated and cooled, yielding 1.7 g of white crystalline solid, m.p. 39–63°. A second crystallization of the latter solid using the same mixed solvent gave 1.2 g of white crystals, m.p. 45–72°. Crystallization from benzene–hexane raised the m.p. to 51–78°.

When 0.37 g of the material, m.p. 51–78°, was treated with *p*-bromophenacyl bromide by the usual procedure, a white solid was formed in the hot reaction mixture and was removed by filtration before cooling. It weighed 0.050 g, m.p. 146–150°. Crystallization from absolute ethanol and acetone raised the m.p. to 150–151°.

A mixture melting point of the latter compound with authentic *p*-bromophenacyl ester of sebacic acid was not depressed.

Isolation and Identification of Sebacic Acid (II) *and 2-Decendioic Acid* (III) *from A by Chromatography*

Isolation of III was achieved by chromatographic separation of A on Whatman seed test paper (1/16 inch) using a 7:3 ratio by volume of propanol and concentrated aqueous ammonia as the developing solvent. Isherwood and Hanes (13) have described the use of this solvent system.

A concentration of 700 mg of A per 9×22.5-inch sheet gave adequate separation of II and III from I. Acid I comprises approximately 90% of A. The various regions containing the acids were located on the paper by cutting out a quarter-inch strip from the center of the sheet and spraying it with a 0.1% solution of thymol blue adjusted to pH 10. No significant separation of II from III was achieved at this concentration.

The region containing acids II and III was cut out and the acids extracted from the paper with propanol in a Soxhlet apparatus. The extract was evaporated to dryness, the residue taken up in 5% aqueous sodium hydroxide solution, acidified with dilute sulphuric acid, and extracted with ether. From 2.7 g of A, 91 mg of the mixture of II and III was obtained. Fractional crystallization from chloroform removed most of II. The resulting crude III was fractionated on Whatman 3 MM chromatography paper using the same solvent system as previously described to remove the residual II.

Compound III was extracted from the paper, m.p. 161–168°. After crystallization from chloroform 25 mg of pure III was obtained, m.p. 172–173°.

The infrared spectrum, mull in mineral oil, of III shows maximum absorptions at 1,710 cm^{-1} (carboxylic acid), 1,655 cm^{-1} (unsaturation), and 1,198 cm^{-1} (carboxylic acid). Anal. calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.00. Found: C, 59.9; H, 7.92.

The identity of III was confirmed by mixture melting point with 2-decendioic acid, m.p. 172–173°, prepared by chromic acid oxidation of 10-hydroxy-2-decenoic acid.

Sebacic acid (II) was also isolated by the same procedure and identified as the *p*-bromophenacyl ester.

Using Whatman No. 1 chromatography paper and the same developing solvent as before, R_f values are I, 0.79; II, 0.43; and III, 0.38 at 25°.

Oxidation of 10-Hydroxy-2-decenoic Acid (I) *to 2-Decendioic Acid* (III)

A mixture of 0.93 g (0.0050 mole) of 10-hydroxy-2-decenoic acid and 1.0 g (0.0034 mole) of potassium dichromate, dissolved in a solution of 0.9 ml of C.P. concentrated sulphuric acid in 15 ml of water, was heated in a 50-ml round-bottomed flask on a steam bath for 3 hours. After the reaction mixture was allowed to stand at room temperature for 10 hours a solid product was removed by filtration. It weighed 0.43 g, m.p. 145–160°. The crude material was crystallized from hot water including treatment with activated charcoal. In this manner 0.20 g (20%) of small white rosettes, m.p. 171–172° was obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

Effect of Ultraviolet Irradiation on Naturally Occurring 10-Hydroxy-2-decenoic Acid (I)

When 10-hydroxy-2-decenoic acid (I), m.p. 62°, isolated from A, was irradiated with sunlight in a thin-walled Pyrex bulb in acetone solution for a total of 20 hours, the melting point of I dropped to 43–46°, suggesting a conversion of the acid from *trans*- to *cis*-configuration. After the solution had been standing for a three-week period the melting point of the irradiated material (IV) rose to 44–54° indicating slow reversion to the more stable *trans*-isomer.

p-Bromophenacyl Ester of 10-Hydroxy-2-decenoic Acid (I)

The *p*-bromophenacyl ester of I has been prepared by Abbott (3) but no melting point has been reported. The ester is readily obtained by treating the sodium salt of I with *p*-bromophenacyl bromide in hot dilute ethanol solution. It has m.p. 89–90°.

ACKNOWLEDGMENTS

We are indebted to Prof. G. F. Townsend and Dr. R. W. Shuel, Department of Apiculture, Ontario Agricultural College, Guelph, for generous supplies of whole and lyophilized royal jelly and 10-hydroxy-2-decenoic acid. Naugatuck Chemicals, Elmira, determinated the infrared spectra. W. C. Hardesty Co. of Canada, Limited, supplied generous samples of pure sebacic acid and esters of sebacic acid.

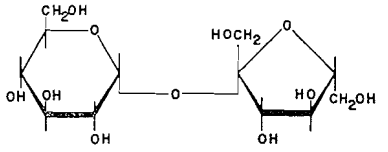
THE REACTION OF SUCROSE WITH GLYCOL-CLEAVING OXIDANTS[1]

A. K. MITRA[2] AND A. S. PERLIN

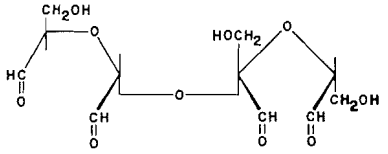
ABSTRACT

Lead tetraacetate in acetic acid is reduced at an unusually rapid rate by sucrose, due to a vigorous preferential cleavage of the 3,4-glycol group in the D-fructofuranosyl moiety. By contrast, periodate attacks the D-glucopyranosyl unit more readily. These marked variations are exhibited also in the same solvent and, therefore, appear to be related to the characteristics of the oxidants themselves. The mechanism of the action of lead tetraacetate is discussed with reference to the stereochemistry of the D-fructofuranose unit. Selective oxidation provides a chemical method for controlled degradation of the sucrose molecule and affords products in which either the D-fructose or the D-glucose residue is modified.

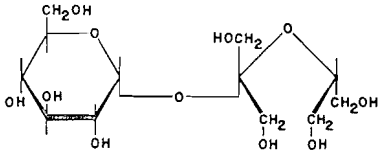
An earlier paper (1) described the chemical degradation of raffinose and stachyose to give sucrose, the method being dependent on selective oxidation by glycol-cleaving agents of the α-D-galactopyranosyl residues present. However, lead tetraacetate promoted a more vigorous oxidation of the sucrose moiety in these oligosaccharides than did periodate. This observation has led to a comparison of the action of these two closely related reagents on sucrose itself.



I



II



III

In the presence of excess periodate or lead tetraacetate, sucrose (I) undergoes normal glycol-cleavage and forms the expected tetraaldehyde (II) in high yield (2, 3). With a limited proportion of oxidant, however, differences become apparent in the *sequence* of attack by the two reagents. Lead tetraacetate in acetic acid is reduced at a relatively rapid rate by the sugar (Table I) due to a vigorous preferential splitting of the 3,4-glycol group in the D-fructofuranosyl unit. This specificity is suggested from a comparison of the

TABLE I

Rate of oxidation of sucrose and related sugars

Reagent	Time (minutes)	Moles oxidant consumed/mole		
		Sucrose	MF[a]	MG[b]
Lead tetraacetate	30	0.54	0.34	—
	60	0.88	0.65	0.08
	120	1.10	0.88	0.11
Sodium periodate	30	0.36	0.05	0.23
	90	0.71	0.13	0.46
	150	1.04	0.21	0.61

[a]Methyl β-D-fructofuranoside (chromatographically pure syrup); the compound was over-oxidized by prolonged treatment, possibly due to partial hydrolysis.
[b]Methyl α-D-glucopyranoside.

rates of oxidation of methyl-β-D-fructofuranoside and methyl α-D-glucopyranoside ((4) see also Table I), and is demonstrated by the fact that reaction with only 1 mole of lead tetraacetate per mole (theoretical uptake, 3 moles/mole) causes oxidation of 90% of the fructose units (Table II). The dialdehyde formed as the major product in the latter reaction was reduced catalytically or with sodium borohydride (5), and the polyol (III) produced was isolated as a crystalline octaacetate. Confirmation of the structure of III was obtained from the fact that it was not attacked by invertase, that methanolysis yielded methyl α-D-glucopyranoside, and hydrolysis followed by bromine oxidation gave 1,3-dihydroxy-2-propanone but not D-fructose. The D-glucose unit of III is intact, but the partially degraded D-fructose unit no longer possesses an asymmetric center. Accordingly, the molecular rotation of the compound ($[M]_D$ of the octaacetate is +45,000) is in close agreement with that expected for the α-D-glucopyranosyl residue in sucrose (6, 7, 8, 9).*

In contrast to the foregoing results, sodium periodate attacks the D-fructose unit even less readily than the D-glucose unit, the latter utilizing as much as 77% of 1 mole of oxidant added per mole (Table II). A relatively high resistance of the β-D-fructofuranosyl

TABLE II

Oxidation of sucrose by 1 mole of glycol-cleaving reagent

structure to periodate cleavage is illustrated also in the comparatively slow oxidation rate for the corresponding methyl glycoside (Table I).† This marked difference from the action of lead tetraacetate did not appear to be related to solvent, as shown by the variation obtained when each oxidant was used in 50% acetic acid (Table II). On treat-

**For example, 2,3,4,6-tetra-O-acetyl methyl α-D-glucopyranoside has $[M]_D$ +47,300; the β-D-glucoside tetraacetate has $[M]_D$ −6600.*

†*Methyl α-L-arabofuranoside, another furanoside containing a trans-glycol group, is also attacked by periodate more slowly than methyl glycopyranosides (10).*

For personal use only.

ment with 1 or 2 moles of periodate in 50% ethanol, followed by reduction, sucrose afforded a mixture of several compounds. Some of the products contained intact D-fructose residues, but were present in low proportion and were difficult to isolate from the mixture. The low yield of D-fructose-containing products shows that both glycol groups of the D-glucose unit consume a substantial proportion of the periodate added, and also that they are, on the average, only slightly more reactive than the single glycol group of the D-fructose unit.

From the stereochemical viewpoint, the *trans*-1,2-glycol group of the D-fructofuranose unit should be less-favorably oriented than those of the D-glucopyranosyl ring for forming a cyclic complex with glycol-cleaving oxidants (11, 12, 13), since the *trans*-glycol group on a 6-membered ring (projected angle of 60°) should approach coplanarity more closely than that on a 5-membered ring (projected angle of 120°) (13). The periodate data is consistent with these considerations.

Lead tetraacetate appears to exhibit anomalous behavior in its preferential attack on the D-fructofuranosyl residue. However, earlier studies of the reaction of lead tetraacetate with cyclic 1,2-diols (14, 15, 16) have shown a similar inconsistency. *trans*-1,2-Cyclopentanediol, for example, consumes lead tetraacetate at about 60 times the rate for *trans*-1,2-cyclohexanediol (14). These and other comparative rate data have been cited (16) as evidence that glycol-cleavage by lead tetraacetate need not involve an intermediate cyclic lead complex. By contrast, the marked resistance to oxidation shown by rigidly fixed *trans*-glycol groups on a 5-membered ring, as in bicyclic systems (16, 17), has been ascribed to an orientation unsuitable for complexing.

If a cyclic intermediate is involved, its formation should be favored by such distortion of the ring which would force the adjacent hydroxyl groups toward the eclipsed state, rendering the glycol structure more nearly coplanar (13). X-ray crystallography has shown (6) that in the D-fructosyl residue of sucrose sodium bromide dihydrate, the ring oxygen atom and carbons-2, -3, and -5 lie essentially in one plane and the ring is puckered at carbon-4 so that the C3—O and C4—O bonds are forced towards coplanarity. In addition, the angles which the 3- and 4-hydroxyl groups make with the adjacent ring bonds are unusually high, tending further to bring the glycol group into the mean plane of the residue. Most probably this conformation is imposed by forces within the crystal lattice and may not represent the D-fructofuranosyl unit in solution. Nevertheless, it is clear that under suitable conditions the furanose ring *can be* distorted so as to afford a glycol group having a projected angle much smaller than 120°, which might occur in the lead-complex transition state. Hence, the "anomalous" lead tetraacetate oxidation behavior of *trans*-1,2-diols on 5-membered rings need not be regarded as inconsistent with a cyclic intermediate pathway. Differences between lead tetraacetate and periodate exhibited in their attack on sucrose, therefore, may be due to factors such as variations in steric requirements of the two reagents, or to the relative ease with which the intermediate complexes decompose to products (18), and not to fundamental differences in reaction mechanism.

EXPERIMENTAL

Paper chromatography was carried out using Whatman No. 1 paper, and benzene–butanol–pyridine–water (19) as solvent. Urea oxalate (20) was used to detect fructose-containing oligosaccharides on chromatograms, and ammoniacal silver nitrate (21) as a general spray.

Measurement of Oxidation Rates

(*a*) *Lead Tetraacetate*

The sugar (10–15 mg) in water (0.2 ml) was taken up in acetic acid (10 ml). A solution of lead tetraacetate (0.2 g) in acetic acid (10 ml) was added, and at chosen intervals aliquots of the reaction mixture were withdrawn and the oxidant content determined iodometrically (11). Results are given in Table I.

(*b*) *Periodate*

The sugar (10–15 mg) in water (5 ml) was taken up in ethanol (10 ml), and a solution of sodium periodate (60 mg) in water (5 ml) added. At chosen intervals aliquots of the reaction mixture were added to phosphate buffer (pH 7.0) (22) and the iodine released titrated. Results are given in Table I.

Partial Oxidation of Sucrose with Lead Tetraacetate and Catalytic Reduction of the Dialdehyde

Sucrose (10 g, 29.2 mmoles) was dissolved in water (500 ml), the solution was diluted with acetic acid (500 ml), and lead tetraacetate (12.4 g, 28.0 mmoles) added with stirring at room temperature. Oxidant was found to be consumed within 0.5 hour (negative starch – potassium iodide test), and excess Amberlite IR-120 was then added to remove divalent lead. The filtered solution was concentrated *in vacuo* at 45°, and most of the residual acetic acid and water removed by codistillation several times with ethanol and toluene, the product being obtained as a white crust (9.5 g). On a paper chromatogram the product streaked heavily, and a small proportion of unoxidized sucrose was detected.

The oxidation product (8.0 g), absolute ethanol (125 ml), and Raney nickel (2.5 g, wet weight) were heated together at 120° in the presence of hydrogen (1800 p.s.i.) for 12 hours. After removal of the catalyst and evaporation of the solvent, the syrup obtained was found to contain a major component (R_{sucrose} 2.5) which gave a negative ketohexose test (urea oxalate spray), together with a small proportion of sucrose. The syrup (6.5 g) in acetic anhydride (75 ml) was heated with anhydrous sodium acetate (6.0 g) on a steam bath for 2 hours. Slow addition of the cooled acetylation mixture to a vigorously stirred ice slurry afforded a solid product which, after 8 hours of continued stirring, was filtered off, washed well with water, and dried. Weight, 9.0 g. The product crystallized rapidly from ethanol as large plates (weight, 7.1 g); when powdered and heated slowly (1°/3–4 minutes) the crystals had m.p. 56–60°, unchanged by two further crystallizations from ethanol $[\alpha]_D^{25}$ +67.2 (*c*, 2.6, chloroform). Calculated for $C_{28}H_{40}O_{19}$: acetyl, 50.40%. Found: acetyl (sapon.), 50.27%. The melting point was virtually unchanged also by two recrystallizations from ether, m.p. 56–59°. Calculated for $C_{28}H_{40}O_{19}$: C, 49.40%; H, 5.92%; acetyl, 50.40%. Found: C, 49.19%; H, 5.97%; acetyl (sapon.), 50.55%.

On deacetylation with sodium methoxide the syrupy polyol was found to be chromatographically pure, and was not attacked by an active preparation of invertase.

Reduction of the Dialdehyde with Sodium Borohydride

Partially oxidized sucrose (above) (6.0 g) in water (50 ml) was added to a cold solution of sodium borohydride (3.5 g in 50 ml ice water) over a period of 45 minutes. After 18 hours acetic acid was added slowly to pH of about 7 and the solution was concentrated *in vacuo* at 45° to dryness.* Borate was removed as volatile methyl borate by repeated (5 times) addition and evaporation of methanol. Acetic anhydride (75 ml) and anhydrous sodium acetate (5.0 g) were added to the dry residue, the mixture was heated on the

**Use of Amberlite IR-120 to remove sodium ions at this stage, as in the usual procedure, resulted in extensive hydrolysis of the reduction product.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

steam bath for 2 hours, and the acetate was isolated as described above and recrystallized from ethanol (weight, 4.5 g). Recrystallized twice from ether the acetate had m.p. 56–60°, $[\alpha]_D^{25}$ +65.0 (*c*, 2.7, chloroform); the X-ray diffraction pattern was indistinguishable from that of the octaacetate prepared via catalytic reduction. Calculated for $C_{28}H_{40}O_{19}$: C, 49.40%; H, 5.92%; acetyl, 50.40%. Found: C, 49.25%; H, 6.02%; acetyl (sapon.), 50.49%.

Degradation of III

The octaacetate of III (1.5 g) in dry methanol (15 ml) was treated with sodium methoxide (3 ml, 0.5 *N*) in the cold for 30 hours. An aliquot (8 ml) of the solution was acidified with 2% methanolic hydrogen chloride (10 ml) and heated under reflux for 12 hours. Ethereal diazomethane was then added to neutrality, and additional ether to cause turbidity. A crystalline product (0.11 g) obtained by cooling was recrystallized from ethanol, m.p. 164–165°, undepressed by admixture with methyl α-D-glucopyranoside; the X-ray diffraction pattern was indistinguishable from that of the D-glucoside. Calculated for $C_7H_{14}O_6$: C, 43.29%; H, 7.27%. Found: C, 43.50%; H, 7.40%. Paper chromatographic examination of the mother liquor (silver nitrate spray) indicated the presence of glyceritol, methyl glucoside, and a third component (faint streak slightly slower than glyceritol), which was presumed to be 1,3-dihydroxy-2-propanone dimethylketal.

A second aliquot (5 ml) of the deacetylation mixture was concentrated to give a syrup (0.20 g), 0.1 *N* sulphuric acid (10 ml) was added, the solution heated on the steam bath for 5 hours, and neutralized with Dowex-1 (bicarbonate form). The hydrolyzate appeared (paper chromatogram) to contain glucose, 1,3-dihydroxy-2-propanone, and glyceritol. Calcium benzoate (23) (1.0 g) was added, followed by bromine (0.5 ml) and, after 6 hours at room temperature with occasional shaking, excess bromine was removed *in vacuo*. The solution was filtered, treated with a mixture of Amberlite IR-120 and Dowex-1 (bicarbonate form), and concentrated to a volume of 5 ml. Phenylhydrazine (0.8 ml) and acetic acid (0.8 ml) were added and the solution was heated on the steam bath for 0.5 hour. After cooling, a yellow precipitate which formed was collected, dried, and recrystallized three times from benzene, m.p. 131–133°; the X-ray diffraction pattern was indistinguishable from that of triose (1,3-dihydroxy-2-propanone) phenylosazone. Calculated for $C_{15}H_{16}ON_4$: C, 67.14%; H, 6.01%. Found: C, 67.20%; H, 5.96%.

Partial Oxidation of Sucrose with Periodate and Reduction of the Product

Sucrose (3.4 g) in 50% ethanol (100 ml) was treated at 0° in the dark for 30 hours with sodium periodate (2.1 g in 43 ml of 50% ethanol). A precipitate which formed was filtered off, a slight excess of hot strontium hydroxide solution was added slowly with efficient stirring, the reaction mixture filtered, and the filtrate treated with a mixture of Amberlite-IR-120 and Dowex-1 (bicarbonate form). The final filtrate and washings were concentrated *in vacuo* at 40°. Weight, 3.0 g.

The partially oxidized sucrose (0.6 g) was reduced with sodium borohydride, followed by acetylation, as described above for lead-tetraacetate-oxidized sucrose. The syrupy acetate (1.0 g), on deacetylation with sodium methoxide, was found (paper chromatogram) to consist of one major and two minor components in addition to a large proportion of unoxidized sucrose. The major product ($R_{sucrose}$ 3.0) was detected on the chromatogram with silver nitrate but not with urea oxalate or *p*-anisidine hydrochloride, and hence appeared to be the polyol derived via oxidation of sucrose by 3 moles periodate per mole. One of the minor components ($R_{sucrose}$ 1.7) contained unoxidized fructose as shown by its color reaction with urea oxalate; the third product ($R_{sucrose}$ 2.4) corresponded on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

chromatogram to compound III, giving a yellow-brown color with *p*-anisidine hydrochloride and a negative ketohexose test with urea oxalate.

When sucrose was oxidized with 2 moles of sodium periodate, reduced, acetylated, and deacetylated (as above) the proportion of sucrose unoxidized was lower, and of the compound ($R_{sucrose}$ 3.0), increased slightly. The compounds having $R_{sucrose}$ 1.7 and 2.4 were now present in relatively higher proportion and a second fructose-containing product ($R_{sucrose}$ 2.0) was detected also. This mixture was not resolved satisfactorily by chromatography on a cellulose column (24) using butanol, containing varying percentages of water, as eluent.

ACKNOWLEDGMENTS

Dr. D. J. Bell very kindly provided a sample of methyl β-D-fructofuranoside. The authors express thanks to J. W. L. C. Christ for technical assistance, to M. Mazurek for microanalyses, and to Miss I. Gaffney, for preparing X-ray diffraction diagrams.

PYRROLE CHEMISTRY

II. 2-PYRROLECARBONITRILE, 1-METHYL-2-PYRROLECARBONITRILE, AND THEIR NITRATION PRODUCTS[1]

HUGH J. ANDERSON

ABSTRACT

The 2-nitriles of pyrrole and 1-methylpyrrole have been prepared by the dehydration of the corresponding aldoximes. These compounds have been nitrated and the ratios of 4- and 5-nitro isomers have been determined. The 2-cyano group appears to be less strongly "meta"-directing (i.e. toward the 4-position) during nitration in the pyrrole series than in the benzene ring.

In a previous paper some investigations were reported concerning directive effects in the pyrrole ring system. These researches have now been extended by the nitration of pyrrole and 1-methylpyrrole possessing a cyano group in the 2-position. The strongly meta-directing effect of this group tending to place an incoming substitutent in the 4-position is thus competing with the normally α-directing hetero atom which would place it in the 5-position. Although many substituted cyanides of pyrrole are known, neither 2-pyrrolecarbonitrile nor 1-methyl-2-pyrrolecarbonitrile are reported in the literature.

These two compounds (I and II) have now been prepared through the dehydration of the oximes of their readily available aldehydes. Fischer and Orth (2) have reported that heating 2-pyrrolecarboxaldoxime with a mixture of acetic anhydride and sodium acetate produced only 5-acetyl-2-pyrrolecarbonitrile, but acetic anhydride alone gave us a good yield of the desired product. Both this nitrile and the 1-methyl homologue could be hydrolyzed by potassium hydroxide in ethylene glycol at 130–140° to moderate yields of the known acids. Attempted acid hydrolysis leads to extensive decomposition. Several authors (3) have reported that substituted nitriles of pyrrole resist hydrolysis, however, these were mostly alkyl-substituted 3-pyrrolecarbonitriles.

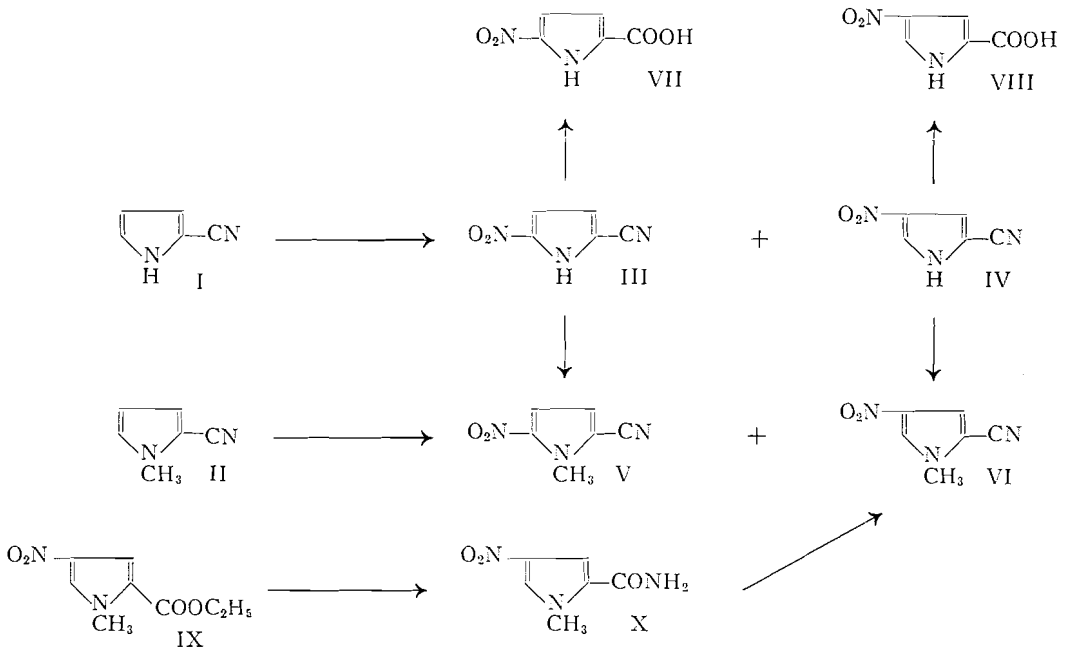
It was hoped that a one-step preparation of these nitriles might be developed by an adaption of the procedure of Lettré, Jungmann, and Salfeld (4), who used N-phenyl-N-methylcyanamide and phenyllithium to prepare benzonitrile. We hoped that it might be possible to substitute the readily available N,N-dimethylcyanamide for their reagent, which is difficult to prepare. However, a trial using a 2-thienyllithium produced no neutral fraction, and another with 2-pyrrylmagnesium bromide also failed to give any of the desired nitrile. Presumably the amidines were formed instead.

As pointed out previously (1, 5) the proportions of 4- and 5-nitro derivatives formed through the reaction of acetyl nitrate and pyrroles possessing a meta-directing substituent in the 2-position are similar to those formed from the corresponding thiophenes although the α-directing effect of the N-atom is somewhat less than that of the sulphur. When a methyl group replaces the N-hydrogen there is a large increase in the proportion of the 4-nitro derivative.

Two fairly recent papers have reported the nitration of 2-thiophenecarbonitrile but their results are totally different. Reynaud and Delaby (6) isolated 80% 4-nitro and

[1]*Manuscript received August 17, 1959.*
Contribution from the Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland.

20% 5-nitro, identifying their products by conversion to known substances. On the other hand Tirouflet (7) established the ratio of 42% 4- to 58% 5-nitro by means of a polarographic reduction, having first standardized against the pure compounds.



The nitration of 2-pyrrolecarbonitrile with "acetyl nitrate" (fuming nitric acid/acetic anhydride) at 0–10° proceeded normally and chromatography was attempted on alumina.

This method had proved satisfactory in previous separations of nitrated pyrrole derivatives and has the advantage of removing the dark tarry by-products as well. However, from the column we isolated only a single product, 4-nitro-2-pyrrolecarbonitrile (IV), using the usual benzene and benzene/ethyl acetate eluants. When we progressed to ethyl acetate and later to 1:1 ethanol/ethyl acetate a bright yellow solid was obtained. This substance was recrystallized from benzene/ethyl acetate and melted at 292°. It proved to be the sodium salt of 5-nitro-2-pyrrolecarbonitrile. The sodium salt was very soluble and quite stable in water. The desired product (III) could be obtained by ether extraction from the acidified aqueous solution.

The very weakly acidic nature of pyrrole is strengthened by the presence of an electron-withdrawing group in the 2-position which decreases the electron density at the nitrogen and facilitates the loss of the proton from the nitrogen. This situation is similar to the behavior of the corresponding *p*-substituted phenol. The same type of group in the 3-position of pyrrole has considerably less effect and thus α-nitro-substituted pyrroles are more acidic than β-nitro ones. Rinkes (5) made use of this observation in separating isomers from the nitration of 2-acetylpyrrole and other compounds. In these mixtures the 4-nitro could be extracted by ether from a basic aqueous solution while the 5-nitro isomer remained behind. The dinitropyrroles were found to be much more acidic, and separation was achieved by extracting 2,4-dinitropyrrole from an aqueous sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

acetate solution leaving 2,5-dinitropyrrole behind. Thus it is not surprising that 5-nitro-2-pyrrolecarbonitrile with two strongly electron-withdrawing groups in α-positions should be quite acidic. Nevertheless, the isolation of such a stable sodium salt is somewhat unusual in the pyrrole series where most preparations have made use of sodium or sodium alkoxide under anhydrous conditions (8, 9).

When the nitrated 1-methylpyrrole was chromatographed it was found that even a long column did not provide a clear separation of the isomers, so eventually a simplified fractional crystallization from petroleum pentanes was used successfully.

The melting points of our 4- and 5-nitro-2-pyrrolecarbonitriles (III and IV) coincide with those recently reported by Tirouflet and Fournari (10), who prepared them by dehydration of the corresponding nitroaldoximes. Hydrolysis in concentrated hydrochloric acid was successful and mixed melting points with authentic specimens of the known nitroacids (VII and VIII) were undepressed.

The 1-methyl analogs (V and VI) would not hydrolyze in acid solution and base destroyed them as it does most nitrated pyrroles. Consequently, we N-methylated the nitro-2-pyrrolecarbonitriles (III and IV) and confirmed the identity of (V and VI) by mixed melting points. In addition it was possible to nitrate ethyl 1-methyl-2-pyrrolecarboxylate although only the 4-nitro isomer (IX) could be isolated. This ester (IX) was then ammonolyzed to the amide (X) and dehydrated with phosphorus oxychloride and pyridine to 4-nitro-1-methyl-2-pyrrolecarbonitrile (VI) which was identical with one of our isomers.

From the nitration of 2-pyrrolecarbonitrile we found that the 4-nitro isomer constituted about 40% of the mononitro fraction. Thus the —CN group seems to have somewhat less meta-directing ability in the pyrrole ring nitration than has the carbomethoxy and considerably less than acetyl or nitro groups. This is quite different from the benzene series where the meta-directing ability of the cyano group lies between nitro and acetyl in nitrations (12). However, it is similar to the proportion found in the thiophene series by Tirouflet, although not by Reynaud and Delaby.

As expected, the proportion of 4-nitro isomer was much higher for 1-methyl-2-carbonitrile—about 70% of the mononitro product. This also falls below the percentage of 4-isomer formed during nitration by the analogous 2-acetyl compound.

EXPERIMENTAL

2-Pyrrolealdoxime

A solution of hydroxylamine hydrochloride (7.5 g, 0.11 *M*) and sodium acetate trihydrate (15 g, 0.11 *M*) in 30 ml water was shaken vigorously with 2-pyrrolealdehyde (9.0 g, 0.095 *M*) for 5 minutes, then refrigerated overnight. The crude product weighed 9.2 g (84%). After recrystallization from benzene its melting point was 164–164.5°. Literature 165–166° (13).

1-Methyl-2-pyrrolealdoxime

This compound was prepared from the corresponding aldehyde by the same procedure. After recrystallization from water its melting point was 148.5–149.5°. Calc. for $C_6H_8N_2O$: C, 58.05; H, 6.49; N, 22.57; O, 12.89. Found: C, 58.10; H, 6.45; N, 22.38%.

2-Pyrrolecarbonitrile (I)

2-Pyrrolealdoxime (9.2 g, 0.084 *M*) in acetic anhydride (30 ml) was warmed slowly and then refluxed gently for 20 minutes. The cooled reaction product was poured into 200 ml cold water, extracted three times with 20-ml portions of ether, and dried over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

sodium sulphate. After removal of the ether the residue was vacuum-distilled and the fraction, b.p. 89–90° at 1.5 mm, was collected. Yield 4.7 g (61%). Calc. for $C_5H_4N_2$: C, 65.20; H, 4.38; N, 30.42. Found: C, 65.09; H, 4.36; N, 30.25%.

The nitrile (0.5 g) was heated at 165–180° with potassium hydroxide (5 g) in ethylene glycol (10 ml) for 1 hour. The crude acid (0.28 g) obtained from this hydrolysis melted at 203–204° (decomp.) after several recrystallizations from water. The mixed melting point with an authentic specimen of 2-pyrrolecarboxylic acid was undepressed.

1-Methyl-2-pyrrolecarbonitrile (II)

1-Methyl-2-pyrrolealdoxime (10 g, 0.079 *M*) was dehydrated with acetic anhydride in the manner described above. The product weighed 5.2 g (61%) and had b.p. 86–88° at 11 mm. Calc. for $C_6H_6N_2$: C, 67.90; H, 5.70; N, 26.40. Found: C, 67.88; H, 5.72; N, 26.35%.

The nitrile (0.5 g) was hydrolyzed as before at 130–140° for 1 hour. The crude product weighed 0.55 g and on recrystallization from aqueous ethanol had m.p. 135–136°. The mixed melting point with authentic 1-methyl-2-pyrrolecarboxylic acid was undepressed.

Nitration of 2-Pyrrolecarbonitrile

The nitrile (1.2 g, 0.011 *M*) was dissolved in acetic anhydride (7 ml) and chilled to 0°. To this was added a mixture of fuming nitric acid (d = 1.5, 1.5 g, 0.023 *M*) and acetic anhydride (2.0 ml) while the temperature was kept below 10°. The dark solution was poured into 25 ml ice water with vigorous stirring and extracted with three 15-ml portions of ether and dried. After removal of all solvents under reduced pressure the crude red solid weighed 1.55 g.

Chromatography was commenced on alumina (150 g) using benzene and later 1:1 benzene/ethyl acetate as eluants. From these fractions a total of 0.5 g of pale yellow solid was obtained. Pure ethyl acetate gave no further solid, however, 1:3 ethanol/ethyl acetate and later 1:1 ethanol/ethyl acetate produced about 0.8 g of a bright yellow solid with a very high melting point (292° from benzene/ethyl acetate).

The first solid, 4-nitro-2-pyrrolecarbonitrile (IV), was recrystallized from water, m.p. 150.5–151°. (Tirouflet reported 152°.) Calc. for $C_5H_3N_3O_2$: C, 43.80; H, 2.21; N, 30.65; O, 23.34. Found: C, 43.84; H, 2.20; N, 30.40%. A small amount of this nitrile was refluxed with concentrated hydrochloric acid for 30 minutes. From the hydrolysis was obtained an acid which, after several recrystallizations from water, was a pale cream solid m.p. 210–212° (slight decomp.). Rinkes found 216° for 4-nitro-2-pyrrolecarboxylic acid.

The second solid from the chromatography was dissolved in a small amount of water, cooled, and acidified with concentrated hydrochloric acid. The colorless solid obtained was filtered, dried, and recrystallized from water. Its melting point was 172.5–173°. (Tirouflet found 174° for 5-nitro-2-pyrrolecarbonitrile (III) and a greenish-yellow color.) Calc. for $C_5H_3N_3O_2$: C, 43.80; H, 2.21; N, 30.65; O, 23.34. Found: C, 43.65; H, 2.28; N, 30.41%. A small amount of this nitrile was hydrolyzed in concentrated hydrochloric acid. The pale cream-colored product after recrystallizing from water melted at 159–161°. Rinkes gives m.p. 161° for 5-nitro-2-pyrrolecarboxylic acid.

Nitration of 1-Methyl-2-pyrrolecarbonitrile

The nitrile (1.3 g, 0.021 *M*) was nitrated and worked up in the manner described above, and the crude product (1.50 g) chromatographed on alumina (150 g). Elution with benzene/petroleum pentanes produced no real separation nor did rechromatography of the first six fractions. Consequently all fractions were extracted repeatedly with small amounts of hot petroleum pentanes. From these extracts 0.36 g of solid was obtained,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

m.p. 86–86.5° after several recrystallizations from water. This was compound V. Calc. for $C_6H_5N_3O_2$: C, 47.68; H, 3.34; N, 27.81; O, 21.17. Found: C, 47.51; H, 3.19; N, 27.60%. Compound V failed to undergo hydrolysis in concentrated hydrochloric acid and was destroyed by hot base.

The less soluble fraction was recrystallized from benzene/petroleum hexanes and weighed 0.86 g. After a final recrystallization from water it had m.p. 157.5–158°. This was compound VI. Calc. for $C_6H_5N_3O_2$: C, 47.68; H, 3.34; N, 27.81; O, 21.17. Found: C, 47.55; H, 3.27; N, 27.68%. Compound VI also failed to undergo hydrolysis to the corresponding acid.

Preparation of Compounds V *and* VI *by* N-*Methylation*

To a solution of 4-nitro-2-pyrrolecarbonitrile (50 mg) in toluene (10 ml) was added a solution of sodium metal (100 mg) in ethanol (1 ml). The mixture was refluxed gently for 3 minutes, methyl sulphate (0.3 g) added, and refluxed 5 minutes longer. The cooled mixture was extracted twice with 5-ml portions of 1 *N* sodium hydroxide solution. The organic layer was dried over sodium sulphate and nearly all solvent removed in vacuum. At this point an excess of petroleum pentanes was added and the precipitate filtered. After recrystallization from water the 4-nitro-1-methyl-2-pyrrolecarbonitrile (25 mg) melted at 156–158° and mixed melting point with compound VI was 156–158°.

In a similar manner 5-nitro-2-pyrrolecarbonitrile was converted to the 1-methyl analog m.p. 83–84° (from water). Mixed melting point with compound V 83–84°.

Nitration of Ethyl 1-Methyl-2-pyrrolecarboxylate

Ethyl 1-methyl-2-pyrrolecarboxylate (1.53 g, 0.01 *M*) in acetic anhydride (8 ml) was treated with a mixture of fuming nitric acid (1.1 g, 0.018 *M*) and acetic anhydride (2.0 ml) keeping the temperature below −5°. After hydrolysis in cold water the product was extracted with ether, dried over sodium sulphate, and all solvent removed under vacuum. The crude red solid (1.33 g) was chromatographed on alumina (150 g) using benzene/petroleum pentanes as eluant. From the chromatogram 0.35 g of unreacted ester was recovered and 0.52 g of a product (IX) which on recrystallization from aqueous alcohol had m.p. 112.5–113°. The reported melting point of ethyl 4-nitro-1-methyl-2-pyrrolecarboxylate is 113–114° (11). In addition the chromatogram produced a small amount of acidic material presumably resulting from the hydrolysis of the ester. It was not identified. None of the isomeric 5-nitro ester was found.

Ammonolysis of the Ester IX

A solution of the 4-nitro ester (0.4 g) was dissolved in methanol (10 ml) and cooled during saturation with ammonia gas. The flask was stoppered tightly and allowed to stand for a week at room temperature. A bright yellow solid which had separated was completely precipitated by the addition of 5 ml water. After several recrystallizations the pale yellow 4-nitro-1-methyl-2-pyrrolecarboxamide (X) (0.32 g) had m.p. 224–225°. Calc. for $C_6H_7N_3O_3$: C, 42.61; H, 4.18; N, 24.85; O, 28.37. Found: C, 42.43; H, 4.15; N, 24.50%.

Dehydration of the Amide (X)

The amide (0.3 g) was dissolved in freshly dried pyridine (3 ml). To this was added phosphorus oxychloride (0.4 g) resulting in vigorous reaction. After this had subsided the mixture was cooled, diluted with 10 ml water, chilled again, and filtered. The crude solid (0.18 g) was recrystallized from water, m.p. 155–157°. A mixed melting point with product VI from the nitration of 1-methyl-2-pyrrolecarbonitrile was undepressed confirming the latter as 4-nitro-1-methyl-2-pyrrolecarbonitrile.

THE DECAY OF ACTIVE NITROGEN AT HIGH TEMPERATURES[1]

R. A. BACK,[2] W. DUTTON, AND C. A. WINKLER

ABSTRACT

Previous studies of the decay of active nitrogen have been extended to higher temperatures. A more detailed treatment of the results suggests that surface recombination of nitrogen atoms may be either first or zero order. Rate constants for both the surface and the homogeneous recombination of nitrogen atoms are reported. The latter shows a slight positive temperature coefficient.

In a previous paper from this laboratory (1), a method was described for measuring the rate of decay of active nitrogen. Measurements were made at 55° C and 400° C, and rate constants for the recombination of nitrogen atoms on the surface and in the gas phase were reported. In the present paper, similar measurements at higher temperatures are described, together with a slightly revised treatment of the previous data.

EXPERIMENTAL

The apparatus and method were similar to those used previously, with a few minor changes. Active nitrogen was produced in a condensed discharge in a fast-flow system under conditions of complete initial dissociation of the nitrogen. It was passed through a "decay tube" of fixed dimensions into a reaction vessel, where the atom concentration was measured chemically using the reaction with ethylene at 400° C. By studying the decay over a range of pressures, it was possible to separate homogeneous and heterogeneous decay processes. A Vycor discharge tube and decay tube permitted measurements up to 1000° C. Much improved estimation and control of the temperature of the decay tube was possible with a concentric thermocouple well, combined with a sectionally wound furnace. The decay tube was larger (455 cc) than in the previous experiments, in anticipation of a shorter contact time at higher temperatures.

It was hoped originally to compare decay rates at various temperatures under the same surface conditions. However, the instability of most poisons above 400° C caused serious difficulty; Na_2HPO_4, which behaved very reproducibly at 55 and 400° C, deteriorated badly at 700° C, and Na_3PO_4 was no better. Although $AlPO_4$ was slightly more stable at 700° C, and consistent data could be obtained from experiments done in a single day, it was completely ineffective as a poison at 1000° C. The most stable poison at 700° C, was $Mg_3(PO_4)_2$ and this was the only substance that was at all effective at 1000° C, at which temperature, however, it deteriorated rapidly.

When a good poison, stable at 400° C, was heated for some time to 700° C or 1000° C, it was practically ineffective when used again at 400° C. Thus, an irreversible physical change in the poison at high temperature was involved, rather than simply a reversible increase in γ, the recombination efficiency.

THEORY

The theory of nitrogen atom decay in a similar apparatus has been treated previously

(1), and will be used here with one or two modifications. Kelly and Winkler considered two possible modes of surface decay, first order and second order in nitrogen atoms. Homogeneous decay was assumed to be second order in nitrogen atoms, and termolecular. Two extreme cases were considered, the first of which assumed nitrogen atoms and nitrogen molecules to be equally effective as third bodies, while the second assumed nitrogen atoms to be completely ineffective. For simplicity, only the former case will be considered in the present work, and the two differential equations for first and second order surface decay are, respectively,

$$[1] \qquad -dN/dt = k_1\mathrm{N} + k_2\mathrm{N}^2p,$$

$$[2] \qquad -dN/dt = k_3\mathrm{N}^2 + k_2\mathrm{N}^2p.$$

A third possible mode of surface decay, not considered previously, is zero order in nitrogen atoms, and for this

$$[3] \qquad -dN/dt = k_4 + k_2\mathrm{N}^2p.$$

Upon integration of these equations over a time of decay, t, assuming initial complete dissociation of the nitrogen, and expressing N atom concentration as partial pressure,

$$[4] \qquad p/p_\mathrm{N} = e^{k_1t} + p^2(e^{k_1t}-1)k_2/k_1$$

$$[5] \qquad 1/p_\mathrm{N} - 1/p = (k_3 + k_2p)t$$

$$[6] \qquad (p-p_\mathrm{N})/t = (k_4 + p_\mathrm{N}p^2k_2)\ (\tan\theta)/\theta$$

where p = total pressure, p_N = partial pressure of nitrogen atoms, and $\theta = t(k_4k_2p)^{\frac{1}{2}}$.

In the previous study, t was taken to be approximately constant, independent of pressure, whereupon it is easily shown that

$$\lim_{p\to 0} \quad p_\mathrm{N}/p = 1, \text{ for equation [5]}$$
$$= e^{-k_1t}, \text{ for equation [4]}$$
$$= 0, \text{ for equation [6]}.$$

Since p_N clearly did not approach p as the pressure was reduced, second order surface decay was ruled out. Since a zero order surface decay had not been considered, it was concluded that the surface decay was first order, and k_1 and k_2 were evaluated from suitable plots of equation [4].

The assumption of constant decay time, while it simplified the treatment considerably, may perhaps introduce appreciable errors under some conditions. The decay time varied considerably with pressure, and increased rather sharply at very low pressures. This could affect both the determination of the order of the surface decay, by affecting the limiting value of p_N/p, and the numerical values of the rate constants. In the present paper, therefore, the variation of t with pressure is taken into account. Decay time was measured, and each of equations [4], [5], and [6] in turn was plotted in a suitable way to determine the order of surface decay and values of the decay constants. If surface decay were first order, a plot of $(p/p_\mathrm{N}) - e^{k_1t}$ versus $(e^{k_1t}-1)p^2$ should be linear, and pass through the origin, with slope k_2/k_1. The value of k_1 could be determined by successive approximations to give the best extrapolation to the origin. If surface decay were second order, a plot of $(1/p_\mathrm{N} - 1/p)/t$ versus p should be linear, with intercept k_3 and slope k_2. If surface decay were zero order, a plot of $(p-p_\mathrm{N})/t$ against $p_\mathrm{N}p^2$ should

be approximately linear. The factor $(\tan\theta)/\theta$, and thence values of k_4 and k_2, could be evaluated by a method of successive approximations.

RESULTS

Consistent data were obtained with Na_2HPO_4 and $Mg_3(PO_4)_2$ poisons at 400° C, and with $AlPO_4$ and $Mg_3(PO_4)_2$ at 700° C, and these were treated in the manner described above. No poisons were sufficiently stable at 1000° C to permit calculation of rate constants. The previous data of Kelly and Winkler, using Na_2HPO_4 poison at 55° C and 400° C, were also treated in the same way, taking into account the variation of t and the possibility of zero order surface decay.

In every case, the plot of equation [5] yielded a curve with negative slope at low pressures, while at higher pressures the slope became positive, which clearly indicates that the surface decay was not second order.

Plots of equation [4], representing first order surface decay, always had positive slopes, and showed considerable curvature. Such curvature may be attributed, as before, to the deviation, with increasing pressure, from required conditions such as complete initial dissociation, negligible radial concentration gradients, and others (1). Rate constants were thus determined from the slopes and intercepts of low pressure asymptotes of these curves.

Plots of equation [6], corresponding to zero order surface decay, also showed positive slopes and some curvature, and rate constants were again estimated from low pressure asymptotes. Some of this curvature is due to the variation of $(\tan\theta)/\theta$ with pressure. These plots were neither more nor less linear than those of equation [4], and it appears impossible to distinguish between first and zero order surface decay by the present method, although the data are clearly incompatible with a second order process.

TABLE I

Rate constants for homogeneous atom combination

Temp., ° C	Surface poison	Source of data	Values of k_2 (molecules^{-2}. cc^2. sec^{-1}) $\times 10^{33}$		
			1st order surface decay, neglecting change in t	1st order surface decay, allowing for change in t	Zero order surface decay

700	$Mg_3(PO_4)_2$	This work	14.4	112	145
	$AlPO_4$	This work	9.3	119	147

In Table I are shown values for k_2, the termolecular rate constants for the homogeneous recombination of nitrogen atoms, assuming either first or zero order surface decay. Two sets of values are reported for the first order surface decay, one calculated by the simpler method of Kelly and Winkler, the other corrected for the variation of decay time with pressure. It should be noted that nitrogen atoms and molecules are assumed to be equally effective as third bodies in this treatment. If nitrogen atoms were completely ineffective, values of k_2 would be approximately doubled.

In Table II are shown values of the surface recombination efficiency, γ, defined in

DISCUSSION

The general effect of neglecting the variation of decay time with pressure (Tables I and II) was to lower the values of k_2 and raise the values of γ. The largest error was introduced in the value of k_2, where it amounted to a factor of 10 at 700° C and a factor of about two at the lower temperatures. The effect on the values of γ was much less pronounced, the largest error being a factor of about 1.5 at 700° C.

The values of k_2 are affected considerably by the order assumed for the surface decay. Zero order surface decay requires a larger value of k_2 than does first order surface decay, the difference being more pronounced at lower temperatures. With both orders, k_2 appeared to increase markedly with increasing temperature. An Arrhenius plot was not linear, and was only slightly improved by plotting log $(k_2/t^{\frac{1}{2}})$ to allow for the increase in the termolecular collision rate with temperature. "Activation energies" of between 0.5 and 2 kcal may be estimated from these plots, although undoubtedly the variation of k_2 with temperature is too complex to be described by a simple exponential temperature dependence. If the termolecular recombination proceeds through the $^5\Sigma$ state of N_2 (2, 3), the radiationless transition to the $^3\pi$ state might depend in a critical way on the vibrational energy of the former state, and hence on the temperature. It is perhaps interesting that other termolecular atom combination processes, which proceed simply through the ground state of the diatomic molecule, show the expected small negative temperature coefficient (4, 5, 6).

Values of k_2 in Table I may be compared with values of 200×10^{-33} (7), 33×10^{-33} (8),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

17×10^{-33} (9), and 15×10^{-33} (10) (molecules^{-2}.cc^2.sec^{-1}), measured by a variety of methods, all at about room temperature. In some of these methods, surface recombination was perhaps not adequately taken into account, and high values were obtained. Atom concentrations were measured in the first two cases by a calorimetric probe technique, of somewhat doubtful efficiency, while the latter two used the nitric oxide flame titration, which yields atom concentrations about 1.5 times those measured by the ethylene reaction (11). Herron *et al.* reported no temperature dependence of k_2 between 25° and 180° C (10).

The surface decay constants showed surprisingly little temperature dependence. A first order surface recombination of atoms is usually interpreted as a reaction between gas-phase atoms and adsorbed atoms on a fully covered surface (12). A zero order surface combination implies a bimolecular surface reaction between adsorbed atoms, again on a fully covered surface. It may be noted that with either mechanism, a sparsely covered surface leads to a second order process, which clearly does not fit the experimental results. Both mechanisms thus require a fully covered surface, over a considerable range of temperature and atom concentration, which implies a very strong adsorption, probably chemisorption, of the nitrogen atoms. The small temperature dependence of the decay constants is in accord with this view.

The observed values of γ are quite compatible with the suggested first order mechanism, and are of the same order of magnitude as those measured for similar recombinations of oxygen and hydrogen atoms (13, 14, 15). The zero order mechanism, on the other hand, perhaps presents some difficulties. In bimolecular surface reactions on a sparsely covered surface, the adsorption of one atom onto a site adjacent to another one is usually thought to be the rate-controlling step. Obviously, in a zero order process, with a fully covered surface, this is no longer true, and the rate must be controlled by the rate of interaction of atoms already adsorbed on adjacent sites. The values of γ, the fraction of collisions with the surface leading to combination, at least permit a rate of combination much slower than the rate of adsorption, if the adsorption process were highly efficient. A bimolecular surface reaction on a fully covered surface would require a high surface concentration of atoms, as the strongly chemisorbed atoms would have little mobility. Superficially, the zero order process seems rather less likely, mechanistically, than the first order one, but it must be emphasized that the present data clearly do not enable distinction between the two.

Finally, the limited accuracy of the present method should be pointed out. Because of inherent approximations and errors, an accuracy of perhaps $\pm50\%$ should be assigned to the numerical values of the decay constants. It might be noted that the variation of k_2 with temperature seems well beyond these limits.

TERNARY COMPOUNDS IN THE SYSTEM NH_3–H_2O_2–H_2O[1]

PAUL A. GIGUÈRE AND DAVID CHIN

ABSTRACT

A thermal analysis of the three-component system ammonia – hydrogen peroxide – water was carried out by adding anhydrous ammonia to the hydrate $H_2O_2 \cdot 2H_2O$. A first compound was found, with formula $NH_3 \cdot 3H_2O_2.6H_2O$, melting at −28.9° C; another compound melting around 15° appears to be a hydrate of ammonium peroxide, $(NH_4)_2O_2 \cdot 2H_2O$. The eutectics are at −54.5°, 0.7% NH_3, and −33.4°, 12.5% NH_3. Careful redeterminations have confirmed that the melting point of the hydrate $H_2O_2 \cdot 2H_2O$ is −52°, not −50° as was sometimes claimed. The latent heat of fusion of that compound is estimated to be 3.9 kcal and the degree of dissociation on melting, about one-third.

Following various investigations, the phase equilibria are now fairly well established for the three binary systems NH_3–H_2O (1, 2), H_2O_2–H_2O (3), and NH_3–H_2O_2 (4, 5). For reference the three phase diagrams are illustrated in Fig. 1. No work has been reported yet on the corresponding three-component system, although formation of ternary

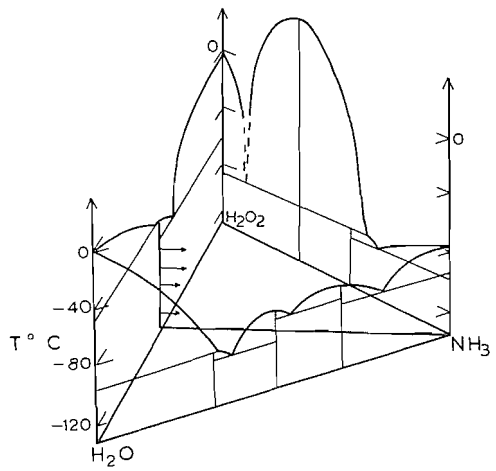

FIG. 1. Phase equilibria in the three binary systems formed between ammonia, hydrogen peroxide, and water. The present investigation was carried out along the plane marked by the arrows.

compounds was to be expected. Some evidence in that connection was detected in a recent spectroscopic study of crystalline ammonium hydroperoxide (6). Using the same thermal analysis apparatus as previously (7) the melting-point curve along the plane NH_3–$H_2O_2 \cdot 2H_2O$ was determined up to 20% ammonia.* Beyond that concentration the method used was impracticable due to the high partial pressure of ammonia over the solutions.

EXPERIMENTAL

The compound $H_2O_2 \cdot 2H_2O$ was selected as the starting point in preference to the

hydrates of ammonia which melt at much lower temperatures; as for ammonium hydroperoxide, m.p. 25° (4), preliminary tests indicated that it decomposes badly when small amounts of water are added. On the contrary, a stable stock solution of hydrogen peroxide 48.6% in water is easily prepared. Anhydrous ammonia gas from a commercial cylinder was first dried over pellets of caustic potash and bubbled slowly through the solution of hydrogen peroxide in the freezing tube. The latter was cooled in ice to prevent decomposition of the peroxide by the heat of solution. A precision bore flow-rator was used to meter the ammonia gas, and the final composition of the solution was determined by titration of an aliquot with 0.1 *N* HCl using methyl orange as indicator; there was no noticeable interference from the hydrogen peroxide. Because of the strong tendency of the solutions to supercool, seeding was required in most cases.

DISCUSSION OF RESULTS

Some 20 melting-point determinations are listed in Table I and shown on the phase diagram in Fig. 2. The first compound encountered at 7.5% NH_3 separated out as a fine white powder that settled at the bottom of the freezing tube. Existence of a definite

TABLE I

Freezing points in the system NH_3–$H_2O_2 \cdot 2H_2O$

6.2	−29.9	19.8	− 4.0

compound with formula $NH_3 \cdot 3(H_2O_2 \cdot 2H_2O)$ was in a way unexpected since the corresponding binary compounds have not been found, either in the ammonia–water or in the ammonia – hydrogen peroxide systems. However, the latter two-component system has not been investigated thoroughly in the low ammonia concentration range. Maass and Hatcher (4) reported no measurement from 4.3 to 18% NH_3, and in the more recent work of Mironov (5) a single determination was carried out at 9.7% NH_3 which pointed to a much lower eutectic temperature, −93°, than at first thought, −47° (4). The difficulty here comes from the extreme viscosity and the turbidity of these solutions at low temperatures so that they cannot be made to crystallize cleanly. A couple of attempts yielded melting points of −17.6° and −4.2° respectively for solutions of 4.5% and 13.9% NH_3 in anhydrous hydrogen peroxide, in fair agreement with the data of Maass and Hatcher. Although that portion of the phase diagram remains unsettled it seems very doubtful, from the trend of the liquidus, if a compound $NH_3 \cdot 3H_2O_2$ exists.

The other ternary compound appeared when solutions containing over 15% NH_3 were cooled. In the melting-point apparatus it separated out as white granular crystals much denser than the liquid; when grown slowly from the appropriate solutions at around −10° it resembled a lump of sugar and was indefinitely stable at 0°. Several melting-point measurements gave only an approximate value. At 12° the crystals looked damp

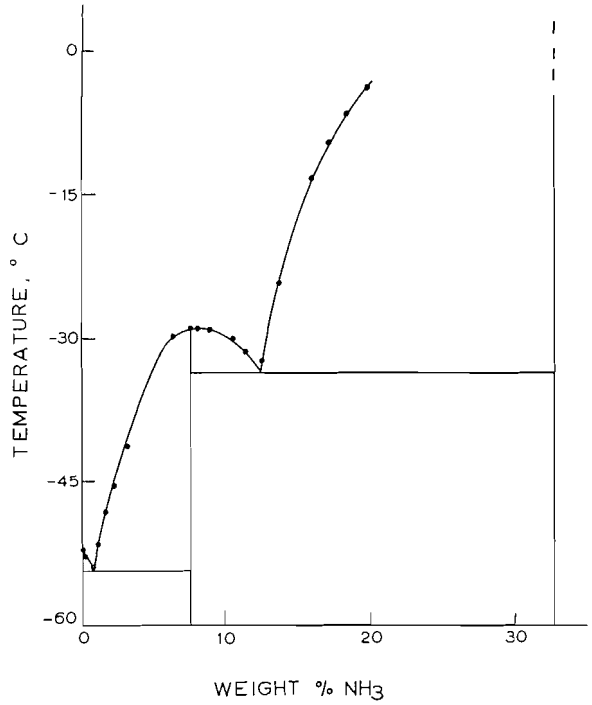

FIG. 2. Melting point curve for the system NH_3–$H_2O_2 \cdot 2H_2O$.

and seemed to wet the glass capillary; at that stage there was some gas evolution. Liquefaction was complete by 15°. The premelting was no doubt caused by some trapped mother liquor as shown by the chemical analysis: 31.5% NH_3 against the theoretical 32.7% for the ratio $2NH_3/H_2O_2 \cdot 2H_2O$.

The nature of the two ternary compounds is of some interest in relation to the various binary compounds of the three systems under consideration. The solid hydrates of ammonia have been proved by spectroscopy (8) and other physical methods (9, 10) to exist as molecular crystals; likewise the dihydrate of hydrogen peroxide is of the molecular type in the solid state (11). On the other hand, the 1:1 ammonia – hydrogen peroxide compound, although molecular in the molten state (12), is actually ionic when solid, NH_4O_2H (6, 13) due, probably, to the mild acid–base character of the two components. As for the meritectic 2:1 ammonia – hydrogen peroxide compound (Fig. 1) discovered recently by Mironov (5) it must have a molecular structure considering its low melting point, −93°, and narrow range of existence. Now, these two criteria point to the same conclusion as far as the first ternary compound $NH_3 \cdot 3H_2O_2 \cdot 6H_2O$ is concerned. For the other ternary compound, however, the apparently sharp melting curve and good thermal stability denote rather some degree of ionic character as would be expected in the hydrate of ammonium peroxide, $(NH_4)_2O_2 \cdot 2H_2O$. An attempt was made to establish that structure by infrared spectroscopy in the 3μ region, but due to difficulties in preparing a suitable sample of the solid, together with strong absorption from the water of crystallization, only vague indications could be found of the characteristic bands of the NH_4^+ ion. It is not clear why the presence of water of crystallization should favor an ionic structure while the anhydrous ammonium peroxide does not exist.

For personal use only.

This time again a very careful redetermination of the melting point of the hydrate $H_2O_2 \cdot 2H_2O$ has confirmed the value $-52°$ found previously in this laboratory by two different methods (7, 14). The higher value $-50.2°$ reported at first (3), and again recently, by Mironov (15, 16) must be discarded for reasons already set forth (7). In addition, further results from the same author on the ammonia–water system (17) show the same systematic discrepancy of 2° with all other published data (2). Lastly, the heat of fusion of the hydrate $H_2O_2 \cdot 2H_2O$ was estimated to be 3.9 kcal from the average of a few calculations based either on its melting curve, after correction for the presence of the solute (H_2O_2) in the solid phase, or on the lowering of its melting point by methanol. Two determinations with the latter gave a $\Delta T_f = 1.42°$ for a 0.838 molal solution and 2.73° for a 1.58 molal solution of CH_3OH in $H_2O_2 \cdot 2H_2O$. By means of the van Laar equation (18) the degree of dissociation of the hydrate on melting is found to be about one-third.

RÉSUMÉ

L'analyse thermique du système NH_3–$H_2O_2 \cdot 2H_2O$ a prouvé l'existence de deux composés ternaires; l'un, $NH_3 \cdot 3H_2O_2 \cdot 6H_2O$ fond à $-28.8°$ C, l'autre, probablement un hydrate du peroxyde d'ammonium, $(NH_4)_2O_2 \cdot 2H_2O$, fond aux environs de 15°. Deux points eutectiques se trouvent à 0.7% de NH_3 et $-54.5°$, et à 12.5% de NH_3 et $-33.4°$. On a de nouveau vérifié que le point de fusion de l'hydrate $H_2O_2 \cdot 2H_2O$ est bien $-52°$ et non pas $-50°$. La chaleur de fusion de ce composé est d'environ 3.9 kcal et il se dissocie dans la proportion d'un tiers en fondant.

ACKNOWLEDGMENT

The preliminary measurements in this investigation were carried out by Mr. Robert Drouin.

L'ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

VI. SUR L'IDENTIFICATION DE L'ISOMÈRE OBTENU PAR L'ARYLATION DE LA TOLUQUINONE[1]

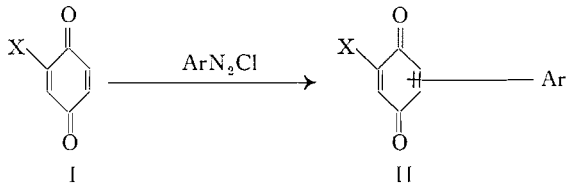
K. HOEGERLE[2] ET P. L'ÉCUYER

RÉSUMÉ

Les trois phényltoluquinones isomères ont été synthétisées à partir de diverses nitroluidines. Ces amines ont donné successivement, par condensation avec le benzène, des méthylnitrobiphényles, par réduction, des méthyl-aminobiphényles et finalement, par oxydation, la 2-méthyl-3-phényl-1,4-benzoquinone, la 2-méthyl-5-phényl-1,4-benzoquinone et la 2-méthyl-6-phényl-1,4-benzoquinone. La 2-méthyl-5-phényl-1,4-benzoquinone ainsi préparée et la phényltoluquinone obtenue par la réaction de la toluquinone avec le chlorure de benzène-diazonium sont identiques.

Une série de réactions analogues à partir de la 4-chloro-2-nitraniline a donné naissance successivement au 4-chloro-2-nitrobiphényle, au 4-chloro-2-aminobiphényle et à la 2-chloro-5-phényle-1,4-benzoquinone. Cette phénylchloroquinone est identique à l'isomère principal isolé de la réaction entre la chloroquinone et le chlorure de benzène-diazonium.

Dans un travail précédent (1) nous avons décrit la réaction de la toluquinone (I, X = CH_3) avec des sels de diazonium aromatiques en milieu tampon aqueux, réaction qui donne des monoaryltoluquinones (II, X = CH_3). Il était déjà connu que, suivant des conditions semblables, des monoaryl-1,4-benzoquinones (I, X = Ar) donnent naissance à des 2,5-bisaryl-1,4-benzoquinones (II, X = Ar) (2, 3, 4, 5) et que la chloroquinone (I, X = Cl) produit des monoarylchloroquinones (II, X = Cl) isomères (6).



I II

X = CH_3, Cl ou Ar Ar: groupe aryle ou phényle

Toutefois, ces résultats ne permettaient pas de déduire d'une façon certaine lequel des trois isomères possibles, la 3-aryl-2-méthyl-1,4-benzoquinone (III), la 5-aryl-2-méthyl-1,4-benzoquinone (IV) ou la 6-aryl-2-méthyl-1,4-benzoquinone (V), est isolé du produit de la réaction de la toluquinone avec les sels de diazonium. Dans le but d'établir la constitution de cet isomère, nous avons synthétisé les trois phényltoluquinones XXI, XXII et XXIII par une suite de réactions non équivoques. Quant aux autres aryltoluquinones qui se forment au cours de l'arylation de la toluquinone avec les sels de diazonium préparés à partir de diverses anilines substituées, il est fort probable qu'elles ont la même structure que la phényltoluquinone (II, X = CH_3, Ar = ϕ) obtenue par la phénylation de la toluquinone (1).

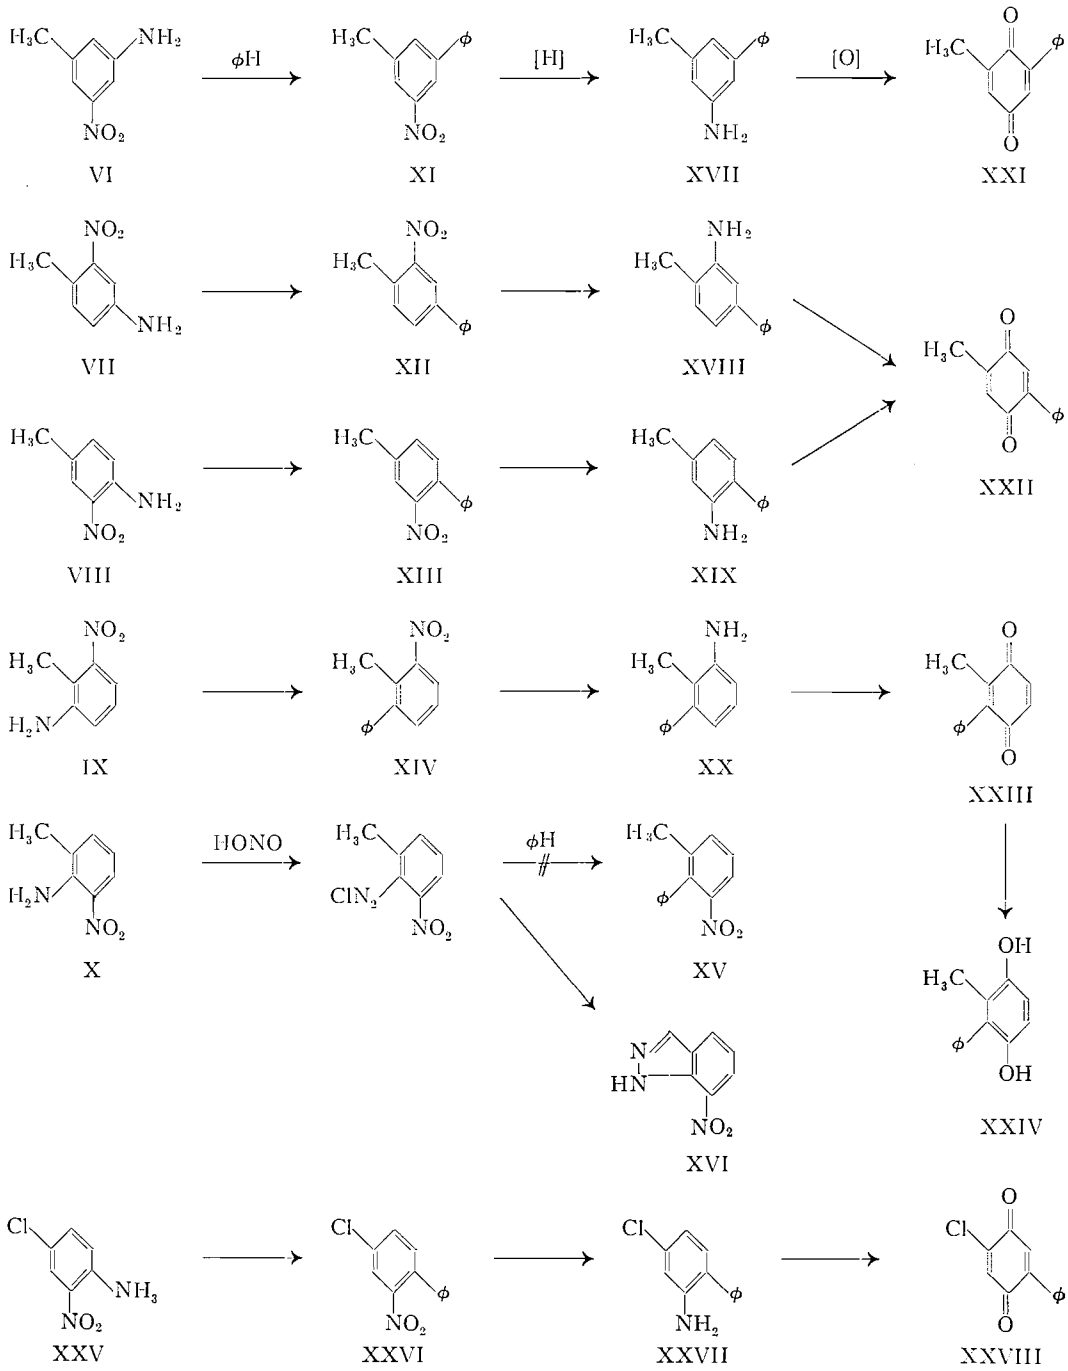
En suivant la modification d'Ellis *et al.* (7), apportée à la réaction de Gomberg (8), nous avons fait agir le benzène sur le chlorure de diazonium provenant de la 3-méthyl-5-nitraniline (VI), de la 4-méthyl-3-nitraniline (VII), de la 4-méthyl-2-nitraniline (VIII), de la 2-méthyl-3-nitraniline (IX) et de la 6-méthyl-2-nitraniline (X). Ainsi nous avons obtenu respectivement le 3-méthyl-5-nitrobiphényle (XI), le 4-méthyl-3-nitrobiphényle (XII), le 4-méthyl-2-nitrobiphényle (XIII) et le 2-méthyl-3-nitrobiphényle (XIV).



Toutefois, exécutée avec la 6-méthyl-2-nitraniline (X), la réaction a conduit à la formation du 7-nitroindazole (XVI), (9, 10) au lieu du 6-méthyl-2-nitrobiphényle (XV).

La réduction catalytique des méthylnitrobiphényles dans l'éthanol en présence de palladium a donné avec de bons rendements le 3-méthyl-5-aminobiphényle (XVII), le 4-méthyl-3-aminobiphényle (XVIII), le 4-méthyl-2-aminobiphényle (XIX) et le 2-méthyl-3-aminobiphényle (XX) correspondants.

L'oxydation de ces méthyl-aminobiphényles par le peroxyde de plomb dans l'acide sulfurique 50% selon la méthode de Willstätter et Dorogi (11) a permis d'obtenir les trois phényltoluquinones isomères désirées, soient la 2-méthyl-6-phényl-1,4-benzoquinone (XXI), la 2-méthyl-5-phényl-1,4-benzoquinone (XXII) et la 2-méthyl-3-phényl-1,4-benzoquinone (XXIII).

La 2-méthyl-5-phényl-1,4-benzoquinone (XXII) ainsi obtenue et la phényltoluquinone isolée du produit de la réaction de la toluquinone avec le chlorure de benzène-diazonium se révélèrent identiques par leur point de fusion, le point de fusion mixte et leur spectre infrarouge (Fig. 1).

C'est aussi fort probablement l'isomère correspondant, c'est-à-dire la 2-méthyl-5-aryl-1,4-benzoquinone (IV), que l'on isole comme produit principal à la suite de la réaction entre la toluquinone et le chlorure de diazonium obtenu d'une aniline substituée (1).

Nous avons observé que la 2-méthyl-3-phényl-1,4-benzoquinone (XXIII) est instable. Lorsque la quinone est exposée à la lumière solaire, soit à l'état solide, soit en solution dans l'eau, l'acétone ou l'éther, elle se transforme assez rapidement en l'hydroquinone (XXIV) incolore correspondante, comme le démontre l'analyse. Fieser *et al.* (12) mentionnent une observation analogue faite au cours de la purification de la 2,3-diméthyl-1,4-benzoquinone. D'après ces auteurs, cette substance, lorsqu'elle est exposée au soleil, se décomposerait en un polymère incolore; mais il nous semble probable qu'elle se transforme plutôt en 2,3-diméthyl-hydroquinone.

Au cours de l'arylation de la toluquinone (1) nous avons constaté à plusieurs reprises l'apparition d'un film blanc à la surface d'échantillons d'aryltoluquinones conservés à la lumière du jour. Ces aryltoluquinones avaient été purifiées au préalable, mais n'avaient pas encore un point de fusion constant. Ceci nous fait supposer la présence de l'isomère 2-méthyl-3-aryle dans le produit de la réaction.

Une série de réactions analogue à celle qui a servi à la synthèse des phényltoluquinones a été exécutée à partir de la 4-chloro-2-nitraniline (XXV). Elle a donné successivement, par condensation avec le benzène, le 4-chloro-2-nitrobiphényle (XXVI), par réduction avec le fer activé (13), le 4-chloro-2-aminobiphényle (XXVII) et, finalement, par oxydation avec du peroxyde de plomb, la 2-chloro-5-phényl-1,4-benzoquinone (XXVIII). Le point de fusion de cette phénylchloroquinone et celui de produit principal obtenu de la réaction entre la chloroquinone et le chlorure de benzène-diazonium que l'on croyait être la 2-chloro-6-phényl-1,4-benzoquinone (6) est le même. Le point de fusion mixte et les spectres infrarouges (Fig. 2) confirment l'identité des deux composés.

La préparation de la 2-méthyl-3-nitraniline (IX) à partir du 1,3,5-trinitrotoluène selon la méthode décrite dans la littérature (14) n'a donné que de mauvais résultats. En particulier, il a été impossible de réaliser le rendement mentionné pour la réduction du trinitrotoluène en 4-méthyl-3,5-dinitraniline. Pour cette raison nous donnons dans la partie expérimentale une description améliorée de sa synthèse par les intermédiaires 4-méthyl-3,5-dinitraniline et 2,6-dinitrotoluène.

PARTIE EXPÉRIMENTALE[3]

3,5-Dinitro-4-méthylaniline

La réduction du 2,4,6-trinitrotoluène (410 g) est exécutée selon la description donnée par Lowe (15) jusqu'à l'essoration du produit brut. Celui-ci est alors agité vigoureusement avec 2000 ml d'acide chlorhydrique 10% à environ 75° et la solution est filtrée à chaud. On extrait le solide deux autres fois de la même façon et les filtrats réunis sont ensuite versés dans environ six fois leur quantité d'eau froide. L'amine brute se sépare alors sous la forme d'un solide jaune de p.f. 135–165°. Celui-ci est dissous à chaud dans de l'éthanol et la solution bouillie avec du noir animal, filtrée et diluée avec un cinquième de son volume d'eau. La 4-méthyl-3,5-dinitraniline (rendement, 76 g; 78.6% de la théorie) cristallise en aiguilles rouges de p.f. 169–171° (p.f. lit. 171–172° (14)).

2,6-Dinitrotoluène

À de la 4-méthyl-3,5-dinitraniline (59.1 g) triturée avec 450 ml d'acide chlorhydrique concentré, on ajoute 130 ml d'eau et 120 g de glace et on diazote à 0° avec 21.6 g de nitrite de sodium solide (½ heure). Dans la solution bien agitée mécaniquement et refroidie à 0° (bain réfrigérant) on laisse dégoutter une solution froide (400 ml) d'acide hypophosreux à 30%. Après l'addition de 150 ml de cette solution un fort dégagement d'azote commence à se produire. Une fois l'addition de l'acide hypophosreux terminée on continue d'agiter pendant 20 heures à la température ambiante. Le précipité rouge-brunâtre formé est alors essoré, séché, dissous dans du benzène et chromatographié sur 300 g d'alumine. Par élution avec le même solvant (500 ml), on recueille 41 g (75% de la théorie) de 2,6-dinitrotoluène de p.f. 66° (lit. 65–66° (14)).

2-Méthyl-3-nitraniline (IX)

Tout en faisant barboter un courant d'acide sulfhydrique gazeux dans une solution de 2,6-dinitrotoluène (59.72 g) dans de l'éthanol (200 ml) bouillie à reflux, on introduit lentement une solution de sulfure d'ammonium (50 ml d'ammoniaque concentrée fraîchement saturée d'acide sulfhydrique). On continue de faire barboter l'acide sulfhydrique pendant 1½ heure, à la température d'ébullition, on filtre ensuite le soufre précipité, le lave deux fois à l'alcool et évapore le filtrat à siccité. Le résidu est extrait deux fois à chaud avec 300 ml d'acide chlorhydrique dilué (1:1). Les extraits réunis sont traités à l'ammoniaque concentrée jusqu'à l'apparition d'un précipité brun. On filtre la solution et la neutralise à l'ammoniaque (pH = 7). On obtient 42.7 g (86% de la théorie) de 2-méthyl-3-nitraniline de p.f. 86–88° (lit. 90–91° (14)).

2-Méthyl-3-nitrobiphényle (XIV)

On triture de la 2-méthyl-3-nitraniline (42.7 g) avec 150 ml d'acide chlorhydrique concentré, on ajoute à cette pâte 80 g de glace et, tout en agitant vigoureusement et en maintenant le mélange à environ 3–4° (bain réfrigérant), on diazote avec 20.5 g de nitrite de sodium solide. À la solution diazoïque filtrée on ajoute 800 ml de benzène et une solution de 200 g d'acétate de sodium trihydraté dans 700 ml d'eau et on continue d'agiter pendant 2 heures à 5° et durant 20 heures à la température ambiante. Ensuite, on chauffe à 70° l'émulsion formée, décante la couche benzénique, extrait la phase aqueuse au benzène chaud et réunit les extraits benzéniques. Ceux-ci sont lavés successivement à la soude 2 *N*, à l'eau, à l'acide chlorhydrique 2 *N* et finalement à l'eau. On évapore le benzène et distille l'huile rouge résiduelle (12.3 g). On recueille ainsi, 4.0 g (12% de la théorie) d'une huile jaune de p.é. 116–118°/0.0001 mm. Le 2-méthyl-3-nitrobiphényle cristallise dans le méthanol en lamelles jaunes de p.f. 72.5–73°. Calculé pour $C_{13}H_{11}O_2N$: C, 73.22%; H, 5.20%; N, 6.57%. Trouvé: C, 73.26%; H, 5.33%; N, 6.57%.

[3]*Les points de fusion (p.f.) ont été pris en tubes capillaires et ne sont, ainsi que les points d'ébullition (p.é.), pas corrigés. Les microanalyses ont été effectuées par M. W. Manser, Zürich, Suisse.*

4-Méthyl-2-nitrobiphényle (XIII)

À 38.04 g de 4-méthyl-2-nitraniline (16) triturée avec 80 ml d'acide chlorhydrique concentré, on ajoute 45 g de glace et diazote à 0–5° avec une solution de 18 g de nitrite de sodium dans 50 ml d'eau. On filtre la solution diazoïque, ajoute 550 ml de benzène et 80 g d'acétate de sodium trihydraté dissous dans 200 ml d'eau et agite pendant 3 heures à 5–10° et 45 heures à la température ambiante. On brise l'émulsion formée en la filtrant dans un entonnoir en verre poreux. La phase benzénique est séparée et lavée successivement à la soude 2 *N*, à l'eau, à l'acide chlorhydrique 2 *N* et à l'eau. En évaporant le solvant et en distillant le résidu on obtient 23.47 g (43.5% de la théorie) d'une huile jaune de p.é. 126–128°/0.0003 mm. (Ritchie (17) donne le p.é. 207–209°/28 mm.)

4-Méthyl-3-nitrobiphényle (XII)

De la 4-méthyl-3-nitraniline (34.25 g) est diazotée et condensée avec le benzène comme il est décrit précédemment pour le 2-méthyl-3-nitrobiphényle. Par distillation du produit brut on obtient 10.3 g (21.5% de la théorie) d'une huile de p.é. 132–134°/0.0003 mm. Le 4-méthyl-3-nitrobiphényle forme dans l'éthanol des cristaux jaunâtres de p.f. 63.5–64.5°. Calculé pour $C_{13}H_{11}O_2N$: C, 73.22%; H, 5.20%; N, 6.57%. Trouvé: C, 73.17%; H, 5.30%; N, 6.66%. Cette substance a déjà été préparée par Wessely *et al.* (18) qui donnent le p.f. 61–62°, mais ni analyse, ni rendement.

3-Méthyl-5-nitrobiphényle (XI)

De la 4-méthyl-2,6-dinitraniline (19) est désaminée dans un mélange alcool – acide sulfurique (1:1) avec du nitrite de sodium solide. Le 3,5-dinitrotoluène est isolé et partiellement réduit selon la méthode utilisée précédemment pour la 2-méthyl-3-nitraniline. On diazote la 5-méthyl-3-nitraniline (23 g) ainsi obtenue et condense son sel de diazonium avec le benzène (500 ml) en présence de 100 g d'acétate de sodium cristallisé. Après 24 heures d'agitation la réaction est terminée. On isole le produit comme il est décrit précédemment dans le cas du 4-méthyl-2-nitrobiphényle et recueille 17 g (54% de la théorie) d'une huile jaune pâle de p.é. 140–143°/0.002 mm. Dans le méthanol le 3-méthyl-5-nitrobiphényle donne des cristaux jaunes pâles de p.f. 85.5–86°. Calculé pour $C_{13}H_{11}O_2N$: C, 73.22%; H, 5.20%; N, 6.57%. Trouvé: C, 73.22%; H, 5.19%; N, 6.62%.

4-Chloro-2-nitrobiphényle (XXVI)

De la 4-chloro-2-nitraniline (52 g) est diazotée selon Fierz-David (20, p. 236). On filtre la solution diazoïque et lui ajoute 750 ml de benzène. Dans ce mélange bien agité et refroidi à 5°, on introduit assez rapidement 100 g d'acétate de sodium trihydraté et agite 2 heures à cette température et 12 heures à la température ambiante. Le produit de la réaction est isolé comme précédemment et distillé. On recueille, à 135–137°/0.0002 mm, 32.78 g (44% de la théorie) de 4-chloro-2-nitrobiphényle, qui cristallise dans le méthanol sous forme de prismes de p.f. 52–53°. Calculé pour $C_{12}H_8O_2NCl$: C, 61.68%; H, 3.45%; N, 6.00%. Trouvé: C, 61.71%; H, 3.65%; N, 6.19%.

7-Nitroindazole (XVI)

De la 2-méthyl-6-nitraniline (21) (56.8 g) est diazotée et condensée avec le benzène tel que décrit précédemment dans le cas du 4-méthyl-2-nitrobiphényle. Après 45 heures d'agitation à la température ambiante, on porte le mélange à 70–80° pour briser l'émulsion et dissoudre le précipité formé. La couche benzénique est décantée et la phase aqueuse extraite une autre fois au benzène chaud. Les extraits réunis sont lavés à la soude et à l'acide, et ensuite concentrés à 200 ml. De cette solution on obtient 14.7 g d'une substance qui, recristallisée dans le benzène et dans le méthanol (noir animal), donne 13 g de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

cristaux jaunes pâles de p.f. 185–187°. L'analyse démontre qu'il ne s'agit pas du 2-méthyl-6-nitrobiphényle attendu, mais du 7-nitroindazole (p.f. lit. 186.5–187.5° (10)). Calculé pour: $C_7H_5O_2N_3$: C, 51.54%; H, 3.09%; N, 25.76%. Trouvé: C, 51.57%; H, 2.84%; N, 25.51%.

4-Méthyl-2-aminobiphényle (XIX)

Du 4-méthyl-2-nitrobiphényle (26.10 g), dissous dans 50 ml d'éthanol, est réduit catalytiquement en présence de 1 g de chlorure de palladium. La réduction terminée, on essore le catalyseur et évapore le solvant sous pression réduite. Le résidu est repris par de l'éther et traité à l'acide chlorhydrique gazeux. Le p.f. du chlorhydrate ainsi obtenu (25.5 g) est 196–198°, et celui du picrate cristallisé dans l'éthanol est 159–161° (lit. 161° (17)).

Le dérivé acétylé, préparé à partir de 200 mg de la base et de 1 ml d'anhydride acétique et cristallisé dans le méthanol, fond à 145.5–146.5°. Calculé pour $C_{15}H_{15}ON$: C, 79.97%; H, 6.71%; N, 6.22%. Trouvé: C, 79.96%; H, 6.77%; N, 6.24%.

4-Méthyl-3-aminobiphényle (XVIII)

Du 4-méthyl-3-nitrobiphényle (10.30 g) est réduit et l'amine formée isolée comme il est décrit précédemment. On obtient 10.6 g (100% de la théorie) de chlorhydrate de 4-méthyl-3-aminobiphényle. En chauffant ce sel, la base se sublime en belles lamelles incolores de p.f. 59–60° (lit. 54–55° (18)).

3-Méthyl-5-aminobiphényle (XVII)

Du 3-méthyl-5-nitrobiphényle (16.8 g) est réduit en présence de palladium et la base formée est isolée à l'état de sulfate (14 g) dans de l'éther anhydre. Le sulfate fond à 196–200°, le chlorhydrate à 220–223° et la base, après cristallisation dans l'éther de pétrole, à 79–82° (lit. 80–82° (22)). Calculé pour $C_{13}H_{13}N$: C, 85.20%; H, 7.15%; N, 5.64%. Trouvé C, 85.14%; H, 7.17%; N, 7.69%.

4-Chloro-2-aminobiphényle (XXVII)

De la poudre de fer (passée au tamis de 40 mailles) (150 g) est activée (13) et ajoutée à une solution de 15 g de 4-chloro-2-nitrobiphényle dans 500 ml de benzène. Le mélange est agité mécaniquement et bouilli à reflux. Au cours de 7 heures on ajoute en petites portions 60 ml d'eau et continue de chauffer et d'agiter pendant 12 heures. La solution est ensuite filtrée et évaporée à siccité. L'huile résiduelle (11.73 g) (90% de la théorie) distille à 105–106°/0.0002 mm. Calculé pour $C_{12}H_{10}NCl$: C, 70.73%; H, 4.95%; N, 6.88%; Cl, 17.41%. Trouvé: C, 70.52%; H, 5.06%; N, 7.00%; Cl, 17.54%.

2-Méthyl-3-phényl-1,4-benzoquinone (XXIII)

Du 2-méthyl-3-nitrobiphényle (3.25 g) est dissous dans 50 ml d'éthanol et réduit catalytiquement à la pression atmosphérique en présence de 300 mg d'oxyde de platine. L'hydrogénation terminée, le catalyseur est éliminé par filtration et la solution de l'amine évaporée à sec. On reprend le résidue à l'éther et ajoute quelques millilitres d'un mélange d'acide sulfurique concentré et d'éthanol (1:1). Le sulfate ainsi obtenu est oxydé sans aucune purification. On l'agite pendant 40 heures à 0° avec 12 g de peroxyde de plomb dans 200 ml d'acide sulfurique à 50%. On dilue ensuite le mélange réactionnel avec deux fois sa quantité d'eau et on le filtre. Le résidu et le filtrat sont épuisés à l'éther et les extraits réunis séchés sur du sulfate de sodium anhydre et évaporés. On recueille ainsi 600 mg de quinone qui, cristallisée plusieurs fois dans de l'acétone aqueux (1:1) et ensuite dans de l'éther de pétrole, fond à 79–81°. Calculé pour $C_{13}H_{10}O_2$: C, 78.77%; H, 5.09%; O, 16.14%. Trouvé: C, 78.57%; H, 5.05%; O, 16.42%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

2-Méthyl-3-phénylhydroquinone (XXIV)

Une solution aqueuse de la 2-méthyl-3-phényl-1,4-benzoquinone (XXIII) est exposée à la lumière solaire. En quelques jours la solution se décolore et l'hydroquinone correspondante cristallise en longues aiguilles incolores de p.f. 133–134°. Calculé pour $C_{13}H_{12}O_2$: C, 77.98%; H, 6.04%. Trouvé: C, 77.91%; H, 6.04%.

2-Méthyl-5-phényl-1,4-benzoquinone (XXII)

(*A*) Du 4-méthyl-2-aminobiphényle (5.83 g) est agité pendant 55 heures à 0–5° avec 32 g de peroxyde de plomb dans 150 ml d'acide sulfurique à 50%. On extrait la phase solide et liquide séparément au benzène, réunit les extrait et les lave une fois à l'eau. Une fois le solvant évaporé, on distille le résidu à la vapeur d'eau et épuise le distillat à l'éther. La solution éthérée fournit 1.5 g de quinone qui, après plusieurs cristallisations dans du méthanol (noir animal), a le p.f. 111–112°. Calculé pour $C_{13}H_{10}O_2$: C, 78.77%; H, 5.09%. Trouvé: C, 78.78%; H, 5.03%. Le p.f. mixte de cette substance avec le produit de p.f. 109–111° obtenu par phénylation de la toluquinone (1) est 109–112°.

(*B*) Comme précédemment, on oxyde le 4-méthyl-3-aminobiphényle (5.61 g) pendant 24 heures avec 31 g de peroxyde de plomb dans 150 ml d'acide sulfurique à 50%. Le rendement de la quinone brute est 5.27 g (86% de la théorie). La substance, cristallisée quelques fois dans un mélange acétone–eau (1:1) (noir animal) et ensuite dans du méthanol, fond à 108–111°. Les p.f. mixtes de cette substance avec le produit obtenu par phénylation de la toluquinone (1) et par la méthode (*A*), ne sont pas abaissés. Les spectres infrarouges (solution à 10% dans le chloroforme) sont également identiques.

2-Méthyl-6-phényl-1,4-benzoquinone (XXI)

Du sulfate de 3-méthyl-5-aminobiphényle (8 g) est oxydé par 32 g de peroxyde de plomb dans 300 ml d'acide sulfurique à 50% et le produit de la réaction est isolé comme il est décrit précédemment. Le produit pur (0.5 g) cristallise dans le méthanol en aiguilles jaune-orange de p.f. 57–58°. Calculé pour $C_{13}H_{10}O_2$: C, 78.77%; H, 5.09%. Trouvé: C, 78.75%; H, 5.05%.

2-Chloro-5-phényl-1,4-benzoquinone (XXVIII)

L'oxydation du sulfate de 4-chloro-2-aminobiphényle (10 g) par 40 g de peroxyde de plomb dans 300 ml d'acide sulfurique à 50% selon le procédé habituel donne 7.1 g de quinone brute. Un échantillon de ce produit, distillé à la vapeur d'eau et cristallisé dans un mélange acétone–méthanol, donne la 2-chloro-5-phényl-1,4-benzoquinone pure de p.f. 130–131.5°. Calculé pour $C_{12}H_7O_2Cl$: C, 65.92%; H, 3.23%; Cl, 16.22%. Trouvé: C, 65.66%; H, 3.19%; Cl, 16.18%. Le p.f. mixte de cette substance et du produit principal isolé de la réaction entre la chloro-1,4-benzoquinone et le chlorure de benzène-diazonium (6) n'est pas abaissé, et les spectres infrarouges des deux (solution à 10% dans le chloroforme) sont de plus identiques.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada pour une bourse d'études postdoctorales qu'il a accordée à l'un de nous (K. H.).

ON THE COUPLING BETWEEN H^1 AND F^{19} NUCLEI IN *p*-FLUOROTOLUENE. II[1]

T. SCHAEFER[2] AND W. G. SCHNEIDER

ABSTRACT

By making use of specific solvent interaction effects it has been found possible to vary the relative chemical shift between ortho and meta protons in *p*-fluorotoluene continuously from about 0.2 p.p.m. to zero. The values of the HF coupling constants were found to be $J_{ortho}^{HF} = 8.7$ c/s and $J_{meta}^{HF} = 5.8$ c/s. As the internal chemical shift goes to zero the ring proton spectrum collapses to two lines with a separation of 7.3 c/s. This splitting is interpreted as equal to $\frac{1}{2}(J_o^{HF} + J_m^{HF})$. Corresponding changes observed in the CH_3 proton spectrum are consistent with this interpretation.

INTRODUCTION

The proton and fluorine high resolution nuclear magnetic resonance spectra of liquid *p*-fluorotoluene at 29.92 Mc/s (for H^1) have recently been interpreted on the basis of a negligible internal chemical shift in the ring proton spectrum and with $J_m^{HF} = J_o^{HF} = 7.4$ c/s (a better value is 7.3 c/s)* (1). The latter condition was sufficient to explain the distribution and intensities of the lines. In addition, there was a coupling of about 0.9 c/s between the methyl protons and the fluorine.

It is known that normally $J_m^{HF} < J_o^{HF}$. In *p*-fluoroaniline, for instance, $J_m^{HF} = 5.1$ c/s and $J_o^{HF} = 8.6$ c/s (2). If one considers a three-spin $\frac{1}{2}$ system such that two of the spins see a field H_2 but are unequally coupled to the third at field H_1 one notes that, under certain circumstances, the *splitting* of the lines is equal to an *average* of the two coupling constants (this does not mean that the coupling between the nuclei is averaged). An approximate example is the ring proton spectrum of 2,5-dichloronitrobenzene (3). The question arises whether the spacing of 7.3 c/s between the two lines of the ring proton spectrum of *p*-fluorotoluene might not also be an average of J_m^{HF} and J_o^{HF}.

If one could change the internal chemical shift in the ring continuously in some way from zero to a relatively large value, some information on this matter should be obtainable. This was found possible by making use of specific solvent effects (4). Dilution of *p*-fluorotoluene in acetone shows a large increase in the relative shift between the protons ortho and meta to the fluorine atom, while dilution in benzene shows a progressive decrease of the shift to zero. It is the purpose of this work to show (*a*) that the values of the proton–fluorine coupling constants are $J_m^{HF} = 5.8$ c/s and $J_o^{HF} = 8.7$ c/s, and (*b*) that in the limit of zero internal chemical shift the line separation of the ring proton spectrum is equal to $\frac{1}{2}(J_m^{HF} + J_o^{HF}) = 7.3$ c/s. Inherent in the analysis is the assumption that solvent effects, while changing the relative chemical shifts, do not perceptibly alter the spin-coupling constants. This assumption is consistent with experimental observations to date.

EXPERIMENTAL

The methyl and ring proton spectra of *p*-fluorotoluene in the pure liquid and at various dilutions in acetone and benzene were measured at 60 Mc/s on a Varian High Resolution NMR spectrometer. The line separations were measured by the side-band technique. The concentrations by volume were approximate since the solvent was used only to change the ring proton shift.

RESULTS

The ring proton and methyl proton spectra of *p*-fluorotoluene at the various concentrations in acetone and benzene are shown in Figs. 1 and 2. The caption 1:35 benzene, for instance, denotes a solution consisting of 1 volume of *p*-fluorotoluene dissolved in 35 volumes of benzene. The relevant line separations are given in c/s. The main field H_0 increases from left to right.

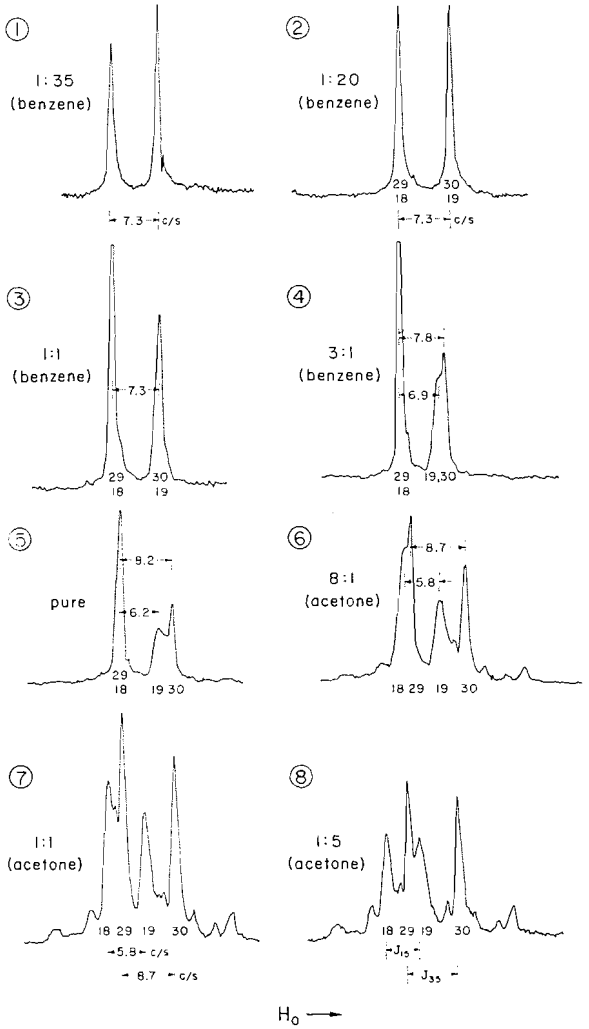

FIG. 1. Ring proton resonance spectra (at 60 Mc/s) of *p*-fluorotoluene and of *p*-fluorotoluene at various concentrations in benzene and acetone. At a concentration of 1:20 in benzene the relative chemical shift of ortho and meta protons is zero.

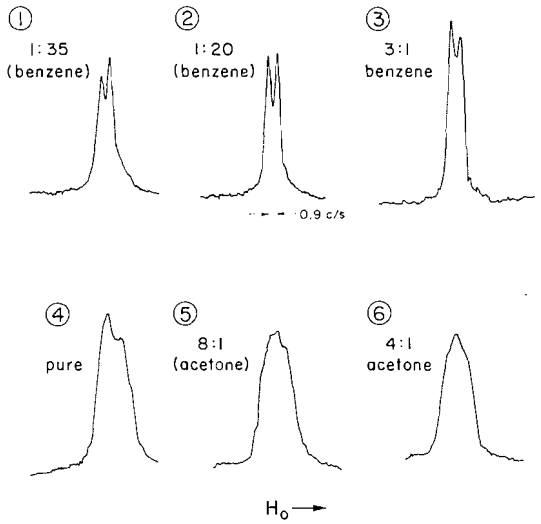

FIG. 2. Proton resonance spectra (at 60 Mc/s) of the methyl group of *p*-fluorotoluene at various concentrations in benzene and acetone.

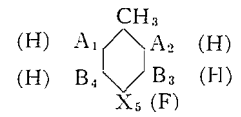
DISCUSSION

(*a*) *Analytics*

As in reference 1, the following labelling and notation is employed.



I

for $\sigma_B > \sigma_A$
$J_{15} = J_m^{HF}$, $J_{35} = J_o^{HF}$
$J_{13} = J_p^{HH}$, $J_{23} = J_o^{HH}$

The ring proton spectrum at, say, 1:1 of acetone (Fig. 1.7) is the A_2B_2 part of an A_2B_2X spectrum (5). This case with the screening constants $\sigma_A > \sigma_B$ has been fully discussed for *p*-fluoroaniline (2). The case $\sigma_A = \sigma_B$ (i.e. $A_2A_2'X$) has been discussed for pure *p*-fluorotoluene measured at 29.92 Mc/s (1). In acetone solutions we have the case $\sigma_B > \sigma_A$: the protons ortho to fluorine are most shielded. We can limit our discussion to the four most intense lines in the proton spectrum, since their separations depend on $(\sigma_B - \sigma_A)$ and on J_m^{HF} and J_o^{HF}. (The other lines go to zero intensity when $\sigma_B = \sigma_A$, as discussed in reference 1.)

From Table VI in reference 1 these four transitions correspond to lines 18, 19, 29, and 30. The energies of these transitions contain corrective terms, A and B, whose values depend on the sign of $\sigma_B - \sigma_A$, which was taken as negative to correspond with the *p*-fluoroaniline case. When $\sigma_B - \sigma_A > 0$, as for *p*-fluorotoluene in acetone, the definitions of A and B as positive quantities change to

$$\begin{aligned} A\cos 2\theta &= \tfrac{1}{2}\nu_0(\sigma_B-\sigma_A)-\tfrac{1}{4}(J_{35}-J_{15}) \\ A\sin 2\theta &= \tfrac{1}{2}(J_{23}+J_{13}) \\ B\cos 2\phi &= \tfrac{1}{2}\nu_0(\sigma_B-\sigma_A)+\tfrac{1}{4}(J_{35}-J_{15}) \\ B\sin 2\phi &= \tfrac{1}{2}(J_{23}+J_{13}). \end{aligned} \qquad [1]$$

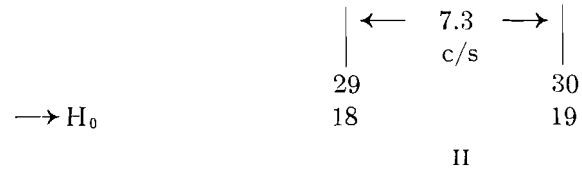
Hence the signs of A and B in transitions 18, 19, 29, and 30 must be changed. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

intensity of transition 18, for instance, changes from a value of $2(1-\sin 2\theta)$ to $2(1+\sin 2\theta)$. The energies of the transitions then become

18. $\frac{1}{2}\nu_0(2-\sigma_B-\sigma_A)+\frac{1}{4}(-2J_{13}-2J_{23}+J_{15}+J_{35})+A$
19. $\frac{1}{2}\nu_0(2-\sigma_B-\sigma_A)+\frac{1}{4}(-2J_{13}-2J_{23}-J_{15}-J_{35})+B$
29. $\frac{1}{2}\nu_0(2-\sigma_B-\sigma_A)+\frac{1}{4}(2J_{13}+2J_{23}+J_{15}+J_{35})-A$
30. $\frac{1}{2}\nu_0(2-\sigma_B-\sigma_A)+\frac{1}{4}(2J_{13}+2J_{23}-J_{15}-J_{35})-B.$

These four lines coalesce to two when $\sigma_B \rightarrow \sigma_A$ as shown below in II.



II

(b) The Ring Proton Spectrum

Consider the series of spectra in Fig. 1, beginning with the solution containing 1:20 of benzene. This spectrum corresponds to the case $\sigma_B-\sigma_A = 0$, as discussed in reference 1. There it was shown that this spectrum is consistent with $J_m^{HF} = J_o^{HF} = 7.3$ c/s and $A = B = \frac{1}{2}(J_{23}+J_{13})$, with the four transitions as in II. However, we now know that when $\nu_0(\sigma_B-\sigma_A)$ is about 0.2 p.p.m. (Fig. 1.8), $J_o^{HF} = J_{35} = 8.7$ c/s and $J_m^{HF} = J_{15} = 5.8$ c/s. It is apparent from the definitions of A and B that these values of J_{15} and J_{35} will also reproduce the ring proton spectrum. Substituting these values into [1] for $\sigma_B-\sigma_A = 0$ we see that $\sin 2\theta$ and $\sin 2\phi$ are very nearly 1 and A and B are very nearly $\frac{1}{2}(J_{23}+J_{13})$. The deviations will be undetectable experimentally. Since $\frac{1}{2}(J_{23}+J_{13})$ is large compared to $\frac{1}{4}(J_{35}-J_{15})$, the analysis yields virtually the same results whether we consider $J_{15} = J_{35}$ or $J_{15} \neq J_{35}$. Physically it is clearly more reasonable to assume J_{15} and J_{35} independent of $\sigma_B-\sigma_A$.*

From the definitions [1] and the transitions 18 to 30 it is also clear that the analysis will yield J_{35} and J_{15} individually (and not only their sum) when $\sigma_B-\sigma_A$ becomes large enough relative to $\frac{1}{2}(J_{23}+J_{13})$. This is illustrated by the series of spectra in Fig. 1. Figure 1.6 corresponds roughly to the smallest value of $\sigma_B-\sigma_A$ at which values of J_{15}, J_{35}, and J_{23} can be extracted. The shift is approximately 8 c/s and shows that we must have $\frac{1}{2}\nu_0(\sigma_B-\sigma_A)+\frac{1}{4}(J_{35}-J_{15}) \approx \frac{1}{2}(J_{23}+J_{13})$ since $J_{23} \approx 8.5$ c/s and $J_{13} \approx 0$.†

It can be seen that in Fig. 1 the lines from the protons ortho to the CH_3 group, i.e., those at low field, are broader than those ortho to the fluorine atom because of a weak coupling to the CH_3 protons. The coupling $J_m^{CH_3,H}$ is not noticeable. When $\sigma_B-\sigma_A \rightarrow 0$, however, we again have the situation that the spectrum will only yield $\frac{1}{2}(J_o^{CH_3,H}+J_m^{CH_3,H})$. Since $J_m^{CH_3,H} \approx 0$ and $J_o^{CH_3,H}$ is about 0.25 c/s at most, the lines of the ring proton spectrum are quite narrow when $\sigma_B-\sigma_A = 0$ (Fig. 1.2).

J_{15} and J_{35} need not always be independent of $\sigma_B-\sigma_A$. An example is formamide (6) where, at sufficiently high temperatures, rotation about the C—N bond results in zero relative shift for the N—H protons while, at the same time, the two coupling constants to the aldehyde proton are "mechanically" averaged from widely different values. These two coupling constants correspond to J_{15} and J_{35} in the present case.

†*We can predict, therefore, that in order to obtain individual coupling constants in similar situations even when $\sigma_B-\sigma_A$ approaches zero, we must have the two protons only weakly coupled. A substituted fluorobenzene with two protons arranged para to one another and meta and ortho to the fluorine atom would be expected to behave in the required way. Such molecules are being investigated.*

(*c*) *The Methyl Spectrum*

The third illustration afforded by *p*-fluorotoluene of an apparent but unreal averaging of coupling constants occurs in the methyl spectrum (Fig. 2). The CH_3 spectrum at 1:20 dilution in benzene is a doublet with a splitting of 0.9 c/s due to coupling to the F^{19} nucleus. This gives $J_p^{F,CH_3} = 0.9$ c/s. The lines are narrow for the reason given in the preceding paragraph.

As $\sigma_B - \sigma_A$ becomes positive the doublet becomes asymmetrical and both lines broaden (e.g. in the pure liquid at 60 Mc/s). Finally the doublet is washed out in the 8:1 acetone solution because of coupling to the ortho protons of the ring. This behavior agrees with that of the ring proton spectrum.

At high dilutions in benzene (1:35) there is a reversal in sign of the chemical shift, i.e. $\sigma_B - \sigma_A < 0$. The protons ortho to the fluorine atom are becoming less shielded than the meta protons.

CONCLUSIONS

$J_m^{HF} = 5.8$ c/s and $J_o^{HF} = 8.7$ c/s in *p*-fluorotoluene. These values are independent of chemical shift in the ring, although at zero chemical shift the line separations yield only the sum of J_m^{HF} and J_o^{HF}. The latter still have the individual values given above. The same behavior is shown by the line splittings due to $J_o^{CH_3,H}$ and $J_m^{CH_3,H}$ when the ring proton chemical shift changes. We conclude that a coupling constant can affect a spectrum significantly even though *it is non-detectable*, viz. $J_m^{CH_3,H}$.

The problem of solvent effects on internal chemical shifts of substituted benzenes has also been investigated and will be discussed in a forthcoming publication.

NOTES

SOLUBILIZATION IN AQUEOUS BUTYRIC ACID SOLUTIONS*

D. MOULE† AND G. C. BENSON

INTRODUCTION

Bury and co-workers (1–3) have interpreted the concentration dependence of a number of the physical properties of aqueous butyric acid solutions as indicating micelle formation. Recent ultrasonic absorption measurements (4) have provided further evidence for the occurrence of some type of aggregation in this system.

The presence of a significant number of fairly large aggregates should have a marked effect on the capacity of aqueous butyric acid solutions to dissolve certain types of water-insoluble organic molecules. The convenience of a colorimetric method of analysis led to the choice of the dye *p*-dimethylaminoazobenzene (DMAB) for the present solubilization study. The solubility of this material in water is less than 1 mg/liter (5).

EXPERIMENTAL

The DMAB (Eastman Organic Chemicals) was purified by recrystallization from ethanol. Purification of the butyric acid has been described previously (4).

Aqueous solutions of the acid were prepared with concentrations in the range 0–7 molar. An excess of dye crystals was added to measured amounts of these solutions contained in long-necked glass vials. After the necks were sealed, the vials were mounted in a horizontal agitator and equilibrated in a thermostat for 4 or 5 days. At the end of this time the solid remaining was allowed to settle and a sample of the liquid was withdrawn through a sintered glass filter into a pipette heated to thermostat temperature. After dilution with a known amount of acidified ethanol the concentration of the solution was determined absorptiometrically using an Evelyn photoelectric colorimeter (6). For most of the concentration range studied duplicate determinations of the concentration agreed to better than 5%. Kolthoff and Stricks (5) have noted that the spectrum of DMAB in ethanol is altered by the presence of water. Errors due to this effect were negligible in the present work.

RESULTS AND DISCUSSION

The solubility of DMAB in butyric acid solutions at four temperatures (0°, 25°, 40°, and 60° C) is shown in Fig. 1. At low acid concentrations the dye is only slightly soluble but the amount solubilized increases noticeably at concentrations above 2 *M*. The solubility at 0° C reaches a maximum of 3.8 g/liter around 5.9 *M* (18 mole % acid) and then decreases. The curve at 25° C also shows a tendency to level off in the same region but this is followed by a further increase. At 40° and 60° C the solubilization rises to successively higher values as the butyric acid concentration is increased.

Kolthoff and Stricks (5) have investigated the solubilization of DMAB by a number of soaps and other detergents. These authors defined the solubilizing power at any detergent concentration as the slope of the solubilization curve at that concentration. They found that it was possible to identify the critical micelle concentration (CMC)

*Issued as N.R.C. No. 5436.

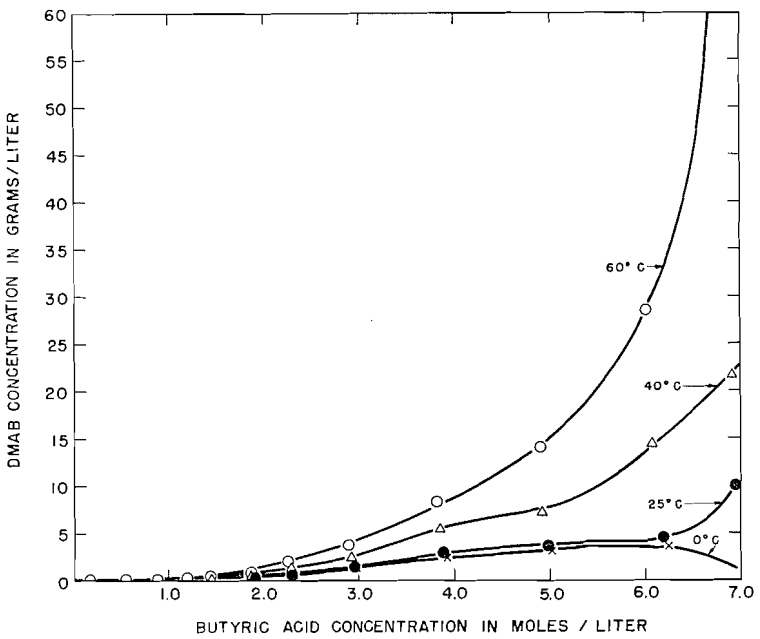

FIG. 1. The solubilization of DMAB in aqueous butyric acid solutions.

with the concentration where there was a rather sharp change in the solubilizing power of the detergent. Values of the CMC for butyric acid solutions obtained in this way are given in Table I along with the solubilizing power in the concentration range just

TABLE I

Data on the solubilization of DMAB in butyric acid solutions

Temp. (° C)	CMC		Solubilizing power (2–3.5 *M*)	
	Molarity	Mole %	(g dye/mole acid)	(molecules acid/molecule dye)
0	1.8_2	3.7_6	1.0_8	2100
25	1.7_5	3.5_9	1.1_5	2000
40	1.5_8	3.2_0	1.9_1	1200
60	1.6_2	3.2_9	3.0_6	740

above the CMC. The values of the CMC agree quite well with other estimates, i.e. 15 wt.% (3.5 mole %) from freezing point data (1), 12–15 wt.% (2.7–3.5 mole %) from density measurements (2), and 13 wt.% (3.0 mole %) from specific heat measurements (3). The solubilizing power of butyric acid for DMAB is of comparable magnitude to values for this dye in a variety of detergents (5).

Figure 2 illustrates the similarity between the concentration dependence of the solubilization of DMAB (curve A) and that for the absorption of ultrasound of frequency 3 mc/sec (curve C, data taken from ref. 4) in butyric acid solutions at 0° C. White, Moule, and Benson (4) in discussing the ultrasonic results noted that the concentration corresponding to the absorption peak (13 mole %) is the same as that of the upper con-

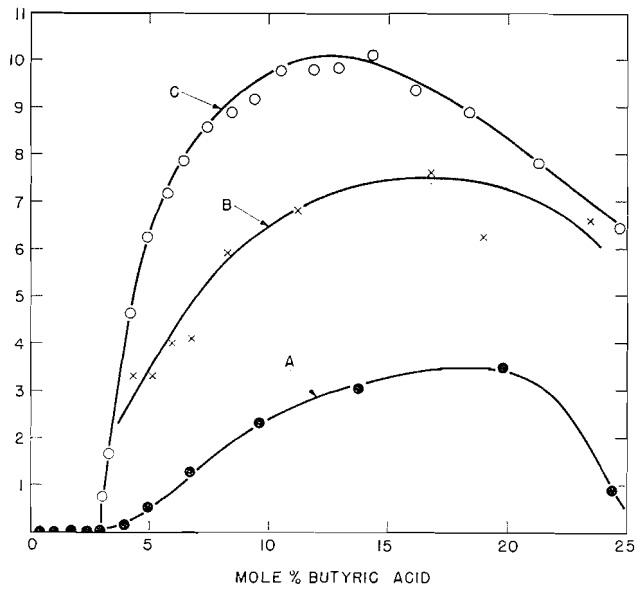

FIG. 2. Comparison of solubilization results with ultrasonic absorption and mean micellar aggregation number. Curve A: solubilization of DMAB at 0° C stated as g dye/liter of solution. Curve B: mean micellar aggregation number $\times 10^{-1}$ (data taken from ref. 8). Curve C: ultrasonic absorption at frequency of 3 mc/sec and 0° C stated in db/cm (data taken from ref. 4).

solute point (7) for the butyric acid – water system and suggested that clusters of acid molecules persist in these solutions at temperatures considerably above the critical region. Curve B in Fig. 2 is taken from the work of Davies and Griffiths (8). These authors applied Kreuzer's analysis (9) to the freezing point data for butyric acid solutions and obtained an estimate of the average micellar aggregation number. At 0° C this changed from 33 at 5 mole % to about 76 at 17 mole % and then decreased slightly as the concentration was increased still further.

White, Moule, and Benson (4) found that with increasing temperature the ultrasonic absorption peak at 13 mole % decreased and that a second maximum developed at about 50 mole %. The disappearance of the maximum in the solubilization curve at higher temperatures roughly parallels the ultrasonic behavior but the solubilization does not show any tendency to decrease as the temperature is raised. This is not surprising since the solubilization process must involve several factors. A change of temperature will not only alter the micellar characteristics of the solution but also the interaction between a solubilizate molecule and a micelle. The present investigation did not extend to high enough acid concentrations to make any comparison between solubilization and ultrasonic behavior in the region of the second absorption maximum.

Finally it should be noted that the solubilizing powers given in Table I must not be taken to indicate a minimum micellar size of 2000 acid molecules required to solubilize 1 dye molecule at 25° C. The error of this interpretation has been pointed out by McBain and Hutchinson (10). From a purely geometric point of view an aggregate of 70 or 80 molecules as estimated by Davies and Griffiths (8) should be able to solubilize at least 1 dye molecule. The larger mole ratios (acid/dye) observed experimentally suggest that there is a fairly broad distribution of aggregate sizes.

VAPOR PRESSURES OF AQUEOUS POTASSIUM OCTANOATE SOLUTIONS[1]

D. MOULE,[2] P. WHITE,[3] AND G. C. BENSON

Recent calorimetric studies in these laboratories (1–3) have yielded thermodynamic data for aqueous potassium octanoate solutions. The present osmotic investigation was undertaken in order to provide independent and supplementary thermodynamic information about this system.

EXPERIMENTAL

Vapor pressure depressions of a series of potassium octanoate solutions were measured with a pair of thermistors in an apparatus similar to that described by several previous workers (4–6). The present form of this consisted of an all-glass cell into which was inserted a long glass tube with a pair of Veco (32A1, 2000 ohm) thermistors projecting from a rubber stopper at the lower end. The upper chamber of the cell was connected by a long neck to a Dewar vessel which served as the solvent well. The response time of the thermistors was reduced by carefully grinding and etching away the main part of the glass coating. The thermistors were placed in the adjacent arms of a Wheatstone bridge to which 0.2 v was applied from a lead storage battery and rheostat. A Leeds and Northrup d-c. amplifier coupled to a Speedomax recorder provided a continuous record of the changes in bridge balance. With this arrangement a resistance change of 0.1 ohm which corresponded to about 1×10^{-3}° C could be detected easily.

The vapor pressure apparatus and all the solutions were kept in an oil thermostat controlled to ±0.01° C. During a measurement, the thermistor tips were washed with water, wiped dry, a drop of solution placed on one thermistor and a drop of water on the other. Measurements were attempted over the range 10° C to 50° C; however, the results much above or below room temperature were not reproducible, and the investigation had to be restricted to the interval 20° to 30° C. For measurements in this range steady resistance values were generally obtained within 30 minutes after the drops were placed on the thermistors.

The apparatus was calibrated with NaCl. Values of the practical osmotic coefficient ϕ for aqueous solutions of this material were taken from the data compiled by Harned and

Owen (7). Plots of observed resistance change against ϕm were good straight lines over the concentration range 0 to 0.5 molal at both 20 and 30° C.

The preparation of the potassium octanoate has been described previously (1, 2). Vapor pressure lowerings were determined for solutions with concentrations 0 to 0.7 molal. All solutions contained an excess of potassium hydroxide (0.042 molal) to suppress hydrolysis, and the osmotic coefficients measured were corrected for the presence of this alkali.

RESULTS AND DISCUSSION

The osmotic results at 20° and 30° C are shown in Fig. 1 as a plot of ϕm against m. The results at 30° have been displaced vertically 0.1 unit for clarity. Osmotic data for NaCl are shown as dashed lines. Within the experimental error the data for potassium octanoate

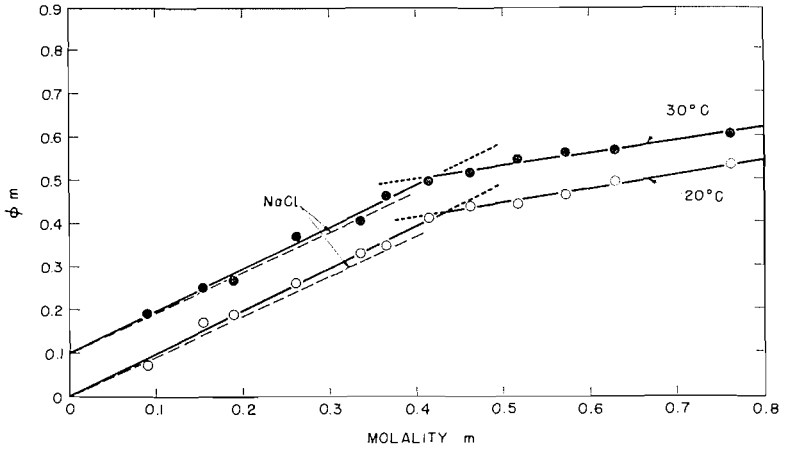

FIG. 1. Osmotic data for aqueous potassium octanoate solutions at 20° and 30° C. The results at 30° C have been increased 0.1 unit.

at each temperature can be fitted by two straight lines as shown. Similar behavior has been observed for a number of detergent systems by Fineman and McBain (8) and by Huff, McBain, and Brady (9), who identified the intersection of the lines with the critical micelle concentration CMC.

The lines in Fig. 1 were fitted with equations of the form

[1] $$\phi m = cm$$

below CMC and

[2] $$\phi m = a + bm$$

above the CMC. The values of the constants a, b, and c are listed in Table I along with

TABLE I

Values of the constants a, b, and c in eqs. [1] and [2]

T° C	a (molality)	b	c	CMC (molality)
20	0.282	0.325	0.973	0.43
30	0.275	0.306	0.961	0.42

values of the CMC calculated from them. It should be noted that the representation of the data below the CMC by eq. [1] with c different from unity is an approximation which cannot hold strictly at low concentration. The values of the CMC given in Table I are somewhat higher than results at 25° C obtained from measurements of refractive index 0.39 (10), heat of dilution 0.38[4] (1), and conductivity 0.35 (3) but lower than the value 0.47 from density determinations (11).

Mean molal activity coefficients $\gamma_{\pm}$ were calculated from the osmotic data at 20° C and at 30° C. The relative partial molal enthalpy of the solute at 25° C was then estimated from the temperature variation of $\gamma_{\pm}$. The results are shown in curve A of Fig. 2, where the difference in partial molal enthalpy $\bar{H}_2-\bar{H}_2^*$ is plotted against molality. The asterisk is used to indicate a reference concentration $m^* = 0.1$. In view of the rather limited accuracy of the original osmotic results the enthalpy data derived in this way are only of a semiquantitative nature. Values of $\bar{H}_2-\bar{H}_2^*$ taken from calorimetric measurements (1) are also shown in Fig. 2 (curve B). Both curves show an increase in enthalpy when micellization occurs. Curve A gives a value of 0.8 kcal mole^{-1} for the enthalpy of micellization ΔH_M which is smaller by a factor of 2 than the value (1.7 kcal mole^{-1}) estimated previously (1) from the calorimetric data. The abrupt step in curve A is due to the discontinuous change in slope at the CMC for the straight line approximations adopted in Fig. 1.

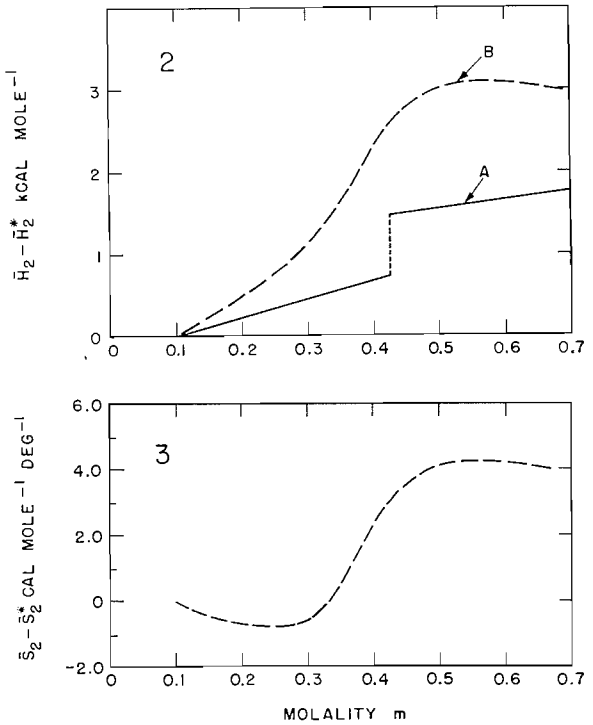

FIG. 2. Plot of the partial molal enthalpy difference $\bar{H}_2-\bar{H}_2^*$ against molality for potassium octanoate solutions at 25° C. Reference concentration is $m^* = 0.1$. Curve A estimated from osmotic data. Curve B calorimetric results from ref. 1.

FIG. 3. Plot of partial molal entropy difference $\bar{S}_2-\bar{S}_2^*$ against molality for potassium octanoate solutions at 25° C. Reference concentration is $m^* = 0.1$.

[4]*This result refers to the point of inflection of a plot of partial molal enthalpy against molality.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 69.46.99.164 on 09/04/12
For personal use only.

Assuming the activity coefficients $\gamma_{\pm}$ at 25° C to be the average of results at 20° C and 30° C, changes in partial molal entropy were calculated from the expression

$$[3] \qquad \bar{S}_2 - \bar{S}_2^* = (\bar{H}_2 - \bar{H}_2^*)/T - 3.972 \ln (\gamma_{\pm} m/\gamma_{\pm}^* m^*).$$

The calorimetric results (1) were used for the enthalpy difference rather than the estimates of this quantity from osmotic data. The resulting curve is plotted in Fig. 3. The increase in entropy on micellization is about 5.5 cal mole^{-1} deg^{-1} and is of course equal to $\Delta H_M/T$. Goddard, Hoeve, and Benson (1) have drawn attention to the importance of changes in solvent structure in the process of micelle formation. The observed increase in entropy is explicable on this basis.

THE SYNTHESIS OF A LIGNIN MODEL SUBSTANCE: 3-HYDROXY-1-(4-HYDROXY-3,5-DIMETHOXYPHENYL)-2-PROPANONE

E. W. Gorecki and J. M. Pepper

A study of the ethanolysis (1) of 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (I (R)) (β-oxyconiferyl alcohol) has provided considerable evidence for the presence in the lignin complex of the side chain —CH_2—CO—CH_2OH or its enolic form. Gardner has shown (1) that the four Hibbert monomers (II–V) are produced by the ethanolysis of I.

(R = 4-hydroxy-3-methoxyphenyl, R′ = 4-hydroxy-3,5-dimethoxyphenyl)

They have been shown previously to be released by the ethanolysis of spruce wood and various isolated lignins (2). Hibbert has proposed a series of interconversions (3) relating the production of II–V from I. Such a scheme would account for the proved absence of primary alcoholic groups in these isolated propylphenyl lignin monomers as contrasted with the presence of such groups in lignin derivatives obtained by other degradation procedures such as hydrogenation (2) and as evidenced from general analytical data. It

THE SYNTHESIS OF A LIGNIN MODEL SUBSTANCE: 3-HYDROXY-1-(4-HYDROXY-3,5-DIMETHOXYPHENYL)-2-PROPANONE

E. W. Gorecki and J. M. Pepper

A study of the ethanolysis (1) of 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (I (R)) (β-oxyconiferyl alcohol) has provided considerable evidence for the presence in the lignin complex of the side chain —CH_2—CO—CH_2OH or its enolic form. Gardner has shown (1) that the four Hibbert monomers (II–V) are produced by the ethanolysis of I.

(R = 4-hydroxy-3-methoxyphenyl, R′ = 4-hydroxy-3,5-dimethoxyphenyl)

They have been shown previously to be released by the ethanolysis of spruce wood and various isolated lignins (2). Hibbert has proposed a series of interconversions (3) relating the production of II–V from I. Such a scheme would account for the proved absence of primary alcoholic groups in these isolated propylphenyl lignin monomers as contrasted with the presence of such groups in lignin derivatives obtained by other degradation procedures such as hydrogenation (2) and as evidenced from general analytical data. It

also explains the fact that carbon–methyl groups are present in these ethanolysis products and in other isolated lignins (4, 5) but not in protolignin itself (4).

From maple wood, by ethanolysis, the corresponding syringyl (R′ = 4-hydroxy-3,5-dimethoxyphenyl) analogues were isolated in addition to, and in greater yield than, the guaiacyl members, II–V (2). Although it is logical to assume that these monomers would be produced by the ethanolysis of the previously unreported 3-hydroxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-2-propanone (VI), this assumption has yet to be proved. Of greater interest would be the comparison in yield of the rearrangement products obtained through ethanolysis of the two analogues. In the degradation of hardwood lignins, syringyl derivatives are obtained in greater abundance than are the corresponding guaiacyl members. A comparative study of the yield of the products obtained by the various established techniques of ethanolysis, oxidation, and hydrogenation as applied to I (R and R′) would assist in estimating the ratio of guaiacyl to syringyl nuclei in angiosperm protolignin.

This note records the synthesis of 3-hydroxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-2-propanone. The method is similar to that used to prepare the analogous β-oxyconiferyl alcohol (6). Homosyringic acid, prepared by three different routes, was acetylated, then converted via the acid chloride, through the diazomethyl ketone, to the O-acetyl derivative of I (R′) which on hydrolysis gave I (R′). Several of the intermediate compounds are reported here for the first time. The yields of the syringyl derivatives are consistently lower than those of the corresponding guaiacyl compounds.

EXPERIMENTAL

All melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrophotometer using sodium chloride optics.

Syntheses of Homosyringic Acid

Via Willgerodt Reaction (Kindler Modification)

Homosyringic acid was obtained starting from acetosyringone (7) by the adoption of the method used by Schwenk and Papa (8) to synthesize *p*-hydroxyphenylacetic. The product, obtained in only 6.7% yield, was recrystallized from water (Norite) to give fluffy white crystals, m.p. 130–131°; reported m.p. 132.5–134.5° (9). Previously a similar synthesis in these laboratories of homovanillic acid from acetovanillone had been achieved in a 43% yield. Arlt *et al.* (9) also reported the synthesis of homovanillic acid by this method.

Via Syringal Rhodanine

Syringal rhodanine.—To a mixture of syringaldehyde (41.0 g), rhodanine (29.9 g), and freshly fused sodium acetate (51.3 g) was added glacial acetic acid (365 ml) and the mixture refluxed for 40 minutes. The hot reaction mixture was decanted into vigorously stirred water (1030 ml), and after the mixture had been stirred for 3 hours, the product was collected, washed well with water, and dried under vacuum. The yield of crude syringal rhodanine was 59.4 g (89%), m.p. 242–246° (decomp.). Three recrystallizations from *n*-butanol (Norite) gave orange microcrystals, m.p. 258–258.5° (decomp.). Calc. for $C_{12}H_{11}NO_4S_2$: C, 48.5; H, 3.72; OCH_3, 20.9%. Found: C, 48.5; H, 3.74; OCH_3, 21.0%.

α-Thioketo-β-(4-hydroxy-3,5-dimethoxyphenyl)-pyruvic acid.—To syringal rhodanine (3.0 g) was added 15% sodium hydroxide (19 ml) and the mixture refluxed for 45 minutes. The red solution was cooled to 0° and acidified rapidly using 10% hydrochloric acid. The yield of the crude precipitated thioketo acid was 2.4 g (92.7%), m.p. 123–125°.

Several reprecipitations of the product from saturated sodium bicarbonate solution yielded dense, orange-yellow crystals, m.p. 130–131°. Calc. for $C_{11}H_{12}O_5S$: C, 51.5; OCH_3, 24.2%. Found: C, 51.1; OCH_3, 24.1%.

α-Oximo-β-(4-hydroxy-3,5-dimethoxyphenyl)-pyruvic acid.—Hydroxylamine hydrochloride (4.1 g) was dissolved in water (4.3 ml) and neutralized with a solution of sodium (1.75 g) in ethanol (45 ml). After filtration, the base was added to α-thioketo-β-(4-hydroxy-3,5-dimethoxyphenyl)-pyruvic acid (5.67 g) and the mixture refluxed on a steam bath for 60 minutes. Cooling to 0° gave fluffy white crystals, which were filtered, washed with ethanol, and dried. From the mother liquor was obtained a further 0.6 g, the combined yield being 4.2 g (75%), m.p. 219–220° (decomp.). Calc. for $C_{11}H_{13}NO_6$: OCH_3, 24.3%. Found: OCH_3, 24.2%.

Acetylhomosyringonitrile.—α-Oximino-β-(4-hydroxy-3,5-dimethoxyphenyl)-pyruvic acid (8.7 g) was treated with acetic anhydride (32.8 ml), the mixture warmed gently until solution of the oximino acid and the evolution of carbon dioxide were complete and then refluxed for 2 hours. Removal of the excess acetic anhydride yielded the crude nitrile, m.p. 84–89°. Several recrystallizations from petroleum ether (80–100°) (Norite) gave white crystals, m.p. 96–96.5°. Calc. for $C_{12}H_{13}NO_4$: OCH_3, 26.4%. Found: OCH_3, 25.8%.

Homosyringic acid.—Potassium hydroxide (7.84 g) was dissolved in a mixture of water (46.8 ml) and ethanol (52.1 ml) and this solution added to acetylhomosyringonitrile (6.0 g). After it was refluxed for 13 hours the solution was concentrated, under reduced pressure, to remove the ethanol. After it had cooled, the reaction mixture was acidified with dilute hydrochloric acid (40 ml) and the precipitated acid collected at 0° and dried. The yield of crude acid was 4.4 g (81.5%), m.p. 100–104°. Four recrystallizations from water (Norite) gave white needles, m.p. 126–128°.

Via Azlactone Synthesis

Homosyringic acid was also prepared from syringaldehyde by means of the intermediate azlactone (9). Recrystallizations of this product from water (Norite) gave white crystals, m.p. 130.5–132°.

Syntheses of 3-Hydroxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-2-propanone

Acetylhomosyringic Acid

Homosyringic acid (1.17 g) was dissolved in 37% sodium hydroxide (2 ml) containing crushed ice (ca. 3 g). After the addition of acetic anhydride (0.75 ml) the cooled solution was shaken for 2–3 minutes. Acidification with 6 *N* hydrochloric acid (5.3 ml) produced an oil which crystallized slowly. The yield of crude acetylhomosyringic acid was 0.92 g (65.6%), m.p. 117–119.5°. Recrystallization from water (Norite) gave white flakes, m.p. 120–121°. Calc. for $C_{12}H_{14}O_6$: C, 56.7; H, 5.55; OCH_3, 24.4%. Found: C, 55.9; H, 5.68; OCH_3, 24.3%.

Acetylhomosyringoyl Chloride

To a solution of acetylhomosyringic acid (1.5 g) in dry benzene (3.0 ml) was added freshly purified thionyl chloride (1.35 ml). The resulting solution was refluxed, under nitrogen, for 1.5 hours. The excess thionyl chloride was removed by the successive addition and distillation of 5×2.0 ml of benzene. Removal of the excess benzene left the crude acyl chloride as a red, viscous oil weighing 1.63 g.

Acetylhomosyringoyl Diazomethane

The above acetylhomosyringoyl chloride (1.63 g) was dissolved in dry benzene (4.3 ml) and the solution added dropwise to a vigorously stirred solution of diazomethane, at 0°, prepared by dissolving the diazomethane from 5.1 g of N-nitrosomethylurea in 60 ml of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

diethyl ether. The solution was allowed to warm slowly to room temperature and react overnight. Removal of the solvents under reduced pressure (nitrogen) left a viscous, red oil weighing 1.7 g.

3-Hydroxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-2-propanone

Acetylhomosyringoyl diazomethane (1.7 g) was dissolved in chloroform (2.15 ml) and this solution added dropwise, with vigorous mechanical stirring, to water (45 ml) in a three-necked flask fitted with a stirrer and a condenser. The mixture was heated on a steam bath at 93° for 4 hours. Dilute hydrochloric acid (0.76 ml) was added to bring the solution to pH 1 and the heating and stirring continued for 1 hour. Decolorizing carbon (0.75 g) was added and the heating continued for a further 1 hour. The hot solution was filtered, the yellow filtrate cooled to 5°, and exhaustively extracted with 6×25-ml portions of ethyl acetate. These combined extracts were dried over anhydrous magnesium sulphate and the solvent removed under reduced pressure at room temperature to leave a viscous, pale red oil. Considerable difficulty was experienced in effecting crystallization, but after thorough drying by the addition and evaporation of three successive portions of dry benzene followed by cooling in a dry ice – acetone bath, with scratching, the oil crystallized (0.46 g). Five recrystallizations from dry benzene gave cream-colored crystals, m.p. 106.5–107.5°. Calc. for $C_{11}H_{14}O_5$: C, 58.4; H, 6.23%. Found: C, 58.8; H, 6.46%. Infrared spectrum: 3455 cm^{-1} (broad) and 3295 cm^{-1} (broad) (hydroxyls); 1700 cm^{-1} (carbonyl); 1611 cm^{-1} and 1515 cm^{-1} (aromatic ring).

The authors are grateful to the Saskatchewan Research Council for continued financial assistance and to the Ontario Paper Company Limited for their donation of acetovanillone.

β-*n*-phenyl, β-cyclopentyl, and β-cyclohexyl derivatives. These syntheses have subsequently been repeated in our laboratory and in addition the β-*n*-hexyl compound was prepared by the same method. We were not successful in obtaining the β-methyl compound; only tarry products were obtained from which no lactone could be isolated. Syntheses of the same type have been carried out in the steroid series by Ruzicka, Reichstein, and Fürst (2).

~~Unsubstituted $\Delta^{\alpha\beta}$-butenolide (I, R = H) has not previously been synthesized~~, and the object of this note is to describe its preparation by the procedure I–VII. Starting

EXPERIMENTAL

Ethylmagnesium bromide was prepared from magnesium (24 g) and ethyl bromide (110 g) in anhydrous ether (250 ml). The ether was removed by distillation with simultaneous addition of benzene (200 ml). The product was cooled with ice, and propargyl alcohol (28 g) added slowly with vigorous stirring. The mixture was next heated for 2 hours on a steam bath with continuous stirring, during which time a pasty solid was deposited. This product was transferred to a 1-liter stainless steel bomb and sealed with solid carbon dioxide (250 g) for 24 hours. The pressure was released slowly, the product scraped from the bomb, and decomposed with 15% sulphuric acid (400 ml) at 0° C. This solution was next saturated with sodium chloride and extracted continuously with ether for 24 hours, after which the ether layer was separated and reextracted with aqueous sodium hydrogen carbonate solution. The aqueous phase after acidification with dilute hydrochloric acid was extracted continuously with ether for 24 hours. The ethereal solution of the acid was next dried with anhydrous magnesium sulphate and the ether removed *in vacuo* to yield 4-hydroxy-2-butynoic acid (III) (22 g) as a crystalline product.

Compound III (10 g) was dissolved in methanol (50 ml), 5% $Pd/BaSO_4$ (1 g) added, and hydrogenated at room temperature and pressure until the theoretical amount of hydrogen for semihydrogenation had been absorbed (2.4 liters). The methanol was removed *in vacuo* and the residue distilled to yield $\Delta^{\alpha\beta}$-butenolide (I, R = H) (5.8 g) as a colorless liquid, b.p. 86–87° (12 mm) n_D^{20} 1.4670. Found: C, 57.03%; H, 4.94%. Calc.: C, 57.14%; H, 4.80%.

We wish to thank Mr. H. Seguin for the carbon and hydrogen analyses.

THE PROTON MAGNETIC RESONANCE SPECTRUM OF THIOPHENE*

R. J. ABRAHAM† AND H. J. BERNSTEIN

In this note, the complete analysis of the proton magnetic resonance spectrum of thiophene in solution is presented as a typical example of the analysis of an A_2B_2 spectrum.

The spectrum of liquid thiophene is too complex to analyze with certainty even at 60 Mc/s. However, in acetone solution the chemical shift difference between the A and B protons increases, and the spectrum shown (Fig. 1) of a 1:1 solution of thiophene in acetone at 60 Mc/s can be analyzed quite easily following the standard A_2B_2 analysis (1).

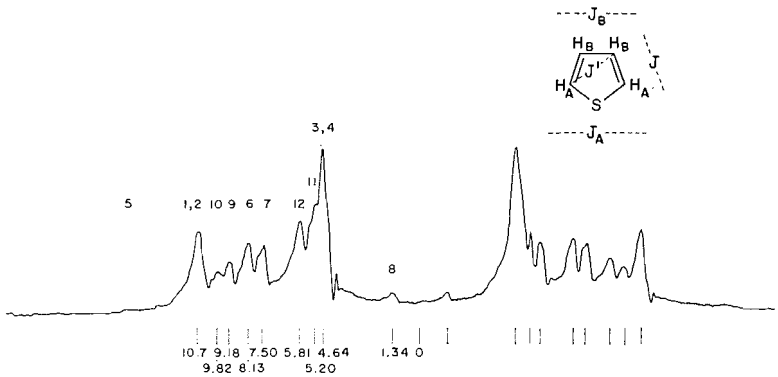

FIG. 1. The proton resonance spectrum of thiophene in a 1:1 mixture of thiophene in acetone at 60 Mc/s.

The nomenclature which will be used is shown in Fig. 1. It is convenient to define the following constants: $K = J_A+J_B$, $L = J-J'$, $M = J_A-J_B$, $N = J+J'$, and $\delta = \sigma_B - \sigma_A$.

By analogy with other five-membered heterocyclic compounds such as furan and pyrrole (2) the spectrum would be expected to be of the type for which $J_B > J_A$ and $J > J'$. This is of use in assigning the lines in the spectrum. A further check on the assignments shown (Fig. 1) is given by comparing the values of the coupling constants obtained with the results of Gronowitz and Hoffman (3) for the coupling constants in substituted thiophenes (viz.: $J_B = 3.8\pm0.3$ c.p.s., $J_A = 2.7\pm0.4$ c.p.s., $J = 5.4\pm0.6$ c.p.s., and $J' = 1.6\pm0.3$ c.p.s.).

From the assignment shown and following the analysis given in reference 1,

$$N-E_1-E_3 = 6.06$$
$$\{(\eta H_0\delta)^2+N^2)\}^{\frac{1}{2}} = E_1+E_3 = 15.34.$$

Hence

$$\eta H_0\delta = 14.1$$

also

$$[1] \qquad (M^2+L^2)^{\frac{1}{2}} = \left\{ \begin{matrix} E_9-E_{11} = 3.98 \\ E_{10}-E_{12} = 4.01 \end{matrix} \right\} = 4.00$$

Issued as N.R.C. No. 5406.

†*National Research Council Postdoctorate Fellow, 1957–59.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

and

$$[2] \qquad \{(\eta H_0\delta+M)^2+L^2\}^{\frac{1}{2}} = E_9+E_{11} = 14.38$$

$$[3] \qquad \{(\eta H_0\delta-M)^2+L^2\}^{\frac{1}{2}} = E_{10}+E_{12} = 15.63.$$

The best fit of equations [1], [2], and [3] gives

$$M = -0.67 \text{ and } L = 3.93.$$

The remaining constant K cannot be found explicitly from the spectrum. From the results of Gronowitz, we will take $K = 6.0$ c.p.s. The energies and intensities for the spectrum can now be calculated directly. These are shown with the observed values, in Table I. The agreement between calculated and observed energies is excellent, but

TABLE I

Observed and calculated energies and intensities for thiophene

	Energy relative to center of band (c.p.s.)		Relative intensity	
Transition	Calc.	Obs.	Calc.	Obs.*
1	10.70	10.70	.61	1.38
2	10.60	10.70	1.99	
3	4.64	4.64	1.40	2.74
4	4.33	4.64	1.54	
5	14.02		0.23	
6	8.07	8.13	1.56	1.18
7	7.27	7.50	1.72	1.19
8	1.32	1.34	0.31	0.33
9	8.99	9.18	.28	0.87
10	9.61	9.82	.45	0.73
11	5.01	5.20	.72	1.59
12	5.63	5.81	.55	1.35

*Normalized to the same total as the calculated values.

there is only fair agreement between the calculated and observed intensities. This is due to two factors. The values for the observed intensities shown in Table I are very approximate. The values shown are the individual peak heights as those are better defined than the integrated intensities for such an unresolved spectrum. However, these obviously only give approximate values for the intensities in such a spectrum. Also a different relaxation time may be associated with each peak in the spectrum. Thus, even when the individual lines are well resolved the observed intensities need not necessarily be the true intensities as relaxation phenomena may affect these values.

The values of the coupling constants obtained from this analysis are, in c.p.s., $J_A = 2.7$; $J_B = 3.3$; $J = 5.0$; $J' = 1.1$. As in the furan ring (2), these values are in close agreement with those obtained for the substituted compounds.

The A_2B_2 analysis provides a means of obtaining approximately the chemical shift difference between the A and B protons of thiophene in an unresolved thiophene spectrum. For example, the spectrum of thiophene in cyclohexane solution at 40 Mc/s has been given by Gronowitz and Hoffman (3). Here the chemical shift difference between the A and B protons is so small that the two parts of the spectrum start to overlap. However, transitions 3 and 4 can still be assigned to the strong central line and transitions 1 and 2 to the weak outermost line. This gives

$$N = E_1-E_3 = 5.5 \text{ c.p.s.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/04/12
For personal use only.

and

$$\{(\eta H_0\delta)^2+N^2\}^{\frac{1}{2}} = E_1+E_3 = 7.4 \text{ c.p.s.}$$
$$\text{i.e. } \eta H_0\delta = 5.0 \text{ c.p.s.}$$

The value of N obtained is in good agreement with the value found above (6.0 c.p.s.), thus confirming the assignment. The above analysis, however, only gives the numerical value of $\eta H_0\delta$ and does not say which of the protons in the thiophene ring give the low field signal. By analogy with the results for furan and pyrrole (2), it may be assumed that the A protons are to low field. This conclusion is supported by the results of Gronowitz and Hoffman, who find that the A proton signal in 3,4-dibromothiophene is to low field of the B proton signal in the analogous compound, 2,5-dibromothiophene. However, the difference between the A and B proton chemical shifts is much less in thiophene (5.0 c.p.s.) than in these dibromo compounds (19 c.p.s.). Gronowitz and Hoffman have taken the ring proton signals in these compounds as the reference chemical shifts in determining the influence of substituents on the ring proton chemical shifts. Thus, the values obtained need to be altered slightly, but this does not affect their general conclusions.

OOSPOREIN FROM AN ACREMONIUM SP.*

P. V. Divekar,† R. H. Haskins, and L. C. Vining

Stationary liquid cultures of a fungus isolated in this laboratory as an air contaminant excreted into the medium a purple pigment which could be extracted with ether and purified by crystallization from aqueous methanol. Analyses and molecular weight estimations on the pigment and derivatives best fitted a molecular formula $C_{14}H_{10}O_8$. A tetraacetate and tetramethyl ether were prepared, and reductive acetylation gave a colorless dihydrooctaacetate with an ultraviolet absorption spectrum similar to that of dibenzoquinone leucoacetate (1). These properties suggested that the pigment might be oosporein, a substance of known chemical structure produced by *Oospora colorans* van Beyma (2) and by *Chaetomium aureum* Chivers (3). Direct comparisons with authentic samples confirmed the identification. Infrared, ultraviolet, and visible absorption maxima of oosporein and of the derivatives mentioned above are reported.

The fungus (PRL 1699) belongs to the family Moniliaceae. As far as can be determined from available literature, it is a member of the genus *Acremonium* and a complete study of its morphology and development will appear as part of a comparative study of the various species of *Acremonium*, a number of which are known to produce purple pig-

ments diffusible in the agar medium on which they are growing (4). Although oosporein has recently been reisolated from *Chaetomium* and other species (5), to the authors' knowledge, its production by an *Acremonium* has not previously been described.

EXPERIMENTAL

Production and Isolation

A batch of twenty 1-liter conical flasks, each containing 350 ml of Czapek-Dox solution (glucose, 50 g; $NaNO_3$, 2 g; KH_2PO_4, 1 g; KCl, 0.5 g; $MgSO_4.7H_2O$, 0.5 g; $FeSO_4.7H_2O$, 0.01 g; and distilled water, 1 liter), were sterilized and inoculated with *Acremonium* sp. (PRL 1699). After incubation in the dark at 24° C for 15 days the wine-red culture fluid (6.4 liters) was filtered, acidified with concentrated hydrochloric acid, and extracted twice with 2-liter portions of ether. The ethereal extract was evaporated to dryness and the reddish-brown amorphous powder (3 g) crystallized three times from aqueous methanol as bronze plates (1.8 g), m.p. 290–295° C, undepressed on admixture with authentic samples of oosporein. Found: C, 55.0%; H, 3.2%; C—CH_3, 9.8%. Calculated for $C_{14}H_{10}O_8$: C, 54.9%; H, 3.3%; 2C—CH_3, 9.8%. Absorption maxima in ethanol 216 and 287 mμ, inflexions at 372 and 415 mμ, log ε 3.51, 4.67, 2.94, and 2.79, respectively. In aqueous solution the inflexion at 415 mμ is displaced bathochromically and appears as a maximum at 500 mμ (log ε, 3.05). Other maxima appear at 244 and 291 mμ, with an inflexion at 374 mμ; log ε 4.09, 4.47, and 3.35, respectively. The pigment has principal infrared maxima (KBr disk) at 3310 (s), 1648 (s), 1625 (s), 1387 (s), 1329 (s), 1297 (s), 1242 (s), 1070 (s), 929 (m), 764 (m), 740 (w), 708 (w) cm^{-1}. No differences were detected between the spectral properties of the pigment and those of authentic samples of oosporein.

Acetate

The pigment (50 mg) boiled for 10 minutes with acetic anhydride (3 ml) gave a pale red solution which, when poured into ice water, deposited yellow crystals (55 mg). These were recrystallized from methanol as bright yellow needles (45 mg), m.p. 190° C, undepressed by an authentic sample of oosporein tetraacetate. Found: C, 55.7%; H, 3.9%; CH_3CO, 36.0%. The molecular weight determined by isothermal distillation in acetone (6) was 463, and by the Rast method in camphor, 428. Calculated for $C_{22}H_{18}O_{12}$: C, 55.7%; H, 3.8%; $4CH_3CO$, 36.3%; mol. wt., 474. Ultraviolet absorption maximum in ethanol at 262 mμ, inflexion at 330 mμ; log ε 4.41 and 3.05, respectively. Infrared absorption maxima (KBr disk) at 1791 (shoulder, s), 1778 (s), 1675 (s), 1640 (w), 1620 (m) cm^{-1}. These spectral properties were indistinguishable from those of authentic samples of oosporein tetraacetate.

Leucoacetate

The pigment (50 mg) was boiled with acetic anhydride (3 ml) and zinc dust for 1 hour. The colorless solution was filtered and poured into ice water giving an amorphous white precipitate (80 mg) which was crystallized twice from methanol to yield small colorless cubes (55 mg), m.p. 243° C. Found: C, 55.7%; H, 4.8%; CH_3CO, 54.6%. Calculated for $C_{30}H_{30}O_{16}$: C, 55.7%; H, 4.7%; $8CH_3CO$, 53.3%. Ultraviolet absorption maximum in ethanol at 270 mμ, inflexion at 234 mμ; log ε 3.42 and 4.17, respectively.

Methyl Ether

Ethereal diazomethane (from 0.5 g of nitrosomethyl urea) was added to the pigment (50 mg) suspended in 2 ml of methanol. After half an hour at room temperature the solution was evaporated to dryness and the product in benzene (50 ml) passed through

For personal use only.

a short column of neutral alumina. The eluate was evaporated to dryness and crystallized three times from aqueous methanol to give orange needles (20 mg), m.p. 123° C. Found: C, 60.0%; H, 5.3%; OCH_3, 31.5%. Calculated for $C_{18}H_{18}O_8$: C, 59.7%; H, 5.0%; $4OCH_3$, 34.2%. Ultraviolet absorption maxima in ethanol at 285.5 and 394 mμ; log ε 4.40 and 2.98, respectively. Infrared absorption maxima (KBr disk) at 1654 (s), 1614 (w), 1588 (s).

The authors are indebted to Mr. A. Funk for the isolation of PRL 1699 and also wish to thank Dr. W. B. Whalley, University of Liverpool, and Prof. F. SYNTHESIS OF POLYMETHYLENEBISISOTHIOCYANATES*

G. D. Thorn and B. Huston

Alkyl isothiocyanates are most conveniently prepared by reacting aqueous alkyldithiocarbamic acid salts with ethyl chloroformate to give carbethoxydithiocarbamates, which undergo fission to the isothiocyanate, carbon oxysulphide, and ethanol (1, 2):

$$RNHCS_2Na + ClCO_2C_2H_5 \rightarrow RNHCS_2CO_2C_2H_5 \rightarrow RNCS + COS + C_2H_5OH.$$

The decomposition reaction can be effected by heating the isolated ester *in vacuo* (3) or with aqueous alkali (4, 5). The decomposition of carbethoxybutyldithiocarbamate was found also to proceed very quickly in chloroform solution containing anhydrous triethylamine (4).

Ethylenebisisothiocyanate has been prepared by the thermal decomposition of the carbethoxy compound (6, 7). In order to obtain yields approaching those reported in the literature it was our experience that the carbethoxy derivative must be purified through several crystallizations before attempting the batchwise thermal cleavage. In this note, two procedures are reported upon for preparation of ethylene- and other polymethylene-bisisothiocyanates which obviate the necessity of purifying the carbethoxy compound.

In method A, the isolated but crude oily carbethoxydithiocarbamate is put through a falling-film molecular still *in vacuo* with the heating surface kept at a temperature a few degrees above the boiling point of the bisisothiocyanate, or at 100–105°, whichever is the higher. Decomposition of the carbethoxy compound and distillation of the resultant

isothiocyanate are immediate. Thus, reaction of the formed isothiocyanate with impurities or by self-condensation at elevated temperatures as obtained in the "batch" method is avoided.

In method B, the crude carbethoxy compound is added to cold 20% aqueous potassium hydroxide. After several minutes, the mixture is extracted with benzene and the organic layer dried with anhydrous sodium sulphate. The residue obtained by removal of the solvent (as in a rotary evaporator) is then subjected to distillation at reduced pressure.

The procedure followed for the preparation of the carbethoxydithiocarbamates is typically that of several examples in the literature. Briefly, the diamine (1.0 mole), carbon disulphide (2.2 mole), and sodium hydroxide (2.0 mole) are reacted together at 35–45° for 3 hours in sufficient water to end up with an approximately 20% solution of the disodium polymethylenebisdithiocarbamate. The solution is then chilled and treated dropwise, with adequate stirring, with 2.0 mole of ethyl chloroformate. After a further reaction period of an hour, the carbethoxy derivative is isolated either by filtration or extraction with benzene.

Aliphatic bisisothiocyanates, SCN—X—NCS

X	B.p./mm	n_D	Log ϵ_{max}	Method	% Yield	Anal. (N%) Calc.	Found
Ethylene	71.5–72/0.3	1.6265/22.8°*	3.30†	A	77	19.45	19.25
Propylene	77–9/0.1	1.5750/23°	3.33	A	23	17.75	17.73
Tetramethylene	102–4/0.1	1.5930/23°	3.32	B	50	16.30	16.05
Pentamethylene	124–30/0.3	1.5680/23.5°	—	A	18	15.05	14.8
Hexamethylene	119–22/0.1	1.5630/26°	3.28	B	41	14.00	13.9

*Yakubovitch and Klimova (6) give b.p. 144° at 10 mm and n_D^{20} 1.6271.

†The isothiocyanates possess a single absorption peak in the ultraviolet region, at 247 mμ. Solvent, ethyl ether.

Table I gives the aliphatic bisisothiocyanates prepared by these methods. It might be noted that, except in the preparation of ethylenebisisothiocyanate, some diethyl polymethylenebisurethane was always obtained, requiring fractional distillation of the isothiocyanate. The urethane arises from incomplete reaction of the diamine with carbon disulphide, and can be avoided either by extending the reaction time for the dithiocarbamate or by purification of the carbethoxy derivative.

The authors wish to thank R. W. White for checking the purity of the isothiocyanates by infrared analysis, and Dorle Bongart for the microanalyses.

THE EFFECT OF HEAT TREATMENT ON THE ACTIVITY OF A SILVER CATALYST*

E. ECHIGOYA,† C. H. AMBERG, AND G. L. OSBERG

In carrying out the oxidation of ethylene on silver catalysts it is customary to stabilize the catalyst in the reacting gas mixture over periods up to several days. Among the few workers that have reported studies of catalytic activity during pretreatment, Orzechowski and MacCormack (1) have given a detailed account of the attendant slow changes. In an earlier paper Murray (2) examined the first few hours of reaction and found an increase in selectivity.‡

In the present study it has been attempted to demonstrate the similarity of activity changes during the first few hours of reaction with changes induced by short periods of preliminary heat treatment. It is important to note that the similar reaction patterns found both by Murray and in this laboratory differ from the common case in which all activity is diminished through destruction of the surface with heating.

The reported experiments were made along with a more detailed examination of ethylene oxidation in fluidized bed reactors (3).

EXPERIMENTAL

The method of catalyst preparation from Ag–Ca alloys has been discussed previously (4). The present batch contained 0.17% Ca and had been derived from a powdered alloy containing 8.05% Ca.

The reactor was a fluidized bed consisting of a mixture of 5 cc (12.2 g) of the 100- to 200-mesh catalyst powder and 20 cc (31.8 g) of 100- to 200-mesh "Scotchlite" glass beads contained in a 1-in. diameter, pyrex column. The glass beads served to inhibit agglomeration of the catalyst granules (5). An air flow of 3.4 l./minute was maintained throughout both the pretreatment and reaction periods, and an air-to-ethylene ratio of 40:1 with maximum fluctuations of ±4% was used for the reaction. All reactions were carried out at 250±2° C and the products analyzed by gas chromatography (6). Pretreatment temperatures and periods are indicated in Fig. 2. Fresh portions of catalyst from the same batch were used for each pretreatment.

A sample of 48- to 100-mesh catalyst (0.21% Ca) was used to follow changes in B.E.T. surface area with prolonged outgassing at 250° C. A conventional volumetric apparatus was employed for the purpose and argon at −195° C was used as the adsorbate.

RESULTS AND DISCUSSION

Figure 1 shows the initial selectivity and total conversion values at 250° C for the different portions of catalyst plotted against the temperature of pretreatment. Since the two curves qualitatively resembled those found for the reaction at, say, 250° C over a period of several hours, it was tempting to assume that the short heat treatments had produced very similar surfaces, but had done so far more rapidly.

That this is so, at least in terms of catalytic activity, was demonstrated by following the selectivity and conversion changes with time of reaction at 250° C for each pretreated batch. Figure 2 shows these changes superimposed on the two curves drawn for

FIG. 2. Silver-catalyzed oxidation of ethylene at 250° C. Changes in total conversion (open points) and selectivity (filled-in points) for catalysts pretreated at different temperatures. Periods of pretreatment given in parentheses. Zero reaction time indicated by arrows. Circles: Pretreatment at 250° for 10 minutes. Triangles: Pretreatment at 303° for 5 minutes. Squares: Pretreatment at 365° for 5 minutes. Dashed circles: Pretreatment at 420° for 5 minutes.

the original catalyst that had never been heated beyond 250° C (solid lines, fitted to circles only). The time axes were shifted so that the initial selectivities would fall on the original selectivity curve (arrows). The grouping of the remaining selectivity and total conversion values near the respective 250° C curves indicates that the catalytic "histories" match that of the original catalyst. This, in turn, supports our original assumption, namely, that the heat treatments merely served to speed up surface changes also occurring during the course of the reaction at 250° C.

Although the data do not warrant a unique mechanistic interpretation of these surface changes, a few additional observations will be found to narrow down the range of possible causes.

(1) The small particle size required for fluidization ensured that leaching of the calcium had taken place throughout the bulk of the granule. Coupled with the fact that catalysts in the 0.1–0.2% range of calcium content show little variation in activity with change in calcium content (7), this means that diffusion of calcium from particle interior to active surface during the course of the reaction can be discounted as a possible explanation for the observed changes.

(2) The observed changes are almost entirely attributable to a decrease in CO_2 production with time, ethylene oxide remaining virtually constant. Any model that is ultimately adopted must incorporate a capacity for undergoing surface modifications resulting in selective changes of this type. For instance, if one were to adopt Twigg's model (8) of two-point contact of C_2H_4 molecules on a silver oxide surface to produce CO_2, this might mean that the number of two-point configurations in the surface has decreased with surface rearrangement, leaving unchanged the available single centers for ethylene oxide production.

It is interesting to note that the rate of CO_2 production decreased linearly as the logarithm of reaction time. This function is formally the same as the Elovich equation, applicable in many cases to the increase with time of the amount of gas chemisorbed on a solid surface. Whether this is significant in terms of selective poisoning in our case cannot, of course, be decided on the basis of the available information.

(3) When the temperatures and times of preliminary heat treatment (both shown in Fig. 2) were combined with their equivalent times at 250° (marked by arrows in Fig. 2) in three Arrhenius-type plots, the maximum spread in slopes was found to be only 10%. Although we do not wish to attach any significance to the absolute value obtained from two-point plots (17 kcal/mole), its relative lack of variation suggests that an essentially uniform change has taken place on the catalyst surface during heat treatment and reaction. This change may well have been complex in nature, involving such processes as recrystallization, diffusion, and chemisorption.

(4) A sample of catalyst was outgassed for 100 hours at 250° C. During the first half of this period its B.E.T. surface area decreased from 0.54 m^2/g by about 6% and during the second half by a further 1%. These data indicate maintenance of a stable skeletal structure of the silver catalyst at 250° C. It must be kept in mind that B.E.T. measurements may not be too sensitive to changes in the fine-structure of the surface. In the present case they serve merely to confirm that gross surface destruction did not take place at 250°. Smeltzer *et al.* (9) found that their catalyst No. I retained about 80% of its original sorption capacity for oxygen after heating at 300° C for over 100 days, thus exhibiting properties similar to those shown by the catalyst in the present work, if one makes allowances for somewhat different conditions. Though chemisorbed oxygen takes part in the oxidation of ethylene, even this set of adsorption experiments was not strictly applicable to the oxidation reaction. The latter takes place on a surface at least partially covered with oxygen and in an environment of other gases. Nevertheless, sorption experiments on out-gassed surfaces are useful, provided their limited applicability to systems under reaction conditions is clearly recognized.
